Apparatus—The following were used: a constant-temperature water bath equipped with a Unitherm Haake constant-temperature circulator¹ and a rotating-bottle apparatus,² Swinney hypodermic adapter,³ Millipore filters (pore size 0.45 μ),³ and 120-ml. amber bottles with polyseal caps.⁴

Compounds—In all the experiments, anhydrous Wy-4508 (Wyeth Laboratories batch C-10777, m.p. 181–182°) was used. The dihydrate form of Wy-4508 was prepared from the anhydrous material by preparing a saturated solution of the penicillin in 1.0 *N* hydrochloric acid and precipitating the hydrated form at pH 7. IR spectra, differential thermal analysis, and Karl Fischer moisture determinations were obtained for the material and conclusively characterized the anhydrous and dihydrate forms.

Dissolution Procedure—An excess of drug, 4 g., in the appropriate form was added to 50 ml. of distilled water previously equilibrated to the desired temperature. The bottles were rotated at a constant speed in a water bath maintained at the appropriate temperature. Samples withdrawn at definite intervals were filtered through a Millipore filter and diluted immediately to avoid any precipitation of the penicillin in the filtered samples due to supersaturation.

The penicillin content was determined by means of the following iodometric titration procedure. To 2.0-ml. aliquots containing 1–3 mg. of Wy-4508, 2.0 ml. of 1 *N* sodium hydroxide was added, and samples were allowed to stand at room temperature for 15 min. At the end of the time, 2.0 ml. of 1.2 *N* HCl was added, followed by 10 ml. of 0.01 *N* iodine. After 15 min., the excess of iodine was titrated, using 0.01 *N* sodium thiosulfate. For the blank determinations, 10 ml. of 0.01 *N* iodine was added to a 2.0-ml. sample and titrated immediately.

RESULTS AND DISCUSSION

The solubility of the anhydrous form of Wy-4508 at 7, 20, 25, 30, 40, 50, and 60° is shown in Fig. 1. Similar data at 10, 20, 25, 30, 40, 50, and 60° for the dihydrate form of this agent are illustrated

Figure 1—Solubility of the anhydrous form of Wy-4508 in distilled water at temperatures ranging from 7 to 60°. Key: ○, 7°; ▲, 20°; □, 25°; ●, 30°; △, 40°; ×, 50°; and ■, 60°.

Figure 2—Solubility of the dihydrate form of Wy-4508 in distilled water at temperatures ranging from 10 to 60°. Key: ○, 10°; ▲, 20°; ■, 25°; ●, 30°; △, 40°; ×, 50°; and □, 60°.

in Fig. 2. These figures show the concentration of the antibiotic attained in solution as a function of time in the presence of the excess of the solid phase in the appropriate form and under essentially constant agitation. An inverse relationship between temperature and solubility for the anhydrous form of this drug was observed. The dihydrate form of the drug shows no significant change in solubility between 10 and 40°. The negative heat of solution noted for this compound is consistent with the data reported for the anhydrous form of the amphoteric penicillin, ampicillin (6).

An inverse relationship between solubility and temperature is not usually observed, especially with organic compounds. However, from the data presented here and previously (6), it appears that such a relationship (negative heat of solution) is characteristic of the anhydrous form of amphoteric penicillins.

The data shown for the solubility in water for the two forms of Wy-4508 investigated suggest that the equilibrium solubilities observed are good approximations of the true solubility of these crystals. Therefore, the measurements made at the several temperatures permit calculation of the thermodynamic values involved in the transition of the anhydrous form to the dihydrate. The thermodynamic relationship involving polymorphism and solubility is extensively discussed in reports by Shefter and Higuchi (5) and Higuchi *et al.* (7).

A classical van't Hoff-type plot of the apparent equilibrium solubilities observed at the various temperatures of this investigation showed a reasonably good linear relationship for both forms of the antibiotic for temperatures up to 40° (Fig. 3). At the higher temperatures, a deviation from linearity was observed for both forms of Wy-4508. This is probably due to degradation of the penicillin at these higher temperatures.

The transition temperature for the anhydrous-dihydrate crystal system of this compound corresponds to the temperature at which the solubility of the two forms is equal. The transition temperature for this system, obtained by extrapolating the straight-line portions

Figure 3—The van't Hoff-type plot for the anhydrous and dihydrate forms of Wy-4508 in distilled water. Key: ○, anhydrous; and ●, dihydrate.

of the van't Hoff-type plot, was determined to be 61° (Fig. 3). This plot also points up the inverse relationship between temperature and solubility for the anhydrous form of the drug, whereas the effect of temperatures ranging from 10 to 40° on the solubility of the dihydrate form is insignificant.

The values of the heat of solution for each of the crystal forms were calculated from the slopes of the van't Hoff-type plot and were determined to be -4700 and 0 cal./mole for the anhydrous and dihydrate forms, respectively. The enthalpy of hydration ($\Delta H_{A,H}$) was determined to be -4700 cal./mole. This value is considerably less than that noted for the anhydrous-trihydrate system of ampicillin (6), where the value was determined to be -6400 cal./mole. This is probably due to the fact that only 2 moles of water are involved in the hydration of Wy-4508 as compared to 3 moles of solvent for each mole of ampicillin.

The free energy difference, ΔF_T , between the anhydrous and hydrated forms at constant temperature and pressure is determined by Eq. 1:

$$\Delta F_T = RT \ln \frac{C_s \text{ (anhydrous)}}{C_s \text{ (dihydrate)}} \quad (\text{Eq. 1})$$

where C_s is the solubility of the form under consideration at a particular temperature, T , and R is the gas constant. This value, ΔF_T , is a measure of the free energy change involved in a conversion of the anhydrous crystal to the dihydrate crystal. The ΔF_T 's at 25 and 37° (corresponding to room and body temperatures) have been determined to be -550 and -390 cal./mole, respectively.

The entropy change, ΔS_T , for the reaction involved in hydrate formation can be calculated by Eq. 2:

$$\Delta S_T = \frac{\Delta H_{A,H} - \Delta F_T}{T} \quad (\text{Eq. 2})$$

The values computed for the hydration of the anhydrous to the dihydrate Wy-4508 crystals at 25 and 37° were -13.9 e.u. At the transition temperature of the anhydrous-dihydrate crystal system, ΔF is equal to zero and the entropy change can be calculated by

$$\Delta S \text{ (trans)} = \frac{\Delta H_{A,H}}{T \text{ (trans)}} \quad (\text{Eq. 3})$$

For Wy-4508, $\Delta S \text{ (trans)}$ was determined to be -14.1 e.u. The hydrated species of this system contains 2 molecules of water; the possible intramolecular hydrogen-bond formation between these associated water molecules may account for the relatively large entropy change noted.

The entropy change involved in the fusion of water at 25° is approximately 6 e.u. This decrease in entropy associated with the formation of ice is approximately the same entropy change obtained for the hydration of glutethimide and theophylline (5). Therefore, the energy involved in the transformation of the dehydrated forms of compounds of such types to the hydrate may be related mainly to the decrease in the entropy of water molecules in the hydrate structure. The results obtained for the entropy change in the ampicillin anhydrous-trihydrate system (6), where 3 associated water molecules result in an entropy change of -20 e.u. at 25°, and for the entropy change observed in the present study, where 2 associated water molecules show a change in this value of -13.9 e.u., are consistent with this hypothesis.

The thermodynamic values calculated for the anhydrous-dihydrate Wy-4508 system are summarized in Table I.

The equilibrium solubilities observed in these experiments apparently correspond to the solubilities of anhydrous and dihydrate crystalline phases for the Wy-4508 molecule. At the temperatures

Table I—Thermodynamic Values Calculated for the Anhydrous-Dihydrate Wy-4508 System

Temp.	ΔH , cal./mole Anhydrous	ΔH , cal./mole Dihydrate	ΔF_T , cal./mole ^a	ΔS_T , e.u. ^a
	(-4700)	(0)		
25°			-550	-13.9
37°			-390	-13.9
61°			0	-14.1

Figure 4—Influence of seeding anhydrous Wy-4508 with 1 and 10% dihydrate crystals on the solubility in distilled water at 10°. Key: ○, anhydrous; ●, seeded with 1% dihydrate; ▲, seeded with 10% dihydrate; and △, dihydrate.

utilized, there was no evidence of conversion of the more soluble anhydrous form to the less soluble dihydrate species as would be expected strictly from thermodynamic consideration. Undoubtedly, this may be due to steric factors involved in the association of the water molecules in the crystal system and to the relatively high water solubility of this particular amphoteric penicillin. Even at lower temperatures (10°), seeding of the anhydrous form with 1% dihydrate crystals did not result in a rapid conversion of the anhydrous form to the less soluble species. However, when the seed was incorporated at the 10% level, a relatively rapid and complete conversion of the anhydrous to the dihydrate form was observed

as shown by the decrease in solubility. These data are summarized in Fig. 4.

SUMMARY

The solubility of the anhydrous and dihydrate forms of Wy-4508 in distilled water has been determined over a temperature range of 7–60°. From the solubility data, the transition temperature for this crystal system was estimated to be 61°. The anhydrous form was found to be significantly more water soluble than the dihydrate at all temperatures below the transition temperature. In addition, the solubility of the anhydrous crystal was shown to be inversely related to temperature (negative heat of solution). The thermodynamic values for the anhydrous–dihydrate Wy-4508 crystal system have been calculated.

Effects of Disulfiram on Growth, Longevity, and Reproduction of the Albino Rat

HARALD G. O. HOLCK, PAUL M. LISH*, DAVID W. SJOGREN†, W. W. WESTERFELD‡, and MARVIN H. MALONE§

Abstract □ Chronic oral ingestion of disulfiram at concentrations of 1:1000 and 1:2000 in powdered food retards the growth and reproductive capacity of the albino rat; a concentration of 1:1000 also decreases longevity. Enhancement of diet with ascorbic acid has no antidotal action on the growth and reproductive effects. Chronic disulfiram feeding appears to have no significant effects on whole animal oxygen consumption, blood counts, tissue xanthine oxidase activity, and liver molybdenum content. Calcium deposition in the cerebellum was absent.

Keyphrases □ Disulfiram—chronic feeding studies, rats □ Blood cells, number—disulfiram effect □ Reproduction, longevity, body weight—disulfiram effects □ Oxygen consumption—disulfiram effect □ Ascorbic acid effect—disulfiram activity

While single oral doses and chronic feeding of disulfiram in the absence of ethanol are considered relatively nontoxic (1–3), chronic feeding of rats on diets containing disulfiram (1:400–1:10,000) has been reported to retard growth and increase mortality (4).

Muscular incoordination was seen in rats chronically fed the 1:400 and 1:1000 diets by the age of 2 years, and microscopic examination of the cerebellum and basal ganglia revealed calcified masses in rats fed 1:400 disulfiram. In addition to its generally accepted inhibitory effect on liver aldehyde oxidase, disulfiram has been reported to have some antithyroid capacity (5). Disulfiram can inhibit the oxygen uptake of rat liver homogenates by apparently acting as a competitive hydrogen acceptor (6). Ascorbic acid overcomes this inhibition and is reported to be effective intravenously in man (7). The metabolic breakdown of disulfiram into diethyldithiocarbamate, an effective chelator, has also been noted (8).

After preliminary work in this laboratory, it was considered important to document the effects of disulfiram in the young rat during the most rapid phases of growth and to see whether longevity and reproductive capacity would be affected.

Figure 4—Influence of seeding anhydrous Wy-4508 with 1 and 10% dihydrate crystals on the solubility in distilled water at 10°. Key: ○, anhydrous; ●, seeded with 1% dihydrate; ▲, seeded with 10% dihydrate; and △, dihydrate.

^a The disulfiram was mechanically admixed with Purina powdered laboratory chow.

EXPERIMENTAL

All rats were albinos, bred originally from Wistar stock in this laboratory, and were maintained in animal quarters (26°) on unrestricted Purina powdered laboratory chow and tap water. Test diets containing 1:1000, 1:2000, 1:4000, and 1:8000 parts of disulfiram¹ per kg. of Purina powdered laboratory chow were prepared with an electric mixer. When ascorbic acid was added to the drinking water, the solution was prepared daily with tap water. From food consumption data, the daily intake of 1:2000 disulfiram in very young rats was equivalent to about 10 times the dosage of an adult man (0.5 g./day or 7 mg./kg.), while the intake for an adult rat was about 5 times the human dose.

RESULTS AND DISCUSSION

Growth Studies—Young rats were weaned after 30 days, segregated by sex, and randomly divided into three groups. Diets were instituted as shown in the first run of Table I. A significant growth lag was apparent after 30 days of feeding (13 and 22% for males and 11 and 22% for females fed 1:2000 and 1:1000 disulfiram, respectively). This lag was maintained up through 90 days of feeding (13 and 17% for males and 7 and 15% for females consuming 1:2000 and 1:1000, respectively). These results compare favorably with a 10 and 21% reduction, respectively, obtained in a preliminary study with only 10 males per diet. A second run, conducted in the same manner but feeding 1:4000 and 1:8000 disulfiram in the diet (Table I, Run 2), indicated that there was no significant retardation of growth with these concentrations. In another experiment, when feeding of male rats was begun at the age of 85 days and continued for 105 days, there was no significant difference in body weight between the controls and the rats fed 1:6750, 1:4500, 1:3000, and 1:2000 disulfiram (12 rats/test group).

Blood Counts—At the age of 175–185 days, red and white blood cell counts, as well as leucocyte differentials, were determined for another group of male and female rats fed continuously with either control, 1:2000, or 1:1000 disulfiram diets since the age of 30 days (10 males and 10 females/group). Mean red counts for the males were: 10.8, 10.5, and 9.6 million/cu. mm., and for the females: 10.2, 9.5, and 9.8 million/cu. mm., respectively. Mean white cell counts for males were: 13,360, 15,810, and 14,640/cu. mm., and for females: 12,570, 12,030, and 14,870/cu. mm., respectively. These figures, as well as the differential counts, all fell within the normal ranges (9), indicating no important differences between the groups that might be due to a chelation effect. Body weight differences were equivalent to those reported in the previous section.

Oxygen Consumption—At the age of 360–400 days, groups of male rats fed continuously either control, 1:2000, or 1:1000 di-

Table II—Effects of Disulfiram in the Diet on Longevity of the Male Albino Rat^a

	Number/Group	Mean Life Span, Days ($\pm SE$)	Significance from Control, <i>p</i>
Control diet	9	944 (33)	—
1:2000 Disulfiram	10	896 (37)	>0.30
1:1000 Disulfiram	10	744 (70)	<0.02

^a Separated from mothers at the age of 30 days, and test diets begun *ad libitum*.

sulfiram diets since the age of 30 days (9–10 animals/group) were placed in a closed system similar to that described by MacLagan and Sheahan (10) for the estimation of ml. oxygen utilized/kg./hr. at standard conditions. Mean oxygen consumption was not significantly different ($p > 0.50$) for the three populations (815, 793, and 846 ml./kg./hr. S.T.P., respectively). Apparently, these concentrations of disulfiram in the diet had not significantly altered thyroid function.

Effects on Longevity and Body Weight—Utilizing the techniques previously described, three groups of males were maintained on either control, 1:2000, or 1:1000 disulfiram diets until death. As shown in Table II, longevity was significantly reduced only in the animals receiving 1:1000 disulfiram. As in the preceding experiments, no signs of motor incoordination (4) were noted, although a general tendency for poor grooming was seen with the disulfiram-fed animals. The body weight of the rats receiving disulfiram in their food was consistently less than that of the control animals. As in previous experiments, there were no significant differences in the daily food intake between the groups. As with all old rats, a 10–20% incidence of tumors was seen in each of the three groups, but no specific tissue susceptibility was noted. Histologic examinations of the cerebella of two control rats, two on the 1:1000 disulfiram diets, and five on the 1:2000 disulfiram diets showed no calcification.² The age at the time of examination ranged from 2.68–2.97, 2.43–2.71, and 2.51–2.71 years, respectively. The age in all instances exceeded the 2-year maximum reported by Fitzhugh *et al.* (4), who found calcium deposition with a diet concentration of 1:400 of disulfiram.

Vitamin Enhancement of Diet—While the rat appears to have some intrinsic capacity to synthesize ascorbic acid (9), an experiment was performed to determine if inclusion of ascorbic acid in the drinking water would reverse or significantly mitigate the disulfiram-induced growth lag. As shown in Table III, a significant

retardation of growth was generally seen after 90 days on the diets (14, 17, and 10% for males, and 8, 14, and 12% for females fed 1:2000 disulfiram, 1:1000 disulfiram, and 1:1000 disulfiram plus ascorbic acid in the drinking water, respectively). With the exception of the males on diet for 30 days, there was no significant difference in weight between animals with and without ascorbic acid on the 1:1000 diet. This exception was unexpected since it appeared to indicate that ascorbic acid might actually enhance disulfiram-induced growth retardation. However, this effect was not seen in the comparable female groups. A separate experiment was then set up to ascertain whether ascorbic acid in the drinking water of rats receiving only the control diet would retard growth or reduce fluid intake. No such effects were seen. In the experiment described in the next section, no consistent ascorbic acid retardation was seen, so this exception in Table III must be discounted as being presently unexplainable.

First- and Second-Generation Studies—In a preliminary study, 1:1000 disulfiram in the diet appeared to have a definite depressant effect on the reproductive capacity of rats, while 1:2000 disulfiram

was without effect. At 130–135 days of age, the males and females of the preceding study (Table III) were mated while continuing to receive their assigned diets. The paired rats remained together until the female showed signs of pregnancy or reached the age of 228 days. The young from this mating were separated from their mothers at 30 days of age and placed on the same diet as their parents. These offspring are termed “first generation” in Table IV. First-generation males and females were then mated at the age of 90–95 days, and the young from this union were weighed at 30 days of age and tabulated as “second generation” in Table IV.

There was no significant effect ($p > 0.05$) between treatments as to the body weight of the first generation at the age of 30 days. However, after the diet was in effect for 30 days (60 days of age), the disulfiram-induced retardation of growth was seen (25, 32, and 34% for males, and 22, 35, and 23% for females fed 1:2000 disulfiram, 1:1000 disulfiram, and 1:1000 disulfiram plus ascorbic acid in the drinking water, respectively). There was one isolated instance of apparent ascorbic acid antagonism of disulfiram (females, 30 days of feeding), and one single instance of apparent ascorbic acid

^a Diet was supplemented with 0.5% ascorbic acid in the drinking water.

synergism with disulfiram (males, 90 days of feeding). Weight comparisons of second-generation animals were hampered by the anti-productive effects of 1:1000 disulfiram; however, there was no significant difference in body weight between second-generation controls and those from parents receiving 1:2000 disulfiram. It would appear in this experiment that disulfiram was not excreted or concentrated to any significant extent in the mother's milk, since offspring reaching 30 days of age did not exhibit significant retardation of growth. Ascorbic acid appears to have no predictable antagonistic effects against disulfiram.

Biochemical Studies—First-generation males (Table IV) were sacrificed and tissue xanthine oxidase activity measured in the presence and absence of methylene blue (11). Methylene blue has the capacity to overcome the disulfiram-induced inhibition of xanthine oxidase almost completely (12). Uric acid—allantoin-creatinine values for urine were determined prior to sacrifice in a manner similar to that of Bass and Place (13). As shown in Table V, lung xanthine oxidase activity was depressed in rats receiving disulfiram; however, this phenomenon is not easily explained since it was also seen with the tissue incubated with methylene blue. With this exception, chronic administration of disulfiram appears to have little to no effect on xanthine oxidase activity. This is in agreement with the finding (14) that xanthine oxidase apparently has little to do with acetaldehyde metabolism *in vivo*. There were no significant differences in the excretory uric acid/creatinine and allantoin/creatinine ratios (15) for the control and test diets. Since both aldehyde oxidase and xanthine oxidase are molybdenum dependent (16), it is of interest to note that the molybdenum content (17) was unaffected by chronic disulfiram feeding.

Effects on Reproduction—Animals were fed control and test diets and mated in a manner similar to that described for the rats in Table IV. The experiment, as summarized in Table VI, indicates that two factors are contributing to the antireproductive effect of disulfiram. By pooling the ratios (litters/pairs mated) for the first and second generations, a 92% incidence of successful conception for rats receiving the control diet is found. This can be contrasted with the 75 and 61% incidence seen for the pooled 1:2000 disulfiram generations and the pooled 1:1000 disulfiram (including those receiving ascorbic acid) generations. However, beyond this anti-conceptive effect, one notes that the survival incidence of the young rats born from disulfiram-fed mothers is much less than the controls. Since malformations were not noted at birth and since those surviving 30 days did not have their growth stunted (Table IV), as could be caused by disulfiram excretion in milk, the cause of infant mortality may be due to decreased milk secretion by the mother. This could be a secondary result of chelation. Disturbances of lactation are often interrelated with cannibalism in the albino rat (9).

SUMMARY

Chronic feeding of 1:1000 and 1:2000 disulfiram in the diet retarded the growth of weanling albino rats, while concentrations of 1:4000 and 1:8000 were without effect. Continued feeding of the active concentrations limited the reproductive capacity of young adults by having an anticonceptive effect, as well as by decreasing the survival incidence of the offspring. This latter effect may be due to decreased lactation and secondary cannibalism. Since Lish

(18) did not note any significant alterations in the rat estrus cycle it is possible that the mechanism of disulfiram's anticonceptive action involves inhibition of spermatogenesis. In this context, it is interesting to note that the experimental agents of the bis(dichloroacetyl) diamine type, such as *N,N'*-bis(dichloroacetyl)-1,8-octanediamine (WIN-18446) which inhibits spermatogenesis in the rat (19) and man (20), produce pronounced disulfiramlike reactions if the subject also consumes ethanol (21).

Chronic feeding of 1:1000 disulfiram decreases the longevity of rats without any significant accompanying gross symptomatology. This concentration is considered equivalent to about 10 (adult rats) to 20 (young rats) times the average human dose (500 mg./day or 7 mg./kg.). Decreased longevity is probably not correlated with blood dyscrasias.

Effects of disulfiram on growth and reproduction were resistant to supplemental feeding with ascorbic acid and also appeared not to be due to a thiouracil-like effect on the thyroid gland. Tissue xanthine oxidase activity was unaffected as was liver molybdenum by feeding 1:1000 and 1:2000 disulfiram.

Stability and Structure of Some Organic Molecular Complexes in Aqueous Solution

JORDAN L. COHEN* and KENNETH A. CONNORS

Abstract □ On the basis of a simple model of 1:1 complex formation between planar molecules, this equation was derived: $\Delta G_u^0 = A(G_{SL}^0 - G_{MS}^0 - G_{ML}^0)$, where ΔG_u^0 is the standard unitary free energy change for complex formation, A is the area of overlap in the plane-to-plane interaction between the two molecules, and G_{IJ}^0 is a free energy of interaction per unit area between I and J . (S , L , and M represent substrate, ligand, and medium.) If the parenthesized term is roughly constant for a series of substrates and ligands in a constant medium, it is suggested that the quantity G_{SL}^0 does not play a major role, and that the complex stability is primarily controlled by repulsive solvent interaction terms (G_{MS}^0 and G_{ML}^0). It follows that the system will assume an orientation of S and L such as to maximize A . Therefore, maximal overlap areas were estimated for 18 neutral and 32 ionic complexes. A substantial improvement in the area correlation was obtained, and the observation was made that there is no significant difference between the average behavior of neutral and charged complexes. The maximal overlap concept provides a general "first-order" description of molecular complex formation in aqueous solution. Deviations from the line are significant and may be associated with specific structure-stability relationships. Application of the maximal overlap approach leads to average complex structures without introducing arbitrary assumptions about specific group interactions. The structures thus generated are consistent with the chemical reactivity of the complexes.

Keywords □ Complexes, organic molecular—aqueous solution □ Stability constants—organic molecular complexes □ Maximal overlap areas, estimated—complexes □ Titration, potentiometric, nonaqueous—analysis □ IR spectrophotometry—structure □ NMR spectroscopy—structure

The earlier suggestion (1) that systematic structural variations in substrates and ligands might be a successful approach to the elucidation of the structures of molecular complexes in solution formed the basis for much of the experimental design, including some of the present work. During the course of these structural investigations, it became increasingly apparent that the authors were studying secondary (specific) effects without having first identified the primary general effect in determining complex stability. This recognition led directly to the conception of the correlation between complex stability and planar area of interactants as described earlier (2). Complexes of neutral interactants gave a rough linear correlation of standard free energy change with planar area of the small interactant; this was interpreted in terms of a simple model of the process. Complexes containing an ionic interactant could not be usefully correlated, and it was suggested that neutral and ionic complexes behave differently in these systems.

The present work was planned to refine the area correlation and to elucidate the differences between neutral and ionic molecular complexes in aqueous solution. An ultimate goal is the ability to determine and to predict complex structures and properties (especially chemical reactivity) in solution, and the area correlation offers a promising point of attack.

EXPERIMENTAL

Materials—Many of the chemicals were prepared or purified as described elsewhere (1, 2). 3- β -Naphthylacrylic acid was prepared from β -naphthaldehyde¹ by the method of Fulton and Robinson (3), and its methyl ester was obtained by treatment with diazomethane. The slightly yellow product was recrystallized twice from ethanol-water, m.p. 88–89° [lit. (4) 93–93.5°]. IR and NMR spectra were consistent with the expected structure (5). Methyl 9-anthroate was prepared by treating 9-anthracene carboxylic acid chloride¹ with methanol in pyridine; it was recrystallized twice from ethanol-water, m.p. 110–111° [lit. (6) 111°]. 2,6-Naphthalenedicarboxylic acid dimethyl ester² was used directly, m.p. 185° [lit. (7) 186°]. Naphthalene³ (resublimed) was used directly, m.p. 79° [lit. (8) 80.3°]. Phenanthrene¹ was recrystallized from ethanol, m.p. 99° [lit. (9) 101°]. The acid chloride of *p*-nitro-*trans*-cinnamic acid was prepared by refluxing the acid (Eastman White Label) with freshly distilled thionyl chloride. The acid chloride was refluxed with methanol to give the methyl ester, which was recrystallized twice from ethanol, m.p. 163° [lit. (10) 161°].

Benzimidazole¹ was recrystallized three times from water, m.p. 172–173° [lit. (11) 171–173°]. Benzimidazole 2-acetonitrile¹ was used directly, m.p. 209–210° [lit. (12) 209.7–210.7°]. 6-Nitrobenzimidazole¹ was recrystallized three times from methanol, m.p. 207–208° [lit. (13) 206°]. Xanthine and hypoxanthine¹ were used directly. Adenine¹ was recrystallized from water and dried at 150° for 8 hr. Nonaqueous titration in glacial acetic acid with acetous perchloric acid (quinaldine red indicator) showed that it was the anhydrous form. 8-Nitrotheophylline² was used directly, m.p. 282–283° dec. [lit. (14) 282–283° dec.]. Potentiometric titration with standard base indicated that it was the dihydrate. Theophylline⁴ was recrystallized from water, dried at 150° for 4 hr., and then ground to a fine powder and dried for 24 hr., m.p. 270–271°. Nonaqueous titration in *N,N*-dimethylformamide with standard sodium methoxide in benzene-methanol solution (thymol blue indicator) showed it to be 100% anhydrous theophylline. Theobromine⁴ was recrystallized from water and its purity checked by nonaqueous titration.

3,5-Dinitrobenzoic acid (Eastman White Label) was recrystallized twice from ethanol-water, m.p. 205–207° [lit. (15) 205–207°].

The pK_a values were determined spectrophotometrically for many of the ligands; these values were found at 25° in water (ionic strength 0.3 *M*): 8-nitrotheophylline, 3.55 ± 0.05; hypoxanthine, 8.50 ± 0.06; xanthine, 9.95 ± 0.05 (for conversion to the anion); benzimidazole 2-acetonitrile, 4.20 ± 0.02 and 11.76 ± 0.02; and 6-nitrobenzimidazole, 2.89 ± 0.03 and 10.69 ± 0.05.

Apparatus and Procedures—The equipment and methods employed for stability constant determinations have been described in detail earlier (1, 2, 5, 16). Stability constants were evaluated by the solubility, spectral, and kinetic techniques (17) and are expressed as apparent 1:1 stability constants (K_{11}') in *M*⁻¹. All constants were determined at 25.0° in aqueous solution of 0.30 *M* ionic strength; in spectral and kinetic studies the solvent usually contained 0.83% acetonitrile, added as the substrate stock solution. An additional parameter provided by the kinetic method is symbolized q_{11} and is interpreted as the fractional decrease in chemical reactivity of the complexed substrate relative to the uncomplexed substrate (16).

RESULTS

Table I lists the substrate-ligand combinations studied, with their stability constants. Systems were investigated by the solubility

method (18) when substrate stability and ligand solubility permitted. Spectral determinations were made on those systems in which a measurable spectral shift occurred upon complexation. The kinetic technique was applied to most of the ester substrates. The reproducibility of most stability constants is about $\pm 10\%$ (the cinnamic acid anion-theobrominate constant is only reliable to $\pm 25\%$ because it was estimated in "infinity" solutions from a kinetic study of methyl cinnamate-theobrominate).

Nearly all of the systems studied include one heterocyclic interactant (methyl cinnamate-3,5-dinitrobenzoate is the only exception), so this limitation must be recognized. As noted earlier, most of the substrates and ligands were selected to provide information on the specific structural requirements for complexing and on the nature of ionic complexes. Another possible feature that was considered was the statistical effect on apparent complex stability (18). Thus, methyl 2-naphthoate (I) and 8-chlorotheophyllinate form a complex with $K_{11}' = 120 M^{-1}$. If 8-chlorotheophyllinate interacts in a specific orientation with methyl 2-naphthoate, and if in a 1:1 complex of 8-chlorotheophyllinate with the dimethyl ester of naphthalene 2,6-dicarboxylic acid (II) this orientation is preserved, then K_{11}' for the complex with II should be twice 120. The observed value is $160 M^{-1}$, possibly indicating either that there

is no specific orientation of the ligand common with I and with II, or that the binding energy of the ligand with II is influenced by the second ester group. Again, comparing the complex naphthalene-theophyllinate ($K_{11}' = 23 M^{-1}$) with phenanthrene-theophyllinate ($K_{11}' = 89 M^{-1}$) shows that a simple statistical effect is not the only factor controlling the constant with the larger substrate. (Anthracene could not be studied because of its very low solubility.)

Methyl 3- β -naphthylacrylate (III) can be viewed either as a 2-naphthoate with a conjugated side chain or as a methyl cinnamate derivative with a *m,p*-fused aromatic ring. A ligand has a "choice" of positions, one of them characteristic of a naphthoate substrate and one resembling a cinnamate. Comparison of the stability constants for III, for methyl cinnamate, and for methyl 2-naphthoate with common ligands suggests that the ligand preferentially resides at the naphthyl portion of III. This conclusion is strengthened by the q_{11} values, which will be considered later. Also consistent with this interpretation is the absence of a useful spectral shift upon complexation, which is typical of benzoate and naphthoate complexes but not of cinnamate complexes.

Some of these data suggest that charge-transfer and simple electrostatic forces are not of major importance in determining complex stability in aqueous solution. The anions of theophylline (IV) and theobromine (V) have very different electronic distributions, but they yield similar K_{11} 's with the common substrate methyl *trans*-cinnamate.

Cinnamic acid anion complexes appreciably with the anions theophyllinate (4) and theobrominate. Methyl *p*-nitrocinnamate

Table II— q_{11} Values for Alkaline Hydrolysis of Ester Complexes^a

Substrate	Ligand	q_{11}
Methyl <i>trans</i> -cinnamate	Theophyllinate	0.90
Methyl <i>trans</i> -cinnamate	Theobrominate	1.0
Methyl 1-naphthoate	Theophyllinate	0.97

^a 25°, 0.3 M ionic strength, phosphate or hydroxide buffers, 0.83% acetonitrile.

interacts with theophyllinate to about the same extent as does methyl cinnamate. The anion of 3,5-dinitrobenzoic acid, which Menger and Bender (19) expected to function as an electron acceptor, complexes significantly with several anions (Table I). Thus, with theophylline, a K_{11}' of 10 M^{-1} is observed. Yet a stability constant of 9 M^{-1} is found for the 3,5-dinitrobenzoate-methyl cinnamate complex, and methyl cinnamate complexes with theophylline with K_{11}' equal to 25 M^{-1} . Simple donor-acceptor relationships do not provide a convincing picture of this cycle of numbers.

3,5-Dinitrobenzoate gave $K_{11}' = 13\text{ M}^{-1}$ with 8-chlorotheophyllinate, whereas Guttman and Brooke (20) found a stability constant of 4.7 M^{-1} between 8-chlorotheophyllinate and 3-carbomethoxy-1-methylpyridinium cation; that is, the 8-chlorotheophyllinate anion interacts more strongly with another anion than it does with a cation.

Earlier results (16) led to an estimate of the uncertainty in q_{11} of about 0.1 unit (q_{11} is constrained, for 1:1 complexes exhibiting inhibition relative to the uncomplexed substrate, to lie in the interval 0–1). In the present study the reactions were simple ester hydrolyses in easily analyzed and controlled systems, and it is estimated that most of the q_{11} values have an uncertainty of about 0.05 unit. These q_{11} values are collected in Table II. Figure 1 shows a plot illustrating the determination of these quantities (16, 17); q_{11} is equal to the reciprocal of the intercept on the ordinate axis.

DISCUSSION

Maximal Overlap Area Correlation—The model of complex formation presented earlier (2) assumes plane-to-plane interaction of substrate *S* and ligand *L* in medium *M*. Equation 1 can be developed from this model:

$$\Delta G_u^0 = A(G_{SL}^0 - G_{MS}^0 - G_{ML}^0) \quad (\text{Eq. 1})$$

where ΔG_u^0 is the standard unitary free energy change for complex formation (21), G_{IJ}^0 is a free energy of interaction per unit area between "surfaces" *I* and *J* at the equilibrium separation distance, and *A* is the area of contact between *S* and *L*. The first use of this model took *A* to be the estimated planar area of the smaller of the two interactants (2). A plot of standard unitary free energy change against planar area of the smaller interactant gave a fair linear correlation for complexes in which both *S* and *L* were neutral, but the attempted correlation was not successful when either, or both, of the interactants was an anion. An obvious fault of the treatment is that numerous points corresponded to the same area (because they involved one of the same interactants) yet represented different complex stabilities. This generated vertical lines in the plot. If the model is a good one for complex formation, part of the lack of success apparently was caused by a poor estimate of the overlap area *A*. *A* cannot be greater than the planar area of the smaller interactant, but it may be smaller than this quantity. A refined estimate of the overlap area was made as follows.

A free energy term of the type G_{IJ} assumes an increasingly negative value as attraction between *I* and *J* increases. (When *I* and *J* are separated to infinity, G_{IJ} equals zero.) In a first approximation, the surfaces are considered homogeneous; that is, no preferred specific (group) interactions are considered. Then *A* will assume a value such as to maximize $-\Delta G^0$ subject to these conditions: (a)

Figure 1—Kinetic plot showing several complex systems (L_t is total ligand concentration). Key: ○, methyl *trans*-cinnamate–theobrominate; ◐, methyl *p*-nitrocinnamate–theophyllinate; and ●, methyl 3- β -naphthylacrylate–theophyllinate.

the more negative the value of G_{SL}^0 , the greater *A* will be; (b) the more positive the value of G_{MS}^0 , the greater *A* will be; and (c) the more positive the value of G_{ML}^0 , the greater *A* will be. In chemical terms, attraction between *S* and *L* will lead to a maximization of overlap area, whereas repulsion would tend to minimize the area. Attraction between *M* and *S* will minimize overlap area, whereas *M*–*S* repulsion will maximize it, and similarly for *M* and *L*. The final structure is then a compromise position depending upon (possibly) opposing factors.

Since most of these compounds are relatively hydrophobic, it is reasonable to suppose that G_{MS}^0 and G_{ML}^0 are fairly large repulsive quantities. That G_{SL}^0 does not play an overwhelmingly important role is indicated by the marked reduction in K_{11} for the methyl cinnamate–theophylline complex as the water concentration is decreased in water-methanol mixtures (22). It seems possible, therefore, that in many of these complexes a structure is assumed in which the overlap area between substrate and ligand is maximized. Therefore, a plot was made of standard unitary free energy change, ΔG_u^0 , against maximal overlap area.

Maximal overlap areas were estimated as shown by Fig. 2. The planar area of the smaller molecule is traced from a Corey-Pauling-Koltun molecular model (23) on translucent tracing paper and is darkened. The planar area of the larger molecule is traced on a transparent plastic sheet. These are superimposed and oriented until the area of overlap is visually maximized, with nothing else being taken into consideration. A photocopy of this orientation is made, and the overlap area (hatched area in Fig. 2) is measured by a planimeter. This gives the maximal overlap area for plane-to-plane interaction between the two molecules. Table III gives maximal overlap areas estimated in this way.

Figure 3 shows the correlation of ΔG_u^0 with maximal overlap area for neutral complexes (dark circles). The correlation seems to be slightly better than the original plot against the planar area of the smaller interactant (2). The open circles in Fig. 3 represent complexes in which one or both interactants are ionic. A marked improvement in the correlation of ionic complexes has been achieved with the maximal overlap area concept.

The 50 complexes plotted in Fig. 3 represent about 70 systems, because, for clarity, one point may represent more than one complex. For example, the methyl *trans*-cinnamate–theophylline complex has the same stability constant and overlap area as do several other cinnamate–theophylline complexes, so these additional points were not plotted. A least-squares line calculated for the 50 points gave an ordinate intercept of 0.1 (in units of $-10^{21} \Delta G_u^0/N$), indicating that the line passes essentially through the origin, in agreement with the model equation. Separate least-squares lines for the neutral and ionic complexes gave the same slope values, with the standard deviation for neutral complexes being 0.58 and for ionic complexes 0.64, in units of $-10^{21} \Delta G_u^0/N$. This treatment has, there-

Figure 2—Maximal overlap area (hatched area) in the methyl *trans*-cinnamate–theophylline complex. Methyl cinnamate is outlined with the heavier line, with the ester group lying to the right.

Table III—Estimated Maximal Overlap Areas for Complexes

System Number	Substrate	Ligand	Maximal Overlap Area (Å ² /molecule)
1	Methyl 2,6-dichloro <i>trans</i> -cinnamate	Theophylline	55.6
2	Acetophenone	Theophylline	44.4
3	Methyl <i>trans</i> -cinnamate	Benzimidazole	39.5
4	Naphthalene	Benzimidazole	41.2
5	Methyl 1-naphthoate	Theophylline	54.7
6	<i>trans</i> -Cinnamaldehyde	Theophylline	49.4
7	Benzalacetone	Theophylline	49.8
8	Methyl <i>trans</i> -cinnamate	2-Methyl imidazole	28.4
9	Benzamide	Theophylline	39.5
10	Naphthalene	Theophylline	49.8
11	Methyl crotonate	Theophylline	27.2
12	Methyl benzoate	Theophylline	39.9
13	Methyl hydrocinnamate	Theophylline	34.2
14	<i>trans</i> -Cinnamyl acetate	Theophylline	37.9
15	Methyl 2-naphthoate	Theophylline	53.1
16	Methyl <i>trans</i> -cinnamate	Theophylline	49.0
17	Methyl <i>trans</i> -cinnamate	Caffeine	46.9
18	<i>trans</i> -Cinnamamide	Theophylline	45.3
19	Methyl <i>trans</i> -cinnamate	Purine anion	33.3
20	Theophylline	Salicylate	39.1
21	Methyl <i>trans</i> -cinnamate	Hypoxanthine anion	35.4
22	Methyl <i>trans</i> -cinnamate	8-Bromotheophyllinate	48.1
23	Methyl <i>trans</i> -cinnamate	3,5-Dinitrobenzoate	39.9
24	Cinnamoylsalicylate	Theophylline	44.9
25	Theophylline	<i>trans</i> -Cinnamate	42.4
26	Theophylline	3,5-Dinitrobenzoate	51.9
27	Methyl <i>cis</i> -cinnamate	8-Nitrotheophyllinate	44.0
28	Methyl <i>trans</i> -cinnamate	8-Nitrotheophyllinate	53.9
29	Methyl 2-naphthoate	8-Nitrotheophyllinate	55.6
30	Methyl <i>trans</i> -cinnamate	8-Chlorotheophyllinate	47.8
31	Methyl 2-naphthoate	8-Chlorotheophyllinate	55.6
32	Methyl 1-naphthoate	8-Chlorotheophyllinate	51.0
33	Naphthalene	8-Chlorotheophyllinate	46.5
34	Phenanthrene	8-Chlorotheophyllinate	56.0
35	9-Methyl anthroate	8-Chlorotheophyllinate	56.8
36	Naphthalene 2,6-dicarboxylic acid, dimethyl ester	8-Chlorotheophyllinate	54.3
37	Methyl 3-β-naphthylacrylate	8-Chlorotheophyllinate	54.3
38	Methyl crotonate	Theophyllinate	27.2
39	<i>p</i> -Nitrophenyl benzoate	Theophylline	38.7
40	Methyl <i>cis</i> -cinnamate	Theophyllinate	42.0
41	Methyl 2-naphthoate	Theophyllinate	53.9
42	Methyl 1-naphthoate	Theophyllinate	53.5
43	Methyl <i>trans</i> -cinnamate	Theophyllinate	50.2
44	Methyl 3-β-naphthylacrylate	Theophyllinate	51.4
45	Methyl <i>p</i> -nitrocinnamate	Theophyllinate	50.2
46	Naphthalene	Theophyllinate	49.0
47	Methyl <i>trans</i> -cinnamate	Theobrominate	47.3
48	Methyl 3-β-naphthylacrylate	Theobrominate	49.8
49	Methyl 1-naphthoate	Theobrominate	51.0
50	Methyl 2-naphthoate	Theobrominate	51.0

fore, revealed the result that, in the first-order approximation, all systems behave similarly and, *on the average*, there is no difference between neutral and ionic complexes. This was not obvious on the basis of data for systematically selected substrates and ligands, and it only became clear when so many systems had been studied that the selection was practically random.

The equation of the line in Fig. 3 is

$$-\Delta G_{\text{SL}}^{\circ}/N = 0.149 \times 10^{-21} \text{ (cal./Å}^2\text{)} \times \text{maximal overlap area (Å}^2\text{/molecule)} \quad (\text{Eq. 2})$$

This slope value is equivalent to 64 dyne/cm. If, as suggested, the *S*-*L* interaction is of minor importance in determining complex stability, then the average value of the G_{MS}° and G_{ML}° terms is 32 dyne/cm. This is approximately the value of interfacial tensions between water and some typical hydrophobic organic compounds (24).

The statistical nature of this first-order approximation is apparent from Fig. 3. If another large group of structurally similar substrates and ligands was studied, the points would be expected to define a line close to the one in the figure. However, no single stability constant value could be predicted to within better than a factor of two. The dispersion seen in Fig. 3 may be considered a second-order effect, probably correlatable with specific structural features in the substrate and ligand. (Most of the deviations from the line are too

large to be ascribed to misestimates of maximal overlap areas.) In terms of the model and Eq. 1, the quantity ($G_{\text{SL}}^{\circ} - G_{\text{MS}}^{\circ} - G_{\text{ML}}^{\circ}$) varies appreciably within the series of complexes represented. This scatter of points does not invalidate the model, which does not include the constraint that the parenthesized quantity should remain constant as *S* and *L* are changed.

Few general inferences can be made at this time concerning the second-order effect (the deviations from the area correlation line) in describing complex stability. One interesting set of data is the stability constants for theophylline and theophyllinate complexes with seven common substrates; the constant for the neutral ligand is nearly always larger than that with the anion, the mean value of the ratio being 2.35 ± 0.73 . This is explicable if it is considered that the anion is less hydrophobic than is the neutral ligand, resulting in a more negative G_{ML}° term and, hence, decreased complex stability. (Since theophylline was the only ligand that could easily be studied in its neutral and anionic forms, these data earlier led to the too general belief that ionic complexes always behave differently from neutral ones.) That this solvation effect is not the only factor is indicated by stability constants for six common substrates with theophyllinate and 8-chlorotheophyllinate; the ratio of these constants (8-chlorotheophyllinate-theophyllinate) is 2.01 ± 0.33 . The larger area of the halogenated xanthine does not account for the effect. These examples indicate a complicated variation in the energy terms even for closely related compounds.

Figure 3—Plot of standard unitary free energy change for complex formation at 25° in aqueous solution against estimated maximal overlap area. Key: ○, ionic complexes; and ●, neutral complexes. See Table III for complex identities.

Structure and Reactivity of Complexes—Previous reports have stated q_{11} values for ester hydrolysis to be either about unity (implying direct contact of the ligand with the ester group and, therefore, substantial inhibition of the reaction) (1, 2, 16) or less than 0.5 (with no direct steric interference but a small polar effect on the rate). In this study, ester substrates have been selected to allow a distinction to be made between q_{11} values in the range 0.7–1 (Table II and Fig. 1).

Repetition of the methyl *trans*-cinnamate-theophyllinate study (1) yielded $q_{11} = 0.90$, which is now thought to be significantly different from unity. The methyl *trans*-cinnamate-theobrominate complex, however, gave a q_{11} value of essentially unity. The stability constants and maximal overlap areas for the two complexes are about the same. The maximal overlap area profiles, developed as described earlier, suggest a possible reversal of the xanthine-cinnamate orientation, with the xanthine occupying a position closer to the ester carbonyl when the ligand is theobrominate; this is consistent with the higher q_{11} value.

Methyl 3- β -naphthylacrylate (III) is a larger molecule than methyl *trans*-cinnamate, and it seemed that a kinetic study with theophyllinate might define the area of interaction between III and this ligand. The q_{11} of 0.71 implies only a small steric involvement with the ester function (a q_{11} of 0.71 corresponds to 0.73 kcal./mole difference in free energy of activation between the complexed and uncomplexed substrate), suggesting that the xanthine lies further away from the ester group than it does in the methyl cinnamate complex. Further, the q_{11} of 0.89 for the 8-chlorotheophyllinate complex of III is consistent with the greater bulk of this xanthine and the possibility that greater steric interference occurs by the ligand in the reaction of the ester function.

It is curious, considering the scatter observed in the area correlation (Fig. 3), that the maximal overlap concept should consistently lead to a picture of the substrate-ligand orientation (that is, the complex structure) that is reasonable in terms of measurable complex reactivity. This leads to the tentative view that the maximal overlap area approach provides a realistic estimate of complex structures in aqueous solution, including an estimate of average complex stability. The actual stability of a particular complex is determined, within this average configuration, by local atomic and group interactions.

Central Hypotensive Activity of *dl*- and *d*-Propranolol

GERALD J. KELLIHER* and JOSEPH P. BUCKLEY

Abstract □ The intraventricular administration of *dl*-propranolol to α -chloralose-anesthetized cats was followed by a decrease in blood pressure and was devoid of an associated tachycardia. *d*-Propranolol in an equivalent dose produced a hypotensive response which was not statistically different from *dl*-propranolol. These data suggest that there is a central component in the hypotensive response to propranolol and that it is independent of the β -adrenergic blocking activity. The intraventricular administration of 500 mcg. of reserpine base produced greater than a 90% depletion of norepinephrine in all brain regions analyzed within 24 hr. This pretreatment with reserpine also reversed the hypotensive response to both *d*- and *dl*-propranolol as well as converted the decrease in heart rate to an increase in heart rate. Thus, at least one of the amines must be required to produce the hypotensive response. Perfusion of the ventricular system with *dl*-propranolol generally produced an increase in epinephrine along with a decrease in norepinephrine in the brain region analyzed. Under the same conditions, *d*-propranolol also increased epinephrine but led to a decrease in norepinephrine in only 50% of the tissues assayed. These changes in amine levels occurred during the perfusion, which also produced a sustained hypotensive effect lasting the duration of the perfusion. The hypotension associated with propranolol therapy may have a central component that is not dependent on the β -adrenergic blocking property of propranolol, which requires one or more of the brain amines, and leads to an increase in the epinephrine level along with a general decrease in the norepinephrine level of the brain.

Keyphrases □ *dl*-, *d*-Propranolol—central hypotensive activity □ Hypotensive action, *dl*-, *d*-propranolol—intraventricular injection □ β -Adrenergic blocking activity—propranolol □ Catecholamines, brain—propranolol effect

Propranolol antagonizes the cardiovascular effects of β -adrenergic receptor stimulation produced by either stimulation of effector fibers or by sympathomimetic amines. The intravenous administration of propranolol produces a decrease in the sympathetic component to the heart and blocks the chronotropic effects of isoproterenol and epinephrine and the peripheral vasodilatory effects of isoproterenol (1–3). The acute response to propranolol is a decrease in cardiac output, whereas prolonged administration fails to produce this effect (4). Several reports have shown that the intravenous administration of propranolol to normotensive

or hypertensive individuals decreased heart rate and cardiac output along with a concomitant decrease in systemic blood pressure but exhibited no significant effects on systemic peripheral resistance (4–6). Epstein *et al.* (5) and Shinebourne *et al.* (6) reported that the increase in arterial pressure that is associated with exercise was abolished by propranolol *via* reduction in cardiac output.

The central nervous system (CNS) manifestations attributed to propranolol classify it as a sedative and general CNS depressant (7–9). Since both propranolol and pronethalol possess these properties while dichloroisoproterenol (DCI) produces CNS stimulation, these authors have concluded that it is the presence of the naphthyl group rather than the β -adrenergic blockade that is responsible for the CNS effects. The depression or tranquilization in humans associated with propranolol administration is invariably apparent only at dosage levels that are many times greater than those necessary to produce β -adrenergic blockade (10–12). Masuoka and Hansson showed that intravenous administration of ^{14}C -labeled propranolol is rapidly taken up by the rat brain and concentrated 50 times greater in the brain than in the blood (13).

The hypotensive effect induced by the administration of β -adrenergic blocking agents in man has been well documented (14–22). This response is not exclusive to humans, because other investigators also have noted depressor effects in animals (23–26). The oral administration of propranolol for several weeks has been reported to result in a gradual and significant decrease in systemic arterial pressure in hypertensive patients (10, 16, 22). In all cases, regardless of the time of onset, the dose of the β -adrenergic blocker was many times that required for the blockade of the β -receptors, thus leading to the hypothesis that this response may not be due to antagonism of these receptors. This hypotensive response was unexpected, since the blocking of a neural mechanism that produces vasodilation in the absence of a significant reduction in cardiac output might be expected to result in a rise in systemic blood pressure

or hypertensive individuals decreased heart rate and cardiac output along with a concomitant decrease in systemic blood pressure but exhibited no significant effects on systemic peripheral resistance (4–6). Epstein *et al.* (5) and Shinebourne *et al.* (6) reported that the increase in arterial pressure that is associated with exercise was abolished by propranolol *via* reduction in cardiac output.

The central nervous system (CNS) manifestations attributed to propranolol classify it as a sedative and general CNS depressant (7–9). Since both propranolol and pronethalol possess these properties while dichloroisoproterenol (DCI) produces CNS stimulation, these authors have concluded that it is the presence of the naphthyl group rather than the β -adrenergic blockade that is responsible for the CNS effects. The depression or tranquilization in humans associated with propranolol administration is invariably apparent only at dosage levels that are many times greater than those necessary to produce β -adrenergic blockade (10–12). Masuoka and Hansson showed that intravenous administration of ^{14}C -labeled propranolol is rapidly taken up by the rat brain and concentrated 50 times greater in the brain than in the blood (13).

The hypotensive effect induced by the administration of β -adrenergic blocking agents in man has been well documented (14–22). This response is not exclusive to humans, because other investigators also have noted depressor effects in animals (23–26). The oral administration of propranolol for several weeks has been reported to result in a gradual and significant decrease in systemic arterial pressure in hypertensive patients (10, 16, 22). In all cases, regardless of the time of onset, the dose of the β -adrenergic blocker was many times that required for the blockade of the β -receptors, thus leading to the hypothesis that this response may not be due to antagonism of these receptors. This hypotensive response was unexpected, since the blocking of a neural mechanism that produces vasodilation in the absence of a significant reduction in cardiac output might be expected to result in a rise in systemic blood pressure

(18, 27–29). The mechanism of the hypotensive response to the prolonged oral administration of propranolol has not been elucidated. Several investigators have attempted to explain this hypotensive response on a resetting of the baroreceptor threshold to respond to alterations in systemic blood pressure at a lower level; however, conclusive evidence is currently lacking (30, 31). Frohlich and Page (10) and Waal (21) have suggested that a more fruitful area of research into the mechanism of this hypotensive response would be the elucidation of a possible central component. The purpose of the present study was to investigate the role of the CNS in the hypotensive effects induced by propranolol.

EXPERIMENTAL

Perfusion of Left Lateral Ventricle—Twenty-two adult cats of either sex weighing 2–3 kg. were anesthetized with α -chloralose (65 mg./kg. i.p.) prepared as a 1% solution in warm saline. Systemic blood pressure was recorded from a catheterized femoral artery onto a Grass polygraph, and the ipsilateral femoral vein was catheterized for the administration of drugs. Tracheal intubation was performed, and the animal was ventilated with room air by means of a Harvard respirator. The left lateral ventricle was then prepared for perfusion with artificial cerebrospinal fluid (CSF) (32), following the method described by Bhattacharya and Feldberg (33), by stereotactically implanting a 22-gauge hypodermic needle which had previously been machined to remove the bevel. The coordinates used were: anterior, 13 mm.; lateral, 2.75 mm.; and horizontal, +7 mm. (34). The successful placement of the cannula was confirmed by the presence of CSF pulsating in the barrel of the cannula. The cannula was then permanently affixed to the skull using dental cement. The perfusate fluid was maintained at 38°, and the lateral ventricle was perfused at a rate of 0.1 ml./min. for 1 hr. prior to drug injection to permit stabilization of the cardiovascular system. After this stabilization period, the perfusion was temporarily interrupted to permit the injection of 0.5 mg. of *d*- or *dl*-propranolol contained in 0.1 ml. of artificial CSF. Perfusion was then resumed.

“Central reserpinization” was performed in 14 cats by implanting a ventricular cannula, following the previously mentioned procedure using an aseptic technique, in cats under pentobarbital anesthesia. Procaine penicillin G (600,000 units i.m.) was administered prior to and on the day following surgery, after which the animal was allowed to recover for 3 days. On the 4th day following surgery, the male cat was removed from the cannula and 500 mcg. of reserpine base¹ in 0.1 ml. of water for injection was then administered into the left lateral ventricle. The cannula then was resealed to effect a functional central sympathectomy (35–38). Twenty-four hours later, the cat was prepared for perfusion of the lateral ventricle as described previously. One-half milligram of *d*- or *dl*-propranolol in 0.1 ml. CSF was administered into the lateral ventricle, and the blood pressure and heart rate were monitored. The brains and hearts from 10 additional adult cats were removed 24 hr. after “central reserpinization” and sectioned into the following regions to delineate the areas adjacent to the ventricular system: medulla, pons, cerebellum, mesencephalon, diencephalon, and telencephalon. These sections were then assayed for norepinephrine content by the method of Brodie *et al.* (39) using a spectrophotofluorometer (Aminco-Bowman).

Eight adult cats weighing 2–3 kg. were prepared for intraventricular perfusion as described and perfused for 1 hr. with either *d*- or *dl*-propranolol (0.5 mg./0.1 ml. CSF, 0.1 ml./min.). The cat then was sacrificed by means of an intravenous injection of air; the brain and heart were rapidly removed, dissected as already described, and frozen. The norepinephrine and epinephrine contents of the various brain sections and myocardia were determined by a modification of the method of Chang (40), in which the fluorescent intensity of the epinephrine in the samples is read within 10 min. following oxidation at an excitation wavelength of 417 m μ (uncorrected) and an emission wavelength of 510 m μ (uncorrected). The samples were then placed in boiling water for 2 min. and cooled

to room temperature. The fluorescent intensity of norepinephrine was read at an excitation wavelength of 385 m μ (uncorrected) with an emission wavelength at 485 m μ (uncorrected). The concentrations of epinephrine and norepinephrine were determined using the simultaneous equations described by von Euler and Lishajko (41). All data were analyzed for statistical significance using Student's *t* test unless otherwise indicated.

RESULTS

Effect of Intraventricular Propranolol on Blood Pressure and Heart Rate of Anesthetized Cats—The intraventricular (IVT) administration of *d*- or *dl*-propranolol produced significant hypotensive responses which are summarized in Table I. Reflexogenic tachycardia in response to the hypotensive effect of propranolol did not occur, but there was a slight but not statistically significant decrease in heart rate (Table II). Although the degree of the hypotensive response to *dl*-propranolol was greater than that produced by the *d*-isomer, there was no statistically reliable difference between the two hypotensive responses. There was, however, a significant difference between *d*- and *dl*-propranolol in the reduction in heart rate produced. The spinal cord of each animal was transected at the C-2 level to ensure that the observed hypotensive response to IVT-administered propranolol was due to a central component; after the blood pressure had stabilized, the experiment was repeated. Neither compound elicited an effect following spinal transection. These data suggest that a portion of the hypotensive response to propranolol is of central origin and may be independent of β -adrenergic receptor blocking activity.

Effect of Central Reserpinization on Central Hypotensive Response to Propranolol—To ascertain the role of endogenous brain amines in the central hypotensive component of propranolol, the compounds were administered IVT to anesthetized cats 24 hr. after administration of reserpine into the lateral ventricle. The data, summarized in Tables III and IV, show that central reserpine pretreatment not only blocked the central hypotensive component previously elicited by both *d*- and *dl*-propranolol but also converted the response to a pressor effect. Whereas propranolol produced a decrease in heart rate in anesthetized nonreserpinized cats, the effect after reserpine was a mild increase in heart rate. These data suggest that the central hypotensive component elicited by both *d*- and *dl*-propranolol is dependent on the presence of central amine stores and a functional sympathetic cardiovascular component. Figure 1 presents a comparison of the effects of IVT propranolol in reserpinized and nonreserpinized anesthetized cats.

Effect of Central Reserpinization on Brain and Cardiac Norepinephrine Stores—To ascertain whether a functional central sympathectomy, which previous investigators have shown requires a 90% depletion of brain norepinephrine (35–38), had been achieved, 10 adult cats were pretreated IVT with reserpine 24 hr. before sacrifice. The brain was sectioned and analyzed as previously described, and the results of these assays are summarized in Table V. Every section of the brain analyzed showed at least a 90% depletion in the level of norepinephrine; however, cardiac norepinephrine stores were reduced by only 75%. These results confirm those reported by previous investigators for the IVT administration of 500 mcg. of reserpine 24 hr. prior to sacrifice (42–44).

Effect of IVT Perfusion with Propranolol on Regional Distribution of Brain Epinephrine and Norepinephrine—Since *dl*-propranolol has been reported to cause a decrease in brain norepinephrine with a simultaneous increase in cardiac norepinephrine, the effect was investigated in light of the central propranolol component described previously, possibly to correlate it with the hypotensive response. Data on the regional distribution of brain epinephrine and norepinephrine following 1 hr. IVT perfusion with either *d*- or *dl*-propranolol are summarized in Tables VI and VII. These data show that both the *d*- and *dl*-propranolol produced an increase in the level of epinephrine in the various brain regions with one exception. *dl*-Propranolol produced an 11% decrease in the epinephrine level of the diencephalon along with a slight decrease in the level of norepinephrine, although neither amounted to a significant depletion. In all other areas, *dl*-propranolol increased epinephrine content in varying degrees up to 125% in the medulla; however, only in the medulla ($p < 0.0005$), pons ($p < 0.005$), and telencephalon ($p < 0.025$) were these increases statistically significant. The level of norepinephrine was consistently reduced after *dl*-propranolol perfusion, with the effect being greatest in the medulla (32%); however, there was a 22% increase in norepinephrine ($p < 0.01$) in the telencephalon. The reduction in norepinephrine level in the pons ($p < 0.05$) and medulla ($p < 0.05$) proved to be statistically significant.

The epinephrine level was increased in each region of the brain following perfusion with *d*-propranolol, with a maximum of 167% in the medulla. The increase in epinephrine proved to be statistically reliable in the medulla ($p < 0.005$), pons ($p < 0.005$), mesencephalon ($p < 0.05$), and telencephalon ($p < 0.025$). The level of norepinephrine increased in the mesencephalon, diencephalon, and telencephalon but decreased in the medulla, pons, and cerebellum; however, the changes noted in any one region fell short of statistical reliability. The results of perfusing with either *d*- or *dl*-prop-

ranolol were parallel in both direction and magnitude of change, with the exception of the mesencephalon and diencephalon.

Masuoka and Hansson (13) have studied the CNS distribution of ¹⁴C-labeled propranolol in rats and have found that propranolol is highly concentrated in those areas corresponding to the regions where the greatest changes in catecholamine levels have been found: telencephalon, mesencephalon, pons, and medulla. These areas showed the highest and most prolonged concentration of the labeled propranolol. There have been no reports to date on the uptake and distribution of ¹⁴C-labeled propranolol in the cat.

The IVT perfusion with either *d*- or *dl*-propranolol resulted in a significant hypotensive response. This response was of a similar

magnitude to that seen previously with single IVT injections and persisted through the entire perfusion period. This hypotensive response also was devoid of a concomitant tachycardia. A comparison of the hypotensive response from *d*- and *dl*-propranolol perfusion is summarized in Fig. 2.

DISCUSSION

Many reports have noted a hypotensive effect of propranolol. This response may occur during the acute administration of the compound in which the fall in blood pressure is usually mediated by a decrease in cardiac output (4-6). The acute hemodynamic response to parenterally administered propranolol has been shown to differ from that observed during prolonged administration, because the decrease in cardiac output observed upon acute administration is absent during chronic administration (4, 45). The results of the present studies utilizing the IVT administration of *dl*-propranolol have shown that propranolol can produce a hypotensive response *via* central mechanisms. The hypotensive response produced was statistically significant and was devoid of a concomitant tachycardia, which may suggest the involvement of vasomotor regulatory centers. The results, however, do not rule out the possibility of a vagal action producing the decrease in heart rate and the absence of a concomitant reflexogenic tachycardia.

Several investigators have presented evidence to suggest that many of the effects noted with propranolol, including those on the CNS, are independent of the β -adrenergic blocking activity of the compound (7-9). This also has been shown to be true with the hypotensive response associated with prolonged oral administration of propranolol (4, 31). The present study involved the use of *d*-propranolol, which has been reported to have only 1-2% of the β -blocking activity of the racemic mixture, to differentiate between the hypotensive and β -blocking activity of propranolol (2, 46, 47). The findings suggest that the central hypotensive response induced by *dl*-propranolol is not dependent on β -adrenergic blocking activity, since the *d*-isomer also produces a centrally mediated hypotensive response which was not statistically different from that produced by the racemic mixture. Although Gagnon and Melville (48) have shown that the response to isoproterenol is similar after intravenous or IVT administration (consisting of myocardial augmentation and hypotension), there remains speculation regarding the nature of the adrenergic receptors involved in mediating these responses. Thus, although the *d*-isomer of propranolol has been demonstrated to exhibit only 1-2% of the β -adrenergic receptor blocking activity of *d*-propranolol peripherally, this relationship may not hold true centrally. The β -receptorlike property exhibited centrally may not necessarily demonstrate an equivalent sensitivity to β -adrenergic agonists or antagonists as shown peripherally and

thus could give a false indication in the differentiation between central and peripheral β -adrenergic functions. Based on present knowledge, however, the evidence suggests that this central hypotensive response is independent of β -adrenergic blocking activity.

The depletion of brain and cardiac norepinephrine produced by IVT reserpine was similar to that previously reported from this laboratory (44). The depletion of brain amines by reserpine was utilized to study the role played by endogenous brain amines in the centrally mediated hypotensive response demonstrated by both *d*- and *dl*-propranolol. These data suggest that either a level of endogenous brain amine exceeding 10% of normal or a functional central sympathetic component is required for the central hypotensive response to propranolol. These data must be evaluated with the knowledge that reserpine does not selectively deplete norepinephrine but rather produces a gross depletion of other biogenic amines as well.

Propranolol has been reported to produce a decrease in brain catecholamines when 10 mg. i.p./kg./day was administered to mice for 4 days. Other investigators, however, have failed to reproduce these effects with propranolol, using the same dose and time schedule (50, 51). The present studies were also undertaken to determine if perfusion of the brain with propranolol would result in an alteration of the catecholamine content of the brain and to investigate the possibility that there may be a change in the epinephrine-norepinephrine balance. Epinephrine has been reported to repre-

Figure 2—A comparison of the hypotensive response to IVT perfusion of propranolol, 0.5 mg./0.1 ml. CSF, 0.1 ml./min., in anesthetized cats. Key: \times — \times , *dl*-propranolol (N = 4); and \circ -- \circ , *d*-propranolol (N = 4).

sent 4–17% of the total concentration of catecholamines in the brain (52–54). The rapid metabolism and enzymatic synthesis of epinephrine in the brain suggest that this potent amine may function as a neuroregulatory agent (55–60); some investigators have reported epinephrine to be an inhibitor of synaptic transmission within the CNS (61–63). The data presented here show that there is an alteration in the brain levels of both epinephrine and norepinephrine caused by perfusion with propranolol; however, these alterations are not uniform. The great increase in epinephrine within the pons and medulla strongly suggests that amine alterations associated with vasomotor regulatory centers may play a role in the central hypotensive response of prolonged therapy with propranolol. Furthermore, these data reinforce the idea that determining the whole brain concentration of a particular compound is less desirable than assaying individual brain regions, since an increase in one region may compromise a concurrent decrease in another region when assayed as a whole. This apparently led to the aforementioned reports noting both a decrease or no change in the brain level of norepinephrine following propranolol (45, 50, 51).

Oil-Water Partitioning of Chlorpromazine and Other Phenothiazine Derivatives Using Dodecane and *n*-Octanol

K. S. MURTHY* and GEORGE ZOGRAFI

Abstract □ The apparent partition coefficients of chlorpromazine and some other phenothiazine derivatives in dodecane-water and *n*-octanol-water systems were measured at 30°. Results in the dodecane system at various pH values demonstrated that only the free base form partitions. Intrinsic partition coefficients for all derivatives, except the very polar metabolite chlorpromazine sulfoxide, range from 10⁴ to 10⁶, indicating the remarkable hydrophobicity of these molecules. Partitioning measurements in *n*-octanol indicate significant extraction of these drugs as ion-pairs, as well as higher intrinsic partition coefficients than in dodecane. Measurement of partitioning at various salt concentrations, utilizing different anions, allowed the calculation of extraction constants. Correlations between intrinsic partition coefficients in dodecane and extraction constants in *n*-octanol are presented. From these studies, it is clear that quantitative studies involving the phenothiazines in heterogeneous systems such as membranes must consider their extreme hydrophobicity and the various factors that influence such behavior.

Keyphrases □ Chlorpromazine, oil-water partitioning—dodecane, *n*-octanol □ Phenothiazine, oil-water partitioning—dodecane, *n*-octanol □ Partition coefficients, apparent—phenothiazines □ Electrolyte, pH effects—apparent partition coefficients, phenothiazines □ Extraction constants—phenothiazines

Previous studies have suggested significant hydrophobic behavior for chlorpromazine and other phenothiazines which appears to be related to their pharmacological activity (1, 2). Such behavior is demonstrated by the very low water solubility of the free base form (3), an apparently high cyclohexane-water partition coefficient (4), significant surface activity at various interfaces (5–7), and accumulation at various biological membranes *in vitro* (8). Measurement of surface activity at charged lipid monolayer surfaces (9, 10), binding to red blood cell ghost membranes at various pH values (11), significant protein binding (12), and accumulation in intestinal membranes during the absorption process (13) all indicate that the ionized form of these drugs participates in hydrophobic interactions when its charge is suitably neutralized by appropriate anions.

In view of these observations, it appeared important to evaluate quantitatively the hydrophobic properties of the phenothiazines so as to characterize the effect of chemical modification and the relative behavior of ionized and free base forms. For this purpose, the influence of variables such as pH, ionic strength, and specific anions on partitioning into dodecane and *n*-octanol was studied.

EXPERIMENTAL

Materials—The chemical structure of each phenothiazine studied is given in Table I. Chlorpromazine (CPZ);¹ chlorpromazine sulfoxide (CPZ-O);¹ 1-chloro, 3-chloro, ethylamino, and butylamino

analogs of CPZ;¹ trifluoperazine (TFP);¹ trifluorpromazine (TFPZ);² and promazine (PZ)³ were studied. All buffer ingredients, electrolytes, and urea were of reagent grade. Sodium methane sulfonate and sodium ethane sulfonate were prepared by adding an equivalent amount of sodium hydroxide to the corresponding alkyl sulfonic acid, followed by recrystallization from absolute methanol. The *n*-dodecane and *n*-octanol⁴ were a spectrally pure grade.

Determination of Apparent Partition Coefficients—In *n*-octanol-aqueous systems, *n*-octanol saturated with buffer and buffer saturated with *n*-octanol were used to minimize volume changes due to mutual miscibility. Equal volumes of the two solvents with given amounts of solute were placed together and shaken for at least 8 hr., the time required to ensure equilibrium. The two phases were then separated in a separator, and the aqueous phase was analyzed. The difference in amount of solute present before and after equilibration was taken as the amount partitioning into *n*-octanol. Occasional assay of the lipid phase confirmed the validity of this procedure.

For experiments in dodecane-aqueous systems, no presaturation of the two solvents was necessary and solute was analyzed in both phases. Analysis of the phenothiazines was performed spectrophotometrically (Hitachi UV spectrophotometer), employing 95% ethanol as the solvent, following the procedure of Warren *et al.* (14). The wavelengths of maximum absorption are given in Table I. Care was taken to avoid any decomposition of these drugs by eliminating contact with light. Concentrations of solute in the range 10⁻⁵ to 10⁻⁴ M were chosen to avoid any effects due to micellar aggregation noted earlier for these compounds (15). Temperature was maintained at 30°. In dodecane-water systems, ion strength was always adjusted with KCl; ions used in the *n*-octanol-water system varied and will be specified with the results. When referring to partition coefficients, the ratio of concentration in oil to that in water will always be used.

RESULTS

Partitioning in Dodecane—Dodecane was chosen as a typical hydrocarbon solvent after it had been shown that the oil-water partition coefficients in *n*-octane, *n*-decane, *n*-dodecane, *n*-tetradecane, and *n*-hexadecane did not differ significantly. The choice of dodecane was advantageous since it is readily available in a high quality grade and since mutual miscibility with water is negligible (16). Partition coefficients were found to be independent of: (a) the final aqueous concentration of drug up to 10⁻³ M; (b) the concentration and type of buffer; (c) the ionic strength over a range of 0.06 to 0.35; (d) different specific counterions used to adjust ionic strength, *e.g.*, Cl⁻, Br⁻, NO₃⁻, and various alkyl sulfonates.

In view of the lack of effect by any of these parameters, particularly ionic strength and counterions, it would appear that only the free base form partitions into dodecane. This agrees with the conclusions of Reese *et al.* (4) concerning CPZ partitioning into cyclohexane and the work of others with many drugs (17–19).

To evaluate this quantitatively, apparent partition coefficients were determined over a pH range of 2.0 to 7.6 (Table II). If the free base is the only form partitioning, then the apparent partition coefficient, P_a , can be expressed in terms of P_i , the true or intrinsic partition coefficient of the free base, and f_B , the fraction of drug present as the free base. Thus,

$$P_a = f_B P_i \quad (\text{Eq. 1})$$

3-“Chlorpromazine”	3-Cl	—	CH ₃ CH ₂ -N	258
Ethyl “chlorpromazine”	2-Cl	—	CH ₃ —N	255
Butyl “chlorpromazine”	2-Cl	—	CH ₃ CH ₂ -CH ₂ -N	257
Trifluoperazine (TFP)	2-CF ₃	—	CH ₂ -N	260

^a Solvent is 95% ethanol.

The value of f_B may be determined as

$$f_B = \frac{K_a}{K_a + [H_3O^+]} \quad (\text{Eq. 2})$$

where K_a is the dissociation constant of the conjugate acid of these drugs.

From Table II, it is apparent that the change in P_a with each unit of pH is about 10-fold, as predicted by combining Eqs. 1 and 2. Therefore, values of P_i were obtained from the slope of P_a versus f_B plots. Values for CPZ and a number of derivatives are listed in Table III, along with calculated values of P_a at pH 7.0. Since TFP has two dissociable groups, the fraction of free base was calculated by taking the two dissociation constants into account (20).

It should be pointed out that there is some uncertainty in the values of pKa for the phenothiazines, except for CPZ-O (Table III), since their significant water insolubility does not allow simple

Table II—Effect of pH of the Aqueous Phase on the Apparent Partition Coefficient, P_a , of CPZ between Dodecane and Water at 30°

titration in aqueous solution. Thus, techniques such as influence of pH on solubility of the free base (3) and titration in mixed solvent systems (21) must be used. Although both methods agree fairly well, the very high partition coefficients of these compounds dictate that a small error in the choice of pKa will give a significantly different answer for P_i . For example, using a pKa of 9.3 for CPZ gives a P_i of 73,100; at 9.2, one obtains a value of 59,300.⁶ Even small differences in pKa due to activity coefficient changes, therefore, will have an effect. For this reason, the authors chose to use values obtained by the same method (3, 23), thus ensuring more consistency when comparing relative hydrophobic properties of the various molecules (Table III). The value of 9.3 for CPZ was confirmed in the laboratory by solubility measurement, and the value for CPZ-O was determined by titration in water since its free base is sufficiently water soluble.

Partitioning in *n*-Octanol—In contrast to the dodecane studies, measurement of P_a in *n*-octanol was significantly influenced by the nature of the aqueous solution. For example, at pH 3.9 in a 0.1 M acetate buffer, the addition of 0.125 M KCl changed the P_a of CPZ from 4.6 to 32.4, while in 0.125 M KBr the value increased to 56.8. Altering the acetate buffer concentration up to 1.0 M increased the value to 23.3. These results and comparison of pH dependency with that seen in dodecane suggest that the free base has a higher intrinsic partition coefficient in *n*-octanol and that the ionic species is partitioning as an ion-pair. This can be seen in Table IV; the values of 32.4 and 32.8 mainly represent ionic species partitioning, while values at pH 6.6 and higher represent the free base contribution primarily. Exact analysis of pH data to obtain P_i values is not possible since each value is dependent on the buffer, its concentration, and the concentration of KCl used to adjust ionic strength. It may be assumed, however, that apparent partition coefficients obtained at pH values in excess of 6.6 are essentially due to the free base. Utilizing the value of P_a at pH 6.6 and a pKa of 9.3, a P_i for CPZ of about 250,000 was obtained. This is in good agreement with a value of 220,000 reported by Hansch (24), utilizing a P_a obtained at pH 6.8. Unfortunately, large amounts of drug were needed at such high pH values, and a limited supply of other derivatives did not allow the determination of the exact P_i values in *n*-octanol.

The effect of various electrolytes on the apparent partition coefficient of CPZ at pH 3.9 is presented in Table V by comparing the effect of 0.125 M concentrations of electrolyte, all other factors being equal. It may be concluded that inorganic counterions have a significant effect, whereas no differences are noted between the inorganic cations. It is interesting to note a reduced P_a for the methane and ethane sulfonates compared to Cl⁻ and this will be discussed later. Note also the significant reduction in partitioning when the tetraalkylammonium chlorides are used: the longer the alkyl chain length, the lower the value of P_a . In all cases, except for the tetraalkylammonium ions, increasing the electrolyte concentration increased partitioning; the opposite effect occurred with increasing organic cation concentration. This latter observation suggested a “water-structure” effect, so urea was added to a solution containing KCl. As seen in Table V, urea also decreases the value of P_a significantly.

The effect of counterions on the value of P_a can be measured quantitatively by determining an extraction constant, E_X , for each anion, X^- . Such a constant may be written for a 1:1 ion-pair

⁶ Such large partition coefficients are usually expressed as logarithms (22); in this form, these values are 4.86 and 4.77, respectively.

Table III—Partition Coefficient for Various Phenothiazine Derivatives between Dodecane and Water at 30°

Compound	pKa	P_i	P_a at pH 7.0
CPZ	9.3	73,100	366
CPZ-O	9.0	0.75	0.0075
PZ	9.4	10,400	42
TPZ	9.2	137,000	863
1-CPZ	9.4	61,200	245
3-CPZ	9.2	46,300	292
Ethyl-CPZ	8.7	28,200	553
Butyl-CPZ	9.7	116,000	232
TFP	3.9, 8.1	12,900	97

as follows:

$$E_{X^-} = \frac{(\text{CPZH}^+X^-)_{\text{org.}}}{(\text{CPZH}^+)_{\text{aq.}}(X^-)_{\text{aq.}}} \quad (\text{Eq. 3})$$

If one assumes the ion-pair, CPZH^+X^- , forms only in the organic phase and, therefore,

$$P_a = \frac{(\text{CPZH}^+X^-)_{\text{org.}}}{(\text{CPZH}^+)_{\text{aq.}}} \quad (\text{Eq. 4})$$

then:

$$P_a = E_{X^-}(X^-)_{\text{aq.}} \quad (\text{Eq. 5})$$

Equations can be written for the possible equilibria involving ion-pairing which occur with divalent anions (SO_4^{2-}) or when two positive charges exist on TFP. However, since these constants are dependent on higher powers of drug or anion concentration, no meaningful comparisons independent of drug concentration are possible. Thus, no extraction constants are given for sulfate-ion extraction of CPZ or for chloride-ion extraction of TFP. Figures 1 and 2 show typical plots for 1:1 ion-pair partitioning. Tables VI and VII contain E_{X^-} values obtained from the slopes of these plots as predicted by Eq. 5. This equation predicts a zero intercept. However, in all cases, intercepts due to the acetate ion of the buffer were present. In all cases of 1:1 ion-pairing, no drug concentration dependence was observed for the E_{X^-} values obtained.

DISCUSSION

Partitioning of the Free Base—As was suspected from the earlier evidence of hydrophobic behavior, the intrinsic and apparent partition coefficients of the phenothiazine derivatives in dodecane and *n*-octanol are many orders of magnitude greater than those usually observed with acidic and basic drugs (17–19). The high intrinsic partition coefficient of the free base form demonstrates the need to consider its role when one assesses the effects of these drugs *in vitro* and *in vivo*, even 3–4 pH units below the apparent pKa. Because of these very high partition coefficients, it is important also to recognize the remarkable changes in hydrophobicity that can occur with very small changes in pH. This appears especially true in the pH range of 6–8 where so many *in vitro* and *in vivo* processes are studied. Likewise, at interfaces many steric and electrical factors can produce local pH changes which will alter partitioning without apparently influencing the bulk solution. This suggests, therefore, that any model system, or even a biological system such as a membrane, can produce significant selectivity with these molecules merely on the basis of free base partitioning.

Partitioning of the Ion-Pair—In view of the marked hydrophobic behavior of these molecules in very nonpolar hydrocarbon solvents

as the free base, it is not surprising that the ionic species will partition when it can be effectively neutralized by an appropriate anion and solvated by a polar oil phase such as *n*-octanol. The need for solvation of the ion-pair in the oil phase has been studied by Higuchi *et al.* (25), utilizing pharmaceutical amines and mixtures of cyclohexane with chloroform, pentanol, or *p*-tert-butyl phenol. In each case, the proton-donating tendencies of the polar solvent were essential for partitioning of the ion-pair. Enhanced partitioning of tetracycline into cyclohexane when *n*-octanol is added presumably is due also to such a mechanism (26).

What is most significant in the present study is the very large partition coefficient obtained for these drugs in the presence of very common inorganic ions at commonly encountered ionic strengths (Tables V and VII). These values are much greater than those found in *n*-octanol for most acids and bases in nonionized form (18), zwitterionic form (27), and as ion-pairs (23, 28). The effects of specific ions such as Cl^- , Br^- , NO_3^- , and SO_4^{2-} appear to follow an order expected for counterion binding to amines: the greater the polarizability and hydrophobicity of the anion, the greater this effect. The relatively small value of P_a for the sulfate ion appears to reflect the difficulty of ion-pairing when two CPZ molecules must interact with each sulfate ion to neutralize completely the partitioning species. When this is compared to other amine systems that show no tendency to partition in the presence of sulfate ion (29), the authors again conclude that the phenothiazines indeed are quite hydrophobic.

Comparison of extraction constants for the organic anions, such as acetate, and the alkylsulfonates reveals a significant reduction relative to that due to chloride ion. Likewise, whereas sodium, potassium, and ammonium ion exhibit no influence on partitioning, the tetraalkylammonium ions markedly reduce partitioning. These results may be interpreted by considering the various thermodynamic factors associated with partitioning of hydrophobic ions. In the oil phase, factors tending to promote partitioning will be the

**Figure 1**—Apparent partition coefficients for CPZ between *n*-octanol and aqueous buffers, pH 3.9, in the presence of various anions at 30°. Key: O, chloride; ●, propane sulfonate; ⊗, ethane sulfonate; and Δ, methane sulfonate.

electrostatic attraction of the ions (their size, shape, and charge) and the interaction of the ion-pair with the solvent, as already discussed. In the aqueous phase, the hydrophobic drug produces an increase in water structure in its vicinity and hence a decrease in water entropy, the process of transfer, therefore, being favored because of the resultant increase in water entropy after transfer. In the presence of tetraalkylammonium ions, however, partitioning of drug is reduced because a major proportion of water structuring now occurs around the added alkyl groups, reducing the entropy increase ordinarily produced by transfer.⁶ This process, a form of salting in, has been noted for micelle formation (30) and surface tension reduction by CPZ (31), and has been discussed theoretically by Diamond (32). It also is presumed that the retarding effect of urea on partitioning into *n*-octanol and dodecane⁷ is caused by water-structure effects.

The results obtained with acetate ion and the alkylsulfonates suggest a reduced tendency to partition when compared with chloride ion, which agrees with earlier observations that these substances reduce the surface activity of CPZ (31). It is possible that solvation of the ion-pair in *n*-octanol is not complete, but another factor must be operating since similar effects are seen at the air-solution interface. Again, water-structuring effects should be examined. One possibility is that acetate and the alkylsulfonates work like the tetraalkylammonium ions (32). Another possibility is the formation of an ion-pair in water with a reduced tendency to partition into oil. Diamond (32) has described the tendency of large hydrophobic ions to combine in water as "water-structure-enforced" ion-pairs, which lower the overall free energy of the aqueous phase without the necessity to expel the ion-pair. Whatever these

Figure 2—Apparent partition coefficients for three phenothiazine derivatives between *n*-octanol and aqueous buffer, pH 3.9, in the presence of chloride ion at 30°. Key: ○, promazine; △, chlorpromazine; and ●, trifluorpromazine.

⁶ The possibility that the tetraalkylammonium ions could partition into octanol, and thus reduce the chloride ion available for CPZ partitioning, exists. However, no detectable partitioning of the tetramethyl- and tetraethylchlorides could be measured, while less than 1% of the tetrapropyl derivative appears to partition.

⁷ The value of P_a for CPZ into dodecane at pH 4.0 is reduced in the presence of 2.0 *M* urea from 0.32 to 0.17.

Table VII—Partitioning of Various Derivatives in *n*-Octanol in Presence of KCl

Drug	E_X^-	P_a (0.125 <i>M</i> KCl)
CPZ	197	32.4
TPZ	384	60.0

CPZ-O	1.5	0.22
1-CPZ	114	17.0
3-CPZ	430	61.3
TFP	—	49.3

mechanisms are, it is clear that the nature of the aqueous phase must be considered significant in controlling the value of P_a . Furthermore, in the choice of buffers and electrolytes in any study with these drugs, one should keep these phenomena in mind.

Chemical Modification—The influence of chemical modification on the partitioning behavior of the phenothiazine derivatives would, of course, be of great interest when attempting to compare structure to biological activity. The approach used by Hansch *et al.* (22) to correlate *n*-octanol-water partition coefficients with such activity is well known. But, as stated earlier, no attempt was made here to determine values in *n*-octanol because of: (a) the limited supply of enough phenothiazines with appropriate substituent group variation, (b) the effects of ion-pairing due to buffers and salts present, (c) the uncertainty of exact pKa values, and (d) the necessity to work at pH values very much lower than the pKa of each drug because of very high intrinsic partition coefficients. However, a number of conclusions should be pointed out concerning structural effects which should be helpful in evaluating phenothiazine structure-activity data obtained in various *in vitro* and *in vivo* studies.

From the data presented in Tables III and VII, it is apparent that comparisons made in dodecane represent the behavior of the free base, while those made in *n*-octanol at low pH represent the ionic species. In both systems the hydrophobic properties of the drug are the major factors contributing to differences between molecules but, in addition, factors controlled by the nature of the ion-pairing mechanism are important in the case of partitioning into octanol. Thus, for example, the P_i values for the 1-, 2-, and 3-Cl derivatives of CPZ in dodecane are close and appear to show a maximum with the 2-Cl compound, whereas the order of extraction constants increases significantly from the 1- to 3-Cl position. The authors suggest that, in the latter case, steric and electronic effects on the ion-binding process are being seen in addition to hydrophobic behavior which occurs in the dodecane system. This latter order of behavior is seen also for adsorption of the ionic species of these derivatives to the air-solution interface (33). Following this reasoning helps to explain the reasonably consistent agreement between the two solvent systems when comparing TPZ and CPZ (about a twofold difference), since now all effects due to position on the ring should be the same. The somewhat poorer quantitative agreement when comparing the relative values of PZ may reflect an additional effect due to differences in size between the hydrogen atom and the other substituents.

Looking at some specific structural effects in both solvents, it is clear that substitution on the phenothiazine ring exerts a significant effect. The marked reduction in hydrophobicity when going from CPZ to CPZ-O clearly indicates why CPZ-O exhibits very little of the physical, chemical, and biological properties of CPZ (1, 9). A relatively large increase in hydrophobicity is also seen when Cl and CF₃ are placed on the aromatic ring, in good agreement with the results of biochemical and pharmacological structure-activity relationships (1, 2). From the results with the ethyl and butyl CPZ analogs and TFP, it is apparent also that the nature of the alkyl-amino portion is important: the greater the number of alkyl groups, the greater the partitioning tendency. Note, however, in Table III that substitution of this portion of the molecule has the greatest effect on pKa changes. Hence, comparisons near pH 7.0, for example, should be made with great caution so as not to attribute effects to the wrong species.

Finally, the behavior of TFP is interesting because its partitioning is not as great as expected, *i.e.*, the presence of a CF₃ group and more —CH₂— groups than TPZ. The explanation in *n*-octanol centers on the presence of a second dissociated group for a sig-

nificant number of molecules at pH 3.9, which should increase polarity and reduce the ease of ion-pair formation. The presence of the polar nitrogen group also appears to reduce the partitioning tendency of TFP in dodecane, which agrees with the reported reduced water solubility of free base when going from CPZ to TFP (3). It also helps to explain the significantly lower accumulation of TFP relative to CPZ in rat intestinal membrane during drug absorption at pH 6.0 (13).

CONCLUSIONS

Based upon the results of this study, it is clear that studies designed to evaluate the behavior of phenothiazines *in vitro* and *in vivo* must consider the extreme hydrophobicity of these molecules. This study has demonstrated also that great variation in hydrophobicity exists between closely related compounds, as well as between different ion-pairs of the same compound. In biological systems, *in vitro* and *in vivo*, any number of membrane phases and anionic species may exist. Therefore, structure-activity studies must take into account the type of phenomena discussed in this paper when dealing with hydrophobic molecules such as the substituted phenothiazines.

Diffuse Reflectance Studies of Solid-Solid Interactions IV: Interaction of Bishydroxycoumarin, Furosemide, and Other Medicinal Agents with Various Adjuvants

J. DAVID McCALLISTER, TING-FONG CHIN, and JOHN L. LACH

Abstract □ Spectral information comparing the diffuse reflectance of drug-metallic-ion adjuvants with those of the isolated metallic chelates is presented. Various metallic-ion chelates of bishydroxycoumarin and furosemide were prepared and isolated, and their diffuse reflectance spectroscopy spectra were found to be comparable to those of drug-adjuvant equilibrated systems. This information, along with the color changes observed in both the chelate and the interaction product, and the new peaks observed in the UV and visible regions of the spectra suggest that these drug interactions due to chemisorption may proceed by a mechanism similar to that of chelation.

Keyphrases □ Solid-solid interactions—diffuse reflectance spectroscopy □ Drug-metal-ion adjuvants, drug-metal chelates—diffuse reflectance comparison □ Spectral changes, drugs—metal-ion adjuvants □ Diffuse reflectance spectroscopy—analysis □ IR spectrophotometry—identity

A number of articles have recently appeared in the literature which point out the existence of drug-excipient interactions in the solid state (1-5). Although drug-excipient interactions in pharmaceutical dosage forms have been recognized, very little information exists concerning the nature and degree of these physical and chemical surface interactions. Such solid-solid interactions may account, in part, for the discrepancies observed in drug availability of similar dosage forms.

This report represents a part of the continuing study of drug-excipient interaction and deals with mechanistic aspects of these drug-metallic-ion adjuvant interactions.

EXPERIMENTAL

Reagents—The following were used: dioxane-recrystallized bishydroxycoumarin, m.p. 288-289°;¹ alcohol-recrystallized furosemide, m.p. 215° dec.;² digoxin, m.p. 266° dec.;³ indomethacin, m.p. 158°;⁴ ergonovine maleate, m.p. 166° dec.;⁵ chloramphenicol, m.p. 151°;⁶ potassium bromide, spectroscopic grade; activated (basic) alumina (Woelm); magnesium oxide; magnesium trisilicate; calcium sulfate; magnesium carbonate; zinc stearate; zinc oxide; acacia powder; magnesium sulfate, A.R.; ferrous chloride, A.R.; ferrous sulfate, A.R.; aluminum chloride, A.R.; zinc sulfate, A.R.; talc; methanol, A.R.; ethanol USP; and 0.1 N NaOH.

Apparatus—The following were used: Beckman DU spectrophotometer with a diffuse reflectance attachment; constant-temperature water bath set at 30 ± 0.5° with rotating spindles; 150-ml. vials with caps sealed with Parafilm;⁸ Frease-Precision Scientific vacuum oven; Beckman IR-5A infrared spectrophotometer; Pasadena Hydraulic bench press; and a capillary melting-point apparatus.⁷

PROCEDURES

Preparation of Sample—An exact amount of the drug (50 mg. of bishydroxycoumarin, 50 mg. of furosemide, 10 and 20 mg. of digoxin, 10 mg. of ergonovine maleate, and 30 mg. of indomethacin and chloramphenicol) is weighed for every 2 g. of adjuvant weighed. The powders are placed in 150-ml. vials, and 25 ml. of water is added as the dispersion medium. The vial is covered with Parafilm and capped. The sample is equilibrated for 8 hr. at 30 ± 0.5° to effect interaction. After equilibration, the sample is dried under vacuum at 40°. The percent reflectance of this sample is measured, using magnesium carbonate as the reference material.

Preparation of Control—The same amounts of drug and of adjuvant are weighed as in the sample preparation and are physically mixed using a mortar and pestle. The percent reflectance of this control is measured, using magnesium carbonate as the reference material.

Preparation of Chelates—Approximately 3 g. of the drug (bishydroxycoumarin or furosemide) is accurately weighed and dissolved, using an equivalent amount of 1.0 N NaOH and the volume of the solution adjusted to 50 ml. with distilled water. A molar equivalent quantity of the metal-ion solution is added dropwise to the solution containing the drug while stirring continuously. The addition is continued until the pH drops to approximately 6; then the solution is filtered under vacuum and the insoluble complex is washed well with water to remove impurities and dried in a vacuum oven.

RESULTS AND DISCUSSION

Although no information in the literature describes metallic chelates of bishydroxycoumarin, previous diffuse reflectance spectroscopy (DRS) studies (6) in these laboratories dealing with bishydroxycoumarin-excipient interactions strongly suggested that the mechanism involved could be one of chemisorption due to surface chelation.

An examination of the structure of bishydroxycoumarin (Structure I) suggests that this compound could undergo chelate formation.

Attempts to study solution chelate formation of bishydroxycoumarin with metallic ions, based on the DRS information, by the solubility and continuous variation method were unsuccessful.

The use of potentiometric titrations, although not totally satisfactory since no significant pH changes were observed, did, however, give evidence of complexation, because visual observation of a precipitate was noted when sodium hydroxide titrant was added to a bishydroxycoumarin solution containing the metal ion under investigation. Since metal hydroxides were also formed in this method, the procedure was modified.

Bishydroxycoumarin was first solubilized by the addition of an equivalent amount of alkali and titrated with an aqueous solution of the metallic ion under investigation, resulting in the formation of highly colored precipitates and suggesting that chelate formation had occurred (Table I).

Table I—Bishydroxycoumarin–Metallic-Ion Chelates

Compound	Color
Bishydroxycoumarin	White
Mg(II) chelate	Light-yellow
Zn(II) chelate	Light-yellow
Fe(II) chelate	Gray
Fe(III) chelate	Brownish-red
Al(III) chelate	Light-yellow

The examination of the IR spectra of these isolated metallic chelates and of the pure bishydroxycoumarin indicated that apparently the accepted conformation (Structure I) of the drug is in disagreement with the present findings. The IR spectrum obtained for bishydroxycoumarin (Fig. 1) does not reveal a free O—H stretching band in the region of $3\ \mu$, as would be expected. Although the spectral data are in agreement with the reported IR spectrum by Hayden *et al.* (7), these authors also fail to account for this in their listed structure. It is interesting to note that free O—H stretching in the $3\text{--}\mu$ region is only evident in the chelate, for example, as seen in the zinc chelate (Fig. 2). This suggests that one hydroxyl group of bishydroxycoumarin, in the pure state, is strongly hydrogen bonded to the keto oxygen and that the hydroxyl group on the other coumarin ring would exist primarily in the keto form, which would account for the absence of free O—H stretching in this region. Data based on the IR spectra of the various isolated bishydroxycoumarin chelates indicate that the conformation of this drug and its chelates could be as shown in Scheme I.

Scheme I

Additional evidence supporting this line of reasoning was obtained using Dreiding models. The isolated metallic chelates were very insoluble in all solvent systems tested and, consequently, difficult to purify and characterize; they were highly colored, as listed in Table I.

The adjuvants used in the study of the solid–solid interactions with bishydroxycoumarin were chosen because of their importance in pharmaceutical formulations. In view of the fact that most of the adjuvants used exhibited reflectance values in excess of 100% throughout the wavelengths employed and, therefore, would not contribute to the absorption spectrum of the control or the equilibrated sample, their spectra are not shown.

Figure 3 represents the DRS spectrum of the interaction of magnesium oxide with bishydroxycoumarin. An examination of this figure does indicate a significant difference in the spectrum of the control and that of the equilibrated sample, as evidenced by the

Figure 1—IR spectrum of bishydroxycoumarin (KBr pellet).

Figure 2—IR spectrum of the zinc-bishydroxycoumarin chelate (KBr pellet).

intensified absorption bands in the UV region. There also appear to be two new absorption peaks generated, one between 360 and 390 $m\mu$ and the other at approximately 450 $m\mu$.

This band formation in the UV region may be explained as an interaction of the magnesium oxide with bishydroxycoumarin where the adsorption facilitates the clarification of an already existing peak in this region, or it may represent the actual reflectance spectrum of a film of the drug adsorbed onto the surface of the magnesium oxide adsorbent. This is suggested in Fig. 4 where the transmittance curve of bishydroxycoumarin in basic medium shows that the λ_{max} at approximately 320 $m\mu$ lies in the same region as that obtained in the DRS spectrum. The appearance of two new bands at approximately 380 and 450 $m\mu$ in the visible region of the DRS spectrum in the equilibrated sample and their absence in the transmittance spectrum indicate the presence of a strong chemical surface interaction between bishydroxycoumarin and the magnesium oxide adsorbent. The high degree of interaction is further substantiated by the large intensity change and the significant bathochromic shift observed in the equilibrated sample as compared to that of the control. A comparison of this interaction DRS spectrum to that of the prepared and isolated magnesium chelate shows some interesting similarities. For example, the chelate also shows a new peak at 450 $m\mu$. Both spectra show a hyperchromic effect throughout the UV region. The equilibrated magnesium oxide sample is light yellow in color, quite similar to the isolated magnesium chelate; in addition to the other similarities noted, this suggests that the mechanism involved in these interactions may be similar.

Other magnesium-ion metallic adjuvant–bishydroxycoumarin interactions, although not shown here, are somewhat similar to that of the magnesium oxide systems. In the magnesium carbonate system, there is a hyperchromic effect in the UV region and the possibility of new band formation, broad and distinct, between 375 and 390 $m\mu$, indicative of strong interaction.

There is also a bathochromic shift of 80 $m\mu$ between 340 and 420 $m\mu$ in the equilibrated *versus* the control spectrum. The interaction of magnesium stearate with bishydroxycoumarin suggests a peak between 375 and 390 $m\mu$, although it is indistinct and quite weak. A bathochromic shift of 40 $m\mu$ is observed between 360 and 400 $m\mu$. The new band formation and bathochromic shifts are indicative of strong chemical interactions, and a mechanism similar to that of chelate formation seems reasonable for these interactions.

An examination of the spectrum of the zinc stearate interaction with bishydroxycoumarin (Fig. 5) reveals a slight hyperchromic effect in the UV region with this adjuvant, along with a λ_{max} at approximately 300 $m\mu$.

No new peak formation was observed in the visible region as in the magnesium-containing systems. The DRS spectrum of the isolated zinc-bishydroxycoumarin chelate, however, does show

Figure 3—DRS of bishydroxycoumarin (50 mg.) and magnesium oxide (2.00 g.). Key: A, control (physical mixture); B, equilibrated sample; C, bishydroxycoumarin, 100%; and D, magnesium-bishydroxycoumarin chelate, 100%.

Figure 4—Transmittance spectra of bishydroxycoumarin (10 mcg./ml.) in 0.1 N NaOH solution.

this new band at 450 mμ and a significant bathochromic shift as compared to the spectrum of the equilibrated sample. The absence of new peak generation in the visible region for the zinc stearate-bishydroxycoumarin system as compared to that of the isolated chelate indicates that the zinc in the zinc stearate molecule is less readily available for surface interactions. However, as with the magnesium-containing adjuvant, the degree of surface interactions will vary with other zinc-containing excipients.

Spectral data obtained for the alumina-bishydroxycoumarin interactions were quite similar to those seen with zinc stearate. Again, new peak generation at 450 mμ was observed only in the prepared chelate. It is possible that zinc stearate and alumina have very highly saturated surfaces and, thus, few active sites available for chemisorption.

Although the iron (II) and iron (III) bishydroxycoumarin chelates were prepared, a comparison of their DRS data to that of the equilibrated samples was difficult because of the highly adsorbing nature of the interaction products.

DRS of Furosemide Interactions and Comparison of Isolated Chelates—The interest in studying this drug was due in part to the color changes observed in certain tablet formulations and to the reported discrepancies in absorption when the drug was formulated with certain excipients.⁸

Furosemide (4-chloro-5-sulfamoyl-*N*-furfuryl anthranilic acid), an effective diuretic-saluretic agent (8–10), is similar chemically to the thiazide diuretics. Furosemide is a weak acid with a pKa of approximately 4.7. It forms salts easily with bases such as sodium hydroxide and has the structure shown in Structure IV.

The large spectral and color changes observed in the diffuse reflectance spectrum of the furosemide-metallic-ion adjuvant interactions, as in the bishydroxycoumarin system, again suggest that this compound could undergo chelate formation in aqueous solution, although such chelates have not been previously reported.

Using the previously discussed modified method, the alkali-solubilized furosemide was titrated with a solution of the metallic ion under investigation. The highly colored isolated precipitate did indicate that interaction had occurred (Table II). An examination of the molecular structure using Dreiding models substantiates

Figure 5—DRS of bishydroxycoumarin (50 mg.) and zinc stearate (2.00 g.). Key: A, control (physical mixture); B, equilibrated sample; C, bishydroxycoumarin, 100%; and D, zinc-bishydroxycoumarin chelate, 100%.

⁸ Private communication.

Table II—Furosemide and Selected Chelates

Compound	Color	Melting Point
Furosemide	Off-white	215°
Mg(II) chelate	Light-yellow	300°
Zn(II) chelate	Yellow-brown	>360°
Fe(II) chelate	Light-cocoa	200°
Fe(III) chelate	Red-brown	>360°
Al(III) chelate	Yellow-gray	>360°

this line of reasoning, as illustrated in Scheme II.

As in the bishydroxycoumarin system, purification of the isolated chelates was extremely difficult due to their highly insoluble nature. Attempts to characterize these isolated chelates after repeated methanol washings in which the drug was relatively soluble were inconclusive because contamination due to the presence of metallic hydroxides was a problem.

Analysis for furosemide and metallic ion contained in the chelates by spectrophotometric, chelometric, and atomic absorption techniques generally indicated a 1:1 ratio, although a 2:1 ratio for the iron (III) system was suggested. Since the stoichiometric relationship is dependent on an exact metallic-ion determination and since trace amounts of metallic hydroxide contamination can result in a large change in this ratio, further purification studies are in progress to determine this ratio and to characterize the complexes. Although it is recognized that these isolated and methanol-washed chelates are not completely pure, results of an elemental analysis assuming a 1:1 ratio are listed in Table III.

In spite of the difficulties encountered in the purification and stoichiometric determination of these metallic chelates, it is of interest to note that this drug does undergo chelate formation in solution and this is reported here for the first time.

With respect to these solid-solid surface interactions, Fig. 6 represents the DRS of the furosemide-magnesium oxide interaction. Again, as seen in the bishydroxycoumarin-magnesium oxide interaction, equilibration of the furosemide with magnesium oxide results in the clarification of strong absorption bands at 230, 275, and 335 mμ; the bands are comparable to those seen in Fig. 7 which represents the transmittance spectrum of furosemide in methanol.

The clarification of absorption bands after the equilibration procedure indicates that a significant interaction has occurred. Comparable absorption peaks can be seen in the DRS spectrum of the isolated furosemide-magnesium chelate, although of signifi-

Table III—Percent of Various Elements Present in Furosemide Chelates Based on a Probable Stoichiometry of 1:1

Chelate	% Carbon		% Hydrogen		% Nitrogen	
	Theoretical	Actual	Theoretical	Actual	Theoretical	Actual
Mg(II)	40.6	39.53	2.84	3.1	7.92	7.27
Zn(II)	36.4	37.31	2.55	2.91	7.1	7.1
Fe(II)	37.36	41.69	2.61	3.2	7.26	8.03
Fe(III)	37.36	35.90	2.61	2.78	7.26	6.83
Al(III)	40.4	38.39	2.82	2.99	7.85	7.56

Figure 6—DRS of furosemide (50 mg.) and magnesium oxide (2.00 g.). Key: A, control (physical mixture); B, equilibrated sample; C, furosemide, 100%; and D, magnesium-furosemide chelate, 100%.

cantly less clarity, since high absorption results due to use of the pure chelate.

The hypochromic shift noted in the furosemide-magnesium oxide interaction to that of the pure drug and for the isolated chelate is also indicative of a strong surface interaction. This is in contrast to the bathochromic shift observed in the bishydroxycoumarin-magnesium oxide system. The spectral changes observed for furosemide-magnesium trisilicate, magnesium stearate, zinc stearate, and alumina and their isolated chelates are comparable to that of the magnesium oxide system and will not be discussed.

The importance of the strong surface interactions pointed out here cannot be overemphasized with respect to their effect on the therapeutic availability of furosemide. It is possible that these interactions could occur during the wet granulation process of tableting and in the compression of the tablet. The fact that these interactions may occur with different classes of compounds as well as with various adjuvants used in pharmaceutical dosage forms should be recognized, since they may contribute to discrepancies in blood levels and therapeutic efficacy of pharmaceutical dosage forms.

DRS of Interactions of Indomethacin, Digoxin, Chloramphenicol, or Ergonovine Maleate with Excipient—Since these drugs are in widespread use, it was felt that information concerning possible drug-excipient interactions would be of interest. Indomethacin, a recently introduced anti-inflammatory agent, exhibited a strong surface interaction with magnesium oxide and magnesium trisilicate. Figure 8, which illustrates the interaction of indomethacin with magnesium oxide, represents the type of interaction involved. Alumina and acacia exhibited slight interaction with indomethacin, since the DRS spectra of the control and equilibrated sample were comparable.

Due to space limitations, the DRS spectra of the interaction of chloramphenicol, ergonovine maleate, and digoxin with magnesium oxide and magnesium trisilicate are not given; however, a significant interaction was observed in these systems.

Figure 7—Transmittance spectrum of furosemide (20 mcg./ml.) in methanol.

Figure 8—DRS of indomethacin (30 mg.) and magnesium oxide (2.00 g.). Key: A, control (physical mixture); B, equilibrated sample; and C, indomethacin, 100%.

SUMMARY

The spectral changes pointed out in this study strongly indicate that solid-solid interactions are not restricted to any particular class of drugs. Although the exact mechanisms of interactions may vary with different drugs, it is significant that they do occur and that they are more widespread than formerly realized.

The nature and strength of these interactions depend on the nature of the drug and of the adjuvant. The nature of adjuvant would include factors such as hydrogen bonding, van der Waals' forces, chemisorption, the amount of adsorbed moisture, and the availability of active sites on the surface of the adjuvant.

The knowledge concerning the availability of the active ingredient cannot be limited to therapeutic aspects but must also encompass the stability of the active ingredient. An awareness of the extent and variety of solid-solid interactions could lead to a more rational and scientific approach to dosage form design.

Physical-Chemical Evaluation of 3-(3-Hydroxy-3-methylbutylamino)-5-methyl-*as*, Triazino [5,6-*b*] Indole (SK&F 30097)

LOUIS J. RAVIN, ELIE G. SHAMI*, and ELISABETH RATTIE

Abstract □ X-ray diffraction, IR spectroscopy, and differential scanning calorimetry data are presented for the identification of two polymorphic forms and a hydrate of SK&F 30097. The relative rates of dissolution and the solubilities of the various forms were determined in artificial gastric fluid, water, and 50% ethanol solution. No appreciable difference in the dissolution rate was detected for the respective forms in artificial gastric fluid; however, Form II had a more rapid dissolution rate in the 50% ethanol solution. Dissolution studies in water indicated the formation of a hydrate. Protective colloids were shown to have an effect on the rate of hydrate formation. The change in particle-size distribution of Forms I and II in electrolyte suspension was investigated using the Coulter counter. The relative rate of crystal growth for Form I in the presence of protective colloids was determined. The data presented indicate that methylcellulose slows down the rate of crystal growth of Form I significantly.

Keyphrases □ 3-(3-Hydroxy-3-methylbutylamino)-5-methyl-*as*, triazino [5,6-*b*] indole (SK & F 30097)—identification □ Polymorphic, hydrated forms, SK & F 30097—determination □ Dissolution, solubility rates—SK & F 30097 □ X-ray diffraction—identification □ IR spectrophotometry—structure □ Differential scanning calorimetry—identification

The emphasis on drug availability in pharmaceutical research today requires that the physical-chemical properties of compounds be studied thoroughly prior to preliminary clinical trials. It has been demonstrated that the absorption and therapeutic efficacy of various

drugs can be influenced by particle size, solubility, dissolution rate, and wettability (1-4). More recent literature reports stress the importance of the crystal form of a drug and its effect on drug availability (5, 6). The present study deals with the physical-chemical evaluation of a potential antiviral compound, 3-(3-hydroxy-3-methylbutylamino)-5-methyl-*as*, triazino [5,6-*b*] indole, SK & F 30097 (Structure I).

Particular emphasis has been placed on the identification of two crystalline forms and a hydrate and the subsequent evaluation of their physical-chemical properties. Specifically, this study was concerned with an investigation of the relative dissolution behavior of the various forms in several solvent systems and an investigation of the rate of crystal growth in the presence and absence of protective colloids.

EXPERIMENTAL

Materials—A propylene glycol derivative;¹ polyvinylpyrrolidone;² carboxymethylcellulose USP; methylcellulose USP; artificial gastric fluid USP; and normal saline solution USP were used. SK&F 30097 Form I was prepared by dissolving SK&F 30097 in HCl solution and subsequently precipitating the compound slowly by adding NaOH solution. The resulting precipitate was filtered and allowed to dry in a vacuum desiccator over phosphorus pentoxide. SK&F 30097 Form I*³ was prepared by suspending Form I in water and allowing it to be stirred overnight. The suspension was filtered and the filtrate was air-dried at room temperature. SK&F 30097 Form II was prepared by dissolving 1 g. of SK&F 30097 in 20 ml. of hot anhydrous methanol. The resulting solution was filtered and poured into anhydrous ethyl ether which had been previously dried over Linde molecular sieves⁴ and cooled in liquid nitrogen. The mixture was shaken and set aside until precipitation was complete. The resulting precipitate was filtered and allowed to dry over phosphorus pentoxide. Extreme care must be taken to maintain anhydrous conditions to prepare Form II.

X-Ray Diffraction Procedure—A diffractometer (General Electric XRD-5) was used. The sample was packed into a planchet having a depression 1.5 mm. deep and 22 mm. in diameter. The flat side of the spatula was used to pack the powder and smooth it so that a uniform level surface was presented to the X-ray beam. Coarse or lumpy powder was first ground in a mortar or mechanical grinder. The instrument variables of the diffractometer were set as follows: (a) 1° beam slit and 0.1° detector slit; and (b) CuK α radiation, 40 kv., 16 ma., Ni filtered. Intensities were measured by recording the time necessary to count a fixed number of particles.

IR Procedure—The IR spectra for the various forms of SK & F

Figure 2—IR spectra of Forms I, I*, and II of SK&F 30097.

30097 were determined using a spectrophotometer (Perkin-Elmer model 21). The compounds were run in a mineral oil mull.

Differential Scanning Calorimetry Procedure—A differential scanning calorimeter (Perkin-Elmer DSC-1B) was used. Samples of indium were used to calibrate the instrument, and dry nitrogen at 20 ml./min. was used as the carrier gas. Since the preliminary work was qualitative, the samples were not accurately weighed. The rate of heating used was 20°/min. at a chart speed of 2 in./min.

Dissolution-Rate Studies—The procedure of Milosovich (7) was utilized to run the dissolution experiments under conditions of constant-surface and diffusion-layer thickness. Essentially, 100 mg. of powder was compressed into a disk in a tablet die at a compression force of approximately 5000 p.s.i. The tablet die holding the disk was placed in a plastic holder, and this assembly was placed into 700 ml. of artificial gastric fluid or 50% ethanol solution in a 1-l. glass-jacketed beaker. The solution was maintained at 37° by circulating water from a constant-temperature bath. The stirring rate was maintained at 200 r.p.m. during the experiment. Ten-milliliter samples were removed periodically and replaced by 10 ml. of the appropriate solvent. The samples were analyzed spectrophotometrically using a recording spectrophotometer (Cary model 15).

Dissolution-rate studies were also carried out according to the method of Shefter and Higuchi (8). Five hundred milligrams of the appropriate form was added to 500 ml. of distilled water maintained at 25° in a glass-jacketed 1-l. beaker thermostatically controlled by circulating water from a constant-temperature bath. The suspension was stirred at a rate of 200 r.p.m. Samples were withdrawn periodically and filtered through a syringe fitted with a Swinney filter adapter containing a 0.45-μ Millipore filter disk. The resulting

Figure 4—Dissolution behavior of Forms I and II in 50% ethanol solution.

clear solutions were analyzed spectrophotometrically (Cary mode 15 recording spectrophotometer). Additional experiments were done in the presence of 0.01% concentration of various protective colloids such as methylcellulose, carboxymethylcellulose, polyvinylpyrrolidone, and propylene glycol derivative.¹ The size of the crystals in the dissolution experiment was not controlled. The same lots of chemical for the various forms of SK & F 30097 were used throughout the study.

Crystal Growth Studies—Crystal growth studies were carried out using a modified procedure of Carless *et al.* (9). A saturated solution of SK&F 30097 was prepared by suspending the compound in normal saline solution containing 0.01% pro-

pylene glycol derivative¹ as dispersing agent. The resulting suspension was stirred overnight and subsequently filtered. The filtrate was ready for use in the crystal growth studies. The seed crystals were prepared by suspending 100 mg. of the appropriate form of SK & F 30097 in 50 ml. of saturated solution. The suspension was sonified for 5 min. in an ultrasonic bath⁶ to ensure deaggregation of the particles. Four milliliters of the seed suspension was pipetted into 70 ml. of electrolyte solution in a 100-ml. screw-cap bottle. The bottles were placed in a water bath set at 25° and rotated. Samples were removed at fixed intervals, and the contents were transferred to a jacketed glass vessel at 25° for crystal-size counting with the Coulter counter (model B). A 100-μ aperture tube was used during these studies. The tube had previously been calibrated with lycopodium having an average particle size of 27 μ. Experiments were carried out with Form I in electrolyte solution alone and in electrolyte solution containing propylene glycol derivative¹ and 0.01% concentrations of methylcellulose, carboxymethylcellulose, and polyvinylpyrrolidone, respectively. Form I* and Form II were studied in electrolyte solution only.

RESULTS AND DISCUSSION

X-Ray Diffraction and IR Spectroscopy—The X-ray diffraction patterns and the IR spectra for Forms I, I*, and II are shown in Figs. 1 and 2. Distinct differences in the profiles are evident. These distinguishing features can be utilized for the identification and possibly for the analysis of the various forms in mixtures.

Differential Scanning Calorimetry—The thermal behavior of the various forms of SK & F 30097 is illustrated in Fig. 3. The thermogram for Form II shows three endothermic transitions; the first at 143° corresponds to a transformation of Form II to Form I, the second at 165° corresponds to a transformation of Form I to a form that has not been isolated under the conditions of this study, and the third at 183° corresponds to melting. The thermogram for Form I* shows an endotherm at approximately 110° suggesting the presence of water, an endotherm at 165°, and melting at 183°. When Forms I* and II are cooled and reheated, the endotherms at 110 and 143° disappear; the endotherm at 165° is present, along with the endotherm corresponding to melting. In all cases, there

¹ L & R Manufacturing Co., Kearney, N. J.

Figure 8—Photomicrographs showing change in crystal size for a suspension of Form I. Each scale division equivalent to 6 μ .

appears to be an apparent transformation to another form; however, it has not been isolated or prepared during this study.

Dissolution-Rate Studies—The dissolution behavior of Forms I and II under conditions of constant-surface and diffusion-layer thickness in 50% ethanol solution is illustrated in Fig. 4. As expected, Form II, which is less stable thermodynamically, had a more rapid dissolution rate. After approximately 50 min., the slope of the line for Form II deviates from linearity. This deviation suggests that Form II is being converted to Form I during the dissolution process.

Figure 5 shows the results of a dissolution-rate study for Forms I and II in artificial gastric fluid. There does not appear to be any difference in the dissolution behavior of either form in this medium. On the basis of this information, it was postulated that no

appreciable difference in the *in vivo* availability of the various forms would be expected after oral administration. Subsequent studies in beagle dogs indicated that there was no statistical difference in the plasma blood levels obtained after the oral administration of Forms I and II in capsules and in a solution of the hydrochloride salt (10).

The solubility and dissolution-rate data obtained with suspensions of Forms I and I* are shown in Fig. 6. This figure shows the concentration of drug attained in solution as a function of time in the presence of an excess of the solid phase under constant agitation. The anhydrous Form I dissolves much faster than the corresponding hydrated Form I* and yields concentrations supersaturated with respect to the stable anhydrous form.

Since protective colloids are known to retard various nucleation

Figure 9—Photomicrographs depicting crystal growth for Forms I and II after 5 min. in 0.9% sodium chloride solution.

Figure 10—Change in cumulative count with time for an aqueous suspension of Form I.

phenomena, their effect on the transformation in this system was investigated. Studies were carried out with propylene glycol derivative,¹ carboxymethylcellulose, polyvinylpyrrolidone, and methylcellulose to determine their influence on the rate of transformation of Form I to Form I*. The dissolution behavior for Form I in 0.01% concentrations of the protective colloids is also shown in Fig. 6. It is apparent that the dissolution process is altered in the presence of the various protective colloids. The slightly higher solubility in the presence of these agents may be attributed to an interaction with the respective colloid. Methylcellulose had a

Figure 11—Rate of growth of Form I in aqueous suspension.

Table I—Relative Rates of Crystal Growth for Suspensions of SK & F 30097, Form I

Protective Colloid 0.01 %	$\mu/\text{min.} \times 10^{-4}$		
	Above 1%	Above 2%	Above 3%
Propylene glycol derivative	1040	930	880
Propylene glycol derivative plus:			
Carboxymethylcellulose	840	720	640
Polyvinylpyrrolidone	970	870	820
Methylcellulose	3	3.1	3

significant effect on the rate of hydrate formation and, after 48 hr., there was no apparent decrease in solubility similar to that observed with the other additives. Seed crystals of the hydrate form added at this point did not induce the conversion to the hydrate in this system.

Crystal Growth Studies—It became apparent during the preliminary studies that the particle size of Forms I and II increased rapidly when they were placed in aqueous suspension. This change is due to the conversion to Form I*. It was also observed that protective colloids slowed down this process. The dissolution-rate studies reflect these observations. As a result, crystal growth studies were undertaken with the various forms in the presence and absence of protective colloids. Figure 7 illustrates data from a typical crystal growth study with Form I where the change in particle-size distribution is plotted against diameter at various time intervals. There was an increase in particle size for intervals up to 6 hr., and then there was no apparent increase after this time. Photomicrographs of the suspension initially and after 6 hr. are shown in Fig. 8. It is apparent that there is a significant increase in particle size with time. Propylene glycol derivative¹ was used as the dispersing agent during these studies. Since this agent had some effect on the nucleation of Form I, which in turn may affect its crystal growth rate, additional studies were done in its absence. The rate of crystal growth for Forms I and II was extremely rapid.

Figure 12—Photomicrographs showing change in particle size with time for a suspension of Form I in the presence of 0.01% methylcellulose.

These phenomena are illustrated in Fig. 9, which contains photomicrographs of these forms after 5 min.

The overall rate of crystal growth for Form I of SK & F 30097 was derived according to the method of Edmundson and Lees (11). A plot of percentage number cumulative frequency oversize against time for diameters from 14 to 25 μ is shown in Fig. 10. This size represents the faster growing end of the distribution obtained from Fig. 7. Horizontal lines corresponding to various percentage cumulative counts were made. The intercepts of these lines at the 1, 2, and 3% levels for the various time intervals give the equivalent diameter, which is then plotted against time. Figure 11 shows the rate plot for a typical crystal growth study. The slope of the lines represents the rate of growth of the crystals expressed as an increase in diameter per unit time. Table I contains values showing the relative rates of crystal growth of Form I in the presence and absence of various protective colloids.

The crystal growth in the presence of methylcellulose was approximately 300 times slower than in the presence of the other colloids. Photomicrographs showing the change in particle size with time in the presence of methylcellulose are shown in Fig. 12. There was no apparent increase in crystal size after 3 days; however, after 8 days, there was some evidence of growth. The fact that the Coulter counter measurements indicated a growth rate of $3 \times 10^{-4} \mu/\text{min.}$ indicates the extreme sensitivity of this instrument to change in crystal size with time.

SUMMARY

1. The presence of two polymorphic forms and a hydrate of SK & F 30097 has been confirmed by X-ray diffraction, IR spectroscopy, and differential scanning calorimetry.

2. Form II, which was less stable thermodynamically, had a more rapid dissolution rate than Form I in 50% ethanol solution; however, in artificial gastric fluid, there was no apparent difference.

3. Forms I and II readily formed the hydrate in aqueous suspension; protective colloids were shown to affect the rate of hydrate formation.

4. Coulter counter measurements were used to follow the change in particle-size distribution for Form I in electrolyte solution. The relative rates of crystal growth were determined in the presence of various protective colloids. Methylcellulose retarded the rate of crystal growth of Form I significantly.

Thermodynamics and Kinetics of Covalent Addition of Bisulfite Ion to Pyrimidinium Ions

IAN H. PITMAN* and MARK A. ZISER

Abstract □ Equilibrium and rate constants have been calculated for the reversible covalent addition of bisulfite ion to 2-aminopyrimidinium ion and to its 1-methyl and 4-methyl derivatives. 2-Amino-4,6-dimethylpyrimidinium ion did not appear to add bisulfite ion under the experimental conditions. The 1:1 covalent adducts had very low solubility in aqueous buffers around pH 4. This was consistent with their being zwitterions. Rate-determining steps in adduct formation appeared to involve attack of both bisulfite ion and sulfite ion on the pyrimidinium cation. In the reverse reactions, the zwitterionic adducts appeared to decompose by both nonbase-catalyzed and specific base-catalyzed reactions.

Keyphrases □ Bisulfite ion, kinetics, thermodynamics—covalent addition to pyrimidinium ions □ Covalent addition—bisulfite ion to pyrimidinium ions □ 2-Amino-1,6-dihydropyrimidinium-6-sulfonate—synthesis □ 2-Amino-1,6-dihydro-4-methylpyrimidinium-6-sulfonate—synthesis □ UV spectrophotometry—identification

Many of the known reactions of sodium bisulfite with organic and inorganic molecules have been studied quantitatively, and a considerable amount of thermo-

dynamic and kinetic data is available for use when considering the inclusion of sodium bisulfite as an antioxidant in drug formulations (1). However, very little quantitative data are available on the reversible covalent additions of bisulfite ion to nitrogen-containing heteroaromatics such as pyridines (2), pyrimidines (3, 4), pteridines (5–8), and quinazolines (9, 10), although many drugs belong to these classes of compounds. The occurrence of the addition reaction in a drug formulation would reduce the effective concentration of the bisulfite ion, and the covalent adduct may have different chemical reactivity to that of the augend.

The present study was undertaken to determine the effects of temperature and pH on the kinetics and thermodynamics of addition of bisulfite ion to 2-aminopyrimidinium ion (I; $R=R'=H$), 2-amino-1-methylpyrimidinium ion (II), 2-amino-4-methylpyrimidinium ion (I; $R=H$, $R'=Me$), and 2-amino-4,6-dimethylpyrimidinium ion (I; $R=R'=Me$). Studies on addi-

These phenomena are illustrated in Fig. 9, which contains photomicrographs of these forms after 5 min.

The overall rate of crystal growth for Form I of SK & F 30097 was derived according to the method of Edmundson and Lees (11). A plot of percentage number cumulative frequency oversize against time for diameters from 14 to 25 μ is shown in Fig. 10. This size represents the faster growing end of the distribution obtained from Fig. 7. Horizontal lines corresponding to various percentage cumulative counts were made. The intercepts of these lines at the 1, 2, and 3% levels for the various time intervals give the equivalent diameter, which is then plotted against time. Figure 11 shows the rate plot for a typical crystal growth study. The slope of the lines represents the rate of growth of the crystals expressed as an increase in diameter per unit time. Table I contains values showing the relative rates of crystal growth of Form I in the presence and absence of various protective colloids.

The crystal growth in the presence of methylcellulose was approximately 300 times slower than in the presence of the other colloids. Photomicrographs showing the change in particle size with time in the presence of methylcellulose are shown in Fig. 12. There was no apparent increase in crystal size after 3 days; however, after 8 days, there was some evidence of growth. The fact that the Coulter counter measurements indicated a growth rate of $3 \times 10^{-4} \mu/\text{min.}$ indicates the extreme sensitivity of this instrument to change in crystal size with time.

SUMMARY

1. The presence of two polymorphic forms and a hydrate of SK & F 30097 has been confirmed by X-ray diffraction, IR spectroscopy, and differential scanning calorimetry.

Thermodynamics and Kinetics of Covalent Addition of Bisulfite Ion to Pyrimidinium Ions

IAN H. PITMAN* and MARK A. ZISER

Abstract □ Equilibrium and rate constants have been calculated for the reversible covalent addition of bisulfite ion to 2-aminopyrimidinium ion and to its 1-methyl and 4-methyl derivatives. 2-Amino-4,6-dimethylpyrimidinium ion did not appear to add bisulfite ion under the experimental conditions. The 1:1 covalent adducts had very low solubility in aqueous buffers around pH 4. This was consistent with their being zwitterions. Rate-determining steps in adduct formation appeared to involve attack of both bisulfite ion and sulfite ion on the pyrimidinium cation. In the reverse reactions, the zwitterionic adducts appeared to decompose by both nonbase-catalyzed and specific base-catalyzed reactions.

Keyphrases □ Bisulfite ion, kinetics, thermodynamics—covalent addition to pyrimidinium ions □ Covalent addition—bisulfite ion to pyrimidinium ions □ 2-Amino-1,6-dihydropyrimidinium-6-sulfonate—synthesis □ 2-Amino-1,6-dihydro-4-methylpyrimidinium-6-sulfonate—synthesis □ UV spectrophotometry—identification

Many of the known reactions of sodium bisulfite with organic and inorganic molecules have been studied quantitatively, and a considerable amount of thermo-

dynamic and kinetic data is available for use when considering the inclusion of sodium bisulfite as an antioxidant in drug formulations (1). However, very little quantitative data are available on the reversible covalent additions of bisulfite ion to nitrogen-containing heteroaromatics such as pyridines (2), pyrimidines (3, 4), pteridines (5–8), and quinazolines (9, 10), although many drugs belong to these classes of compounds. The occurrence of the addition reaction in a drug formulation would reduce the effective concentration of the bisulfite ion, and the covalent adduct may have different chemical reactivity to that of the augend.

The present study was undertaken to determine the effects of temperature and pH on the kinetics and thermodynamics of addition of bisulfite ion to 2-aminopyrimidinium ion (I; $R=R'=H$), 2-amino-1-methylpyrimidinium ion (II), 2-amino-4-methylpyrimidinium ion (I; $R=H$, $R'=Me$), and 2-amino-4,6-dimethylpyrimidinium ion (I; $R=R'=Me$). Studies on addi-

tions to molecules which are widely used as drugs are continuing in the authors' laboratories.

RESULTS AND DISCUSSION

The Addition Reaction—Compound II has previously been shown (4) to react with bisulfite ion reversibly to yield, in dilute aqueous solution at 25°, an approximately 0.8:1 mixture of the covalent adducts III and IV. These adducts appear to have similar UV spectra (4), and the spectrum of their equilibrium mixture has the characteristics shown in Table I. Because addition of sodium bisulfite (0.2 *M*) to dilute aqueous solutions of (I; R=R'=H) and (I; R=H, R'=Me) produced solutions with similar UV spectra to that of a mixture of III and IV (Table I), it was deduced that covalent addition of bisulfite ion was occurring in these cases also. The addition of sodium bisulfite (1.0 *M*) to saturated aqueous solutions of the pyrimidinium ions (I; R=R'=H) (II), and (I; R=H, R'=Me) resulted in the formation of white crystalline products which had the elemental analysis of 1:1 adducts of the respective pyrimidinium ion and bisulfite ion. The reversibility of all of the addition reactions was indicated by the fact that dilution of solutions of the adducts in aqueous sodium bisulfite with water led to reformation of the original pyrimidine. Addition of sodium bisulfite (0.2 *M*) to dilute aqueous solutions of (I; R=R'=Me) did not lead to any significant changes in its UV spectrum (when the absorbance of the bisulfite ion was taken into account), and it was assumed that covalent addition of bisulfite ion was not occurring to this compound under these conditions.

The 1:1 adduct of Compound (I; R=R'=H) would have the same structure whether addition occurred at C₄ or C₆ and was thus believed to be 2-amino-1,6-dihydropyrimidin-6-sulfonate (V; R=R'=H). The strong blocking effects of methyl groups at C₄ and C₆ in Compound (I; R=R'=Me) to addition at those sites strongly suggest that addition to (I; R=H, R'=Me) would occur predominantly at C₄ to yield 2-amino-1,6-dihydro-4-methyl-

pyrimidin-6-sulfonate (V; R=H, R'=Me). Similar blocking effects of C-alkyl groups to nucleophilic additions at that site have been observed (11) for nucleophilic additions to other heteroaromatic molecules. More exact structural determinations by NMR spectroscopy of the adducts (V; R=R'=H) and (V; R=H, R'=Me) were difficult because of their low solubility in aqueous sodium bisulfite (<1 g./100 ml.). This low solubility is consistent with their being zwitterionic in aqueous buffers between pH 3 and 5.

Because of the acidic or basic nature of the reactants and products in the addition reactions, the reaction mixtures always contained varying concentrations of pyrimidinium ion PyH⁺, neutral pyrimidine Py, sulfurous acid H₂SO₃, bisulfite ion HSO₃⁻, sulfite ion SO₃²⁻, cation H₃Add⁺, zwitterion HAdd[±], and anion Add⁻ of the covalent adduct. At any particular pH, the overall addition reaction was

where Py_T, S_T, and Add_T were the total pyrimidine, sulfurous acid, and adduct species, respectively, present at any time. The acid-dissociation constants of the various acidic species were measured under experimental conditions and are listed in Table II.

Equilibrium Constants for Addition—Apparent equilibrium constants, *K*_{app.}, were calculated from differences in UV absorbance at fixed wavelengths between aqueous buffered solutions of the pyrimidines and similar solutions which had equilibrated after the addition of different amounts of sodium bisulfite. As shown in Fig. 1, the *K*_{app.} values for addition to the very weakly acidic compound (II) were independent of pH in the pH region investigated, but the values for the more strongly acidic compounds, (I; R=R'=H) and (I; R=H, R'=Me), decreased with increasing pH. No evidence could be found for adduct formation by any of the compounds at pH values above 8.5 or below 0.5.

The *K*_{app.} values were the combined equilibrium constants at each pH for the reactions represented by Eq. 1 and are defined as

$$K_{app.} = \frac{[\text{Add}_T]}{[\text{Py}_T][\text{S}_T]} \quad (\text{Eq. 2})$$

If the true addition reactions were

then, in the pH range where [HSO₃⁻] ≫ [H₂SO₃] or [SO₃²⁻] and [HAdd[±]] ≫ [H₂Add⁺] or [Add⁻], values of *K*_{app.} and *K* would be related by the identity

$$K_{app.} = \frac{K[\text{H}^+]}{(K_a + [\text{H}^+])} \quad (\text{Eq. 4})$$

where *K*_a is the acid-dissociation constant of the pyrimidinium ion.

Because plots of *K*_{app.} ([H⁺] + *K*_a) against [H⁺] were linear between pH 3.3 and 5 for addition to each of the pyrimidinium ions studied, it is believed that these addition reactions are adequately described by Eq. 3 and that the zwitterionic forms of the adducts are the most stable forms in this pH region. Values of the

^a $K = [\text{HAdd}^+]/([\text{PyH}^+][\text{HSO}_3^-])$. ^b K_6 and K_4 are defined in the text.

pH-independent equilibrium constant K were calculated from the slopes of the graphs and are listed in Table III, together with standard enthalpy and entropy changes for addition.

The K values for addition to Compounds (I; R = R' = H) and (I; R = H, R' = Me) are each related to the differences in free energy between a particular adduct and the reactants, because only one covalent adduct is formed in each reaction. On the other hand, an approximately 0.80:1 ratio of III and IV results (4) from addition to II at 25°. Thus, the K value for the addition reaction is really the sum of two microequilibrium constants, $K_6 \simeq K/2.25$ and $K_4 \simeq K/1.8$, where K_6 and K_4 relate to addition at C_6 to yield III and at C_4 to yield IV, respectively. The values of K_6 and K_4 have to be compared with K values for the other compounds in discussion of differences in free energy between a particular adduct and its pyrimidinium ion augend.

It can be seen from Table III that substitution of methyl groups for protons anywhere in the pyrimidinium ring decreases the extent to which covalent addition occurs. The very marked reduction in the value of K produced by methyl groups at the potential sites of addition [comparing additions to (I; R = R' = Me) and (I; R = R' = H)] is probably due to both steric and electronic (+I) destabilization of the adduct and electronic stabilization (+I) of the original pyrimidinium ion. The electronic effects are expected to be the major ones when methyl substitution is at sites distant from the site of addition, i.e., at C_4 and N_1 of the 2-aminopyrimidinium ion. A possible explanation for the lower K value obtained for addition to the compound with the C -methyl substituent (I; R = H, R' = Me) than to that with the N -methyl substituent (II) would be that the +I effect of the N -methyl substituent was partially shielded from the ring by the positive charge on the nitrogen atom.

Figure 1—Plot against pH of $\log K_{app}$ for covalent addition of bisulfite ion to: (●) (I; R = R' = H), (○) (II), and (▲) (I; R = H, R' = Me).

Covalent addition of bisulfite ion to pyrimidinium ions involves saturation of charged imino group $>\text{C}=\text{N}^+<$ and can be compared with the well-known addition to aldehydic or ketonic carbonyl groups $>\text{C}=\text{O}$. These reactions have many similarities; they occur readily at room temperature, they are reversible, and they are both inhibited by alkyl substitution at the site of addition. However, as seen by comparison of the thermodynamic data in Table IV with that in Table III, the standard enthalpy change is more favorable and entropy change less favorable for addition to the carbonyl compounds. These differences are most likely due largely to the different "charge types" of the reactions, and they reflect the changes in solvation of reactants and products which accompany the reactions.

Kinetics of Formation and Decomposition of Covalent Adducts (V; R = R' = H) and (V; R = H, R' = Me)—The kinetics of the reversible formation of (V; R = R' = H) and (V; R = H, R' = Me) were studied to determine the effect of total sulfurous acid species concentrations, pH, and buffer-ion concentrations on the covalent addition of bisulfite ion to pyrimidinium ions. These systems were chosen for study because they each involved only one covalent adduct and proceeded cleanly and rapidly at room temperature.

First-order rate constants, k_{obs} , values, for the consumption of the pyrimidinium ion plus the pyrimidine were calculated from the changes in UV absorbance at 302 m μ , which followed mixing of aqueous buffered (succinic acid and borax) solutions of the (I; R = R' = H) or (I; R = H, R' = Me) (6.26×10^{-4} M) with equal volumes of solutions containing sodium bisulfite at an initial concentration that was at least 10 times that of the pyrimidine. Values of k_{obs} increased with increasing pH in the pH range 3.3–4.8 when the initial bisulfite-ion concentration was kept constant, and they increased linearly with increasing initial sodium bisulfite concentrations at constant pH. Examples of this behavior for addition to (I; R = R' = H) are shown as the circles in Fig. 2. Values of the k_{obs} did not change more than $\pm 2\%$ when the total buffer concentration was varied between 10^{-1} M and 10^{-3} M at pH 4.20. The ionic strength of all reaction mixtures was maintained at 0.1 M with sodium chloride.

When only one covalent adduct is formed in the addition reaction, the rate of consumption of total pyrimidine species according to Eq. 1 would be

$$\text{rate} = k_f[\text{Py}^+][\text{S}_T] - k_b[\text{A}_T] \quad (\text{Eq. 5})$$

Table IV—Thermodynamic Data for Addition of Bisulfite Ion to Carbonyl Compounds

Figure 2—Plot against $[Sr]_0$ of k_{obs} , for covalent addition to 2-aminopyrimidinium ion at 25°. Open circles are experimental points and lines were calculated from values of pH-independent rate constants as described in text.

and the observed first-order rate constant for approach to equilibrium in the presence of a considerable excess of total sulfurous acid species could be related to k_f and k_b values by the identity:

$$k_{obs} = k_f [Sr]_0 + k_b \quad (\text{Eq. 6})$$

where $[Sr]_0$ was the initial sodium bisulfite concentration. Values of k_f were thus calculated from the slope of linear plots of k_{obs} against $[Sr]_0$ and are listed in Table V.

Although it should be possible to calculate k_b values from the Y-axis intercepts of these plots, this was only done in a few cases because of the extreme sensitivity of these values to small variations in the slopes of the lines. The k_b values were usually calculated from the k_f value and the appropriate K_{app} value by assuming the principle of microscopic reversibility and using the identity

$$k_b = k_f / K_{app} \quad (\text{Eq. 7})$$

Justification for this assumption came from the fact that at high pH values, the Y-axis intercepts of plots of k_{obs} vs $[Sr]_0$ were rela-

Figure 3—Plots against $1/[H^+]$ of (O) $k_f ([H^+] + K_{ap})/[H^+]$ and (●) k_b for addition of bisulfite ion to (I; R = R' = H) at 25°.

tively large and the graphically determined and calculated k_b values did not vary more than $\pm 3\%$.

The pH dependence of k_f and k_b values is consistent with a hypothesis that two independent and competitive reaction paths are followed in the equilibrium reactions. In the forward reaction, both bisulfite ion and sulfite ion react with the pyrimidinium ion; in the reverse reactions, the neutral (zwitterionic) adduct decomposes in both nonbase-catalyzed and specific base-catalyzed reactions. This hypothesis requires that the rate of consumption of pyrimidinium ion would be

$$\text{rate} = k_1 [\text{PyH}^+][\text{HSO}_3^-] + k_2 [\text{PyH}^+][\text{SO}_3^{2-}] - k_{-1} [\text{HAdd}^\pm] - k_{-2} [\text{HAdd}^\pm][\text{OH}^-] \quad (\text{Eq. 8})$$

In terms of the total pyrimidine concentration $[\text{PyT}]$ and total sulfurous acid concentrations $[\text{Sr}]$, and assuming that the adduct exists predominantly as a zwitterion in the pH region studied, this rate law becomes:¹

$$\text{rate} = \frac{k_1 [\text{H}^+]^2 + k_2 [\text{H}^+] K_{a8,2}}{(K_{ap} + [\text{H}^+])(K_{a8,2} + [\text{H}^+])} [\text{PyT}][\text{Sr}] - (k_{-1} + k_{-2}[\text{OH}^-])[A_T] \quad (\text{Eq. 9})$$

Comparison of rate laws 5 and 9 shows that if this hypothesis is correct, plots of $\{k_f(K_{ap} + [\text{H}^+])\}/[\text{H}^+]$ against $1/[\text{H}^+]$ and of k_b against $1/[\text{H}^+]$ should be linear between pH 3 and 5.5 with intercepts on the Y-axis greater than 0.

Plots of this type were obtained for addition to (I; R = R' = H) and (I; R = H, R' = Me). An example of results for addition to (I; R = R' = H) at 25° is shown in Fig. 3. Least-squares treatments of the 8 data points for the forward reaction shown in Fig. 3 showed that they fell on a line with a slope of $2.46 \pm 0.03 \times 10^{-4}$ and with an intercept on the Y-axis (at $1/[\text{H}^+] = 0$) of 0.19 ± 0.08 . These results indicated that attack of sulfite ion on the pyrimidinium ion ($k_2 = 2103 \text{ M}^{-1} \text{ sec}^{-1}$) was a much more favorable reaction than attack of bisulfite ion on the pyrimidinium ion ($k_1 \approx 0.19 \text{ M}^{-1} \text{ sec}^{-1}$). Similarly, for the decomposition of the covalent adduct (V; R = R' = H), the 8 data points shown in Fig. 3 lay on a line with slope $1.376 \pm 0.017 \times 10^{-7}$ and an intercept on the Y-axis of $1.03 \pm 0.46 \times 10^{-4}$. These results indicated that the second-order rate constant for the specific base-catalyzed decomposition of the adduct was $1.367 \times 10^7 \text{ M}^{-1} \text{ sec}^{-1}$, while the first-order rate constant for the nonbase-catalyzed reaction was $10.31 \times 10^{-5} \text{ sec}^{-1}$. The consistency of this data with the proposed mechanisms was demonstrated by the close correspondence between the experimentally determined values of k_{obs} , which are shown as circles in Fig. 2, and the solid lines which were calculated from values of k_1 , k_{-1} , k_2 , and k_{-2} .

Because of the large standard errors associated with k_1 and k_{-1} values, they could not be used to make meaningful calculations on the enthalpy and entropy of the reactions between bisulfite ion

¹ K_{ap} and $K_{a8,2}$ are the acid dissociation constants of the pyrimidinium ion and bisulfite ion, respectively. The concentration of H_2SO_3 has been neglected in this equation because it is very much less than $[\text{HSO}_3^-]$ between pH 3 and 5.

Table VI—Kinetic Data for Formation of Bisulfite Adducts by Attack of Sulfite Ion on the Pyrimidinium Ion (k_2) and the Base-Catalyzed Decomposition of the Adduct (k_{-2})

Table VII—Kinetic Data for Formation and Decomposition of Bisulfite Adducts of II at 25°

pH	$10(k_{f_4} + k_{f_6})$, $M^{-1} \text{sec}^{-1}$	$10^4 \left(\frac{k_{b_4}K^* + k_{b_6}}{1 + K^*} \right)$ sec^{-1}
3.36	5.00	9.98
3.53	7.60	15.2
3.74	11.4	22.7
3.93	17.6	35.1

and (I; R = R' = H) or the nonbase-catalyzed decomposition of the adduct. However, the errors associated with k_2 and k_{-2} values were much less, and they were used in Arrhenius plots to calculate enthalpies and entropies of reaction between sulfite ion and (I; R = R' = H) and for the specific base-catalyzed decomposition of the adduct (V; R = R' = H). These values are listed in Table VI.

Whereas both bisulfite ion and sulfite ion appeared to be attacking nucleophiles in the addition reaction, it has been reported that the rate-determining step in additions to aldehydes and ketones (12) only involves the attack of sulfite ion on the neutral carbonyl compound. These differences probably arise because of the greater electrophilicity of the charged pyrimidinium ion compared to the uncharged carbonyl compound. This is exemplified by the fact that the second-order rate constant for attack of sulfite ion on neutral benzaldehyde is $240 M^{-1}$ at 13°, whereas it is $754 M^{-1}$ for attack on 2-aminopyrimidinium ion at 12°.

Kinetics of Reversible Addition of Bisulfite Ion to II—The changes in UV absorbance which followed mixing of aqueous buffered solutions of II ($5.2 \times 10^{-4} M$) with solutions of sodium bisulfite (4.0 – $20.0 \times 10^{-3} M$) appeared to be similar to those observed for additions to (I; R = R' = H) and (I; R = H, R' = Me). Thus, plots against time of $\log(D - D_\infty)$ values which had been calculated from measurements at a wavelength where II was the main absorbing species (303 mμ) were linear through at least two half-lives. Apparent first-order rate constants, k_{obs} values, were calculated from these types of plots.

The precise interpretation of the meaning of k_{obs} values for this reaction was complicated by the fact that addition to II yields the isomeric products III and IV, and their relative concentrations ($\approx 1.3:1$) at the time when most of the pyrimidine has been consumed is different from that ($\approx 0.8:1$) at thermodynamic equilibrium (4). In the extreme, the kinetics for approach to equilibrium of such a system would not be first order. However, because approximate first-order kinetics were observed, it was assumed that the initial reactions between II and bisulfite and sulfite ions led to a "pseudoequilibrium" system and that the subsequent isomerization of the products took place much more slowly.

On this basis, when $[S_T]_0 \gg [Py]_0$, the apparent first-order rate constant for approach to the "pseudoequilibrium" condition would be given by Eq. 6:

$$k_{\text{obs}} = (k_{f_4} + k_{f_6})[S_T]_0 + \frac{k_{b_4}K^* + k_{b_6}}{1 + K^*} \quad (\text{Eq. 10})$$

where k_{f_4} and k_{f_6} are rate constants for addition at C_4 and C_6 , respectively; k_{b_4} and k_{b_6} are the rate constants for decomposition of isomers III and IV, respectively; and $K^* = [\text{III}]/[\text{IV}]$ at "pseudoequilibrium." This treatment was consistent with the experimental results, and plots of k_{obs} against $[S_T]_0$ were linear at several pH values and temperatures. Values of $(k_{f_4} + k_{f_6})$ and $(k_{b_4}K^* + k_{b_6})/(1 + K^*)$ were calculated from such plots and are listed in Table VII.

The pH dependence of $(k_{f_4} + k_{f_6})$ and $(k_{b_4}K^* + k_{b_6})/(1 + K^*)$ values appeared to be similar to that for addition to (I; R = R' = H), and (I; R = H, R' = Me) because plots of both $(k_{f_4} + k_{f_6})$ and $(k_{b_4}K^* + k_{b_6})/(1 + K^*)$ against $1/[H^+]$ at constant temperature were linear with intercepts on the Y-axis (when $1/[H^+] = 0$) greater than 0. Thus, it appears that the additions of bisulfite ion to II and decomposition of both III and IV occur by similar mechanisms to those described for addition to (I; R = R' = H) and (I; R = H, R' = Me).

The fact that $[\text{III}]/[\text{IV}] \approx 1.3$ when most of II had been consumed, together with the observation that the pyrimidinium ion was apparently consumed in a first-order reaction, strongly suggests that addition to the carbon atom in II, which is adjacent to the alkylated nitrogen atom, occurs more rapidly than addition to the carbon atom adjacent to the nonalkylated nitrogen atom.

EXPERIMENTAL

Materials and Apparatus—2-Aminopyrimidine and 2-amino-4-methylpyrimidine (K & K Laboratories Inc.) were crystallized from petroleum ether and sublimed before use. 1,2-Dihydro-2-imino-1-methylpyrimidine hydrochloride was prepared as described by Brown and Harper (13), m.p. 277–278°. Sodium bisulfite solutions were prepared immediately before use by dissolving sodium pyrosulfite (Mallinckrodt A.R.) in freshly boiled and cooled distilled water through which oxygen-free nitrogen had been bubbled for 1 hr. One milliliter of methanol was added per 100 ml. of sodium bisulfite solution to stabilize it against oxidation (1). Final bisulfite concentrations were determined by iodometric titration. All solutions were made with freshly boiled and cooled distilled water through which oxygen-free nitrogen had been bubbled for 1 hr.

Spectrophotometric measurements were made on Cary 14 and 16 UV spectrophotometers. Temperatures were controlled to within 0.01° with circulating water from a Lo-tempral 154 water bath (Precision Scientific Co.). The pH values were measured using an Orion model 801/digital pH meter.

Isolation of Bisulfite Adducts—The 1:1 bisulfite adducts of the pyrimidinium ions (I; R = R' = H) and (I; R = H, R' = Me) were obtained as white microcrystalline powders following addition of sodium bisulfite (1M) to saturated aqueous solutions of the pyrimidines at 25°. After washing the powders with a little water and drying over calcium chloride at atmospheric pressure, the adducts had the following elemental analysis.

Anal.—Calcd. for 2-amino-1,6-dihydropyrimidinium-6-sulfonate (V; R = R' = H): C, 27.12; H, 3.98; S, 18.10. Found: C, 27.15; H, 4.12; S, 18.33. Calcd. for 2-amino-1,6-dihydro-4-methylpyrimidinium-6-sulfonate (V; R = H, R' = Me): C, 31.40; H, 4.73; N, 21.98; S, 16.77. Found: C, 31.18; H, 4.82; N, 21.70; S, 16.88.

Equilibrium Constants—The pK_a values were measured by potentiometric titration using the method described by Albert and Serjeant (14). The ionic strength was maintained at $10^{-1} M$ with sodium chloride. Equilibrium constants for addition of bisulfite ion to the pyrimidinium ions were calculated from the equilibrium concentrations of pyrimidinium ion, bisulfite ion, and covalent adduct which existed following mixing of equal volumes of solutions of the pyrimidine in borax-succinic acid buffers and sodium bisulfite solutions. The ionic strength of all reaction mixtures was maintained at $10^{-1} M$ with sodium chloride. The equilibrium concentrations were calculated from spectrophotometric measurements at wavelengths where the pyrimidine or pyrimidinium ion was the main absorbing species, and corrections were made for the absorbance of the other species.

Kinetics—Rate constants were calculated from spectrophotometric measurements of concentration changes. Standard kinetic procedures were followed. The ionic strength of all reaction mixtures was maintained at $10^{-1} M$ with sodium chloride.

CONCLUSIONS

1. Covalent addition of bisulfite ion occurs to Position C₄ or C₆ of 2-aminopyrimidinium ion derivatives so long as these positions are not blocked by alkyl substituents and the pH of the system is such that the reactants exist to an appreciable extent as the mono-anion (HSO_3^-) and the cation (pyrimidinium ion).
2. Alkyl substituents at any position in the pyrimidinium ring reduce the extent and rate of addition.
3. The covalent adducts are zwitterions, between pH 3 and 5, and have very low water solubility.
4. The mechanism of addition appears to involve attack of both the bisulfite ion and sulfite ion on the pyrimidinium ion. The reverse reaction involves both a nonbase-catalyzed and a base-catalyzed decomposition of the neutral adduct.

Kinetics of the Hydrolysis of Pilocarpine in Aqueous Solution

PING-HONG CHUNG, TING-FONG CHIN, and JOHN L. LACH

Abstract □ The kinetics of the hydrolysis of pilocarpine in aqueous solution were investigated utilizing pH-stat titrimetry and polarimetry. A cyclic mechanism was proposed for the hydrolysis, which is catalyzed by both hydrogen ion and hydroxide ion. The appropriate rate constants, equilibrium constants, and the energy of activation for the hydroxide-ion catalyzed hydrolysis were calculated. The hydrolysis in high alkaline pH was found to be accompanied by some epimerization. An optimum condition for the preparation of pilocarpine ophthalmic solution was also suggested.

Keyphrases □ Pilocarpine in aqueous solution—hydrolysis □ Kinetics—pilocarpine hydrolysis □ Hydrolysis, pilocarpine—hydrogen-ion catalyzed □ TLC—separation □ UV spectrophotometry—identity □ Titration, pH-stat—pilocarpine degradation determination □ Polarimetry—pilocarpine cyclization

Pilocarpine is used topically as a miotic in the treatment of glaucoma. The isomer, isopilocarpine, although qualitatively similar in its pharmacological effects, is almost completely inactive as a miotic (1). However, little clinical data are available concerning isopilocarpine. Pilocarpine solutions ranging from 0.5 to 10% have been used, although there seems to be no advantage in concentrations above 4%. Pilocarpine is less irritating than physostigmine salicylate and can be employed for long periods without producing undesirable side effects (2).

Although pilocarpine was isolated early in 1875, its structure and that of the isomer were elucidated by Jowett (3, 4) in 1900; total synthesis was achieved by several workers in different ways during the 1930's (5-7). In 1966, the absolute configurations of these compounds were established as (2S:3R) (I) and (2R:3R) (II) for pilocarpine and isopilocarpine, respectively (8).

Pilocarpine possesses a γ -lactone with two asymmetric centers. In the dry state and at high temperature, the two isomers, pilocarpine and isopilocarpine, interconvert, isopilocarpine predominating at equilibrium (8). This property has been used for the preparation of isopilocarpine hydrochloride from pilocarpine hydrochloride (9). It has been shown recently that, in the presence of alkali, isomerization may proceed via the enol intermediate (10).

In aqueous solution, pilocarpine presents at least two possible pathways of degradation, including hy-

Kinetics—Rate constants were calculated from spectrophotometric measurements of concentration changes. Standard kinetic procedures were followed. The ionic strength of all reaction mixtures was maintained at $10^{-1} M$ with sodium chloride.

CONCLUSIONS

1. Covalent addition of bisulfite ion occurs to Position C₄ or C₆ of 2-aminopyrimidinium ion derivatives so long as these positions are not blocked by alkyl substituents and the pH of the system is such that the reactants exist to an appreciable extent as the mono-anion (HSO_3^-) and the cation (pyrimidinium ion).
2. Alkyl substituents at any position in the pyrimidinium ring reduce the extent and rate of addition.
3. The covalent adducts are zwitterions, between pH 3 and 5, and have very low water solubility.
4. The mechanism of addition appears to involve attack of both the bisulfite ion and sulfite ion on the pyrimidinium ion. The reverse reaction involves both a nonbase-catalyzed and a base-catalyzed decomposition of the neutral adduct.

Pilocarpine is used topically as a miotic in the treatment of glaucoma. The isomer, isopilocarpine, although qualitatively similar in its pharmacological effects, is almost completely inactive as a miotic (1). However, little clinical data are available concerning isopilocarpine. Pilocarpine solutions ranging from 0.5 to 10% have been used, although there seems to be no advantage in concentrations above 4%. Pilocarpine is less irritating than physostigmine salicylate and can be employed for long periods without producing undesirable side effects (2).

Although pilocarpine was isolated early in 1875, its structure and that of the isomer were elucidated by Jowett (3, 4) in 1900; total synthesis was achieved by several workers in different ways during the 1930's (5-7). In 1966, the absolute configurations of these compounds were established as (2S:3R) (I) and (2R:3R) (II) for pilocarpine and isopilocarpine, respectively (8).

Pilocarpine possesses a γ -lactone with two asymmetric centers. In the dry state and at high temperature, the two isomers, pilocarpine and isopilocarpine, interconvert, isopilocarpine predominating at equilibrium (8). This property has been used for the preparation of isopilocarpine hydrochloride from pilocarpine hydrochloride (9). It has been shown recently that, in the presence of alkali, isomerization may proceed via the enol intermediate (10).

In aqueous solution, pilocarpine presents at least two possible pathways of degradation, including hy-

hydrolysis to pilocarpic acid and epimerization to isopilocarpine. The most important of these is the opening of the lactone ring. As long as the lactone is intact, the alkaloid maintains its stereochemical configuration (11, 12).

Pilocarpine is relatively stable in solutions of acidic pH (12–14). As the pH increases, pilocarpine progressively becomes unstable (12, 13, 15, 16), especially at elevated temperatures. Its stability has also been shown to be affected by certain buffers. Phosphate and carbonate catalyze the degradation of pilocarpine, whereas borate does not (16, 17). Additions of 0.5% of methylcellulose slightly improve the stability of pilocarpine solutions (18). In all cases, the degradation has been accompanied by a marked drop in pH (14, 16–18), phosphate buffers failing to maintain a constant pH (17).

Since stability studies appearing in the literature were of a preliminary nature, providing limited kinetic information, the purpose of this study was to obtain additional data dealing with the rates of hydrolysis and the mechanisms involved.

EXPERIMENTAL

Reagents—The following were used: pilocarpine nitrate USP; hydrochloric acid, reagent grade; sodium hydroxide, reagent grade; potassium chloride, reagent grade; dibasic potassium phosphate trihydrate, reagent grade; monobasic potassium phosphate, reagent grade; citric acid monohydrate USP; silica gel G, TLC grade; Whatman No. 4 chromatography paper (4 cm. \times 25 cm.); methanol, reagent grade; chloroform, reagent grade; and *n*-butanol, reagent grade.

Apparatus—The following were used: radiometer pH-stat (a combination of type TTT1c titrator, SBR2c titrigraph, SBU1a syringe burette, and TTA3 titration assembly), with G2222C glass electrode, K4122 calomel electrode, and B101 0.5-ml. syringe; modified pH-stat titration assembly (19), with G202C glass electrode and K401 calomel electrode; Precision Scientific Co. Temp-Trol circulating system; radiometer PHM4c pH meter; Zeiss polarimeter with sodium lamp, 589-m μ interference filter, and 40-cm. tube; and Beckman DK-2 recording spectrophotometer.

Procedure—(a) *Preliminary Test*—A 25-ml. portion of an aqueous 2% pilocarpine nitrate solution was placed in each of three 50-ml. volumetric flasks. One of these was brought to strong alkalinity with sodium hydroxide; another was brought to strong acidity with hydrochloric acid. The flasks were then made up to 50 ml. with water and heated in a boiling water bath for 3 hr. After cooling, the solutions were neutralized to approximately the same pH and were chromatographed using TLC [plates: microscope slides coated with a slurry of 30 g. silica gel G in 65 ml. chloroform-methanol (3:1 v/v) and activated at 100° for 1 hr.; solvent system: chloroform-methanol (1:1 v/v); spots located using iodine vapor] and paper chromatography (paper: 4-cm. \times 25-cm. Whatman No. 4 filter paper impregnated with 0.2 M pH 6.8 phosphate buffer prepared by mixing approximately equal volumes of solutions of 0.2 M KH₂PO₄ and 0.2 M K₂HPO₄; mobile phase: water-saturated *n*-butanol; spots located using iodine vapor).

(b) *Hydroxide-Ion Catalyzed Hydrolysis*—The pH-stat was utilized to follow hydrolytic degradation. Fifty milliliters of water and an appropriate quantity of potassium chloride (for adjusting ionic strength to 0.1) were placed in the reaction vessel, which was then flushed with nitrogen and sealed from contact with the atmosphere in the manner recommended by Chong *et al.* (19). As the temperature reached the desired value, the pH-stat was turned on to adjust the pH to the preset value. A 0.5-ml. aliquot of stock solution (sample) was introduced into the vessel. When the desired pH equilibrium was achieved, the recording pen was returned to zero to start recording the rate of reaction, and the reaction was allowed to proceed either to completion (for pH 11–12) or until sufficient data were obtained (for pH 8–10). The pseudo-first-order rate constants were then obtained either from a Guggenheim plot or the initial rate method.

(c) *Hydrogen-Ion Catalyzed Hydrolysis*—Since the hydrogen-ion catalyzed hydrolysis is negligibly small in comparison to the opposing cyclization reaction, comparable information would be obtained more easily and accurately by following the rate of cyclization. A polarimeter was used to follow the rate of cyclization, because there is a large change in optical activity when pilocarpic acid is cyclized to pilocarpine.

RESULTS AND DISCUSSION

In the preliminary study, as would be expected, all of the heat-treated solutions showed no characteristic absorption in the UV region, except that all exhibited a comparable magnitude of end-absorption. However, it should be noted here that pilocarpine does exhibit a maximum at 215 m μ . The thin-layer chromatograms for the heat-treated acidic and neutral (pilocarpine nitrate solution without addition of acid or alkali) solutions showed a single spot, which had the same *R_f* value as the reference spot, whereas that for the heat-treated alkaline solution exhibited a much smaller *R_f* value in spite of producing a single spot. This did indicate that pilocarpine is stable in acidic solution but labile in alkaline solution. By repeating the chromatographic separation in a 0.2 M pH 6.8 phosphate buffer-treated paper, using water-saturated *n*-butanol as the mobile phase, the alkaline degraded spot and the reference spot showed significantly different and reproducible *R_f* values, 0.19 and 0.88, respectively. Repeating the test using weaker alkali, the degraded solution displayed two spots with *R_f* values of 0.19 and 0.88, respectively, indicating only partial degradation as opposed to one spot in strongly alkaline degraded solution. Authentic pilocarpine and isopilocarpine, when chromatographed by the same techniques, showed, however, almost the same *R_f* value. Therefore, the described chromatographic techniques could not separate the two isomers and epimerization, if present, would not be detected.

From the titration curves, the heat-treated acidic and neutral solutions showed a single pK_a value, 6.85, which is similar to that of pilocarpine nitrate; on the other hand, the alkaline degraded solution, when acidified with hydrochloric acid and titrated immediately with alkali, gave two pK_a values, 4.05 and 7.50, respectively. However, if the acidified degraded solution was allowed to stand for several hours, the amount of alkali consumed in the titration for the pK_a value, 4.05, was decreased, but that for the pK_a value, 7.50, was not affected, except that pK_a was shifted toward 6.85. This decrease in alkali consumption probably indicates that the free carboxylic acid group in the degraded solution has undergone cyclization.

When freshly prepared pilocarpine base was dissolved in water and immediately titrated with hydrochloric acid, a pK_a value of 6.85 for the conjugate acid was produced. However, upon standing, the same solution of pilocarpine base generated an additional inflection in its titration curve, but the equivalent amount of total acid consumed was unchanged, indicating that an acid created from lactone hydrolysis immediately protonated on the original basic group of the molecule to form a zwitterion.

These observed phenomena are consistent with the fact that the lactone ring in the pilocarpine molecule was hydrolyzed in an alkaline condition and subsequently recycled when acidified. This has also been confirmed by Baeschlin *et al.* (20). Since the hydrolysis of a lactone produces an acid and since reaction at a constant pH is desirable, a pH-stat that not only keeps the pH constant but also records the rate of reaction was used to follow the hydroxide-ion catalyzed hydrolysis of pilocarpine. The theory behind the use of a pH-stat was discussed by Jacobsen *et al.* (21) and will not be discussed here.

For hydroxide-ion catalyzed hydrolysis, a radiometer pH-stat with a closed-type reaction vessel, as suggested by Chong *et al.* (19), and a Precision Scientific Temp-Trol circulating system were used. In the 11–12 pH range, the entire course of the reaction was recorded; pseudo-first-order rate constants were obtained either from Guggenheim plots (22) or by the differential method (22). Both methods were equally satisfactory as applied to the result in this pH range. At pH 8–10, the reaction at each pH level studied was allowed to proceed until sufficient data were obtained. This procedure was used since the recording of the entire course of the reaction would have taken more than 1 day to complete. The initial rate method was used to obtain the pseudo-first-order rate constants. Since all initial rate *versus* initial concentration plots resulted in straight lines at constant pH, the rate law would have the follow-

Figure 1—pH profile of the hydrolysis of pilocarpine in alkaline pH.

ing form:

$$-\frac{d(\text{pilocarpine})}{dt} = k'(\text{pilocarpine}) \quad (\text{Eq. 1})$$

where k' is the pseudo-first-order rate constant. When $\log k'$ was plotted against pH, a straight line was obtained with a slope of 1. Therefore, the rate law for the hydroxide-ion catalyzed hydrolysis of pilocarpine would be:

$$-\frac{d(\text{pilocarpine})}{dt} = k_{\text{OH}^-}(\text{pilocarpine})(\text{OH}^-) \quad (\text{Eq. 2})$$

where k_{OH^-} is the second-order rate constant for the specific hydroxide-ion catalysis.

At pH 7, however, the rate constant was found to be slightly smaller than expected. Intuitively, it could be argued that the *N*-methylimidazole moiety could be acting as a catalyst. Consequently, the possibility of intermolecular catalysis was investigated, using added quantities of *N*-methylimidazole. At pH 10 and up to a concentration of 0.1 *M* of *N*-methylimidazole, no appreciable catalytic effect was observed. (At this pH, *N*-methylimidazole exists entirely in its basic form.)

The effect of ionic strength on alkaline hydrolysis of pilocarpine was also studied at this pH, and no noticeable effect up to the 1.0 *M* potassium chloride level was observed.

This rate constant deviation at pH 7, therefore, probably is due to other facts. For example, the opposing (cyclization) reaction may become significant at this pH, or it may be due to the limitation of pH-stat performance at high buffer capacity and very slow

reaction rate. Since recording of sufficient data at this pH would take almost 1 day, the drift in electrode potential could cause a significant error. It should be pointed out that the error recorded by a pH-stat is proportional to the buffer capacity of the system and the magnitude of the potential drift (21).

The temperature effect at different pH's for the hydroxide-ion catalyzed hydrolysis was also studied at 25, 30, 40, and 50°. The pH profiles at these temperatures are shown in Fig. 1 and are consistent with the mentioned rate law. Arrhenius plots for the two pH levels, 9 and 10, are shown in Fig. 2. Both plots show reasonable straight lines of the same slope. The energy of activation was found to be 11.0 kcal./mole after correction for enthalpy of ionization of water. This is in good agreement with the 10.8–12.1 kcal./mole values, as reported by Grace and Symons (23), for the hydroxide-ion catalyzed hydrolysis of substituted and unsubstituted γ -butyrolactones.

In acidic pH, however, pilocarpine is fairly stable. As pointed out by Grace and Symons (23), most γ -lactones are not hydrolyzed appreciably in acid. Therefore, it is difficult to follow the hydrogen-ion catalyzed hydrolysis directly. However, since Long *et al.* (24) reported that the hydrolysis of γ -lactone was catalyzed by hydrogen ion, and since the cleaved acid would recyclize to the lactone in acidic pH, it can be expected that the rate expression would take the form of opposing reactions. Since these reactions would reach equilibrium after a period of time, and since the equilibrium position would lie far toward the lactone in acidic pH, it would be simpler to follow the rate of cyclization than to follow the rate of hydrolysis to obtain this information.

In view of the fact that the opening of the lactone ring in a pilocarpine molecule is accompanied by a large drop in its optical activity (to about 20% of its original value), the rate of cyclization was followed by measuring the optical rotation change with a polarimeter.

To determine the dependence of optical activity on pH, 0.0625 *M* solutions of pilocarpine, which give a reading of about 5° in a 40-cm. polarimeter tube, and similar solutions that had been hydrolyzed completely at pH 12 were adjusted to constant ionic strength (0.2) and to different pH values. Their optical rotations were measured immediately after the adjustment of pH. The optical rotation–pH profiles obtained are shown in Fig. 3. In this figure, it can be clearly seen that the optical rotation–pH profile for the hydrolyzed product, pilocarpic acid, exhibits two inflections which correspond exactly to its two pK_a values. This is obvious if the titration curve is superimposed on the optical rotation–pH profile (Fig. 4). In fact, this provides another way for the determination of pK_a values of a compound possessing optical activity. This approach is superior to the potentiometric method, since it is not affected by the acidity or alkalinity of the solvent. The presence of optical activity in the completely hydrolyzed product also revealed that the assumption made by Anderson (17), which states that “all products of the degradation other than isopilocarpine have no optical activity,” was not valid.

Figure 2—Arrhenius plot of hydroxide-ion catalyzed hydrolysis of pilocarpine.

Figure 3—Optical rotation–pH profile of pilocarpine and pilocarpic acid.

To follow the rate of cyclization, a pilocarpine solution was hydrolyzed at pH 12 for 1 hr. to achieve complete hydrolysis. The hydrolyzed solution was then brought to acidic pH with hydrochloric acid and diluted to a final concentration corresponding to that of a 0.0625 *M* hydrolyzed pilocarpine solution. The pH of the solution was measured, and the cyclization was immediately followed by measuring the optical rotation at different times. These results are shown in Fig. 5. As cyclization proceeds, the optical rotation increases rapidly at first, then gradually slows down, and finally converges to a fixed value which is smaller than the original optical rotation of the corresponding concentration of pilocarpine (Fig. 5). This could indicate that the opposing reactions, namely cyclization and hydrolysis, have attained an equilibrium. Since the rate of the optical rotation change is higher at lower pH, both reactions would be catalyzed by hydrogen ion. If this statement is valid, one should also be able to attain this equilibrium by starting with pilocarpine instead of pilocarpic acid. However, it has been found that the equilibrium optical rotation obtained from pilocarpine is higher than that obtained from pilocarpic acid (Fig. 5). When analyzed for lactone, both equilibrium solutions showed almost equal amounts of lactone remaining, clearly indicating that some epimerization occurred during or after hydrolysis. From the work of Döpke and d'Heureuse (10) and from the fact that the equilibrium optical rotation of the cyclized solution was the same no matter how long the starting compound, pilocarpic acid, remained in an alkaline condition, the former is more likely the case. A study of the extent of epimerization is being conducted in this laboratory and will be reported later.

Assuming that cyclization of pure pilocarpic acid is followed, the simplified mechanism of cyclization may be stated as in Scheme I:

Scheme I

or in symbolic form (Scheme II):

Scheme II

where A^- , A , and L represent pilocarpate, pilocarpic acid, and pilocarpine, respectively; K is the association constant of pilocarpic acid (i.e., $K = 1/K_a$); and k_1 and k_{-1} represent the rate constants of the

Figure 4—Optical rotation–pH profile and titration curve of pilocarpic acid. Key: ---, titration curve; and —, optical rotation–pH profile.

Figure 5—Optical rotation versus time plot for cyclization of pilocarpic acid.

hydrogen-ion catalyzed cyclization and hydrolysis, respectively (i.e., $k_1 = k_{-H^+}$, and $k_{-1} = k_{H^+}$).

If one starts with an initial concentration, C_0 , then the material balance equation is

$$C_0 = (A^-) + (A) + (L) = (A_T) + (L) \quad (\text{Eq. 3})$$

where $(A_T) = (A^-) + (A)$. (A) can be expressed in terms of C_0 and (L) :

$$(A) = \frac{K(H^+)}{K(H^+) + 1} [C_0 - (L)] = F[C_0 - (L)] \quad (\text{Eq. 4})$$

where $F = K(H^+)/[K(H^+) + 1]$.

The rate of formation of pilocarpine is

$$\frac{d(L)}{dt} = k_1(H^+)(A) - k_{-1}(H^+)(L) \quad (\text{Eq. 5})$$

Combination of Eqs. 4 and 5 gives

$$\frac{d(L)}{dt} = k_1 F(H^+)C_0 - (k_1 F + k_{-1})(H^+)(L) \quad (\text{Eq. 6})$$

which can then be integrated if the pH is kept constant. Upon integration of this equation, using the fact that $(L) = 0$ when $t = 0$, at constant hydrogen-ion concentration, gives

$$\ln \frac{k_1 F C_0}{k_1 F C_0 - (k_1 F + k_{-1})(L)_t} = (k_1 F + k_{-1})(H^+)t \quad (\text{Eq. 7})$$

At equilibrium, $d(L)/dt = 0$, and Eq. 6 gives

$$(L)_{eq} = \frac{k_1 F}{k_1 F + k_{-1}} C_0 \quad (\text{Eq. 8})$$

Combination of Eqs. 7 and 8 gives rise to

$$\ln \frac{(L)_{eq}}{(L)_{eq} - (L)_t} = (k_1 F + k_{-1})(H^+)t \quad (\text{Eq. 9})$$

From the titration curve of pilocarpic acid, K was found to be 1.12×10^4 l./mole.

At $\text{pH} \leq 2$, $F = K(H^+)/[K(H^+) + 1] = 1$, and Eq. 9 can be reduced to

$$\ln \frac{(L)_{eq}}{(L)_{eq} - (L)_t} = (k_1 + k_{-1})(H^+)t \quad (\text{Eq. 10})$$

Equation 10 states that a plot of $\log [(L)_{eq}/\{(L)_{eq} - (L)_t\}]$ versus t will be a straight line, and the slope is given by

$$\text{slope} = (k_1 + k_{-1})(H^+)/2.303 \quad (\text{Eq. 11})$$

It should be noted that this slope is hydrogen-ion concentration dependent.

The quantity " $(L)_{eq}/[(L)_{eq} - (L)_t]$ " can be determined from optical rotation measurements, as derived from Scheme III:

From this mechanism, the material balance can be written as:

$$C_o = (A^-) + (A) + (L) = (A_T)_t + (L)_t = (A_T)_{eq} + (L)_{eq} \quad (\text{Eq. 12})$$

for any time t and at equilibrium. For convenience, the following terms are defined:

- $[\alpha]_L$ = optical rotation of pilocarpine with concentration C_o
- $[\alpha]_{AT}$ = optical rotation of 100% hydrolyzed pilocarpine solution of the same concentration
- R_t = optical rotation of sample solution at time t
- R_{eq} = optical rotation of sample solution at equilibrium

Since optical rotation is an additive property of a system, the optical rotation of the sample solution can be considered as having contribution from the optically active species present. Thus,

$$R_t = [\alpha]_{AT} \cdot \frac{(A_T)_t}{C_o} + [\alpha]_L \cdot \frac{(L)_t}{C_o} \quad (\text{Eq. 13})$$

$$R_{eq} = [\alpha]_{AT} \cdot \frac{(A_T)_{eq}}{C_o} + [\alpha]_L \cdot \frac{(L)_{eq}}{C_o} \quad (\text{Eq. 14})$$

Subtraction of Eq. 13 from Eq. 14 leads to

$$R_{eq} - R_t = \frac{1}{C_o} [\alpha]_{AT} \{ (A_T)_{eq} - (A_T)_t \} + [\alpha]_L \{ (L)_{eq} - (L)_t \} \quad (\text{Eq. 15})$$

Rearrangement of Eq. 12 produces

$$(A_T)_t - (A_T)_{eq} = (L)_{eq} - (L)_t \quad (\text{Eq. 16})$$

Combination of Eqs. 15 and 16 renders

$$(L)_{eq} - (L)_t = \frac{C_o}{[\alpha]_L - [\alpha]_{AT}} \cdot (R_{eq} - R_t) \quad (\text{Eq. 17})$$

$(L) = 0$ when $t = 0$, and $R_t = R_o$. As a result, Eq. 17 is reduced to

$$(L)_{eq} = \frac{C_o}{[\alpha]_L - [\alpha]_{AT}} \cdot (R_{eq} - R_o) \quad (\text{Eq. 18})$$

Dividing Eq. 18 by Eq. 17 gives

$$\frac{(L)_{eq}}{(L)_{eq} - (L)_t} = \frac{R_{eq} - R_o}{R_{eq} - R_t} \quad (\text{Eq. 19})$$

Equation 19 suggests that the quantity " $(L)_{eq}/[(L)_{eq} - (L)_t]$ " can be obtained from measurement of the optical rotation of the sample solution at the beginning, at any time t , and at equilibrium, without knowing the concentration.

In the 100% hydrolyzed solution of pilocarpine, isopilocarpic acid is present in much smaller amounts than pilocarpic acid. Since there is a smaller contribution to optical rotation change when isopilocarpic acid is cyclized (about one-half of the value when pilocarpic acid is cyclized), and since isopilocarpic acid cyclizes at a much faster rate ($t_{1/2} = 182$ sec. at pH 1) (25), to the first approximation, the derived equations can be used to obtain information about cyclization of pilocarpic acid in the hydrolyzed pilocarpine solution.

Thus, the plots of $\log [(L)_{eq}/\{(L)_{eq} - (L)_t\}]$ versus t for different pH values are illustrated in Fig. 6. Reasonable straight lines are indicated.

Taking the logarithm of Eq. 11 yields

$$\log (\text{slope}) = \log [(k_1 + k_{-1})/2.303] - \text{pH} \quad (\text{Eq. 20})$$

which implies that a plot of $\log (\text{slope})$ against pH will have a straight line with a slope equal to -1 , with intercept being $\log [(k_1 + k_{-1})/2.303]$. This plot is shown in Fig. 7, and the $(k_1 + k_{-1})$ so obtained is 4.10 l./mole/hr.

At pH greater than 2, Eq. 20 will no longer hold, since $F = K(H^+)/[K(H^+) + 1] \neq 1$, and the slope is now given by

$$\text{slope} = \left[k_1 \frac{K(H^+)}{K(H^+) + 1} + k_{-1} \right] (H^+)/2.303 \quad (\text{Eq. 21})$$

Upon rearrangement of Eq. 21, Eq. 22 is obtained:

$$\frac{2.303 (\text{slope})}{(H^+)} = k_1 \frac{K(H^+)}{K(H^+) + 1} + k_{-1} \quad (\text{Eq. 22})$$

Figure 6—Cyclization of pilocarpic acid at different pH's.

Figure 7—pH profile of the hydrolysis of pilocarpine in acid pH (log slope versus pH plot).

which denotes that a plot of $2.303 (\text{slope})/(\text{H}^+)$ against $k(\text{H}^+)/[K(\text{H}^+) + 1]$ will be a straight line with slope equal to k_1 and intercept equal to k_{-1} . However, at a pH higher than 3, the change in pH value becomes significant as the cyclization proceeds. It is, therefore, necessary to use a pH-stat or buffer to maintain the pH constant. The rate of cyclization at a pH higher than 3 was found to be so slow that utilization of a pH-state was impractical. The use of a buffer such as citrate not only failed to maintain the pH constant but also catalyzed the reactions. For this reason, the application of Eq. 22 was unsuccessful.

Nevertheless, k_1 and k_{-1} can be calculated from the results obtained in Fig. 7 and the data obtained from the analysis of the cyclized solution for pilocarpine. This is because at low pH (for example, pH = 1), the hydrolyzed product would exist essentially in its acidic form and the ratio k_1/k_{-1} would be equal to $(\text{pilocarpine})_{\text{eq}}/[C_0 - (\text{pilocarpine})_{\text{eq}}]$. Thus, the results from Fig. 7 and from the analysis of cyclized solution give

$$k_1 + k_{-1} = 4.10 \text{ l./mole/hr.} \quad (\text{Eq. 23})$$

$$k_1/k_{-1} = 29.3 \quad (\text{Eq. 24})$$

Solution of the simultaneous Eqs. 23 and 24 results in $k_1 = 3.97 \text{ l./mole/hr.}$ and $k_{-1} = 1.35 \times 10^{-1} \text{ l./mole/hr.}$

Up to this point, the mechanism for the hydrolysis of pilocarpine can be written as the cyclic equilibrium process shown in Scheme IV:

Scheme IV

where k_{H^+} is equal to k_{-1} , and $k_{-\text{H}^+}$ is equal to k_1 . By considering "the principle of microscopic reversibility," a reversible reaction for the hydroxide-ion catalyzed pathway can be inferred. Consequently, the complete cyclic mechanism may be stated as in Scheme V:

Scheme V

Here, $k_{-\text{OH}^-}$ is defined as the first-order rate constant for the cyclization of pilocarbate to pilocarpine and may be calculated from k_{OH^-} , k_{H^+} , $k_{-\text{H}^+}$, and K . The $k_{-\text{OH}^-}$ so calculated is $2.49 \times 10^{-6}/\text{hr.}$

The hydrolytic information was obtained by following the rate of cyclization to approach equilibrium. (The hydrolysis of isopilocar-

pine would take the same mechanism but with different values of rate constants.) Since there wasn't noticeable epimerization indicated in acidic pH (14), the hydrolytic information obtained in this study and the postulated degradative pathway do not take into account the epimerization aspect.

The information obtained in this study is different from the recent publications by Baeschlin and Etter (26, 27), in which certain kinetic parameters were not fully considered.

CONCLUSION

1. Hydrolysis of pilocarpine in aqueous solution is a cyclic equilibrium process which is catalyzed by hydrogen ion and hydroxide ion.

2. The equilibrium position depends on pH; it shifts to pilocarbate at high pH and shifts to pilocarpine at low pH. The equilibrium constant and the rate constants at 25° , as well as the energy of activation for the hydroxide-ion catalyzed hydrolysis, were determined and are as follows:

$$\begin{aligned}
 K &= 1.12 \times 10^4 \text{ l./mole} \\
 k_{\text{H}^+} &= 1.35 \times 10^{-1} \text{ l./mole/hr.} \\
 k_{-\text{H}^+} &= 3.97 \text{ l./mole/hr.} \\
 k_{\text{OH}^-} &= 7.56 \times 10^3 \text{ l./mole/hr.} \\
 k_{-\text{OH}^-} &= 2.49 \times 10^{-6}/\text{hr.}
 \end{aligned}$$

$$E_a \text{ (for OH}^- \text{ catal. hydrolysis)} = 11.0 \text{ kcal./mole}$$

3. It is suggested that pilocarpine solutions be prepared at pH 4–5 for acceptable stability and physiological availability.

4. In alkaline pH, pilocarpine also undergoes some epimerization but at a rate much slower than hydroxide-ion catalyzed hydrolysis.

Solubility Profiles for Several Barbiturates in Hydroalcoholic Mixtures

T. L. BREON and A. N. PARUTA

Abstract □ The solubilities of eight physiologically active barbiturates were determined in binary mixtures of alcohol and water. The solubility curves for these substances varied, showing either solubility maxima or asymptotic solubility isotherms. The dielectric requirement of the barbiturates investigated illustrated an approximate inverse relationship with the number of carbon atoms in the molecule. A similar correlation was found with the solubilities in pure water, with the ratios of the solubilities in ethanol, and at the dielectric requirement to the solubility in water. The therapeutic indexes of duration of action and the period of time involved between administration of the drug and the time when the activity is first manifested increased as the relative polarity of these barbiturates declined. An approximate correlation between activity and solubility ratios is considered.

Keyphrases □ Barbiturates, solubility—ethanol—water systems □ Dielectric requirement—barbiturates □ Polarity, barbiturates—activity correlation □ Solubility ratios—barbiturates, ethanol—water systems

The pharmacological action exerted by a drug molecule in contact with a biological system is the net result of the interactions and extent of interactions with the complex biological environment. The degree as well as the rate of interaction is governed by many parameters, many of which depend on the physical and chemical properties associated with the drug molecule.

To be physiologically active, a drug must be absorbed and distributed throughout the biological fluids. More specifically, it is noted that these actions occur on a molecular level; under these conditions, it would be assumed that solution properties and characteristics are operative. Many biologically active substances are weak electrolytes, and properties such as the pH of the medium, pKa of the drug, concentration gradients, surface tension, and the aqueous and lipid solubilities of the various species contribute to the overall extent of activity.

The biologically active species, to initiate a response, would be presumed to have interacted with cellular constituents; this process is involved with diffusion and permeability as well as those factors previously discussed. Thus, this study is an initial investigation into the possible approximate correlation between solubility

characteristics of several barbiturates and therapeutic activity.

The wide variety of available barbiturates certainly attests to the importance of these materials, with a wide spectrum of uses such as sedatives and anticonvulsants. They are derivatives of barbituric acid with a variety of substitutions in the 5-position, and about 20 of these are presently available as therapeutic agents.

Although the general sedative action of all these barbiturates is about the same, they do vary in the duration of depressant action. Since these barbiturates are chemically different, it would be judicious to study them in attempting to relate known duration of action and chemical structure.

Thus, if in a series of barbiturates, a property such as solubility was determined as a function of polarity, there may be an indication of the relative lipoidal nature of these materials. It would be well to consider the solubility of these types of materials in a manner previously described (1). The cosolvent action on these barbiturates by mixtures of decreasing polarity should be instructive.

It might be expected that the position of the dielectric requirement (DR) and the magnitude of solubility at that point would be indicative of the effect of substituents and the relative polarity of the drug molecule. In view of this possibility, some eight barbiturates with a spectrum of values for the onset and duration of action were studied relative to their solubility behavior in hydroalcoholic solutions.

Several long-, intermediate-, and short-acting barbiturates (2) were chosen to test this hypothesis, including barbital as the comparing standard.

The very important work of Hansch and Anderson (3) should be mentioned here since they showed a definitive correlation of the activity of barbiturates with the log of the partition coefficients for various derivatives. This would suggest the importance of the hydrophobic character of substituted barbiturates in a wide variety of biochemical systems.

The model used by Hansch and Anderson (3) is a partitioning between phases to calculate the coefficients or a measure of lipophilicity of these drugs, *i.e.*, the

Amobarbital	—CH ₂ CH ₃	$\begin{array}{c} \text{CH}_3 \\ \\ \text{CH}_2-\text{CH}_2-\text{CH} \\ \\ \text{CH}_3 \end{array}$	H	O
Pentobarbital	—CH ₂ CH ₃	$\begin{array}{c} \text{CH}_3 \\ \\ \text{CH}-\text{CH}_2-\text{CH}_2-\text{CH}_3 \\ \\ \text{CH}_3 \end{array}$	H	O

greater the lipophilicity, the greater the partition coefficient. It is assumed that the partition coefficients in 1-octanol–water systems are additive in nature.

In the present study, the extent of lipophilicity is measured in a relative fashion, since it is assumed that the molecule possessing the greatest lipophilicity should have the least solubility in the most polar solvent. Further, the ratios of the solubilities, using a standard compound, should indicate the relative polarities of the molecules in a continuously varying spectrum of polarity.

In Table I, the pertinent chemical characteristics are shown for the barbiturates studied. Barbituric acid is also given in Table I and used to illustrate the parent compound.

EXPERIMENTAL

Materials—The materials used in this study were as follows: barbituric acid,¹ m.p. 252–255°; metharbital,² m.p. 151–155°; butabarbital,³ m.p. 166–168°; thiamylal,⁴ m.p. 133–135°; barbital,⁵ m.p. 189°; pentobarbital,⁶ m.p. 131°; amobarbital,⁷ m.p. 153°; and phenobarbital USP, m.p. 176°. Thiopental was prepared from the sodium salt.⁸ The sodium salt was dissolved in a quantity of distilled water, and the free acid precipitated by the addition of 1.0 *M* hydrochloric acid⁹ solution. The slurry was filtered and washed with three portions of distilled water. The melting point range of the dried precipitate was 156–158°. Melting points of

pooled and dried samples from the gravimetric procedure were also made and found not to vary more than ± 1 –2° outside the range of the original material. This was done to ascertain if any aberrant behavior such as hydrate formation or crystalline modification (polymorphism) occurred in these binary solvent mixtures.

Hydroalcoholic solvents were prepared volumetrically by the use of burets, previously determined densities for absolute ethyl alcohol,¹⁰ and distilled water at ambient room temperature. These mixtures ranged from 0.0 to 100.0% w/w distilled water in 2.5% increments and represent a polarity range in terms of dielectric constant values of 24.3–78.5.

A pH 10.7 buffer was prepared with 71 g. of anhydrous sodium dibasic phosphate¹¹ (reagent grade) dissolved in 1000 ml. of distilled water and adjusted to pH 10.7 with 1.0 *M* sodium hydroxide¹² solution.

Equipment—A rotating apparatus was constructed which held 48 screw-capped glass vials of 21-ml. volume and revolved at 32 r.p.m. The vials were rotated in such a way that the solute traversed the full length of the vial twice per revolution, thus causing sufficient agitation of the contents. No caking was observed in any of the samples. This apparatus was immersed in a 10-gal. water bath maintained at $25.0 \pm 0.3^\circ$ by a Tecan Tempunit.¹³

A Cary model 16 spectrophotometer,¹⁴ a Mettler type H6T¹⁵ analytical balance, a Leeds Northrup model 7401 pH meter,¹⁶ and a Sorvall model GLC-1¹⁷ centrifuge were utilized in the assay procedure. Computational treatment of the data was aided through utilization of an IBM System 360 model 50 digital computer.¹⁸

Procedure—The procedures used in this study have been previously given (4) and consist essentially of a gravimetric analytical technique with a spectrophotometric check run. Each solubility curve represents the average values from at least three runs of the 41 samples comprising the total variation in solvent composition.

Figure 1—Solubilities of the barbiturates noted are plotted in milligrams per milliliter at 25° as a function of the weight percent water.

RESULTS AND DISCUSSION

In Fig. 1, the solubilities of barbital, phenobarbital, and metharbital in milligrams per milliliter as a function of the percent w/w water in binary mixtures are presented. The solubility curves show maxima at 10% w/w water for phenobarbital and 15% w/w water for barbital. Metharbital, on the other hand, shows a maximum at 15% w/w water and a shoulder at 35% w/w water. These values lead to DR (dielectric requirement) values of 29.0 for phenobarbital, 30.6 for barbital, and 30.6 and 41.3 for metharbital, respectively. The values for barbital and phenobarbital agree with those previously given (5–7).

The basic correlation of the interpretation of solubility phenomena in terms of dielectric constants is substantiated by considering Khalil and Martin's (5) value for barbital. The value of the solubility parameter is given as approximately 13.5 in their excellent work on model membranes. The DR of barbital in this present study was found to have a value of 31, which gives a solubility parameter value of 13.7 from a previously presented relationship (6), which has been modified slightly and presented in another communication (8).

Further, Khalil and Martin (5) obtained a value for the solubility parameter of salicylic acid as 10.8, which coincides well with the value of 10.5 derived on a dielectric constant basis (8).

It is interesting to note the nature of these curves, since a cross-over occurs in the magnitude of solubility. Barbital is seen to have greater solubility than phenobarbital over a wide range of polarity, *i.e.*, dielectric constant values of 33 to 78, whereas phenobarbital has greater solubility in the range of 24 to 33. These three barbiturates have been grouped together for convenience, since these materials possess a DR and approximately the same duration of action. The solubility of these substances varies about 5–13% w/v in pure alcohol to the maxima. The solubility of these substances are summarized in Table II.

In the case of metharbital, it is noted from Fig. 1 that the addition of a methyl group to the R_3 position of the molecule dramatically reduces the maximum solubility as compared to barbital with a hydrogen at this position. A DR is observed at 30.6 and a solubility at this point of 51.2 mg./ml. It is also seen that a shouldering effect, unique to this derivative, is observed in the range

of 40–44 in terms of dielectric constants. The pharmacological activity of this derivative is also unusual in that it not only produces sedation but possesses anticonvulsant properties.

A brief consideration of the chemical structure of the metharbital molecule will also yield some unusual characteristics relative to the nonmethylated analogs. It has been reported (9) that the barbituric acid derivatives undergo enol–keto tautomerism. Molecules devoid of alkyl substituents on the nitrogen atoms can provide a maximum of two (N–H) hydrogen atoms which would be available for contribution to mono-enolized and dienolized structures with the three neighboring carbonyl groups.

Scheme 1a illustrates the three possible dienolized structures as

a—derivatives devoid of *N*-alkyl substituents showing only the dienol combinations

b—*N*-alkyl derivatives showing all possible combinations of enol species

Scheme 1a,b—Enol–keto tautomerism of the barbituric acid derivatives

well as the keto form. It is noted from this illustration that the carbonyl group at carbon-2 has twice the number of chances of becoming enolized as those at carbon-4 or 6, due to its vicinal position to both nitrogen atoms. Metharbital, on the other hand, has only one (N–H) hydrogen available. With the methyl group on the nitrogen at position-3, only two possible mono-enolized species can form, as shown in Scheme 1b. Other effects being equal, the chances of the carbonyl group at position-2 or 6 being converted to the enol form are equal.

Tautomerism is not a static situation where tautomeric species of molecules exist in only keto or enol forms, but rather it is a dynamic equilibrium where active hydrogen atoms are rapidly interchanging between the various species.

It may be possible that the limitations imposed on the tautomerism of the metharbital molecule by the *N*-methyl group could cause the shouldering effect on the solubility profile. A second possibility for this unusual behavior for a barbiturate derivative is that the polarity of the various tautomeric forms is different. The assay procedure, not being specific for any particular species of this molecule, would detect the cumulative solubility of all the various species present.

The solubility data for butabarbital are found in Table III. Figure 2 represents the isothermal data graphically as solubility in milligrams per milliliter as a function of solvent composition. This molecule is identical to barbital with the exception of the ethyl group on the R₂ position, which is replaced with a *sec*-butyl group. The addition of these two carbon atoms decreased the solubility over the entire range of the solvent composition.

Reber and Pathamanon (10) have determined the solubility of vinbarbital in ethanol–water mixtures. A tabulation of values derived from smoothing their data is found in Table III and plotted in Fig. 2, as described previously. This particular derivative has a fifth carbon atom and an olefinic bond added to the substituent at the R₂ position of the butabarbital molecule.

For the purpose of obtaining the solubility profiles for vinbarbital, special treatment of the data presented by Reber and Pathamanon (10) was necessary. Their profile consisted of 11 pieces of data, only one of which corresponded to an exact solvent composition used in this study. It was necessary, therefore, to analyze their data and determine the apparent solubility of vinbarbital in each of the 41 solvent systems employed for the remaining compounds. Rather than arbitrarily picking points off a plot of their data, the data were subjected to a polynomial regression. A previously compiled and published digital computer program (11) was employed in double precision. This program is based on a mathematical method presented by Ostle (12). The coefficients of an eighth-degree polynomial, representing the best fit of a curve to the

data of Reber and Pathamanon (10), were computed. From this equation, the apparent solubilities of vinbarbital in hydroalcoholic solvents of identical composition to those used in this study were calculated. It is suggested by Ostle (12) that this particular method is not valid for data presented in uneven increments of the independent variable. However, it is felt that the published solubility data for vinbarbital closely approximate even increments of solvent composition and, therefore, a close approximation of the true equation describing the data should be rendered by this method. A comparison of the original data in Table IV may be made with the values computed by this method which are found in Table III.

Amobarbital, the third of the intermediate-acting barbiturates of this group, is also illustrated in Fig. 2. However, in this case, the solubility curve rises asymptotically toward a maximum value in pure ethanol. The DR would presumably have a value of about or less than the dielectric constant of pure ethanol, *i.e.*, 24.3. The solubility data for these compounds are given in Table III.

Three barbiturates of short to ultrashort duration were also studied. Pentobarbital, the 5-ethyl-5-(1-methyl butyl) derivative of barbituric acid, showed a solubility curve also running asymptotically toward pure alcohol. Again, it would be assumed that the DR would be about 24.3, that being the value for pure ethanol. Although there is a discrimination between amobarbital, the 5-ethyl-5-isopentyl derivative, and pentobarbital based on duration of action, both possess similar solubility curves and magnitudes of solubility. Certainly, there is considerable overlap in the duration

of sedative effect for these materials; however, although amobarbital has an intermediate duration, it is closer to short-acting pentobarbital (especially chemically) than it is to intermediate-acting vinbarbital and butabarbital.

The following two compounds to be discussed differ from the previously mentioned derivatives, because the oxygen at the R₄ position has been replaced with a sulfur atom in the ultrashort-acting thiamylal and thiopental. The effect of this substitution may decrease the polarity of the molecule from its oxy-analog. On the electronegativity scale, the value for the oxygen atom is 1 unit higher than those for the sulfur and carbon atoms which are approximately equal. Thus, the chemical bond between the oxygen at the R₄ position and the adjacent carbon atom may be more polar in character than the similar situation with the sulfur atom.

Aside from this substitution, the chemical structure of thiopental varies from barbital by a 1-methylbutenyl group replacing an ethyl substituent on the R₂ position.

Table V and Fig. 3 tabulate and graphically illustrate the solubility data for thiopental, in the manner previously described.

The ultrashort-acting barbiturate thiamylal is similar in chemical structure to thiopental, with the exception of an allyl substituent replacing an ethyl group in the R₁ position. Data for this derivative are found in Table V. A plot of these data, in the usual fashion, is represented in Fig. 3. This curve is unique in that no maximum is observed, but the solubility profile rises sharply toward pure

Table V—Summary of the Solubility of the Barbiturate Noted in Ethanol-Water Mixtures in Milligrams per Milliliter at 25° as a Function of w/w Percent Water and Dielectric Constant

Figure 2—This plot parallels that for Fig. 1 for the barbiturates noted.

ethanol, having a dielectric constant of about 24.3. This would indicate that a DR of less than 24.3 would exist for this compound.

It was noted in the case of all the barbituric acid derivatives that some portion of the solubility isotherm possessed a fair degree of linearity relative to the solvent composition. The rates calculated as the slopes of the straight line best representing these approximately linear sections are summarized in Table VI, along with the ranges in solvent composition in which this relationship is valid.

The limits of solvent composition, within which these rates are operative, lie well within the range of pharmaceutical interest. It might be assumed then that there would be some pharmaceutical formulation advantages in this information.

It would be pertinent then to consider the changes in solubility produced by altering the substituent groups on the barbituric molecule in a relative manner where barbital is used as the standard of comparison.

The ratios computed in this manner for metharbital are shown and the data plotted as a function of w/w percent water in Fig. 4. It can be seen in this illustration that the magnitude of solubility of metharbital is substantially lower than that of barbital over the entire range of solvent composition. The peak observed between 30 and 40% water by weight corresponds to the shoulder on the solubility profile. An inflection on this curve may be observed at 15% w/w water, which corresponds to the maximum solubility of both metharbital and barbital.

Phenobarbital, on the other hand, produces an interesting spectrum of values, wherein at low polarities the ratio is greater than

Figure 3—Solubilities of the noted barbiturates are illustrated as described in Fig. 1.

unity and is isodielectric at 20% w/w water. The fair degree of linearity for the ratio curve up to about 70% w/w water implies a unique discriminatory effect due to the phenyl substituent in the incremental polarity shifting due to the varying aqueous content. This would seem to support the concept of a continuous polarity spectrum in ethanol-water mixtures possessing constant forces of interaction or dissolution. The approximate slope for this line is

Figure 4—Ratio of the solubility of phenobarbital and metharbitol relative to barbitol (defined as unity) is given as a function of the weight percent water.

Figure 5—This plot parallels that of Fig. 4 for amobarbital, butabarbital, and vinbarbital.

$1.4 \times 10^{-2}/\%$ change in water by weight. Thus a 10% change in water content from 10 to 20% would decrease the ratio by 0.14.

In Fig. 5, the ratio curves for amobarbital, butabarbital, and vinbarbital are shown. These three curves are similar in that there is an inflection point at about 15% w/w water and again, as expected, the curves converge from about 70–100% w/w water. Amobarbital also possesses an isodielectric point at 42.5% w/w water. In Fig. 6, the ratio curves are given for pentobarbital, thiamylal, and thiopental. Pentobarbital shows an inflection point at about 20% w/w water and an isodielectric point at 45% w/w water. A very large change in the ratio is seen, from a 270% increase in pure ethanol due to the 1-methyl butyl group to about a 300% reduction in pure water. This ninefold change in solubility ratio varies non-linearly throughout the intermediate range.

The ratio curves for thiamylal and thiopental are also interesting, the "spike" for thiopental due to the sharp maximum in the solubility profile. Further, the convergence of these plots extends over a very wide spectrum of concentration values, i.e., 30–100% w/w water.

To attempt to collate this information in a coherent fashion, the solubility values in pure water, pure ethanol, and at the DR (where applicable) were considered.

In Table VII, a summary of the duration and onset of action (13, 14) is shown for the compounds in this study, as well as the pertinent characteristics of the solubility profiles.

Table VI—Summary of Rates of Change in Solubility in Milligrams/Percent w/w Water, Calculated from the Linear Portion of the Solubility Profiles

Derivative	Range in % w/w Water	Rate in mg./% w/w Water
Barbital	15.0–55.0	–1.8
Phenobarbital	15.0–50.0	–2.9
Metharbitol	20.0–60.0	–1.0
Butabarbital	20.0–55.0	–1.9
Vinbarbital	20.0–60.0	–1.2
Amobarbital	15.0–50.0	–4.4
Pentobarbital	10.0–50.0	–5.0
Thiopental	10.0–30.0	–3.0
Thiamylal	0.0–30.0	–4.0

Table VII—Summary of the Dielectric Requirement (DR), the Solubilities in Absolute Ethanol, in Water, and at the Dielectric Requirement in Milligrams per Milliliter, as a Function of the Duration and Onset of Action

Derivative	Duration of Action		Onset of Action Reference 13	DR	Solubility in Ethanol, mg./ml.	Solubility at DR, mg./ml.	Solubility in Water, mg./ml.
	Reference 13	Reference 14					
Barbital	Long	Long	30–60 min.	30.6	92	121	7.3
Metharbital	Long	Long	30–60 min.	30.6	42	51	2.00
Phenobarbital	Long	Long	20–40 min.	29.7	118	132	1.20
Butabarbital	Intermediate	Short to intermediate	20–30 min.	29.7	84	91	0.86
Vinbarbital	Intermediate	Short to intermediate	20–30 min.	27.6	62	63	0.70
Amobarbital	Intermediate	Short to intermediate	20–30 min.	24.3	219	219	0.56
Pentobarbital	Short	Short to intermediate	20–30 min.	24.3	250	250	0.50
Thiopental	Ultrashort	Ultrashort	30 sec.	27.6	56	97	0.08
Thiamylal	Ultrashort	Ultrashort	20–60 sec.	24.3	161	161	0.05

Table VIII—Summary of the Therapeutic Action, and the Ratios of the Solubility in Ethanol and at the Dielectric Requirement (DR) to the Solubility in Water

Derivative	Duration (Reference 13)	Onset (Reference 14)	Sol. in Ethanol		Group
			Sol. in Water	Sol. at DR Sol. in Water	
Barbital	Long	30–60 min.	12	16	I
Metharbital	Long	30–60 min.	21	25	I
Phenobarbital	Long	20–40 min.	98	110	II
Butabarbital	Intermediate	20–30 min.	98	104	II
Vinbarbital	Intermediate	20–30 min.	88	91	II
Amobarbital	Intermediate	20–30 min.	390	390	III
Thiopental	Ultrashort	30 sec.	670	1200	III
Thiamylal	Ultrashort	20–60 sec.	2300	2300	III
Pentobarbital	Short	20–30 min.	500	500	III

The onset of action for all the compounds listed is after the oral dose except with thiamylal and thiopental which are given intravenously. Intravenous administration of barbiturates other than

thiamylal and thiopental would have an onset of action about 3–5 min., with barbital and phenobarbital at the upper value and the others at the lower. The DR's for these compounds shift to lower values as the duration of action decreases, indicating greater lipophilicity for the ultrashort barbiturates. The solubilities of these compounds in pure ethanol, pure water, or at the DR show no discernible pattern relative to direction and magnitude.

It was thought, however, that some sort of approximate correlation should exist relative to the pharmacological parameters and physical properties, although this relationship is undoubtedly complex (13). In Table VIII, the ratios of the solubilities of these compounds in pure ethanol and at the DR relative to water are shown. For compounds with a long duration of action, these ratios have values of about 10 to 100. However, if phenobarbital is omitted, the ratios vary from about 10 to 25. For the compounds listed as intermediate in action, these ratios vary from about 100 to 400 for butabarbital through amobarbital. Again, overlapping is suggested by these values since amobarbital is substantially greater than either butabarbital or vinbarbital. For those barbiturates possessing short or ultrashort action, the ratios are substantially larger, ranging in value from 500 to 2300, which indicates relatively greater lipophilicity for these substances. Since amobarbital is closer to pentobarbital in the properties of the solubility curves, they might also be considered in a given group.

Thus, a classification scheme for the barbiturates might be considered from both points of view, *i.e.*, pharmacological values and physical measurements. The last column of Table VIII breaks down the nine barbiturates in this study into three groups denoted by a Roman numeral. Although this type of classification would be very limited, it would provide a means by which exact and simple physical measurements could place a compound in the appropriate pharmacological range.

This correlation is rather good in view of the nature of the solvents. Such a relationship might be expected with pure water and ethanol which anchor the ends of the spectrum of solvent composition. Between these end-points, however, nonideal solvents are involved; this cosolvency phenomenon produces solubilities that deviate from those which may be expected of ideal solutions.

It may be conjectured that the magnitude of these ratios are an indication of the extent to which these compounds become concentrated in the less polar biological fluids. Thus, the derivatives

Figure 6—This plot parallels that of Fig. 4 for pentobarbital, thiopental, and thiamylal.

possessing a higher ratio, *i.e.*, thiopental and thiamylal, become concentrated to a higher degree in the body lipids than do barbital or metharbital and might be expected to be ultrashort acting.

In considering these solubility data in total, an approximate correlation has been observed between the lipophilic nature of the various barbiturate analogs and their therapeutic action. One must view this study with proper perspective in relation to the numerous other physical and chemical properties as well as the various biopharmaceutical parameters which all contribute to the variation in the final therapeutic activity possessed by the members of this series. The net result of the complex interaction of these and other factors determines the type and degree of the pharmacological activity involved.

The underlying concept of the pH-partition hypothesis as an approximate model would seem to be confirmed. However, such phenomena as binding, detoxification, active or passive diffusion, and complexation would play important roles in biological read-outs which were not patternized or aberrant in behavior.

It is anticipated that several studies on the barbiturates and sulfonamides relative to solubility and partitioning will be undertaken in these laboratories and will be the subject of future communications.

Metabolism and Excretion of Chromonar and Its Metabolite in Dog and Man

YVONNE C. MARTIN and RONALD G. WIEGAND

Abstract □ A simple method for the detection of chromonar and its acid metabolite by fluorescence techniques is described. Following oral or intravenous administration, chromonar is rapidly hydrolyzed to its metabolite, the corresponding acid. No further metabolism is observed. The metabolite distributes according to a single-compartment model. The plasma half-life is 1 hr. in man and dog. Excretion of the metabolite into the bile accounts for approximately 25% of the dose, and excretion into the urine accounts for the remainder.

Keyphrases □ Chromonar—metabolism, excretion □ Metabolite, chromonar—in *vitro*, in *vivo* determination □ Blood levels, chromonar and acid metabolite—human, dog □ Excretion—chromonar acid metabolite □ TLC—separation, identification □ Fluorometry—analysis

The coumarin compound chromonar¹ is used for the treatment of angina pectoris in Germany and Japan. The early report by Klarwein and Nitz (1) demonstrated that when the drug comes in contact with biological tissues, it is rapidly hydrolyzed to the corresponding acid (Scheme I), which exists as a zwitterion at the pH

of the blood and urine. The present authors, therefore expected that the tissue distribution and further metabolism of the compound would be minimal and that the study of plasma and urine concentrations of the acid metabolite at various times after dosage would provide the information necessary to assess the way that chromonar is handled by the body.

Scheme I—Metabolism of Chromonar

¹ 3-(β-Diethylamino-ethyl)-4-methyl-7-carbethoxy-methoxy-2-oxo-(1,2-chromene). Also known as Cassella 4489, Abbott-27053, and Intensain hydrochloride. Chromonar is marketed by the Cassella Co. of Germany.

9	150	0.25	0.65 \pm 0.04	1.06	2.80 \pm 0.11
Mean			0.616	1.16	5.31

^a Estimated by the method of Wiegand and Sanders (2), the variance was minimized by manipulation of the time lag.

Since both compounds are highly fluorescent, it was possible to modify the original assay method of Klarwein and Nitz (1) to make it more sensitive. To determine the amount of chromonar in a sample, it was extracted immediately after collection into ether from basic solution; then it was reextracted into acid, and the fluorescence of the acid phase was determined. The amount of the acid metabolite in a sample was determined by the fluorescence of the supernatant solution after trichloroacetic acid precipitation.

EXPERIMENTAL

Reagents—Chromonar and the acid metabolite¹ were used. The standards used in the analytical procedures were homogeneous on TLC in Solvent Systems I and II. The chromonar hydrochloride, which was administered to animals and to human subjects, contained 0.6% of 3-(β -diethylamino-ethyl)-4-methyl-7-hydroxy-2-oxo-(1,2-chromene), which is the immediate chemical precursor of chromonar. The fluorescence spectrum of this compound did not interfere with the determination of chromonar or the acid metabolite.

Diethyl-*p*-nitrophenyl monothiophosphate² was the commercial product. All other reagents were commercial products of reagent grade.

Fluorescence Analysis of Chromonar—Within 5 sec. after withdrawal from the subject, the blood sample (usually 1 ml.) was shaken vigorously by hand for 1 min. in a 50-ml. ground-glass-stoppered centrifuge tube with 1 ml. 1 *M* tris chloride buffer, pH 8.6, and 25 ml. diethyl ether. These ether extracts are stable for several hours. When a convenient number of samples had been extracted, within 1–3 hr. of the original extraction, the tubes were centrifuged at low speed and 20 ml. of the ether phase was trans-

ferred to a second tube which contained 3 ml. 0.1 *N* HCl. The samples were then mechanically shaken for 10 min. and centrifuged. The ether layer was discarded, and the fluorescent intensity of the aqueous layer was determined in an Aminco-Bowman spectrophotofluorometer. The excitation wavelength was 334 m μ and the emission wavelength was 400 m μ . A tissue blank, standard chromonar solution, and tissue blank plus standard were analyzed with each set of samples.

Fluorescence Analysis of Chromonar plus Its Acid Metabolite—When the total of chromonar plus the acid metabolite is to be analyzed, there is no need for the pH 8.6 extraction. Consequently, the sample is treated with trichloroacetic acid to precipitate proteins, and the fluorescence is read on the supernatant solution.

Plasma or urine samples were used as such or diluted with isotonic saline. Feces were homogenized with five volumes of isotonic saline and then further diluted with saline if necessary. Samples could be stored at -15° for several weeks with no apparent degradation of the acid metabolite.

For the analysis, 2 ml. of 5% trichloroacetic acid was added with vigorous shaking to 0.1 ml. of the sample. The fluorescence of the clear supernatant layer was determined after the samples were centrifuged. A tissue blank, standard, and tissue blank plus standard were included with each set of samples.

TLC of Urine, Bile, and Fecal Samples—The methods and solvent systems were similar to those used by Klarwein and Nitz (1). Following sample applications the TLC plates (Analtech silica gel G, 200 μ thick) were first developed with water, then dried for 1 hr. at 100°, and then redeveloped with one of the following systems: I, ethanol-chloroform-water in a 10:2:1 volume ratio; II, ethylacetate-isopropyl alcohol-ammonium hydroxide in a 9:7:4 volume ratio; or III, chloroform-isopropyl alcohol-acetic acid-water in a 4:2:1:1 volume ratio. The location of fluorescent spots was detected under long wavelength UV light by comparison with authentic compounds; chromonar and the acid metabolite emit a characteristic yellow-green color.

To quantitate the acid metabolite after chromatography of a known volume of sample, the spots with the same *R_f* as the standard were scraped off and extracted with several portions of 95% ethanol. The samples were diluted with water, and the metabolite

² Parathion, K & K Laboratories, Inc., Plainview, N. Y.

content was then determined in 5% trichloroacetic acid solution as previously described.

In Vitro Conversion of Chromonar to Its Metabolite by Human Plasma—Freshly collected human plasma from three subjects was incubated with chromonar. At 1, 2, 3, 4, and 5 min., samples were removed and analyzed for the concentration of unchanged drug.

Dog Blood Level Studies—The plasma concentration of chromonar and its acid metabolite was determined after intravenous administration of chromonar in isotonic saline to six dogs. Dogs 1 and 2 were 10-kg. female mongrels which had been anesthetized by 3 mg./kg. s.c. morphine followed in 15 min. by 250 mg./kg. sodium barbital. Three doses were given to each animal, with intervals of 2 hr. Blood samples were taken from the jugular vein. Dogs 3 (female, 9.5 kg.) and 4 (male, 9.6 kg.) were on a chronic toxicity study for 25 months at the same dose. They were not anesthetized. Blood samples from these dogs were taken from the femoral vein. Female mongrels, Dogs 5 (5.5 kg.) and 6 (14 kg.), were anesthetized as described. The ureters and common bile ducts were cannulated, and the total urinary and biliary output was collected for 4 hr.

The plasma concentration of the acid metabolite was also determined after oral administration of chromonar in a capsule. Dog 7 was a 14.5-kg. male. Dogs 8 (female, 7.1 kg.) and 9 (male, 13.8 kg.) had been on a chronic toxicity study for 25 months at the same dose. None of these dogs was anesthetized. Blood samples from these dogs were taken from the femoral or jugular vein.

Human Blood Level Studies—In a multiple-dose study, 12 normal volunteers were divided into two groups of six. The first group, Subjects 1–6, took 150 mg. of chromonar orally on Day 1 and, for the following 6 days (2–7 inclusively), 150 mg. orally, t.i.d. On the 8th day of the experiment, they were given a final oral dose of 150 mg. In addition, Subjects 1 and 2 received an intraduodenal dose of 150 mg. prior to Day 1. The second group was given 40 mg. of chromonar intravenously on Day 1; for the subsequent 6 days, they received 150 mg. of the drug orally, t.i.d. On the 8th day, they were given a second 40 mg. of chromonar intravenously. Plasma samples were collected from blood taken from the femoral vein on Days 1 and 8 at appropriate times. Urine samples were collected prior to and 0–4, 4–8, and 8–24 hr. following drug administration.

Six additional normal adult subjects were given three 150-mg. oral doses of chromonar tablets with 6 hr. between doses. Plasma was obtained from blood drawn at 0, 1, 2, 4, 6, 8, 10, 12, 14, and 24 hr.

Excretion of the Acid Metabolite by Humans—To quantitate the amount of acid metabolite recovered in urine and feces, four subjects (19–22) were given a single 150-mg. tablet of chromonar. Urine and feces were collected for 4 days after drug administration.

Calculation of Kinetic Constants from Blood Level Studies—For the calculation of the disappearance constant and the apparent relative volume of distribution of the metabolite, the computer program of Wiegand and Sanders (2) was used. The curve of the plasma levels of the metabolite, which was determined following the oral administration of chromonar to dogs, often indicated an apparent delay in absorption of 10–15 min. In these cases the kinetic constants were recalculated using several time lags. The lag which resulted in the best fit (lowest sum of squares of deviations of experimental points from the calculated curve) was chosen, and these values are reported in the tables. For the case of blood levels of the metabolite following oral administration of chromonar to humans, data were not sufficient for use of this program. In the case of intravenous administration of chromonar to dogs, the first-order constant that describes the increase in plasma concentration of the metabolite relates to the conversion of chromonar to its metabolite rather than to absorption of drug, as in the original formulation of the program (3).

For intravenous administration of chromonar to humans, plasma samples were not taken until 0.5 hr. after the dosing. Thus, the conversion to the acid metabolite was complete. Since the disappearance curve suggested a single-compartment model, the plasma half-life of the metabolite was calculated for these subjects, assuming an exponential decline of plasma levels with time. The slope of the least-squares line of the logarithm of concentration against time gives the first-order disappearance constant, k_d . The plasma half-life, $t_{1/2}$, is related to k_d by the expression $t_{1/2} = \ln 2/k_d$. The intercept of this plot is c_0 , the theoretical initial plasma concentration. However, this theoretical initial concentration is also equal to the

Table III—Recovery of the Acid Metabolite 4 hr. after the Intravenous Administration of 5 mg./kg. Chromonar to Dogs

Dose, %	Dog 5	Dog 6
Urine	53.2	75.3
Bile	27.4	16.6
Total recovery, %	80.6	91.9

dose of the drug, a_0 , divided by the apparent relative volume of distribution of the drug V_d' . Thus, V_d' was evaluated as $V_d' = a_0/c_0$.

Calculation of Area under the Blood Level Curves—Areas under the acid metabolite plasma level curves for the subjects who had received chromonar orally were calculated by the addition of the area of each triangular or trapezoidal segment of the actual curve. The areas on Day 8 were corrected for the area due to the initial plasma concentration of the metabolite.

Areas under the metabolite blood level curve following intravenous administration were calculated from the extrapolated theoretical initial plasma concentration of the metabolite. The relationship is: area = c_0/k_d .

RESULTS

Analytical Methods—Klarwein and Nitz (1) reported that diethyl-*p*-nitrophenyl monothio-phosphate could be used to prevent the hydrolysis of chromonar. However, in preliminary investigations, it was observed that when diethyl-*p*-nitrophenyl monothio-phosphate was used, a slight excess of this inhibitor (twice the concentration necessary for inhibition of the serum esterase) quenched the fluorescence of the chromonar in the final solution. Thus, diethyl-*p*-nitrophenyl monothio-phosphate was not used in the present method; instead, all samples analyzed for the concentration of chromonar were extracted immediately (within 5 sec.) from the basic solution with ether. With this procedure, 95–100% of the standard chromonar which had been added to a blood or tissue homogenate sample was recovered. A typical blank blood sample corresponded to 0.02 mcg. chromonar/ml.

In the assay method for the total of chromonar and its acid metabolite, the simple trichloroacetic acid precipitation to remove most of the interfering substances from plasma, urine, bile, and feces was practical because of the intense fluorescence of the drugs. A relatively selective and sensitive spectrophotofluorometer is also necessary. In this procedure, a typical plasma blank in the determination of either chromonar or its acid metabolite corresponded to 0.01 mcg./ml.

For both methods the range of concentrations over which the fluorescence is linear with respect to concentration was 0.04–10.0 mcg./ml. sample. Above this range the fluorescence decreased with concentration. Since the concentration of drug in certain urine and bile samples exceeded 10 mcg./ml., appropriate dilutions were necessary.

The intensity of fluorescence of chromonar and its metabolite depends on the pH of the sample (1). It was, therefore, essential that the samples, standards, and blanks were prepared in the same way. If a sample exhibited too high a fluorescence, it was not further diluted with water but rather with the same concentration of acid that had been used in the original determination.

In Vitro Conversion of Chromonar to Its Metabolite by Human Plasma—The half-life ($\pm SD$) was calculated to be 2.68 ± 0.96 min.; thus, chromonar is extremely short-lived in human plasma.

Blood Levels in Dogs—Calculations derived from the plasma concentration of chromonar and its metabolite at various times after an intravenous dose of chromonar are summarized in Table I. The half-life of chromonar is very short in the dog; essentially none remained in the blood after 10 min. (0.17 hr.). The plasma half-life of the metabolite averaged 0.87 hr. This relatively short half-life represents either efficient excretion or rapid metabolism of the metabolite. The decline in plasma levels of the metabolite parallels the decline of coronary vasodilation.³ The half-life of the metabolite was not significantly shorter in Dogs 3 and 4, which had been on a chronic study for 25 months prior to this study.

^a Probability value, which should be less than 0.05 if slopes are significantly different on Days 1 and 8 in same subject.

With oral administration of chromonar, a 0.25-hr. time lag in absorption was observed (Table II); this is approximately the disintegration time of the gelatin capsules used to administer the drug. The mean half-life of the metabolite in blood was 1.16 hr.; this is somewhat longer than that determined after intravenous administration.

In the case of oral dosage, the V_d' term as calculated also includes the fraction of the drug that is not absorbed. The ratio of the intravenous to oral volumes of distribution, 0.088, indicates that in the dog 8.8% of an oral dose of chromonar is absorbed.

Excretion of the Metabolite by Dogs—Within 4 hr. after a single intravenous dose of 5 mg./kg. of chromonar, an average of 86% of the dose was recovered in the urine and bile as the metabolite (Table III). The identity of the fluorescent material was confirmed by quantitative TLC. At least 90% of the fluorescence was co-chromatographic with the authentic sample of the acid metabolite. Since the plasma half-life of the metabolite is the same in these dogs (Dogs 5 and 6) as in the others studied, one may conclude that the major route of disappearance of the metabolite from blood is excretion into the urine and bile. There is no evidence for further metabolism or tissue accumulation of the drug. In these cases the bile was collected as it was excreted. Since the plasma half-life of the acid metabolite was not shortened by this procedure, enterohepatic circulation apparently does not occur.

Human Blood Level Studies—The mean half-life of the acid metabolite following the intravenous administration of chromonar was 0.80 hr. (Table IV). There were no apparent differences between males and females. When these six subjects (7–12) were given 150 mg. chromonar, t.i.d., orally for 6 days and the intravenous study was repeated, the half-life was not significantly altered. There was also no significant change in the intercept, the area under the plasma

curve, or the apparent relative volume of distribution. Thus, as in the case of the dog, there is apparently no metabolic adaptation to chromonar after continued administration.

The actual values for the plasma concentration of the metabolite following intravenous administration of chromonar to Subject 11 are plotted in Fig. 1. This is graphic illustration of the lack of metabolic adaptation by repeated doses of chromonar. The plot of the logarithm of concentration against time is linear, which confirms the appropriateness of using the single-compartment model for distribution of the metabolite.

The standard deviation of the values calculated for the first-order disappearance constants of the plasma levels in each subject is usually approximately 10% of the value of the constant. This also indicates that the data are fit very well by a single-term equation or a single-compartment model. There was no indication of a deviation from simple first-order disappearance in any of the data.

The six subjects (1–6) who were given oral doses of chromonar separated by 6 days of 150-mg. t.i.d. dosage showed no consistent change in the area under the metabolite plasma curve (Table V). The area under the curve is a measure of availability of drug by the oral route. The two subjects (1 and 2) who received an intraduodenal dose showed essentially the same area under the plasma curve after this dose as after oral drug, indicating that chromonar may be absorbed from the intestine.

Table V—Calculated Areas under the Metabolite Plasma Level Curves in Six Subjects Given 150 mg. Chromonar Orally

^a Low weights of fecal samples in this subject (see text). ^b Corrected for difference in molecular weights and purity of administered drug.

The actual serum levels of the metabolite following oral administration of chromonar to Subject 2 are plotted in Fig. 2. Note that the rate of decline of serum levels of the metabolite is approximately the same as that of Subject 11 to whom the dose was administered intravenously. The variation in the amount of chromonar absorbed by the same subject on different days is often seen.

A comparison of the areas under the plasma curves after intravenous and oral dosage allows estimation of the fraction of the dose absorbed orally. Correction for the dose by each route must be made. Calculated on this basis from the data in Tables IV and V, 32% of the drug was absorbed on the 1st day of oral administration; on the 8th day, 25% was absorbed. Thus, the overall average absorption was 28%.

After a 6-day (i.i.d.) regimen of chromonar orally, the mean plasma concentration of the metabolite was 0.06 mcg./ml. 10 hr. following the last dose. (This compares with a mean of 0.9 mcg./ml. at the peak following an oral dose.) Thus, there was no appreciable accumulation of the metabolite.

The plasma concentrations of the metabolite when the drug was given at 6-hr. intervals (Subjects 13-18) are summarized in Fig. 3. The pattern of absorption does not appear to vary from one dose to another. There was also no accumulation during the day, and by 24 hr. the plasma levels of the metabolite were essentially zero. The plot of the mean plasma concentration against time was fit very

well by a calculated curve in which first-order absorption and elimination were assumed. A value of 1.60 hr.⁻¹ was used for the

Figure 2—Plasma levels of the acid metabolite after single duodenal (Day 0) or oral (Days 1 and 8) doses of 150 mg. chromonar to Subject 1 (Table V). On Days 2-7, 150 mg. chromonar i.i.d. was given orally.

Figure 3—Plasma levels of the acid metabolite. Three 150-mg. tablets were given with 6 hr. between doses.

absorption constant, 0.820 hr.^{-1} for the disappearance constant, 1.53 l./kg. for the apparent volume of distribution, and 2.28 mg./kg. for the dose.

From the intravenous studies the apparent volume of distribution of the acid metabolite in man was 0.44 l./kg. (Table IV).

Human Excretion Studies—The urinary excretion data from Subjects 1–12 are summarized in Table VI. Excretion of the metabolite occurred primarily in the first 4 hr. after administration. In the second 4-hr. period, relatively less drug was excreted after intravenous dosage than after oral dosage, which is consistent with the plasma curves and with the expected delay after oral administration due to the absorption phase. When the drug was administered intravenously, an average of 68% of the dose of chromonar was excreted into the urine as the metabolite, with the remainder probably excreted into the bile. From the urinary excretion data for these subjects, it is also possible to calculate the percent of an oral dose which was absorbed. Calculated from the average percent of the doses excreted in the urine, absorption was 36% on the 1st day and 34% on the 8th day, for an overall average of 35%. This agrees very well with the figure of 28% absorption determined from the plasma levels of the same subjects.

Following a single oral dose of chromonar, an average of 77% of the dose is recovered as the acid metabolite in urine plus feces (Table VII). The fecal weights from Subject 22 were very low; excluding this subject, the recoveries averaged 85%. The identity of the fluorescent material in the samples was confirmed by TLC in Solvent Systems II and III.

Bishydroxycoumarin, ethyl biscoumacetate, and warfarin are well-known drugs which also contain the coumarin ring system.

All three of these drugs are completely metabolized, although the coumarin portion of the molecules is usually not degraded (4–6). The apparent multicompartment distribution reported for bishydroxycoumarin (7) is not seen with the acid metabolite of chromonar.

SUMMARY

Following the oral or intravenous administration of chromonar, the drug is rapidly hydrolyzed to the corresponding acid. It is largely in this form that the drug circulates in the blood and is excreted into the bile and urine. In dogs as well as humans, the plasma half-life of the acid metabolite is approximately 1 hr. The decline in plasma levels conform to a single-compartment model. Excretion, not further metabolism, accounts for the decline in blood levels of this metabolite. Biliary excretion is an important factor; in the dog an average of 22% of an intravenous dose was recovered in the bile and 64% in the urine. There is no evidence of accumulation of the metabolite when chromonar is administered on a chronic basis.

Content Uniformity in Rectal Suppositories

IVO SETNIKAR and FEBO FONTANI

Abstract □ The content variability in five types of suppositories was evaluated in terms of coefficient of variation. The observed content variability had a coefficient of variation in the range of 1.2–4.5; the method variability had a coefficient of variation in the range of 0.3–4.3. Method variability interferes with the assessment of the actual content variability and, according to the official content uniformity specifications, may lead to the rejection of complying samples or to the acceptance of noncomplying samples. The rationale and the structure of the official content uniformity specifications were studied. The performance of official content uniformity specifications declines as method variability increases. An alternative approach for the evaluation and the restriction of content variability, based on the coefficient of variation, may be advantageous in some instances.

Keyphrases □ Suppositories, rectal—content uniformity □ Content uniformity, suppositories—official specifications □ Variability, drug content—suppositories

In discrete dosage forms, the content accuracy and the content unit-to-unit uniformity of the active ingredient are basic and obvious requirements for assuring reliable and constant therapeutic effects. Several investigators (1–5) have studied the manufacturing, analytical, and statistical problems involved in the control of content uniformity of tablets and capsules. In fact, content uniformity specifications are already given for some tablets in the USP XVII (6) and in the NF XII (7).

But content nonuniformity may affect other dosage forms besides tablets and capsules. For instance, sedimentation, heterogeneous repartition during the melting-casting process, or weight variations (8) may result in an excessive unit-to-unit content variation in rectal suppositories, which are dosage forms designed either to develop a local therapeutic effect or to serve as the vehicle for a drug with a general action. Especially in the second instance, the content uniformity of the active ingredient is as important as for oral dosage forms. Nevertheless, little attention has been given to this subject, apart from Elste *et al.* (9) who investigated some assay methods of content in individual suppositories.

The present investigation was undertaken to study the analytical and statistical aspects of the content uniformity control in rectal suppositories and to give a further contribution to this subject.

EXPERIMENTAL

Materials—Five types of suppositories, containing from 0.19 to 30% active principle, were investigated:

1. DIN, *i.e.*, 2.3-g. suppositories containing 15 mg. of dehydroepiandrosterone sodium sulfate in a water-soluble base of poly-

ethylene glycol 1450 and 6000,¹ glyceryl monostearate, propylene glycol, and succinonitrile.

2. VAL, *i.e.*, 2.0-g. suppositories containing 100 mg. dimenhydrinate in a water-insoluble base of theobroma oil.

3. GAM, *i.e.*, 2.7-g. suppositories containing 800 mg. phenprobamate in a water-insoluble base of triglycerides of natural fatty acids.²

4. MAL, *i.e.*, 2.1-g. suppositories containing 4 mg. dimeflin hydrochloride (3-methyl-7-methoxy-8-dimethylaminomethylflavone hydrochloride) and 500 mg. aminopyrine in a water-insoluble base of triglycerides of natural fatty acids.³

5. TEF, *i.e.*, 2.1-g. suppositories containing 276 mg. of theophylline and 46 mg. of ethylenediamine (to form aminophylline) in a water-insoluble base of theobroma oil.

The suppositories were manufactured by the melting-casting process previously outlined (8). Before casting, the active ingredients were in suspension in the melted base and the homogeneity was maintained by continuous mechanical stirring.

Methods—Ten replicates of the following assays were done: (a) bulk drug used for the preparation of suppositories; (b) drug content in samples equivalent in weight to one suppository (samples were taken from a mass obtained by homogenizing, without melting, 30 suppositories of each type) and (c) drug content in individual suppositories after weighing each suppository to within a precision of 0.1 mg.

The drug of replicates (a) and the samples of replicates (b) and (c) belonged to the same production batch.

The assays were done manually by the following methods.

Bulk Drugs—Dehydroepiandrosterone Sodium Sulfate—The bromometric method for Δ^5 -steroids, according to Gorac (10), was used.

Dimenhydrinate—Assay was done with perchloric acid in glacial acetic acid as proposed by Meulenhoff and Van Sonsbeek (11).

Phenprobamate—Kjeldahl's method of nitrogen determination, using the accelerator "selenium mixture Merck" proposed by Wiener (12), was used.

Dimeflin Hydrochloride—This method involved titration in glacial acetic acid after adding mercuric chloride solution, using perchloric acid and methyl violet as indicator. One milliliter of 0.1 N perchloric acid is equivalent to 35.98 mg. of dimeflin hydrochloride.

Aminopyrine—Perchloric acid method in anhydrous medium (13) was used.

Ethylenediamine—The method of De Lorenzi (14), based on the addition of formaldehyde to neutralized solutions of ethylenediamine hydrochloride and titration of the developed acidity with 0.1 N sodium hydroxide, was followed.

Theophylline—About 250 mg., exactly weighed, was dissolved in 30 ml. of anhydrous pyridine previously neutralized to thymolphthalein. The solution was then titrated with 0.1 N alcoholic potassium hydroxide to a deep-blue color. One milliliter of 0.1 N potassium hydroxide is equivalent to 18.02 mg. of anhydrous theophylline.

Drugs Vehicled in the Suppository Bases—DIN—The procedure described by Clark and Thompson (15) for the pure ingredient was adapted to suppositories. One suppository was dissolved in 100

ml. of methanol by refluxing for 15 min. and, after cooling, was diluted to 200.0 ml. with methanol. The mixture was left to rest, and 2.0 ml. of the decanted limpid liquid was evaporated to dryness in a test tube. One milliliter of antimony trichloride reagent (150 g. SbCl₃ in 50 ml. of acetic anhydride) was added, and the test tube was kept for 5 min. in a water bath at 50 ± 2°. After cooling, 2.0 ml. of acetic anhydride and 3.0 ml. of acetic acid were added. After 40 min., the developed color was measured and compared with a standard solution of dehydroepiandrosterone sodium sulfate submitted to the same procedure.

VAL—One suppository was added to 100.0 ml. of water in a stoppered flask and heated to 45° until the base melted. The flask was shaken and cooled to room temperature. The content was filtered, and 5.0 ml. of the filtrate was diluted to 100.0 ml. with 0.01 *N* sodium hydroxide. The absorbance was determined at 276 mμ using 0.01 *N* sodium hydroxide as blank. As the standard, a solution of dimenhydrinate in 0.01 *N* sodium hydroxide was used. Dimenhydrinate was taken from the same batch used for manufacturing the suppositories.

GAM—One suppository was stirred in 50 ml. of petroleum ether (40–70°) until the base dissolved. The insoluble drug was quantitatively filtered on a tared sintered-glass funnel and washed with three

20-ml. portions of petroleum ether. The funnel was dried to constant weight in a vacuum over P₂O₅. The weight of the residue (melting at 100–105°) was taken as the phenprobamate in the sample.

MAL: Assay of Dimefine Hydrochloride (MAL-DIM)—One suppository was dissolved in 50.0 ml. of chloroform. A portion of 20.0 ml. of this solution was evaporated to dryness on a water bath. To the residue, 50 ml. of 0.1 *N* hydrochloric acid was added. The mixture was heated and stirred on a water bath at 45° for 5 min., cooled, diluted to 100.0 ml. with 0.1 *N* hydrochloric acid, and filtered; 25.0 ml. of the filtrate was diluted to 50.0 ml. with 0.1 *N* hydrochloric acid. On this solution the absorbance was determined at 309 mμ using 0.1 *N* hydrochloric acid as blank. The *a* for dimefine hydrochloride is 61.9.

MAL: Assay of Aminopyrine (MAL-AMI)—To another portion of 20.0 ml. of the chloroformic solution, prepared for the MAL-DIM assay, 20 ml. of glacial acetic acid was added. The titration was done with 0.1 *N* perchloric acid, using methyl violet as indicator. One milliliter of 0.1 *N* perchloric acid corresponds to 23.13 mg. of aminopyrine.

TEF: Assay of Ethylenediamine (TEF-ETHYL)—One suppository was stirred in 50 ml. ethyl ether until the base dissolved. After extraction with four 20-ml. portions of water, the aqueous extracts

were filtered through a filter paper and diluted to 100.0 ml. with water (Solution A). To this solution, 0.1 *N* hydrochloric acid was added until the solution was neutral to methyl orange indicator. Five milliliters of 40% aqueous formaldehyde, previously neutralized to the same indicator, was added; the developed acidity was titrated with 0.1 *N* sodium hydroxide. One milliliter of 0.1 *N* sodium hydroxide corresponds to 6.0 mg. of anhydrous ethylenediamine.

TEF: Assay of Theophylline (TEF-THEO)—Exactly 1 ml. of Solution A, prepared as already described, was diluted to 250.0 ml. with 0.01 *N* sodium hydroxide, and the absorbance was measured at the maximum (about 275 mμ). The amount of drug in the sample was calculated according to the British Pharmacopoeia (16) taking 65.0 as the value of *a* for anhydrous theophylline.

RESULTS

Compliance with the Official Content Uniformity Specifications (OCUS)—The content ranges of the active ingredient (Table I, Entry NR) in the investigated suppositories were within the limits prescribed in the first step of the OCUS given by USP XVII (6) for some oral dosage forms. In fact, in the 10 specimens investigated, the active ingredient found was always within the $M \pm 0.15 M$ limits (M = nominal content). The OCUS may, therefore, be extended to rectal suppositories, where a heterogeneous distribution of discrete particles of the active ingredients between the individual dosage units is likely, as in oral dosage forms with a relatively small quantity of active ingredient compared to the inert ingredient (3, 4).

Assay Method for Content Uniformity Tests—The large amount of interfering vehicle and the small quantities of active ingredient present in the individual suppositories necessitated different assay methods for the bulk drug from those for the content of each suppository. Table I shows the performance of these assay methods in the different conditions, namely: (a) on the bulk drug, (b) on the homogenized suppository mass, and (c) on the individual suppositories. The analytical intrinsic variability, expressed by the coefficient of variation (*CV*), was usually smaller in the assays of the bulk drug than in the content assays on suppositories. In several instances, the difference between the *CV* of the two types of assay was significant to a $p < 0.05$ level. [The critical value for the ratio between the larger and the smaller *CV* is 1.56 (17).]

Since the assay method on the bulk drug must usually be changed or modified for assaying the content in individual suppositories, its performance cannot be taken as a standard for content assay. The most representative standard is the assay with the elimination of the unit-to-unit content variability, i.e., the assay on samples, of the size of one dosage unit, taken from homogenized suppositories.

Relationship between Content Variability and Observed Unit-to-Unit Variability—The unit-to-unit variability found in the content assays of the individual suppositories is composite and depends on the variability inherent in the analytical method as well as on the actual content variability.

It has been assumed that the different variables follow a Gaussian distribution (1, 18), so that they may be related by the following equation:

$$CV_{obs.}^2 = CV_{ana.}^2 + CV_{con.}^2 \quad (\text{Eq. 1})$$

where $CV_{obs.}$ is the *CV* observed, $CV_{ana.}$ is the *CV* inherent in the analytical method, and $CV_{con.}$ is the *CV* depending on the actual

Table II—Analysis of the Variabilities Observed in the Assays

Suppository Type	Active Ingredient, %	$\frac{CV_{obs.}^2}{CV_{ana.}^2}$	$\frac{CV_{obs.}^2}{\sqrt{CV_{ana.}^2 + CV_{w.}^2}}$
DIN	0.65	0.56	0.53
VAL	5.0	6.03	1.99
GAM	29.3	1.63	0.99
MAL-DIM	0.19	1.82	0.96

TEF-ETHYL	2.06	0.97	1.00
TEF-THEO	13.4	1.40	1.31

^a The critical value for the ratio is 1.56 ($\alpha = 0.05$, one-tailed).

Table III—Regressions of Content over the Weight of Different Types of Suppositories

Suppository Type	Regression ^a	<i>r</i> ^b of Difference (<i>a</i> = 0; <i>b</i> = 1)
DIN	$C = (0.68 \pm 0.52) + (0.32 \pm 0.52) W$	1.31
VAL	$C = (0.64 \pm 0.77) + (0.36 \pm 0.77) W$	0.83
GAM	$C = (-0.09 \pm 0.21) + (1.09 \pm 0.21) W$	0.42
MAL-DIM	$C = (0.76 \pm 0.40) + (0.24 \pm 0.40) W$	1.92
MAL-AMI	$C = (-0.24 \pm 0.56) + (1.24 \pm 0.56) W$	0.42
TEF-ETHYL	$C = (-0.05 \pm 0.89) + (1.05 \pm 0.89) W$	0.06
TEF-THEO	$C = (-1.16 \pm 0.99) + (2.16 \pm 0.99) W$	1.18

^a The regressions are standardized on average content and on average weight units. ^b $t = 2.31$ for $\alpha = 0.05$.

content variability. Equation 1 shows that $CV_{con.}$ cannot be estimated directly from $CV_{obs.}$, unless $CV_{ana.}$ is negligible compared to $CV_{obs.}$. Some $CV_{ana.}$'s found, represented by the *CV* obtained on the homogenized suppository mass, were rather large, namely in the same range as those found by other authors in assays of the content in individual tablets or capsules with drug combinations or with small quantities of active ingredient compared to the inert ingredients (3, 18–21). The $CV_{ana.}$, therefore, interfered with the estimation of the $CV_{con.}$. As a matter of fact, the $CV_{obs.}/CV_{ana.}$ ratio was not significantly greater ($p < 0.05$) than 1 in the DIN, TEF-ETHYL, and TEF-THEO content assays (Table II). Thus, in these suppositories, there is no proof of an actual content variability, since this is concealed by the assay method variability. Conversely, the presence of an actual content variability is demonstrable at a $p < 0.05$ level in the VAL, GAM, MAL-DIM, and MAL-AMI suppositories (Table II).

The actual content variability may depend on a heterogeneous dispersion of the active ingredient in the suppository mass, or on the suppository-to-suppository weight variability, or on both. The relationship between the different coefficients of variation is

$$CV_{con.}^2 = CV_w^2 + CV_{het.}^2 \quad (\text{Eq. 2})$$

where CV_w represents the unit-to-unit weight variability, and $CV_{het.}$ is the coefficient of variation due to heterogeneous dispersion of the active ingredient in the vehicle. From Eqs. 1 and 2, a heterogeneous distribution of the active ingredient is demonstrable when $CV_{obs.} > \sqrt{CV_{ana.}^2 + CV_w^2}$. This seems to be the case of VAL and of MAL-AMI suppositories (Table II). Table II shows that it is not possible to relate heterogeneous distribution to the percentage of active ingredient in the dosage form, as is often the case in solid oral dosage forms (22).

Correlation between Content and Weight—The correlation between content and weight may be studied using the linear regression (23) of content (*C*) over the suppository weight (*W*) in the equation

$$C = a + bW \quad (\text{Eq. 3})$$

Comparison becomes easier by standardizing the regression, i.e., by adopting as units average content and average weight. By this procedure, Eq. 3 shows a strict weight dependence of content when $a = 0$ and $b = 1$.

The regressions calculated by the least-squares method are given in Table III. Consistency with the hypothesis that $a = 0$ and $b = 1$ was tested with the Student's *t* test. Even though the regressions obtained apparently differ greatly from the theoretical one in which weight depends on content (expressed by $C = W$), the obtained results do not disprove such dependence. Data scatter, however, prevents any valid conclusion.

Correlation between Drugs in Combination—The TEF suppositories contain a combination of ETHYL and of THEO; the MAL suppositories contain a combination of DIM and of AMI. Since in both suppository types, the two ingredients were assayed simulta-

Table IV—Linear Regressions between Active Ingredients in MAL and TEF Suppositories^a

DIM = (0.52 ± 0.18) + (0.48 ± 0.18) AMI
$t_a = 2.95; t_b = 2.70$
ETHYL = (0.94 ± 0.27) + (0.07 ± 0.27) THEO
$t_a = 3.48; t_b = 0.26$

^a The critical t value is 2.26 ($\alpha = 0.05$).

neously in each individual suppository, the possible correlation between the two ingredients may be investigated by the linear regression. The regressions found, standardized into units of average content, are given in Table IV.

No statistically significant correlation was found between ETHYL and THEO, and a very small one ($0.05 > p > 0.02$) was found between DIM and AMI. For these suppositories the content uniformity found on one of the two combined drugs is not transferable to the other one, since each active ingredient varies independently.

Content Accuracy—Content accuracy, *i.e.*, correspondence between the actual average content and the labeled content, may either be investigated on a composite sample or evaluated from the average of the contents of the individual dosage units. In the latter case, the coefficient of variation of the mean (CVM) indicates the precision by which content accuracy is evaluated. The $p = 0.05$ confidence limits are the product of CVM multiplied by the appropriate t value (2.26 for 9 degrees of freedom).

Table I shows that the $p = 0.05$ confidence limits of the average content covered or were very close to the labeled content in most instances. The largest difference between the actual average content and the labeled content was found for TEF-ETHYL suppositories (-5.4%). Nevertheless, the TEF-ETHYL suppositories may still conform to the specification that the content must be between 95 and 105% of the nominal content, since the upper confidence limits are only 3% lower than the nominal content. Therefore, there is no proof to a $p = 0.05$ level that the content found is lower than 97%.

It should be emphasized that the content accuracy found is not the true one, since it depends also on the accuracy of the assay method. The performance of the method in terms of accuracy cannot be investigated with statistical tools, as in the case of uniformity, but must be evaluated by comparing different methods, preparing samples with known quantities of the substance under investigation, *etc.* (24). While theoretically it is impossible to be sure that an assay method is 100% accurate, in practice some methods, especially when a comparison with a proper standard is involved, yield an acceptable accuracy.

In the case of TEF-ETHYL suppositories, it was found that the method used was inaccurate because of suppository base interference. The alternative accurate method, which is now under investigation, has a wide intrinsic variability and, therefore, is not suitable for evaluating content uniformity. The results of the study on content accuracy of TEF-ETHYL suppositories will be the subject of another paper.

DISCUSSION

The samples of the different types of rectal suppositories conformed to USP XVII OCUS (16) for tablets. It may be shown, however, that this does not imply that every sample taken from the investigated lots of suppositories complies with the OCUS or that the OCUS are appropriate for restricting content variability in rectal suppositories. In fact, the OCUS call for comment before evaluating their adaptability to more general conditions.

Structure of the OCUS—The OCUS are based on sampling plans devised for "attributes" and for the restriction of "defective" specimens in a lot. The content is a continuous variable, which is transformed into an attribute by confronting the content found to the $M \pm 0.15 M$ limits (M is the labeled content), a transformation which implies by itself a loss of information. Nevertheless, the OCUS "attributes" plan was adopted by USP XVII after a multi-laboratory study (2), mainly because it was shown that some variables, *e.g.*, the weights of sterile solids, occasionally may not follow a Gaussian distribution (25). In these cases, the "attributes" plan may be advantageous because it is more "robust," *i.e.*, less suscep-

tible to the biasing effects of non-Gaussian distributions on the evaluation of variability.

The "attributes" plan of the OCUS, however, is not flexible; even a minor change in sample size, in acceptance number, or in critical limits radically changes the performance of the plan. Furthermore, the OCUS plan does not take intrinsic analytical variability into account and so sometimes leads to wrong conclusions.

The TEF-ETHYL suppositories, for instance, would not comply with the OCUS in approximately 1.7% of the samplings. More generally, an ideal lot with a perfect content uniformity, investigated for compliance with the OCUS with an assay procedure having an intrinsic variability expressed by a $CV_{ana.} = 5$, would not comply in approximately 1% of the samplings. Conversely, the same analytical variability might result in acceptance of a bad lot.

One reason for the choice of the "attributes" plan for the OCUS was the extensive experience already acquired with similar plans for the control and restriction of weight variability in different types of dosage forms. It should be remembered, however, that weight uniformity is investigated with a very precise and accurate method, namely the analytical balance, with an inherent $CV_{ana.}$ usually smaller than 0.1. When introduced into the equation

$$CV_{obs.}^2 = CV_{ana.}^2 + CV_W^2 \quad (\text{Eq. 4})$$

the $CV_{ana.}$ is negligible, so CV_W is directly evaluable from the $CV_{obs.}$. Moreover, for measuring weight, there is only one well-known and well-defined analytical method independent of a particular drug or formulation.

On the other hand, content uniformity is tested by methods which may have large intrinsic variabilities, interfering with the evaluation of the true content variability. Further, each drug and often each formulation call for a particular assay method, with a different intrinsic variability and, therefore, also a different consequence on the evaluation of true content variability.

For these reasons, the experience acquired with the weight uniformity specifications cannot be transferred to the control of content uniformity, unless the assay method is extremely precise and accurate.

Another point which should be emphasized is that the results obtained with the OCUS depend on the precision and on the accuracy of content of active ingredient and of its assay method. As a matter of fact, the name "test for content uniformity" is misleading, since actually the allowed variability decreases with the increase of inaccuracy, as shown in Fig. 1. Since the inaccuracy actually found depends also on the random composition of the sample and is biased by the imprecision and the inaccuracy of the assay method, a single specimen may sometimes be classified as within the $M \pm 0.15 M$ limits and sometimes as outside. The OCUS do not provide for a clear discrimination between good and defective specimens or for an explicit and fixed margin for content variability, so that among other drawbacks the OCUS cannot be transferred to the production control charts or to the inspection of portions of the lot which are larger than the sample sizes required by the OCUS.

When discussing weight variability, it was shown that the confidence in the results increases with the precision of the assay method. Since compliance with the OCUS depends both on precision and on accuracy, the assay method used for the OCUS must be accurate, a requirement which does not always go hand in hand with precision, economy, and sometimes even feasibility. This, for instance, is the case with biological assay methods, where the investigation of content uniformity can be performed only with inaccurate and unspecific methods (26). The need for different methods of testing accuracy and uniformity of content is becoming more and more obvious with the introduction of automated methods of analysis and is considered in the new editions of the USP and of the NF (21, 27, 28). But different methods, one for accuracy and the other for uniformity of content, are incompatible with the very structure of the OCUS.

In conclusion, the OCUS have several disadvantages. These are: (a) lack of flexibility so that it is very difficult to adapt the OCUS to different sample sizes, to the control of larger portions of a lot, or to control during production; (b) misleading results due to the neglect of the intrinsic analytical variability of the assay method; (c) dependence of content variability on content accuracy, which in

some instances prevents the use of precise methods for investigating content uniformity; (d) indefinite allowance for variability, impeding generalization, and the transfer of the OCUS to production control charts; (e) "yes or no" type of results, whereas often the knowledge of the degree of compliance or noncompliance of the sample is desirable to alert the producer or consumer to the presence of a borderline condition; (f) difficulty of gaining better knowledge of the OCUS through the experience acquired by content variability investigations, since most practical and theoretical studies evaluate the content as a continuous variable and express content variability in terms of standard deviation; and (g) loss of information due to the transformation of a continuous variable into an attribute.

These disadvantages are of secondary importance when the intrinsic variability of the assay method is small. But when the analytical variability is large enough to interfere with the evaluation of the actual content variability, or when a precise but inaccurate method is appropriate for checking content uniformity, an alternative approach to the control and the restriction of content variability seems desirable, e.g., one based on a "variables" sampling plan, as already advanced by Breuning and King (29), or based on the CV since many published investigations evaluate content uniformity through the CV method.

Content Uniformity Specifications Based on the Restriction of the Coefficient of Variation (CUS- CV)—According to Eq. 1 the basic acceptance condition of a CUS- CV , which takes into account the analytical variability, is

$$CV_{\text{con}}^2 = CV_{\text{obs}}^2 - CV_{\text{ana}}^2 \leq AQL^2 \quad (\text{Eq. 5})$$

where AQL is the acceptance quality level for content uniformity. Since the CV_{ana} depends on the assay method used for the content determination of the particular drug in the individual dosage form, the content uniformity specification must state for each drug and for each dosage form: (a) the official method for the content assay in the individual dosage units, and (b) the maximum method variability allowed for accepting the results (as for biological assay methods).

It has been shown (30) that the CV_{con} consistent with a 95% acceptance probability of USP XVII OCUS is 5.4 in the first sample of 10 and 6.2 in the composite sample of 30 dosage units. The AQL

Table V—Limits for CV_{con} at Different Sample Sizes

Sample Size, units	CV_{con}^a	
	AQL'	UQL
10	3.7	6.9
15	4.1	6.6
20	4.3	6.4
30	4.5	6.3
60	4.7	6.0
100	4.9	5.9

^a Calculated according to Eq. 5.

for content uniformity may, therefore, be located between 5.4 and 6.2, e.g., restrictively at 5.4.

The AQL' of a sample should give a 95% confidence that the CV in the lot is equal to or lower than 5.4. Therefore, the AQL' 's were calculated from the one-tailed 95% fiducial limits of Table H of Davies (17) for different sample sizes and are given in Table V. Also, the unacceptable quality level (UQL), i.e., the quality found which gives 95% confidence that the CV_{con} in the lot is higher than 5.4, depends on the sample size and is given in Table V.

In an actual inspection for uniformity, one may, for instance, start with a sample of 10 units and then take any further decision, i.e., upon acceptance, rejection, or expansion of the sample, on comparing the CV_{con} found with the values of Table V. In this way, the sample size is open and flexible.

As already pointed out, the OCUS link together two types of quality levels: one for uniformity and one for accuracy.

The requirements implied in the OCUS must, therefore, be translated into terms of AQL for accuracy consistent with the AQL for uniformity. According to Breuning and King (29), this condition is satisfied by expressing accuracy as the CVM . In a sample of 10 and for a $CV_{\text{con}} = 5.4$, the $CVM = 5.4/\sqrt{10} = 1.71$. This CVM means that about 99% of the averages of the assays on 10 units, or of the assays of composite samples of 10 units, should be within 95 and 105% of the nominal content, a condition which in fact is similar to the requirements of several monographs of USP XVII.

In sum, the CUS- CV may be outlined as the AQL' of the CV_{con} found on the basis of Eq. 5 should be within the values given in Table V for the different sample sizes. Since the OCUS implies also a specification for content accuracy, it must be added that the average content, assayed with a given accurate method on a composite sample of 10 homogenized dosage units, or calculated from 10 assays on individual dosage units, should be within 95 and 105% of the labeled content. The analytical variability must be considered in terms of CV_{ana} or of CVM_{ana} in order to rid the found average content of the bias due to analytical variability.

These specifications are both flexible and transferable to production control charts.

The main argument against a CUS- CV plan is that it is less "robust" than the "attributes" plan when the distribution of the investigated variable is non-Gaussian (25). A non-Gaussian distribution, however, seems an exception rather than the rule for the content of active ingredients (19). On the other hand, the advantages of the greater "robustness" of the OCUS are diminished by the greater room for uncertainty inherent in an "attributes" plan. In fact, according to Pietra and Setnikar (30), the AQL implied by the OCUS attribute plan for a lot is equal to 5.4 (or to 6.2 after the second sampling) and the UQL is equal to 12. This difference for lot CV is greater than the differences for sample CV listed in Table V. Although lot conditions are not comparable to sample conditions, the latter usually imply a larger margin of uncertainty but are, nevertheless, the actual conditions for inspecting uniformity.

Given the advantages and disadvantages both of the "attributes" plan and of the CV plan, reconsideration of the general approach to content uniformity control would seem to be indicated. The present investigation aims to be a contribution to this subject.

USP Collaborative Study of the Assay of Atropine and Scopolamine Dosage Forms

LEE T. GRADY and RUPERT O. ZIMMERER, Jr.

Abstract ☐ Several tablet and injection dosage forms of atropine and scopolamine are covered by USP XVIII monographs. Gas chromatographic unit dose assay and content uniformity procedures were developed for these monographs. Interlaboratory reliability was evaluated by means of a collaborative study. The methods afford substantial improvements in sensitivity, specificity, and speed over previous official methods.

Keyphrases ☐ Atropine, scopolamine dosage forms—analysis ☐ Scopolamine, atropine dosage forms, analysis—collaborative study ☐ Content uniformity method—atropine, scopolamine dosage forms ☐ GLC—analysis

Previous official methods of assaying dosage forms for belladonna alkaloids have relied largely on titrimetry. These methods lacked sensitivity and specificity. Unit doses could not be assayed and decomposition products were not excluded. Such problems aroused some criticism. A notable exception was an IR method (1) which, although failing in sensitivity, did offer specificity with some control over decomposition. Assay methods for USP XVIII were desired which would be accurate, reliable, and highly specific and yet be sufficiently sensitive, precise, and rapid to allow content uniformity determinations on unit doses.

Various other approaches to belladonna alkaloid analysis may be noted. A colorimetric method (2, 3) was applied to preparations containing phenobarbital along with the alkaloids, and a dye-complex method was applied to atropine tablets and elixir (4). Neither

of these approaches distinguishes one belladonna alkaloid from another. A fluorometric method has been reported for atropine (5). Paper chromatography (6, 7), partition-column chromatography (2, 3, 8), counter-current distribution (9), TLC (10), and TLC with densitometry (11) have all achieved separation of scopolamine from atropine-hyoscyamine.

Initial efforts in the gas chromatography of belladonna alkaloids were reported by Kazyak and Knoblock (12), Brochmann-Hanssen and Fontan (13), Jain and Kirk (14), and Solomon *et al.* (15). Penner (16) studied atropine assay by GLC, both as a silyl derivative and later untreated, using tetraphenylethylene as the internal standard. Alber (17) recently reported a broad study of the gas chromatography of drugs and alkaloids using the methylphenylpolysiloxane liquid phase which was used in this collaboration.

The procedures developed for this collaborative study are related to a method previously reported (18) for dose forms of belladonna alkaloids containing phenobarbital. Other official methods¹ were developed earlier for belladonna alkaloids using anthracene as an internal standard for control of injection volume alone.

MATERIALS

Methylene Chloride—Gas chromatography or 99 mole % grade was used.

¹ Hyoscyamine sulfate tablets NF and morphine and atropine sulfates tablets NF.

USP Collaborative Study of the Assay of Atropine and Scopolamine Dosage Forms

LEE T. GRADY and RUPERT O. ZIMMERER, Jr.

Abstract ☐ Several tablet and injection dosage forms of atropine and scopolamine are covered by USP XVIII monographs. Gas chromatographic unit dose assay and content uniformity procedures were developed for these monographs. Interlaboratory reliability was evaluated by means of a collaborative study. The methods afford substantial improvements in sensitivity, specificity, and speed over previous official methods.

Keyphrases ☐ Atropine, scopolamine dosage forms—analysis ☐ Scopolamine, atropine dosage forms, analysis—collaborative study ☐ Content uniformity method—atropine, scopolamine dosage forms ☐ GLC—analysis

Previous official methods of assaying dosage forms for belladonna alkaloids have relied largely on titrimetry. These methods lacked sensitivity and specificity. Unit doses could not be assayed and decomposition products were not excluded. Such problems aroused some criticism. A notable exception was an IR method (1) which, although failing in sensitivity, did offer specificity with some control over decomposition. Assay methods for USP XVIII were desired which would be accurate, reliable, and highly specific and yet be sufficiently sensitive, precise, and rapid to allow content uniformity determinations on unit doses.

Various other approaches to belladonna alkaloid analysis may be noted. A colorimetric method (2, 3) was applied to preparations containing phenobarbital along with the alkaloids, and a dye-complex method was applied to atropine tablets and elixir (4). Neither

of these approaches distinguishes one belladonna alkaloid from another. A fluorometric method has been reported for atropine (5). Paper chromatography (6, 7), partition-column chromatography (2, 3, 8), counter-current distribution (9), TLC (10), and TLC with densitometry (11) have all achieved separation of scopolamine from atropine-hyoscyamine.

Initial efforts in the gas chromatography of belladonna alkaloids were reported by Kazyak and Knoblock (12), Brochmann-Hansen and Fontan (13), Jain and Kirk (14), and Solomon *et al.* (15). Penner (16) studied atropine assay by GLC, both as a silyl derivative and later untreated, using tetraphenylethylene as the internal standard. Alber (17) recently reported a broad study of the gas chromatography of drugs and alkaloids using the methylphenylpolysiloxane liquid phase which was used in this collaboration.

The procedures developed for this collaborative study are related to a method previously reported (18) for dose forms of belladonna alkaloids containing phenobarbital. Other official methods¹ were developed earlier for belladonna alkaloids using anthracene as an internal standard for control of injection volume alone.

MATERIALS

Methylene Chloride—Gas chromatography or 99 mole % grade was used.

¹ Hyoscyamine sulfate tablets NF and morphine and atropine sulfates tablets NF.

Buffer—Prepare 0.2 M, pH 9.0 buffer, standardized against the glass electrode, by dissolving 34.8 g. dibasic potassium phosphate in 900 ml. water. Adjust to pH 9.0 and make to 1 l. with water.

Atropine Sulfate Standard Solution—Dissolve 30.0 mg. atropine sulfate in distilled water in a 100-ml. volumetric flask to obtain a solution of 0.30 mg./ml. Prepare fresh daily.

Homatropine Hydrobromide Standard Solution—Similarly, prepare a final concentration of 0.04 mg./ml. by weighing 40.0 mg. homatropine hydrobromide.

Scopolamine Hydrobromide Standard Solution—Similarly, prepare a final concentration of 0.25 mg./ml. by weighing 25.0 mg. scopolamine hydrobromide.

PROCEDURES

Atropine Sulfate Tablets—Place 1 tablet, or its equivalent from a composite of 20 tablets, in 5 ml. buffer in a 30-ml. separator and add exactly 1.0 ml. homatropine standard solution. Extract with 10 ml. methylene chloride, passing the separated organic layer through 2 g. anhydrous sodium sulfate supported by a small pledget of glass wool in a funnel. Evaporate the methylene chloride at reduced pressure to about 0.3 ml. Inject an appropriate volume, about 1 μ l., into the chromatographic system. Perform the assay in duplicate. Repeat the procedure, pipeting duplicate 1.0-, 2.0-, 3.0-, and 4.0-ml. aliquots of atropine standard solution in place of the tablets.

Measure the height, H , of the atropine and homatropine peaks in each chromatogram and calculate $R = H \text{ atropine} / H \text{ homatropine}$. Plot the value of R obtained from the standards *versus* amount of standard atropine sulfate added. Determine the amount of atropine sulfate in the sample preparation directly from the graph.

Atropine Sulfate Injection—Proceed as directed under tablets, substituting 1.0 ml. or the measured contents of a single-dose container of the injection for the tablets.

Atropine Sulfate Ophthalmic Solution—Pipet 1.0- or 2.0-ml. aliquots of the preparation into duplicate 50-ml. volumetric flasks and make to volume with distilled water so that the final concentration of atropine sulfate is 200–800 mcg./ml. Pipet 1.0 ml. of the sample preparation in place of the tablet, and proceed as directed in the assay for atropine sulfate tablets. Multiply the amount of atropine sulfate in the sample preparation by the dilution factor.

Scopolamine Hydrobromide Tablets—Place 1 tablet, or its equivalent from a 20-tablet composite, in 5 ml. buffer in a 30-ml. separator and add exactly 1.0 ml. atropine sulfate standard solution. Extract with 10 ml. methylene chloride, filtering the organic layer through 2 g. anhydrous sodium sulfate supported by a small pledget of glass wool in a funnel. Evaporate the solution under reduced pressure to about 0.3 ml. Inject an appropriate quantity, about 1 μ l., into the chromatographic system. Perform the assay in duplicate. Repeat the procedure, substituting duplicate 1.0-, 2.0-, and 3.0-ml. aliquots of scopolamine hydrobromide standard solution for the tablet.

Measure the peak heights, H , of atropine and scopolamine in each chromatogram, and calculate the ratio $R = H \text{ scopolamine} / H \text{ atropine}$. Plot the ratios of the standards *versus* the amount of scopolamine hydrobromide added. Read the amount of scopolamine hydrobromide in the tablet or sample preparation from the calibration graph.

Scopolamine Hydrobromide Injection—Proceed as directed in the assay for the tablets, substituting 1.0 ml. or the measured contents of a single-dose container of the injection for the tablet.

GAS CHROMATOGRAPHY

Analyses should be performed using 0.6–1.2-m. glass columns, 4 mm. i.d., packed with 3% w/w methylphenylsilicone oil² on 80/100- or 100/120-mesh silanized, acid-washed, flux-calcined diatomite. Flame-ionization detectors are used. Helium carrier gas is used at a flow of about 60 ml./min. The temperature of the injection port is not more than 25° above that of the column; on-column injection is preferred. Column temperature and flow may

be adjusted to permit rapid (5–10 min.) and optimum analysis, about 210° for an 0.6-m. column or 225° for the 1.2-m. column.

Low-polarity methylphenylsilicone² is coated on silanized, acid-washed, flux-calcined diatomite. A special curing sequence has been found to increase inertness and efficiency: maintain the column at 250° for 1 hr. with helium flowing to remove oxygen and solvents, stop the flow of helium and heat at about 340° for 4 hr., lower temperature to 250°, and condition with the helium flowing until stable. A suitable initial test for support inertness, which is valuable with any low-polarity liquid phase, is the delivery of a single symmetric peak for injected cholesterol with no evidence of decomposition. The alkaloid peaks should be symmetric with little tailing.

PROTOCOL

The previously discussed details of methods and materials were supplied³ to the collaborators along with samples of commercial dosage forms. The stated objective of the study was to evaluate these gas chromatographic methods for use in USP XVIII monographs on atropine sulfate tablets, injection, and ophthalmic solution, and on scopolamine hydrobromide tablets and injection.

Separate report sheets for each alkaloid were supplied. These requested, in addition to assay results, the identities of the instruments, support material, and supplier. Chromatographic data requested were column parameters, retention times, occurrence of peaks in reagent blanks, resolution factors (19), and efficiencies (20). The variance of an individual drug-standard ratio was to be reported for eight injections of a single sample. Procedural variance was to be estimated by 6–8-fold assay of a single bottle of an injection or of a tablet composite.

The following paragraphs were included in the protocol by way of explanation to the collaborators.

Both atropine and scopolamine are available in multiple strengths for each of the official items (tablets, injection, and solution). These procedures were prepared with this in mind and feature the use of a standard curve hinged on a single amount of internal standard. This course was chosen rather than manipulating all sample preparations to a single specified concentration,⁴ because a calibration curve must be prepared in the process of approving a column for use in a single-point assay. Such a single-point approach requires a linear standard curve passing exactly through zero, an unnecessarily strict and often unattainable requirement for some drugs.

The isolation scheme is the simplest possible. Basic phosphate buffer is added so that the pH of the aqueous phase is 9 and is used instead of alkali to minimize ester cleavage. Homatropine was chosen as the "extracted" internal standard for atropine preparations for several reasons. It differs from atropine only in a methylene group and the nature of substitution of the carbinol; thus, chromatographic and chemical characteristics are similar. Multiple extractions or complete recoveries along the way are rendered unnecessary, since the molecular ratio of standard to analyte is controlled from the first step of the assay. Because of the close chemical similarities, minor alkaline ester cleavage or amine degradation also is controlled. Similarly, atropine is chosen as the standard for scopolamine. Both standards are or will be readily available. Heat and air during evaporation should be avoided.

Belladonna alkaloids are polar compounds, and the particular difficulties associated with the GLC of amines are well known. Improperly or partially cured and conditioned columns often cause extensive tailing of such compounds. An additional problem can be partial, on-column dehydration (13, 15) of atropine and scopolamine. Although the preparation of less polar derivatives may allow successful chromatography in poorer systems, the additional steps and problems are appreciable. Modern phases, supports, and column treatments have extended greatly the range of molecules that can be chromatographed directly, without prior formation of less polar derivatives. The authors had successfully determined belladonna alkaloids previously and found no reason for including derivatization in the assays. The key to this assay is in the selection of the column.

² OV-17. This oil contains approximately equal proportions of methyl and phenyl radicals. Other proportions are, or are becoming, available. Substitution is permitted but only if the chromatographic parameters discussed herein are met.

³ During the summer of 1969 with all responses completed by midfall.

⁴ USP XVIII since has specified a single-sample concentration but retains the calibration curve.

^aDiatoport S support; the others used OV-17 on Gas-Chrom Q. ^bOV-1 on Chromosorb WHP.

It was recognized that some collaborators would prefer purchasing a prepared packing. The Drug Standards Laboratory (DSL) arranged for a lot,^b tested by DSL, to be reserved by Applied Science Laboratories, State College, Pa. The collaborators were advised that after packing the column, the described curing and conditioning were necessary.

RESULTS AND DISCUSSION

Each assay value in Table I is the average of that collaborator's individual values (as given in the second column), whether he reported duplicate or 10-fold determinations. In this way, each collaborator's result is not allowed to obscure interlaboratory variation.

Accuracy—The average assay values given in Table I are compared in Table II to the manufacturer's in-house extraction-titrimetry values determined at time of pass. The assay results by the GLC method exhibited less deviation from declared contents than the in-house extraction-titrimetry methods. On the average, the GLC values appeared to run about 0.5% lower. However, this GLC method does not measure decomposition products and should yield more realistic values.

Reference standards for each drug will now be available. What effect this standardization would have on the interlaboratory variation or on the actual assay values cannot be predicted, although some reduction in interlaboratory variation may be anticipated. With regard to assay values, results from Laboratory A, for example, averaged 3.2% below results from other laboratories, suggesting some bias in procedure, very likely related to the standards used. Laboratory H, which used a programmed temperature run, reported assay values approximately 5% lower than other laboratories. No other systematic error was apparent.

Overall, the GLC methods given here must be judged as accurate and suitable for the official USP assay methods in light of the following features.

Reliability—The data were evaluated grossly in the following manner. A mean, standard deviation, and coefficient of variation were generated for each dosage form. In four of six cases, the magnitude of the standard deviation was similar; since chromatographic properties for the two drug standard situations were essentially similar, it appears that all the data in Table I may be pooled. An average, $\bar{c}\bar{v}$, of the nine coefficients of variation was obtained. The deviation of the individual assay values from the mean, \bar{x} , for that dosage form was considered; if $x - \bar{x} \geq 3(\bar{c}\bar{v})(\bar{x})$, with \bar{x} calculated without rejection, then the assay value was rejected, with the additional limitation that only one value from any column could be rejected. Only the two values in brackets out of the 52 values in Table I were rejected. This course was chosen to allow conservative estimation of reliability.

A new average of the nine recalculated coefficients of variation was then calculated to be 3.4%. This value is one estimate of the overall reliability of the methods and is composed of both intralaboratory and interlaboratory variations, as well as of significant deviations from the protocol. True reliability, of course, is a

Table II—Comparison of Assay Values

Dosage Form	Manufacturer	USP Collaborative
Atropine Sulfate Tablets		
0.4 mg.	94.0%	100.0%
0.3 mg.	95.0	98.4
0.6 mg.	97.3	99.2

0.4 mg./ml.	103.6	99.0
Scopolamine HBr Injection		
0.43 mg./ml.	101.0	98.4
0.32 mg./ml.	100.4	98.0
Average	99.7	99.2

composite of this variation with accuracy, specificity, sensitivity, and precision. The contribution of each factor to the overall reliability will be discussed.

Specificity and Sensitivity—The inherent specificity and sensitivity of gas chromatography, combined here with an extracted internal standard, are utilized by these methods. In addition to serving as the monograph assay, the comparison of the sample chromatogram to that of the reference standard serves also as a strong identity test. Degradation products do not interfere. Tropic acid is not extracted in the first step, and tropine and scopine elute prior to the standards and drugs. No collaborator reported evidence of decomposition products.

The methods are directly applicable to available strengths of dosage forms covered by the monographs identified in the object of the collaborative study. Indeed, only a fraction of a percent of the available sample is actually analyzed. Use of this sensitivity in proof of content uniformity of tablets is obvious; however, this application depends also on intralaboratory chromatographic precision.

Precision—Collaborators supplied data for both the reproducibility of the ratio obtained upon multiple injection of a single drug—

Table III—Precision Data Presented as Coefficients of Variation

^a Programmed run, 135–210° at 10°/min.

standard mixture and of the ratio obtained from multiple assay of a single commercial item. Their results are found in Table III. The directions are for peak height ratios; however, two laboratories used area-measuring devices.

Laboratory H erroneously did a programmed 10° per minute run, and the degraded precision is, therefore, understandable. Laboratories B and F generated a variable in obtaining sample preparations which F did not carry over from atropine to scopolamine. Otherwise, the assay manipulations appear to contribute little to (im)precision which, therefore, must be largely dependent on chromatographic precision. An approximation of the difference in the two sets of precision data is about 0.5% in coefficient of variation. Indeed, any significant departure from this level should signal a possible procedural error to the analyst.

Without rejecting any value, the average of coefficients of variation in *R* is 1.3% for atropine and 1.4% for scopolamine, with a further estimate of about 1.9% for dosage form assay, which is moderately good for a GLC method. Several values can be accounted for by graphical error alone. This is completely satisfactory (21) for use in content uniformity testing.

The collaborative procedures construct calibration curves for the alkaloids with four points for atropine and three points for scopolamine, based on the range of anticipated concentration of sample preparations from the range of dose strengths. Nonlinear absorption, tailing, and relative graphical error could be expected to cause somewhat greater imprecision in the lower values on the calibration curve than in the higher values. These factors would similarly affect precisions for the absolute sizes of samples injected. A plot of the percent coefficient of variation against the value of *R* for each alkaloid, as given in Table III, failed to support any such correlation between precision and magnitude of *R*. Therefore, the precision discussions in this report must pool all values irrespective of magnitude or the identity of the drugs. Variations in sample size injected and magnitude of *R* conversely cannot be cited as causes of interlaboratory variations. This also is consistent with the judgment that reference standards are the only further vehicle needed to control interlaboratory variation in these assays.

Dosage Forms—The 0.4-mg. atropine sulfate tablets were compressed tablets; the other two were hypodermic tablets. The results show the method to be equally applicable. Although the protocol gave a separate procedure, scopolamine hydrobromide tablets were not issued to collaborators. The atropine sulfate ophthalmic solutions available are sufficiently concentrated to require an initial 25- or 50-fold dilution to enter the assay concentration range. Thus, samples were not issued to collaborators. Results in this laboratory have shown that the procedure works as well for the nonofficial ophthalmic solutions containing cellulose derivatives.

General Observations—Intralaboratory precision was found to be primarily a matter of chromatographic reproducibility. It would appear worthwhile to prepare a packed column giving good performance, particularly where use is anticipated in content uniformity testing. The collaborators' data are of some guidance here.

The chromatographic parameters reported by the collaborators are given in Table IV. A minimum resolution of *R*, not less than 3.0, is one reasonable standard which an analyst might apply to a column. Laboratory I reported much lower resolution (Table III) and experienced poor precision; both results may reflect the use of a different (OV-1) phase. The authors' initial studies (18) leading to the choice of packing would support this conclusion. Similarly, efficiencies of the order of 1000 plates for any peak appear suitable,

but much less efficiency can be tolerated, as shown by Laboratory E using a 0.6-m. column. Some of the reported efficiencies appear in error for the claimed column lengths. Most collaborators reported linear standard curves with the intercept near or at the origin.

However, perhaps the parameter most predictive of precision would be tailing. The authors found that tailing factors⁶ larger than 1.6 correlated with diminished precision and, for this reason, the protocol sent to collaborators stated that peaks should be symmetric with little tailing.

Laboratory H erroneously used a programmed temperature run. This commonly degrades both precision and accuracy,⁷ and the authors are strongly against this unnecessary operation. Speed also is lost.

The collaborators offered several comments on procedure. Laboratory H found the concentrates following evaporation were stable for 1 or 2 days. The authors made similar observations but do not recommend unnecessary sample storage. Laboratory H also reported that initial experiments indicated that evaporation at 60° in an airstream was satisfactory.

Laboratory A reported an extraneous peak in the homatropine and scopolamine standards; the homatropine appeared to contain 1.5% atropine. Such problems are best avoided by reference standards.

No collaborator reported evidence of decomposition, probably because the alkaloids were injected as free bases at moderate temperatures, with injection block temperatures only slightly greater than on-column temperatures. There have been reports (15, 22) of additional injection-site decomposition, possibly related to the glass wool at the top of the column or the injection of salts. The authors used commercial silanized glass wool and did not observe decomposition.

SUMMARY

The gas chromatographic assay methods for atropine sulfate tablets, injection, and ophthalmic solution and for scopolamine hydrobromide tablets and injection, now covered by USP XVIII monographs, have been studied in a nine-laboratory, collaborative study. The drug is extracted once from alkaline buffer along with added internal standard, homatropine for atropine and atropine for scopolamine. The extract is concentrated and injected into a defined system without further treatment. The methods are accurate, reliable, sensitive, highly specific, rapid, and reasonably precise. The methods are suited to content uniformity testing and serve as strong identity tests for all these monographs. Some interlaboratory variations suggest the need for alkaloid reference standards keyed to these methods to control systematic error. No changes in the procedures were found necessary.

Determination of Total Iron in Hematinics by Atomic Absorption Spectrophotometry

HARRIS I. TARLIN and MARTIN BATCHELDER

Abstract □ The total iron content of six hematinic preparations was determined rapidly, precisely, and accurately by atomic absorption spectrophotometry. Hematinics comprising iron-carbohydrate complexes required ashing prior to assaying by atomic absorption spectrophotometry while those with an iron chelate or simple salt structure may be determined directly by atomic absorption spectrophotometry. A statistical evaluation of the data indicated that the atomic absorption spectrophotometry method was equivalent to the official colorimetric and volumetric methods and to a classical gravimetric procedure.

Keyphrases □ Iron in dosage forms—analysis □ Atomic absorption spectroscopy—analysis □ Colorimetric analysis—spectrophotometer □ Titration—iron analysis □ Gravimetric analysis—iron

Hematinic preparations generally fall into three structural categories: iron-carbohydrate complexes, iron chelates, and iron salts. Preparations consisting of iron-carbohydrate complexes are usually assayed for total iron by a lengthy colorimetric (1) or gravimetric procedure.¹ The usual USP (2) or NF (3) procedure for determining the total iron content of iron chelates

and iron salts involves a sodium thiosulfate or ceric sulfate titration. Extensive studies (4, 5) indicate that atomic absorption spectrophotometry (AAS) offers a technique for assaying iron which is relatively free from interfering ions. To date, no studies have been reported in the literature concerning the assay of total iron in hematinics by AAS.

EXPERIMENTAL

Instruments—A Perkin-Elmer model 303 double-beam spectrophotometer, equipped with an iron hollow cathode lamp and single-slot burner head, was used for all atomic absorption measurements. The instrument was optimized with a 10-p.p.m. standard iron solution. A sensitivity of 0.18 mcg./ml. for 1% absorption was achieved. Instrument parameters appear in Table I. All colorimetric measurements were carried out on a Perkin-Elmer model 202

double-beam UV-visible spectrophotometer using a 1-cm. Corex cell and a slit width of 25.

Reagents—Iron standard solution for atomic absorption spectroscopy was used.² All other reagents were ACS, USP, or NF grade. Distilled water was used for all solutions. Iron standard solutions used for calibrations were 7, 10, and 12 mcg. Fe/ml., respectively.

PROCEDURES

Colorimetric Method—The total iron content of the three iron–carbohydrate preparations was determined colorimetrically by the 2,2'-bipyridine method described in USP XVII (1). Calculation of the mg. Fe/ml. solution was according to the following equation:

$$100 \times \frac{A_u}{A_s} \times \frac{d}{W} = \text{mg. Fe/ml. solution} \quad (\text{Eq. 1})$$

where A is the absorbance of the sample, A_s is the absorbance of the standard; d is the density of the sample measured with a pycnometer at 20°, and W is the weight of the sample in grams.

Titration Method—Tablet and sustained-release capsule preparations were assayed for iron following the USP XVII (2) sodium thiosulfate titration procedure. For the hard gelatin capsule, the NF XII (3) ceric sulfate titration procedure was followed.

Gravimetric Method—Accurately weigh a portion of iron–carbohydrate solution equivalent to about 90 mg. of iron into a platinum crucible. Ash the sample with a Meker burner for 30 min., and dissolve the ash in a 400-ml. beaker by boiling with 75 ml. of 6 *N* HCl. Dilute with water to 150–200 ml. and make alkaline with NH₄OH. Acidify with nitric acid and again make alkaline with an excess of NH₄OH. Heat to 70–80° for approximately 1 min. and allow to cool and stand for 2 hr. Filter through Whatman No. 41-H filter paper and wash the precipitate thoroughly with 1% NH₄OH. Ash the filtered precipitate in a tared platinum dish and determine the weight of the ash. Calculate the mg. total Fe/ml. solution as follows:

$$WA \times \frac{699.4}{W} \times d = \text{mg. total Fe/ml. solution} \quad (\text{Eq. 2})$$

where WA is the weight of the ash in grams, d is the density of the sample measured with a pycnometer at 20°, and W is the weight of the sample in grams.

ATOMIC ABSORPTION WITH ASHING³

Iron–Carbohydrate Preparations—Accurately weigh a portion of solution equivalent to about 90 mg. of Fe into a platinum crucible

and ash for 30 min. over a Meker burner. Dissolve the ash in a 400-ml. beaker by boiling with 75 ml. of 6 *N* HCl. After the solution is cool, transfer to a 1-l. volumetric flask and dilute to the mark with water. Pipet a 6.0-ml. aliquot from the 1-l. volumetric flask into a 50-ml. volumetric flask and dilute to the mark with water. Aspirate the sample against a blank consisting of 100 ml. of 6 *N* HCl prepared according to the same dilution sequence as the sample. Calculate the mg. Fe/ml. solution as follows:

$$\text{mg. Fe/ml. solution} = \frac{(F_{AV})(A)(0.001)}{W/d \times 1/1000 \times 6/50} \quad (\text{Eq. 3})$$

where F_{AV} is the average mcg. Fe/ml./absorbance unit (determined from standards). F_{AV} was calculated as follows:

$$F \text{ (for a given standard)} = \frac{\text{concentration of standard, mcg. Fe/ml.}}{\text{absorbance}}$$

$$F_{AV} = \frac{\Sigma F}{\text{no. of standards measured}}$$

A = absorbance of the sample
 d = density of the sample measured with pycnometer at 20°

Tablet—Weigh and finely powder 20 tablets. Weigh a portion of powder equivalent to about 90 mg. of Fe into a platinum crucible. Follow the procedure used for iron–carbohydrate preparations in the *Atomic Absorption with Ashing* section starting with “and ash for 30 min.” up to “transfer to a 1-l. volumetric flask and dilute to the mark with water.” Filter a portion of the solution through Whatman No. 2 filter paper. Pipet 6.0 ml. of the filtrate into a 50-ml. volumetric flask, and dilute to the mark with water. After aspirating the sample, calculate the mg. Fe/tablet as follows:

$$\text{mg. Fe/tablet} = F_{AV} \times A \times \frac{50}{6} \times \frac{1000}{1000} \times \frac{\text{average tablet weight, g.}}{\text{sample weight, g.}} \quad (\text{Eq. 4})$$

Table III—Ratio of Variance

	Critical, 5%	Calculated Value
Colorimetric vs. gravimetric vs. AAS with ashing ^a	3.88	1.88
Colorimetric vs. gravimetric vs. AAS with ashing ^b	6.94	3.63
AAS direct vs. AAS with ashing ^c	7.71	27.07

^a Based on seven batches of iron–carbohydrate complex 1. ^b Based on three batches of iron–carbohydrate complex 2. ^c Based on five batches of iron–carbohydrate complex 1. These results showed significant difference at the 0.01 level.

² Fisher Scientific.
³ In all the following AAS assays, the sample was aspirated against a blank consisting of the appropriate volume of 6 *N* HCl which was subjected to the same dilution sequence as the sample.

Table IV—Analysis of Tablet and Capsules

Type of Sample	Amount of Fe Declared	Titration	mg. Fe/Tablet or Capsule ^a	
			Atomic Absorption— Direct	Ashed
Tablet	40 mg./tablet	39.25	40.48	38.95
Capsule (hard gelatin)	37.52 mg./capsule	39.48	40.54	38.95
Capsule (sustained release)	50 mg./capsule	50.11	52.23	51.71
SD		±2.10 ^b	±1.79 ^b	

^a Based on a minimum of two assays. ^b Based on four determination of the sustained-release capsule.

where F_{AV} is the average mcg. Fe/ml./absorbance unit, and A is the absorbance of the sample.

Hard Gelatin Capsule and Sustained-Release Capsule—Weigh the contents of 20 capsules, mix thoroughly, and weigh a portion equivalent to about 90 mg. of Fe into a platinum crucible. Follow the procedure used for iron-carbohydrate preparations in the *Atomic Absorption with Ashing* section starting with "and ash for 30 min." up to "transfer to a 1-l. volumetric flask and dilute to the mark with water." Filter a portion of the solution through Whatman No. 2 filter paper, pipet 6.0 ml. of the filtrate into a 50-ml. volumetric flask, dilute to the mark with water, and aspirate. Calculate the mg. Fe/capsule as follows:

$$\text{mg. Fe/capsule} = F_{AV} \times A \times \frac{50}{6} \times \frac{1000}{1000} \times \frac{\text{average net fill weight, g.}}{\text{sample weight, g.}} \quad (\text{Eq. 5})$$

where F_{AV} is the average mcg. Fe/ml./absorbance unit, and A is the absorbance of the sample.

ATOMIC ABSORPTION BY DIRECT DILUTION

Iron-Carbohydrate Preparations—Accurately weigh a portion of solution equivalent to about 90 mg. of Fe into a tared beaker. Quantitatively transfer the solution to a 1-l. volumetric flask with 30 ml. of water, add 100 ml. of 6 N HCl, and dilute to the mark with water. Pipet a 6.0-ml. aliquot into a 50-ml. volumetric flask, dilute to the mark with water, and aspirate. Calculate the mg. Fe/ml. as described in the section entitled *Atomic Absorption with Ashing: Iron-Carbohydrate Preparation*.

Tablet, Hard Capsule, and Sustained-Release Capsule—Weigh 20 tablets or the contents of 20 capsules. Weigh a portion of tablet powder or capsule content equivalent to about 90 mg. of Fe and transfer to a 1-l. volumetric flask with 30 ml. of water. Add 100 ml. of 6 N HCl,⁴ and dilute to the mark with water. Filter a portion of the solution through Whatman No. 2 filter paper, pipet 6.0 ml. of filtrate into a 50-ml. volumetric flask, and dilute to the mark with water. Aspirate the sample against a blank. Calculate the mg. Fe/tablet or mg. Fe/capsule as described in the section entitled *Atomic Absorption with Ashing: Tablet or Atomic Absorption with Ashing: Hard Gelatin Capsule and Sustained-Release Capsule*.

In the case of individual sustained-release capsules, the following procedure is used. Add the contents of one capsule to a 500-ml. volumetric flask. Add 50 ml. of 6 N HCl and 100 ml. of water, heat until solution is effected, and dilute to the mark with water. Filter a portion of the solution through Whatman No. 2 filter paper, pipet 6.0 ml. of the filtrate into a 50-ml. volumetric flask, and dilute to the mark with water. Aspirate the sample against a blank and calculate the mg. Fe/capsule as follows:

$$\text{mg. Fe/capsule} = F_{AV} \times A \times \frac{500}{1000} \times \frac{50}{6} \quad (\text{Eq. 6})$$

⁴ It was necessary to heat the contents of the sustained-release capsule to effect solution after adding 6 N HCl. The insoluble material observed was no doubt due to the coating excipients commonly used in sustained-release preparations.

Table V—Recovery Studies

Type of Sample	Amount of Fe ^a Added, mcg.	% Fe Recovered ^b by Atomic Absorption
Iron-carbohydrate complex	100	98 ^c
Capsule	100	101.6 ^d
Tablet	100	100.4 ^d

^a In all cases, the final concentration of the added iron was 2 mcg./ml. ^b Average recovery for two trials. ^c Ashed before analysis. ^d Assayed directly without ashing.

where F_{AV} is the average mcg. Fe/ml./absorbance unit, and A is the absorbance of the sample.

Recovery Study—Known amounts of iron were added to each of the three dosage forms studied, and the iron content was determined by AAS.

RESULTS AND DISCUSSION

The assay results for the three iron-carbohydrate preparations are summarized in Table II. These results show that there is a significant difference between iron-carbohydrate preparations assayed directly by AAS and those ashed prior to assay by AAS. Although the standard deviation of the AAS ashed method is greater than the colorimetric or gravimetric method, the analysis of variance shown in Table III indicates that there is no significant difference between the colorimetric, gravimetric, and AAS with ashing method. The assay results summarized in Table IV indicate that the tablet and capsules studied may be analyzed directly for iron by AAS. Table V summarizes data from the recovery study.

It is recommended that an initial study of a hematinic preparation should consist of an ashed and a direct AAS assay procedure. This generally will give a measure of interferences caused by organic molecules that complex or chelate the iron or excipients which may refract or absorb light and thus interfere with the assay.

ACKNOWLEDGMENTS AND ADDRESSES

Received February 16, 1970, from the *Analytical Laboratory, Astra Pharmaceutical Products, Inc., Worcester, MA 01606*
Accepted for publication April 1, 1970.

The authors express their appreciation to William Webber, Dr. S. G. Davis, and Sheila Tarlin for reviewing this manuscript and to Frances Edgeworth and John Andronic for assisting with the colorimetric and gravimetric assay procedures.

Assay of Chloramphenicol and Its Esters in Formulations

M. S. KARAWYA* and M. G. GHOURAB

Abstract □ A method for the estimation of chloramphenicol and its esters in some pharmaceutical preparations is described. The method is based on measuring the violet color produced by the interaction of chloramphenicol with hydroxylamine and ferric chloride in an alcoholic medium.

Keyphrases □ Chloramphenicol, esters in dosage forms—analysis □ Colorimetric analysis—spectrophotometer □ Hydroxylamine HCl, ferric chloride—color formation, chloramphenicol

The estimation of chloramphenicol and its esters has been, and is still, the subject of much investigation. The need for further investigation is evidenced by the fact that most of the methods reported for the estimation of chloramphenicol are subject to difficulties during their application. These difficulties may be attributed to the unfavorable solubility of chloramphenicol or its derivatives in the solvent of the experiment, as in case of titrimetric (1) and polarographic methods (2). Most color reagents used in colorimetric assays (3–7) may interact also with the decomposition products of chloramphenicol, thus giving erroneous results. These decomposition products may also interfere in spectrophotometric methods (8). Aihara *et al.* (4) proposed a method based on measuring the color developed from the action of ferric chloride on the hydroxamic acid which is produced by the interaction of chloramphenicol and hydroxylamine in aqueous alkaline medium. The method, however, is applicable only to free chloramphenicol and not to its water-insoluble esters.

In the present investigation, the authors used the hydroxylamine reaction in establishing another colorimetric method suitable for estimating chloramphenicol and its esters in various pharmaceutical forms.

EXPERIMENTAL

Reagents—The following were used: (a) authentic samples of chloramphenicol, chloramphenicol palmitate, chloramphenicol stearate, and chloramphenicol succinate; (b) standard test solution of chloramphenicol or its esters: a 0.2% solution of chloramphenicol or any of the mentioned derivatives was prepared by dissolving 100 mg. of the sample in absolute ethanol and adjusting to 50 ml. with the same solvent; (c) ethanolic hydroxylamine hydrochloride reagent: a saturated solution of hydroxylamine hydrochloride in absolute ethanol; (d) ethanolic sodium hydroxide solution: a saturated solution of sodium hydroxide in absolute ethanol; (e) ethanolic hydrochloric acid: 20 ml. of hydrochloric acid (35% w/v) completed to 100 ml. with absolute ethanol; (f) ferric chloride solution: 1% w/v in distilled water; and (g) ethanolic succinic acid solution: 91.3 mg. of succinic acid dissolved in absolute ethanol and adjusted to 50 ml. with the same solvent.

Analytical grade reagents were used whenever possible.

In a spectrophotometric study of the violet color resulting from the action of hydroxylamine hydrochloride and ferric chloride on chloramphenicol, a Prolabo spectrophotometer was used. The optimum wavelength for the measurement was found to be 505 mμ.

Procedure—Pipet a volume of the ethanolic solution of chloramphenicol or its esters, equivalent to 1–5 mg., into a small conical

flask. (In the case of free chloramphenicol, add 1 ml. of succinic acid solution.) Add 1 ml. of hydroxylamine hydrochloride solution to the solution in the flask, and then add 1 ml. of sodium hydroxide solution. Complete to 5 ml. with absolute ethanol and heat on a water bath at 85–95° for 5 min. Transfer the flask to a refrigerator freezer and allow to stand for 15 min. Transfer the contents of the flask quantitatively to a 10-ml. measuring tube with the aid of absolute ethanol (previously cooled to the same temperature as the mixture) and adjust the volume to approximately 7.5 ml. Add to the mixture, in the following succession, 1 ml. of distilled water (cooled as described), 1 ml. of 20% hydrochloric acid in absolute ethanol, and 0.5 ml. of ferric chloride solution; mix well. Measure the violet color after 2–5 min. in a 1-cm. cell at 505 mμ against a blank made simultaneously, omitting the addition of hydroxylamine reagent. The results are deduced from absorbance-concentration curves of chloramphenicol esters according to the sample analyzed. In the case of the chloramphenicol base, the results are deduced by comparing with standard preparations containing the same amount of succinic acid treated simultaneously.

Precision of the Method—Absorbance *versus* concentration of chloramphenicol palmitate was measured and the deviation was 1.5%.

Mechanism of Reaction—It has been suggested (4) that hydroxylamine reacts with the amide group of chloramphenicol to give a hydroxamic acid. The addition of ferric ion to the hydroxamic acid solution produces a color (9–11) which could be utilized in the quantitative measurement. Feigl *et al.* (12) suggested that a carboxylic acid cannot be converted into a hydroxamic acid by the action of hydroxylamine and sodium hydroxide, while its ester can be converted under the same conditions (Scheme I).

The hydroxamic acid formed gives a violet color with ferric chloride due to the formation of a water-soluble inner complex with ferric ion (Scheme II).

Scheme II

Accordingly, the esters of chloramphenicol would behave similarly.

Range—The color produced with chloramphenicol esters obeys Beer's law in the range of 300–500 mcg./ml. for the palmitate, 300–575 mcg./ml. for the stearate, and 300–485 mcg./ml. for the succinate.

Reproducibility—The reproducibility of the results is measured by applying the proposed method on solutions of known concentrations of chloramphenicol and its esters. The results are shown in Table I.

Application of the Method on Pharmaceutical Preparations—Extraction of Chloramphenicol and Its Derivatives—With a formulated preparation, it is necessary first to isolate chloramphenicol from the other accompanying ingredients. This can be accomplished by extracting the chloramphenicol or its derivatives by means of a suitable organic solvent as follows.

Chloramphenicol eye drops contain chloramphenicol, boric acid, borax, and phenyl mercuric nitrate. A volume equivalent to 50 mg. of chloramphenicol is mixed with an equal volume of phosphate buffer at pH 6.5 in a separating funnel and shaken with successive portions of chloroform (4 × 20 ml.) until complete

425	424.0	-0.2	475	471.0	-0.8	425	419.0	-1.4
450	440.5	-2.1	500	491.5	-1.7	450	436.5	-3.0

extraction is effected. The chloroform is evaporated, and the residue is dissolved in 50 ml. of ethanol.

Chloramphenicol ear drops contain chloramphenicol and propylene glycol. A volume equivalent to 50 mg. chloramphenicol is directly extracted with chloroform (4 × 15 ml.), and the procedure described for eye drops is followed.

Chloramphenicol suppositories contain chloramphenicol in a suppository base. A weight of the suppositories equivalent to 50 mg. chloramphenicol is shaken with hot water and allowed to cool; the base is extracted with petroleum ether (3 × 10 ml.). The chloramphenicol remaining in the liquid is then extracted with chloroform (4 × 15 ml.) and treated as previously described.

Chloramphenicol palmitate suspension contains chloramphenicol palmitate and suspending, coloring, and flavoring agents.

Chloramphenicol palmitate and streptomycin suspension contains chloramphenicol palmitate, streptomycin sulfate, and suspending, coloring, and flavoring agents.

Chloramphenicol stearate suspension contains chloramphenicol stearate and suspending, coloring, and flavoring agents.

A volume of each of these three suspensions equivalent to 50 mg. of chloramphenicol is treated as described for eye drops.

Chloramphenicol succinate injection contains chloramphenicol succinate with a diluent in a powder form. An equivalent to 50 mg. of chloramphenicol is dissolved in 50 ml. ethanol.

All of the formulations were supplied from freshly prepared batches. The resulting ethanolic solutions of chloramphenicol or its esters were then assayed as described under *Procedure*. The results obtained were compared with those of the Aihara *et al.* (4) method, the spectrophotometric method (1), and the α -naphthol method (6). They are compiled in Table II.

Estimation of Chloramphenicol in Degraded Samples—The estimation of chloramphenicol in degraded samples of palmitate suspension, eye drops, and ear drops was carried out to examine the potentialities of the proposed method.

Degradation of chloramphenicol was achieved by incubating the preparation at different temperatures for 2 months. The suspension darkened in color and acquired a caramel-like odor. The eye

drops and ear drops acquired a yellow color. The results were also compared with those of the spectrophotometric (1) and α -naphthol methods (6) and are represented in Table III.

RESULTS AND DISCUSSION

The ethanol used in the experiment was found advantageous due to its solubilizing effect and for increasing the sensitivity of the reaction. Minimum sensitivity is given by 70% ethanol and maximum sensitivity by 90% ethanol. The performance of the interaction in absolute ethanol is 5 times as sensitive as in ethanol 70%. However, the presence of about 15% water is necessary to dissolve the resulting sodium chloride and ferric hydroxamate. To choose the optimum pH for the hydrolysis step, many alkalies and buffer solutions were tried. When using boric acid buffer (pH 10), a faint green, fluorescent, unstable color was produced. The addition of 1 ml. of phosphate buffer (pH 8) together with 1 ml. of sodium hydroxide solution stabilized the final violet color, but the sensitivity of the reaction decreased. The use of higher concentrations of phosphate buffer inhibited the resulting color. Higher and lower concentrations of sodium hydroxide solution and hydroxylamine reagent were tried, and 1 ml. of saturated ethanolic solutions of each was found most convenient for the color formation. At concentrations below 300 mcg./ml. of chloramphenicol, another grade of color is formed and this does not obey Beer's law.

The interaction was favored by heating. The time and temperature of heating affected the sensitivity of the reaction; heating for 5 min. at a temperature of 85–95° was found most suitable for the completion of the reaction. In the acidification step, the optimum pH was found in the range of 2.1–2.3; this was obtained by employing 1 ml. of ethanolic 20% hydrochloric acid. Hydrochloric acid buffer and organic acids were found to lessen the sensitivity of the color.

The intensity of the color increases greatly by cooling and reaches its maximum at 0° and falls to a minimum at 15°. The time of cooling affects the intensity of the produced color; the maximum color is obtained after 15 min. of cooling.

It is of great importance to adhere to the specified amount and concentration of ferric chloride (0.5 ml. of 1% solution); lower

	55°			60°		
Palmitate suspension	82	110	140	76	130	^a
Eye drops	80	101	110	50	^a	^a
Ear drops	64	104	130	35	^a	^a

^a Discordant results.

concentrations gave incomplete reactions, and higher concentrations vitiated the violet color and changed it to yellow. When impure ferric chloride or an unfresh solution of it was employed, the addition of 2 drops of hydrogen peroxide (10 vol.) restored and potentiated the violet color. However, excess hydrogen peroxide was found unfavorable as the color changed to orange. The violet color, produced by the action of ferric chloride, develops within 2 min. and should be measured within 2–5 min. The color is not affected by light but is very sensitive to temperature.

Free chloramphenicol gave the same reaction as the salts, but the sensitivity was 5 times lower (≤ 15 mg.) and the results were not reproducible. The addition of a carboxylic acid, however, was found to increase the sensitivity of the reaction. Many acids were tried, and succinic acid gave the highest sensitivity (≤ 3 mg.). Although succinic acid alone gave negative reactions with the reagent, its presence affected the sensitivity of the reaction. Therefore, equal amounts of succinic acid were added to both test and standard preparations.

Due to the slight yellowish color produced by the action of sodium hydroxide on chloramphenicol or its esters, the blank experiment was done exactly like the experiment, omitting the addition of hydroxylamine hydrochloride reagent.

Data presented in Table I indicate the accuracy of the proposed method and the reproducibility of the results. The percentage of error with respect to the added and found amounts (Table I) ranges from ± 2.1 to 2.3 in chloramphenicol, from ± 1.7 to 1.9 in chloramphenicol palmitate, and from ± 2.7 to 3 in chloramphenicol succinate. The method was found applicable to different freshly formulated preparations, and the results (Table II) are comparable with those of the Aihara *et al.* method (4), the spectrophotometric method, and the α -naphthol method (6). The method of Aihara *et al.* (4), however, was not applicable to chloramphenicol esters. The comparison of the proposed method to the α -naphthol method and the spectrophotometric method on degraded samples of chloramphenicol and its palmitate produced varying results (Table III). The chloramphenicol analysis of the heated preparation decreased with an increase in temperature in the case of the proposed method and increased with the other two methods. This fact indicates that by means of the hydroxylamine method, chloramphenicol and its

esters can be determined, while some of the degradation products interfere in the results of the other two methods. In addition, the color produced by the α -naphthol method was not the same in all cases; it ranged from greenish to bluish.

Application of Absorbance Ratios to Analysis of Pharmaceuticals VI: Analysis of Binary Mixture Using a Reference Spectrum

M. J. CHO and M. PERNAROWSKI

Abstract □ Binary mixtures may be resolved by using absorbance ratio values and a reference spectrum for one component in the mixture. The method is based on the differences between the absorbance values for the mixture at any two wavelengths and the values for a solution containing only one component in the mixture. Three constants are required to resolve the mixture, but only one of these is an absorptivity value. Unlike the absorbance ratio method described in the literature, this method does not depend on the use of a wavelength at which the two components in the mixture have identical absorptivity values.

Keyphrases □ Binary mixture analysis—reference spectrum □ Caffeine-Na benzoate—spectral characteristics □ Absorbance ratios—analysis □ UV spectrophotometry—analysis, absorbance ratios

† The ratio of two absorbance values determined on the same solution at two different wavelengths is a constant. These ratios may be used to determine both the relative

and absolute concentrations of the components in a binary mixture (1). However, absolute concentrations (w/v) cannot be determined unless one of the two wavelengths chosen for the analysis represents an isoabsorptive point.

Isoabsorptive points (those wavelengths at which the two components in a mixture have identical absorptivity values) are difficult to isolate. The mathematical derivations in the next section show that absolute concentration values can be obtained by analyzing the mixture at wavelengths that do not represent isoabsorptive points, and that the number and nature of the constants in the derived equations are the same as those associated with the absorbance ratio method of analysis (1). This method of analysis is based, therefore, on the use of two absorbance ratio values (*Q* values), one absorptivity value, and the differences, at two wave-

concentrations gave incomplete reactions, and higher concentrations vitiated the violet color and changed it to yellow. When impure ferric chloride or an unfresh solution of it was employed, the addition of 2 drops of hydrogen peroxide (10 vol.) restored and potentiated the violet color. However, excess hydrogen peroxide was found unfavorable as the color changed to orange. The violet color, produced by the action of ferric chloride, develops within 2 min. and should be measured within 2–5 min. The color is not affected by light but is very sensitive to temperature.

Free chloramphenicol gave the same reaction as the salts, but the sensitivity was 5 times lower (≤ 15 mg.) and the results were not reproducible. The addition of a carboxylic acid, however, was found to increase the sensitivity of the reaction. Many acids were tried, and succinic acid gave the highest sensitivity (≤ 3 mg.). Although succinic acid alone gave negative reactions with the reagent, its presence affected the sensitivity of the reaction. Therefore, equal amounts of succinic acid were added to both test and standard preparations.

Due to the slight yellowish color produced by the action of sodium hydroxide on chloramphenicol or its esters, the blank experiment was done exactly like the experiment, omitting the addition of hydroxylamine hydrochloride reagent.

Data presented in Table I indicate the accuracy of the proposed method and the reproducibility of the results. The percentage of error with respect to the added and found amounts (Table I) ranges from ± 2.1 to 2.3 in chloramphenicol, from ± 1.7 to 1.9 in chloramphenicol palmitate, and from ± 2.7 to 3 in chloramphenicol succinate. The method was found applicable to different freshly formulated preparations, and the results (Table II) are comparable with those of the Aihara *et al.* method (4), the spectrophotometric method, and the α -naphthol method (6). The method of Aihara *et al.* (4), however, was not applicable to chloramphenicol esters. The comparison of the proposed method to the α -naphthol method and the spectrophotometric method on degraded samples of chloramphenicol and its palmitate produced varying results (Table III). The chloramphenicol analysis of the heated preparation decreased with an increase in temperature in the case of the proposed method and increased with the other two methods. This fact indicates that by means of the hydroxylamine method, chloramphenicol and its

esters can be determined, while some of the degradation products interfere in the results of the other two methods. In addition, the color produced by the α -naphthol method was not the same in all cases; it ranged from greenish to bluish.

Application of Absorbance Ratios to Analysis of Pharmaceuticals VI: Analysis of Binary Mixture Using a Reference Spectrum

M. J. CHO and M. PERNAROWSKI

Abstract □ Binary mixtures may be resolved by using absorbance ratio values and a reference spectrum for one component in the mixture. The method is based on the differences between the absorbance values for the mixture at any two wavelengths and the values for a solution containing only one component in the mixture. Three constants are required to resolve the mixture, but only one of these is an absorptivity value. Unlike the absorbance ratio method described in the literature, this method does not depend on the use of a wavelength at which the two components in the mixture have identical absorptivity values.

Keyphrases □ Binary mixture analysis—reference spectrum □ Caffeine-Na benzoate—spectral characteristics □ Absorbance ratios—analysis □ UV spectrophotometry—analysis, absorbance ratios

† The ratio of two absorbance values determined on the same solution at two different wavelengths is a constant. These ratios may be used to determine both the relative

and absolute concentrations of the components in a binary mixture (1). However, absolute concentrations (w/v) cannot be determined unless one of the two wavelengths chosen for the analysis represents an isoabsorptive point.

Isoabsorptive points (those wavelengths at which the two components in a mixture have identical absorptivity values) are difficult to isolate. The mathematical derivations in the next section show that absolute concentration values can be obtained by analyzing the mixture at wavelengths that do not represent isoabsorptive points, and that the number and nature of the constants in the derived equations are the same as those associated with the absorbance ratio method of analysis (1). This method of analysis is based, therefore, on the use of two absorbance ratio values (*Q* values), one absorptivity value, and the differences, at two wave-

lengths, between the absorbance values for a solution and the values for a reference solution containing one of the two components in the mixture.

THEORY

Hypothetical spectrophotometric curves for *X* and *Y* are shown in Fig. 1 and will be used to clarify the derivations. It is assumed that Beer's law is obeyed at all wavelengths and at all spectrophotometrically significant concentrations.

The total absorbance of a mixture containing *X* and *Y* (A_M) is equal to the sum of the absorbances due to *X* (A_X) and *Y* (A_Y). Therefore, at λ_4 ,

$$A_{M4} = a_6 C_X + a_1 C_Y \quad (\text{Eq. 1})$$

C_X and C_Y are the concentrations of *X* and *Y* in the mixture. Similarly, at λ_2 ,

$$A_{M2} = a_2 C_X + a_5 C_Y \quad (\text{Eq. 2})$$

The absorbance values, at λ_4 and λ_2 , for a reference solution containing only *X* are:

$$A_{X4} = a_6 C_{XR} \quad (\text{Eq. 3})$$

$$A_{X2} = a_2 C_{XR} \quad (\text{Eq. 4})$$

C_{XR} is the concentration of *X* in the reference solution.

Subtracting Eq. 3 from Eq. 1 and rearranging yield:

$$a_1 C_Y = D_4 - a_6 C_X + a_6 C_{XR} \quad (\text{Eq. 5})$$

D_4 is defined as $A_{M4} - A_{X4}$. Similarly, at λ_2 ,

$$a_5 C_Y = D_2 - a_2 C_X + a_2 C_{XR} \quad (\text{Eq. 6})$$

Figure 1—Hypothetical spectrophotometric curves for *X* (—) and *Y* (---).

Dividing Eq. 6 by Eq. 5 yields:

$$\frac{a_5 C_Y}{a_1 C_Y} = \frac{D_2 - a_2 C_X + a_2 C_{XR}}{D_4 - a_6 C_X + a_6 C_{XR}} \quad (\text{Eq. 7})$$

However, a_5/a_1 is equal to Q_Y , the absorbance ratio value for pure *Y*. Therefore:

$$Q_Y D_4 - a_6 Q_Y C_X + a_6 Q_Y C_{XR} = D_2 - a_2 C_X + a_2 C_{XR} \quad (\text{Eq. 8})$$

Dividing both sides of Eq. 8 by a_6 and substituting Q_X , the absorbance ratio value for pure *X*, for a_2/a_6 yield:

$$\frac{Q_Y D_4}{a_6} - Q_Y C_X + Q_Y C_{XR} = \frac{D_2}{a_6} - Q_X C_X + Q_X C_{XR} \quad (\text{Eq. 9})$$

After rearranging:

$$C_X = C_{XR} + \frac{D_2 - Q_Y D_4}{a_6(Q_X - Q_Y)} \quad (\text{Eq. 10})$$

Therefore, the absolute concentration of *X* (C_X) in a solution containing *X* and *Y* can be determined by measuring the differences, at two wavelengths, between the absorbance values for the mixture and the absorbance values for a reference solution containing only *X*. The constants, Q_X and Q_Y , are concentration independent and are easily determined by measuring absorbance values of solutions containing only *X* or *Y*.

The absorptivity value, a_6 , is determined by measuring absorbance values, at the specified wavelength, of accurately prepared solutions containing only *X*.

The method described herein was checked experimentally by determining the absolute concentrations of sodium benzoate in solutions containing sodium benzoate and caffeine.

EXPERIMENTAL

Apparatus—A UV spectrophotometer^{1,2} was used.

Reagents—Sodium benzoate USP and caffeine USP were used.

Spectral Characteristics of Sodium Benzoate and Caffeine—Caffeine and sodium benzoate (in water) absorb a maximum of radiant energy at 273 and 225 $m\mu$, respectively. An examination of the sodium benzoate spectrum indicated that the analysis of this substance in the presence of caffeine could be carried out by determining absorbance values at 225 $m\mu$ (the absorption maximum for sodium benzoate) and at 235 $m\mu$ (a region in which the spectra have slight inflection points).

Two series of solutions were prepared, one containing caffeine and the other containing sodium benzoate. The absorbance value of each solution was determined at 225 and 235 $m\mu$. The $Q:235:225$ values for caffeine and sodium benzoate were then calculated by dividing the absorbance at the first wavelength (235 $m\mu$) by that at the second wavelength (225 $m\mu$). Based on seven such solutions, the $Q:235:225$ value for caffeine was 0.721 ± 0.002 ; for sodium benzoate, it was 0.619 ± 0.003 .

A series of solutions was prepared to contain from 5.0 to 14.0 mg. of sodium benzoate per liter of solution. The absorptivity value for sodium benzoate at 225 $m\mu$ was found to be 59.2 ± 0.3 .

Procedure—Accurately dilute the solution containing caffeine and sodium benzoate. Determine absorbance values at 225 and 235 $m\mu$.

Prepare a reference solution, by dilution, to contain a known quantity of sodium benzoate. (The reference solution used in these analyses contained 14 mg. of sodium benzoate per liter.) Determine absorbance values at 225 and 235 $m\mu$.

Subtract the values for the reference solution from the values for the mixture. Substitute these D_2 and D_4 values into the numerical form of Eq. 10:

$$C_X (\text{g./l.}) = 0.014 + \frac{D_2 - 0.721 D_4}{59.2 (0.619 - 0.721)} \quad (\text{Eq. 11})$$

Calculate the concentration of sodium benzoate in the solution.

¹ Beckman model DU-2.

² Bausch & Lomb Spectronic 505.

Table 1—Analysis of Sodium Benzoate in Sodium Benzoate-Caffeine Mixtures

mg. Drug/l.		mg. Sodium Benzoate/l. Recovered
Sodium Benzoate	Caffeine	
4.5	7.5	4.54
5.0	7.0	5.06
5.0	5.0	5.02
6.0	6.0	6.05
6.5	5.5	6.32
7.0	5.0	7.11

Sixteen solutions were prepared to contain from 4.5 to 7.5 mg. of sodium benzoate per liter. Caffeine and sodium benzoate injection USP usually contains equal quantities of caffeine and sodium benzoate. However, to test the accuracy of the method, the solutions contained from three parts of sodium benzoate for every five parts of caffeine to five parts of sodium benzoate for every three parts of caffeine. To check the accuracy of the method further, a second set of six solutions was prepared and analyzed. The results for this set are shown in Table 1. The percent recovery for the 22 solutions was 100.1%; the standard deviation value was $\pm 2.9\%$.

DISCUSSION

The caffeine-sodium benzoate mixture can be resolved by using simultaneous equations (2) or by the absorbance ratio method of analysis (1). If the former method is used, four absorptivity values must be determined. If the latter method is used, one absorptivity value and two absorbance ratio values must be determined. Absorbance ratio values are concentration independent; for this reason, the absorbance ratio method of analysis yields accurate results more quickly than does the method utilizing simultaneous equations. However, the absorbance ratio method of analysis yields absolute concentrations only if one of the two wavelengths chosen for the analysis is an isoabsorptive point. Such points are difficult to isolate, and the absorptivity values at such wavelengths cannot be determined with accuracy.

The method of analysis described here utilizes three constants. The absorbance ratio values are the same as those used in the absorbance ratio method of analysis. The absorptivity value, on the other hand, is determined at a wavelength at which one of the components absorbs a maximum of radiant energy. It is, therefore, not necessary to isolate an isoabsorptive point to calculate the absolute concentration of a drug in a mixture.

The method does require the use of a reference solution. However solutions must be prepared to determine constants, and one of these can be designated as the reference solution. This solution must, however, contain a quality of drug which will yield absorbance values somewhat greater than those observed for the mixture. If the difference between the absorbance values at the two specified wavelengths is small, the error in the analysis will be greater than necessary.

The results reported here indicate that the method is capable of yielding reasonably accurate results. The maximum percent recovery observed for the 22 solutions was 105.8%. The minimum percent recovery was 95.6%. A reexamination of these two solutions indicated that slight changes in absorbance readings can result in fairly substantial changes in percent recovery. This implies that each absorbance value should be determined twice (and the mean value used in the calculation) and that a stable, single-beam spectrophotometer should be used to measure absorbance values. Since the solutions were read in sequence, the values could not be rejected. Even so, the overall percent recovery for the 22 solutions was 100.1%. A standard deviation value of $\pm 2.9\%$ is acceptable if the speed and ease of analysis are taken into consideration.

The caffeine concentration in the solutions can be determined by using an equation similar to that given for sodium benzoate. Both equations, therefore, are based on absorbance differences. However, the equations may be derived by summing absorbance values. If this is done, the form of Eq. 10 is the same except that the C_{XR} term becomes negative.

Absorbance ratio values are used in both this method of analysis and that previously published (1). The appropriate references (1, 3) should, therefore, be consulted for a full discussion of the advantages and limitations of the use of such ratios in analysis.

Lactose USP (Beadlets) and Dextrose (PAF 2011): Two New Agents for Direct Compression

N. L. HENDERSON and A. J. BRUNO

Abstract □ Lactose USP (beadlets) and dextrose (PAF 2011) have been evaluated and compared with two commonly used agents for direct compression—spray-dried lactose USP and anhydrous lactose USP—as to their relative physical properties and stability for tableting by direct compression. The compression characteristics of all four materials were defined with the aid of a rotary tablet machine instrumented with strain gauges. Compression and ejection forces were monitored continuously and correlated with tablet hardness, friability, weight variation, and disintegration times. It was concluded that the two new agents are generally superior to the other materials tested for use as fillers for direct compression. Both exhibited excellent flow and compressional characteristics. Neither agent represents an improvement over the older materials with regard to physical stability.

Keyphrases □ Lactose (beadlets), dextrose, evaluation—direct compression □ Dextrose, lactose beadlets—spray-dried, anhydrous lactose comparison □ Tablets, direct compression—lactose beadlets, dextrose, anhydrous, spray-dried lactose □ Physical properties, tablets—lactose beadlets, spray-dried, anhydrous lactose, dextrose

Most therapeutic agents lack the compression and flow characteristics required for tableting on a rotary tablet press and must be processed prior to the tableting operation. Classically, the techniques of granulation, either the wet method or the dry granulation method, have been used for this purpose. Each of these time-consuming procedures often necessitates the use of specialized equipment. Wet granulation is unsuitable for materials that are heat or solvent labile. In addition, the incorporation of active ingredients into granules often leads to decreased drug availability.

At present, one of the most promising alternatives to granulation techniques is direct compression. It is for this reason that the concept of compressing pharmaceuticals directly into tablets has received much attention in the past decade (1–8).

The process of direct compression, by definition, involves the blending of the active ingredient with a compressible, free-flowing agent for direct compression, along with required lubricants and disintegrating agents. Direct compression allows optimum utilization of production time. Since the active ingredient is not incorporated into a granule, tablet dissolution becomes more dependent on compression force and less subject to other, less controllable parameters.

The ideal agent for direct compression should be compressible, free-flowing, inert with respect to chemical and physical reactivity, and relatively inexpensive. To date, no single agent has been found that is suitable

for all direct compression formulas. If such an agent was available, it would surely gain rapid and widespread acceptance throughout the pharmaceutical industry.

Samples of two new agents for direct compression, *i.e.*, lactose USP (beadlets)¹ and dextrose–corn syrup solids,² hereafter termed dextrose (PAF 2011), were obtained for study. The first of these materials is a form of lactose USP monohydrate, spray-dried, which has been specially processed to form white, free-flowing “beads” having a very faint caramel-like odor similar to that of spray-dried lactose. Dextrose (PAF 2011) is produced by the controlled hydrolysis of starch and is composed of 95–96% dextrose combined with 4–5% higher saccharides. The result is a white, free-flowing, odorless material composed of aggregated, porous, crystalline beads. The two materials have been evaluated and compared with two agents commonly used for direct compression, namely, spray-dried lactose USP¹ and anhydrous lactose USP,³ as to their relative physical properties and stability with respect to tableting by direct compression.

Microcrystalline cellulose, a widely used agent for direct compression, was not included in this study for comparative purposes since it has been reviewed thoroughly in previous publications (3, 9).

EXPERIMENTAL

Materials—Lactose USP was employed as a control in physical and color stability tests. Lubrication of tablets was accomplished by the addition of 1% of either magnesium stearate USP or stearic acid USP. Starch USP was used as the disintegrating agent in samples used to determine disintegration times. Where the effect of amines on the tablets was to be determined, *D*-amphetamine sulfate USP or phenylephrine hydrochloride USP was incorporated in the formulations at a concentration of 10% by weight.

Test Methods and Equipment—Tablet Machines—The compression characteristics of all four materials for direct compression were defined with the aid of a Stokes RBB2 tablet machine instrumented to permit the simultaneous monitoring of tablet compression and ejection forces (10). The selection of this machine was based on the fact that it is routinely used in tablet production and the die-filling operation is dependent on the force of gravity and the flow properties of the material to be tableted. The press was fitted with standard concave punches 0.87 cm. (¹¹/₃₂ in.) in diameter and was set to operate at 1200 tablets/min.

¹ Foremost Dairies, Inc., San Francisco, Calif. In the case of the lactose USP (beadlets), only one lot of material was available for testing.

Anhydrous lactose USP	0.60	53–55 58–60	15–450
Dextrose (PAF 2011)	0.67	39–41 54–56	75–350
Lactose USP	0.70	62–64 70–72	5–175

^a Control angle of repose. ^b Angle of repose after exposure to 75% R.H. in open containers for 5 days.

The many samples of tablets required for evaluation of the physical and color stability of the various sugars were prepared with the aid of a Stokes Model F tablet machine using 1.27-cm. (0.5-in.) standard concave tooling.

Hardness—Tablet hardness was determined on a hardness tester⁴ which was modified to operate from a compressed air line. All values were expressed as the average of the values obtained for 10 individual tablets.

Friability—Friability was determined in a Roche Friabilator (11). Samples of 10 tablets were weighed, subjected to rotation for 20 min. at 25 r.p.m., and then reweighed after careful dusting. The percentage of tablet weight lost was then calculated. Tablets that capped were taken as 100% loss, and the number capped was recorded.

Disintegration Time—Disintegration times were determined using the standard USP apparatus both with and without disks (12). These data were reported as the average time required for 12 tablets to disintegrate.

Bulk Density—The bulk density of each sugar was determined according to the tap method of Butler and Ramsey (13).

Particle Size—Particle size was determined by sieve analysis. Sizing was accomplished in an End Shake⁵ sieve shaker using a series of 20- to 200-mesh stainless steel U. S. Standard sieves. The unit was operated for 15 min. The sample for each test was 100 g. The finite particle shape was determined by examination of each material under low power (100 \times) magnification.

Angle of Repose—The angle of repose for each substance was measured by a tilting box technique as previously reviewed by Train (14).

Color Stability Testing—Tests were carried out by exposing samples of 10 tablets, in open glass Petri dishes, to one of the following conditions: (a) heat storage at 56° for 10 days; (b) moisture storage at 75% R.H. for 30 days; (c) heat/moisture storage at 37°/75% R.H. for 10 days; or (d) light exposure to 600 foot candles (fc.) fluorescent illumination for 12 weeks (15).

Initial and Equilibrium Moisture Content—The initial moisture content of each material was determined by loss on drying in a vacuum oven after exposure for 16 hr. at 60° in open containers.

To determine the hygroscopicity of these agents for direct compression, tared samples of each were stored at various relative humidities in open containers in desiccators at 25° for a 7-day period. Samples were then weighed to determine the percentage of moisture picked up.

RESULTS AND DISCUSSION

Some of the physical properties of four sugars for direct compression are summarized in Table I. Data for lactose USP were also included for comparison.

The angle of repose of a powder is often regarded as providing a measure of the internal friction of the material. The determination of this angle, therefore, serves to quantify the relative degree of flowability of materials (16, 17). All of the agents for direct compression tested were found to have a low angle of repose, indicating excellent flow properties. It should be noted that, after exposure to 75% R.H. for 5 days in open containers, an increase in angle of

Figure 1—Histograms displaying particle-size distribution of four materials for direct compression. Key: A, lactose USP (beadlets); B, spray-dried lactose USP; C, anhydrous lactose USP; and D, dextrose (PAF 2011).

repose resulted. Dextrose (PAF 2011) exhibited the greatest decrease in flowability. This material was found to be considerably more hygroscopic than the lactose sugars (Table II).

Sieve analysis indicated a wide range of particle size for each sugar tested. In general, when a material has a narrow particle-size distribution, it will exhibit less tablet-to-tablet weight variation than a material with a wider distribution of particle sizes. Dextrose (PAF 2011) was found to have not only the most narrow particle-size distribution, but it also contained the smallest percentage of "fines" (Fig. 1).

Color Stability—Several references indicate that tablets prepared from lactose tend to discolor upon storage (18, 19). This phenomenon is accelerated by the presence of amines and/or certain lubricants, and it is dependent upon the temperature, humidity, and illumination under which the tablet is stored. The mechanism governing this process has been previously elucidated (18, 20).

A study was undertaken to determine the degree of discoloration produced in the five sugars (four agents for direct compression plus a lactose USP control) when stored in open containers under four testing conditions—heat, moisture, heat/moisture, and light—in the presence of lubricants and selected amines. Results of visual observation are summarized in Table III. Samples stored at 37° at 75% R.H. for 10 days exhibited no more color change than those stored at either 56° or 75% R.H.

There is no evidence that stearic acid USP produces any less discoloration than magnesium stearate USP under these conditions. Control samples, which had been stored in a cool, dark environment (in closed containers) for a 12-week period, showed the same degree of discoloration as the test samples. Unlubricated control samples showed no color change after a 12-week storage period in closed containers. This indicates that the lubricants alone are capable of causing discoloration.

It was found that the incorporation of amines, such as *d*-amphetamine sulfate USP or phenylephrine hydrochloride USP, in the formulations both accentuated and accelerated the degree of darkening produced under all test conditions. In the presence of amines, magnesium stearate USP showed a greater tendency than stearic acid USP toward producing discolored sugar tablets.

Of the four materials tested for direct compression, only anhydrous lactose USP was able to withstand adequately the effects

	Stearic acid	None	Slight	None

of high temperature, humidity, and exposure to light. These findings agree with those of Batuyios (21). Neither lactose USP (beadlets) nor dextrose (PAF 2011) represents a substantial improvement over spray-dried lactose USP with regard to overall physical and color stability.

Compression Characteristics—The compression characteristics of the four sugars for direct compression were defined with the aid of a rotary tablet machine instrumented with strain gauges. Compression and ejection forces were monitored continuously and correlated with the tablet parameters of hardness, friability, tablet-to-tablet weight variation, and disintegration time.

Figure 2, illustrating waveforms resulting from compression and ejection events, is included for comparative purposes. The top tracing is a series of typical compression responses, the mean value for which was about 1200 lb. force (each major division is equivalent to 786 lb.). The lower tracing represents the response obtained from ejection-force measurements using an ejection cam instrumented with metal foil strain gauges (10). A mean value of about 22 lb. force was obtained in this instance (each major division is equivalent to 12.5 lb.).

Tablets were prepared from each of the four materials for direct compression at two levels of pressure: a "normal" pressure level (approximately 2200 lb.) to simulate typical production conditions and a "high" pressure level (approximately 4100 lb.) to encourage

compressional difficulties. The physical specifications of the tablets prepared are listed in Table IV.

After careful examination of the compression curves and evaluation of the physical properties of the tablets, those prepared from dextrose (PAF 2011) were found to be the hardest and least friable of the four agents tested. At "normal" pressure and speed, tablets prepared from spray-dried lactose USP began capping after 6 hr. This was not the case with the other three materials. Figure 3A shows a waveform resulting from the ejection of spray-dried lactose USP tablets 15 min. after commencement of operation. Figure 3B is a similar photograph taken 6 hr. later. The twin peak effect is indicative of capping insofar as the materials tested in this study are concerned. The initial peak is representative of the force required to overcome die wall-tablet adhesion. Under ordinary conditions, this force is rapidly dissipated as the tablet emerges from the die. However, when capping and/or lamination occur, the rapid expansion of the tablet results in an increase in force which manifests itself as the second peak in the ejection waveform. The possibility that these second peaks were the result of buildup of material in the dies or on the lower punch tips was minimized because both these sites were checked for cleanliness at regular intervals throughout the run.

At the higher pressure, tablets prepared from anhydrous lactose USP began capping as depicted by the ejection waveforms shown in Fig. 4. The secondary peaks in this figure are not as pronounced as those in Fig. 3B. However, when one compares the waveforms in Fig. 4 with those seen in a typical noncapping situation (Fig. 2), the secondary peak becomes more apparent. A secondary peak of this type indicates a latent tendency toward capping; the tablets do not cap as they come off the machine but cap during handling

Figure 3—Oscilloscopic tracing resulting from the ejection of spray-dried lactose USP tablets; each large division represents 6.27 lb. Key: A, no capping; and B, capping.

Figure 2—Oscilloscopic tracing of force waveforms obtained from Stokes RBB2 tablet press. See text for explanation.

and packaging. Tablets prepared from lactose USP (beadlets) also exhibited, to a lesser degree, a latent tendency toward capping at high pressure when run with standard concave punches.

It was decided to subject the two best performers [lactose USP (beadlets) and dextrose (PAF 2011)] to a more severe test. Each material was run on the same tablet machine at 1200 tablets/min., using extra deep concave (modified ball) tooling at the high pressure level. Under these conditions, pronounced capping was evident in the case of the lactose USP (beadlets). In contrast, tablets prepared from dextrose (PAF 2011) did not cap under these same test conditions (Fig. 5).

Weight Variation—Extremely close weight tolerances were obtained with all agents except anhydrous lactose USP. To determine the magnitude of tablet-to-tablet weight variation, each material

Dextrose (PAF 2011)	195.63	±0.9652

^a Average of 20 tablets and expressed in mg. ^b $p = 0.0165$. Significant at 95% confidence limits.

was run for 1 hr. on the instrumented RBB2 tablet press. The presence of a blank station in the die table served to index the compression forces at each individual station. It was, therefore, possible to determine if fluctuations in compression force levels were due to tablet-to-tablet weight variation or to tooling variation (*i.e.*, the combined length of the upper and lower punches was either more or less than the norm for the particular set of tooling). Figure 6 shows a series of waveforms resulting from the compression of dextrose (PAF 2011) in which a pattern of variable peak heights is evident. Since this pattern recurs in successive revolutions, one may assume that it is due to tooling variation. Hence, the dextrose (PAF 2011) exhibited remarkably close weight tolerances. In comparison, the waveforms for anhydrous lactose USP depicted in Fig. 7 showed a considerable degree of fluctuating peak heights. Since the pattern obtained in this case does not recur at regular intervals, the force variations cannot be attributed to tooling variations.

Samples were taken from the machine at 10-min. intervals. Twenty tablets were selected, at random, from these samples and weighed individually on a semimicro balance. The statistical data obtained are tabulated in Table V.

Disintegration—To obtain disintegration information, samples were prepared from each of the four agents for direct compression according to the following formula:

Ingredients	g./Tablet
Material for direct compression	0.190
Starch USP	0.010
Magnesium stearate USP	0.001
Stearic acid USP	0.001
	0.202

Tablets were compressed on the instrumented RBB2 tablet

Figure 6—Oscilloscopic tracing resulting from the compression of dextrose (PAF 2011); each large division represents 786 lb.

Figure 7—Oscilloscopic tracing resulting from the compression of anhydrous lactose USP; each large division represents 786 lb.

machine. The uniformity of the compression force, weight, and tablet thickness was maintained within narrow limits. Disintegration times, as determined by the official USP method (12), are recorded in Table VI.

Although all samples had disintegration times of less than 9 min., those prepared from dextrose (PAF 2011) exhibited the shortest and most uniform times. This observation could well have been predicted in view of the difference in solubility between dextrose and lactose.

SUMMARY AND CONCLUSIONS

Lactose USP (beadlets) and dextrose (PAF 2011) have been evaluated and compared with two commonly used agents for direct compression, namely, spray-dried lactose USP and anhydrous lactose USP, as to their relative physical properties and stability for tableting by direct compression.

The physical properties, *i.e.*, bulk density, angle of repose, and particle-size distribution, of all four agents were determined. The effects of heat, moisture, and light, as well as the presence of selected amines and lubricants, on the physical properties and color stability of tablets prepared from the materials were compared with a lactose USP control. The compression characteristics of all four materials were defined with the aid of an instrumented rotary tablet machine. Compression and ejection forces were monitored continuously and correlated with tablet hardness, friability, weight variation, and disintegration time.

Both dextrose (PAF 2011) and lactose USP (beadlets) exhibited excellent flow characteristics, as evidenced by minimal tablet-to-

tablet weight variation. The hygroscopic nature of the dextrose (PAF 2011) detracts considerably from its overall physical stability. Neither new agent represented a significant improvement over the older materials with regard to color stability. Of the four agents tested, only anhydrous lactose USP was able to withstand adequately the exposure to heat, light, and moisture.

The compressional characteristics of dextrose (PAF 2011) were superior to those of the lactose sugars. When identical formulations were tested, dextrose (PAF 2011) produced the hardest and least friable tablets. The compression characteristics of lactose USP (beadlets) were superior to those of spray-dried lactose USP and anhydrous lactose USP.

It is felt that both dextrose (PAF 2011) and lactose USP (beadlets) warrant serious consideration for use as agents for direct compression in the pharmaceutical industry.

Permeability of Double-Layer Films I

TSUNETO KURIYAMA, MICHIHARU NOBUTOKI, and MICHIO NAKANISHI

Abstract □ To make a pharmaceutical preparation that contains a water-unstable ingredient, it is preferable that the preparation be coated with a less permeable film. When rapid disintegration is required, however, the coating film should be made as thin as possible. The present study was carried out on the permeability of the double-layer film in order to create a thin film with sufficient protectivity from moisture. It was found that the permeability of most double-layer films had a directional property and could be made thinner than single films. This finding suggests the potential usefulness in the manufacturing process of pharmaceutical preparations.

Keyphrases □ Films, double layer—permeability □ Permeation, water vapor—double-layer films □ Solvent evaporation rate—effect on film

Coating is an important and basic technique which is widely used in the field of pharmaceuticals. Film coating of tablets is a typical example. One important purpose of coating is to prevent moisture from permeating into preparations, because decomposition of the ingredient is often attributable to hydrolysis (and oxidation). For protection from moisture, it is of primary importance to select a proper coating agent. Several kinds of coating agents are available, but the selection is not always easy because a coating agent should fulfill various incidental requirements. A coating agent should be soluble in the gastric or intestinal fluids as desired, while its solvents should not react with the ingredients and its water vapor permeability should be as low as possible. The water vapor permeability of a film may be reduced by making the film thicker, but such films may prolong the time of tablet disintegration in the digestive fluids. Therefore, the thickness of the coating film is limited. It may be possible to create a more useful coating film by combining currently available agents. For this purpose, two methods may be feasible: making a film from a mixed solution or combining single films to make a multilayer film. The authors studied the latter and found that the multilayer film had very interesting and useful properties which were worthy of reporting.

To study quantitatively the water vapor permeability of a coating film, it may be advisable to perform an experiment on a simple system such as the free film rather than on a complicated system such as the film-coated tablet. Many reports are available concerning the permeability of a single film (1-5). In this report, the water vapor permeability was measured on the double-layer film as well as its constituent single films in a manner similar to that described by the former reporters.

EXPERIMENTAL

Cell for Measuring Water Vapor Permeability—A cell was assembled according to the method of Patel *et al.* (1). The cell was filled with distilled water and horizontally sealed with a sample

film. The initial weight of the cell was accurately measured after 1 hr. of thermal equilibration at a given temperature and humidity environment (generated by the Tabai Lucifer model TL-21P). The cell was again weighed after 20 hr. at the same conditions and the decrease of the weight was calculated. In this experiment, it was necessary to maintain a constant distance between the sample film and the surface of water in the cell to avoid inconsistencies in the data obtained. The shortest possible distance was advisable (6), but for practical reasons the authors used a distance of 1.5 cm.

Film Preparation—(a) *Single Films*—The coating agents were dissolved in suitable solvents, and the film solutions were then poured on horizontal glass plates equipped with a holding frame around the perimeter. The solvent was allowed to evaporate gradually. In this process, the rate of evaporation was controlled by setting a cover which limited the diffusion of solvent vapor. The thickness of the film was adjusted by changing the concentration (5-15%) and the quantity of the solution poured on the glass plate. Free films were peeled from the plates. Each free film was cut into circles 4 cm. in diameter to make the sample films. These samples were dried in a vacuum for 12 hr. to remove residual solvent.

(b) *Double-Layer Films*—It was necessary to use a double-layer free film which contained no air layer between, because an actual multilayer-coating film on the tablet contains no air layer. Two single films, which had the same thickness but were of different types, were selected from the prepared films and combined to form a double-layer film by using a solvent which dissolved only a surface of either film.

Measurement of Thickness of Film—The thickness of a single film produced in the manner described was measured with a dial gauge (precision: 0.001 mm.). The thickness of a double-layer film was taken as a total of the thickness of each single film.

Materials—Coating agents used are shown in Table I.

Measurement of Water Vapor Permeability—Several films were selected to distribute properly the thickness of each film in the range of 0.05-0.4 mm., and their water vapor permeability was measured. Permeability is generally described as follows (8):

$$q = PA t (p_1 - p_2) / l \quad (\text{Eq. 1})$$

Quantity (q) of water vapor, which passes through a given film at a given temperature, depends upon area (A), thickness (l), vapor pressure difference ($\Delta p = p_1 - p_2$), and time (t). The proportional coefficient (P) was termed the permeability coefficient. Permeability (Q), which is defined in Eq. 2, was obtained at a given condition:

$$Q = q / At \quad (\text{g./m.}^2 \text{ 24 hr.}) \quad (\text{Eq. 2})$$

Comparison was made on Q -values for various samples in terms of 0.3-mm. film thicknesses. It was, of course, very hard to produce a sample film of the exact thickness intended, and Q -value depended upon the thickness (l) of a film. But because the relationship between $1/Q$ and l was linear, Q for exactly 0.3-mm. thickness was obtained graphically.

RESULTS AND DISCUSSION

In the case of preparing sample films, the rate of evaporation of the solvent was a problem. Too rapid evaporation produced turbidity in the film, and the water vapor permeability of the film depended upon such turbidity, producing inconsistencies in data. The rate of evaporation was controlled to make the films transparent. All results reported were obtained from transparent sample films.

The relationship between $1/Q$ and l should be a straight line passing through the origin according to Eq. 1. But this experiment revealed that the line did not pass through the origin but intersected

the ordinate ($1/Q$ -axis), indicating that the permeability of coating film does not perfectly agree with the classical theory (Eq. 1).

This fact has been reported also by Patel *et al.* (1), who pointed out that the linear plots resulted for various samples extrapolated to the same point on the abscissa (l -axis). However, the latter

was not always supported experimentally, as shown in Fig. 1, as Patel himself suspected contingency. In the case of double-layer films also, the relationships between $1/Q$ and l were linear, just as in Fig. 1.

Table II shows the results obtained. "Types" in the table are defined in Table III.

Table II shows the permeability for double-layer films as well as that for single-layer films, which are the components of the double-layer films. Differences in permeability were noted even in the same double-layer film, depending upon which layer was set on the side of higher humidity or depending upon the direction of permeation. This property is called "two-sidedness" by Rogers *et al.* (9, 10). In the present report, the double-layer film is expressed as $X + Y$ (or $Y + X$), which means that the film is made from material X and material Y , and X -layer (or Y -layer)—written before the + mark—is set on the side of higher humidity, and Y -layer (or X -layer)—written after the + mark—is set on the side of lower humidity. In Table III, A, B, C, and D are defined as follows: when X is more permeable than Y , A refers to the permeability of X and B refers to that of Y ; C refers to the permeability observed for $Y + X$, and D to the permeability for $X + Y$. Therefore, A is always larger than B, and C or D is usually between A and B.

It was found, however, that D can be greater than A or that C can be smaller than B in some cases. In Table III, all the possible orders of A, B, C, and D are listed; they are classified into four groups. Twelve orders of A, B, C, and D are called by "types" in this report. Table III also shows the number of cases falling under each "type." Rogers *et al.* (9) and Ninneman and Simerl (10) measured the permeability of double-layer films used for packaging and observed the "two-sidedness." "Two-sidedness" is expressed as $C \neq D$, according to the definition already mentioned. This property, which was confirmed in the present experiment on coating films, may be useful in pharmaceuticals. More concretely, moisture should be minimized in a tablet which contains a water-unstable ingredient; in this sense, it will be practically useful to utilize the "two-sidedness" of the double-layer film for protecting the tablet from moisture. If coating layers are properly combined, the film-coated tablet can be dried easily even at a mild condition and, at the same time, the tablet will absorb little moisture. In addition, Table III indicates a much greater merit of double-layer film coating. Permeability of the double-layer film and that of each layer were compared on the same unit thickness basis in the present experiment. It revealed the

^a Measured under the following conditions: temperature, 40°; vapor pressure at higher pressure side p_1 , 55.3 mm. Hg (100% R.H. at 40°); vapor pressure at lower pressure side p_2 , 42.0 mm. Hg (76% R.H. at 40°). Every double-layer film is composed of two kinds of single films which have the same thickness. ^b Dimension of permeability Q ; g./m.² 24 hr., value obtained for 0.3-mm. thickness both of double-layer and single films. ^c Defined in Table III. ^d HECAP was set at the lower pressure side. ^e EC-50 was set at the lower pressure side.

presence of a particularly interesting effect of the "two-sidedness," as shown in Table III. For example (HECAP + EC-50, HECAP + CAB, CC + PVA), some double-layer films made from the materials X and Y showed greater permeability than that of either X or Y film when water vapor permeated from one direction and, on the contrary, their permeability was smaller than that of either X or Y film when water vapor permeated from the other direction (Group α). This means that some double-layer films can accomplish effective protection from moisture when the combined thickness of the

layers is less than that of a single film. A coating film on a tablet should be less permeable as well as thinner, because it should effectively protect the ingredients from moisture and be disintegrated quickly in the digestive fluid. These two requirements generally disagree with each other, but the effect of the "two-sidedness" (Group α) will be a great help to the reconciliation of these antinomial requirements. The incidence of the Group γ is naturally the highest. No case classifiable into Group β was found, as was assumed theoretically. Examples of the Groups α and δ are actually observed.

SUMMARY

Water vapor permeability of the coating film, single- and double-layer films, was measured at a certain condition. It was revealed that plotting the relationship between the resistance for permeation ($1/Q$) and the film thickness (l) gave a straight line, but the line did not intersect the $1/Q$ -axis at the origin, indicating that the permeability of coating film does not perfectly agree with the classical theory. The permeability of the double-layer film varies, depending upon the direction of permeation (two-sidedness). The "two-sidedness" was classified into some groups according to the relationship of permeability of each single film and that of the composite film. The most remarkable characteristic was observed in the Group α , which was interpreted to mean that the permeability of the double-layer film from one side and that from the other side are larger or/and smaller than that of any of its elemental single films of the same thickness. This fact is very important and may be useful from the viewpoint of pharmaceutical technology.

NOTES

Permeability of Double-Layer Films II

TSUNETO KURIYAMA, MICHIHARU NOBUTOKI, and MICHIO NAKANISHI

Abstract □ Most of the combinations of coating films showed "two-sided" permeability, while this property has not been reported for films composed of hydrophobic layers only. Any coating film is more or less hydrophilic, and its water vapor permeability varies according to the mean humidity condition in which the film is placed. It was found that double-layer films with "two-sidedness" have characteristic relations (as classified into Groups α , β , γ , and δ) between specificity of permeability and humidity range.

Keyphrases □ Permeability, two-sided—double-layer films □ Double-layer films—permeability, relationship of water vapor, humidity

In the first part of this study, the authors reported the so-called "two-sided" directional property of the water vapor permeability of double-layer films, and classified this property into four groups: α , β , γ , and δ (1). In double-layer films with two-sided water vapor permeability of the Group α , the permeability is either smaller or greater than that of either component layer, depending on the direction of permeation. The latter feature is a phenomenon that cannot be elucidated in a simple manner. Ninneman and Simerl (2) studied the permeability of multilayer films and introduced the following equation:

$$\Delta p = Q \sum_{i=1}^n \frac{l_i}{P_i} \quad (\text{Eq. 1})$$

where Δp stands for the difference in water vapor pressure between the higher humidity atmosphere and lower humidity atmosphere (*i.e.*, $p_1 - p_2$), Q is the permeability of an n -layer film, l_i is the thickness of the i th layer in the n -layer film, and P_i is the permeability coefficient of the i th layer. This equation may estimate the permeability of the multilayer film at a certain condition, where the material and the thickness of each

component layer are given. It cannot explain the two-sided property of the multilayer film, however, because the permeability thus calculated is independent of the permutation of component layers of a film. In other words, Eq. 1 is practically applicable to the hydrophobic film only but not to the coating film, which is more or less of a hydrophilic nature.

Equation 3 is derived from Eq. 2 (1), which is known to be applicable to the hydrophobic film.

$$q = P \frac{p_1 - p_2}{l} At \quad (\text{Eq. 2})$$

$$\frac{1}{Q} = \frac{At}{q} = \frac{l}{P \Delta p} \quad (\text{Eq. 3})$$

where A is the area of film through which water vapor is permeated, t is the time of permeation, and q is the quantity of moisture permeated. But Eq. 3 does not always apply to the coating (hydrophilic) film. While $1/Q$ should be proportional to l according to Eq. 3, previously reported experiments (1) revealed that the value of $1/Q$ for $l=0$ did not come to zero in spite of the linearity of the relationship between $1/Q$ and l . This finding suggests that the permeability of the coating film is different from that of the usual hydrophobic film and its behavior is rather complex. The two-sided property of the coating film may be attributed to these very facts.

Takeda (3), studying the permeability of cellulose films, introduced the following equation:

$$\frac{1}{Q} = \frac{l}{P \Delta p} + \frac{2}{k \Delta p} \quad (\text{Eq. 4})$$

where k is a coefficient which indicates how easily water molecules drive into the film from the higher humidity atmosphere. This equation explains that the relationship between $1/Q$ and l is not proportional;

NOTES

Permeability of Double-Layer Films II

TSUNETO KURIYAMA, MICHIHARU NOBUTOKI, and MICHIO NAKANISHI

Abstract □ Most of the combinations of coating films showed "two-sided" permeability, while this property has not been reported for films composed of hydrophobic layers only. Any coating film is more or less hydrophilic, and its water vapor permeability varies according to the mean humidity condition in which the film is placed. It was found that double-layer films with "two-sidedness" have characteristic relations (as classified into Groups α , β , γ , and δ) between specificity of permeability and humidity range.

Keyphrases □ Permeability, two-sided—double-layer films □ Double-layer films—permeability, relationship of water vapor, humidity

In the first part of this study, the authors reported the so-called "two-sided" directional property of the water vapor permeability of double-layer films, and classified this property into four groups: α , β , γ , and δ (1). In double-layer films with two-sided water vapor permeability of the Group α , the permeability is either smaller or greater than that of either component layer, depending on the direction of permeation. The latter feature is a phenomenon that cannot be elucidated in a simple manner. Ninneman and Simerl (2) studied the permeability of multilayer films and introduced the following equation:

$$\Delta p = Q \sum_{i=1}^n \frac{l_i}{P_i} \quad (\text{Eq. 1})$$

where Δp stands for the difference in water vapor pressure between the higher humidity atmosphere and lower humidity atmosphere (*i.e.*, $p_1 - p_2$), Q is the permeability of an n -layer film, l_i is the thickness of the i th layer in the n -layer film, and P_i is the permeability coefficient of the i th layer. This equation may estimate the permeability of the multilayer film at a certain condition, where the material and the thickness of each

component layer are given. It cannot explain the two-sided property of the multilayer film, however, because the permeability thus calculated is independent of the permutation of component layers of a film. In other words, Eq. 1 is practically applicable to the hydrophobic film only but not to the coating film, which is more or less of a hydrophilic nature.

Equation 3 is derived from Eq. 2 (1), which is known to be applicable to the hydrophobic film.

$$q = P \frac{p_1 - p_2}{l} A t \quad (\text{Eq. 2})$$

$$\frac{1}{Q} = \frac{A t}{q} = \frac{l}{P \Delta p} \quad (\text{Eq. 3})$$

where A is the area of film through which water vapor is permeated, t is the time of permeation, and q is the quantity of moisture permeated. But Eq. 3 does not always apply to the coating (hydrophilic) film. While $1/Q$ should be proportional to l according to Eq. 3, previously reported experiments (1) revealed that the value of $1/Q$ for $l=0$ did not come to zero in spite of the linearity of the relationship between $1/Q$ and l . This finding suggests that the permeability of the coating film is different from that of the usual hydrophobic film and its behavior is rather complex. The two-sided property of the coating film may be attributed to these very facts.

Takeda (3), studying the permeability of cellulose films, introduced the following equation:

$$\frac{1}{Q} = \frac{l}{P \Delta p} + \frac{2}{k \Delta p} \quad (\text{Eq. 4})$$

where k is a coefficient which indicates how easily water molecules drive into the film from the higher humidity atmosphere. This equation explains that the relationship between $1/Q$ and l is not proportional;

Figure 1—Relationship between Q and Δp . Temperature, 40° ; thickness of film, 0.1 mm.; $p_1 = 100\%$ R.H. = 55.3 mm. Hg; and $\Delta p = p_1 - p$.

i.e., the value of $1/Q$ is not zero even when the value of l equals zero. The authors attempted to elucidate various features of two-sidedness by using Eq. 4, but the results did not clarify every finding of a series of experiments.

The present report describes the results of a study of the two-sided permeability of double-layer films and the permeability of the component single-layer films according to the changes of p_1 and p_2 . The symbol p_1 means a certain fixed water vapor pressure at the higher humidity side, and p_2 means that at the lower humidity side. The symbol p is used as the variable of either p_1 or p_2 .

EXPERIMENTAL

Method—Experiments were performed in the same manner as reported in the preceding part of this study (1). Various p_2 (water vapor pressure of lower humidity atmosphere) conditions and temperatures were generated by a Tabai Lucifer model TL-21P. The permeation cell containing a solution to generate various p_1 (water vapor pressure of higher humidity atmosphere) conditions in the cell was placed in the cited apparatus. The weight decrease of the cell after permeation was measured.

Materials—The materials used are the same as in the previous report (1); they are designated by abbreviations defined in that paper.

RESULTS AND DISCUSSION

The permeability (Q) of the single films was determined at 40° , where water vapor pressure at the higher humidity side p_1 was 55.3

Figure 2—Relationship between P and Δp . Temperature, 40° ; thickness of film, 0.1 mm.; $p_1 = 100\%$ R.H. = 55.3 mm. Hg; and $\Delta p = p_1 - p$.

mm. Hg (relative humidity, 100%), and water vapor pressure at the lower humidity side p_2 was varied over a wide range. Some of the results thus obtained are illustrated in Fig. 1.

The figure shows the results with 0.1-mm-thick films only; similar results were obtained with films of various thicknesses.

Figure 3—Relationship between Q and Δp . Temperature, 40° ; composition of double-layer films:

(Higher humidity side)		(Lower humidity side)	
HECAP	+	EC-50	
EC-50	+	HECAP	

Thickness of film: double-layer film, 0.05 mm. + 0.05 mm.; single film, 0.1 mm.; $p_1 = 100\%$ R.H. = 55.3 mm. Hg; and $\Delta p = p_1 - p$.

Since it was difficult to obtain directly in a single experiment films of exactly 0.1-mm. thickness, several films were selected so that the thickness of each film might be distributed in a range from 0.05 to 0.4 mm. and the respective water vapor permeability was measured at various humidity conditions. Plotting the relationship between permeation resistance ($1/Q$) and film thickness (l) gave a straight line. Thus, the permeability (Q) of the film of a given thickness (l) in various conditions could be obtained.

Figure 1 suggests some noteworthy points. According to Eq. 2, the relationship between Q ($=q/A$) and Δp ($=p_1 - p_2$) should be linear and proportional. As shown in Fig. 1, however, most of the obtained curves do not agree with Eq. 2. In particular, the value of Q for PVA does not increase after the maximum point, even when the value of Δp increases. The cause of this apparently controversial phenomenon may be that the permeability, Q , depends not only on the pressure difference between the higher vapor pressure side and the lower side, but also on the mean humidity condition to which the test film is subjected. This feature may be called the water vapor pressure dependency of permeability.

The permeability coefficient (P) for a hydrophobic film is constant, because water vapor does not interact with the film, and the experimental data correspond to Eq. 1 or 2. On the other hand, for hydrophilic films such as coating films, the value of P changes according to the humidity condition, because water vapor interacts with the film; thus Eq. 1 or 2 does not apply to the hydrophilic film. The relationship between P and Δp was obtained from Eq. 2 by using the data of Fig. 1. Figure 2 shows the results obtained. The value of P changed sharply, especially for the PVA film.

Figure 3 illustrates the relationship between Q and Δp for the double-layer film, which has the remarkable two-sided feature of permeation. For comparison, this figure also shows the curves obtained with each single-component film. The permeability Q of the single films and of the double-layer film is expressed on the basis of 0.1-mm. thickness. It was found (Fig. 3) that two-sided features, classified as Group α and Group δ (1), occurred over different humidity ranges. These features will, of course, change according to the sort of double-layer film or the combination of single films used therein.

SUMMARY

With both single-component films and a double-layer film, the relationship between water vapor permeability (Q) and humidity condition was studied. It was found that the permeability of the films depended not only upon the difference in vapor pressure (Δp) between the higher and lower humidity sides, but also upon the mean humidity condition to which the test film was subjected. It was also found that a double-layer film with two-sided permeability displayed the feature of Group α in a certain humidity range and the feature of Group δ in another humidity range.

GLC Determination of Guaiacol Glyceryl Ether in Blood

WILLIAM R. MAYNARD, Jr., and ROBERT B. BRUCE

Abstract □ A method has been developed for the determination of guaiacol glyceryl ether in blood by extraction with methylene chloride followed by conversion to the heptafluorobutyrate ester and quantitation using an electron-capture detector. Blood levels following oral administration of the drug indicate a rapid absorption and elimination with a half-life of 1 hr.

Keyphrases □ Guaiacol glyceryl ether—GLC determination, in blood □ NMR—identification □ GLC—determination, guaiacol glyceryl ether, in blood

Guaiacol glyceryl ether (GGE) has been used for many years as an expectorant and, more recently, it has been claimed to have activity as a muscle relaxant (1) and as an hypocholesteremic (2-5), and to reduce platelet adhesiveness (6). In spite of its extensive use and study, no methods appear to be available for its determination in man following usual dosages. Morgan *et*

al. (7) studied blood levels in dogs, and Mizutani and Naito (8) have determined blood levels in rabbits. However, relatively large doses were administered in each case, and these methods do not appear adaptable to present needs. Therefore, a method has been developed using GLC which appears to be satisfactory.

EXPERIMENTAL

The method is based on extraction of GGE from blood with methylene chloride and conversion to the heptafluorobutyrate ester and quantitation by GLC using an electron-capture detector. Mephensin [3-(*o*-toloxy)-1,2-propanediol] is used as an internal standard.

The procedure is carried out as follows. To 5.0 ml. of blood, add 1.0 mcg. of mephensin, 3 ml. of distilled water, and 0.5 ml. of 2 *N* H₂SO₄. Then extract with 20 ml. of redistilled methylene chloride by shaking for 10 min. Separate the phases by centrifuging, and dry the methylene chloride extract by passing it through a layer of anhydrous sodium sulfate in a funnel. Repeat the extraction with an

Since it was difficult to obtain directly in a single experiment films of exactly 0.1-mm. thickness, several films were selected so that the thickness of each film might be distributed in a range from 0.05 to 0.4 mm. and the respective water vapor permeability was measured at various humidity conditions. Plotting the relationship between permeation resistance ($1/Q$) and film thickness (l) gave a straight line. Thus, the permeability (Q) of the film of a given thickness (l) in various conditions could be obtained.

Figure 1 suggests some noteworthy points. According to Eq. 2, the relationship between Q ($=q/A$) and Δp ($=p_1 - p_2$) should be linear and proportional. As shown in Fig. 1, however, most of the obtained curves do not agree with Eq. 2. In particular, the value of Q for PVA does not increase after the maximum point, even when the value of Δp increases. The cause of this apparently controversial phenomenon may be that the permeability, Q , depends not only on the pressure difference between the higher vapor pressure side and the lower side, but also on the mean humidity condition to which the test film is subjected. This feature may be called the water vapor pressure dependency of permeability.

The permeability coefficient (P) for a hydrophobic film is constant, because water vapor does not interact with the film, and the experimental data correspond to Eq. 1 or 2. On the other hand, for hydrophilic films such as coating films, the value of P changes according to the humidity condition, because water vapor interacts with the film; thus Eq. 1 or 2 does not apply to the hydrophilic film. The relationship between P and Δp was obtained from Eq. 2 by using the data of Fig. 1. Figure 2 shows the results obtained. The value of P changed sharply, especially for the PVA film.

Figure 3 illustrates the relationship between Q and Δp for the double-layer film, which has the remarkable two-sided feature of permeation. For comparison, this figure also shows the curves obtained with each single-component film. The permeability Q of the single films and of the double-layer film is expressed on the basis of 0.1-mm. thickness. It was found (Fig. 3) that two-sided features, classified as Group α and Group δ (1), occurred over different humidity ranges. These features will, of course, change according to the sort of double-layer film or the combination of single films used therein.

SUMMARY

With both single-component films and a double-layer film, the relationship between water vapor permeability (Q) and humidity condition was studied. It was found that the permeability of the films depended not only upon the difference in vapor pressure (Δp) between the higher and lower humidity sides, but also upon the mean humidity condition to which the test film was subjected. It was also found that a double-layer film with two-sided permeability displayed the feature of Group α in a certain humidity range and the feature of Group δ in another humidity range.

GGE—mcg./ml. Blood—		Recovery, %
Added	Found	
0.080	0.078	97.5
0.16	0.15	92.5
0.20	0.19	97.0
1.00	1.02	102.0
2.00	1.89	94.4
3.00	3.07	101.0

additional 10 ml. of methylene chloride, and combine the extracts. Wash sodium sulfate with an additional 3 ml. of methylene chloride which is added to the combined extract. Evaporate the combined extracts under a stream of nitrogen to 100 μ l. Add 300 μ l. of a solution of heptafluorobutyric anhydride in methylene chloride (1 ml./100 ml.), mix, heat to 60° for 30 sec., and allow to stand for 10 min. with occasional mixing. Evaporate to complete dryness with nitrogen, add 0.50–3.0 ml. of redistilled ether, mix, and inject 1–4 μ l. into the gas chromatograph.

The gas chromatograph used in this study was a Barber-Coleman, Series 5000, with a ^{63}Ni -detector. The column was 1.21 m. (4 ft.) long, stainless steel, and contained 3% XE-60 on diatomaceous earth.¹ Temperatures were: column, 144°; detector, 280°; and injection port, 260°. The flow rate was 40 ml./min. of nitrogen. The retention time of mephenesin heptafluorobutyrate was 4 min. 50 sec. and that of GGE heptafluorobutyrate was 6 min. 10 sec. The column was preconditioned by four rapid injections of 4 μ l. of a mixture of heptafluorobutyric anhydride in ether (1:4) and

Figure 1—Chromatograms showing results of the analysis of control blood (left) and blood sample from subject receiving GGE (right): a, mephenesin heptafluorobutyrate; and b, GGE heptafluorobutyrate.

Figure 2—Average blood levels following the oral administration of 600 mg. of GGE to three human subjects.

allowing the column to remain at 144° for 30 min. The column temperature was raised to 200° for 2 hr. The column exit was disconnected during this preconditioning.

Three normal male subjects were administered an oral liquid dose of 600 mg. of GGE. The subjects received no solid food from the midnight before drug administration until 2 hr. after drug administration. Blood samples were drawn at frequent intervals for 8 hr. after the dose.

RESULTS AND DISCUSSION

GGE has been determined (9, 10) by GLC in pharmaceutical preparations. These methods did not give the sensitivity needed for blood level determination. Amides and esters prepared from halogenated acid chlorides or anhydrides give a high response with the electron-capture detector. Heptafluorobutyric anhydride was used because it reacts easily and quickly with GGE at room temperature and can be readily separated from the ester by simple evaporation. The procedure is straightforward and simple to carry out. The only precaution is to remove completely the solvent—methylene chloride—before the sample is injected into the gas chromatograph, since the detector is very sensitive to halogenated compounds.

The results found from the analysis of blood samples to which known amounts of GGE had been added are shown in Table I. The standard deviation at the 1.00-mcg./ml. level was 0.046. These results appear to be satisfactory for the analysis of blood. Chromatograms from actual analysis of blood samples are shown in Fig. 1. A comparison of the chromatogram of the control blood with that of the sample containing GGE shows that nothing present in

¹ Gas-Chrom Q, Applied Science Laboratories, Inc., State College, PA 16801

the control interferes with the determination. Some uninvestigated materials are eluted earlier than the esters of GGE and mephenesin. Quantitation is made comparing peak heights of the internal standard with that of the GGE ester.

A large amount of the ester was prepared by the procedure described to determine whether reaction had occurred with both or only one of the hydroxyl groups. NMR spectra showed that only the primary hydroxyl had reacted.

The results from the blood level determinations following the oral dose are shown in Fig. 2. GGE is readily absorbed, with the maximum amount determined occurring in the 0.25-hr. sample. The half-life was 1.00 hr. Detectable amounts of the drug were no longer present in the 8-hr. samples of any of the subjects, indicating rapid metabolism and excretion.

Antiradiation Compounds XIV: Dithiocarbamates of Aminothiophenes

WILLIAM O. FOYE, JAMES MICKLES, and GERARD M. BOYCE

Abstract □ Dithiocarbamates of 2-amino-3-cyano(or carbethoxy)-4,5-dialkylthiophenes and a corresponding furan have been obtained. Dithiocarbamate formation of 2-amino-3-cyano-4,5-diphenylfuran resulted in a conversion to the corresponding thiophene dithiocarbamate. A dithiocarbamate trithiocarbonate of 2-amino-3-carbethoxy-4-mercaptomethylthiophene was also synthesized, and ring closure of the 2-amino-3-cyanothiophenes to thiopheno[2,3-*d*]pyrimidines was observed. None of the compounds tested showed radiation-protective or antimalarial properties.

Keyphrases □ Antiradiation compounds—dithiocarbamates of aminothiophenes □ Aminothiophenes, dithiocarbamate derivatives—radiation-protective capacity, antimalarial properties □ IR spectrophotometry—structure

Although thiophene derivatives have not appeared frequently with radiation-protective properties, a basic derivative, *N*-phenyl-2-thiophenecarboxamidine, has been reported to have appreciable protection in rats (1). Since several heterocyclic dithiocarbamates in the pyridine, pyrimidine, and acridine series (2) are radiation protective, dithiocarbamates of thiophenes and furans having basic functions appeared to be logical candidates as radiation-protective compounds. Methods for obtaining thiophenes and furans having primary amino substituents in the ring have recently been announced (3), and the conversion of compounds of this type to dithiocarbamates has been attempted. Inclusion of this sulfur-containing function provides a thiol anion capable of undergoing rapid hydrogen-atom exchange reactions (4), which could account for radiation protection.

PROCEDURE

Preparation of 2-aminothiophenes was carried out by the method of Gewald *et al.* (5) with modifications. This procedure involved the base-catalyzed condensation of a carbonyl compound with an active methylene nitrile and sulfur. Using methyl ethyl ketone and malononitrile, the reaction was found to be best catalyzed with morpholine, with excess ketone as the solvent. Using methyl ethyl ketone and malononitrile, the product was 2-amino-3-cyano-4,5-dimethylthiophene; with ethanol as the solvent, the product was 2-butyldenemalononitrile. By the same procedure, but with ethanol as the solvent, the following were obtained: 2-amino-3-carbethoxy-4,5-dimethylthiophene, 2-amino-3-cyano-4,5-tetramethylenothiophene, and 2-amino-3-carbethoxy-4,5-tetramethylenothiophene. Also obtained by the same general procedure, without sulfur, were 2-amino-3-cyano-4,5-dimethylfuran and the corresponding 4,5-diphenyl compound.

Attempts to form the dithiocarbamates of the 2-aminothiophenes previously mentioned, using carbon disulfide and ethanol as the solvent, gave only small yields over a period of 24–72 hr. In the case of 2-amino-3-cyano-4,5-dimethylthiophene, the thiourea was formed instead. By using the procedure of Fairfull and Peak (6), however, triethylammonium salts of the dithiocarbamates (I) of the aminothiophenes and one of the aminofurans were obtained in good yield and sufficiently pure for analysis.

The attempted conversion of 2-amino-3-cyano-4,5-diphenylfuran to the dithiocarbamate gave a product having a poor analysis for the ethyl ester of the dithiocarbamate. By allowing the reaction to take place during a much longer time (2 weeks), a product was obtained for which the analysis indicated formation of the dithiocarbamate salt of 2-amino-3-cyano-4,5-diphenylthio-

the control interferes with the determination. Some uninvestigated materials are eluted earlier than the esters of GGE and mephensin. Quantitation is made comparing peak heights of the internal standard with that of the GGE ester.

A large amount of the ester was prepared by the procedure described to determine whether reaction had occurred with both or only one of the hydroxyl groups. NMR spectra showed that only the primary hydroxyl had reacted.

The results from the blood level determinations following the oral dose are shown in Fig. 2. GGE is readily absorbed, with the maximum amount determined occurring in the 0.25-hr. sample. The half-life was 1.00 hr. Detectable amounts of the drug were no longer present in the 8-hr. samples of any of the subjects, indicating rapid metabolism and excretion.

Antiradiation Compounds XIV: Dithiocarbamates of Amino thiophenes

WILLIAM O. FOYE, JAMES MICKLES, and GERARD M. BOYCE

Abstract □ Dithiocarbamates of 2-amino-3-cyano(or carbethoxy)-4,5-dialkylthiophenes and a corresponding furan have been obtained. Dithiocarbamate formation of 2-amino-3-cyano-4,5-diphenylfuran resulted in a conversion to the corresponding thiophene dithiocarbamate. A dithiocarbamate trithiocarbonate of 2-amino-3-carbethoxy-4-mercaptomethylthiophene was also synthesized, and ring closure of the 2-amino-3-cyanothiophenes to thiopheno[2,3-*d*]pyrimidines was observed. None of the compounds tested showed radiation-protective or antimalarial properties.

Keyphrases □ Antiradiation compounds—dithiocarbamates of amino thiophenes □ Amino thiophenes, dithiocarbamate derivatives—radiation-protective capacity, antimalarial properties □ IR spectrophotometry—structure

Although thiophene derivatives have not appeared frequently with radiation-protective properties, a basic derivative, *N*-phenyl-2-thiophenecarboxamidine, has been reported to have appreciable protection in rats (1). Since several heterocyclic dithiocarbamates in the pyridine, pyrimidine, and acridine series (2) are radiation protective, dithiocarbamates of thiophenes and furans having basic functions appeared to be logical candidates as radiation-protective compounds. Methods for obtaining thiophenes and furans having primary amino substituents in the ring have recently been announced (3), and the conversion of compounds of this type to dithiocarbamates has been attempted. Inclusion of this sulfur-containing function provides a thiol anion capable of undergoing rapid hydrogen-atom exchange reactions (4), which could account for radiation protection.

PROCEDURE

Preparation of 2-amino thiophenes was carried out by the method of Gewald *et al.* (5) with modifications. This procedure involved the base-catalyzed condensation of a carbonyl compound with an active methylene nitrile and sulfur. Using methyl ethyl ketone and malononitrile, the reaction was found to be best catalyzed with morpholine, with excess ketone as the solvent. Using methyl ethyl ketone and malononitrile, the product was 2-amino-3-cyano-4,5-dimethylthiophene; with ethanol as the solvent, the product was 2-butyldenemalononitrile. By the same procedure, but with ethanol as the solvent, the following were obtained: 2-amino-3-carbethoxy-4,5-dimethylthiophene, 2-amino-3-cyano-4,5-tetramethylenothiophene, and 2-amino-3-carbethoxy-4,5-tetramethylenothiophene. Also obtained by the same general procedure, without sulfur, were 2-amino-3-cyano-4,5-dimethylfuran and the corresponding 4,5-diphenyl compound.

Attempts to form the dithiocarbamates of the 2-amino thiophenes previously mentioned, using carbon disulfide and ethanol as the solvent, gave only small yields over a period of 24-72 hr. In the case of 2-amino-3-cyano-4,5-dimethylthiophene, the thiourea was formed instead. By using the procedure of Fairfull and Peak (6), however, triethylammonium salts of the dithiocarbamates (I) of the amino thiophenes and one of the aminofurans were obtained in good yield and sufficiently pure for analysis.

The attempted conversion of 2-amino-3-cyano-4,5-diphenylfuran to the dithiocarbamate gave a product having a poor analysis for the ethyl ester of the dithiocarbamate. By allowing the reaction to take place during a much longer time (2 weeks), a product was obtained for which the analysis indicated formation of the dithiocarbamate salt of 2-amino-3-cyano-4,5-diphenylthio-

phene (I, R=C₆H₅, Y=CN). During this prolonged reaction, the furan ring apparently opened and reacted with carbon disulfide to give the corresponding thiophene.

IR absorption of the dithiocarbamates containing cyano groups showed either very weak or no peaks for cyano absorption. This may be attributed to interaction with the adjacent, negatively charged dithiocarbamate group. In addition, absorption due to C=S occurred at lower wavenumbers than in the case of the 3-carbethoxy compounds, again indicating interaction with cyano groups.

2-Amino-3-ethoxycarbonyl-4-mercaptomethylthiophene was obtained by a modification of the method of Gewald and Schinke (7) for the disulfide. The mercaptan was not isolated but was treated with carbon disulfide and triethylamine to give the dithiocarbamate trithiocarbonate (II) from condensation at both the amino and thiol functions. A previous dithiocarbamate trithiocarbonate, prepared from cysteine, was found to be strongly radiation protective in mice (8). A similar attempt to obtain 2-amino-3-cyano-4-methyl-5-mercaptothiophene gave the sulfide.

Thiopheno[2,3-*d*]pyrimidines (III) were also obtained using the method of Gewald (9) for synthesis of furo[2,3-*d*]pyrimidines. These compounds resulted on refluxing the appropriate 3-cyanothiophene with formamide and acetic anhydride.

BIOLOGICAL TESTING RESULTS

Antiradiation screening of several of the compounds was carried out.¹ Tests were carried out in mice *versus* 825 r (X-rays) or 950 r (γ-rays) with an observation period of 30 days. The dithiocarbamate of 2-amino-3-carbethoxy-4,5-dimethylthiophene (I) was inactive against 950 r (γ-rays), and the dithiocarbamate trithiocarbonate (II) and the two thiopheno[2,3-*d*]pyrimidines (III) were inactive against 825 r (X-rays).

The three compounds (II and III) were also screened for anti-malarial activity in mice infected with *Plasmodium berghei* and in *Aedes aegypti* infected with *Plasmodium gallinaceum*; they were inactive in both tests. Also, the dithiocarbamates of the 2-amino-3-cyano(or carbethoxy)-4,5-dialkylthiophenes (I) were inactive in the mouse test.

It may be concluded from the lack of radiation-protective activity for the dithiocarbamate trithiocarbonate (II) reported here and the powerful protective effect of the corresponding cysteine derivative (8) that a rigid structure connecting these functions is detrimental to radiation protection.

EXPERIMENTAL

Analyses for carbon, hydrogen, and nitrogen were performed.² Sulfur analyses were done by Parr bomb peroxide fusion. Melting points were taken on a Mel-Temp apparatus and are corrected. IR absorption spectra were obtained with a Perkin-Elmer model 137B spectrometer.

Triethylammonium 3-Cyano-4,5-dimethylthiophene-2-dithiocarbamate—A mixture of 5.3 g. (0.035 mole) of 2-amino-3-cyano-4,5-

dimethylthiophene (5), 42 ml. (0.600 mole) of carbon disulfide, 76.5 ml. (0.550 mole) of triethylamine, and 2.5 ml. of absolute ethanol formed a red-orange solution. The solution was stirred at room temperature for 48 hr. and yielded 3.3 g. (28%) of orange-yellow product; m.p. 241–242°; IR (KBr) 880 (β-ring), 1135 (C=S), 2200 (C≡N, weak) cm.⁻¹.

Anal.—Calcd. for C₁₄H₂₃N₃S₃: C, 51.02; H, 7.03; N, 12.75; S, 29.19. Found: C, 51.37; H, 6.97; N, 12.29; S, 29.63.

Triethylammonium 3-Carbethoxy-4,5-dimethylthiophene-2-dithiocarbamate—A mixture of 7.0 g. (0.035 mole) of 2-amino-3-carbethoxy-4,5-dimethylthiophene (5), 42 ml. (0.600 mole) of carbon disulfide, 76.5 ml. (0.550 mole) of triethylamine, and 2.5 ml. of absolute ethanol formed a red-orange solution, which was allowed to stand at room temperature for 2 days, giving 7.5 g. (56%) of bright-yellow crystals; m.p. 105–107°; IR (KBr) 990 (C=S), 1650 (C=O) cm.⁻¹.

Anal.—Calcd. for C₁₆H₂₅N₂O₃S₃: C, 51.02; H, 7.49; N, 7.44; S, 25.54. Found: C, 50.86; H, 7.11; N, 7.15; S, 25.10.

Triethylammonium 3-Cyano-4,5-tetramethylenothiophene-2-dithiocarbamate—A mixture of 8.9 g. (0.05 mole) of 2-amino-3-cyano-4,5-tetramethylenothiophene (5), 60 ml. (0.86 mole) of carbon disulfide, 109 ml. (0.78 mole) of triethylamine, and 3.5 ml. of absolute ethanol formed a yellow solution, which was allowed to stand for 3 days at room temperature, giving 6.5 g. (36%) of rust-colored product; m.p. 210–212°; IR (KBr) 875 (β-ring), 1115 (C=S) cm.⁻¹.

Anal.—Calcd. for C₁₆H₂₅N₂S₃: C, 54.04; H, 7.09; N, 11.82; S, 27.05. Found: C, 54.11; H, 6.82; N, 11.70; S, 27.50.

Triethylammonium 3-Carbethoxy-4,5-tetramethylenothiophene-2-dithiocarbamate—A mixture of 11.25 g. (0.05 mole) of 2-amino-3-carbethoxy-4,5-tetramethylenothiophene (5), 60 ml. (0.86 mole) of carbon disulfide, 109 ml. (0.78 mole) of triethylamine, and 3.5 ml. of absolute ethanol formed a yellow solution, which was allowed to stand at room temperature for 3 days, giving 11.3 g. (56%) of bright-yellow product; m.p. 101–103°; IR (KBr) 965 (C=S), 1660 (C=O) cm.⁻¹.

Anal.—Calcd. for C₁₈H₃₀N₂O₃S₃: C, 53.69; H, 7.51; N, 6.96; S, 24.89. Found: C, 53.97; H, 7.36; N, 6.75; S, 24.76.

***N,N'*-Bis(3-cyano-4,5-dimethyl-2-thienyl)thiourea**—A solution of 2-amino-3-cyano-4,5-dimethylthiophene (5) (3.04 g., 0.02 mole) in 50 ml. of absolute ethanol was treated with carbon disulfide (42 ml., 0.06 mole). The yellow solution was stirred at room temperature for 2 days, and 0.95 g. (27%) of yellow compound was obtained which did not melt below 300°; IR (KBr) 1290 (C=S, thioamide), 2200 (C≡N) cm.⁻¹.

Anal.—Calcd. for C₁₅H₁₄N₄S₂: C, 52.0; H, 4.1; S, 27.7. Found: C, 51.7; H, 4.5; S, 27.5.

Triethylammonium 3-Cyano-4,5-dimethylfuran-2-dithiocarbamate—A solution of 3.1 g. (0.02 mole) of 2-amino-3-cyano-4,5-dimethylfuran (9), 60 ml. (0.44 mole) of triethylamine, and 32.5 ml. (0.44 mole) of carbon disulfide was stirred at room temperature for 2 weeks. The orange solid was triturated with absolute ethanol, giving 0.64 g. (9%) of compound which slowly decomposed on standing; m.p. 195–200° dec.; IR (KBr) 880 (β-ring), 1145 (C=S) cm.⁻¹.

Anal.—Calcd. for C₁₄H₂₃N₂OS₂: C, 53.7; H, 7.3; N, 13.3; S, 20.4. Found: C, 53.3; H, 7.4; N, 12.7; S, 20.5.

Triethylammonium 3-Cyano-4,5-diphenylthiophene-2-dithiocarbamate—A solution of 2.28 g. (0.009 mole) of 2-amino-3-cyano-4,5-diphenylfuran (9), 10.5 ml. (0.150 mole) of carbon disulfide, 19.1 ml. (0.138 mole) of triethylamine, and 6 ml. of absolute ethanol was allowed to stand at room temperature for 2 weeks. A yield of 0.61 g. (15%) of orange crystals was obtained; m.p. 256–258°; IR (KBr) 987 (C=S), 2050 (C≡N) cm.⁻¹.

Anal.—Calcd. for C₂₄H₂₉N₂S₃: C, 63.5; H, 6.0; N, 9.2; S, 21.2. Found: C, 63.4; H, 5.8; N, 9.0; S, 20.7.

Bis(triethylammonium)-3-carbethoxy-2-dithiocarbamate-4-thienyl-trithiocarbonate—A solution of 7.3 g. (0.06 mole) of 1,3-dimercaptoacetone and 6.8 g. (0.06 mole) of ethyl cyanoacetate in 30 ml. of absolute ethanol was treated with 3 ml. of triethylamine. After 15 min., 35 ml. (0.47 mole) of carbon disulfide and 45 ml. (0.30 mole) of triethylamine were added; the solution was stirred for 1 hr. and allowed to stand overnight at room temperature. A red oil was separated and crystallized by the addition of 200 ml. of absolute ethanol. After being stirred for 2 hr., the yellow product (10.8 g., 31%) was isolated; m.p. 106–108°; IR (KBr) 1010 (C=S), 1125 (C=S), 1670 (C=O) cm.⁻¹.

Anal.—Calcd. for $C_{22}H_{11}N_3O_3S_6$: C, 46.20; H, 7.23; N, 7.35; S, 33.64. Found: C, 45.97; H, 7.05; N, 7.05; S, 33.62.

Bis(2-amino-3-cyano-4-methyl-5-thienyl)sulfide—A mixture of 58 g. (1 mole) of acetone, 13.2 g. (0.2 mole) of malononitrile, and 6.4 g. (0.2 g. atom) of sulfur was treated dropwise with 20 ml. of triethylamine. The mixture was stirred at 30–35° for 7 hr. and allowed to stand at room temperature for 36 hr. After addition of 400 ml. of aqueous ethanol (1:1) and vigorous stirring, a tan, crystalline product was obtained which was extracted with boiling ethanol, giving 1.85 g. (3%) of product; m.p. 255–257°.

Anal.—Calcd. for $C_{12}H_{10}N_4S_2$: C, 47.03; H, 3.29; N, 18.28; S, 31.39. Found: C, 47.14; H, 3.38; N, 18.15; S, 31.28.

4-Amino-5,6-dimethylthiopheno[2,3-*d*]pyrimidine—A mixture of 3.04 g. (0.02 mole) of 2-amino-3-cyano-4,5-dimethylthiophene (5), 30 ml. of formamide, and two drops of acetic anhydride was refluxed at 160–165° for 2 hr. After being cooled, a solid product was isolated and recrystallized from dioxane, giving 1.48 g. (39%) of white crystals; m.p. 261–263°; IR (KBr) 1650 (NH_2), 3400 (NH_2) cm^{-1} .

N-Substituted Aminoethanethiols and N-Substituted Aminoethanethiol S-Sulfonic Acids as Radioprotective Agents

F. I. CARROLL and MONROE E. WALL

Abstract □ Several *N*-substituted aminoethanethiols and *N*-substituted aminoethanethiol *S*-sulfonic acids were tested as potential radioprotective agents. 2-(2'-Carbamidoethylamino)-ethanethiol (Ia), 2-(2'-carboxyethylamino)-ethanethiol (Ib), 2-(2'-cyanoethylamino)-ethanethiol (Ic), and 2-(2'-carbamidoethylamino)-ethanethiol *S*-sulfonic acid (IIa) exhibited significant protective effects against ionizing radiation. Compound Ia showed the highest activity and was selected for further radiation-protection test studies. The structure-activity relationships of this class of compounds are discussed.

Keyphrases □ Aminoethanethiols, *N*-substituted—radioprotective capacity, structure-activity relationships □ Aminoethanethiol *S*-sulfonic acids, *N*-substituted—radioprotective capacity, structure-activity relationships □ Radioprotective agents—aminoethanethiols, aminoethanethiol *S*-sulfonic acids, *N*-substituted

A recent list of the various types of compounds that show radioprotective properties has appeared and their structure-activity relationships have been discussed (1). Aminoalkylthiols constitute the most effective class of radioprotective agents. The initial discovery

that 2-mercaptoethylamine (MEA) offered protection to mice against ionizing radiation (2) led to the synthesis of several hundred derivatives of this compound. Structural requirements necessary for radioprotective activity have evolved from the test results on these compounds and have been summarized (1). This effect was not observable when one or two alkyl substituents were placed on the carbon containing the thiol-function of MEA (3, 4).¹ Subsequently, it was found that some *N*-substituted aminoethanethiols and *N*-substituted aminoethanethiol *S*-sulfonic acids, prepared in this laboratory, showed significant protection against ionizing radiation. In this report the radioprotection test results on these compounds are presented, and their structure-activity relationships are discussed.

¹ Subsequent antiradiation test results have shown that 2-mercapto-2-methylaminopropane hydrochloride, when administered at 90 mg./kg. i.p. using CMCTW as vehicle, gave 67% survival to mice irradiated with 825 r. (See footnotes to Table II for explanation of test data.)

N-Substituted Aminoethanethiols and N-Substituted Aminoethanethiol S-Sulfonic Acids as Radioprotective Agents

F. I. CARROLL and MONROE E. WALL

Abstract □ Several *N*-substituted aminoethanethiols and *N*-substituted aminoethanethiol *S*-sulfonic acids were tested as potential radioprotective agents. 2-(2'-Carbamidoethylamino)-ethanethiol (Ia), 2-(2'-carboxyethylamino)-ethanethiol (Ib), 2-(2'-cyanoethylamino)-ethanethiol (Ic), and 2-(2'-carbamidoethylamino)-ethanethiol *S*-sulfonic acid (IIa) exhibited significant protective effects against ionizing radiation. Compound Ia showed the highest activity and was selected for further radiation-protection test studies. The structure-activity relationships of this class of compounds are discussed.

Keyphrases □ Aminoethanethiols, *N*-substituted—radioprotective capacity, structure-activity relationships □ Aminoethanethiol *S*-sulfonic acids, *N*-substituted—radioprotective capacity, structure-activity relationships □ Radioprotective agents—aminoethanethiols, aminoethanethiol *S*-sulfonic acids, *N*-substituted

A recent list of the various types of compounds that show radioprotective properties has appeared and their structure-activity relationships have been discussed (1). Aminoalkylthiols constitute the most effective class of radioprotective agents. The initial discovery

that 2-mercaptoethylamine (MEA) offered protection to mice against ionizing radiation (2) led to the synthesis of several hundred derivatives of this compound. Structural requirements necessary for radioprotective activity have evolved from the test results on these compounds and have been summarized (1). This effect was not observable when one or two alkyl substituents were placed on the carbon containing the thiol-function of MEA (3, 4).¹ Subsequently, it was found that some *N*-substituted aminoethanethiols and *N*-substituted aminoethanethiol *S*-sulfonic acids, prepared in this laboratory, showed significant protection against ionizing radiation. In this report the radioprotection test results on these compounds are presented, and their structure-activity relationships are discussed.

¹ Subsequent antiradiation test results have shown that 2-mercapto-2-methylaminopropane hydrochloride, when administered at 90 mg./kg. i.p. using CMCTW as vehicle, gave 67% survival to mice irradiated with 825 r. (See footnotes to Table II for explanation of test data.)

METHOD

The synthesis of all the compounds listed in Tables I and II has been reported previously (5, 6). The irradiation was performed utilizing either a 300-kvp. GE Maxitron Unit, dose rate in air 45 r/min., or a ^{60}Co irradiator, which contained a 1200-c. source, with dose rate between 100–50 r/min. (7). Female mice of the Walter Reed Bagg Swiss or Inbred Charles River (ICR) strain, 5–6 weeks old and weighing 21–25 g., were used. Forty mice were exposed to whole body lethal irradiation. Equal numbers of control mice injected with only the vehicle used for the particular drug evaluation were irradiated simultaneously. The mice were exposed in a perforated Lucite dish which rotated continuously during exposure. A 30-day period for survival was observed. All control animals died before the 21st day following exposure. Survival of treated mice was interpreted as good (>45% survival), fair (25–44% survival), slight (1–24% survival), and none (0% survival).²

RESULTS AND DISCUSSION

Structure–activity relationship studies on MEA and its derivatives have established that the presence of a basic function and a free thiol group or function readily convertible to a free thiol *in vivo* is necessary for high radioprotective effect. Alkylation of the amino group of MEA gives compounds with varied activities. Simple *N,N*-dialkyl derivatives of MEA exhibited little or no effect, whereas significant effects were observed in *N*-(2'-phenethylamino)-ethanethiol and *N*-(2'-thienylethylamino)-ethanethiol (8). Good radioprotection was also found in several other *N*-substituted aminoethanethiols. The results are summarized in Table I. Significant activity was observed in the case of the 2-carbamidoethyl derivative (Ia), 2-carboxyethyl derivative (Ib), or 2-cyanoethyl derivative (Ic), and the activity was considerably reduced with the 2-carbethoxyethyl derivatives (Id and Ie). This reduction of activity could possibly be connected with the ester function, since several other ester derivatives (If–k) offered either slight activity or no effect at all.

A similar structure–activity relationship was also observed in the *N*-substituted aminoethanethiol *S*-sulfonic acids: good activity when the *N*-alkyl group was 2-carbamidoethyl (IIa) and reduced activity when a methyl group was placed alpha to the amide func-

tion, *N*-alkyl equal 2-carbamidopropyl (II*d*). Placement of alkyl substituents on the amide nitrogen, Compounds II*b* and II*c*, resulted in a complete loss of activity. With the exception of Compound II*e*, which showed only slight activity, the remaining compounds were inactive.

The good radioprotective property of Compounds Ia–c and IIa, with their relatively low toxicity, has created additional interest in these agents. In particular, the amide (Ia) that showed the highest activity was selected for further radioprotection studies.

The *S*-triphenylmethyl derivative (III) of Ia was tested for potential latent antiradiation activity but proved to be completely inactive.

Drug Absorption from the Rectum III: Aspirin and Some Aspirin Derivatives

WERNER LOWENTHAL, JOSEPH F. BORZELLECA, and CHARLES D. CORDER, Jr.

Abstract □ The rectal absorption of aspirin, aluminum aspirin, and calcium carbaspirin was studied in dogs. Cocoa butter, polysorbate 61, polyethylene glycol mixture, and a mixture of natural saturated vegetable fatty acid glycerides were the bases used. The areas under the plasma concentration-time curves, peak salicylate levels, and the time the peak levels occurred were used as the criteria for comparison. The absorption of aluminum aspirin from cocoa butter and the polyethylene glycol mixture was poor. Plasma salicylate levels from aspirin and calcium carbaspirin in the polysorbate 61 base were minimal. The highest peak and largest area under the curve were seen with calcium carbaspirin in vegetable fatty acid glycerides base. The commercial aspirin product had the lowest peak and smallest area under the curve but the earliest peak. The two latest peaks in salicylate plasma levels were observed following the use of cocoa butter base suppositories. No conclusions can be reached concerning any differences in absorption of aspirin or calcium carbaspirin in the various bases or the commercial aspirin product.

Keyphrases □ Drug absorption—aspirin, derivatives, rectum, dog □ Aspirin, derivatives—drug absorption, rectum, dog □ Rectal absorption, dog—aspirin, derivatives □ Suppositories, absorption— aspirin, derivatives, dog

Suppositories resemble a type of sustained-release tablet where it is desired that the matrix rapidly disintegrates. The drug is incorporated into a wax-type matrix which can be either hydrophilic, such as polyethylene glycol waxes, or hydrophobic, such as cocoa butter. With this in mind, one would expect the ordinary suppository to release the drug more slowly than a rapidly disintegrating tablet. This should result in slower absorption and possibly a lower peak. In addition, there is relatively little fluid present in the rectum compared to the stomach and intestine. As a result, as the suppository matrix liquifies, the drug is diffused through a viscous medium to get to the absorbing membrane. This also decreases the rate of absorption and may explain the erratic and incomplete absorption that occurs in the rectum.

Aspirin suppositories became official in the USP XVII and are widely used. Coldwell and Boyd (1) reported that LD_{50} of rectally administered suppositories to male albino rats was significantly less than the LD_{50} of orally administered aspirin.

Only a few *in vivo* studies have been reported (2). Thomsen (3) indicated that polysorbate 60 at 20% concentration modified aspirin absorption from a mixture of natural saturated vegetable fatty acid glycerides base.¹ The surfactant caused an earlier peak level. Coldwell *et al.* (4) studied the effect of dosage form and route of administration on the absorption and excretion of aspirin in 10 human volunteers. Results indicated that oral absorption from tablets (640 mg.) pro-

ceeded uniformly with a peak in 2 hr. Absorption from suppositories (640 mg.) was more variable. Aspirin tablets given rectally had lower levels and gave erratic blood level patterns. The rate of disappearance of salicylate from plasma was slower for the rectal route than the oral route. No salicylate could be detected in the plasma following administration of an aspirin suspension rectally. Recovery of salicylate from urine was less for the tablets and the suspension given rectally than for tablets given orally or for aspirin rectal suppositories. Neuwald and Kunze (5) found that *in vitro* dissolution tests with suppositories were misleading and did not predict *in vivo* absorption.

Since there is a potential bioavailability problem with rectal suppositories and due to the potential toxic hazard, especially in children, it was decided to investigate the effects of various bases on the absorption of aspirin, aluminum aspirin,² and calcium carbaspirin (calcium aspirin carbamide).³

Aspirin is soluble to the extent of 1 g. in 100 ml. water at 37° (6); aluminum aspirin NF is "insoluble"; and 1 g. calcium carbaspirin dissolves in 4.33 ml. of water at 20° (7). These were used to represent aspirin compounds with three different solubilities. The rate of absorption and the amount absorbed are dependent upon the rate of release of the drug from the dosage form matrix and the rate of solution of the drug in the rectum. To evaluate these factors, the three forms of aspirin were incorporated in four different suppository bases. The bases were: (a) cocoa butter USP;⁴ (b) a mixture containing partial glycerides or triglycerides of natural saturated vegetable fatty acids of C_{12-18} chain length with m.p. 33.5–35.5°, saponification value of 220–230, iodine value (Kaufman) of >7, and a hydroxyl value of 50–56¹ (S-55); (c) polysorbate 61 [polyoxyethylene (4) sorbitan monostearate];⁵ and (d) a mixture of polyethylene glycols (PEG).

Cocoa butter and S-55 are hydrophobic bases melting below the normal body temperature of humans and dogs. Cocoa butter is widely used and may be considered a "standard" against which other bases are compared. S-55 represents the new synthetic bases which are being used as cocoa butter substitutes. Polysorbate 61 is a tan waxy solid, dispersible in water, with a pour-point of approximately 38° and a hydrophile-lipophile balance of 9.6, and represents the nonionic surfactant type of base. The polyethylene glycol mixture is a water-soluble base but does not melt at normal body temperature.

Figure 1—Plasma salicylate levels for cocoa butter base suppositories. A, aspirin, standard deviation (—); B, calcium carbaspirin, standard deviation (—).

As a result, three different drugs were to be studied in four different bases, resulting in 12 different products. A commercial aspirin product in a water-soluble base was included for comparative purposes.

EXPERIMENTAL

Procedures and Methods—These were the same as those previously reported (2). The dogs used weighed between 11.3 and 14.5 kg. Dogs were used in this study because of their larger size and because the rectal physiology of the dog and the human are similar. Four or five dogs were used for each preparation.

Analytical Procedure—These were the same as those previously reported (2).

Figure 2—Plasma salicylate levels for S-55 base suppositories. A, aspirin, standard deviation (—); and B, calcium carbaspirin, standard deviation (—).

Figure 3—Plasma salicylate levels for PEG mixture suppository base and the commercial aspirin product. A, aspirin, standard deviation (—); B, calcium carbaspirin, standard deviation (—); and C, commercial aspirin product, standard deviation (—).

Suppository Formulation—Aspirin⁶ USP comminuted through an 80-mesh screen, aluminum aspirin² NF, and calcium carbaspirin³ were used. The suppositories were made by the hot-melt method using metal molds. Drug displacement in the four bases was first determined, and the amount of base required was calculated (8). The drugs were mixed with the melted base and poured into molds; the molten mass was allowed to solidify in a refrigerator. The suppositories were removed from the molds and stored in a refrigerator in a well-closed container until used. The same molds were always used. The PEG base was made from 6 parts polyethylene glycol 1540⁷ and 4 parts polyethylene glycol 6000⁷.

A 330-mg. dose of aspirin base or equivalent amounts of aluminum aspirin and calcium carbaspirin were used. This dose was lower than the one used in the previous study. This was deemed necessary to reduce the interference by the biotransformation systems (9).

RESULTS AND DISCUSSION

Aluminum aspirin was poorly absorbed from cocoa butter and PEG bases, and in two dogs no salicylate could be detected. When salicylate was detected in the plasma, its appearance was later than either the aspirin or calcium carbaspirin. Due to the insignificance of the low levels obtained, the data were not tabulated. The peak was about 1.21 mg. % in 4-7 hr. in cocoa butter and about 0.81 mg. % in 3-7 hr. in PEG base.

Calcium carbaspirin in polysorbate 61 base caused defecation and expulsion of the suppositories in 3 out of 4 dogs. Although there was no visual evidence of damage to the mucosa nor was any bleeding evident, irritation may have occurred and could have caused expulsion. Aspirin in polysorbate 61 base did not cause defecation, but the suppository or parts of it was removed in 3 out of 4 dogs. Again there was no visual evidence of mucosal damage or blood. The salicylate levels for these two products were very low and were not tabulated because they would be of doubtful value. The peak level for calcium carbaspirin was 1.84 mg. % in 8 hr., for aspirin it was 1.74 mg. % in 4-8 hr.

Individual dogs were fairly consistent in the salicylate levels they exhibited after administration of the various products; e.g., dogs that showed high salicylate levels generally did so for all products.

Table I—Data from Graphical Concentration of Salicylate in Plasma-Time Plots

Preparation	Area under Curve, mg./hr.	Peak Level	
		Height, ^a mg. %	Time, ^a hr.
Aspirin-cocoa butter	26.1	4.10 (2.85-6.27)	6(3-7)
Calcium carbaspirin-cocoa butter	21.9	3.46 (2.85-4.40)	6(4-6)
Aspirin-commercial product	18.9	2.94 (1.86-3.70)	3(2-4)
Aspirin-PEG	24.9	3.80 (2.77-4.95)	3(3-4)
Calcium carbaspirin-PEG	23.8	4.12 (3.28-4.91)	5(4-6)
Aspirin-S-55	21.7	3.27 (2.48-4.30)	4(2-5)
Calcium carbaspirin-S-55	29.0	4.56 (2.95-6.39)	3(3-4)

^a Obtained by averaging data for individual dogs. Numbers in parenthesis are the ranges.

The average salicylate levels at the various sampling intervals and the standard deviations are shown in Figs. 1-3. As can be seen, there are no trends or consistencies among the drugs or bases.

Areas under the curves were determined with a planimeter.⁸ These findings, together with the height of the peaks and time the peak levels occurred, are given in Table I. Using this information the products were ranked in the following ways: (a) order of decreasing area under the curves; (b) order of decreasing peak height; and (c) order of increasing length of time for peak blood level to occur.

Decreasing Area under the Curve:

1. Calcium carbaspirin-S-55
2. Aspirin-cocoa butter
3. Aspirin-PEG
4. Calcium carbaspirin-PEG
5. Calcium carbaspirin-cocoa butter
6. Aspirin-S-55
7. Commercial aspirin product

Decreasing Height of Peak:

1. Calcium carbaspirin-S-55
2. Calcium carbaspirin-PEG
3. Aspirin-cocoa butter
4. Aspirin-PEG
5. Calcium carbaspirin-cocoa butter
6. Aspirin-S-55
7. Commercial aspirin product

Time Peak Occurs:

1. Commercial aspirin product
2. Calcium carbaspirin-S-55
3. Aspirin-PEG
4. Aspirin-S-55
5. Calcium carbaspirin-PEG
6. Calcium carbaspirin-cocoa butter
7. Aspirin-cocoa butter

From these rankings the following conclusions can be made:

1. Calcium carbaspirin in S-55 base has the highest peak and the largest area under the curve but only the second earliest peak.
2. The commercial aspirin suppositories in a water-soluble base had the smallest area under the curve and the lowest peak height, but the peak occurred earliest.
3. Calcium carbaspirin in cocoa butter base ranked fifth in area under the curve and peak height and sixth in time of occurrence of the peak.
4. Aspirin in S-55 base ranked sixth in area under the curve and height of peak level but was fourth in time that the peak level occurred.
5. The two latest peaks in salicylate blood levels were observed following the use of cocoa butter base suppositories.

No conclusions can be made concerning any difference in absorption of aspirin or calcium carbaspirin in cocoa butter, PEG, or

the synthetic fatty base. Aluminum aspirin appears to be only poorly absorbed from the rectum in 8 hr. The reasons may be the insolubility of the salt and the lack of fluid to dissolve it. Also the reason postulated by Levy and Procknal (10) that a protective gel forms around the drug to reduce its bioavailability may also occur in the rectum. Polysorbate 61 appears to cause irritations resulting in expulsion of the suppositories, although absorption from this base does occur. There was no visual evidence of tissue damage or bleeding due to polysorbate 61. The results here do confirm those of Neuwald and Kunze (5) who reported that aspirin and calcium salicylate absorption was identical. The peak blood levels were of similar height. Cummings *et al.* (11) reported that a polymeric condensation product of Al_2O_3 and aspirin from the interaction of aluminum isopropoxide and aspirin was absorbed equally well as was aspirin after oral administration. Absorption of the aluminum aspirin was delayed about 0.5 to 1 hr, but the total salicylate excreted in the urine was the same for the two products. This aluminum aspirin compound should also be tested for rectal absorption.

Preparation and Biological Activity of Substituted 1,3-Distyryl-4,6-dinitrobenzenes

Keyphrases ☐ 1,3-Distyryl-4,6-dinitrobenzenes—synthesis ☐ Cytotoxic, antimicrobial activity—1,3-distyryl-4,6-dinitrobenzenes

Sir:

In 1931, it was shown by Ruggil *et al.* (1) that one molecule of 4,6-dinitro-1,3-xylene (I) condensed with two molecules of benzaldehyde to give 1,3-distyryl-4,6-dinitrobenzene (II) (Scheme I). As an extension of this approach, we studied the condensation of a variety of

Scheme I

substituted aromatic aldehydes with 4,6-dinitro-1,3-xylene. The condensations were conducted by heating under reflux a solution of the appropriate aromatic aldehyde (0.2 mole), Compound I (0.1 mole), and piperidine (10 ml.) for 20–90 min. at 150–160°. The reaction mixture was diluted with a large volume of benzene or

III _g	R ₂ = OH, R ₃ = OCH ₃	0.648

^a See Table I for Structure III.

75% ethanol, and the crystalline products (III) (Table I) were isolated by filtration and drying. The yields of 1,3-distyryl-4,6-dinitrobenzenes ranged between 40 and 60% and furnished satisfactory elemental (C, H, and N) analyses.

These compounds were examined for their antimicrobial activities (2). In these tests, the microorganisms were grown in agar media. The compounds to be tested were dissolved in acetone at concentrations of 1 mg./ml. and applied to paper disks of 13-mm. diameter. After incubation, the diameters of the zones of growth inhibition were measured. The compounds which showed significant antimicrobial activity are given in Table I.

Some of these compounds were also subjected to L-1210 *in vitro* assay for cytotoxic activity (3). In these screening experiments, the samples were weighed (about 5–10 mg.) into glass homogenizers (12-ml. size) sterilized with 0.1 ml. of 70% ethanol and about 0.1 ml. dimethylsulfoxide (DMSO) was added to help solubilize. The sample was ground with sterile water to make a suspension containing L-1210 leukemic cells. The tubes were stoppered and incubated at 37° for 3 days; then cell counts were made on each tube by a Coulter counter. The percent inhibition and the ID₅₀ values were calculated. Values of 1 or less for ID₅₀ were considered potentially

Observations on the Micelle Formation of 2-Butyl-3-benzofuranyl-4-[2-(diethylamino)ethoxy]-3,5-diiodophenyl Ketone Hydrochloride (SK&F 33134-A) by NMR Spectroscopy

Keyphrases □ 2-Butyl-3-benzofuranyl-4-[2-(diethylamino)ethoxy]-3,5-diiodophenyl ketone hydrochloride (SK&F 33134-A)—micelle formation □ Critical micelle concentration—SK&F 33134-A □ NMR spectroscopy—micelle formation determination

Sir:

In recent years, several papers (1-3) have dealt with the use of high-resolution NMR for the determination of CMC. In our laboratories, we have used NMR to show the existence of micelles in a 5% aqueous solution of SK&F 33134-A(I).¹ Micelle formation has not previously been reported for this system.

All measurements were carried out with a Jealco C60H NMR spectrometer equipped with a variable

temperature probe. Spectra were recorded at temperatures ranging from 25 to 95°. Figure 1 illustrates the NMR spectrum for a 5% solution of SK&F 33134-A in D_2O at 25°. There are no sharp resonance lines as one would expect under normal conditions. Instead, there is a large broadening effect of all resonance lines. We attribute this broadening to dipolar interaction in the micellar structure where molecular motion is se-

Figure 2—A plot showing the effect of temperature on the resolution (peak width at half-height) at 504 c.p.s. for a 5% solution of SK&F 33134-A in D_2O .

Figure 3—NMR spectrum for SK&F 33134-A solution diluted with methanol- d_4 .

verely inhibited. Raising the temperature of this solution in small increments and recording the NMR spectra at selected temperature intervals resulted in spectra having increasing resolutions, with corresponding increases in signal intensities. The spectrum for SK&F 33134-A at 75° is also shown in Fig. 1. The sharpening of the spectrum with an increase in signal intensity suggests the gradual breakdown of the micellar structure as the temperature increases. The resolution reaches its maximum at approximately 60°. We assume that the micellar structure is completely disrupted at this temperature. The effect is further illustrated in Fig. 2, which contains a plot of band width at half-height of the aromatic protons on the iodinated benzene ring at 504 c.p.s. (resolution) versus temperature. The fact that band width at half-height reaches a minimum constant value at approximately 60° again illustrates the apparent breakdown of the micellar structure at this temperature.

Water-miscible organic solvents have been shown to have some effect on micelle formation (4). Figure 3 illustrates the effect of the addition of methanol- d_4 to the micellar solution of SK&F 33134-A at 25°. The NMR spectrum becomes highly resolved, indicating that the micelle has been disrupted.

Figure 4—Plot showing the effect of temperature on the specific conductance of a 5% aqueous solution of SK&F 33134-A.

To substantiate the effect of temperature on the micellar state of SK&F 33134-A, conductivity studies were done over the same temperature range. A Serfass conductivity bridge, model RCM15B1, and a Beckman K 1.00/cm. conductivity cell were used. An aqueous solution of SK&F 33134-A was poured into two small jacketed glass vessels connected to each other and to a constant-temperature bath. The conductivity cell was immersed into one vessel and a thermometer into the other vessel. The temperature of the water bath was increased slowly. The temperature and the conductivity of the test solution were recorded. The results are shown in Fig. 4. The conductivity increases gradually to 60° and then becomes relatively constant. These conductivity data are in good agreement with the NMR data, indicating the presence of micelles at 25° and the subsequent complete destruction of the micelles as the temperature is increased. In both cases the temperature effect is reversible.

Imidazole and Pyrazole Bis(2-fluoroethyl)triazenes

Keyphrases ☐ Bis(2-fluoroethyl)triazene derivatives—synthesis ☐
Antileukemic activity—triazenoimidazoles

Sir:

Among a considerable number of 5-(disubstituted-triazeno) and 5-(monosubstituted-triazeno) derivatives of imidazole-4-carboxamide and of imidazole-4-carboxylic acid esters tested against lymphoid leukemia L-1210, 5-[3,3-bis(2-chloroethyl)-1-triazeno]imidazole-4-carboxamide (I, NSC-82196) has proved to be the most effective. In certain of the standard L-1210 tests, a majority of the afflicted mice treated with NSC-82196

I: Y = NH₂; X = Cl
 II: Y = NH₂; X = F
 III: Y = OCH₃; X = F

IV: Y = NH₂; X = F
 V: Y = OC₂H₅; X = F

The data in Table I show that the two bis(2-fluoroethyl)triazenoimidazoles (II and III) increased the lifespan of leukemic mice by 50–70% at tolerated doses. By way of comparison, the doses of NSC-82196 reported (1, 2) to be most effective are 300–625 mg./kg. for single-dose treatment and 50–100 mg./kg./day for daily treatment. The data appear to justify the following conclusions: (a) the bis(2-fluoroethyl)triazenes are more toxic than is NSC-82196; (b) at doses tolerated by the host animals, II and III are less effective than NSC-82196; and (c) in the standard L-1210 test system, the increases in lifespan caused by II and III are comparable to those produced by the corresponding dimethyltriazenes of the amide (NSC-45388) (8) and methyl ester (NSC-87982) (5) series.

Both the v-triazole (9) and the pyrazole (10) analogs of 5-(3,3-dimethyl-1-triazeno)imidazole-4-carboxamide (NSC-45388, DIC) cause significant increases in the lifespan of mice bearing L-1210, and other triazeno-pyrazole amides and esters have likewise demonstrated activity against L-1210 (7). However, in tests conducted in accordance with the protocols of the Cancer Chemotherapy National Service Center, amide IV displayed minimal activity, whereas the ethyl ester did not significantly increase survival time as a result of either the single-dose or the daily therapeutic regimens. Again, both are more toxic than NSC-82196.

Amides II and IV, like NSC-82196, undergo a change in aqueous solutions to ionic transformation products (11, 12), but the bis(2-fluoroethyl)triazeno derivatives are considerably more stable than NSC-82196. Esters III and V likewise undergo a change, presumed to be the same type. Obviously, the greater toxicity of II–V, in comparison with NSC-82196, may be due to replacement of chloro groups by fluoro groups. It is also conceivable that the lower toxicity of NSC-82196 results in part from its instability. If this is true, the instability may be advantageous.

The work described was supported by Contract No. PH43-64-51 from Chemotherapy, National Service Center, National Institutes of Health, U. S. Public Health Service. Elemental analyses and spectrophotometric determinations were performed under the supervision of Dr. W. C. Coburn, Jr., by members of the Molecular Spectroscopy Section of this Institute. Screening of Compounds II–V was performed under the auspices of Chemotherapy, National Service Center, Contract No. PH43-65-594, and under the supervision of Dr. F. M. Schabel, Jr., and Dr. W. R. Laster, Jr., of the Chemotherapy Department of this Institute.

Aggregation Mechanisms in Pharmaceutical Suspensions

Keyphrases ☐ Suspensions, pharmaceutical—aggregation mechanism ☐ Flocculation, coagulation—suspensions

Sir:

The method of prevention of impaction and caking in pharmaceutical suspensions by controlled flocculation is usually credited to Haines and Martin (1). The work of these authors is, however, sometimes quoted in review articles (2, 3) without reference to the important criticisms subsequently published by Wilson and Ecanow (4) and Ecanow *et al.* (5). We have endorsed (6) some of these criticisms, but have suggested that several generalizations proposed by Ecanow and his coworkers were based on inadequately controlled experiments. The purpose of this communication is to clarify some aspects of suspension theory recently commented upon by Ecanow *et al.* (7), since this area is of considerable importance to the pharmaceutical formulator.

We are grateful to Ecanow *et al.* (7) for amplifying some points in their earlier paper (5), since we had previously found that the almost complete absence of experimental data, such as particle size of the drug and concentration of electrolyte, made an adequate appraisal impossible. Despite the recent criticisms of these authors, we see no reason to retract from our claim that Figure 1 in *Reference 6* demonstrates differences between coagulation and flocculation. Ecanow and coworkers appear to have forgotten that suspensions of drugs in anionic surfactants (1, 8) and cationic and nonionic surfactants (9) in the absence of electrolyte cake on storage. The control suspension described in the uppermost curve of Figure 1 in *Reference 6* caked after ultimate sedimentation. However, we do not consider it semantically or scientifically helpful to refer to this process as coagulation for the following reason. If the particles were slightly smaller, they would remain in permanent colloidal suspension due to Brownian motion

I: Y = NH₂; X = Cl
 II: Y = NH₂; X = F
 III: Y = OCH₃; X = F

IV: Y = NH₂; X = F
 V: Y = OC₂H₅; X = F

The data in Table I show that the two bis(2-fluoroethyl)triazenoimidazoles (II and III) increased the lifespan of leukemic mice by 50–70% at tolerated doses. By way of comparison, the doses of NSC-82196 reported (1, 2) to be most effective are 300–625 mg./kg. for single-dose treatment and 50–100 mg./kg./day for daily treatment. Received March 12, 1970.

Accepted for publication May 22, 1970.

The work described was supported by Contract No. PH43-64-51 from Chemotherapy, National Service Center, National Institutes of Health, U. S. Public Health Service. Elemental analyses and spectrophotometric determinations were performed under the supervision of Dr. W. C. Coburn, Jr., by members of the Molecular Spectroscopy Section of this Institute. Screening of Compounds II–V was performed under the auspices of Chemotherapy, National Service Center, Contract No. PH43-65-594, and under the supervision of Dr. F. M. Schabel, Jr., and Dr. W. R. Laster, Jr., of the Chemotherapy Department of this Institute.

Aggregation Mechanisms in Pharmaceutical Suspensions

Keyphrases ☐ Suspensions, pharmaceutical—aggregation mechanism ☐ Flocculation, coagulation—suspensions

Sir:

The method of prevention of impaction and caking in pharmaceutical suspensions by controlled flocculation is usually credited to Haines and Martin (1). The work of these authors is, however, sometimes quoted in review articles (2, 3) without reference to the important criticisms subsequently published by Wilson and Ecanow (4) and Ecanow *et al.* (5). We have endorsed (6) some of these criticisms, but have suggested that several generalizations proposed by Ecanow and his coworkers were based on inadequately controlled experiments. The purpose of this communication is to clarify some aspects of suspension theory recently commented upon by Ecanow *et al.* (7), since this area is of considerable importance to the pharmaceutical formulator.

We are grateful to Ecanow *et al.* (7) for amplifying some points in their earlier paper (5), since we had previously found that the almost complete absence of experimental data, such as particle size of the drug and concentration of electrolyte, made an adequate appraisal impossible. Despite the recent criticisms of these authors, we see no reason to retract from our claim that Figure 1 in *Reference 6* demonstrates differences between coagulation and flocculation. Ecanow and coworkers appear to have forgotten that suspensions of drugs in anionic surfactants (1, 8) and cationic and nonionic surfactants (9) in the absence of electrolyte cake on storage. The control suspension described in the uppermost curve of Figure 1 in *Reference 6* caked after ultimate sedimentation. However, we do not consider it semantically or scientifically helpful to refer to this process as coagulation for the following reason. If the particles were slightly smaller, they would remain in permanent colloidal suspension due to Brownian motion

because of their high mutual repulsion. This is the *exact opposite* of coagulation in true colloids. The reason why the particles come together at the base of the container is that they sediment individually and roll over one another until they can go no farther. The repulsion only extends a short distance from the particle surface and is not sufficient to keep them far apart. We prefer to call this process "impaction," thus preserving what Chwala (10) called the "sedimentation paradox." The control suspension of Ecanow *et al.* (7) showed no sedimentation after 7 days due to the presence of glycerol. We would suggest, however, that if it were allowed to sediment, it would impact as did similar suspensions recently described (11). This is another reason why we feel that the inclusion of thickening agents in this type of study may mask important effects.

We naturally accept the statement by these authors that interactions between electrolytes and surfactants are concentration dependent and, if reference is made to our earlier paper (8), it will be found that the interaction of the ammonium salt of the same surfactant was tested under a wide range of electrolyte concentrations. Similar tests were also performed with the purer sodium salt used subsequently (6, 12). Only in much higher concentrations of electrolyte than were used did opalescence occur. We accept, of course, that there is bound to be interaction between ions of opposing charge in solution, whether they are surfactants or simple inorganic ions. Such interactions within the double layer are responsible for the reduction of ζ -potential and subsequent coagulation. Yet, we maintain that this type of interaction should not be called flocculation unless a definite precipitation of the surfactant-metal complex occurs, giving a continuous physical bridge between the particles. This would be analogous to the flocculation of colloids by starch polymer molecules described by La Mer (13). We would remind Ecanow *et al.* (5) that they used the precipitation effect as the decisive criterion for coagulation or flocculation.

We would also like to answer an earlier criticism, by Wilson and Ecanow (4), of the validity of the concept of flocculation (or rather coagulation) of large particles by ζ -potential reduction and van der Waals' attraction. They refer to the statement by Kruyt (14) of the possibility of long-range London-van der Waals' forces between particles of 2–5 μm . in diameter and the statement that such flocculation has not been experimentally verified.¹ Kruyt was referring to *secondary minimum* flocculation. This is only possible with intermediate concentrations of electrolyte, and we have shown (12, 15) that aggregation in the secondary minimum is unlikely to be the explanation of our results. We have produced calculated energy-of-interaction curves to show that coagulation is more likely in the primary minimum. The depth of this minimum is restricted by the film of surfactant at the solid-liquid interface and makes the suspension still readily redispersible. This is because particle-particle attraction is strong enough to maintain the open structure of the coagulum, although, as Ecanow

et al. (7) pointed out, such structures can be broken down by centrifuging.

The results of the work by Schenkel and Kitchener (16) on the coagulation of 10- μm . polymer particles show that, at the highest concentrations of electrolyte, rapid coagulation occurred, forming an open structure. In this case the particles seized on contact, since there was no film of surfactant at the interface.

We suggest that secondary minimum coagulation may be the cause of the effect noted by Ecanow *et al.* with the monovalent ions. Such coagulation would produce very loosely bound aggregates which would settle out more rapidly, but interparticulate forces might not be strong enough to maintain the open structure under the accumulating weight of the growing sediment. The wetting action of the surfactant would still be maintained and would assist the particles to slide over one another.

Calculations and carefully controlled measurements, similar to those previously published (12), may substantiate this point.

We would also like to question the distinction which Wilson and Ecanow (4) and Ecanow *et al.* (7) have made between hydrophobic and hydrophilic particles. The drug particles under consideration are fundamentally hydrophobic and, for this reason, need the presence of an adsorbed layer of amphiphilic surfactant to form suspensions. It is important to realize that the stabilizing effect of surfactant films only extends a comparatively short distance from the particle surface (17). For this reason, the diagrams published by Ecanow *et al.* (18) are so far from true scale as to be misleading.

It is accepted that, in suspensions of pharmaceuticals, Brownian motion is less important, but it is not, as Ecanow *et al.* (5) state, negligible. We have calculated (6, 11) that for an aqueous suspension of drug particles, Brownian motion was a greater source of displacement than sedimentation up to a diameter of 2 μm . For sizes above this value, differential sedimentation rates in polydisperse systems will also cause particle collisions and coagulation. Since, however, glycerol will slow down both Brownian motion and sedimentation, we still consider its use likely to complicate experiments designed to differentiate between aggregation mechanisms. We have also shown (9) that, in some systems, glycerol itself can cause aggregation. We have studied aggregation phenomena in model paracolloidal systems, using a Coulter counter and a digital computer (19–21). It is apparent that much of the theory developed for colloidal systems may, with certain modifications, be applied to dispersions of particles in the 2–10- μm . regions, this being a size range of peculiar importance to the pharmaceutical formulator. Our results indicate that there is no abrupt particle-size boundary between colloidal and paracolloidal systems but rather a gradual change of properties exists. With regard to the question of period of induction, it is important to stress that coagulation rate is number concentration dependent. Although a suspension may have a small proportion by weight of particles in the region where Brownian motion is important, this can be a significant proportion by number.

We have provided further evidence (12) that coagulation in our suspensions is qualitatively analogous to

¹ Experimental verification of secondary minimum flocculation has been published by Schenkel and Kitchener (16).

that in a lyophobic colloid.

We found that similar coagulation curves could be produced with sodium, calcium, and aluminum salts and that the only real difference was in the position of the vertical region of the sigmoid curve (12). The effect of valency was approximately as would be predicted by the Schulze-Hardy rule. The suspensions coagulated with the calcium chloride were particularly interesting since, with the highest concentration of electrolyte used, a further step in the sedimentation height curve was observed. Compatibility tests between the electrolyte and surfactant showed that, at this concentration, slight precipitation occurred. We interpret this as being perhaps the point of transition between coagulation and flocculation.

Ecanow *et al.* (5, 7, 18) appear to argue that since coagulation and flocculation must produce qualitatively different results and that we merely found quantitative differences, we could not be studying two different phenomena. We find it difficult to answer such circular reasoning. We would still maintain, on the basis of carefully controlled experiments whose results are compared with fundamental theory, that both coagulation and flocculation can produce suspensions that remain free from caking on storage.

Effect of Macromolecules on Aqueous Solubility of Cholesterol

Keyphrases ☐ Cholesterol, cholesterol-26-¹⁴C solubility—macromolecule effects ☐ Macromolecular substances—cholesterol solubility effect ☐ Pectin, acacia, dextrans effect—cholesterol solubility ☐ Scintillometry—analysis

Sir:

Intravenous administration of dextran solution has been suggested for treatment of hypercholesterolemia and atherosclerosis (1), and numerous investigations have been carried out to determine the effect of dextran on experimental hypercholesterolemia (2-6). Oral administrations of pectin and acacia have been studied for their hypocholesterolemic effects (7-14). The cited reports contain various and conflicting statements concerning the *in vivo* effect, value, and mechanisms of action of macromolecular substances for lowering serum cholesterol. However, there have been no reports of studies conducted to determine the *in vitro* effects of these carbohydrate macromolecules on the solubilization of cholesterol. It was, therefore, considered desirable to study the effect of these macromolecules on the aqueous solubility of cholesterol.

Cholesterol concentrations were determined using a radioactive technique suitable for very low amounts of cholesterol in water. A 10.0-ml. volume of a benzene stock solution, containing 10 mcg. of cholesterol and 0.1 μ c. of cholesterol-26-¹⁴C/ml., was transferred to a 125-ml. iodine flask, and the solvent was evaporated under a mild stream of nitrogen with constant shaking. A 50-ml. volume of the aqueous solution of the particular macromolecular substance was added to the flask. The dissolution studies were carried out at $30 \pm 0.5^\circ$, and the test solutions were agitated using magnetic stirrers. At predetermined intervals of time, samples were withdrawn from the system and filtered immediately through a Millipore filtration assembly containing 0.45- μ filter paper. An accurately measured 0.20-ml. volume of the particle-free filtrate was pipeted into a liquid-scintillation vial. To this was added 15 ml. of dioxane-naphthalene phosphor (15), and the vials were shaken for 30 sec. to ensure thorough mixing. Duplicate samples, along with appropriate standards and blanks, were counted directly using a liquid-scintillation system.¹ The counts per minute involved after 12 hr. were between 150 and 415.

The data from the solubility studies are illustrated in Fig. 1. Each point on the solubility curves represents an average of at least eight determinations. Pectin (0.5%) and acacia (0.5%) solutions significantly increased the aqueous solubility of cholesterol, while slight increases were observed for the solubility of cholesterol in dextran solutions. The results for both high and low molecular weight dextrans² were similar.

The results for both high and low molecular weight dextrans² were similar.

¹ Unilux II, Nuclear Chicago.

² Dextran T70 and T40, Pharmacia Laboratories.

Figure 1—Effect of various macromolecules on the aqueous solubility of cholesterol at 30°. Key: 1, water; 2, 6% dextran; 3, 10% dextran; 4, 0.5% acacia; and 5, 0.5% pectin.

Statistical analyses of the data by means of *t* and *F* tests at 95% confidence levels indicate the differences in solubilities between various test solutions to be significant.

It is well known that dextran, pectin, and acacia form colloidal solutions. It is possible that cholesterol might be suspended, dispersed, or adsorbed on these colloidal particles. Another possibility is that these macromolecules might entrap the relatively smaller molecule of cholesterol. Brintzinger and Beier (16) suggested a number of mechanisms for the ability of gum acacia to increase the solubility of substances such as benzoic acid, anisic acid, sulfanilic acid, strychnine, and nitroaniline. The suggested mechanisms included adsorption on the acacia micelle, solution in the micelle, adsorption exchange between the added substance and water of hydration, and formation of chemical bonds.

The large increase in the apparent solubility of cholesterol in 0.5% pectin solution is most interesting when related to the findings of Wells and Ershoff (8). They found that pectin inhibited the increase in liver cholesterol following cholesterol feeding of rats, even when the rats were fed on alternate days with cholesterol. These authors suggested that more is involved than the simple tying up of cholesterol (possibly by the formation of a nonabsorbable pectin-cholesterol complex). Another possibility they suggested was that pectin induces changes in the intestinal flora which result in greater degradation of cholesterol, thereby leaving less of this material available for absorption. The present finding that pectin increases cholesterol solubility suggests the possibility that cholesterol in a solubilized form might be more susceptible to degradation in the intestine. Other possibilities are that cholesterol is adsorbed or dispersed in the colloidal particles formed by pectin or that a water-soluble complex is formed which is nonabsorbable. The fact that significant increases in the solubility of cholesterol in acacia and

pectin solutions were observed after 24 hr. suggests that there may be more than one mechanism.

Since in the current studies the solubility of cholesterol was greatly increased in acacia and pectin solutions, it would appear that acacia might have the same *in vivo* cholesterol-lowering effect as pectin. However, Lin *et al.* (7) reported that addition of pectin to a basal diet containing cholesterol increased the excretion of exogenous cholesterol, while the addition of acacia or arabinose to this ration produced practically no change in the amount of fecal lipids and in the recovery of exogenous cholesterol in the feces.

Flotte and Buxton (2, 3) and Ditzel and Dyerberg (6) observed that administration of dextran has a profound effect in lowering serum cholesterol. Ditzel and Dyerberg discussed the possible modes of action of dextran on plasma lipids and cholesterol. They postulated that a dextran-lipid complex might influence cholesterol synthesis or breakdown or facilitate cholesterol transport through the cell membranes by altering its solubility characteristics or charge. Rothschild *et al.* (17) postulated that the mode of action of dextran might be explained by a stimulating effect on the reticuloendothelial system. The current findings suggest that dextran might facilitate at least part of the transport redistribution of cholesterol by an increase in the apparent solubility of cholesterol.

Further investigations are being conducted to determine the effect of a variety of macromolecules on the aqueous solubility of cholesterol and related hormone drugs and to elucidate the mechanism(s) of action of solubilization phenomena.

Objective Visual Evaluation of the Relative Content of Major and Minor Defects in Tablets and Capsules

Keyphrases □ Tablets, capsules—relative defect determination □ Defects, tablets and capsules—visual determination method

Sir:

Recently, it became desirable for our Quality Control Department to develop and subsequently implement a reasonably objective analysis for the evaluation of major and minor physical defects in tablets and capsules. The results would then be used to determine if additional processing was required prior to packaging.

Even though major and minor physical defects are routinely monitored by most pharmaceutical manufacturers, we were unable to find a reference regarding a test method in the literature. Consequently, a visual method has been developed which allows for the monitoring of major and minor physical defects in tablets and capsules.

Basically, the method consists of filling a rectangular plastic (Plexiglas) tray, a monolayer in depth, with the test tablets or capsules. The tray is placed on a workbench and positioned under a lamp containing a 100-watt incandescent lightbulb. The tray's width is placed parallel to the front bench edge about 7.62–15.24 cm. (3–6 in.) from the edge. The lamp is connected to a timer¹ that activates illumination of the lightbulb for a required amount of time.

Table I—Definition of Major and Minor Defects

Major Defects	Minor Defects
Surface spots	Polishing not uniform
Breaks or cracks	Feathered edges
Coated base tablet exposed	Chips
Foreign particulate matter ^a	Pitting or pimples
	Atypical mottling
	Nonuniform color
	Nonuniform size or shape
	Not smooth
	Smeared printing
	Thin-coated edges

^a Detection of this major defect results in rejection of the lot until it is freed of any health hazard resulting from this defect.

Subsequently, the start button of the timer is depressed and the tablets are scanned for both major and minor defects (Table I); the defective tablets are marked, using a felt-tipped pen (or equivalent). Automatically, the light is turned off, signifying the end of the analysis. The number and types of defects are sorted, and the results are recorded on an assay report

form. The report is designed so that the number and types of defects are identified.

An empty tray is superimposed over the tablet-containing tray, and the two trays are rotated 180° around the x- or y-axis so that the reverse side of the tablets are exposed. The original tray is removed, and the assay is performed on the new exposed side of the samples. The procedure is repeated until the total number of tablets or capsules required in the evaluation is assayed, and the results are recorded accumulatively.

The total number of units assayed is related to batch size and based on Military Standard 105D. Using the average tablet or capsule weight, the number of units to be tested are weighed into a beaker for subsequent transfer to the testing tray. A double sampling plan is used in which the acceptable quality level (A. Q. L.) is 0.65 and 4.0%, respectively, for major and minor defects.

Two sets of trays (two identical trays per set) are required to accommodate capsules, capsule-shaped tablets, and the conventional standard-shaped tablets. All the trays are 22.86 × 15.24 cm. (9 × 6 in.); however, the trays used for capsules and capsule-shaped tablets have an inner depth of 0.32 cm. (0.125 in.), and the trays used for the standard-shaped tablets have an inner depth of 0.16 cm. (0.062 in.).

Since the size of the tablet or capsule being assayed dictates the number of units in each tray load, the time interval (length of time light is illuminated) is correspondingly adjusted. In effect, the illumination duration is longest for the smallest tablet assayed. After a year of using this technique, we have developed the following formula for determining the time interval for a given sample:

$$P \text{ seconds/tablet} \times \frac{\text{total number of tablets to be assayed}}{\text{number of filled trays}} = \text{seconds/tray (Eq. 1)}$$

The value of *P* chosen should reflect the desired rigidity of the inspection. In our laboratory, *P* has an average value of 0.035 sec./tablet. If 1000 tablets were to be tested and five filled trays were involved, the time interval would be 7 sec./tray. If the last tray is less than half a tray, half the time interval is used. Otherwise, the tray is considered a full tray.

We found that the number of tablets scanned per tray varies between analysts, and the formula attempts to compromise these differences. Otherwise, the natural tendency of the analyst is to become overcritical of the sample appearance.

REVIEWS

Thin-Layer Chromatography. Edited by EGON STAHL. Springer-Verlag New York, Inc. 175 5th Ave. New York, NY 10010, 1969. xxiv + 1041 pp.

Egon Stahl's *Thin-Layer Chromatography* (second edition) is the most complete and current compilation of TLC theory and practice available today. The book, published in 1967 in German, is an expansion of his first work, organized in much the same manner. There is the same review of nomenclature before each compound class, the same history, and a much expanded theory section covering new apparatus and additional techniques.

The book has a much more complete section on heterocyclic nitrogen compounds than Kirchner's *Thin-Layer Chromatography*. Phenothiazines, the diazepines, carbamate esters, compounds of antihistamine activity, and the narcotics are all more thoroughly covered by Stahl than in the other available books on the market. Moreover, most charts list the structural formula where feasible or the chemical name of the compound in addition to its common name. The amino acid section is also well done. There is an extensive listing of general test conditions and solvent systems for these compounds.

The volume, however, is not specific in its treatment of the steroids. For the most part, it lists general systems for the various groupings of steroids and does not treat each drug individually. An incomplete and inconsistent index is also a hindrance, varying between listing drugs as to their activity, group name, or the name of one compound in the group. However, no existing TLC handbook approaches the amount of data contained in this volume and, as such, this work is a definitive addition to any TLC library.

Cationic Surfactants. Vol. 4. Edited by ERIC JUNGEMANN. Marcel Dekker, New York, NY 10016, 1970. xiv + 652 pp. 16 × 23.5 cm. Price \$37.50.

This, the fourth volume in Dekker's Surfactant Science Series, is concerned with the organic, physical, and analytical chemistry of cationic surfactants. A fourth section deals with the biological aspects of this class of surfactants.

The eighteen authors are drawn from both industry and the universities. Following an introductory chapter, the next six chapters deal with the synthesis of straight chain and cyclical alkylammonium compounds, petroleum-derived and polymeric forms, and nonnitrogen-containing surfactants. Brief references to the applications, physical properties, and toxicities of the compounds under discussion are made. As would be expected, major emphasis is placed on commercial products. Considering the potentially unexciting subject matter, the presentation is clear and readable.

There then follows a group of six chapters concerned with the physical chemistry of cationic surfactants. Specific topics covered are micelle formation in aqueous and nonaqueous media, adsorption by a variety of substrates, and coacervation. A brief section on adsorption on biological substrates has obvious pharmaceutical implications. In most cases the treatment is sufficiently basic; inevitably, much of the discussion is common to all classes of surfactants.

A single chapter comprises the section on the analytical chemistry of cationic surfactants. The approach taken is a practical one, with emphasis placed on methods that have been developed for carefully purified surfactants. The chapter considers both qualitative and

quantitative aspects of analysis. Most discussion of the latter centers around absorptiometric, volumetric, and gravimetric analysis.

The final section, on the biology of these compounds, contains two chapters that review the germicidal properties and toxicology, respectively, of cationic surfactants. In the chapter on germicidal properties, little consideration is given to a discussion of the mechanisms of action involved. However, the descriptive literature in this area is covered satisfactorily. Cationic surfactant toxicology is well summarized in the final chapter, which also contains a comprehensive listing of reported toxicities.

While this text undoubtedly represents a comprehensive presentation on cationic surfactants, its major appeal to the pharmaceutical scientist will probably be limited to the last two sections which comprise approximately one-third of the total material.

Pharmaceutical Chemistry, Volume 2: Instrumental Techniques.

Edited by L. G. CHATTEN. Marcel Dekker, Inc., 95 Madison Ave., New York, NY 10016, 1969. xiv + 773 pp. 17 × 24 cm. Price \$17.75.

Eighteen authors and the editor have collaborated to present 19 chapters in this second volume of a two-volume set on the analytical aspects of pharmaceutical chemistry. When the objectives stated in the preface are compared with the final written work, this reviewer finds that, in general, the mission has been accomplished. In an attempt to evaluate this book, each chapter has been examined and the following comments are respectfully set down.

The chapters may be conveniently divided into three groups: (1) topics involving electromagnetic radiation; (2) topics dealing with electrochemistry; and (3) subjects not classified as either (1) or (2). In many cases, questions, problems, and answers as well as experiments have been provided.

The first group of items is concerned with analytical techniques utilizing electromagnetic radiation in its various forms. The first two chapters concerning absorption spectrophotometry in the visible and ultraviolet region and in the infrared are well written and employ pretty much the standard approach to the subjects. In the first case, spectrophotometric titrations and a welcome treatment of the chemistry of chromogenesis in some colorimetric analyses are included. The presentation of structure-spectra correlations is done well; unknown spectra are provided for practice and study.

In both chapters, the experiments are appropriate but the instrumental features receive only brief attention. Raman spectroscopy, becoming more useful as instrument prices diminish, is discussed in a separate chapter. The theory is examined carefully and requires an appreciation of group theory and fundamental spectroscopy for adequate understanding. At present, no good examples of the application of this technique to pharmaceuticals are evident.

In the division of fluorometry, the explanations of theory, derivations of equations, and the examination of pharmaceutical examples are excellent. Particularly noteworthy is the portion discussing spectra-structural correlations. The choice of experiments includes the study of the physiological availability of riboflavin. The 16 pages of the atomic absorption chapter are used with efficient economy, the various points being well presented. This simple technique is certain to be used to a much greater extent than it is today. The qualitative elucidation of the nuclear magnetic resonance phenomena is clearly written as is the section of interpretation of spectra, so very useful in organic compound identification. There is little quantitative work in this area, however. Turbidimetry and

Pharmaceutical Chemistry, Volume 2: Instrumental Techniques.

Edited by L. G. CHATTEN. Marcel Dekker, Inc., 95 Madison Ave., New York, NY 10016, 1969. xiv + 773 pp. 17 × 24 cm. Price \$17.75.

Eighteen authors and the editor have collaborated to present 19 chapters in this second volume of a two-volume set on the analytical aspects of pharmaceutical chemistry. When the objectives stated in the preface are compared with the final written work, this reviewer finds that, in general, the mission has been accomplished. In an attempt to evaluate this book, each chapter has been examined and the following comments are respectfully set down.

The chapters may be conveniently divided into three groups: (1) topics involving electromagnetic radiation; (2) topics dealing with electrochemistry; and (3) subjects not classified as either (1) or (2). In many cases, questions, problems, and answers as well as experiments have been provided.

The first group of items is concerned with analytical techniques utilizing electromagnetic radiation in its various forms. The first two chapters concerning absorption spectrophotometry in the visible and ultraviolet region and in the infrared are well written and employ pretty much the standard approach to the subjects. In the first case, spectrophotometric titrations and a welcome treatment of the chemistry of chromogenesis in some colorimetric analyses are included. The presentation of structure-spectra correlations is done well; unknown spectra are provided for practice and study.

In both chapters, the experiments are appropriate but the instrumental features receive only brief attention. Raman spectroscopy, becoming more useful as instrument prices diminish, is discussed in a separate chapter. The theory is examined carefully and requires an appreciation of group theory and fundamental spectroscopy for adequate understanding. At present, no good examples of the application of this technique to pharmaceuticals are evident.

In the division of fluorometry, the explanations of theory, derivations of equations, and the examination of pharmaceutical examples are excellent. Particularly noteworthy is the portion discussing spectra-structural correlations. The choice of experiments includes the study of the physiological availability of riboflavin. The 16 pages of the atomic absorption chapter are used with efficient economy, the various points being well presented. This simple technique is certain to be used to a much greater extent than it is today. The qualitative elucidation of the nuclear magnetic resonance phenomena is clearly written as is the section of interpretation of spectra, so very useful in organic compound identification. There is little quantitative work in this area, however. Turbidimetry and

related methods are presented together, but the discussion is somewhat difficult to read. Many equations are introduced and the treatment includes light-scattering measurements. Numerous references are listed and classified, but the single experiment chosen is disappointing. It was hoped that some work in light scattering might be suggested.

Refractometry and polarimetry are discussed in two relatively short sections. The theoretical discussion of refractometry is good and the use of this property in monitoring chromatographic eluants and in structural studies is presented together with its well-known application in liquid identification. The theory involving polarimetry and related properties, such as optical rotatory dispersion and circular dichroism, is most complex and cannot be handled in a few pages as is evident from this chapter. The discussion of circularly and plane polarized light and the resolution of the former into the latter is not quite clear. Optical rotatory dispersion is treated in terms of the octant rule. The proposed experiments deal with pharmaceutical compounds or preparations and are good. Unfortunately, quantitative analysis by polarimetry is limited by lack of instrumental sensitivity.

Crystallography is introduced in a chapter which describes properties that are measurable optically. Although most interesting, the work proved very hard to read. Concomitant performance of the suggested experiments seems necessary. Possibly the use of photomicrographs, colored if colors are to be seen, together with diagrams using various colors to emphasize coordinate axes, angles, and lines would have improved this important section. The techniques of X-ray analysis in terms of topics such as powder diffraction, single crystal studies, and X-ray fluorescence are part of a chapter that reads well and cites good pharmaceutical examples, both in cases of identity study and quantitative determinations. Considering the analyses possible with the powder technique and the trace level detection possible when fluorescence is measured, it is disappointing that some experiments are not proposed for those fortunate enough to have an X-ray spectrometer.

Electrochemical topics are covered in five chapters. The presentation on potentiometry is rather standard and includes a discussion of electron tubes and some simple circuits. However, the use of 12 photographs of commercial instruments and in judiciously plotted curves is not making the most of space. The omission of specific ion electrodes is surprising. The conductimetric and high-frequency methods are discussed in a chapter entitled *Current Flow Methods*. The discussions are done well and include measurement circuits and Wheatstone bridge concepts with a description of critical micelle measurements. Coulometry and chronopotentiometry are written in a direct, crisp, clear, readable style. The pertinent equations and the salient differences between the techniques are made plain. At the end of each subsection, the pharmaceutical applications are listed and an experiment using an appropriate pharmaceutical is supplied for each technique.

The polarography and amperometry chapters are well done. The various equations necessary for polarography are derived, and concepts are lucidly introduced and developed. In addition to classical polarography, solid microelectrodes and measurements in non-aqueous media are discussed. The commentary on instrumental aspects is pertinent, and the experiments and summary of pharmaceutical applications are good. It was disappointing not to find any mention of AC polarography. Both one- and two-polarized electrode systems used in amperometric titrations are considered and the applications to pharmaceuticals are summarized.

The final group of topics includes chapters on mass spectrometry, gas chromatography, and radiochemistry. The survey of mass spectrometry begins with a good introduction to theory, but the study of fragmentation patterns clearly requires more intense work than could be presented in the available space. Although good use has been made of this technique, together with pyrolysis and gas chromatography with simplified interpretation by means of computer techniques, the utility in quantitative analysis, discussed in this section, has not been established. Gas chromatography is developed in the usual manner and seems generally satisfactory. However, the discussion of the detectors and their mode of operation is disappointing, as is the omission of pyrolysis techniques. Likewise, the choice of experiments is not imaginative with work such as the separation of steroids and the monitoring of barbiturates in the

urine published in the literature. The closing chapter on radiochemistry presents a logical development of the theory and measurements appropriate to this area. However, the very important aspect of radiation safety procedures, decontamination, and waste disposal, as well as radioaseptic techniques, has not been included. The experiments are disappointing; it was hoped that procedures such as neutron-activation analysis (if a neutron source is available), scintillation spectrometry, or nuclide standardization and calibration would be included.

This reviewer recommends that this book be considered as a text for a course in instrumental analysis. It may be necessary to supplement this work from many available sources if some aspects of electronics or instrumental function and design are to be taught. But this is not a serious drawback since this text presents the analysis of pharmaceuticals, information not available in a text at this level before.

Codeine and Its Alternates for Pain and Cough Relief. By NATHAN B. EDDY, HANS FRIEBEL, KLAUS-JURGEN HAHN, and HANS HALBACH. World Health Organization, Geneva, Switzerland, 1970. i + 253 pp. 17.5 x 24 cm. Price \$6.00.

This review of the analgesic and antitussive effects of codeine and its alternates was originally published, in five installments, in the *Bulletin of the World Health Organization* during 1968 and 1969.

The five chapters included are codeine, exclusive of its antitussive action; alternates for pain relief; the antitussive action of codeine—mechanism, methodology, and evaluation; potential alternates for cough relief; and discussion and summary.

Codeine, which has been used increasingly for the relief of pain and cough since it was first isolated in 1832 from morphine, is an effective analgesic and antitussive either alone or in combination with other compounds. This publication reviews the literature concerning the experimental and clinical effectiveness of codeine and a wide range of alternative substances.

Effectiveness and lack of undesirable side-effects, including tolerance, dependence, and liability to abuse, are among the leading characteristics to be considered in the evaluation of codeine and its potential alternates. These aspects are taken up in this review.

Staff Review

related methods are presented together, but the discussion is somewhat difficult to read. Many equations are introduced and the treatment includes light-scattering measurements. The five chapters included are codeine, exclusive of its antitussive action; alternates for pain relief; the antitussive action of codeine—mechanism, methodology, and evaluation; potential alternates for cough relief; and discussion and summary.

Codeine, which has been used increasingly for the relief of pain and cough since it was first isolated in 1832 from morphine, is an effective analgesic and antitussive either alone or in combination with other compounds. This publication reviews the literature concerning the experimental and clinical effectiveness of codeine and a wide range of alternative substances.

Effectiveness and lack of undesirable side-effects, including tolerance, dependence, and liability to abuse, are among the leading characteristics to be considered in the evaluation of codeine and its potential alternates. These aspects are taken up in this review.

Staff Review

related methods are presented together, but the discussion is somewhat difficult to read. Many equations are introduced and the treatment includes light-scattering measurements. Numerous references are listed and classified, but the single experiment chosen is disappointing. It was hoped that some work in light scattering might be suggested.

Refractometry and polarimetry are discussed in two relatively short sections. The theoretical discussion of refractometry is good and the use of this property in monitoring chromatographic eluants and in structural studies is presented together with its well-known application in liquid identification. The theory involving polarimetry and related properties, such as optical rotatory dispersion and circular dichroism, is most complex and cannot be handled in a few pages as is evident from this chapter. The discussion of circularly and plane polarized light and the resolution of the former into the latter is not quite clear. Optical rotatory dispersion is treated in terms of the octant rule. The proposed experiments deal with pharmaceutical compounds or preparations and are good. Unfortunately, quantitative analysis by polarimetry is limited by lack of instrumental sensitivity.

Crystallography is introduced in a chapter which describes properties that are measurable optically. Although most interesting, the work proved very hard to read. Concomitant performance of the suggested experiments seems necessary. Possibly the use of photomicrographs, colored if colors are to be seen, together with diagrams using various colors to emphasize coordinate axes, angles, and lines would have improved this important section. The techniques of X-ray analysis in terms of topics such as powder diffraction, single crystal studies, and X-ray fluorescence are part of a chapter that reads well and cites good pharmaceutical examples, both in cases of identity study and quantitative determinations. Considering the analyses possible with the powder technique and the trace level detection possible when fluorescence is measured, it is disappointing that some experiments are not proposed for those fortunate enough to have an X-ray spectrometer.

Electrochemical topics are covered in five chapters. The presentation on potentiometry is rather standard and includes a discussion of electron tubes and some simple circuits. However, the use of 12 photographs of commercial instruments and injudiciously plotted curves is not making the most of space. The omission of specific ion electrodes is surprising. The conductimetric and high-frequency methods are discussed in a chapter entitled *Current Flow Methods*. The discussions are done well and include measurement circuits and Wheatstone bridge concepts with a description of critical micelle measurements. Coulometry and chronopotentiometry are written in a direct, crisp, clear, readable style. The pertinent equations and the salient differences between the techniques are made plain. At the end of each subsection, the pharmaceutical applications are listed and an experiment using an appropriate pharmaceutical is supplied for each technique.

The polarography and amperometry chapters are well done. The various equations necessary for polarography are derived, and concepts are lucidly introduced and developed. In addition to classical polarography, solid microelectrodes and measurements in non-aqueous media are discussed. The commentary on instrumental aspects is pertinent, and the experiments and summary of pharmaceutical applications are good. It was disappointing not to find any mention of AC polarography. Both one- and two-polarized electrode systems used in amperometric titrations are considered and the applications to pharmaceuticals are summarized.

The final group of topics includes chapters on mass spectrometry, gas chromatography, and radiochemistry. The survey of mass spectrometry begins with a good introduction to theory, but the study of fragmentation patterns clearly requires more intense work than could be presented in the available space. Although good use has been made of this technique, together with pyrolysis and gas chromatography with simplified interpretation by means of computer techniques, the utility in quantitative analysis, discussed in this section, has not been established. Gas chromatography is developed in the usual manner and seems generally satisfactory. However, the discussion of the detectors and their mode of operation is disappointing, as is the omission of pyrolysis techniques. Likewise, the choice of experiments is not imaginative with work such as the separation of steroids and the monitoring of barbiturates in the

urine published in the literature. The closing chapter on radiochemistry presents a logical development of the theory and measurements appropriate to this area. However, the very important aspect of radiation safety procedures, decontamination, and waste disposal, as well as radioaseptic techniques, has not been included. The experiments are disappointing; it was hoped that procedures such as neutron-activation analysis (if a neutron source is available), scintillation spectrometry, or nuclide standardization and calibration would be included.

This reviewer recommends that this book be considered as a text for a course in instrumental analysis. It may be necessary to supplement this work from many available sources if some aspects of electronics or instrumental function and design are to be taught. But this is not a serious drawback since this text presents the analysis of pharmaceuticals, information not available in a text at this level before.

Consulting, Establishing and Maintaining An Independent Practice

By RICHARD A. STEMM. SiSi: Stemm's Information Systems & Indexes, P. O. Box 42576, Los Angeles, CA 90050, 1970. iii + 29 pp. 13.5 x 21 cm. Price \$2.50.

Despite its brevity, this booklet, written by Richard Stemm, contains a vast amount of information for the practicing or aspiring consultant. The author states in the Preface that the primary value of the publication is helping an individual objectively plan and prepare a course of action to establish himself as an independent consultant.

The material appears to be applicable to individuals in most fields and specialties. Among the topics covered are proposing, quoting, negotiating, contracts, fees, and costs. The booklet also contains forms for the National Consulting Register, a division of the author's organization.

Codeine and Its Alternates for Pain and Cough Relief. By NATHAN B. EDDY, HANS FRIEBEL, KLAUS-JURGEN HAHN, and HANS HALBACH. World Health Organization, Geneva, Switzerland, 1970. i + 253 pp. 17.5 x 24 cm. Price \$6.00.

This review of the analgesic and antitussive effects of codeine and its alternates was originally published, in five installments, in the *Bulletin of the World Health Organization* during 1968 and 1969.

The five chapters included are codeine, exclusive of its antitussive action; alternates for pain relief; the antitussive action of codeine—mechanism, methodology, and evaluation; potential alternates for cough relief; and discussion and summary.

Codeine, which has been used increasingly for the relief of pain and cough since it was first isolated in 1832 from morphine, is an effective analgesic and antitussive either alone or in combination with other compounds. This publication reviews the literature concerning the experimental and clinical effectiveness of codeine and a wide range of alternative substances.

Effectiveness and lack of undesirable side-effects, including tolerance, dependence, and liability to abuse, are among the leading characteristics to be considered in the evaluation of codeine and its potential alternates. These aspects are taken up in this review.

Microencapsulation

LOUIS A. LUZZI

Keyphrases ☐ Microencapsulation—review ☐ Coacervation simple, complex—microencapsulation ☐ Phase separation—microencapsulation ☐ Interfacial polymerization—microencapsulation ☐ Electrostatic methods—microencapsulation of aerosols ☐ Pharmaceutical applications—microcapsules

Microencapsulation may be thought of as a method of wrapping small entities in individual, protective coatings. These coatings may be designed to protect, separate, or aid in storage and handling. Alternatively, the coatings may be constructed so that the encapsulated material is released under prescribed conditions to control or prolong the action from the microscopic-size capsules. The conditions for release may be made dependent upon moisture, pH, physical force, or combinations thereof. The mechanism for release may be associated with leaching, erosion, rupture, or other such actions, depending upon wall construction.

Microencapsulation encompasses both science and technology. A great deal has been written concerning current applications and future possibilities for encapsulating those materials whose original activities, actions, or stabilities may be altered or controlled by packaging in microcapsules. The technology of microencapsulation, involving several varied disciplines, is advancing rapidly, but the application of the principles involved has not yet approached its full potential. Knowledge from several disciplines is often essential to the technology of microencapsulation. For example, it may be necessary for pharmacology and therapeutics

to join with colloidal and polymer chemistry for the encapsulation of medicinals.

Much of the available information pertaining to microcapsules and microencapsulation is found in the patent literature. Many applications of microencapsulation, employing varied and ingenious techniques, are patented. However, as is typical with patent literature, control and testing data as well as completeness of details essential for reproducibility are either lacking or alluded to in ambiguous terms. Definitive literature in these areas is limited and will probably remain so for some time, due to security measures on the part of those companies holding patent rights.

In this review of microencapsulation, an attempt will be made to bring together the published information from the scientific, patent, and company-prepared literature. In cases in which the scientific or patent literature is accompanied by company brochures, only the former literature will be discussed and the latter will be referenced.

Microcapsules are measured in microns and usually fall into the range of from several to approximately 200 μ (1). Some of the literature (2) alludes to microcapsules as a form produced by a specific mechanism which yields discretely packaged materials regardless of size, as opposed to discrete, microscopic packages of material. For this paper, microcapsules are defined as being discrete packages of material in the size range of 0.5–200 μ (3), and the term applies to all small, discrete packages produced by any number of techniques. Figures 1–3 illustrate microcapsules in different stages of preparation.

Figure 1—Microcapsules of individual oil droplets before drying. (Courtesy of The National Cash Register Co.)

SURVEY OF MICROENCAPSULATION METHODS

The processes of microencapsulation have been used to encase particles of liquids, solids, or gases. These particles must be immiscible in the liquid phase containing the material that will ultimately form the capsule wall. The first practical use of microencapsulation appears in United States patents issued to Green and Schleicher (4–6). The principles of microencapsulation enumerated in these patents involve both simple and complex coacervation. Coacervation, as a method of microencapsulation, was also claimed in two other patents by Green and Schleicher (7) and by Green (8); these patents were filed at the same time but issued several years later.

Coacervation—The term “coacervation” has been used by chemists to describe the salting out of or phase separation of lyophilic solids into liquid droplets rather than into solid aggregates (9). The term was introduced into colloidal chemistry by Bungenberg de

Jong and Kruyt (10) to describe the flocculation or separation of liquids from solution where at least one of the liquids contained a colloidal solute.

Coacervation has been subdivided into two categories: simple coacervation and complex coacervation. Briefly, simple coacervation usually deals with systems containing only one colloidal solute, while complex coacervation usually deals with systems containing more than one colloid (11).

Simple coacervation is a process involving the addition of a strongly hydrophilic substance to a solution of a colloid. This added substance causes two phases to be formed, one phase rich in colloidal droplets and the other poor in such droplets. This process depends primarily on the degree of hydration produced. For example, addition of alcohol or sodium sulfate, as typical hydrophilic substances, to an aqueous solution of gelatin can lead to phase formation. When suitable conditions, including the presence of suitable nuclei, are prevalent, microcapsules may result.

Complex coacervation (Fig. 4) is primarily dependent on pH. It has been reported that in gum arabic–gelatin systems, complex coacervation occurred and microcapsules formed at pH values below the isoelectric point (IEP) of the gelatin but would not occur above this pH. At pH values below the IEP of gelatin, it becomes positively charged while acacia particles retain their negative charge regardless of pH. The same was found to be true of other systems containing two dispersed colloids, one of which was ampholytic (12).

Two mechanisms have been suggested for the formation of microcapsules by these methods (13): (a) individual coacervate droplets may be drawn to and coalesce about particles immiscible in the system, or (b) a single coacervate droplet may encompass one or a group of immiscible nuclei. Either or both mechanisms may be operative in a given system. However, unpublished data seem to indicate that, in certain cases, complex coacervate systems may be controlled to yield reproducible “compound capsules.” That is, capsules may be formed which contain smaller, previously formed capsules from the same mother liquid, without first removing the smaller capsules or rejuvenating the liquid.

Phase Separation—This technique involves the dispersion of a polymer or copolymer in a solvent system in which the nucleus material is not soluble. Another liquid, which is miscible with the solvent system but which must be a nonsolvent for the polymer and nuclei, may be added. The rate of stirring, subsequent dispersion of the polymer-rich phase, and the rate of addition of the nonsolvent may be controlled to regulate the porosity of the capsule wall.

Several other methods of microencapsulation have been reported. These include interfacial polymerization, electrostatic methods, mechanical processes, and vacuum metalization.

Interfacial Polymerization—Microencapsulation by this method is a process whereby a monomer is made to polymerize at the interface of two immiscible substances. If the internal phase is a liquid, it is possible to disperse or solubilize the monomer in this phase and to

Figure 2—Capsules within a capsule or aggregate microcapsules containing a liquid, before drying. (Courtesy of The National Cash Register Co.)

emulsify the mixture in the external phase until the desired particle size is reached. At this point, a cross-linking agent may be added to the external phase. Since there is usually some migration of the monomer from the internal to the external phase, and since it is preferred that the crosslinking agent not transfer to the internal phase, the bulk of any polymerization will take place at the interface (15).

An interesting dual-walled capsule formulation embodying a combination of coacervation and interfacial polymerization was disclosed by Brynko and Scarpelli (16). They prepared dual-walled oil-containing capsules whose inner wall consisted of polymerized styrene-divinylbenzene monomer with an outer wall of a gelatin-acacia coacervate shell. The monomer was dissolved in the internal phase, and polymerization took place during and after coacervation. The individual processes were controlled by temperature adjustment.

Electrostatic Methods—Preparation of microcapsules by these methods (17, 18) involve a bringing together of the wall material and the material to be encapsulated when both are aerosols. The material must be liquid during the encapsulation stage and must be capable of wetting the core material. Should the internal phase be liquid during the process, then it must have the higher interfacial tension to ensure encapsulation. The two aerosols must be oppositely charged; this can be accomplished prior to the mixing of the two. Three chambers are used in this process, with two of the chambers being atomization chambers and the third a mixing chamber. Oppositely charged ions are generated and directed into the two atomization chambers and are deposited on the liquid drops while they are being atomized. The capsules are allowed to cool in order to solidify the coating and then are collected by an appropriate aerosol collection system.

Mechanical Methods—One mechanical method (19) for producing microcapsules involves the use of counter-rotating disks. The inner rotating disk produces small particles of the core material. These particles are projected toward a point on the outer counter-rotating disk, which is lined with liquid coating material and has a row of orifices. When a sufficient weight of core material has collected at a particular orifice, centrifugal force separates the core and wall-forming material from the rotating cylinder, thus completing capsule formation. The amount of wall material applied is related to the initial concentration of the wall solution and the rate at which the solution flows onto the outer disk.

Another method (20) involves the dripping of the material to be encapsulated onto a continuous film of the liquified wall material and subsequent collection of the capsules. Here, again, the accumulated weight of core material causes the film to separate, with subsequent capsule formation (Fig. 5).

Still another method for the mechanical coating of small particles is the Wurster fluidized-bed coating technique (21–23). Figure 6 shows that the apparatus may consist of a vertical, somewhat conical column. A gas, carrying the coating material, is introduced at the base or constricted part of the column at a velocity high enough to suspend the particles. The gas velocity

Figure 3—Microencapsulated solid before drying.

in the flared part of the column is greatly decreased, so the particles cannot be supported in this region and they fall outward and downward into the constricted region where they are again lifted by the gas flow. The wall material is dissolved in a solvent (usually volatile) and is sprayed onto the supported particles, in a fine mist, from a nozzle located near the bottom of the column. The solution coats the suspended particles, and heated air drives off the solvent. When the particles are sufficiently dry, the air flow is cut off and the coated product falls to the bottom of the apparatus for collection. The amount of wall material applied is generally proportional to the atomizing time, since the coating material is sprayed at a uniform rate and the particles

Figure 4—Flow diagram of a typical method of manufacture of microcapsules via complex coacervation. Emulsification may be carried out with or without gelatin present. The particle size of the emulsified oil may be controlled, thus affecting the size of the ultimate capsule. Adjustment of pH to 4.5 causes coacervate droplets to form and encapsulate the emulsified oil. Formaldehyde addition, lowering of temperature, and increase in pH all fix the coacervate droplets in place about nuclei.

Figure 5—Schematic of a counter-rotating, multiorifice apparatus for the coating of particles.

are uniformly exposed to the spray. The time and air velocity required to coat the particles depend upon: (a) the starting surface area of the particles to be coated (the smaller the particle, the greater the surface area per pound of material to be coated and, therefore, the longer the time needed to coat); (b) the desired thickness of the coating; (c) the weight of particles coated per batch; and (d) the rate of flow of the coating liquid.

Vacuum Metalization—Although not directly applicable to pharmaceuticals when using metallic substances as the coating material, this process presents a very interesting methodology (24, 25). The apparatus (Fig. 7) consists of a container in which a vacuum can be pulled and which is equipped with a heated metal vaporization mechanism, a refrigerated hopper, and an inclined refrigerated vibrating tray. The particles to be coated are fed onto the tray and, in their cooled state, condense the metal vapors emerging from the heated

Figure 6—Schematic of the Wurster coating apparatus.

crucible. The thickness of the coating may be regulated by controlling the rate at which the particles descend the inclined tray. Other factors which may be controlled to regulate wall thickness are the rate of metal vaporization and its consequent condensation.

Many more devices have been reported. However, most of the principles have been discussed here. The specific mechanisms not mentioned are usually part of, or a combination of, several of those discussed.

PREPARATION OF MICROCAPSULES

Bungenberg de Jong (26) described many coacervate systems along with the behavior of coacervate droplets under a variety of conditions. Although he did not attempt the technique of microencapsulation, his descriptions and observations are the bases for the current technology of microencapsulation via coacervation. The first practical use of the process of coacervation was made by Wagner (3), Green and Schleicher (4), and Green (27, 28). Two of the early patents (3, 4) indicated that various oils, some of which contained dissolved dyes, had been encapsulated in gelatin-acacia microcapsules.

One procedure (4) consisted of dissolving 20 g. of acacia in 160 g. of water and emulsifying into this 80 g. of trichlorodiphenyl containing 3–6%, by weight, of color reactant materials. Emulsification was continued until the oil droplet size was from 2 to 5 μ . Next, 20 g. of gelatin was dissolved in 160 g. of water and mixed with the emulsion. This mixture of colloids and oil was then diluted by adding approximately 525 g. of water, at which time (the patent states) coacervation occurred and the gelatin-acacia complex formed about the oil droplets; all ingredients were kept at 50°. The mass was then cooled by pouring it into a quantity of cold (0°) water. The mixture was agitated and allowed to stand for 1 hr. at not more than 25°. The pH was adjusted to between 7 and 9 with sodium hydroxide, and the material was left in this state for at least 30 min. The capsules were hardened by adding 20 g. of formaldehyde solution USP and mixed at 3° or lower for about 10 min. Since the ultimate use of this material was for the preparation of "carbonless carbon paper,"¹ the capsules were not dried but the water content of the mixture was adjusted to suit this application.

In another patent (5), Green and Schleicher, again using similar materials, related that encapsulation may be brought about by adjusting pH and by controlling the degree of hydration of pigskin gelatin through salt addition. Using the pH adjustment method, the oily material was emulsified into an acacia solution; a solution of pigskin gelatin, with an IEP of pH 8, was added to the emulsion. Then, the pH of the mixture was brought to 6.5 with a 20% w/w solution of sodium hydroxide. Three hundred grams of this mixture was diluted with 700 g. of water at 50°. The pH of the diluted mixture was then lowered to approximately 4.5 with diluted acetic acid. It was during this step that the coacervate droplets formed and were deposited about

¹ The National Cash Register Co., Dayton, Ohio.

the oil droplets. While still at 50°, 2.19 g. of formaldehyde solution was added to help fix in place the coacervate droplets. The mixture was cooled to 10° and, subsequently, the pH was brought to 9. The cooling and pH adjustment further immobilized the formed shell.

Another method of microencapsulation is given in the same patent and describes coacervation by salt addition. In this case, the emulsion, containing 100 parts of 10% w/w gelatin and 20 parts of oil but no acacia, is treated in a similar manner, except that coacervation is induced by slowly adding, with stirring, a strongly hydrophilic salt solution. In this instance, 1.51 l. of a 20% solution of sodium sulfate was added at 50°. The mixture was then placed in 37.85 l. of 7% sodium sulfate solution at about 20°. The material was filtered and washed to remove the salt and was later treated with formaldehyde solution.

In later patents, Green and Schleicher (7) and Green (8) presented schematic diagrams for the preparation of microcapsules by both simple and complex coacervate systems. They also offered further explanation of these reactions and included an enumeration of other core materials consisting of naturally occurring and synthetic oils. A list of anions and cations arranged according to their relative hydrophilic nature was given to aid in determining the efficiency of various salts which may be used for simple coacervate systems.

In other patents involving coacervation of phase separation, several inventors added to the technology of microencapsulation. Materials other than, and in addition to, gelatin, albumin, casein, pectin, acacia, *etc.*, have been used. Solids as well as oils have been encapsulated, wall materials have been altered, sealing coats have been applied, and various combinations of natural and synthetic materials have been used as coating agents. The following is a sampling of the many variations perpetrated to attain microcapsules having various "improved" characteristics. An attempt will be made, in this section, to discuss patent information in a chronological manner, using filing dates as a guide.

Brynko and Scarpelli (16), in their patented process of making dual-walled capsules, dissolved two monomers, dichlorodiphenyl monomer and styrene monomer, in an internal oil phase. The oil phase was emulsified into an aqueous phase containing acacia, gelatin, and (to act as the catalyst for the monomers) potassium persulfate. The initial pH of the emulsion was 6.5 and the temperature was 55°. The pH was subsequently lowered and the temperature brought to 15°. Polymerization of the monomers began with the initial mixing of the phases and was substantially completed at the interface by the time coacervation had been accomplished. To harden the capsule walls, formaldehyde solution was added and the pH was raised to 10. Agglomeration of capsules was controlled by the addition of a maleic anhydride copolymer such as the polyvinylmethyl ether-maleic anhydride copolymer.

Brynko and Scarpelli (29) also reported that dual-walled capsules have been formed by causing deposition, *via* coacervation, of a lower molecular weight copolymer followed by an addition of a higher mo-

Figure 7—Vacuum metalization apparatus for encapsulation.

lecular weight copolymer. They reported a mixture of polyethylene-maleic anhydride copolymer, of approximate 1000–2000 molecular weight, in an aqueous solution containing gelatin and acacia at 35° and at pH 9. The material to be encapsulated was dispersed in the mixture and the pH was lowered to 4.8. A wall thickness of about 5 μ was found when coacervation was completed using the prescribed quantities of materials. The pH was then raised to about 6.8 to allow for the addition of an aqueous medium containing polyethylene-maleic anhydride copolymer having a molecular weight of 60,000–70,000. At pH 6.8, decoacervation took place and, consequently, it was important that the time during which the mixture was at this pH was at a minimum. Upon addition of the higher molecular weight copolymer, the pH was lowered to approximately 5. The resultant deposition yielded capsules with a total wall thickness of about 100 μ . When the mixture was cooled to 13°, the walls became rigid and solid but were still in a reversible state; formaldehyde, glutaraldehyde, or a similar crosslinking material was used to fix the wall material.

In another patent (30), fractionated gelatin along with acacia was used as the wall-forming material. Fractionation was accomplished by heating a solution of pigskin gelatin (IEP 8) at pH 7 and treating this with ethyl alcohol. Two distinct layers formed, one rising to the top and the other sinking. The lower layer was collected, dried, and comminuted. The powdered gelatin fraction, along with acacia, was dissolved in water, and capsules were formed by complex coacervation. Discrete capsules were collected and were found to be more pervious to light than capsules formed using nonfractionated gelatin.

Jensen (31) reported a method for encapsulation of water-soluble solid materials. The solid material was first coated with a liquefied lipid material by one of several mechanical methods. The coated solid was then encapsulated, using either simple or complex coacer-

Table I—Effect of pH on Diffusion Rate of Dye

pH of Material prior to Spray Drying	Diffusion Rate of Dye, % dye released/min.
4.00	0.125
5.00	0.125
6.00	0.128
7.25	0.180
8.50	0.302

vation or a partially hydrolyzed maleic anhydride copolymer. The solubility of the partially hydrolyzed copolymer was found to vary in different hydroalcoholic systems; the solubility was also found to decrease with the addition of selected salts. For example, completely hydrolyzed styrene-maleic anhydride copolymer was found to be about 2% soluble in water but at least 20% soluble in a 50-50 mixture of methanol and water. When the partially hydrolyzed copolymer was used, phase separation and consequent encapsulation of suspended material were brought about by the addition of an appropriate solvent or a salt such as magnesium sulfate. The sulfate salt was found to be effective over a wide concentration range. An adjustment of pH, either up or down depending on the polymer, was necessary to reduce the solubility of the wall material, thereby ensuring irreversibility.

Another method for the encapsulation of hydrophilic materials that involves precoat was disclosed by Heistand *et al.* (32). In this case, the precoat procedure was carried out from nonaqueous systems. For example, 50% hydrolyzed styrene-maleic anhydride copolymer was dissolved in a nonaqueous liquid. Into this an aqueous solution of the desired core material was emulsified. A third liquid, soluble in the organic liquid but not a solvent for the polymer, was added to induce phase separation and encapsulation of the suspended aqueous phase. The precoat was hardened, separated, and dried. The resultant precoat material was then suspended in an aqueous system from which encapsulation was brought about by any of several previously mentioned methods.

In a patent granted to Jensen (33), styrene-maleic anhydride copolymers and the hydrolyzed species of these copolymers were used as part of the negatively charged species to effect encapsulation *via* complex coacervation. It is stated that encapsulation by this method produces a shell which is less permeable than that obtained using, for example, gelatin and acacia. The gelation or cooling step may be eliminated when using this combination of materials.

Another method of preparing less permeable microcapsules was patented by Jensen (34) and involves controlling pH during the drying procedure. This included a spray-drying process which was used to obtain a free-flowing powder form of microcapsules and which was carried out at pH values between 4 and 6. It is stated in the patent that although the reason for the decrease in permeability was unknown and unexpected, nevertheless there existed an optimum between pH 4 and 6. Table I is a presentation of some of the data generated for this patent. The data were

collected from 1 g. of dry product having a gelatin-acacia shell and suspended in 250 ml. of chloroform and stirred at a constant rate. The rate of diffusion of an encapsulated dye was measured spectrophotometrically using filtered aliquots of the chloroform suspension (Table I).

Jensen and Wagner (35) also were granted a patent in which they described the preparation of microcapsules using a partially hydrolyzed styrene-maleic acid copolymer. The method for the preparation of the acid copolymer was disclosed in this case.

In a patent entitled "Encapsulation in Natural Products" (36), the lipophilic material to be encapsulated was dispersed in a solution of egg albumin and, in order to bring about encapsulation, was heated to between 70 and 90°. In examples given in this patent, other techniques that aid coagulation were cited. These included addition of formaldehyde solution, alternations of ratios, variations of temperature and time, and use of additional polymers. The inventor stated that one advantage of this process was that it was particularly suitable for volatile substances since only moderately high temperatures were necessary.

Capsules with a wall material consisting of acacia and low viscosity ethylcellulose (ratio not more than 2:1) and gelatin were disclosed in a patent granted to Maieron (37). The process of encapsulation follows that of Green and Schleicher (5) and Green (6), differing only in the inclusion of ethylcellulose in the lipid phase. It was claimed that this modification of the process causes ethylcellulose to be deposited at the inside of the capsule walls, thereby plugging pores which may be present in the walls. Deposition of the ethylcellulose was said to be brought about by the presence of an aqueous phase. The film of ethylcellulose continues to deposit during coacervation and acts as host for acacia-gelatin droplets.

A cyclic process (38) for the manufacture of microcapsules that may contain acetylsalicylic acid and which employs nonaqueous dispersion media was disclosed in a patent issued to Miller and Anderson. Given as "Example I" of encapsulation in this patent is the following:

"This example utilizes (a) cyclohexane as the solvent vehicle, (b) butyl rubber . . . to maintain the wall material solution as a separate phase, (c) aspirin of a particle size . . . , and (d) ethylcellulose . . . solution in a 20% alcohol/toluene solvent as a wall material.

"Into a 600 ml. vessel, there are introduced, with agitation sufficient to produce liquid entities of ethylcellulose-cyclohexane solution of several microns average drop size at 80°, 200 grams of a 3% by weight, solution of the specified butyl rubber in cyclohexane, 4 grams of the specified ethylcellulose, and 48 grams of the specified particulate size acetylsalicylic acid, to form a system which is heated to 80°." (38)

When the desired dispersion had been reached, the system was cooled and the wall began to form at about 70°. The cooling was carried to room temperature. The capsules were removed and the remaining liquid reconstituted to its original proportions of starting ingredients. The capsules were recovered, in an appropriate manner, and dried.

Anderson *et al.* (39) also patented a method of encapsulation for aspirin using ethylcellulose. In this system, the aspirin particles were first wetted with an aqueous buffering solution of monobasic potassium phosphate previously adjusted to pH 2.3 with phosphoric acid. The aspirin particles were dried and the encapsulation procedure begun.

Ethylcellulose, acetic anhydride, and polyethylene were dispersed in cyclohexane at room temperature and solubilized by raising the temperature to 80°. At this point, the buffered aspirin particles were dispersed with continued agitation, and the temperature was lowered to approximately 25°. The capsules thus formed were separated from the insoluble polyethylene particles by washing through a screen. Polyethylene was used in this system as a phase separation inducing material, which caused no hydrolysis of aspirin as may have been the case with water-soluble materials.

When the phase separation of a polymer is used as the method of coating small particles, difficulties are sometimes encountered in recovering discretely coated nuclei. To overcome this, Rowe (40) incorporated mineral silicates into the system and thus minimized adhesion and coalescence of capsules. Generally speaking, when phase separation of polymers is to be the method of encapsulation, an organic solvent solution of the polymer is prepared, the particles to be coated are dispersed in it, and an organic nonsolvent for both the polymer and particles is added to the dispersion. A polymer-rich dispersed phase separates during the addition of the nonsolvent; this phase, while dispersed, may migrate to and coat suspended particles. It was found that incorporation of the mineral silicate (40) (talc was preferred) into the system during the addition of the nonsolvent minimized coalescence.

Another method of preventing capsules from aggregating during the isolation or drying step was patented by Maieron (41). In this method, cationic surfactants were added to redispersed capsules prior to drying. More than one surfactant was added, in varied sequences, to achieve optimum particle dispersion.

Ranney (42) compiled techniques from the U. S. patent literature pertaining to microencapsulated products. The techniques were abstracted from 81 U. S. patents, some of which have been presented here and some of which are yet to be discussed. He also included numerous flow charts and schematics obtained from the literature.

STUDIES OF MICROENCAPSULATION SYSTEMS

The most widely known application of microcapsules to date is, of course, manifest in the copying material produced by The National Cash Register Co. Their major product, in this area, is record paper commonly known as "carbonless carbon paper." Several methods of microencapsulation are utilized to encapsulate the system of leuco dyes used in this process. In all cases, however, the dyes are dissolved in an oily base prior to encapsulation. The formed capsules are coated or spread on paper along with a material which will cause color formation of the leuco dyes when the

capsules are ruptured and contact between reactants is possible. This is not only the major application but, as mentioned earlier, is the first to become widely used in a commercial product. As noted, the technology has been widely patented and there has been a rapid diversification of application. Materials ranging from volatile oils to solids and semisolids are now being encapsulated. The materials used as encapsulating agents are just as varied, ranging from the gelatin-acacia complexes to ethylcellulose, hexamethylenediamine, and combinations of two or more of these or similar materials. In spite of the wealth of technology, and with one or two exceptions, microcapsules and the microencapsulation processes remain a curiosity. Figure 8 illustrates some of the characteristics of microcapsules. Numerous potential applications have been advanced in various patents and elsewhere (1, 43, 44) and have served to stimulate exploration of the area.

The discussion to this point has primarily involved the patent literature. As such, it was descriptive in areas of technology but lacked depth of detail due to the nature of the literature covered. Several definitive treatments of restricted areas of microencapsulation have appeared in the literature. The object of an important, continuing, in-depth study (45-52) has been to encapsulate enzymes in semipermeable microcapsules for use in enzyme-replacement therapy. Thus far, these investigators have reported several successes using both shunt systems and, in certain cases, interperitoneal injection. They have encapsulated catalase,

urease, and erythrocyte hemolysates as well as detoxicants useful in conjunction with the experimental enzyme therapy.

Various encapsulation methods have been used by these investigators in attempts to achieve workable systems. Microcapsules have been prepared with walls of nylon, collodion, and heparin-complexed collodion. The nylon microcapsules are of special interest, since neither the methods by which they may be prepared nor the products themselves have, as yet, been discussed in this presentation. The nylon monomer, 1,6-hexanediamine, was dissolved in water along with a solution of the material to be encapsulated. This was emulsified into a mixture of chloroform and cyclohexane until the desired particle size was reached. At this point, a suitable polymerizing agent, such as sebacyl chloride, which had been dissolved in some of the external phase of the emulsion, was added. As there was migration of the nylon monomer across the interface, and since a polymerizing agent was present in the external phase, polymerization of the nylon took place in the immediate vicinity of the aqueous droplet. Improved capsules, in the sense that they existed individually by virtue of strong negative charges, were achieved when 4,4'-diamino-2,2'-diphenyldisulfonic acid was substituted for 50% of the nylon monomer.

Luzzi *et al.* (53) modified this technique to produce a sustained-release pharmaceutical dosage form. In this work, nylon was used to encapsulate a barbiturate. Particle-size range of the resultant free-flowing powder was noted, and kinetic data were given for the release of medication from tablets formulated in different manners.

Table III—Effect of Final pH on Permeability of Capsule Walls when a Solid Barbiturate Has Been Encapsulated via Complex Coacervation^a

In other work by Luzzi and Gerraughty (54), some selected oils used in pharmacy were encapsulated and evaluated for their effect on capsule permeability (Table II). The capsules were prepared by complex coacervation, using gelatin and acacia, and contained oils with a variety of acid and saponification values and surfactant properties. In additional publications by the same authors (55, 56), a similar encapsulating system, modified for the encapsulation of solids, was evaluated. Manufacturing variables such as starting pH, starting temperature, ratio of encapsulated material to wall material, quantity of denaturant, and final pH (Table III) were examined to determine the effect on capsule formation. Techniques of altering and controlling the release of drugs from microcapsules were also studied.

Phares and Sperandio (57) used a simple coacervate encapsulating system to investigate the possibility of coating pharmaceuticals. They investigated the encapsulation of five solids and two liquids, with emphasis on regulation of coating thickness and on controlling the volume of coacervate. These authors (58) also investigated the preparation of phase diagrams for coacervate systems, using parameters of physical measurement rather than chemical analysis methods which had previously been used.

Very basic work has been and is being carried out in the area of phase separation by Veis and coworkers (59–63). Although microencapsulation was not cited as the objective in these references, the information presented is important for an understanding of the area. These authors have explored phase separation in complex and simple coacervate systems, both with and without fractionated gelatin. In some cases, mathematical models were prepared; in others, the degree of separation of polymeric material was examined.

ADDITIONAL PRESENT AND FUTURE APPLICATIONS

Although wide ranging applications have been found for microcapsules, their potential use in pharmaceuticals has not yet been realized. The following brief overview of a few current and projected applications may suffice to stimulate further the reader's imagination.

The first application was, as mentioned, the preparation of "carbonless carbon paper." Many other uses for these capsules have since followed. The encapsulation of magnetizable materials was disclosed by Schleicher and Boughman (64). The encapsulated material may be permanently magnetized or may be magnetized by magnetic fields applied to the capsules. When the encapsulated and magnetizable materials are light-opaque platelets, light transmission through the area covered by these capsules may be controlled by the direction of the magnetic field. This type of application has potential in fields such as computerology, printing, data processing, copying, and light shuttering (Fig. 9).

Another application for microcapsules may be found when it is desired to apply a thin film of a volatile or partially volatile mixture on surfaces. One such application (65, 66) involves the encapsulation of ad-

Figure 9—Schematic of encapsulated magnetic pigments in different magnetic fields.

hesives and subsequent distribution of the encapsulated adhesive on a surface. In the encapsulated form, the adhesive is nontacky and remains so until the capsules are ruptured. Various adhesive systems have been advanced and include heat reactivatable, resin-catalyst, solvent reactivatable, and totally encapsulated systems.

Another application (67) using films of microcapsules involves absorbent material which may be used for cleaning and wiping. In this case, the pressure applied during use releases an encapsulated soil-removing liquid. Similar products are becoming increasingly popular in the advertising media for fragrances and foods.

Other microencapsulated products, such as aspirin, have been marketed, and the potential for products seems to be unlimited. This is due to the variety of techniques that exists for encapsulating particles as a means of packaging, separating, and/or storing materials on a microscopic level for later release under controlled conditions. Pharmaceutical applications such as taste-masking of bitter drugs, formulation of prolonged-action medicinals, separation of incompatible materials, protection of moisture- and light-sensitive drugs, and formulations for enzyme-replacement therapy are areas currently receiving considerable attention.

Other areas, allied to pharmaceuticals, which are being investigated include agricultural chemicals and foods. In agriculture, microcapsules of insecticides, fungicides, and various microorganisms, for example, have been made in attempts to increase the longevity of action of the encapsulated material.

The food industry is using microcapsules as containers for maintaining the quality of fats, oils, and flavors. The encapsulated materials are released during the preparation of the meal or during ingestion.

Perhaps the most imaginative area for the application of encapsulated materials is in aerospace studies. Cosmic dosimeters utilizing encapsulated live bacteria are already in use. Measurement of survival of bacteria during a space trip can indicate how much cosmic radiation was encountered. Another possibility in the area of space travel may be in the construction of urethan-type shelters. This application depends on the encapsulation of a polymer which foams when the capsules are broken. This and other applications may be found in many of the references cited to this point; however, no attempt has been made to exhaust this type of reference. References 68–81 have been included

in the list so that the interested reader may pursue the topic further.

Thermodynamic Analysis of Structure-Activity Relationships of Drugs: Prediction of Optimal Structure

TAKERU HIGUCHI and STANLEY S. DAVIS*

Abstract □ A new quantitative and comprehensive approach relating structures of congeneric drugs to their relative biological activities is presented. The analysis is derived on the basis that structure-activity relationships represent a family, a different situation applying to each phenomenon such as drug absorption, drug transport, drug transformation, and drug excretion. The present treatment considers the relationship under equilibrium or quasiequilibrium conditions, thus permitting rigorous thermodynamic treatment. On the basis of the effect of structural changes on the distributive tendencies of the drug in various body tissues, including the receptor site, relationships have been derived which are surprisingly in good agreement with available experimental data. The approach suggests a rational way to predict the degree of lipophilicity which would result in maximal activity.

Keyphrases □ Structure-activity relationships, drugs—optimal structure prediction □ Thermodynamic analysis—structure-activity relationships □ Equilibrium conditions, model compartments—thermodynamic activity, drugs □ Energy change—aqueous-lipid partitioning

Persistent efforts have been made over many decades to bring some satisfactory order to the correlation of the relative activities of drugs with their molecular

structure. The last few years have seen a great upsurge in interest in this direction. In this publication, the authors: (a) review many of the earlier hypotheses and theories dealing with structure-activity relationships, and (b) present a new formulation of the problem based on thermodynamics.

The proposed approach, which will be treated in depth later in this paper, assumes that any observed biological activity in the animal or any test system usually involves one or more time-independent situations and a large number of time-dependent processes such as drug absorption, drug transport, drug transformation, and drug excretion. Since structural alterations affect each of these differently, it would appear highly unlikely that any single relationship can account for the observed situation. The present treatment has been largely limited to analysis of the effects of structural changes on the time-invariant activity of drugs.

As a general approximation, overall interaction of a drug molecule with its receptor site appears to be resolvable into two parts. The first is highly specific in nature and is presumably responsible for the "lock and

Persistent efforts have been made over many decades to bring some satisfactory order to the correlation of the relative activities of drugs with their molecular

structure. The last few years have seen a great upsurge in interest in this direction. In this publication, the authors: (a) review many of the earlier hypotheses and theories dealing with structure-activity relationships, and (b) present a new formulation of the problem based on thermodynamics.

The proposed approach, which will be treated in depth later in this paper, assumes that any observed biological activity in the animal or any test system usually involves one or more time-independent situations and a large number of time-dependent processes such as drug absorption, drug transport, drug transformation, and drug excretion. Since structural alterations affect each of these differently, it would appear highly unlikely that any single relationship can account for the observed situation. The present treatment has been largely limited to analysis of the effects of structural changes on the time-invariant activity of drugs.

As a general approximation, overall interaction of a drug molecule with its receptor site appears to be resolvable into two parts. The first is highly specific in nature and is presumably responsible for the "lock and

key" relationship between the two interactants (1). It is suggested that this part of the interaction involves those portions of the drug and receptor species that are in intimate fixed contact with each other. The second, which is largely unspecific in nature, is generally considered to arise simply from hydrophobic interaction between the lipoidal parts of the drug molecule and various lipophilic portions of the receptor. The present treatment is limited essentially to the influence on drug activity arising from the effects of changes in its molecular structure on the latter contribution to drug-receptor binding.

It is recognized, however, that the effect on activity of any structural changes in the drug molecule cannot always be totally ascribed to one or the other of the two interaction categories. Introduction of a hydrophobic grouping in the near vicinity of the specific site, for example, may increase the nonspecific interactions while interfering with the "lock and key" relationship. However, if the specific-type binding is assumed to be limited to a fractionally small part of the molecular surface of the drug, it would appear that most structural changes would not affect the specific interaction but would manifest their effect essentially through their influence on hydrophobic binding. Most serious approaches relating group contribution to drug activity have been limited primarily to effects arising from the same unspecific part of the overall interaction.

EARLIER APPROACHES

Some of the more interesting earlier studies on structure-activity relationships were those made by Overton (2), Meyer (3), and Meyer and Hemmi (4), who related narcotic activity to partition coefficients and suggested that narcosis occurred when a definite molar concentration was reached in the receptive lipid biophase. In a normal homologous series, for example, the increase in activity upon the addition of a methylene group was shown to be in the narrow range of 2.5-3.3 times, depending on the nature of the drug series and the test organism. Many physicochemical properties of aliphatic compounds, which depend on an equilibrium between two phases, increase or decrease with change in chain length in a similar manner. The increase in biological response with chain length does not continue indefinitely as predicted by this relationship; instead, a cut-off point is reached where higher homologs have little or no activity. Hansch (5) rightly commented that such effects are of extreme importance and should be explained by any proposed model dealing with structure-activity relationships.

Ferguson (6) rationalized the picture of narcotic action using thermodynamics and suggested that an equilibrium exists between the extracellular phase and the phase at the site of action (receptor site) such that substances present at the same proportional saturation in a given medium have the same degree of biological action. Or, as stated by Brink and Posternak (7), "equal degrees of narcosis are produced at about equal thermodynamic activities."¹ This generalization, unlike the earlier theories of Overton (2) and Meyer (3), has the great advantage of not requiring any specific mechanism of action. Ferguson (6) also considered that physical toxicity involved no chemical reaction and that the narcotic substance left the body unchanged (8). For example, the substitution of a halogen in a hydrocarbon leaves the potency practically unchanged, and no specific narcotic character can be ascribed to the chlorine atoms in

chloroform, their presence merely lowers the vapor pressure of methane to a level convenient for administration.

McGowan (9) related the bioactivity of organic compounds to their size (parachor), while Mullins (10) examined the problem with the help of the solubility parameter concept (11). The latter concluded that narcosis, by chemically inert molecules, took place when constant fraction of the total volume of some nonaqueous phase in the cell was occupied by narcotic molecules. If the narcotic behaved ideally in the biophase, the thermodynamic activity multiplied by the volume fraction of narcotic was a constant. Higher values of thermodynamic activity, which occurred when a homologous series was ascended, were attributed to an increase in the activity coefficient of the narcotic in the biophase.

Crisp and Marr (12) examined the action of a range of narcotic substances from a more strictly thermodynamic standpoint and concluded that the mechanism of narcotic action in small organisms is only consistent with an equilibrium condition between the narcotic in the biophase and in the external medium. They felt that no theory that relied solely on a rate process, such as diffusion through a lipid layer, could account adequately for the facts. However, Hansch and Fujita (13) recently concluded that, in the great majority of cases, a true equilibrium condition is rarely achieved and that a probabilistic approach may be far more realistic. These aspects will be discussed at greater length with relation to the proposed model.

By far the most widely known and employed linear free energy approach to structure-activity correlation is that due to Hansch (5, 14-16) and Hansch and Fujita (13). Originally, a four-parameter approach was suggested:

$$\log BR = k\pi^2 + k'\pi + \rho\sigma + k'' \quad (\text{Eq. 1})$$

where π is a constant derived from partition studies between water and 1-octanol, σ is the Hammett constant, and ρ is a reaction constant derived from regression analysis. Correlation between biological response (BR) and chemical structure was achieved with a great many diverse systems. When only the π -term was necessary for good correlation, the response was considered to be controlled by a physical process (*e.g.*, partitioning of the drug), whereas a chemical interaction was thought to be responsible for correlations dominated by the σ -term. However, this type of one-parameter approach was limited, no doubt, to the complex nature of the biological test systems which would include problems such as drug penetration, possible differential rates of metabolism and excretion, and steric, electronic, and hydrophobic interactions with critical sites in the biophase. Also of equal importance is the very limited accuracy of much of the biological data.

In free energy terms the response can be considered as being governed by one rate-limiting process for which K_{BR} is the equilibrium constant (14). Then:

$$\Delta F_{BR}^0 = \Delta F_{L/H}^0 + \Delta F_{\text{electronic}}^0 + \Delta F_{\text{steric}}^0 \propto \log K_{BR} \quad (\text{Eq. 2})$$

where L/H = hydrophobic and BR = biological response.

In partial terms for substituent effects and for a true equilibrium condition:

$$\delta_x F_{BR}^0 = \delta_x F_{L/H}^0 + \delta_x F_{\text{electronic}}^0 + \delta_x F_{\text{steric}}^0 \propto \delta_x \log K_{BR} \quad (\text{Eq. 3})$$

Attempts can then be made to associate the various free energy terms with definite physicochemical constants (Table I). For example,

$$\delta_x F_{L/H}^0 = f(\log P, \pi, R_M, \Delta R_M, \beta, \text{ and parachor}) \quad (\text{Eq. 4})$$

$$\delta_x F_{\text{electronic}}^0 = f[\sigma, \text{etc., quantum mechanically calculated electron densities or chemical shifts (NMR)}] \quad (\text{Eq. 5})$$

The $\delta_x F_{\text{steric}}^0$ terms are somewhat difficult to ascribe to definite parameters, although E_S and E_S^C have been used. Often, a two-parameter approach seems to be successful.

Detailed examples of the use of the various parameters can be found in one of the many recent reviews of Hansch's work (13-15). In some cases, this has indicated that, while steric interactions are extremely important [for example, see Portoghese (17)], the concept of "lock and key" fit of drug and substrate has been overemphasized at the expense of hydrophobic bonding (14).

¹ The use of the term "thermodynamic activity" in this sense is questionable. As defined by G. N. Lewis (*Proc. Amer. Acad. Arts Sci.*, **37**, 49(1901), activity of Component A can only be compared to some other state of A. The authors will treat this in greater detail in a subsequent paper.

Hansch's approach is not without its shortcomings (18) and by and large it cannot cope with steric factors or with metabolic inactivation processes too successfully. Also, some surprising results appear in regression analysis. For example, in one case the derived equations would indicate that the mode of action of thiobarbiturates differs from that of the analogous barbiturates (19).

The linear free energy relations of Zahradnik (20, 21) are also of the basic Hammett type but are restricted in their application to aliphatic compounds of the type R—X. They can be written as:

$$\log(BR_i/BR_0) = \alpha\beta \quad (\text{Eq. 6})$$

where BR terms refer to the response of the species (i) and the reference species (0); β is a constant characterizing the alkyl substituent R and its value is independent of the nature of the functional group X; and α characterizes the susceptibility of the biological system to the influence of the substituents R. The two constants are mutually independent. The β is linearly related to the logarithm of the activity coefficient of the drug and Hansch's π (22). Success in correlation has been demonstrated for situations where specific electronic and steric effects are not crucial, and the approach has also been extended (21) using Hammett and Taft substituent constants.

In continuing investigations designed to elucidate structure-activity relationships, Purcell *et al.* (23) attempted correlation with a wide range of parameters, including dielectric and surface-active properties, dipole moments, and electronic structure. A number of attempts have also been made to apply molecular orbital methods, but progress has been slow due to the lack of a reasonable theoretical framework within which to work (24). Hansch (5) has not attempted to factor out hydrogen bonding, although Purcell *et al.* (23) have suggested ways of dealing with such a term.

Table I lists some of the parameters that have been used in linear free energy correlations of the Hansch type. In multiparameter cor-

Table I—Linear Free Energy Correlation Parameters ($\log BR = a(1) + b(2) + \dots + k$)

Parameter	
1. π	Hydrophobic bonding constant from partition coefficients ^{a-e}
2. π^2	
3. σ	
4. σ^2	Hammett linear free energy constant ^{a-g}
5. σ^*	
6. σ_I	Taft aliphatic constant ^{h, i}
7. σ_+	Inductive parameter ^j
8. σ_p	Electrophilic radical constant ^j
9. σ_m	Electronic effect of substituent attached to side chain and positions <i>ortho</i> to it ^k
10. σ'	
11. $\pi\sigma$, etc.	
12. E_s	Taft steric parameter ^m
13. E_s^c	Hancock's corrected steric parameter ⁿ
14. N	Number of carbon atoms in substituent ^{n, o}
15. nH	Number of hydrogens attached to protonated nitrogen ^o
16. $\log P$	Partition coefficient ⁿ
17. $\log VP$	Vapor pressure (from GLC) ^o
18. P_E	Molar electronic polarizability ^o
19. γ	Arbitrary steric constant ^r
20. μ^2	Dipole moment ^s
21. $t_{1/2}$	Reaction parameter ^r
22. $S_o(Z)$	Superdelocalizability ^{t, u}
23. $f_{oxy}(E)$	Frontier electron density (ether oxygen) ^{t, u}
24. ϵ	Electron density on nitrogen ^v
25. pK_a	(Reference 1)
26. ΔpK_a	Dissociation constant difference between parent and derivative ^w
27. E_R	Constant obtained from hydrogen abstraction reaction of nuclear-substituted cumenes ^j
28. Δk	Hydrogen bonding parameter ^z
29. P	Orientation polarization of amide groups ^z
30. A	Wheland's atomic localization energy ^h
31. $[P]$	Parachor ^v
32. E_A	Interaction parameter (hydrogen bonding) ^{z, aa}
33. F	Molar attraction constant ^{bb}
34. πF	^{bb}
35. R_M	Chromatography constant derived from R_f ^{cc}

Table I—Continued

Parameter	
36. $HOMO$	Energy of highest occupied molecular orbital ^{dd}
37. $[P^*]$	Adjusted parachor ^{ee, ff}
38. δ_c	Occupation number (extended Huckel theory) ^{gg}
39. e_c	Electron density by extended Huckel theory ^{gg}
40. ϵ_c	As 39, but by complete neglect of differential overlaps ^{gg}
41. θ	Total interaction energy hydride ion ^{gg}
42. Δ_E	Eigen value differences ^{gg}
43. δ_E	Incipient transition state energy differences ^{gg}
44. M	Molecular weight ^{ff}

relations, the mathematical significance of the various terms, π , σ , etc., as well as π^2 , σ^2 , and $\sigma\pi$, are determined using regression analysis. The physicochemical significance of the various squared and product terms is not clear.

The choice of terms is often bewildering; and in many cases, little can be said about a particular parameter except that it "works" and gives improved correlation. The complexity of some of the more recent equations is also disturbing. A recent illustrative example cited by Hansch (25) but not recommended contains seven terms to correlate 16 data points:

$$\log BR = -0.123 \pi^2 + 0.633 \pi - 1.823 \sigma^2 + 3.162 \sigma - 0.796(\pi\sigma) + 0.639 E_s + 1.450 \quad (\text{Eq. 7})$$

Leo *et al.* (26) recently examined some of the parameters currently used in structure-activity relationships and their improvement, if any, over simple correlations using molecular weight. In general, the octanol-water partition coefficient was more suitable for satisfactory correlation than polarizability, molar attraction constant, parachor, or adjusted parachor. A great number of linear free energy constants (27) have yet to be tested but this would appear to be only a matter of time.

Free and Wilson (28) developed a purely mathematical approach to structure-activity relationships from an original proposal by Bruce *et al.* (29). Here it is assumed that the contribution due to each substituent is additive and constant, regardless of substituent variation in the remainder of the molecule. Although being restricted to a series of chemically related species, it has the great apparent advantage over linear free energy methods in that no physicochemical data are required. Smithfield and Purcell (30) discussed the application and requirements of the method. These are: (a) closely re-

lated analogs that provide a gradual change in biological response; (b) accurate biological data; and (c) additive activity parameters. Although somewhat limited for these reasons, it has been used with success by Purcell and Clayton (31), Ban and Fujita (32), and many others. A similar additive method is that of Kopecký *et al.* (33) in which constants are fitted to a semiempirical equation using regression analysis. This too is limited, at present, to specialized classes of compounds.

Singer and Purcell (34) compared the linear free energy and Free and Wilson (28) types of correlation technique. Each has its own merits and disadvantages. In particular, the Free and Wilson additive constant group contribution concept is not suitable for cases where there is a parabolic relation between the partition coefficient and biological response.

Interrelationships between the various methods have also been discussed by Cammarata (24) who showed that many of the physico-chemical approaches to the study of drug action can be related, in a quantitative manner, to the principle of hard and soft acids. Here the drug-receptor interaction was discussed in terms of each pair of interacting atoms making an independent contribution to the electronic, steric, and desolvation free energies of interaction.

A NEW PROPOSAL BASED ON THE EQUILIBRIUM MODEL

It is apparent from the preceding analysis of the various approaches to structure-activity relationships that no single proposed system has been widely accepted and, at the same time, been based on rational grounds. To a certain degree, this has been due apparently to the fact that a single, simple correlation was sought when none was possible for the multifaceted situation. The authors wish to suggest a more limited approach which seems to be rational, relatively simple, and perhaps more useful. It is designed for any test system that rapidly achieves distributive equilibrium or quasiequilibrium with respect to the added drug. It assumes, in brief, that: (a) any test system, whether a culture of microorganisms, a mouse, or a man, consists of a number of widely differing physical regions having widely differing affinities for the added drug species, and (b) biological activity is determined by the relative amount distributed to the receptor from the total system.

For the purpose of analysis, the authors make the following conditions and fundamental assumptions.

1. A biological test system can be represented by t number of accessible compartments, $w, 1, 2, 3, \dots, t + r$, where compartment w is the aqueous phase; 1, 2, 3, *etc.*, are tissue, lipoidal, protein, *etc.*, phases; and r is the receptor. The receptor can either be some definite site (*e.g.*, an enzyme surface) or some unspecialized region in some cells. The effective volume of each compartment is $V_w, V_1, V_2, \dots, V_t$.

2. Thermodynamic equilibrium or quasiequilibrium is reached in all accessible phases, and the thermodynamic activity of the drug in the r th compartment is the same as that in the aqueous, first, second, *etc.*, all with reference to a common standard state. If a drug is added to the aqueous compartment, it will be distributed to all the other available compartments according to Nernst's distribution law.

3. For a series of drugs of closely related structures, biological activity is proportional to the fraction of the active sites occupied. If the fractions occupied are made the same, then equal biological response will be elicited.

4. Essentially all of the administered drug will be distributed to the various accessible body compartments, and only an insignificant amount will actually be attached to the receptor site.

Apparent observed overall activities of a series of drugs in any animal test system will obviously be dependent on effects of structural changes on, for example, the process of absorption, the process of transport to the area of the receptor site, the process of excretion, the process of chemical transformation into metabolites, *etc.* As is apparent, the authors have in the present analysis restricted the definition of drug activity to equilibrium situations, the term drug activity being related to the intensity of biological response observed when the test drug is assumed to be completely distributed over all of the readily accessible tissue and fluid space. The equilibrium, or more correctly, the pseudoequilibrium definition of drug activity can be, to a certain extent, considered as the intrinsic (time-independent) activity, and other (time-dependent) effects can be considered modifications of it. The pseudoequilibrium situation commonly prevails,

Table II—Affinity Constants for the CH₂ Group

Solvent	<i>F</i>
Carbon tetrachloride	4.6
Cyclohexane	4.5
Chloroform	4.4
Hexane	4.2
Benzene	4.2
Ethyl ether	3.6
Octanol	3.2
Oleic acid	3.1
Ethyl acetate	3.0
<i>n</i> -Butanol	2.6
2-Butanol	2.2
3-Pentanone	2.1

because a significant number of the body compartments of the test systems are not accessible to many drugs.

The influence of the distributive effects on drug activity can be formalized as follows. Consider the situation when an amount of drug, S , is administered to the test system. It is evident that

$$S = C_w V_w + C_1 V_1 + C_2 V_2 + \dots + C_t V_t$$

$$= C_w V_w + \sum_{i=1}^{i=t} C_i V_i \quad (\text{Eq. 8})$$

where C 's refer to the effective concentrations in each accessible bio-phase compartment and V 's to their volumes. As previously stated, the number of accessible compartments is taken as t , and the amount of drug incorporated into the receptor phase is normally negligible.

If the drug distribution between the aqueous phase and each bio-phase is assumed to follow a linear partition isotherm, a distribution constant can be defined:

$$K_i = \frac{C_i}{C_w} \quad (\text{Eq. 9})$$

and

$$S = C_w \left(V_w + \sum_{i=1}^{i=t} K_i V_i \right) \quad (\text{Eq. 10})$$

The effective concentration of the drug on the receptor can then be formulated by solving for C_w in Eq. 10:

$$C_r = K_r C_w = \frac{SK_r}{V_w + \sum_{i=1}^{i=t} K_i V_i} \quad (\text{Eq. 11})$$

or

$$E = \frac{C_r}{S} = \frac{K_r}{V_w + \sum_{i=1}^{i=t} K_i V_i} \quad (\text{Eq. 12})$$

E being the concentration of drug produced on the receptor per unit amount of drug administered. It relates directly to the expected relative activity of the drug.

What change in activity can be expected on this basis when, for example, a hydrogen in the reference (parent) drug is replaced by a methyl group? It is apparent from Eq. 12 that the activity of the new derivative will differ from that of the parent compound as the chemical change influences the various K , the partition coefficient,

values in the equation. For a system where $V_w \gg \sum_{i=1}^{i=t} K_i V_i$ (that is, for

a system where the bulk of the drug is in the aqueous phase), it is evident that the substitution of a methyl for a hydrogen will produce a marked increase in lipophilicity and activity corresponding to a similar increase in K_r (usually of the order of 2-3 \times), the partition coefficient of the receptor site. This relates as a first approximation to the amount of free energy necessary to bring a methylene group from aqueous to the receptor bond state. It is evident that if two methylene groups are introduced (*e.g.*, by substituting with C₂H₅ rather than CH₃), the increase in activity will correspond to the

Figure 1—Two-compartment model analysis of drug distribution: $F_{(CH_2)r} = 3$ and $F_{(CH_2)l} = 3$.

square of the first; i.e., if the first increase is by a factor of 2.5, the second will be approximately $(2.5)^2$ or 6.25. This follows essentially the group contribution approach developed by Hansch and others (5).

For the situation, $V_w < \sum_{i=1}^t K_i V_i$, i.e., for systems in which the drug has been largely distributed into the tissue phases leaving only a small fraction in the aqueous, substitution of a methyl for a hydrogen may be expected to lead to a decrease in activity in instances where the receptor may be intermediate in polarity. This can be seen by using a highly simplified test system consisting only of an aqueous phase and a single lipoidal phase in addition to the receptor. For such a case:

$$E = \frac{K_r}{V_w + K_l V_l} \cong \frac{K_r}{K_l V_l} \quad \text{since } K_l V_l \gg V_w \quad (\text{Eq. 13})$$

where subscript l refers to the lipoidal phase. It is evident that K_r may still increase by a factor of 2.5, but K_l may increase by a factor of 4.5, the expected decrease in activity in this example being $2.5/4.5$ or by a factor of $5/9$. For the same system, introduction of C_2H_5 for CH_3 will be expected to produce a $(5/9)^2$ decrease in activity.

These concepts, as they apply to Eq. 12, can be generalized. Thus, when substituents α , β , etc., are introduced, the effective drug concentration on the receptor is

$$E = \frac{K_r^*(F_\alpha)(F_\beta) \cdots}{V_w + \sum_{i=1}^t [K_i^*(F_\alpha)(F_\beta)_i \cdots] V_i} \quad (\text{Eq. 14})$$

where the asterisk (*) refers to the partitioning properties of the parent reference drug into compartment i , and the F 's are the factorial group contribution in modifying them with respect to each biophase. An F value, as used here, is the ratio of the partition coefficient of a substituted substance to the partition coefficient of the parent compound. For the example of the methyl substitution given in this illustration, $F_{(CH_2)r} = 2.5$ and $F_{(CH_2)l} = 4.5$. It is evident that for systems obeying equilibrium or pseudoequilibrium conditions, Eq. 14 will permit prediction of the effects of such substituents whose F values are known.

For comparison of relative activities of derived compounds with those of their parents, it is convenient to define another function:

$$R = E/E^* = \frac{K_r \left(V_w + \sum_{i=1}^t K_i^* V_i \right)}{K_r^* \left(V_w + \sum_{i=1}^t K_i V_i \right)} \quad (\text{Eq. 15})$$

It is apparent that if $R > 1$, a derived compound is more active than its parent; conversely, if $R < 1$, it will be less active.

The relationships discussed can perhaps be seen more effectively graphically. For the two-compartment model discussed, select the situation such that $V_w = 1$ and $K_l^* = 0.33$. The resulting activity values expressed as R as functions of the number of added methylene groups are shown in Figs. 1–3. In all cases, R initially increases in magnitude with increase in chain length. When the volume of the lipoidal phase is somewhat less than that of the aqueous phase, this increase is more or less geometric in nature. However, the linear (geometric) region does not continue indefinitely, and a maximum or limiting value of R is obtained. If $F_{(CH_2)l} = F_{(CH_2)r}$, a plateau region is reached where further increase in chain length has little effect on R . If $F_{(CH_2)l}$ is greater than $F_{(CH_2)r}$, a maximum value for R is obtained. The exact shapes of the various hypothetical curves are dependent on the values of V_i and $F_{(CH_2)l}$, $F_{(CH_2)r}$. If $F_{(CH_2)l} = 2F_{(CH_2)r}$, a parabolic relationship results (Fig. 3). The position in the alkyl chain for maximum activity depends on the difference between the affinity factors (F values) of the receptor and lipoidal phase and the volume of the lipoidal phase. As the difference between $F_{(CH_2)r}$ and $F_{(CH_2)l}$ becomes greater, maximal R occurs at lower chain lengths. A similar result is obtained by increasing the volume of the lipoidal phase.

It is evident that for any real multicompartment system, the fractional distribution of drug into various compartments will be such that it will move from the aqueous phase gradually toward the most lipophilic compartment as the drug itself is made more lipoidal. In the extreme cases, the drug will be found largely in the aqueous or in the most lipoidal compartment (adipose tissues), which correspond roughly to the simplified example. The receptor sites, because of their locations, may be expected to offer intermediate environments

Figure 2—Two-compartment model analysis of drug distribution: $F_{(CH_2)r} = 3$ and $F_{(CH_2)l} = 4$.

Figure 3—Two-compartment model analysis of drug distribution: $F_{(CH_2)_r} = 2$ and $F_{(CH_2)_l} = 4$.

The authors found that for nearly all nonpolar lipoidal solvents such as benzene, cyclohexane, carbon tetrachloride, chloroform, and hexane, the free energy change in transferring a methylene function from water to the lipoidal environment is such that an addition of a CH_2 produces a partition coefficient increase by a factor close to 4.5 at 25° (Table II). Similarly, a CF_2 produces an increase by a factor of 5.5. It would appear, therefore, that if the effect on K_r is by a factor of 2–3, any significant increase in lipophilicity can be expected to lead to decreased activity at longer chain lengths. It is apparent that at some point of balanced lipophilicity, the optimal concentration of the drug on the receptor surface will be obtained. The so-called “parabolic” relationship between drug activity and lipophilicity, therefore, is a thermodynamically predictable situation, as shown in Figs. 1–3. Figure 4 shows an example of the “parabolic” relationship in biological response data between drug activity and lipophilicity.

Affinity constants, the F values, corresponding to effects of individual groupings on distributions of the drug between water and various lipoidal media (solvents) can most conveniently be estimated by partitioning experiments. For many systems, this would involve simply measuring the partition coefficient of a selected compound and that of the same compound containing in addition the grouping under study. The affinity constant for a methylene group, for example, can be evaluated by measuring the factorial increase in the partition coefficient of, for example, *p*-propylphenol as compared to that of *p*-butylphenol, the difference corresponding to the free energy of transfer of a methylene from water to the selected solvent. Some of these constants have been evaluated in the authors' laboratory in this manner, including the use of the ion-pair extraction procedure

Figure 4—Dilution of alkyl rhodanates required for 50% kill of green chrysanthemum aphid. [Plotted from the data of E. E. Bousquet, P. O. Salzberg, and H. F. Dietz, *Ind. Eng. Chem.*, 27, 1342(1935).]

described earlier (35). It is evident that if the F values for all common substituent groupings were available, it would permit much greater insight into the potential distributive behavior of new drugs.

The $F_{(CH_2)}$ for inert hydrocarbon solvents, determined as described, is in the region of 4.2–4.5, while for polar liquids this value appears to be considerably lower and is dependent on the nature of the polar liquid in question. Some representative values calculated from partition data are shown in Table II. Values for other isolated groupings in various solvents can be also obtained from published data or from partition experiments. For example, $F_{(C_6H_5)}$ is 1000 in cyclohexane and 60 in octanol. The addition of a halogen atom brings about an increase in the partition coefficient in the majority of cases; for aromatic species, this increase can be correlated quite well with the size of the added groupings. Although different F values for the halogens are evident for different solvents, detailed accurate partition experiments will be necessary before a table of values similar to Table II can be derived for them.

Polar groupings, of course, present a very diverse picture, and a great variety of F values will be possible, depending on the nature of the lipid phase. To a first approximation, the hydroxyl group, for example, has an F value of 2×10^{-2} in octanol and 4×10^{-4} in cyclohexane. In general, polar groupings will have a solubilizing effect in water and will increase the hydrophilic nature of a drug species. Some insight into the possible variation in values of F can be gained by calculating activity coefficient values for various functional groups in different organic solvents (Table III). The magnitudes of the various contributions can be rationalized largely on the basis of hydrogen bonding interactions. When both hydrogen-donating and hydrogen-accepting groupings are present in a single drug molecule, there is always the possibility of intramolecular bonding resulting in marked departure from additivity situations for these groupings.

A semiquantitative concept of the effect of adding various functional groups to a hypothetical drug molecule can be obtained by using the F values given, employing arbitrary values for K_l , V_l , and V_w , and considering that in the simple two-compartment model the lipoidal phase is similar to an inert hydrocarbon (cyclohexane) and the receptor biophase is similar to a long-chain alcohol (octanol). The calculated R values (Table IV) show that the quantity of substituted drug reaching the receptor site, as compared to the parent drug, depends on the partition coefficient of the parent drug and the volume

Table III—Activity Coefficients of Aliphatic Functional Groups in Different Organic Solvents

Group	Solvent					
	Benzene	Chloroform	Carbon Tetra- chloride	Octanol	Ether	Cyclohexane- Hexane
CH_3	1.00	0.96	0.92	1.32	1.15	1.00

of the lipoidal compartment, all other factors being equal. The usual generalization that the addition of a hydrophobic grouping results in a greater quantity of drug at the receptor site and the converse for a hydrophilic grouping are of limited value. The CH_2 and C_6H_5 groups will give increased drug concentration at the receptor site and, hence, biological activity when K_1 and V_1 are small. However, when K_1 and V_1 become larger, the drug will be contained almost exclusively in the lipoidal phase. This is especially true for the C_6H_5 grouping in the present example, where R becomes very much less than unity, indicating a greatly reduced activity for the substituted form. At the other extreme, a hydroxyl group brings about reduced activity at low K_1 and V_1 but has the opposite effect at higher values.

One major point of interest resulting from this approach is that it suggests that within the stated limitations it is possible to predict the degree of lipophilicity required to elicit the optimal activity for a given drug series. As pointed out earlier, whether a given substituent will effect an improvement in the drug activity will depend on whether R as defined in Eq. 15 is greater than 1 or not, the optimal lipophilicity for the drug usually corresponding to $R = 1$ when a single CH_2 grouping is added. It is evident that if, for example, a methylene group is added to a parent drug molecule and the resulting derivative drug possesses essentially the same biological activity, R would be close to unity and these structures would represent nearly the peak in the parabolic relationship between activity and the number of, for example, methylene carbons. For the simple two-compartment model systems consisting only of the aqueous and lipoidal phases, R can be readily estimated by using Eq. 15 in terms of the relative amounts of the drug found in the aqueous phase (V_w) and in the lipid phase (V_l). In Fig. 5, R corresponding to addition of a single methylene is shown for $F_{(\text{CH}_2)_l} = 4.5$ as a function of the logarithm of $K_1 \cdot V_l / V_w$, the ratio of amount of drug concentrated in the lipid phase to that in the aqueous for several values of $F_{(\text{CH}_2)_r}$, the affinity constant for the receptor site. Although the selection of the affinity constant for the receptor affects the ratio at which point $R = 1$, the maximum point in the parabolic relationship, the effect is relatively small, the ratio of the amounts of the drug in the two phases for $R = 1$ being 0.40 for $F_{(\text{CH}_2)_r} = 2.00$, 0.56 for $F_{(\text{CH}_2)_r} = 2.25$, and 1.25 for $F_{(\text{CH}_2)_r} = 3.0$. Since the $F_{(\text{CH}_2)_r}$ values for most receptors would usually fall in the range of 2.25–2.50, assuming that the receptor site has an intermediate polar nature, the ratio would normally be expected to be within the range of 0.40–1.00 for maximum drug activity. Since this variance is well within the range produced by a single methylene group, it would appear that normally a rather sharp maximum in activity could be expected when approximately one-half to an equivalent amount of drug is concentrated in the adipose and other lipoidal tissues, as compared to that found free in the aqueous phase of the test system. This postulate is readily amenable to experimental test.

Although this approach was based on the simplified two-phase model, it is more widely applicable to real animal systems than it may first appear. The adipose tissue in man is normally the largest and the most important lipophilic depot, along with fat deposits in

Figure 5—Influence of distribution ratio and affinity constant for receptor site on the relative activity of drug containing CH_2 grouping over that of the parent compound.

the circulatory and other systems. It is evident that it is largely to these accessible, similar, essentially nonpolar lipid deposits that lipophilic drugs tend to accumulate as they are made increasingly hydrophobic.

The present general approach has been described in terms of equilibrium interaction with a definite, although usually unidentified, receptor site. It is evident that essentially the same development and conclusions would apply to systems in which the drug activities are governed by rates of transport across membrane barriers. Since in such situations the rate is directly influenced by the equilibrium concentration on the surface of the barrier, all of the relationships derived apply with equal validity.

The authors recognize the fact that the present treatment attempts to treat an extremely complex problem in a simplistic way. Situations have been ignored that involve irreversible interaction with the receptor, induced conformational changes in the receptor, non-linear distribution function (for the receptor and any of the remaining biophases), and any other complicating factor. The authors have not considered the specific interactions between the receptor and the drug nor between the competing sites in other biophases. The analysis treats the test system as being in equilibrium, a state that is not altogether realistic for any large living organism. Yet the present approach points to the start that must be taken in recognizing the influence of substituents on distributive tendencies to compartments other than the receptor in affecting the observed apparent activity.

Metal Complexes of Thiouracils I: Stability Constants by Potentiometric Titration Studies and Structures of Complexes

EDWARD R. GARRETT and DENNIS J. WEBER

Abstract □ The divalent metals, Cu^{++} , Pb^{++} , Cd^{++} , Ni^{++} , and Zn^{++} , complex with the 5- and/or 6-alkyl-substituted thiouracils, HU. Significant concentrations of MU^+ and MU_2 complexes in homogeneous solution for all but Cu^{++} permitted estimation of the respective K_1 and K_2 stability constants by potentiometric titrations, where the $\log K_1$ values were directly proportional to the pK_a values of the parent thiouracils. Thus, the complex with 5,6-dimethyl-2-thiouracil (pK_a' 8.08) was the most stable, and the complex with 5-carboethoxy-2-thiouracil (pK_a' 6.43) was the least stable of those studied. The initial MU^+ complex is formed by the covalent bonding of the divalent cation at the anionic sulfur. When sulfhydryl formation in thiouracil is blocked by prohibiting tautomerization, as with 6-methyl-*N,N'*-diethyl-2-thiouracil, or by alkylation of the sulfur, as with 2-ethylmercapto-4-hydroxypyrimidine, no complexation with metal ions was observed. Pb^{++} and Cd^{++} ions have stability constants, K_1 , for MU^+ formation with thiouracils that are 100 times greater than with Ni^{++} or Zn^{++} . No complexation of thiouracils with Fe^{+++} , Fe^{++} , Co^{++} , Ca^{++} , or Mn^{++} was observed. The MU_2 complex is formed by the covalent bonding of the divalent metal to two sulfur anions; this bis(6-*n*-propyl-2-thiouracil)-cadmium (II) is the first complex to precipitate from solution on the titration of cadmium ion and 6-*n*-propyl-2-thiouracil at 25 and 35°. The structure was confirmed by elemental analysis and IR spectra

of synthesized compounds. In all other cases of studied complexation of Cd^{++} and Pb^{++} with 2-thiouracil, 6-methyl-2-thiouracil, 5-methyl-2-thiouracil, 5,6-dimethyl-2-thiouracil, 5-carboethoxy-2-thiouracil, and 6-*n*-propyl-2-thiouracil, the first complex that precipitated on potentiometric titration had a 1:1 stoichiometry and was most probably the cyclic dimer, M_2U_2 , bis(thiouracil-metal) (II), although the polynuclear polymer, M_nU_n , was possible. The heightened acidity of the 4-OH of the initial MU^+ complex promoted dissociation at low pH values and subsequent covalent bonding of the divalent cation to the sulfur of one thiouracil and the oxygen of another. The resultant M_2U_2 or M_nU_n structure was confirmed by elemental analysis and IR spectra of synthesized complexes. The formed and precipitated complexes of Pb^{++} and Cd^{++} as MU^+ , MU_2 , and M_2U_2 were stable, at least in mildly alkaline solutions, whereas those of Ni^{++} and Zn^{++} were destroyed in mild alkali with the final precipitation of the metal hydroxides.

The antithyroid activities of 5-methyl-, 6-methyl-, and 5,6-dimethyl-substituted thiouracils have been claimed to be 0.7, 1.0, and 1.2 relative to 2-thiouracil (Structure Ia) (1–3).

The present antithyroid derivative of choice, because of its claimed maximal activity and low toxicity in the intact animal, is 6-*n*-propyl-2-thiouracil (1–5). Alkylation of thiouracil at the N-1, N-3, or sulfur positions greatly reduced (2), and substitution by electronegative groups at the 5- or 6-position practically eliminated, any antithyroid activity (1–3).

Cupric ion has been implicated in thyroid function (6). The copper content of the normal and pathologic thyroid has been determined (7) and verified by Kasanen and Viitanen (8) who found elevated copper levels in toxic and nontoxic goiters. The formation of diiodoty-

rosine and thyroxine is increased when cupric ion is added to homogenates of thyroid gland (9). Other evidence that cupric ion aids in the formation of thyroxine, by formation of iodine from iodide, has been presented (10–12).

Since cupric ion and other heavy metals precipitate thiouracil and its derivatives from aqueous solution, Libermann (13, 14) conjectured that complexing ability and antithyroid activity may be correlated. He assumed that completeness of precipitation could be taken as a measure of the stability of the complex. However, this assumption is not necessarily valid. Some ethylenediaminetetraacetic acid (EDTA) complexes have high stability and high water solubility. Libermann (14) suggested the structure for the cupric–thiouracil complex (Structure Ib), which assumed a 1:1 stoichiometry of

metal to ligand and chelate binding of the cupric ion by the sulfur at the 2-position and the oxygen at the 4-position. Consideration of the stereochemistry of 2-thiouracil and the square-planar nature of cupric ion shows that the proposed structure is impossible because the phenolic oxygen and thionyl sulfur are coplanar and physically distant.

The oxidation of thiouracil by iodine has been shown to occur with ease at physiological pH values. The product is the disulfide (Structure Ic) (15):

The disodium salt of this disulfide is stable, but the free acid readily disproportionates to thiouracil and higher oxidation products (15).

This ease of the oxidation of 2-thiouracil by iodine suggests that thiouracil's antitumor mechanism of action may be the reduction of iodine to the ineffective iodide. However, since cupric ion has been implicated in thyroid function at the level of iodine production, the removal of cupric or cuprous ion by complexation with thiouracil could be an alternate explanation for its mode of action. If the complexation of cupric or cuprous copper is important in the mechanism of action of the thiouracils, then the stability constant of the complex may be larger for copper than with other physiological metal ions. Furthermore, it may be possible to correlate the stability constant of the copper complex or complexes of thiouracils and other metals with the biological activity of the particular thiouracil derivative. The correlation can only be expected under the conditions of

equal concentrations at the site of action. Any differences in the *in vivo* solubility or stability of the thiouracil derivative should be considered.

The principal purpose of these studies was to provide quantitative information on the complexation of metal ions with thiouracils. The types of metal ions which complex, the effect of thiouracil substituents on the stability constants, and the structure of the complexes were to be determined. This first paper in the series applies the method of potentiometric titrations to the study of aqueous solutions of metal complexes of thiouracil that maintain homogeneous solutions for portions of the titrations. This excludes the study of solutions of mixtures of copper ions and thiouracils that give immediate precipitation by this method. The complexes of lead, cadmium, nickel, zinc, ferric, ferrous, manganese, calcium, and cobaltous ions with 2-thiouracil (TU), 6-*n*-Propyl-2-thiouracil (PTU), 6-methyl-2-thiouracil (6MTU), 5-methyl-2-thiouracil (5MTU), 5,6-dimethyl-2-thiouracil (5,6DMTU), 5-carboethoxy-2-thiouracil (5CETU), *N,N*'-diethyl-6-methyl-2-thiouracil, and 2-ethylmercapto-4-hydroxypyrimidine (2EM4HP) are to be considered, however.

EXPERIMENTAL

Purification of 2-Thiouracil (TU)—2-Thiouracil¹ was recrystallized from hot water. The product was washed with water and acetone and dried in a vacuum oven at 80°, m.p. 322–323° dec. (all melting points are uncorrected); literature value 310–312° dec. (16), about 340° (17). Equivalent weight 130.3; calculated for C₄H₄N₂OS 128.1. IR spectrum (18), $\bar{\nu}$ in cm⁻¹ (Nujol mull): 3020 (NH); 1680 (C=O); 1280, 1240, 1177. UV spectrum (16), (0.1 M HClO₄), λ_{max} . 273 (ϵ 13,700), λ_{max} . 212 (ϵ 16,600).

Purification of 6-*n*-Propyl-2-thiouracil (PTU)—The compound² was recrystallized from hot water and dried at 80°, m.p. 219–221°; literature value 219–221° (19). Equivalent weight 170.0; calculated for C₇H₁₀N₂OS 170.2. IR spectrum, $\bar{\nu}$ in cm⁻¹ (Nujol mull): 3100 (NH); 1650 (C=O); 1550, 1240, 1190. UV spectrum (0.1 M HClO₄), λ_{max} . 272 (ϵ 15,840), λ_{max} . 214 (ϵ 15,840).

Purification of 6-Methyl-2-thiouracil (6MTU)—The compound³ was recrystallized from hot water and dried in a vacuum oven at 50°, m.p. 331–332° dec.; literature value >300° (1). Equivalent weight 142.1; calculated for C₆H₈N₂OS 142.1. IR spectrum, $\bar{\nu}$ in cm⁻¹ (Nujol mull): 3100 (NH); 1640 (C=O); 1195, 1165. UV spectrum (0.1 M HClO₄), λ_{max} . 274 (ϵ 15,460), λ_{max} . 213 (ϵ 15,760).

Purification of 5,6-Dimethyl-2-thiouracil (5,6DMTU)—This material⁴ was recrystallized from hot water and dried at 50° in a vacuum oven, m.p. 286–287° dec.; literature value 283–285° (1). Equivalent weight 156.5; calculated for C₈H₁₀N₂OS 156.2. IR spectrum, $\bar{\nu}$ in cm⁻¹ (Nujol mull): 3210, 3110 (NH); 1660 (C=O); 1600, 1210, 1130. UV spectrum (0.1 M HClO₄), λ_{max} . 276 (ϵ 17,340), λ_{max} . 215 (ϵ 14,020).

Purification of 5-Methyl-2-thiouracil (5MTU)—5-Methyl-2-thiouracil⁵ was recrystallized from hot water, washed with water, and dried at 50° in a vacuum oven, m.p. 334° dec; literature value not available (17). Equivalent weight 141.2; calculated for C₆H₈N₂OS 142.1. IR spectrum, $\bar{\nu}$ in cm⁻¹ (Nujol mull): 3090 (NH); 1640 (C=O); 1240, 1200, 1165. UV spectrum (0.1 M HClO₄), λ_{max} . 274 (ϵ 15,450), λ_{max} . 213 (ϵ 15,730).

Purification of 5-Carboethoxy-2-thiouracil (5CETU)—5-Carboethoxy-2-thiouracil⁶ was used as received, m.p. 245–246°; literature value 245° (17). Equivalent weight 197.5; calculated for C₇H₈N₂O₃S

200.2. UV spectrum (0.1 *M* HClO₄), λ_{max} . 310 (ϵ 15,121), λ_{max} . 269 (ϵ 18,991), λ_{max} . 213 (ϵ 10,762).

Purification of 2-Thio-6-aminouracil—2-Thio-6-aminouracil was used as received, m.p. 330°; literature value 295° (17). UV spectrum (0.1 *M* HClO₄), λ_{max} . 275 (ϵ 18,413), λ_{max} . 202 (ϵ 5856).

Synthesis and Purification of 6-Methyl-*N,N'*-diethyl-2-thiouracil (X)—This material was synthesized by the procedure of Lacey (20). *N,N'*-Diethylthiourea⁷ (3.2 g.) was added to 20 ml. of glacial acetic acid and brought to a boil in a round-bottom flask fitted with a reflux condenser and a dropping funnel containing 8.6 g. of diketene.⁸ The diketene was added over a 0.5-hr. period, and the reaction was allowed to cool overnight. The reaction was further heated for 0.5 hr. and then cooled; the acetic acid was removed by vacuum evaporation. Twenty milliliters of water was added to the residue; the mixture was shaken to emulsify and put into a refrigerator overnight. The precipitated contents were recrystallized from hot water and dried in a vacuum oven at 50°, m.p. 97–98°; literature value 97–98° (20). IR spectrum, $\bar{\nu}$ in cm.⁻¹ (Nujol mull): 1680 (C=O); 1250, 1105. UV spectrum (H₂O), λ_{max} . 278 (ϵ 13,100), λ_{max} . 222 (ϵ 15,250). Potentiometric titration with 0.1 *N* NaOH indicated that no titratable acid function was present. The yield was 73%.

Synthesis and Purification of 2-Ethylmercapto-4-hydroxypyrimidine (2EM4HP) (IX)—Eight grams of 2-thiouracil (0.062 mole) was added to 2.49 g. NaOH (0.062 mole) in 100 ml. of water, and acetone was added; the solution was cooled overnight in a refrigerator. A precipitate of the sodium salt of 2-thiouracil formed (8.3 g., 0.055 mole), which was filtered and collected.

The sodium salt of 2-thiouracil (0.055 mole) and ethyl iodide (0.06 mole, 9.35 g.) were added to 120 ml. of 95% ethanol in a round-bottom flask and refluxed until the sodium thiouracil had gone into solution. It was necessary to add an additional 4 g. (0.026 mole) of ethyl iodide during the reaction to put the sodium thiouracil into solution. The reaction mixture was cooled and the ethanol removed by vacuum evaporation. A white residue was left, which was recrystallized from ethanol once and then finally purified by sublimation, m.p. 152–153°; literature value 152° (17). IR spectrum, $\bar{\nu}$ in cm.⁻¹ (Nujol mull): 1660 (C=O), 1270, 1170, 1540. UV spectrum (H₂O), λ_{max} . 280 (ϵ 5500), λ_{max} . 230 (ϵ 11,750). Equivalent weight 156.4; calculated for C₈H₈N₂OS 156.2.

Anal.—Calcd. for C₈H₈N₂OS: C, 46.13; H, 5.16; N, 17.94; S, 20.52. Found: C, 46.40; H, 5.31; N, 18.04; S, 20.37.⁹

Potentiometric Titrations—All potentiometric titrations were performed using a Sargent model D automatic titrator equipped with a 2.5-ml. capacity syringe buret. The sample solutions were titrated under nitrogen in water-jacketed titration cells at constant temperature. A Beckman combination electrode with Ag–AgCl reference was used. The pH standardization at 4 and 7 was checked before and after each titration. In no case was the pH drift larger than 0.05 pH unit and usually was less than 0.02 unit.

The 0.1 *N* sodium hydroxide titrant was prepared and maintained carbonate-free. Sample solutions for titration were prepared with constant concentrations of thiouracil (2×10^{-3} *M*) and varying concentrations of metal ion, as listed in Table I. The ionic strength was maintained constant at 0.006 *M* by substituting 0.03 *M* sodium perchlorate for equal volumes of 0.01 *M* divalent metal nitrate, since the ratio of the molar concentrations of sodium perchlorate to divalent metal nitrate is 1:3 for equal ionic strengths.

The p*K*a' values of the various thiouracils (Table II) were determined by potentiometric titration with standard alkali, with an initial ionic strength of 0.006 *M* and estimated from the pH of half-neutralization. The p*K*a' values at 25.0° were the averages of at least three separate determinations and had standard deviations of less than 0.05. The p*K*a' values at 35.0 and 45.0° were usually single determinations made at the same time and under the same conditions as the titrations of the metal–thiouracil mixtures. The equivalent weights of the thiouracils have been given under the characterization of the individual compounds.

Standardization of Metal-Ion Solutions—Analytical grade nitrate salts of cupric, cadmium, lead, nickel, ferric, cobalt, calcium, zinc, and manganese were used to prepare stock solutions in distilled water. The stock solutions were standardized using the mercury, mercury–EDTA electrode¹⁰ (21, 22). The general procedure was to

titrate potentiometrically solutions containing 2-ml. aliquots of 0.01–0.04 *M* metal nitrate, 25.0 ml. of buffer (22), and 1 drop of 1.0×10^{-3} *M* Hg–EDTA solution (22) with 0.1000 *M* EDTA. The reference electrode was a saturated calomel electrode. In the case of cobalt, an excess of standard calcium was added, and the excess was determined by titration with EDTA according to the general procedure outlined. Since the procedure of Reilly *et al.* (22) cannot be used to standardize ferric ion, the procedure of Pribil *et al.* (23) was used. The procedure was to titrate a solution containing 5 ml. of 0.01 *M* ferric ion, 25.0 ml. of a pH 3 chloroacetic acid buffer (0.2 *M*), and 1 drop of a 0.01 *M* ferrous perchlorate solution. The titrant was 0.1000 *M* EDTA, and the electrode system consisted of a platinum indicator electrode and a calomel reference. Since ferrous ion is easily oxidized, fresh ferrous-ion stock solutions were prepared as needed from analytical grade FeSO₄ · 7H₂O¹¹ and boiled, nitrogen-purged water.

Aqueous Solubility of Thiouracils—Saturated aqueous solutions (50 ml. of 0.1 *M* HClO₄ in 100-ml. sealed flasks) of 2-thiouracil, 6-*n*-propyl-2-thiouracil, 6-methyl-2-thiouracil, 5-methyl-2-thiouracil, 5,6-dimethyl-2-thiouracil, 5-carboethoxy-2-thiouracil, and 6-amino-2-thiouracil were equilibrated at 25.0° in a controlled temperature shaker bath. Filter sticks (Sargent No. S-30417) were used to remove samples from the equilibrated solutions. The first filtrate was discarded; 2.0-ml. aliquots of the filtered, equilibrated solution were taken, appropriately diluted with 0.1 *M* HClO₄, and read on the Cary spectrophotometer or the Beckman DU against a 0.1 *M* HClO₄ blank solution. Repetitive samples were taken with time to assure complete equilibration. Possible oxidation (15) of the equilibrating solutions of TU, PTU, 5MTU, and 6MTU were denied by the fact that the absorbances at several wavelengths were of the same ratio to similar absorbances for fresh solutions of these thiouracils. The calculated solubilities are listed in Table II.

Spectrophotometric Titrations of Thiouracils—Thirty milliliters of solutions, 0.921×10^{-4} and 1.00×10^{-4} *M* in 2-thiouracil and 8.00×10^{-3} *M* in sodium perchlorate, contained in a water-jacketed titration cell (25.0°), were titrated with 1.00 *N* NaOH and 0.0499 *N* NaOH, respectively. Nitrogen gas, free of carbon dioxide (passed through an Ascarite tube) and saturated with water (passed through a sparger tube immersed in water) at 25.0°, was passed into the cell for each run. The cell solution was stirred with a magnetic stirrer. A constant-rate buret (Sargent) equipped with a 2.5-ml. syringe buret was used to deliver the titrant to the cell. The volume delivered could be read to the nearest 0.5 μ l. A microaperture flow cell (Beckman catalog No. 97290) was connected by polyethylene tubing (Clay-Adams Co., No. PE 200) to the titration cell and to a 5.0-ml. gastight syringe (Hamilton). After each addition of standard alkali, the gastight syringe was actuated by hand to draw the titration cell solution into the flow cell and the spectrum recorded *versus* a water blank. The gastight syringe was actuated several times before each spectrum was recorded to ensure thorough mixing of any solution that may have remained in the flow cell or tubing. The pH of the solution was read after mixing using a glass-calomel electrode system and a Radiometer pH meter (No. TTT 1). The total volume change during the titration of the sample solution was less than 2% and was considered negligible.

The absorbances at the λ_{max} and other wavelengths were plotted against pH. The p*K*a' values were determined from the intercept of plots of $\log [(A - A_{\text{H}^+})/(A_{\text{OH}^-} - A)]$ *versus* pH, where *A* is the absorbance at a given pH value, *A*_{H⁺} is the absorbance in 0.10 *M* HClO₄, and *A*_{OH⁻} is the absorbance at pH 9 in accordance with the expression (24):

$$\log \left(\frac{A - A_{\text{H}^+}}{A_{\text{OH}^-} - A} \right) = \text{p}K_a' - \text{pH} \quad (\text{Eq. 1})$$

The p*K*a' values determined by spectrophotometric titrations are given in Table II.

Synthesis of Bis(2-thiouracil)cadmium (II) or Cd(TU)₂ (IV)—A solution containing 0.06 mole of 2-thiouracil in 2 l. of hot water was prepared. To the 2-thiouracil solution was added slowly, with stirring, a solution containing 0.03 mole of cadmium nitrate in about 200 ml. of water. The resulting mixture was allowed to stand 0.5 hr. on low heat (about 70°). It was then allowed to cool to room temperature, and the pH was adjusted to 6.5 with concentrated NaOH.

^a The ligand concentration was 0.002 M, ionic strength was 0.006 M, and initial volume of the titrating solution was 25.00 ml. The ligand abbreviations represent the following compounds: (TU) 2-thiouracil; (PTU) 6-*n*-propyl-2-thiouracil; (6MTU) 6-methyl-2-thiouracil; (5MTU) 5-methyl-2-thiouracil; (5,6DMTU) 5,6-dimethyl-2-thiouracil; and (5CETU) 5-carboethoxy-2-thiouracil. ^b These are the slopes of plots of $\log(1 - \bar{n})/\bar{n}$ versus $p[U^-]$, where \bar{n} is the degree of formation of a postulated 1:1 complex (MU⁺) in accordance with $\log(1 - \bar{n})/\bar{n} = pK_1 + p[U^-]$. For those cases where the slope was consistent with the theoretical expectation of unity, it can be postulated that the only complex present in significant concentration is the 1:1 complex, MU⁺. The values of log K₁ estimated from the intercept of these plots for unit slopes are given in parentheses. ^c Log K₁ and log K₂ values were derived from the slope and intercept values of plots of $\bar{n}/(1 - \bar{n})[U^-]$ versus $[(\bar{n} - 2)/(\bar{n} - 1)][U^-]$ in accordance with $\bar{n}/(1 - \bar{n})[U^-] = K_1 + [(\bar{n} - 2)/(\bar{n} - 1)][U^-] K_1 K_2$, where K₁ is the stability constant for the formation of the 1:1 complex, MU⁺, and K₂ is the stability constant for the formation of MU₂ from MU⁺. The mean values of the log K values are given for each temperature with the estimated standard deviations. ^d This value was considered anomalous and was not included in the calculation of the mean values. ^e There was immediate precipitation on addition of Pb(NO₃)₂ to the 5CETU solution.

The resulting suspension was warmed again, cooled to room temperature, and filtered through a medium fritted-glass funnel. The product was washed with cold water and acetone and dried in a vacuum oven at 60°. IR spectrum, $\bar{\nu}$ in cm⁻¹ (Nujol mull): 1620, 1550, 1530, 1300, 1210, 1180, 827.

Anal.—Calcd. for C₈H₆CdN₄O₂S₂: Cd, 30.65. Found: Cd, 31.54, 30.96.

Synthesis of Bis(2-thiouracil)lead (II) or Pb(TU)₂ (IV)—The procedure for the synthesis of bis(2-thiouracil)cadmium (II) was exactly the same as in the case of bis(2-thiouracil)cadmium (II) except that lead nitrate was used in place of cadmium nitrate. IR spectrum, $\bar{\nu}$ in cm⁻¹ (Nujol mull): 1660, 1630, 1560, 1500, 1280, 1000, 815.

Anal.—Calcd. for C₈H₆N₄O₂PbS₂: Pb, 44.90. Found: Pb, 44.51.

Synthesis of Bis(2-thiouracil-cadmium) (II) or Cd₂(TU)₂ (VII)—A solution containing 0.06 mole of 2-thiouracil in a minimum of hot water was added slowly, with stirring, to a 1-l. solution contain-

ing 0.06 mole of cadmium nitrate heated to the same temperature (about 80°) as the hot thiouracil solution. The resulting mixture was maintained at the initial temperature for 0.5 hr. and then allowed to cool to room temperature. Concentrated sodium hydroxide was added to pH 6.8, and the resulting suspension was reheated. After 30 min. the suspension was cooled to room temperature and the product filtered through a medium fritted-glass funnel. The resulting product was washed with water and then acetone and dried in the vacuum oven at 60°. IR spectrum, $\bar{\nu}$ in cm⁻¹ (Nujol mull): 3400, 1570, 1510, 1335, 1020.

Anal.—Calcd. for C₈H₄Cd₂N₄O₂S₂: Cd, 47.2. Found: Cd, 45.8.

Synthesis of Bis(2-thiouracil-lead) (II) or Pb₂(TU)₂ (VII)—The procedure for bis(2-thiouracil-lead) (II) was exactly the same as in the case of bis(2-thiouracil-cadmium) (II) with lead nitrate substituted for cadmium nitrate. IR spectrum, $\bar{\nu}$ in cm⁻¹ (Nujol mull): 1560, 1520, 1430, 1330, 1000, 820.

Scheme I—Relations among the divalent metal-ion complexes of thiouracils except that no experimental evidence exists in support of MUOH (V). MU⁺ (III) and MU₂ (IV) exist in significant concentrations in solution, and characterized MU₂ (IV), M₂U₂ (VII), and/or M_nU_n (VIII) are precipitated from solutions of metal-ion and thiouracil mixtures.

Table II—Intrinsic Solubilities^a at 25.0° and pKa' Values of Various Thiouracils

^a Determined from the absorbances of saturated solutions in 0.1 M HClO₄ where the absorptivity values for wavelengths of maximum absorbance have been given in the *Experimental* section. ^b Determined by potentiometric titration with standard alkali with an initial ionic strength of 0.006 M, where the pKa' was estimated from the pH of half-neutralization. The pKa' values at 25.0° were the averages of at least three separate determinations and had standard deviations less than 0.05. The parenthetical pKa' values at 25.0° were determined by spectrophotometric titration of 10⁻⁴ M thiouracil from the intercept values of plots of log [(A - A_{H+})/(A_{OH-} - A)] versus pH, where A is the absorbance at a given wavelength at a given pH value, A_{H+} is the absorbance in 0.10 M HClO₄, and A_{OH-} is the absorbance at pH 9 in accordance with the expression log [(A - A_{H+})/(A_{OH-} - A)] = pKa' - pH.

Anal.—Calcd. for C₈H₄N₄O₂PbS₂: Pb, 62.15. Found: Pb, 62.54.

Synthesis of Bis(6-*n*-propyl-2-thiouracil)cadmium (II) or Cd(PTU)₂ (IV)—The preparation of this complex was performed in the same manner as for bis(2-thiouracil)cadmium (II). The molar amounts of 6-*n*-propyl-2-thiouracil and cadmium nitrate were 0.06 and 0.03, respectively. IR spectrum, $\bar{\nu}$ in cm.⁻¹ (Nujol mull): 3100, 1630, 1500, 1270, 1220, 1175, 1015, 970, 830.

Anal.—Calcd. for C₁₄H₁₈CdN₄O₂S₂: C, 37.29; H, 4.02; Cd, 24.9; N, 12.43; S, 14.22.¹² Found: C, 37.94; H, 4.15; Cd, 24.7; N, 11.95; S, 13.77.

Synthesis of Bis(6-*n*-propyl-2-thiouracil-lead) (II) or Pb₂(PTU)₂ (VII)—This complex was prepared by the same procedure as for bis(2-thiouracil-cadmium) (II). The molar amounts of 6-*n*-propyl-2-thiouracil and lead nitrate used were 0.06. IR spectrum, $\bar{\nu}$ in cm.⁻¹ (Nujol mull): 1550, 1420, 1280, 1165, 1020, 825.

Anal.—Calcd. for C₁₄H₁₈N₄O₂PbS₂: Pb, 55.2. Found: Pb, 55.4.

Analysis of Cadmium Content of Complexes—Accurately weighed (200-mg.) samples of the dried cadmium complex were dissolved in 150 ml. of 0.01 M H₂SO₄ and heated (70°) until all of the sample had dissolved. Approximately 150 mg. of sodium hydrogen sulfide in 15 ml. of water was added, and the resulting cadmium sulfide precipitate was digested for about 2 hr. until the crystals were large. The precipitate was filtered onto a tared, fritted-glass funnel, washed with warm water, and dried in a vacuum oven at 50° overnight. The dried precipitate was weighed in the funnel, and the cadmium was calculated by multiplying the weight of cadmium sulfide by the gravimetric factor 0.7780 (25a).

Analysis of Lead Content of Complexes—Accurately weighed samples (300 mg.) of the lead complex were digested in 100 ml. of 1.0 M nitric acid until everything had dissolved. The volume was reduced to 25 ml. by evaporation; 100 ml. of a solution 2.0 M in sulfuric acid and 1.0 M in sodium sulfate was added. The precipitate was digested to give large crystals, and the volume was reduced by evaporation to about 50 ml. The precipitate was collected on a tared, fritted-glass funnel, washed with water, dried at 120° overnight, and weighed. The gravimetric factor is 0.6832 (25b).

THEORY AND METHODS OF CALCULATION

The derivation of the general equation for the calculation of stability constants from potentiometric titration data was first given by Bjerrum (26). An excellent summary of computational techniques is also available (27). The following derivations are made for the specific circumstances in this study. They do not assume the formation or precipitation of significant amounts of the hydroxides of the free metal ion, i.e., MOH⁺ or M(OH)₂, and require all species (ligands, metal ions, and complexes) to be in solution and in instantaneous equilibrium. They can be and were applied only under such valid circumstances. All possible species and complexes and the rational equilibria among them are shown in Scheme I. The discussion of the following section is in respect to these relationships.

Equations for Stability Constants of Complexes of Thiouracil (HU) and Doubly Charged Metal Cations (M⁺⁺) where the Significant Complexes in Solution Have Only the Forms MU⁺ and MU₂—The formation of 1:1 (MU⁺) and 2:1 (MU₂) complexes of thiouracil anion (U⁻) and metal ion (M⁺⁺) in homogeneous solution can be formulated as:

The apparent acid-dissociation constant of the thiouracils is:

$$K_a' = \frac{[\text{U}^-][\text{H}^+]\gamma_{\pm}}{[\text{HU}]} \quad (\text{Eq. 3})$$

where [U⁻] and [HU] are the molar concentrations of thiouracil anion, II, and undissociated thiouracil acid, I, respectively; and [H⁺] γ_{\pm} = a_{H+} = 10^{-pH} is the hydrogen-ion activity, where γ_{\pm} is the mean activity coefficient of the hydrogen-ion concentration, [H⁺]. The stability constant for the first complex of metal ion with thiouracil is:

$$K_1 = \frac{[\text{MU}^+]}{[\text{M}^{++}][\text{U}^-]} \quad (\text{Eq. 4})$$

where [MU⁺] is the concentration of the first complex, III; and [M⁺⁺] is the concentration of free metal ion. The step stability constant for the formation of the 1:2 complex is:

$$K_2 = \frac{[\text{MU}_2]}{[\text{MU}^+][\text{U}^-]} \quad (\text{Eq. 5})$$

where [MU₂] is the concentration of the second complex, IV. The overall stability constant, the product of K₁ and K₂, is:

$$\beta_2 = K_1 K_2 = \frac{[\text{MU}_2]}{[\text{M}^{++}][\text{U}^-]^2} \quad (\text{Eq. 6})$$

The mass balance equations for thiouracil, metal-ion, and sodium hydroxide titrant are:

$$[\text{HU}]_0 = [\text{U}^-] + [\text{HU}] + [\text{MU}^+] + 2[\text{MU}_2] \quad (\text{Eq. 7})$$

$$[\text{M}^{++}]_0 = [\text{M}^{++}] + [\text{MU}^+] + [\text{MU}_2] \quad (\text{Eq. 8})$$

$$[\text{NaOH}] = [\text{U}^-] + [\text{MU}^+] + 2[\text{MU}_2] + [\text{OH}^-] - [\text{H}^+] \quad (\text{Eq. 9})$$

The initial stoichiometric concentrations of thiouracil and metal ion in the solution to be titrated are given by [HU]₀ and [M⁺⁺]₀. The stoichiometric concentration of alkali, calculated on the basis that of the amount added at any point in the titration none had yet been consumed, is given by [NaOH]. The concentration of hydroxyl ion in Eq. 9 is the sum of the hydroxyl ion from the titrant and from the dissociation of water. Since a hydrogen ion is produced when a water molecule dissociates, the hydrogen-ion concentration corrects the hydroxyl-ion concentration for this phenomenon, so the resultant equation only accounts for the hydroxyl ion due to the titrant.

¹² Elemental analysis by Huffman Laboratories Inc., Wheatridge, Colo.

The degree of formation, \bar{n} , is defined as the average number of ligands bound to a metal ion:

$$\bar{n} = \frac{[\text{MU}^+] + 2[\text{MU}_2]}{[\text{M}^{++}]_0} \quad (\text{Eq. 10})$$

When the appropriately rearranged Eqs. 3 and 7 are substituted into Eq. 10,

$$\bar{n} = \frac{[\text{HU}]_0 - [\text{U}^-] \left(1 + \frac{[\text{H}^+]\gamma_{\pm}}{K_a'} \right)}{[\text{M}^{++}]_0} \quad (\text{Eq. 11})$$

When Eq. 9 is subtracted from Eq. 7,

$$[\text{HU}]_0 - [\text{NaOH}] = [\text{HU}] - [\text{OH}^-] + [\text{H}^+] \quad (\text{Eq. 12a})$$

If the potentiometric titrations are performed near neutrality and/or significant thioracil is present during the titrations, the differences between the relatively small quantities of $[\text{OH}^-]$ and $[\text{H}^+]$ can be ignored and

$$[\text{HU}]_0 - [\text{NaOH}] = [\text{HU}] \quad (\text{Eq. 12b})$$

This was true for all cases. The value for $[\text{HU}]$ in Eq. 12b may be obtained from a rearrangement of Eq. 3. After substitution of this value for $[\text{HU}]$ into Eq. 12b, the following equation is obtained on rearrangement:

$$[\text{U}^-] = \frac{[\text{HU}]_0 - [\text{NaOH}]}{[\text{H}^+]\gamma_{\pm}/K_a'} \quad (\text{Eq. 13})$$

The right-hand side of Eq. 13 contains only experimentally obtainable quantities; therefore, $[\text{U}^-]$ can be calculated. Substitution of $[\text{U}^-]$ into Eq. 11 allows the calculation of \bar{n} .

Substitution of the rearranged equilibrium expressions for $[\text{MU}^+]$, $[\text{MU}_2]$, (Eqs. 4 and 6) and the mass balance (Eq. 8) for $[\text{M}^{++}]_0$ into Eq. 10 gives, on simplification and rearrangement, a relation between \bar{n} , K_1 , and β_2 :

$$\frac{\bar{n}}{(1 - \bar{n})[\text{U}^-]} = \left(\frac{\bar{n} - 2}{\bar{n} - 1} \right) \beta_2[\text{U}^-] + K_1 \quad (\text{Eq. 14})$$

Equation 14 is linear when $\bar{n}/(1 - \bar{n})[\text{U}^-]$ is plotted against $[(\bar{n} - 2)/(\bar{n} - 1)][\text{U}^-]$. The slope is β_2 and the intercept is K_1 . If β_2 is assumed to be zero, Eq. 14 reduces to an equation whose logarithmic transformation is:

$$\log \frac{1 - \bar{n}}{\bar{n}} = pK_1 + p[\text{U}^-] \quad (\text{Eq. 15})$$

where pK_1 and $p[\text{U}^-]$ represent the negative logarithm of K_1 and $[\text{U}^-]$, respectively. Equation 15 is linear when $\log(1 - \bar{n})/\bar{n}$ is plotted against $p[\text{U}^-]$ and has a slope of 1 and an intercept of pK_1 .

Equations for Stability Constants of Complexes of Thioracil (HU) and Doubly Charged Metal Cations (M^{++}) where Significant Complexes in Solution Have Only the Forms MU^+ , MU_2 , and MUOH (or MU^\pm)—The formation of MUOH (V), the mixed ligand complex (or its reaction equivalent zwitterion MU^\pm , VI) can conceivably occur by reaction of III, Scheme I, or Eq. 2, with OH^- (or by its equivalent, the removal of a H^+):

This derivation of the equations for the calculation of the stability constants of MU^+ (III) and MUOH (V) assumes that no significant amounts of MOH^+ and/or $\text{M}(\text{OH})_2$ are formed and all species are in solution and at equilibrium. The use of the symbol MUOH in the following equations may stand for either MUOH (V) or MU^\pm (VI) or the sum of both. The fact that both are products of hydroxyl-ion reaction with MU^+ (III) makes them mathematically equivalent in all calculations.

The expressions for the apparent acid-dissociation constants, K_a' , and the equilibrium constant, K_1 , for the first complex, MU^+ (III), have already been given (Eqs. 3 and 4). The step stability con-

stants, K_2' , of the mixed ligand complex is:

$$K_2' = \frac{[\text{MUOH}]}{[\text{MU}^+][\text{OH}^-]\gamma_{\pm}'} \quad (\text{Eq. 17})$$

where $[\text{MUOH}]$ is the molar concentration of the mixed ligand complex (V), and $[\text{OH}^-]\gamma_{\pm}' = a_{\text{OH}^-} = 10^{-p\text{OH}} = 10^{-(pK_w - p\text{H})}$ is the activity of hydroxyl ions. The mean activity coefficient is given by γ_{\pm}' . The expression for the autoprotolytic constant of water is:

$$K_w = [\text{H}^+]\gamma_{\pm}[\text{OH}^-]\gamma_{\pm}' \quad (\text{Eq. 18})$$

The overall stability constant, the product of K_w , K_1 , and K_2' , for the mixed ligand complex is:

$$\beta_{11} = K_1 K_2' K_w = \frac{[\text{MUOH}][\text{H}^+]\gamma_{\pm}}{[\text{M}^{++}][\text{U}^-]} \quad (\text{Eq. 19})$$

The value of $[\text{OH}^-]\gamma_{\pm}'$ has been substituted by $K_w/[\text{H}^+]\gamma_{\pm}$ from Eq. 18. The mass balance equations for thioracil, metal-ion, and sodium hydroxide titrant are:

$$[\text{HU}]_0 = [\text{U}^-] + [\text{HU}] + [\text{MU}^+] + [\text{MUOH}] + 2[\text{MU}_2] \quad (\text{Eq. 20})$$

$$[\text{M}^{++}]_0 = [\text{M}^{++}] + [\text{MU}^+] + [\text{MUOH}] + [\text{MU}_2] \quad (\text{Eq. 21})$$

$$[\text{NaOH}] = [\text{U}^-] + [\text{MU}^+] + 2[\text{MUOH}] + 2[\text{MU}_2] + [\text{OH}^-] - [\text{H}^+] \quad (\text{Eq. 22})$$

When the degree of formation for the complexes MU^+ , MUOH , and MU_2 is considered

$$\bar{n} = \frac{[\text{MU}^+] + [\text{MUOH}] + 2[\text{MU}_2]}{[\text{M}^{++}]_0} \quad (\text{Eq. 23})$$

Substitution of rearranged Eqs. 3 and 20 into Eq. 23 results in:

$$\bar{n} = \frac{[\text{HU}]_0 - [\text{U}^-] \left(1 + \frac{[\text{H}^+]\gamma_{\pm}}{K_a'} \right)}{[\text{M}^{++}]_0} \quad (\text{Eq. 11})$$

Subtracting Eq. 22 from Eq. 20, substituting $[\text{HU}]$ from Eq. 3 and $[\text{MUOH}]$ from Eq. 19, and dropping the relatively small quantities $[\text{OH}^-]$ and $[\text{H}^+]$ give:

$$\frac{[\text{HU}]_0 - [\text{NaOH}]}{[\text{H}^+]\gamma_{\pm}/K_a' - \beta_{11}[\text{M}^{++}]/[\text{H}^+]\gamma_{\pm}} = [\text{U}^-] \quad (\text{Eq. 24})$$

The left-hand side of Eq. 24 contains the free metal-ion concentration; therefore, the value of $[\text{U}^-]$ cannot be accurately calculated unless the free or uncomplexed metal-ion concentration is determinable. If the assumption is made that MUOH is not present in any significant amount during some interval in the titration, then Eq. 24 reduces to Eq. 13. This assumption would permit the observed data to conform to Eq. 14. Equation 24 is valid when MUOH is present, whether or not significant amounts of MU_2 are formed.

The relation of \bar{n} to K_1 , β_2 , and β_{11} for mixed ligand complexes is derived by substitution of the equilibrium expressions for $[\text{MU}^+]$ (Eq. 4), $[\text{MUOH}]$ (Eq. 19), $[\text{MU}_2]$ (Eq. 6), and $[\text{M}^{++}]$ (Eq. 21) into Eq. 23 to give:

$$\bar{n} = \frac{K_1[\text{U}^-] + \beta_{11} \frac{[\text{U}^-]}{[\text{H}^+]\gamma_{\pm}} + 2\beta_2[\text{U}^-]^2}{1 + K_1[\text{U}^-] + \beta_{11}[\text{U}^-]/[\text{H}^+]\gamma_{\pm} + \beta_2[\text{U}^-]^2} \quad (\text{Eq. 25})$$

Rearrangement of Eq. 25 by multiplication of both sides by the denominator of the right-hand expression and collection of similar terms gives:

$$\frac{\bar{n}}{(1 - \bar{n})[\text{U}^-]} = K_1 + \frac{\beta_{11}}{[\text{H}^+]\gamma_{\pm}} + \frac{\bar{n} - 2}{\bar{n} - 1} \beta_2[\text{U}^-] \quad (\text{Eq. 26})$$

which is not linear when $\bar{n}/(1 - \bar{n})[\text{U}^-]$ is plotted against $1/[\text{H}^+]\gamma_{\pm}$ or $[(\bar{n} - 2)/(\bar{n} - 1)][\text{U}^-]$ when \bar{n} is calculated from Eq. 11 for $[\text{U}^-]$ calculated from Eq. 24. When it is assumed that the concentration of MUOH is not significant, β_{11} approaches zero, Eq. 26 reduces to Eq. 14, $[\text{U}^-]$ may be calculated from Eq. 13, and only potentiometric titration data are needed. When it is assumed that the concentration

of MU_2 is not significant and that only MU^+ and $MUOH$ complexes may exist, β_2 approaches zero and Eq. 26 becomes

$$\frac{\bar{n}}{1 - \bar{n}[U^-]} = K + \frac{\beta_{11}}{[H^+]\gamma_{\pm}} \quad (\text{Eq. 27})$$

which is linear when $\bar{n}/(1 - \bar{n})[U^-]$ is plotted against $1/[H^+]\gamma_{\pm}$ with a slope of β_{11} and an intercept of K_1 when \bar{n} is calculated from Eq. 11 for $[U^-]$ calculated from Eq. 24, which demands an independent estimate of metal-ion concentration in addition to the potentiometric titration data.

Equations for Stability Constants of Thiouracil (HU) and Doubly Charged Metal Cations (M^{++}) in the General Case where Complexes Have Only the Possible Forms MU^+ , MU_2 , MU^{\pm} (or $MUOH$), and M_2U_2 or n Complexes as M_nU_n .—The formation of positively charged MU^+ (III) and neutral MU^{\pm} (VI) [or its equivalent $MUOH$ (V)] 1:1 complexes, as well as the polynuclear complexes, M_2U_2 (VII), can be formulated as an extension of Eq. 16:

Molecular models of M_2U_2 (VII) in Scheme I are easily formed and exhibit no strain. It is also possible to write polynuclear complexes, M_nU_n , of variable n in the linear form of VIII in Scheme I. This derivation of the equations to relate stability constants of MU^+ , MU^{\pm} , M_2U_2 , and polynuclear complexes, M_nU_n , assumes that no significant amounts of MOH^+ are formed and all species are in solution and in equilibrium.

The expressions for the apparent acid-dissociation constant of the ligand and the stability constant of the first complex (MU^+ , III) have been given (Eqs. 3 and 4). The expression for the acid-dissociation constant of MU^+ (III) to MU^{\pm} (VI) is:

$$K_{a2}' = \frac{[MU^{\pm}][H^+]\gamma_{\pm}}{[MU^+]} \quad (\text{Eq. 28})$$

The equation for the step stability constant of M_2U_2 (VII) is:

$$K_2'' = \frac{[M_2U_2]}{[MU^{\pm}]^2} \quad (\text{Eq. 29})$$

Substitution of the equilibrium expression for $[MU^+]$ (Eq. 4) into Eq. 17 and collection of constants give:

$$\beta_{a2} = K_{a2}'K_1 = \frac{[MU^{\pm}][H^+]\gamma_{\pm}}{[M^{++}][U^-]} \quad (\text{Eq. 30})$$

where β_{a2} has the same value as β_{11} in Eq. 19. Substitution of the expression for $[MU^{\pm}]$ from Eq. 30 into Eq. 29 and collection of constants give:

$$\beta_{22} = K_2''\beta_{a2} = \frac{[M_2U_2][H^+]^2\gamma_{\pm}^2}{[M^{++}][U^-]^2} \quad (\text{Eq. 31})$$

The mass balance equations for thiouracil, metal-ion, and sodium hydroxide titrant are:

$$[HU]_0 = [U^-] + [HU] + [MU^+] + [MU^{\pm}] + 2[M_2U_2] + 2[MU_2] \quad (\text{Eq. 32})$$

$$[M^{++}]_0 = [M^{++}] + [MU^+] + [MU^{\pm}] + 2[M_2U_2] + [MU_2] \quad (\text{Eq. 33})$$

$$[NaOH] = [U^-] + [MU^+] + 2[MU^{\pm}] + 4[M_2U_2] + 2[MU_2] + [OH^-] - [H^+] \quad (\text{Eq. 34})$$

The degree of formation when the complexes MU^+ , MU_2 , MU^{\pm} , and M_2U_2 are considered is:

$$\bar{n} = \frac{[MU^+] + [MU^{\pm}] + 2[M_2U_2] + 2[MU_2]}{[M^{++}]_0} \quad (\text{Eq. 35})$$

Equation 35, when substituted by rearranged Eqs. 3 and 32, is

$$\bar{n} = \frac{[HU]_0 - [U^-] \left(1 + \frac{[H^+]\gamma_{\pm}}{K_{a1}'}\right)}{[M^{++}]_0} \quad (\text{Eq. 11})$$

Subtracting Eq. 34 from Eq. 32; substituting Eqs. 3, 30, and 31 for $[HU]$, $[MU^{\pm}]$, and $[M_2U_2]$, respectively; and dropping the relatively small quantities $[OH^-]$ and $[H^+]$ give:

$$[U^-] = \frac{[HU]_0 - [NaOH]}{[H^+]\gamma_{\pm}/K_{a1}' - \beta_{a2}[M^{++}]/[H^+]\gamma_{\pm} - 2\beta_{22}[M^{++}]^2[U^-]/[H^+]^2\gamma_{\pm}^2} \quad (\text{Eq. 36})$$

where β_{a2} (Eq. 30) has the same value as β_{11} (Eq. 19).

The general equation for the ligand-anion concentration, where n polynuclear complexes M_nU_n (VIII) exist for all n values in addition to the complex MU^+ (III) and independent of whether an MU_2 (IV) complex is present or not, is:

$$[U^-] = \frac{[HU]_0 - [NaOH]}{[H^+]\gamma_{\pm}/K_{a1}' - \sum_0^n \left(\frac{n\beta_{nn}[M^{++}]^n[U^-]^{n-1}}{[H^+]^n\gamma_{\pm}^n} \right)} \quad (\text{Eq. 37})$$

where MU^{\pm} (or its equivalent, $MUOH$) is considered to be a polynuclear complex of the form M_1U_1 . When $n = 1$, the only complexes in solution can be MU^+ , MU^{\pm} , and possibly MU_2 , and Eq. 37 reduces to Eq. 24. When $n = 0$ or if it is assured that M_nU_n complexes including MU^{\pm} (or $MUOH$) are not significant during the titration, the only complexes in solution are MU^+ and possibly MU_2 , and Eq. 37 reduces to Eq. 13 which can be calculated from the homogeneous potentiometric titrations. The values of $[U^-]$ in Eqs. 25 and 37 are functions of the free or uncomplexed metal-ion concentration and cannot be calculated accurately unless this concentration is obtained in addition to the potentiometric titration data.

The relation of \bar{n} to K_1 , β_2 , β_{a2} , and β_{22} is derived by substitution of the equilibrium expressions for $[MU^+]$ (Eq. 4), $[MU_2]$ (Eq. 6), $[MU^{\pm}]$ (Eq. 30), $[M_2U_2]$ (Eq. 31), and $[M^{++}]_0$ (Eq. 33) into Eq. 35 to give:

$$\bar{n} = \frac{K_1[U^-] + 2\beta_2[U^-]^2 + \beta_{a2}[U^-][H^+]^{-1}\gamma_{\pm}^{-1} + 2\beta_{22}[M^{++}][U^-]^2[H^+]^{-2}\gamma_{\pm}^{-2}}{1 + K_1[U^-] + \beta_2[U^-]^2 + \beta_{a2}[U^-][H^+]^{-1}\gamma_{\pm}^{-1} + 2\beta_{22}[M^{++}][U^-]^2[H^+]^{-2}\gamma_{\pm}^{-2}} \quad (\text{Eq. 38})$$

which can be rearranged to:

$$\frac{\bar{n}}{(1 - \bar{n})[U^-]} = K_1 + \frac{\beta_{a2}}{[H^+]\gamma_{\pm}} + \left(\frac{\bar{n} - 2}{\bar{n} - 1}\right)\beta_2[U^-] + \frac{2\beta_{22}[M^{++}][U^-]}{[H^+]^2\gamma_{\pm}^2} \quad (\text{Eq. 39})$$

The general equation to relate \bar{n} and the stability constants for all possible complexes in solution, MU^+ , MU_2 , and n complexes of the form M_nU_n (which includes MU^{\pm} or $MUOH$ as M_1U_1) is:

$$\bar{n} = \frac{K_1[U^-] + 2\beta_2[U^-]^2 + \sum_0^n n\beta_{nn}[M^{++}]^{n-1}[U^-]^n[H^+]^{-n}\gamma_{\pm}^{-n}}{1 + K_1[U^-] + \beta_2[U^-]^2 + \sum_0^n n\beta_{nn}[M^{++}]^{n-1}[U^-]^n[H^+]^{-n}\gamma_{\pm}^{-n}} \quad (\text{Eq. 40})$$

which, when $n = 0, 1$, and 2 , reduces to Eqs. 14, 25 or 26, and 38 or 39, respectively. Only in the case where $n = 0$ and the significant complexes in solution can be only MU^+ and MU_2 will \bar{n} be independent of the free metal-ion concentration and can it be calculated from potentiometric titration data alone.

RESULTS

Potentiometric Titrations of Various Thiouracil-Metal-Ion Mixtures—The addition of an amount of cupric nitrate as low as $2 \times 10^{-4} M$ to a $2 \times 10^{-3} M$ aqueous solution of a 2-thiouracil (2-thiouracil, 6-*n*-propyl-2-thiouracil, 6-methyl-2-thiouracil, 5-methyl-2-thiouracil, and 5,6-dimethyl-2-thiouracil) caused an immediate drop in pH from about 5.5 to about 3.0 and the immediate formation of a precipitate, the amount of which increased with time. Attempts at potentiometric titration of such mixtures with smaller concentrations of thiouracils in the presence of minimal amounts of cupric nitrate were unsuccessful in maintaining a homogeneous solution. Since the complexes of cupric ion and the thiouracils had such low

Figure 1—Potentiometric titration curves of aqueous solutions of lead nitrate and 2-thiouracil with $\mu = 0.006$ at 25.0° . Twenty-five-milliliter solutions were 2.00×10^{-3} M in 2-thiouracil and: (A), 2.00×10^{-3} M; (B), 1.60×10^{-3} M; (C), 1.40×10^{-3} M; (D), 1.20×10^{-3} M; (E), 1.00×10^{-3} M; (F), 8.00×10^{-4} M; (G), 6.00×10^{-4} M; and (H), 0 M in lead nitrate. Curve I is the titration of 25.0 ml. of 4.00×10^{-4} M lead nitrate. The titer of alkali between inflections 1 and 2 are: (B), 6.50×10^{-3} ; (C), 1.14×10^{-2} ; (D), 1.76×10^{-2} ; (E), 2.10×10^{-2} ; (F), 2.30×10^{-2} ; and (G), 3.03×10^{-2} meq.

solubilities, it was technologically infeasible to use the potentiometric titration method which demands instantaneous equilibration in homogeneous solution for the estimation of complexation constants of copper-ion-thiouracil complexes.

Fortunately this was not the general case. Homogeneous solutions were maintained for significant titer additions to mixtures of other metal-ion solutions and various 2-thiouracils.

Typical Potentiometric Titration Curves of Metal-Ion-Thiouracil Mixtures which Initially Form Homogeneous Solutions; Thiouracil-Lead-Ion Mixtures—A typical set of potentiometric titration curves is given in Fig. 1 for solutions of 25.00 ml. of 2.00×10^{-3} M 2-thiouracil (25.0° , $\mu = 0.006$). Various amounts of lead nitrate have been added to each of these solutions so that the original concentration ranged from 2.00×10^{-3} M to 0.00 M $\text{Pb}(\text{NO}_3)_2$ for Curves A to H, Fig. 1. The plots are given in terms of the milliequivalent of NaOH necessary to achieve an observed pH value for each of these solutions. Homogeneous solutions were maintained for a portion of the titrations, and the points of precipitation are clearly indicated in Fig. 1. They occurred in excess of pH 6, except for the particular case (Curve H) of the thiouracil in the absence of lead ion where no precipitation was observed throughout the titration. The titration curve for 25.00 ml. of 4.00×10^{-4} M lead nitrate is given in Curve I.

When the titrations of the precipitating solutions were continued past the points of precipitation, two apparent inflections, labeled as 1 and 2 in Fig. 1, were observed in all cases, except for the equimolar solution (Curve A) of Pb^{++} and 2-thiouracil when only one inflection was observed. The total milliequivalents of NaOH consumed by the equimolar solution (Curve A, Fig. 1) to the first observed inflection at pH 8.3 closely corresponded to twice the milliequivalents of NaOH necessary to neutralize the same concentration of 2-thiouracil alone (Curve H, Fig. 1). This strongly indicates that

the precipitated lead-thiouracil complex is of 1:1 stoichiometry and that the precipitate is the net result of equal numbers of lead ions displacing two protons per molecule from equal numbers of thiouracil molecules. If the added milliequivalents of NaOH necessary to reach the pH of this inflection 1 (Curve A, Fig. 1) had been greatly in excess of twice the milliequivalents necessary to neutralize the ligand, it could be proposed that additional NaOH reacted with the precipitated complex and destroyed it or that the metal hydroxide $\text{Pb}(\text{OH})_2$ was precipitated simultaneously. If all the metal had been reacted to form hydroxide, the milliequivalents of NaOH to this inflection 1 would have been three times the milliequivalents of NaOH necessary to neutralize the ligand alone. IR analysis of the precipitate, isolated at pH 7.5, gave a curve identical to the IR curve of bis(2-thiouracil-cadmium) (II), M_2U_2 (VII).

Further confirmation is obtained from the titrations (Curves B–G, Fig. 1) of solutions where the 2-thiouracil concentrations are in molar excess of $\text{Pb}(\text{NO}_3)_2$ concentrations. The titrations of the excess 2-thiouracil in these curves appear to occur after the completion of the precipitation of the Pb^{++} -thiouracil complex of apparent 1:1 stoichiometry at inflection 1. The milliequivalents of titer between this inflection 1 and inflection 2 may represent the neutralization of the excess 2-thiouracil. It is apparent that this titer between the inflections (Curves B–G, Fig. 1) is for a compound of pK_a 7.5, a fact consistent with the pK_a of 2-thiouracil (Curve H, Fig. 1).

The 10^2 meq. of NaOH consumed between inflections 1 and 2 for the various titrations of Fig. 1 were: B, 0.7 (1.0); C, 1.2 (1.5); D, 1.8 (2.0); E, 2.1 (2.5); F, 2.3 (3.0); and G, 3.0 (3.5). The parenthetical values are the molar excess of 10^3 meq. of 2-thiouracil over Pb^{++} ion; the close correspondence with the titration values is apparent. Exact

Figure 2—Potentiometric titration curves of aqueous mixtures of cadmium nitrate and 6-n-propyl-2-thiouracil (PTU) with $\mu = 0.006$ at 25.0° . Twenty-five-milliliter solutions were 2.00×10^{-3} M in PTU and: (A), 2.00×10^{-3} M; (B), 1.00×10^{-3} M; (C), 4.00×10^{-4} M; and (D), 0 M in Cd^{++} . Curve E is the titration of 25 ml. of 8.00×10^{-4} M cadmium nitrate.

coincidence of these values is not to be expected since it is based on the titration of a heterogeneous and precipitating system which is not in instantaneous equilibria. If the values are taken as absolute, the precipitates may be a mixture of 1:1 stoichiometry and a compound of higher ratio of thiouracil to metal with the former predominating.

Similar titration curves with Pb^{++} ion were observed for the variously 5- and 6-alkyl-substituted 2-thiouracils listed in Table I. Only in the case of the ligand 5-carboethoxy-2-thiouracil was there immediate precipitation on the addition of lead ion.

Titration of Thiouracil-Cadmium-Ion Mixtures—Potentiometric titrations of mixtures of cadmium ion and the variously 5- and 6-alkyl-substituted 2-thiouracils listed in Table I, except 6-*n*-propyl-2-thiouracil, gave sets of curves very similar to those obtained on titration of thiouracil mixtures with lead ion (Fig. 1). Precipitation occurred during the titration at about pH 6.5, so the calculation of stability constants could be based on a region of homogeneous solution. The milliequivalents of NaOH consumed to inflection 1 for the equimolar mixtures of Cd^{++} and substituted 2-thiouracils (Curve A, Fig. 1) corresponded to twice the milliequivalents of NaOH consumed by the same concentration of ligand alone (Curve H, Fig. 1) to indicate strongly the precipitation of a complex of metal ion-thiouracil of 1:1 stoichiometry, which was not destroyed by the addition of further alkali to result in $Cd(OH)_2$. As stated previously, the formation or precipitation of $Cd(OH)_2$ would have consumed milliequivalents NaOH greatly in excess of twice the available milliequivalents of ligand. If the cadmium-thiouracil complex had been completely hydrolyzed, or if the cadmium had been completely precipitated as the hydroxide, three times the milliequivalents of ligand would have been consumed as NaOH.

The IR curve of the precipitate from such titrations was isolated at pH 10.5 and was identical to the IR curve of synthesized bis(2-thiouracil-cadmium) (II), M_2U_2 (VII).

Further confirmation was obtained from the titrations of solutions where the thiouracil concentrations were in molar excess of the $Cd(NO_3)_2$ concentrations. These titrations were similar to Curves B–G of Fig. 1 for the lead-ion studies in that the titration of excess thiouracil assigned to the milliequivalents NaOH between inflections 1 and 2 (about pH 7 and 9) were consistent with the thiouracil added to the original solutions in excess of 1:1 molar stoichiometry with the cadmium ion.

Anomalous Titration Curves of 6-*n*-Propyl-2-thiouracil-Cadmium-Ion Mixtures—The titration curves of cadmium-6-*n*-propyl-2-thiouracil solutions at 25 and 35° (Fig. 2) differed from the curves obtained from mixtures of cadmium ion and the other studied 5- and/or 6-substituted 2-thiouracils or obtained from thiouracil-lead-ion mixtures (Fig. 1). The titration curves for mixtures of cadmium ion and 0.002 *M* 6-*n*-propyl-2-thiouracil (Fig. 2) showed precipitation near pH 6 as before. However, the first inflection, near pH 8.0, for all concentrations of cadmium ion equal or greater than 0.001 *M* (Curves A and B, Fig. 2) occurred when milliequivalents of NaOH were consumed that were equal to the milliequivalents of NaOH consumed by the ligand alone. Only when the total cadmium concentration was less than 0.001 *M* (Curve C, Fig. 2), *i.e.*, when it was less than half of the ligand concentration, did the titration curve give any indication of any excess or uncomplexed ligand. Such excess 6-*n*-propyl-2-thiouracil is postulated to be titrated between the designated inflections of Curve C, Fig. 2, and characterized by the 7.8 pK_a' which is essentially the titration curve of 6-*n*-propyl-2-thiouracil alone (Curve D, Fig. 2) in the absence of cadmium ion. Such a behavior on titration, where the synonymous inflections of Curves A and B (Fig. 2) at the same milliequivalents of NaOH are considered to represent the complete precipitation of all available complex, must demand that the metal to thiouracil precipitate have a 1:2 stoichiometry. The fact that when the added Cd^{++} was in excess of this 1:2 stoichiometry (Curve A, Fig. 2) indicated hydroxide-ion consumption by the excess cadmium ion is confirmatory. This is readily seen from the similarities of the titration curves above pH values of 8 for Curve A and Curve E, where Curve E is for the alkaline potentiometric titration of cadmium ion alone.

The above analysis was performed on titration curves obtained at 25 and 35°. However, at 45° the potentiometric titrations of cadmium-6-*n*-propyl-2-thiouracil solutions gave curves which were similar to Fig. 1. This indicates that at elevated temperatures the precipitation of cadmium complexes of 6-*n*-propyl-2-thiouracil of 1:1 stoichiometry is preferred over the precipitation of cadmium-6-*n*-

Figure 3—Potentiometric titration curves of aqueous mixtures of nickel nitrate and 2-thiouracil (2TU) with $\mu = 0.006$ at 25.0°. Twenty-five-milliliter solutions were 2.00×10^{-3} *M* in 2TU and: (A), 2.00×10^{-3} *M*; (B), 1.20×10^{-3} *M*; (C), 8.00×10^{-4} *M*; (D), 4.00×10^{-4} *M*; and (E), 0 *M* in nickel nitrate. Curve F is the titration of 25 ml. of 4.00×10^{-4} *M* nickel nitrate.

propyl-2-thiouracil complexes of 1:2 stoichiometry that occurs at lower temperatures.

Titration of Nickel-Thiouracil and Zinc-Thiouracil Mixtures—Titrations of 2-thiouracil, 6-*n*-propyl-2-thiouracil, 6-methyl-2-thiouracil, 5-methyl-2-thiouracil, and 5,6-dimethyl-2-thiouracil in the presence of nickel gave curves that showed an initial pH drop from 6.0 to 5.5 and precipitation during the titration near pH 8 (Fig. 3 Curves A–D).

Titration of 6-*n*-propyl-2-thiouracil in the presence of zinc gave an initial pH drop from 6.5 to 6.0 and precipitation occurred near pH 7.3. The titration curves for the zinc complexes were very similar to those found for nickel (Fig. 3).

The potentiometric titrations of equimolar solutions of Zn^{++} or Ni^{++} and thiouracil (Curve A, Fig. 3) when continued past the points of precipitation did not give evidence of clear-cut stoichiometry of the precipitating complexes as had been so evident in the lead and cadmium cases. The total milliequivalents of NaOH consumed to the observed inflection in such a titration was greatly in excess of twice the milliequivalents of NaOH which would have been necessary to neutralize the thiouracil ligand alone (Curve E, Fig. 3). This is definite indication that metal hydroxide precipitation, $M(OH)_2$, must also occur concomitant with the possible precipitation of a metal-thiouracil complex. The fact that the milliequivalents of NaOH consumed between inflections 1 and 2, in Curves B–D, Fig. 3, presumably assignable to the excess thiouracil if the metal-thiouracil complex was at least 1:1, had no relation to milliequivalents of such excess thiouracil, was further evidence that the added hydroxide ion was consumed by the metal and that any metal-thiouracil complexes were probably disrupted by the addition of this excess hydroxide ion.

Figure 4—Plot of $\log(1 - \bar{n})/\bar{n}$ against the negative logarithm of 6-*n*-propyl-2-thiouracil anion concentration ($p[PTU^-]$) obtained from a lead nitrate (2.00×10^{-3} M)–PTU (2.00×10^{-3} M) mixture in water with $\mu = 0.006$ at 25.8° . Slope of plot is 1.00 and $\log K_1$ is 4.82 from the pK_1 intercept.

Titration of 2-Thiouracil and 6-*n*-Propyl-2-thiouracil in the Presence of Other Metal Ions—Potentiometric titrations of 2-thiouracil and 6-*n*-propyl-2-thiouracil in the presence of ferric, ferrous, manganese, calcium, and cobaltous ions gave no indication of any complex formation. The titration curves of the mixtures could be assigned to uncomplexed ligand in the case of calcium and manganese and to hydrolysis of the metal ion in the case of ferric, ferrous, and cobaltous ions.

Titration of Sterically Blocked Thiouracil in the Presence of Cu (II), Cd (II), and Pb (II)—Solutions of 2-ethylmercapto-4-hydroxypyrimidine (2EM4HP) and *N,N'*-diethyl-6-methyl-2-thiouracil in the presence of cadmium, lead, and cupric ions were titrated with standard alkali. The titration curve of 2EM4HP in the presence of cadmium ion was the same as the titration of the ligand alone. The titration curves of 2EM4HP in the presence of cupric and lead ion could be assigned to a simple summation of the metal hydrolysis and ligand titration curves and indicated no apparent complexation. The titration of solutions of *N,N'*-diethyl-6-methyl-2-thiouracil alone showed no titratable group, and the titrations of metal ion mixtures gave curves showing only metal hydrolysis. In the case of 2EM4HP, the pK_a' of the 4-hydroxy group was 7.01 at 25° . The fact that no complexation occurred at the 4-hydroxy position, even when it could form an anion more easily than 2-thiouracil itself ($pK_a' 7.49$), argues for complexation at the sulfur position in the sterically unblocked compounds.

Calculation of Complexation Constants from Potentiometric Titrations—Those portions of the potentiometric titration curves where homogeneous solutions are maintained prior to the points of precipitation (Figs. 1–3) permit the estimation of complexation constants. The highest pH values at which usable data could be obtained in these studies were about 6.5 since the precipitation which occurred destroyed the equilibrium conditions.

Such feasible titration data were analyzed on the basis of the derived equations. First, the assumption was made that the only significant concentration of complex in solution derived from the

doubly charged metal cation M^{++} , and the thiouracil was the 1:1 complex, MU^+ , with the anion of the latter. If this were true, derived Eq. 15:

$$\log \frac{1 - \bar{n}}{\bar{n}} = pK_1 + p[U^-] \quad (\text{Eq. 15})$$

would be applicable and the plot of $\log(1 - \bar{n})/\bar{n}$ against $p[U^-] = -\log[U^-]$ should have a slope of one and an intercept of pK_1 , a measure of the complexation constant of MU^+ . The values of \bar{n} were calculated from:

$$\bar{n} = \frac{[HU]_0 - [U^-] \left(1 + \frac{[H^+]\gamma_{\pm}}{K_a'}\right)}{[M^{++}]_0} \quad (\text{Eq. 11})$$

where $[HU]_0$ and $[M^{++}]_0$ are the molar concentrations of the added thiouracil and metal ion, respectively, where K_a' is the dissociation constant of the thiouracil acid, where $[H^+]\gamma_{\pm}$ is the activity of the hydrogen ion, a_{H^+} , and is calculated from $a_{H^+} = 10^{-pH}$ where the pH is experimentally observed, and where the concentration of thiouracil anion $[U^-]$ is calculated at the same pH value from:

$$[U^-] = \frac{[HU]_0 - [NaOH]}{[H^+]\gamma_{\pm}/K_a'} \quad (\text{Eq. 13})$$

where $[NaOH]$ is calculated on the premise that it would have been the concentration of the added milliequivalent of NaOH at the point in the titration if no NaOH had been reacted or consumed. Typical plots in accordance with Eq. 15 are given in Figs. 4 and 5 and the tabulated slopes of such plots are listed for all available titration studies in Table I. In those cases where the solutions were prepared so that the metal-ion and the thiouracil concentration were equimolar, the slopes of such plots were unity and it was reasonable that the intercept represented the pK_1 of the MU^+ complex (Table I). However, when the total metal-ion concentration $[M^{++}]_0$ was made up to be less than the total thiouracil concentration $[HU]_0$, the estimated slopes of such plots were in excess of unity (Table I). At very high ligand-metal ratios, these slopes approached two in some cases. This would be expected if appreciable amounts of MU_2 were formed which would be favored under conditions of high lig-

Figure 5—Plot of $\log(1 - \bar{n})/\bar{n}$ against the negative logarithm of 6-*n*-propyl-2-thiouracil anion concentration ($p[PTU^-]$) obtained from a lead nitrate (2.00×10^{-4} M)–PTU (2.00×10^{-3} M) mixture in water with $\mu = 0.006$ at 25.8° . Slope of plot is 1.13.

Figure 6—Plots of $\bar{n}/(1-\bar{n})[U^-]$ against $[(\bar{n}-2)/(\bar{n}-1)][U^-]$ from aqueous mixtures of 2-thiouracil ($[2TU] = 2.00 \times 10^{-3}$ M) and lead nitrate with $\mu = 0.006$ at 25.0° . Key: (A), 2.00×10^{-3} M Pb^{++} ; (B), 1.80×10^{-3} M Pb^{++} ; (C), 1.40×10^{-3} M Pb^{++} ; (D), 8.00×10^{-4} M Pb^{++} ; and (E), 2.00×10^{-4} M Pb^{++} . Intercept on ordinate is K_1 and slope is K_1K_2 .

and concentrations and as the titrations proceeded. At these higher slopes the premises for the use of such plots derived from Eq. 15 become invalid, and equations based on the postulates of additional complexes in solution must be used.

Thus, the assumption was made that there were two significant complexes in solution, the 1:1 complex MU^+ and the 1:2 complex MU_2 . If this were true, the derived:

$$\frac{\bar{n}}{(1-\bar{n})[U^-]} = \left(\frac{\bar{n}-2}{\bar{n}-1} \right) \beta_2[U^-] + K_1 \quad (\text{Eq. 14})$$

would be applicable and the plot of $\bar{n}/(1-\bar{n})[U^-]$ against $(\bar{n}-2)/(\bar{n}-1)[U^-]$ would be linear for all thiouracil-metal-ion mixtures and the statistically significant estimated slopes β_2 and intercepts K_1 would be the same for all such mixtures. The \bar{n} and $[U^-]$ data are calculated from the experimental values and Eqs. 11 and 13, as has been explained previously, and typical plots are given in Fig. 6.

The derived values of $\log K_1$ and $\log K_2$ (where $K_2 = \beta_2/K_1$) are related to the complexation constants of MU^+ and MU_2 (from MU^+), respectively, and are listed in Table I. The facts that the calculated values of $\log K_1$ and $\log K_2$ did not vary with the total metal-ion concentration (Table I) were consistent with the premise that only MU^+ and MU_2 complexes are in significant concentrations in the homogeneous solutions of mixtures of metal ions and thiouracils maintained prior to the observance of precipitation on the further addition of alkali. It has been shown in the *Theory and Methods of Calculation* section that the presence of significant amounts of other complexes in solution, such as MU^\pm (VI) or its equivalent $MUOH$ (V), M_2U_2 (VII) or M_nU_n (VIII) would make $[U^-]$ a function of the metal-ion concentration as denoted in Eqs. 24, 36, or 37. If this were true, plots (Fig. 5) made on the assumption of only significant concentrations of MU^+ (III) and MU_2 (IV) in the homogeneous solutions in accordance with Eq. 14 and on the premise of $[U^-]$ being independent of M^{++} concentration (Eq. 13) would not be expected to be linear. This can be readily seen from the forms of Eqs. 26 and 39 where it is apparent that $\log K_1$ and $\log K_2$ values estimated from plots in accordance with Eq. 14 would vary widely as a function of the metal-ion concentration, $[M^{++}]_0$. Since such plots were linear (Fig. 6) and there was no significant variation of the derived $\log K_1$ and $\log K_2$ values with M^{++} concentration (Table I), it is reasonable to accept the premise that only the MU^+ (III) and MU_2 (IV) complexes are in significant concentrations in the titrated homogeneous solutions prior to the observed precipitation on further addition of alkali.

DISCUSSION

Stability Constants of the Significantly Soluble MU^+ and MU_2 Complexes—Analyses of the homogeneous portions of the alkaline titration curves of solutions of mixtures of lead, cadmium, nickel, or zinc nitrate and various thiouracils [2-thiouracil (TU), 6-*n*-propyl-2-thiouracil (PTU), 6-methyl-2-thiouracil (6MTU), 5-methyl-2-thiouracil (5MTU), 5,6-dimethyl-2-thiouracil (5,6DMTU), and 5-carboethoxy-2-thiouracil (5CETU)] to the pH values of precipitation were consistent with the facts that the species present in significant concentrations in the homogeneous solutions of the titration must be the MU^+ (III) and MU_2 (IV) complexes of Scheme I. Plots (Fig. 5) in accordance with Eq. 14 where $[U^-]$ was calculated from Eq. 13 demonstrated linearity for all the metal ions and thiouracils studied that showed significant complexation. The values of $\log K_1$ and $\log K_2$ that were calculated from such plots (Eq. 14 and Fig. 5) did not show significant variation with various metal-ion concentrations $[M^{++}]_0$ (Table I). These facts are indicative that complexes such as $MUOH$ (V), MU^\pm (VI), M_2U_2 (VII), or M_nU_n (VIII) of Scheme I were not of significant concentrations in the alkaline titrated homogeneous solutions prior to precipitation.

The stability constant K_1 (Table I) is the largest for the formation of the MU^+ complex from Pb^{++} and Cd^{++} with 5,6DMTU and smallest from Cd^{++} with 5CETU. The $\log K_1$ values were available for CdU^+ complexes with the substituted thiouracils that had the highest range in pK_a' values (Table II). A plot of such $\log K_1$ values against these pK_a' values at 25.0° showed definite linearity and conformed to the expression:

$$\log K_1 = 0.50 pK_a' + 0.32 \quad (\text{Eq. 41})$$

Single alkyl substitution at the 5 or 6 position of 2-thiouracil slightly increased the pK_a' values to about 7.7 from 7.5 and similarly increased the $\log K_1$ value of the CdU^+ complex. Simultaneous alkyl substitution at the 5 or 6 position significantly elevated the pK_a' to 8.1 and the $\log K_1$.

Substitution of the electronegative carboethoxy group at the 5 position significantly reduced both the pK_a' to 6.43 and $\log K_1$ value. This is readily understandable in that the electronegative 5-carboethoxy group (R_2 in Id, Scheme I) would be expected to reduce the electron availability of the *para* sulfur atom. Thus the sulfur's electronic charge would be reduced to result in lessened ability to bind both hydrogen ions and metal cations with the concomitant

Figure 7—Apparent linear relation between the logarithm of the stability constant K_1 for the formation of the CdU^+ complex in solution, $Cd^{++} + U^- \xrightleftharpoons{K_1} CdU^+$ (where U^- is the 5- and/or 6-alkyl 2-thiouracil anion) and the pK_a' for the dissociation of the respective thiouracil acid, $HU \xrightleftharpoons{K_a'} H^+ + U^-$.

results of lowered pK_a' (or higher acidity) and diminished affinity, K_1 , of thiouracils for metal ions.

No obvious relations were observed as to the significant effects of 5 and/or 6 substituents of 2-thiouracil and their related pK_a' values on the formation constants, K_2 , of the MU_2 complexes (Table I). No significant temperature effects could be concluded within the narrow temperature range studied.

The potentiometric titration studies demonstrated that the order of decreasing stability of complexes of divalent metal cations with thiouracils (Table I) to form MU^+ is $Pb^{++} > Cd^{++} \gg Ni^{++} \sim Zn^{++}$. Metal ions which do not complex thiouracils are Fe^{+++} , Fe^{++} , Co^{++} , Ca^{++} , and Mn^{++} .

Evidence for the Necessity of a Potential Anionic Sulfur in Thiouracils for Divalent Metal-Ion Complexation—The increase in pK_a' of the ionizable sulfhydryl group of the thiouracil is related to the stability of the metal complex (Fig. 7 and Table I) and implicates the need for an anionic sulfur in thiouracil for metal complex formation. In addition, when the dissociable proton is removed by alkylation as in 2-ethylmercapto-4-hydroxypyrimidine (IX), no complexation with metal ions was observed. Since the acidic hy-

droxyl group, pK_a' 7.01, still exists at the 4 position in IX, it can be stated that metal ions do not readily bind to the oxygen at the 4 position in the *parent* thiouracils. Alkylation of the N-1 and N-3 nitrogens of thiouracil, as in *N,N'*-diethyl-6-methyl-2-thiouracil (X) also destroyed the ability to complex metal ions. These substitutions on both the ring nitrogens prohibit the tautomeric formation of the dissociable sulfhydryl group of the complexing thiouracils, HU (I) in Scheme I. This is further evidence that metal-ion complexation occurs at the sulfur atom and is dependent on the formation of the sulfur anion.

Possible Structures of Precipitates from Alkaline Titrated Solutions of Metal-Thiouracil Complexes—Although only concentrations of MU^+ and MU_2 complexes appear to be significantly present in the homogeneous solutions of mixtures of metal ions and thiouracils on alkaline potentiometric titration, this does not exclude the probability that the $MUOH$ (V), MU^\pm (VI), M_2U_2 (VII), and M_nU_n (VIII) complexes given in Scheme I may also be present.

It is apparent that if the concentration of any one of these complexes is limited by its solubility, precipitation will occur as the titrations proceed. It is also apparent from Scheme I that concentrations of all complexes must increase with the addition of hydroxyl ions. It may be presumed *a priori* that the charged complexes MU^+ and MU^\pm would not readily or preferentially precipitate as such, or as salts with appropriate counterions.

Alkaline titrations of precipitating equimolar thiouracil-metal-ion solutions of Pb^{++} and Cd^{++} with all thiouracils (Fig. 1, Curve A),

except for the Cd^{++} -PTU mixture (Fig. 2, Curve A), consumed titer up to the inflection pH of complete precipitation that was twice the alkaline titer expected for the titration of the thiouracil alone. Solutions (except for Cd^{++} and PTU mixtures) that contained less than equimolar amounts of metal to ligand showed that uncomplexed free ligand consumed equivalent moles of alkali but that the formed precipitate consumed twice the milliequivalents of alkali expected for the titration of that amount of thiouracil that was equimolar with the added Pb^{++} or Cd^{++} ions (Fig. 1, Curves B-G). These facts indicated that the complex precipitated must have a stoichiometry of 1:1, metal to ligand, or some multiple of 1:1. This behavior required that the species MU_2 present in homogeneous solutions for all Pb^{++} or Cd^{++} with all thiouracils (Table I), except for Cd^{++} and PTU mixtures, was not the precipitating species.

These phenomena may be summarized in the following expressions given in reference to Scheme I. The expected stoichiometry for neutralization of thiouracil is:

If no more than the milliequivalent of NaOH necessary to neutralize the total amount of available thiouracil is necessary to complete the precipitation of adducts of divalent metal ion and thiouracil (Fig. 2), then:

and

and, as in the special case of 6-*n*-propyl-2-thiouracil and cadmium ion, the precipitated complex may have the stoichiometry, metal to ligand, of 1:2. Further confirmation was obtainable from the facts that when cadmium ion was equal to, or in excess of, one-half the available moles of PTU (Fig. 2, Curves A and B), the precipitation of complex (as monitored by the alkaline titration to the appropriate pH inflection where the precipitation of $Cd(OH)_2$ could not possibly interfere) was completed when the milliequivalents of added NaOH were just equivalent to the available PTU in accordance with Eqs. 43 and 44. Furthermore, $Cd(OH)_2$ precipitation, indicative of uncomplexed cadmium ion, was observed only when the cadmium-ion concentration was in excess of half the molar concentration of PTU (Fig. 2, Curve A). Free uncomplexed PTU was only observed (Fig. 2, Curve C) when the cadmium-ion concentration was less than half the molar concentration of PTU.

If twice the milliequivalents of NaOH necessary to neutralize the thiouracil completes the precipitation of equimolar amounts of divalent metal ion and thiouracil (Fig. 1), then in reference to Scheme I,

or

where

or

There was no tendency for such precipitated complexes of lead and cadmium ion with the various thiouracils to be disrupted at relatively high concentrations of hydroxyl ions, at least to a pH of 9.0. This is indicative of the fact that the complexes of lead and cadmium of Scheme I have relatively high stabilities.

Consumption of more than twice the milliequivalents of NaOH necessary to neutralize the available thiouracil to the inflection corresponding to complete precipitation (Fig. 3) would be indicative of ready disruption and lessened stability of complexes such as those of Scheme I. It would imply that the metal hydroxides would be more readily formed on the further addition of hydroxide ion.

Consider the example when 3 times the milliequivalents of NaOH necessary to neutralize the total amount of available thiouracil complete the precipitation of an equimolar solution of a divalent metal ion and a thiouracil (Fig. 3, Curve A). Then,

Alternatively the possible precipitated complexes of MU_2 , MUOH , M_2U_2 , or M_nU_n in equilibrium with their relatively unstable counterparts in solution can be disrupted by additional alkali as

and

In the cases of the complete titrations after precipitation of the equimolar mixtures of Ni^{++} or Zn^{++} with thiouracils the alkaline titers to the completion of precipitation were greatly in excess of twice the titer necessary to neutralize the available thiouracil, HU, alone (Fig. 3, Curve A). This definitely indicates that the potential complexes of Scheme I for Ni^{++} and Zn^{++} with thiouracils were readily disrupted in solution by hydroxide ion in accordance with Eqs. 49–51. This is not unexpected since the stability constant of the MU^+ complexes for nickel and zinc are about a hundred times smaller than those for lead and cadmium (Table I).

Confirmation of Structures of Precipitates and Complexes of Cadmium and Lead Complexes of Thiouracils—The equilibria of Scheme I are consistent with the potentiometric titration studies. The precipitation of a relatively stable MU_2 (IV) complex from Cd^{++} and 6-*n*-propyl-2-thiouracil and of relatively stable either MUOH , M_2U_2 , or M_nU_n complexes from Cd^{++} and Pb^{++} with the other thiouracils (Table I) is highly probable and consistent with the data.

These high probabilities were put to the test by the deliberate synthesis, isolation, and characterization of MU_2 (IV) and M_2U_2 (VII) or M_nU_n (VIII) complexes. The MU_2 complexes were prepared by the use of forcing conditions where a solution of the metal ion was added to the thiouracil solution in molar excess. The complexes of 1:1 stoichiometry were prepared from equimolar concentrations of thiouracil and metal ion where the thiouracil solution was added to that of the metal ion. The precipitation was effected by adjustment of the pH of the solutions to 6.5 (see *Experimental*).

The synthesized MU_2 (IV) complexes of bis(2-thiouracil)-cadmium (II), $\text{Cd}(\text{TU})_2$; bis(2-thiouracil)-lead (II), $\text{Pb}(\text{TU})_2$; and bis(6-*n*-propyl-2-thiouracil)-cadmium (II), $\text{Cd}(\text{PTU})_2$, and the synthesized M_2U_2 (VII) (or M_nU_n , VIII) complexes of bis(2-thiouracil)-cadmium (II), $\text{Cd}_2(\text{TU})_2$; bis(2-thiouracil)-lead (II), $\text{Pb}_2(\text{TU})_2$; and bis(6-*n*-propyl-2-thiouracil)-lead (II), $\text{Pb}_2(\text{PTU})_2$, had the proper metal analyses and the proper complete elemental analysis [as in the $\text{Cd}(\text{PTU})_2$ case] to confirm fully these assigned structures.

Further confirmation of the validity of the assignment of the MU_2 structure, IV, of Scheme I was obtained from the IR spectra. The

synthesized $\text{Cd}(\text{TU})_2$, $\text{Pb}(\text{TU})_2$, and $\text{Cd}(\text{PTU})_2$ had a strong absorption band at 1630 cm^{-1} assignable to the absorption of the tautomerizable carbonyl group at the 4 position of thiouracils (28). Strong absorption bands between 1440 and 1660 cm^{-1} indicated the presence of $\text{C}=\text{N}$ bonds (29) that were not bound to metal ion. In contrast, the IR spectrum of the synthesized 6-methyl-*N,N'*-diethyl-2-thiouracil (X), a compound incapable of tautomeric formation of $\text{C}=\text{N}$ bonds, did not demonstrate such $\text{C}=\text{N}$ absorption bands.

Further confirmation of the validity of the assignment of an M_2U_2 (or M_nU_n) structure, VII (or VIII) of Scheme I, was obtained also from the IR spectra. The synthesized $\text{Cd}_2(\text{TU})_2$, $\text{Pb}_2(\text{TU})_2$, and $\text{Pb}_2(\text{PTU})_2$ (or their M_nU_n equivalents) showed no significant band above 1570 cm^{-1} that could be assigned to a potential carbonyl group at the 4 position of the thiouracil ring (28) but did show bands assignable to the $\text{C}=\text{N}$ group (29). The validity of secondary metal binding to the 4-oxygen is well indicated.

Further evidence for such an assignment as in VII or VIII of Scheme I is that the pK_a' of 2-ethylmercapto-4-hydroxypyrimidine (IX) is 7.01 compared to 7.46 for 2-thiouracil. Since alkyl substitution at the sulfur atom increased the acidity of the potential hydroxyl group at the 4 position, it is expected that substitution by a cation on the sulfur with retention of positive charge, as with MU^+ (III), would further increase the acidity. This facilitated dissociation of the 4-hydroxy group of the MU^+ (III) complex to MU^\pm (VI) should be highly favored at lowered pH values and promote ready reaction with other MU^+ or MU^\pm molecules to form the M_2U_2 (VII) or M_nU_n (VIII) polynuclear complexes of Scheme I early in the alkaline potentiometric titrations. Such neutral cyclic or polynuclear complexes with lessened hydrophilic groups must, in general, have lower solubilities and precipitate more readily than the MU_2 (IV) complexes which have been shown to exist readily at lower pH values (Fig. 5 and Table I).

The one observed exception was the cadmium and 6-*n*-propyl-2-thiouracil mixture where the neutral 1:2 complex $\text{Cd}(\text{PTU})_2$ preferentially precipitated at the lower temperatures of 25 and 35°. Equations 43, 44, and 46–48 are valid explanations of the multiple equilibria and precipitation that may occur with some mixtures of metal ion and a thiouracil. It can be argued that the larger alkyl group significantly decreased the solubility of the MU_2 complex, significantly increased the pK_a' of the 4-OH group of the MU^\pm complex, or significantly increased the stability constant, K_2 , of the MU_2 complex for PTU. Of these, the first and third arguments are most probable. The latter is confirmed by the data of Fig. 1, where K_2 for MU_2 formation exceeded K_1 for MU^+ formation by more than two-fold for the cadmium complex of PTU; whereas for the cadmium complexes of CETU and 5,6MTU, they were approximately equal and for lead and cadmium complexes of the other thiouracils studied, K_1 was 5–20-fold greater than K_2 .

The precipitates produced by the potentiometric titrations of solutions containing 2-thiouracil in the presence of lead and cadmium ions were isolated, at pH 7.5 and 10.5, respectively, washed, and the IR spectra recorded. The IR spectra of these precipitates were identical with the spectra of the synthesized M_2U_2 complexes $\text{Pb}_2(\text{TU})_2$ and $\text{Cd}_2(\text{TU})_2$, respectively. Thus, it can be concluded that complexes of the form MUOH (V) are neither of significant concentration in homogeneous solutions of Cd^{++} or Pb^{++} ions with thiouracil, nor are they readily precipitated from such solutions on the addition of alkali. Equations 44, 47, and 48 from Scheme I are valid explanations of the multiple equilibria and precipitation that occur with most mixtures of Pb^{++} or Cd^{++} and thiouracils.

The elemental and IR analyses of the synthesized $\text{Pb}_2(\text{TU})_2$, $\text{Cd}_2(\text{TU})_2$ and $\text{Pb}_2(\text{PTU})_2$ complexes do not permit rigorous discrimination between the preferred assignments as the cyclic dimers M_2U_2 (VII) or as the polynuclear polymers M_nU_n (VIII). When the synthesized $\text{Cd}_2(\text{TU})_2$ was recrystallized from an ammoniacal solution and dried, its IR spectrum was almost exactly the same as the original $\text{Cd}_2(\text{TU})_2$. However the physical form was noncrystalline in nature and appeared as "paper pulp." It is possible that the ammonia complexed with the cadmium and opened the ring of $\text{Cd}_2(\text{TU})_2$, VII, and, on removal of the ammonia, the polymeric structure $\text{Cd}_n(\text{TU})_n$ (VIII) was formed.

In Vitro Release of Chloramphenicol from Polymer Beads of α -Methacrylic Acid and Methylmethacrylate

S. C. KHANNA* and P. SPEISER

Abstract □ The *in vitro* release behavior of chloramphenicol from four different bead polymers containing methylmethacrylate and α -methacrylic acid in various buffer solutions has been studied. The concentration of α -methacrylic acid in the copolymer beads and the pH and ionic strength of the buffer solutions were observed to influence the release rate of the chloramphenicol from these beads. The beads containing no α -methacrylic acid did not release the drug in any buffer solution, and the beads containing only α -methacrylic acid released the drug at almost the same rate in all buffer solutions. The smaller beads released the drug more quickly than the larger ones.

Keyphrases □ Polymer beads—chloramphenicol release □ Chloramphenicol release— α -methacrylic acid, methylmethacrylate beads □ α -Methacrylic acid, concentration effect—release rates, polymer beads □ pH, ionic strength effects—chloramphenicol release, polymer beads

In an earlier publication (1), the possibility of utilizing the bead polymerization method for the preparation of a sustained-release dosage form was discussed. Physical barriers are used in the majority of the prolonged-

release dosage forms to decrease the rate of drug release to the absorption site. The swelling or dissolution property of the polymer materials in which the drug is embedded is the major contributing factor in the release of drug from such dosage forms. Nelson (2) reported that the dissolution or release rate of a drug from a dosage form is the rate-determining factor in the absorption and physiological availability of the drug. Hence, an *in vitro* release procedure may be used to screen the materials worthy of inclusion as a potential physical barrier for sustained-release products. Furthermore, it may show the direction in which the right copolymers or polymers for the purpose may be found. The final required sustained-release dosage form containing these beads may consist of a single specimen of the polymer beads or a mixture of many different polymer and copolymer beads.

As the drug is incorporated in a large number of small individual beads, the chances of consistent availability of the drug at the intended site of the gastrointestinal tract increase considerably. In the present work, the

S. C. KHANNA* and P. SPEISER

Abstract □ The *in vitro* release behavior of chloramphenicol from four different bead polymers containing methylmethacrylate and α -methacrylic acid in various buffer solutions has been studied. The concentration of α -methacrylic acid in the copolymer beads and the pH and ionic strength of the buffer solutions were observed to influence the release rate of the chloramphenicol from these beads. The beads containing no α -methacrylic acid did not release the drug in any buffer solution, and the beads containing only α -methacrylic acid released the drug at almost the same rate in all buffer solutions. The smaller beads released the drug more quickly than the larger ones.

Keyphrases □ Polymer beads—chloramphenicol release □ Chloramphenicol release— α -methacrylic acid, methylmethacrylate beads □ α -Methacrylic acid, concentration effect—release rates, polymer beads □ pH, ionic strength effects—chloramphenicol release, polymer beads

In an earlier publication (1), the possibility of utilizing the bead polymerization method for the preparation of a sustained-release dosage form was discussed. Physical barriers are used in the majority of the prolonged-

release dosage forms to decrease the rate of drug release to the absorption site. The swelling or dissolution property of the polymer materials in which the drug is embedded is the major contributing factor in the release of drug from such dosage forms. Nelson (2) reported that the dissolution or release rate of a drug from a dosage form is the rate-determining factor in the absorption and physiological availability of the drug. Hence, an *in vitro* release procedure may be used to screen the materials worthy of inclusion as a potential physical barrier for sustained-release products. Furthermore, it may show the direction in which the right copolymers or polymers for the purpose may be found. The final required sustained-release dosage form containing these beads may consist of a single specimen of the polymer beads or a mixture of many different polymer and copolymer beads.

As the drug is incorporated in a large number of small individual beads, the chances of consistent availability of the drug at the intended site of the gastrointestinal tract increase considerably. In the present work, the

Table I—Polymeric Beads of α -Methacrylic Acid and Methylmethacrylate with Chloramphenicol

Preparation No.	Monomeric Mixture α -Methacrylic Acid	Polymerized, % Methylmethacrylate	Chloramphenicol in Beads, %
1	100	—	9.5
2	66.6	33.3	15.0
3	33.3	66.6	19.5
4	—	100.0	7.0

influence of the following factors on the *in vitro* release of chloramphenicol USP embedded in beads of α -methacrylic acid, methylmethacrylate, or mixtures thereof has been studied: (a) content of α -methacrylic acid in the polymer beads, (b) pH and ionic strengths of the buffer solutions, and (c) size of the bead.

EXPERIMENTAL

In Vitro Release Test—A modified USP tablet disintegration test apparatus was used under the same conditions as previously described (3). In each glass tube, a fine nylon filter was fitted so that the beads could be separated from the buffer solution from time to time. Approximately 100–150-mg. beads from an 800–1000- μ diameter sieve fraction were accurately weighed and eluted with 50 ml. of buffer solution. At a fixed time interval, selected according to the polymer and the buffer solution used, the buffer solution was filtered through the fine nylon filter fitted in the tube and was replaced with the same amount of the fresh buffer solution. The amount of chloramphenicol released was determined spectrophotometrically at the 278-m μ wavelength. This procedure was repeated until either the whole of the embedded drug was released or a maximum period of 14 hr. was reached. Triplicate experiments were performed with each buffer solution, and the results are the average of these.

Buffer Solution Used—Various buffer solutions in the range of pH of gastrointestinal fluids have been used as eluting liquids for the *in vitro* release of chloramphenicol from the polymer beads. Buffer solutions of pH 1.2 (HCl–NaCl), 3.2, 5.2, 6.2, 7.2, and 8.2 (all phosphates), each with ionic strengths of 0.1, 0.2, and 0.3, were prepared. Buffer solutions of either pH 8.2 or of ionic strength 0.3 are less common in the human gastrointestinal tract, but they were selected in this study to check the effect of these factors at this high limit on the release behavior of chloramphenicol from the polymer beads.

Figure 1—Release of chloramphenicol from Preparation 1 in different buffer solutions (μ = ionic strength). Key: \circ , pH 1.2, μ 0.1; ∇ , pH 1.2, μ 0.2; \bullet , pH 1.2, μ 0.3; \odot , pH 5.2, μ 0.1; \times , pH 5.2, μ 0.2; and \times , pH 5.2, μ 0.3.

Figure 2—Release of chloramphenicol from Preparation 2 in different buffer solutions (μ = ionic strength). Key: \blacktriangle , pH 3.2, μ 0.1; \circ , pH 3.2, μ 0.2; ∇ , pH 3.2, μ 0.3; \times , pH 5.2, μ 0.1; \blacksquare , pH 5.2, μ 0.2; \square , pH 5.2, μ 0.3; \odot , pH 7.2, μ 0.1; \circ , pH 7.2, μ 0.2; and \bullet , pH 7.2, μ 0.3.

To calculate the amount of the substances for the preparation of the buffer solutions, the following equations were used (4):

$$\text{pH} = \text{pK}_n + \log \frac{(\text{salt})}{(\text{acid})} - \frac{A(2n-1)\sqrt{\mu}}{1+\sqrt{\mu}} \quad (\text{Eq. 1})$$

$$\mu = 1/2 \sum C_i Z_i^2 \quad (\text{Eq. 2})$$

All symbols have the same meaning as in the literature (4).

The pH's of the buffer solutions were determined using a Metrohm pH meter, type E 396, and the buffers were adjusted to the correct value if required. The ionic strength, if required, was adjusted by the addition of sodium chloride. All substances used were of analytical quality.

Beads Used—The materials used and the method of preparation of these polymeric beads in the presence of chloramphenicol USP have already been reported (1). The composition of the beads used in the present study is shown in Table I.

Bead Size Used—Sieve analysis of the polymeric beads was carried out (1). The fraction left on each sieve (400–500 μ , 500–630 μ , 630–800 μ , and 800–1000 μ) was used to study the effect of bead size on the release rate of chloramphenicol from the polymeric beads.

RESULTS AND DISCUSSION

To select the appropriate polymer or copolymer of α -methacrylic acid and methylmethacrylate for incorporation into the sustained-release dosage form, the influence of different ionic strengths and the pH's of the various buffer solutions on the release behaviors of chloramphenicol embedded in them has been studied. Although gastric juice varies individually in composition (5), the acidity ranges generally in terms of pH values from 1.2 to 2.5. In some healthy persons, it may even exhibit higher pH values. The pH values of the fluids from the duodenum to the large intestine may vary from 5 to 8 (6). Therefore, the release studies of the drug from the polymeric beads were carried out in buffer solutions from pH 1.2 to 8.2. Although the ionic strengths of the gastrointestinal fluids are constant under normal conditions, they may change due to uptake of ionic substances during meals, etc. Therefore, the influence of the different ionic strengths (0.1, 0.2, and 0.3) at all the pH levels of the buffer solutions on the release of drug from beads also has been studied. As the enzymatic activity of gastrointestinal fluids is of minor importance in the release behaviors of the drug from the polymers, pure buffer solutions of either HCl–NaCl or phosphates having the given pH's and ionic strengths have been used.

In the course of the experiments, it became evident that in most cases the release of chloramphenicol from the various polymer and

^a The values for each were taken from Figs. 1–3. ^b The values obtained by extrapolation.

Copolymer beads of α -methacrylic acid and methylmethacrylate gave curves of a higher order when plotted as percent cumulative release against time, or as logarithms of the amount of drug remaining in the beads (as a percentage) against time, or as the amount of drug released against the square root of time. However, since most of the drug release data from the various bead formulations showed that up to 80% of the release of the chloramphenicol apparently followed a first-order rate, except the release during the first interval, it was decided to represent the results as logarithms of the amount of chloramphenicol remaining in the beads as a percentage against time (Figs. 1–3). The faster release rate in the beginning may be due to the presence of the drug on the surfaces of the beads. The orthogonal polynomials were used where adequate data were available to calculate the best fitting equations for the regression of the complete curve of log percent of drug remaining in beads against time. In extreme cases, polynomials up to the third degree were required to provide an adequate equation. The comparison of the functions of these equations was rather complex; therefore, the times for release of 20, 50, and 80% of chloramphenicol (represented as t_{20} , t_{50} , and t_{80}) from beads were used as the comparative measures to prove the influence of the various factors in the study on the release behavior of the drug from polymeric beads (Table II). In a few cases, where even 20%

release over a study period could not be obtained from the experimental values, it was calculated from the respective regression equations.

Influence of α -Methacrylic Acid Content in Bead Polymers on Release of Chloramphenicol—In the absence of α -methacrylic acid in the polymeric beads, Preparation 4, the release of the drug did not take place in buffer solutions of pH 8.2 and below. The release from these beads in buffer solution of higher pH's than this was not carried out. In copolymers, Preparations 3 and 2, incorporating 33.3 and 66.6% α -methacrylic acid, respectively, the release of chloramphenicol started in the buffer solutions of pH 6.2 and 3.2, respectively. The release of chloramphenicol from these copolymer beads in the buffer solutions of pH 5.2 and 2.2, respectively, was almost negligible. The beads containing only α -methacrylic acid, Preparation 1, released the drug quite rapidly in buffer solutions of pH 1.2 and above.

Thus, the content of α -methacrylic acid in the polymer and copolymers influences the onset of the release of chloramphenicol in the buffer solutions. The higher the acidic content in the polymeric beads, the lower is the pH at which the release of drug starts. The results are given in Table III.

There is a rather complicated relationship between the α -methacrylic acid content of the polymer and the properties (pH and ionic strength) of the buffer solutions. This is observed from the irregular release behavior of chloramphenicol from these polymeric beads in the different buffer solutions. For this reason, a quantitative comparison between α -methacrylic acid content in the polymers and the release rates of drug from them in buffer solutions seems difficult to establish. However, it may be observed (Table II) that the higher the α -methacrylic acid content in the polymeric beads, the quicker the release of the drug from them into the buffer solutions.

Influence of pH's and Ionic Strengths of Buffer Solutions on Release Rate of Chloramphenicol from Beads—The polymeric beads containing only α -methacrylic acid showed no significant change in the release rate of chloramphenicol embedded in these beads with variation of either pH or ionic strength of the buffer solution (Table II). It is possible that, due to the large number of acidic groups in the polymer beads, identical solubility and swelling of the beads occurred in the acidic to neutral buffer solutions.

Table III—Influence of Acidic Content in Beads on the Onset of Drug Release

800–1000	7.0	17.4	2.5	5.9	6.5	15.5

However, with the increase of either pH or ionic strength of the buffer solutions, the rate of release of chloramphenicol from the polymer beads containing either 66.6 or 33.3% of α -methacrylic acid was enhanced (Table II, Figs. 2 and 3). In the case of a preparation containing 66.6% α -methacrylic acid in the polymer, the most pronounced increase in the release of chloramphenicol took place in buffer solutions having pH's between 3.2 and 5.2; for a preparation containing 33.3% α -methacrylic acid, the same effect was observed in buffer solutions of pH's between 6.2 and 7.2.

The ionic strength had a more pronounced effect in the case of the bead formulation containing 33.3% α -methacrylic acid than in the case of one containing 66.6% α -methacrylic acid. This change in the release rate of the drug may be due to different swelling and solubility properties of the polymer beads in various buffer solutions.

Influence of the Bead Diameter on the Release Rate—As the release of chloramphenicol from the copolymer beads was found to be dependent on the ionic strengths and pH's of the eluting buffer solutions, it was considered that these beads could be ion-exchange-type resins. The release rate of the drug from such resins is inversely proportional to the radius of the spherical particles. Thus, the release behavior from different bead sizes of the first three preparations was studied. Preparation 4 could not be considered for the study because no release took place from this preparation in any buffer solution below pH 8.2 (Table III). However, no such relationship between t_{50} release and $1/\text{radius}$ could be observed. It may be that the fraction of the sieve-analyzed beads taken in these release studies is not representative of the uniform size distribution of the beads in that fraction. Moreover, the geometry of these beads is altered by swelling and dissolution; hence, the mean radius taken will not be correct for such correlation. However, the results (Table IV) clearly show that the release rate

of drug increases with decreasing bead size. Therefore, the uniform release from the sustained-release dosage form may be obtained by varying the particle size in the formulation.

SUMMARY

The release behavior of the drug from these beads in the buffer solutions depends mainly on the amount of α -methacrylic acid content in the polymer. The polymer beads containing 100% α -methacrylic acid released the drug easily in strong acidic buffer solutions of pH 1.2 and above. Hence, these beads may be used to form the initial dose portion in a sustained-release dosage form. The copolymer beads containing 66.6 and 33.3% α -methacrylic acid released the drug in buffer solutions of pH 3.2 and 6.2, respectively, and over. These may be incorporated as a sustained-release portion in such dosage forms. The combination of these beads in the appropriate proportion will show a right release pattern for a sustained-release dosage form.

On the basis of this study, copolymer beads of α -methacrylic acid and methylmethacrylate having the property of predetermined release of drug in specific buffer solution may possibly be prepared. The release rate of the sustained-release portion may also be controlled by varying the bead sizes.

Micellar Solubilization of Barbiturates II: Solubilities of Certain Barbiturates in Polyoxyethylene Stearates of Varying Hydrophilic Chain Length

M. WAFIK GOUDA*, A. A. ISMAIL†, and M. M. MOTAWI†

Abstract □ A study has been made of the solubilities of a series of 5,5-disubstituted barbituric acid derivatives in aqueous solutions of polyoxyethylene stearates of varying polyoxyethylene chain length. Except for phenobarbital, which forms an insoluble precipitate complex with the solubilizers, all other barbiturates studied were micellarly solubilized. On a molar basis, solubility increases with an increase in hydrophilic chain length but decreases if solubility is expressed in terms of the amount solubilized per ethylene oxide unit. A possible explanation for such a pattern was given. The partition coefficient, K , of the drug molecules between a micellar pseudophase and an aqueous phase was found to be dependent on both the polar effect and the number of carbon atoms of the substituents on the 5-position. The formation of an insoluble precipitate complex by phenobarbital was attributed to the presence of the aromatic phenyl group in the molecule.

Keyphrases □ Barbiturates, 5,5-disubstituted—solubility □ Micellar solubilization—barbiturates □ Solubilization, barbiturates—polyoxyethylene stearates □ Hydrophilic chain length, polyoxyethylene stearates—barbiturates solubilization

The micellar solubilization of certain barbiturate drugs in polysorbates 20, 40, 60, and 80¹ was previously reported (1). These polysorbates have the same hydrophilic portion in their molecule but differ in the length of the carbon atom chain of their lipophilic portion. This investigation was undertaken to study the effect of the hydrophilic group of nonionic solubilizers and the chemical structure of solubilizates on the degree of solubilization. Polyoxyethylene stearates are nonionic surfactants used as solubilizing agents in the same manner as polysorbates (2). Polyoxy 40 stearate was official in USP XVII as a pharmaceutical aid. A group of four polyoxyethylene stearates² was chosen as the solubilizing agents for this study. Since these solubilizers are all of one chemical type, differing only in ethylene oxide content, they serve as a good model to compare solubilization of the barbiturates as a function of hydrophilic chain length.

EXPERIMENTAL

Materials—The following surfactants² were used as received: polyoxyethylene 30 monostearate, polyoxyethylene 40 monostearate, polyoxyethylene 50 monostearate, and polyoxyethylene 100 monostearate.

The barbiturates used and their melting points³ were: phenobarbital, 5-ethyl-5-phenylbarbituric acid, m.p. 173–174°; barbital, 5,5-diethylbarbituric acid, m.p. 185–187°; amobarbital, 5-ethyl-5-

Figure 1—Solubility of barbital in polyoxyethylene stearate solutions at 30°. Key: ■, solubility in water; ●, polyoxyethylene 30 stearate; △, polyoxyethylene 40 stearate; ○, polyoxyethylene 50 stearate; and ◐, polyoxyethylene 100 stearate.

isoamylbarbituric acid, m.p. 153–155°; diallylbarbituric acid, 5,5-diallylbarbituric acid, m.p. 169–170°; and cyclobarbitol, 5-(1-cyclohexenyl)-5-ethylbarbituric acid, m.p. 89–91°.

Assay Procedure—The differential UV procedure of Walker *et al.* (3), using a Unicam SP 500 spectrophotometer, was used to assay for the barbiturates.

Solubility Determinations—The solubilities of the barbiturates in solutions of polyoxyethylene stearates in 0.003 *N* sulfuric acid at 30° were determined by the procedure described earlier (1). Equilibrium solubility was attained after 24 hr.

RESULTS AND DISCUSSION

The solubilization of barbital, diallylbarbituric acid, cyclobarbitol, amobarbital, and secobarbital in the polyoxyethylene stearate surfactants is shown in Figs. 1–5. The concentrations of the polyoxyethylene stearates used were well beyond their CMC (4). All of these barbiturate drugs showed a linear increase in solubilities in the presence of the solubilizers characteristic of micellar solubilization of such polar solubilizates.

To compare the solubilizing power of the different homologs of solubilizer, the slopes of the solubilization isotherms were calculated using the method of least squares. Table I shows the solubilization capacities expressed as moles drug per gram solubilizer, moles drug per mole solubilizer, and moles drug per equivalent of ethylene oxide in the surfactant. The latter values are the slopes of the solubilization isotherms if the moles of solubilizate were to be plotted against the surfactant concentration in equivalents of ethylene oxide per liter. The solubilizing power of the solubilizers, expressed on a molar basis, is found to increase slightly but gradually as the polyoxyethylene chain increases. However, when the solubilizing power of the surfactants is expressed in terms of moles drug per gram surfactant or moles drug per ethylene oxide equivalent, the

efficiency of solubilization decreases with the increasing length of the polyoxyethylene chain.

Other authors have reported a similar pattern for the solubilization of benzoic acid derivatives in the same polyoxyethylene stearate surfactants (5) and for the solubilization of benzaldehyde and *p*-methyl benzaldehyde in polyoxyethylene ethers of varying hydrophilic chain length (6). No explanation for such a pattern was given. A possible explanation could be forwarded, however, on the basis of the study of Schick *et al.* (7) of the effect of the polyoxyethylene chain length of polyoxyethylene ethers on the micellar weight and the number of surfactant molecules per micelle. From light-scattering measurements, these authors found that, for polyoxyethylene ethers of branched nonylphenol and *n*-decanol having a hydrophobic chain of 10.5 and 12 carbon atoms, respectively, both the aggregate number (number of molecules per micelle) and the aggregate molec-

Figure 3—Solubility of cyclobarbitaral in polyoxyethylene stearate solutions at 30°. Key: ■, solubility in water; ●, polyoxyethylene 30 stearate; △, polyoxyethylene 40 stearate; ○, polyoxyethylene 50 stearate, and ●, polyoxyethylene 100 stearate.

Figure 4—Solubility of amobarbital in polyoxyethylene stearate solutions at 30°. Key: ■, solubility in water; ●, polyoxyethylene 30 stearate; △, polyoxyethylene 40 stearate; ○, polyoxyethylene 50 stearate; and ●, polyoxyethylene 100 stearate.

ular weight of the micelles decrease as the polyoxyethylene chain increases from 10 to 50 ethylene oxide units. However, for *n*-octadecanol ethers with a hydrophobic chain of 18 carbon atoms, the increase in ethylene oxide units from 14 to 100 resulted in a decrease of the aggregate number but an increase of the aggregate molecular weight of the micelle. This increase in micellar weight was also found to be associated with increase in the micellar size. Such an increase in both micellar weight and micellar size was not linearly parallel to the increase in ethylene oxide units. For example, the aggregate molecular weight for the *n*-octadecanol ether surfactants with 14 ethylene oxide units was found to be 330,000; while for the surfactant with 100 ethylene oxide units, it was found to be 465,000. This means that the micellar size per ethylene oxide equivalent will actually be seen to decrease with the increasing length of the polyoxyethylene chain. Since the authors here are dealing with surfactants having the same 18 carbon atom hydrophobic chain length, it seems reasonable to expect that if the solubilization efficiency is expressed on a molar basis, it will increase with the hydrophilic chain length due to formation of larger micelles which could accommodate more solubilize. On the other hand, if the solubilization efficiency is expressed in terms of number of moles solubilized per ethylene oxide equivalent, then it is expected to decrease as the hydrophilic chain increases.

The effect of the chemical structure of the solubilize on the degree of solubilization was determined by regarding the solubilization

^a Percentages of ethylene oxide per surfactant molecules are: polyoxyethylene 30 stearate, 80.0% w/w; polyoxyethylene 40 stearate, 84.5% w/w; polyoxyethylene 50 stearate, 89.5% w/w; and polyoxyethylene 100 stearate, 94.0% w/w (5). ^b Calculations are based on the following molecular weights: polyoxyethylene 30 stearate, 1604; polyoxyethylene 40 stearate, 2044; polyoxyethylene 50 stearate, 2484; and polyoxyethylene 100 stearate, 4684. ^c The molar solubilities and partition coefficients of the drugs in polysorbate 60 were obtained from Reference 1.

as a partition between a micellar phase and a water phase. The partition coefficient, K , associated with this process was calculated using the equation reported previously (1). Table I lists the values of K for the various barbiturates in the different polyoxyethylene stearates. The values of K for the same drugs in polysorbate 60, polyoxyethylene 20 sorbitan monostearate, is also included for comparison. The order (decreasing) of the partition coefficients for the mentioned barbiturates between the micellar pseudophase and the aqueous phase was: secobarbital > amobarbital > cyclobarbitol > diallylbarbituric acid > barbital. This same order was found for the partition coefficients of the same barbiturates between the polysorbate micellar phase and the aqueous phase (1). It is also the order of their distribution coefficients between 1-octanol and water (8). As expected, the value of K is dependent on the lipophilic character, as well as the inductive effect of the substituents on the 5-position of the barbituric acid molecule. The extent of solubilization, as expressed by K , was found to be higher for the polyoxyethylene stearate solubilizers than for polysorbate 60. Both types of solubilizers have a stearate hydrophobic chain length but the former has more ethylene oxide units. The higher solubilizing power of the polyoxyethylene stearates is considered to be due to their larger size micelles.

The results obtained for these barbiturates indicate that their solubilization in the polyoxyethylene stearate solutions is essentially a micellar solubilization and similar in mechanism to their solubilization in polysorbate solutions. The solubilization mechanism appears to be essentially an inclusion within the micelles. For non-ionic surfactants containing polyoxyethylene chains, the micelle may be considered to consist of two parts, an inner core of hydrocarbon tails and an outer shell of hydrated polyoxyethylene (9). The

position of the solubilize molecule inside the micelle cannot be determined with certainty from these results. However, it seems reasonable to expect that the lipophilic character of the substituents on the 5-position of the barbiturate molecule, as well as their influence on the rest of the molecule, will determine whether the solubilize molecule is predominantly within the hydrocarbon core or the polyoxyethylene shell of the micelles.

The interaction of phenobarbital with the polyoxyethylene stearate surfactants resulted in the formation of an insoluble precipitate. The effect of varying polyoxyethylene 40 stearate concentrations, expressed as ethylene oxide equivalents per liter, on the solubility of phenobarbital is shown in Fig. 6. The results are typical of the solubilization curves obtained with all the solubilizers studied. This phase diagram shows a plateau region, indicating that phenobarbital interacts strongly with the surfactant and forms an insoluble precipitate complex. The stoichiometric ratios of the phenobarbital-surfactant complex formed in the plateau region could be calculated from the phase diagrams (10). Analysis of this region shows that 1 molecule of phenobarbital reacts with 3 equivalents of ethylene oxide. This stoichiometric ratio of 1:3 was obtained for all the surfactants studied. Because of the heterogeneity of the surfactants, this value is regarded as an approximation.

Higuchi and Lach (10) found that while pentobarbital and barbital do not interact with polyethylene glycols, phenobarbital forms an insoluble complex with a stoichiometric ratio of 1:2 phenobarbital-PEG. Chakravarty *et al.* (11) showed that polyoxyethylene 40 stearate interacted with phenol and resorcinol to form insoluble complexes. Saito and Shinoda (12) reported that benzene mixes with the polyoxyethylene shell of polyoxyethylene nonylphenyl ethers and depresses the cloud points of their solution to below 0°. Such a depression results in turbidity and separation into two phases at any temperature above the cloud point. The strong interaction of phenobarbital with the surfactants is attributed to the presence of the aromatic ring in the molecule, the phenyl group causing an increased interaction between the barbiturate molecule and the polyoxyethylene chain of the surfactant resulting in the formation of an insoluble precipitate complex.

Potential Antiarrhythmic Agents II: Effects of Amide Reversal and *ortho*-Methylation on Activity of Procaine Amide

D. K. YUNG, M. M. VOHRA, and I. CHU

Abstract □ Substitution of a methyl group at one or both of the *ortho*-positions of the benzene ring in procaine amide and procaine provides analogs that are more active in prolonging the refractory period of isolated rabbit atria than procaine amide itself. These analogs, however, fail to abolish ouabain-induced ventricular and aconitine-induced atrial arrhythmias in cats. On the other hand, analogs like 2-diethylamino-4'-amino-2',6'-dimethylacetanilide dihydrochloride monohydrate, 4-amino-*N*-(2-diethylaminoethyl)-2',6'-dimethylbenzamide, 2-diethylaminoethyl 4-amino-2-methylbenzoate, and 2-diethylaminoethyl 4-amino-2,6-dimethylbenzoate produce a significant increase in the amount of ouabain required to elicit ectopic rhythm in cats when administered before the infusion of the glycoside. Of these four compounds, the last three also show local anesthetic activity in the corneal reflex test in rabbits. Reversal of the amide group in procaine amide significantly reduces the activity in prolonging the refractory period of cardiac tissue and does not seem to improve the antiarrhythmic activity of the parent compounds.

Keyphrases □ Antiarrhythmic agents, potential—synthesis □ Procaine amide activity—amide, reversal, *ortho*-methylation, effects □ Structure-activity relationships—procaine amide derivatives □ IR spectrophotometry—identity

It is frequently noted that several pairs of compounds with analogous pharmacological activities can be obtained by reversing the position of the functional group. For example, a large increase in analgesic activity is reportedly caused by this type of reversal in the ester functional group of meperidine (1). As part of a continuing investigation on the structure-activity relationships of procaine amide (2), it was, therefore, considered of interest to determine whether this type of isosterism is possible in procaine amide. Accordingly, 3-diethylamino-4'-aminopropionanilide (Ia) was synthesized. For comparative purposes, 2-diethylamino-4'-aminoacetanilide (Ib), 3-diethylamino-4'-amino-2',6'-dimethylpropionanilide (Ic), and 2-diethylamino-4'-amino-2',6'-dimethylacetanilide (Id) were also prepared. Compounds Ic and Id can be regarded as analogs of lidocaine, which is useful clinically in the prevention and treatment of cardiac arrhythmias.

this study to determine whether or not steric protection of the ester group in procaine can produce active anti-arrhythmic substances. The observation of activity in 2-diethylaminoethyl 2,3,5,6-tetramethylbenzoate (4) made the proposed structural modification appealing.

EXPERIMENTAL

Chemical Synthesis¹

Compounds **Ia** (3-diethylamino-4'-aminopropionanilide HCl) and **Ib** (2-diethylamino-4'-aminoacetanilide HCl) were prepared according to the procedure reported by DiGangi (5) and Lofgren and Lundquist (6), respectively. The procedure of Dahlbom *et al.* (7) was followed in preparing Compound **Ic** (3-diethylamino-4'-amino-2',6'-dimethylpropionanilide 2HCl) and 2-diethylamino-4'-amino-2',6'-dimethylacetanilide. Compound **Ic** and its intermediates are new compounds whose physical data and yields are listed in Table I. The dihydrochloride salt of 2-diethylamino-4'-amino-2',6'-dimethylacetanilide (**Id**) has not been reported previously.

2-Diethylamino-4'-amino-2',6'-dimethylacetanilide 2HCl—Yield was 95%, m.p. 250–252°, after recrystallization from absolute ethanol.

Anal.—Calcd. for C₁₄H₂₁N₃O·2HCl·H₂O: C, 49.41; H, 8.00; N, 12.35. Found: C, 49.41; H, 7.86; N, 12.28.

Compound **IIa** [4-amino-*N*-(2-diethylaminoethyl)-2-methylbenzamide] was synthesized by the reaction of 4-nitro-2-methylbenzoic acid, which was prepared according to the method of Peltier (9), with thionyl chloride, followed by condensation of the acid chloride

with *N,N*-diethylethylenediamine and reduction of the resultant 4-nitro-*N*-(2-diethylaminoethyl)-2-methylbenzamide with iron-hydrochloric acid. Attempts to make the hydrochloride salt of Compound **IIa** failed because of the hygroscopic nature of the salt. The physical data and yields of Compound **IIa** and its intermediates are summarized in Table II.

The preparation of Compound **IIb** [4-amino-*N*-(2-diethylaminoethyl)-2,6-dimethylbenzamide] was analogous to that of Compound **IIa**. 4-Nitro-2,6-dimethylbenzoic acid was obtained by converting 4-nitro-2,6-dimethylaniline to 4-nitro-2,6-dimethylbenzonitrile via the Sandmeyer reaction, followed by acidic hydrolysis of the nitrile. Attempts to prepare the hydrochloride salt of Compound **IIb** were unsuccessful because of the hygroscopic nature of the salt. Compound **IIb** and its intermediates have been reported in the literature (10). The intermediate 4-nitro-*N*-(2-diethylaminoethyl)-2,6-dimethylbenzamide and Compound **IIb** are liquids; for purpose of identification, picrate salts were prepared.

4-Nitro-*N*-(2-diethylaminoethyl)-2,6-dimethylbenzamide Picrate—Yield was 85%, m.p. 189–191°, after recrystallization from acetone and methanol.

Anal.—Calcd. for C₂₁H₂₆N₆O₁₀: C, 48.27; H, 5.02. Found: C, 48.15; H, 5.43.

4-Amino-*N*-(2-diethylaminoethyl)-2,6-dimethylbenzamide Dipicrate—Yield was 90%, m.p. 200–203°, after recrystallization from acetone and methanol.

Anal.—Calcd. for C₂₇H₃₁N₉O₁₅: C, 44.93; H, 4.33. Found: C, 44.80; H, 4.51.

Compounds **IIIa** (2-diethylaminoethyl 4-amino-2-methylbenzoate) and **IIIb** (2-diethylaminoethyl 4-amino-2,6-dimethylbenzoate) were synthesized by a previously reported procedure (10). While Compound **IIIb** and its intermediates have appeared in the literature (10), Compound **IIIa** and its intermediates are new compounds. The physical data and yields of Compound **IIIa** and its intermediates are listed in Table III. Compounds **IIIa** and **IIIb** failed to form stable hydrochloride salts. Since 2-diethylaminoethyl 4-nitro-2,6-dimethylbenzoate and Compound **IIIb** are liquids, picrate salts were prepared.

¹ Melting points were taken with a Thomas-Hoover capillary melting-point apparatus and are uncorrected. Elemental analyses were performed by Weiler and Strauss, Oxford, England. The absorption peaks of IR spectra of all compounds synthesized were as expected. IR spectra were recorded on a Perkin-Elmer model 237B spectrophotometer.

Anal.—Calcd. for C₂₁H₂₅N₅O₁₁: C, 48.18; H, 4.81; N, 13.37. Found: C, 48.17; H, 4.86; N, 13.70.

2-Diethylaminoethyl 4-Amino-2,6-dimethylbenzoate Dipicrate—Yield was 83%, m.p. 107–111°, after recrystallization from acetone and methanol.

Anal.—Calcd. for C₂₇H₃₀N₈O₁₆: C, 44.88; H, 4.18. Found: C, 45.14; H, 4.50.

Determination of pKa Values—An accurately weighed amount of the compound (about 120 mg.) was dissolved in a stoichiometric quantity of 0.1 N HCl or in water, and the solution was diluted to 200 ml. with freshly boiled distilled water. To the solution was added a known amount of 0.1 N NaOH. The pH of the solution was then determined by means of a pH meter. The pKa value of the compound was calculated, using the formula $pK_a = pH - \log [B]/[BH^+]$.

Pharmacological Testing

For the biological testing, compounds that formed hydrochloride salts were dissolved in distilled water. The others were dissolved in a stoichiometric amount of 0.4 N HCl. All solutions were then buffered with potassium phosphate solution of pH 7.4, followed by dilution with normal saline to give the desired concentrations. Procaine amide and procaine were used in the form of hydrochloride salts.

Determination of Maximum Stimulation Rate (MSR)—The method of determination was that reported by Dawes (11). The rate and amplitude of contraction of the rabbit atria were recorded by a force displacement transducer on an E & M model DMP-4A

physiograph. Four or more determinations were carried out, using at least two isolated atria for each compound. The average percent depression on the MSR for procaine amide was arbitrarily set to have an activity of 1 unit.

General Methods for Experiments on Cats—Cats of either sex, weighing from 2 to 4 kg., were anesthetized with pentobarbital² (35 mg./kg. i.p.). Artificial respiration was maintained throughout the experiment. Mean atrial blood pressure was recorded from the femoral artery with a Satham P-23C pressure transducer. Electrocardiograms were recorded on a standard Lead II. All recordings were made on a direct ink-writing Beckman type R dynograph. The solutions of the test compounds were injected intravenously through indwelling polyethylene catheters in the femoral vein, followed by a 2-ml. saline flush.

Prior to the testing for antiarrhythmic activity, the cardiotoxicity of Compounds Ic, Id, IIa, IIb, IIIa, and IIIb was studied by injecting the compound intravenously at increasing doses of 1, 2.5, 5, and 10 mg./kg. at 10-min. intervals until ectopic rhythm appeared in the electrocardiograms. The total dose was taken as the maximum tolerated dose.

Determination of Activity in Termination of Ouabain-Induced Arrhythmias—The method used to induce arrhythmias with ouabain was that described by Raper and Wale (12). An initial loading dose of ouabain (40 mcg./kg.) was injected intravenously into cats; starting 30 min. later, doses of 10 mcg./kg. were repeated at 15-min. intervals until a persistent ventricular tachycardia was produced. When arrhythmias had persisted for 10 min., increasing doses of the compound to be tested were given every 10 min. until the maxi-

² Nembutal.

Table V—Arrhythmic and Lethal Doses of Ouabain^a in Cats Pretreated with Compounds

Compound ^b	Approx. LD ₅₀ , mg./kg.	Dose of Compd, ^c mg./kg.	No. of Cats	Average Dose to Ectopic Rhythm, mcg./kg.	<i>p</i> ^d	Average Lethal Dose, mcg./kg.	<i>p</i> ^d

IIIb	67	8.5	3	128 ± 5	<0.01	193 ± 31	>0.05

^a Ouabain administered by intravenous infusion at a rate of 5 mcg./kg./min. ^b Compounds administered by slow intravenous injection before ouabain infusion. ^c Maximum tolerated dose of the compounds. ^d *p* values compared with control.

maximum tolerated dose was reached. The criterion used to define antiarrhythmic activity was the reversion to sinus rhythm for a period of not less than 30 min.

Determination of Activity in Prevention of Ouabain-Induced Arrhythmias—In this series of experiments the compound to be tested was injected intravenously in cats in one single dose. Ouabain was administered 10 min. later by intravenous infusion at the rate of 5 mcg./kg./min. The amount of ouabain required to produce ectopic rhythm and death was determined.

Determination of Activity in Termination of Aconitine-Induced Arrhythmias—Atrial arrhythmias were produced in cats according to the procedure described by Schmid and Hanna (13). A 0.05% solution of aconitine nitrate in normal saline was used. Compounds Id and IIIa were administered intravenously at the rate of 1 mg./kg./min., and Compounds IIb and IIIb were administered at the rate of 0.5 mg./kg./min.

Determination of Surface Anesthesia in Rabbits—Albino rabbits of either sex, weighing 2 to 3 kg., were used. The eyelashes of the rabbit were clipped off; into each conjunctival sac was instilled 0.5 ml. of a 2% solution of the test compound. Normal saline solution was used as a control. The corneal reflex was elicited by touching the cornea with a feather five times at 2, 5, 10, 15, 20, 30, and 35 min. after the compound was applied. The degree of anesthetic activity was expressed in terms of percent anesthesia. For example, a score of 50 failures of corneal reflex out of a possible maximum of 120 gave 41.7% anesthesia.

Acute Toxicity Studies in Mice—Male albino mice, weighing 20 to 35 g., were used in the tests. Compounds were injected intraperitoneally. The median lethal dose (LD₅₀) for each compound was calculated by the method of Litchfield and Wilcoxon (14) and was based on 1 day's observations.

RESULTS AND DISCUSSION

Results in Table IV indicate that although Compound Ia showed some activity in prolonging the refractory period of isolated rabbit atria at a concentration of 30 mcg./ml., the activity, being only one-third of the activity of procaine amide, was hardly significant. Shortening the hydrocarbon chain length between the carbonyl carbon and the terminal amino nitrogen atoms in Compound Ia failed to improve the activity of the parent compound. This suggests that reversing the amide functional group in procaine amide does not improve the antiarrhythmic activity of the compound.

The activity of procaine amide to depress the MSR of isolated rabbit atria was increased significantly (*p* < 0.05) when one or two methyl groups were substituted at the *ortho*-positions of the benzene ring. This information led to the synthesis of the two lidocaine analogs, Compounds Ic and Id. These two compounds had an activity of about 1.7 times that of procaine amide in depressing the MSR. Compared with the corresponding nonmethylated compounds, Ia and Ib, the methylated ones were at least 5 times more active.

In view of the favorable effect of the methyl substituents, it was considered of interest to modify the structure of procaine in the same fashion. Accordingly, Compounds IIIa and IIIb were prepared. When tested on isolated rabbit atria, both compounds demonstrated marked depressant action on the force and rate of contraction of the atria at a concentration of 30 mcg./ml. Determinations of MSR were, therefore, carried out at lower concentrations, 5 and

10 mcg./ml. Results showed that Compounds IIIa and IIIb were about 4 times more active than procaine amide.

Since Compounds Ic, Id, IIa, IIb, IIIa, and IIIb showed significant prolongation of the refractory period of isolated rabbit atria, they were tested for their ability to antagonize or prevent ouabain-induced arrhythmias. Prior to these experiments, the maximum tolerated dose of the compounds was determined. For Compounds Ic, IIb, and IIIb, the maximum tolerated dose was found to be 8.5 mg./kg.; for Compounds IIa and IIIa, the maximum was 18.5 mg./kg. It appeared that compounds with a methyl substituent at both *ortho*-positions of the benzene ring had a higher cardiotoxicity, as indicated by the lower maximum tolerated dose value, than those that were only mono-*ortho* substituted.

None of the compounds tested appeared to show any activity in terminating arrhythmias induced by ouabain. To make certain that the animals were not refractory, procaine amide was given after each experiment in doses of 28.5 to 38.5 mg./kg., and this resulted in the successful conversion to sinus rhythm. It should be noted, however, that procaine amide was also ineffective at doses of 8.5 and 18.5 mg./kg.

The effectiveness of the compounds in preventing ouabain-induced arrhythmias was determined by the increase in the amount of the glycoside needed to evoke ectopic rhythm, as indicated in the electrocardiograms by three successive QRS complexes not clearly related to a preceding P wave (15), and to cause the death of the animal. Results of the determinations are listed in Table V. On a weight basis, the di-*ortho*-methyl-substituted procaine amide analog (IIb) showed a higher prophylactic activity against arrhythmias than procaine amide, whereas the monosubstituted analog (IIa) did not appear to have any activity at all. The corresponding analogs of procaine, Compounds IIIa and IIIb, also showed protective action against ouabain-induced arrhythmias. Again, on a weight basis, the di-*ortho*-methyl-substituted compound (IIIb) was more active than the monosubstituted analog (IIIa).

After Compounds Id, IIb, IIIa, and IIIb were found to be active prophylactically against ventricular arrhythmias caused by ouabain, it was decided to test them for activity in abolishing established atrial arrhythmias induced by aconitine. None of the compounds showed any activity.

The effects of Compounds Ic, Id, IIa, IIb, IIIa, and IIIb on blood pressure were studied. The compounds did not demonstrate any significant effect on the blood pressure, although a transient lowering of blood pressure was observed with Compounds IIb and IIIa at cumulative doses of 6 mg./kg.

Table VI—Local Anesthetic Activity of Compounds and Their Ionization Constant (H₂O, 25°)

Compound	No. of Tests	Average Percent Anesthesia	pKa
Saline (control)	—	—	—
Procaine	6	34.6	8.86 ^a
Id	3	Inactive	8.24
IIb	3	54.1	8.68
IIIa	2	41.3	8.80
IIIb	3	41.7	8.64

^a Reported pKb value, 5.2 (16).

Since many antiarrhythmic agents seem to possess some degree of local anesthetic action, those compounds, namely, Id, IIb, IIIa, and IIIb, were tested for local anesthetic activity. Table VI is the summary of the results of the testing. Due to the limited number of tests, the data in this table were not analyzed statistically to determine if the average percent anesthesia of the compounds was significantly higher than that of procaine. Therefore, the results should be treated qualitatively rather than quantitatively. It is not surprising that Compounds IIb, IIIa, and IIIb showed local anesthetic activity, because in addition to structural similarity these compounds had a pKa value very close to that of procaine.

In Vivo Evaluation of Absorption and Excretion of Pentylene-tetrazol-10-¹⁴C from Sustained-Release and Nonsustained-Release Tablets

WILLIAM R. EBERT*, ROBERT W. MORRIS*, SUSAN G. ROWLES†, HENRY T. RUSSELL‡, GORDON S. BORN§, and JOHN E. CHRISTIAN§

Abstract □ Sustained-release and nonsustained-release tablets containing pentylenetetrazol-10-¹⁴C were administered orally to human volunteers. The levels of the drug and/or its labeled metabolites in the plasma and urine were determined by liquid scintillation counting. These data showed that the sustained-release tablets provided a consistent plasma level of ¹⁴C for about 12 hr. and that the drug and/or its labeled metabolites were excreted in the urine at a fairly constant rate during this period. The nonsustained-release tablets given in divided doses resulted in three separate peak plasma-¹⁴C levels and a urinary excretion pattern similar to that of the sustained-release tablet. A single dose of the nonsustained-release tablet was followed by a peak plasma-¹⁴C level, which decreased during the 12 hr. after administration, and by a fairly constant rate of urinary excretion of ¹⁴C during this period.

Keyphrases □ Pentylenetetrazol-10-¹⁴C—absorption, excretion □ Tablets, sustained-, nonsustained-release—pentylenetetrazol-10-¹⁴C □ Absorption, excretion—pentylenetetrazol-10-¹⁴C from sustained-, nonsustained-release tablets □ Scintillometry—analysis

Sustained-release¹ and nonsustained-release tablets containing pentylenetetrazol and niacin in common therapeutic dosages have been evaluated for their *in vivo* performance in humans by following niacin—plasma

levels (1). This evaluation was accomplished by using ¹⁴C-labeled niacin in the tablets and determining the plasma and urine levels of niacin-¹⁴C and/or its labeled metabolites subsequent to oral administration of the tablets. The results of this study showed that after ingestion of sustained-release tablets, the plasma level of niacin-¹⁴C and/or its labeled metabolites was sustained for a 12-hr. period. In contrast, three doses of nonsustained-release tablets, administered at 4-hr. intervals, resulted in three peak plasma levels. The drug excretion patterns observed after both dosage regimens were similar.

Because of the various chemical, pharmacological, and metabolic differences between niacin and pentylenetetrazol, different absorption and excretion patterns for the two drugs were expected. The present paper reports a study of the absorption and excretion patterns characteristic of pentylenetetrazol administered orally, combined with niacin, in both sustained-release and nonsustained-release dosage forms. Pentylenetetrazol-10-¹⁴C was used in this study to permit determination of these patterns by radiotracer techniques similar to those originally reported by Rosen and Swintosky (2) for following the appearance of a drug in human plasma and urine.

EXPERIMENTAL

Radioactive Pentylene-tetrazol—Pentylene-tetrazol-10-¹⁴C with a specific activity of 17.8 μ C/mg., as synthesized² by Stiver, and with radiochemical purity established by TLC (3) was diluted (4) with nonradioactive pentylene-tetrazol NF XII. Three separate dilutions of pentylene-tetrazol-¹⁴C were prepared, and the resulting specific activities were 23.4 μ C/300 mg., 18.5 μ C/100 mg., and 9.3 μ C/100 mg. Each dilution was prepared by dissolving pentylene-tetrazol-10-¹⁴C and pentylene-tetrazol NF XII in methanol (99.85%) with stirring. The methanol was evaporated over a steam bath. The pentylene-tetrazol-¹⁴C thus obtained was then cooled to room temperature and dried in a vacuum desiccator at 0.05 mm. at room temperature for 6 hr.

Radioactive Tablets—Three different compressed tablet formulations were manufactured from the pentylene-tetrazol-¹⁴C dilutions as follows.

Formula A—Sustained-release tablets, of the insoluble matrix type, from which the active ingredients are slowly leached; identical to commercial forms,¹ with the exception of the use of pentylene-tetrazol-¹⁴C. These tablets contained pentylene-tetrazol-¹⁴C, 300 mg. (equivalent to 23.4 μ C of ¹⁴C); niacin, 150 mg.; fatty substances; and inert excipients.

Formula B—Nonsustained-release tablets containing pentylene-tetrazol-¹⁴C, 100 mg. (equivalent to 18.5 μ C of ¹⁴C); niacin, 50 mg.; and inert excipients.

Formula C—Nonsustained-release tablets containing pentylene-tetrazol-¹⁴C, 100 mg. (equivalent to 9.3 μ C of ¹⁴C); niacin, 50 mg.; and inert excipients.

Quality Control—Tablets were selected at random from all three tablet formulations; they were subjected to routine quality control tests to establish the conformance of the pentylene-tetrazol-¹⁴C-containing sustained-release tablets to the commercial forms and to determine that the physical and chemical characteristics of the non-sustained-release tablets were satisfactory with reference to commercially available tablets of similar composition. Tablets were tested for pentylene-tetrazol content, niacin content, weight, thickness, and hardness. The disintegration time of the nonsustained-release tablets was determined by the USP Tablet Disintegration Test, and the *in vitro* release rate was determined for the sustained-release tablets.

In Vitro Release Rate Tests—Before the sustained-release tablets were administered to human subjects, the *in vitro* release rates of pentylene-tetrazol and niacin were determined to establish conformance of the radioactive tablets to commercial forms. The USP Tablet Disintegration Test Apparatus (5) was used to determine the *in vitro* release rates as follows. Six tablets were chosen at random and tested individually by placing one tablet in one of the six tubes of the basket-assembly, which was then immersed in 600 ml. of simulated gastric fluid T.S. (6) at 37 \pm 1°. After operation of the apparatus for 1 hr., the basket was removed, rinsed, and transferred immediately to 600 ml. of simulated intestinal fluid T.S. (7) at 37 \pm 1° in which the apparatus was operated for 7 hr.

At the end of the 1st hour, samples of the gastric test fluid were assayed for pentylene-tetrazol by both the liquid scintillation counting technique and by gravimetric analysis. In the latter procedure,

Figure 1—Average plasma levels of equivalent pentylene-tetrazol following oral administration of pentylene-tetrazol-¹⁴C tablets. Group A: One sustained-release tablet. Group B: One nonsustained-release tablet. Group C: One nonsustained-release tablet at 0, 4, and 8 hr. For clarity, standard deviations are not shown on the curves but are given in Table II.

an aliquot of the test fluid was saturated with ammonium sulfate and the pentylene-tetrazol quantitatively extracted with carbon tetrachloride. After evaporation of the solvent, the residue was dissolved in a small volume of ether and evaporated to dryness; the process then was repeated. The weight of the residue was determined after drying in a vacuum at room temperature to constant weight. The niacin was quantitated by UV spectrophotometry with a correction for the background absorbance due to the gastric test fluid. Samples of the intestinal test fluid were withdrawn at 4 and 8 hr. after the start of the test and were assayed similarly after acidification of the release solutions.

In Vivo Protocol—Twelve healthy adult human volunteers, determined by medical history and physical examinations to be free of any disorders associated with abnormal absorption or excretion patterns, were used in this study. The subjects were all Caucasian males, ranging in age from 25 to 34 yr. and weighing between 72.3 and 102.8 kg. Plasma and urine samples were obtained from all subjects before the experiment began for later use in background correction of sample assays. All subjects fasted for 12 hr. prior to the experiment and for 5 hr. after it began.

The 12 volunteers were assigned experimental subject numbers at random. Each of four subjects (Group A: Subjects 1, 2, 3, and 4) was given one tablet of Formula A, the sustained-release dosage form. Each of four other subjects (Group B: Subjects 5, 6, 7, and 8) was given one tablet of Formula B, a nonsustained-release tablet. Each of four additional subjects (Group C: Subjects 9, 10, 11, and 12) was given one tablet of Formula C, a nonsustained-release tablet, at time zero and again at 4 and 8 hr. after time zero. All tablets were ingested with water.

Ten-milliliter blood samples were withdrawn from all subjects at 1, 2, 4, 5, 8, 9, 12, 24, and 48 hr. after time zero. All blood samples were treated with 20 mg. of disodium EDTA, and the plasma was immediately separated by centrifugation and frozen until assayed. Total urinary collections were made for all subjects during the following intervals after time zero: 0–3, 3–6, 6–9, 9–12, 12–24, 24–36, 36–48, and 48–72 hr. The urine was frozen until analyzed.

Assay of ¹⁴C—Liquid scintillation counting techniques were employed to determine the quantity of ¹⁴C in each plasma and urine sample. In a preliminary experiment, replicate plasma samples were prepared for counting by three different methods, using Insta-Gel emulsifier,³ hyamine hydroxide⁴ solution, and perchloric acid. All three methods gave satisfactory results, but the Insta-Gel emulsifier system was determined most suitable on the basis of its simplicity and low quenching characteristics (counting efficiencies of approximately 80% were obtained).

Remaining plasma samples were prepared for counting as follows. Exactly 1 ml. of plasma was slowly added to a counting vial containing 10 ml. of emulsifier (Insta-Gel). The vial was tightly capped and allowed to remain at room temperature for 20 hr., with

48	0.7 \pm 0.1	0.2 \pm 0.1	0.9 \pm 0.4

^a Mean of four subjects. ^b Any ¹⁴C-labeled metabolites have been equated to the administered pentylene-tetrazol-¹⁴C. ^c Group A: One sustained-release tablet containing 300 mg. of pentylene-tetrazol-¹⁴C. ^d Group B: One nonsustained-release tablet containing 100 mg. of pentylene-tetrazol-¹⁴C. ^e Group C: One nonsustained-release tablet containing 100 mg. of pentylene-tetrazol-¹⁴C at 0, 4, and 8 hr.

occasional shaking. Upon cooling to 4°, a viscous one-phase system was obtained.

Urine samples were prepared for counting by adding 1.0-ml. aliquots to 15 ml. of a scintillation solution containing 2,5-diphenyl-oxazole (PPO), 10.0 g.; naphthalene, 80.0 g.; *p*-xylene, 143 ml.; *p*-dioxane, 429 ml., and a sufficient quantity of 2-ethoxyethanol to make 1 l.

All samples were cooled to 4° and were counted at that temperature in a Packard Tri-Carb liquid scintillation spectrometer equipped with bialkali photomultiplier tubes. The discriminators were set at 50 and 900, and the gain was adjusted to optimize the counting rate. All samples were counted for a length of time sufficient to assure counting errors less than 5% (at the 95% confidence level) in all cases and less than 1% for the majority of the samples.

All sample count rates were corrected for background and converted to absolute count rates by the internal standardization method of quench correction. The results of the sample assays are expressed in terms of "equivalent pentylene-tetrazol," thus equating any ¹⁴C-labeled metabolites to the administered pentylene-tetrazol-¹⁴C, and assuming that the specific activities of all labeled compounds present in the urine and plasma are identical to the specific activity of the administered pentylene-tetrazol-¹⁴C.

RESULTS AND DISCUSSION

Tablet Assays—The *in vitro* release rate data for the sustained-release tablets (Formula A) are given in Table I. These data indicate that the radioactive sustained-release tablets met the specifications of the corresponding commercial form.

The data for quality control tests for total pentylene-tetrazol, total niacin, weight, thickness, hardness, and disintegration time are not summarized in this paper but showed that all tablets tested conformed to corresponding commercially available forms.

Plasma Data—The average plasma levels of equivalent pentylene-tetrazol are plotted for each test group in Fig. 1. This graph shows that the plasma levels of the parent compound and/or its labeled metabolites were identical (± 0.01 mg./l.) for all three groups 1 hr. after drug administration. Plasma concentrations of equivalent pentylene-tetrazol gradually rose during the 1-4-hr. period after administration of the sustained-release tablet and then remained constant (3.2-3.5 mg./l.) until about the 12th hour. However, during the 1-4-hr. period following administration of the nonsustained-release tablet, plasma-¹⁴C levels gradually decreased. Typical rises and falls in plasma levels of equivalent pentylene-tetrazol were observed following the repeated administration of the nonsustained-release tablet. The plasma level of equivalent pentylene-tetrazol decreased continually after the peak seen 1 hr. after single-dose administration of the nonsustained-release tablet.

Table II gives the mean plasma levels of equivalent pentylene-tetrazol and the standard deviations for all three groups at the various times studied. Student *t* values (8) were determined to compare the mean plasma levels of ¹⁴C of the different groups at various times. At the 99% confidence level ($p = 0.01$), there were no statistically significant differences between the mean plasma levels of any

Figure 2—Cumulative average urinary excretion of equivalent pentylene-tetrazol following oral administration of pentylene-tetrazol-¹⁴C tablets. Group A: One sustained-release tablet. Group B: One nonsustained-release tablet. Group C: One nonsustained-release tablet at 0, 4, and 8 hr. For clarity, standard deviations are not shown on the curves but are given in Table III for the noncumulative excretion data. (The value of Group C, 24-36-hr. collection, includes an estimate of the amount of pentylene-tetrazol present in a quantity of urine which was voided but not collected for analysis. (One subject forgot to collect one urine sample voided during this interval.)

two groups 1 hr. after drug administration. At all times after 1 hr., the mean plasma levels of Groups A and B (the sustained-release tablet group and the single-dose, nonsustained-release tablet group) were significantly different. This indicates that the sustained-release tablet was still releasing pentylene-tetrazol after the 1st hour, whereas the peak plasma level resulting from dosage with one nonsustained-release tablet occurred prior to or approximately at 1 hr.

Statistically significant differences were found between Groups A and C (the sustained-release tablet group and the group that received three divided doses of a nonsustained-release tablet) only at 2, 4, 9, and 12 hr. These results suggest that the sustained-release tablet released about one-third of the pentylene-tetrazol rapidly and that the remainder was smoothly and continuously released.

As expected, there was no statistically significant difference between Groups B and C (the groups receiving nonsustained-release tablets in single doses and in three divided doses) at 1, 2, or 4 hr. From 5 hr. on, differences between these two groups were significant.

Urine Data—Urinary excretion of equivalent pentylene-tetrazol proceeded at a nearly constant rate for approximately 36 hr. after administration of the sustained-release tablet and then gradually decreased (Fig. 2). A similar excretion pattern was shown by those subjects receiving three nonsustained-release tablets at 4-hr. intervals. A constant rate of urinary excretion of equivalent pentylene-tetrazol was evident for approximately 24 hr. following single oral

Table III—Urinary Excretion of Equivalent Pentylene-tetrazol following Oral Administration of Pentylene-tetrazol-¹⁴C Tablets

Time after Administration, hr.	Mean ^a Equivalent Pentylene-tetrazol ^b Excreted, mg. \pm SD		
	Group A ^c	Group B ^d	Group C ^e
0-3	12.3 \pm 4.4	9.3 \pm 3.9	8.8 \pm 3.0
3-6	19.5 \pm 2.7	9.3 \pm 3.4	13.9 \pm 2.8
6-9	23.0 \pm 4.9	10.8 \pm 1.5	19.7 \pm 7.2
9-12	24.7 \pm 4.1	8.2 \pm 1.3	26.4 \pm 7.7
12-24	65.9 \pm 5.2	21.5 \pm 0.4	79.7 \pm 10.6
24-36	51.8 \pm 11.9	12.8 \pm 4.9	55.3 \pm 11.5
36-48	27.2 \pm 5.5	7.9 \pm 2.0	31.2 \pm 7.0
48-72	23.5 \pm 4.8	7.6 \pm 1.6	30.6 \pm 10.6

^a Mean of four subjects. ^b Any ¹⁴C-labeled metabolites have been equated to the administered pentylene-tetrazol-¹⁴C. ^c Group A: One sustained-release tablet containing 300 mg. of pentylene-tetrazol-¹⁴C. ^d Group B: One nonsustained-release tablet containing 100 mg. of pentylene-tetrazol-¹⁴C. ^e Group C: One nonsustained-release tablet containing 100 mg. of pentylene-tetrazol-¹⁴C at 0, 4, and 8 hr. This value includes an estimate of the amount of pentylene-tetrazol present in a quantity of urine which was voided but not collected for analysis. (Subject forgot to collect one urine sample voided during this interval.)

administration of the nonsustained-release tablet, with the rate decreasing after the 24-hr. point.

The mean equivalent pentylenetetrazol excretion values and the standard deviations for the three groups are given in Table III. Student *t* values (8) were calculated to compare the mean ¹⁴C excretion values of the different groups at various times. Statistically significant (*p* = 0.01) differences were seen between Groups A and B at all collection intervals after the first (0–3 hr.).

No significant differences between Groups A and C were present at any of the collection intervals. These results indicate that urinary excretion of 300 mg. of pentylenetetrazol proceeds at approximately the same rate whether the dose is administered in one sustained-release tablet or divided and administered in three doses at 4-hr. intervals. These results also indicate that the same fraction of pentylenetetrazol was absorbed from the sustained-release tablets as from the nonsustained-release tablets.

There were no significant differences between Groups B and C until the fourth collection (9–12 hr.). Mean excretion values for these two groups were significantly different in all of the last five urine collections.

SUMMARY

Sustained-release and nonsustained-release tablets containing pentylenetetrazol-10-¹⁴C were administered to human subjects. The resulting plasma and urine concentrations of equivalent pentylenetetrazol were determined by liquid scintillation counting techniques. Subjects receiving the sustained-release tablets exhibited smoothly sustained plasma levels of equivalent pentylenetetrazol for a period of about 12 hr. and a nearly linear urinary excretion rate of ¹⁴C during a period of 36 hr. Subjects receiving three doses of nonsustained-release tablets at 4-hr. intervals exhibited typical rises and falls in plasma ¹⁴C levels and an excretion pattern similar to that of the subjects receiving the sustained-release tablets. Subjects receiving a single dose of a nonsustained-release tablet showed one peak plasma ¹⁴C level which then decreased continuously. A fairly constant rate of urinary ¹⁴C excretion was evident for 24 hr. The results of this study showed that the sustained-release tablet produced

absorption and excretion patterns similar to those obtained following three doses of the drug administered in nonsustained-release form at 4-hr. intervals.

Permeability of Double-Layer Films III

TSUNETO KURIYAMA, MICHIHARU NOBUTOKI, and MICHIO NAKANISHI

Abstract □ Moisture permeability of most double-layer films has a directional property. This "two-sidedness" may be brought about mainly by a change in the permeability coefficient as a result of the change in vapor pressure. To utilize this characteristic, it should be clarified as to how the permeability coefficient varies. For this purpose the differential permeability coefficient was calculated, making it easy to estimate the permeability of moisture under various conditions and making it possible to obtain the distribution of both vapor pressure and the water concentration in double-layer films. When the permeability on single films under various moisture conditions is given, the "two-sidedness" feature of double-layer films made from them will be grasped.

Keyphrases □ Double-layer films—theoretical considerations □ Films, double layer—moisture permeability □ Differential permeability coefficients—double-layer films □ Water concentration, vapor pressure—films

Previous reports (1, 2) dealt with variations of "two-sidedness" in the moisture permeability of double-layer films with changing conditions. It is very important to

investigate the cause (or principle) of these phenomena. Rogers *et al.* (3) explained the two-sidedness skillfully, even though they did not classify such characteristics as were reported in a previous report (1). Their theory can be regarded as applicable to understand various types of two-sidedness and their behavior under changing moisture conditions. As stated in a previous report (2), the permeability coefficient, *P*, is not constant but varies with the moisture changes. Rogers *et al.* (3) introduced the concept of the differential permeability coefficient to solve this problem. The following theoretical considerations are mainly based on these ideas.

EXPERIMENTAL

The experimental method and the abbreviation for each film are the same as those in previous reports (1, 2).

Cell for Measuring Water Vapor Permeability—The cell and measuring method are modifications of those of Patel *et al.* (4). Permeation through a sample film was determined by measuring weight change of the cell at a certain condition.

administration of the nonsustained-release tablet, with the rate decreasing after the 24-hr. point.

The mean equivalent pentylenetetrazol excretion values and the standard deviations for the three groups are given in Table III. Student *t* values (8) were calculated to compare the mean ¹⁴C excretion values of the different groups at various times. Statistically significant (*p* = 0.01) differences were seen between Groups A and B at all collection intervals after the first (0–3 hr.).

No significant differences between Groups A and C were present at any of the collection intervals. These results indicate that urinary excretion of 300 mg. of pentylenetetrazol proceeds at approximately the same rate whether the dose is administered in one sustained-release tablet or divided and administered in three doses at 4-hr. intervals. Permeability of Double-Layer Films III

TSUNETO KURIYAMA, MICHIHARU NOBUTOKI, and MICHIO NAKANISHI

Abstract □ Moisture permeability of most double-layer films has a directional property. This "two-sidedness" may be brought about mainly by a change in the permeability coefficient as a result of the change in vapor pressure. To utilize this characteristic, it should be clarified as to how the permeability coefficient varies. For this purpose the differential permeability coefficient was calculated, making it easy to estimate the permeability of moisture under various conditions and making it possible to obtain the distribution of both vapor pressure and the water concentration in double-layer films. When the permeability on single films under various moisture conditions is given, the "two-sidedness" feature of double-layer films made from them will be grasped.

Keyphrases □ Double-layer films—theoretical considerations □ Films, double layer—moisture permeability □ Differential permeability coefficients—double-layer films □ Water concentration, vapor pressure—films

Previous reports (1, 2) dealt with variations of "two-sidedness" in the moisture permeability of double-layer films with changing conditions. It is very important to

investigate the cause (or principle) of these phenomena. Rogers *et al.* (3) explained the two-sidedness skillfully, even though they did not classify such characteristics as were reported in a previous report (1). Their theory can be regarded as applicable to understand various types of two-sidedness and their behavior under changing moisture conditions. As stated in a previous report (2), the permeability coefficient, *P*, is not constant but varies with the moisture changes. Rogers *et al.* (3) introduced the concept of the differential permeability coefficient to solve this problem. The following theoretical considerations are mainly based on these ideas.

EXPERIMENTAL

The experimental method and the abbreviation for each film are the same as those in previous reports (1, 2).

Cell for Measuring Water Vapor Permeability—The cell and measuring method are modifications of those of Patel *et al.* (4). Permeation through a sample film was determined by measuring weight change of the cell at a certain condition.

Figure 1—Relationship between Q and Δp . Temperature, 40° ; thickness of film, 0.2 mm.; $p_1 = 100\%$ R.H. = 55.3 mm. Hg; and $\Delta p = p_1 - p$.

Film Preparation—Single Film—Free film was prepared by casting a solution of coating agent on a glass plate.

Double-Layer Film—Two single films were combined to form a double-layer film by using a solvent that dissolved only a surface of either film.

Measurement of Film Thickness—The thickness of a single film is expressed as the mean value of 12 different points measured with a dial gauge (precision 0.001 mm.) in a sample film (4 cm. in diameter). Standard deviation of the thickness in a sample film was less than 0.0006 mm. at 0.05-mm. thickness, 0.0008 mm. at 0.15-mm. thickness, and 0.001 mm. at 0.25-mm. thickness.

Materials—The coating agents used are as follows:

Abbreviation	Chemical Name	Manufacturer (Specification)
EC	Ethylcellulose	Dow Corning (50 cps.)
MC	Methylcellulose	Shin-etsu Chemical Co. (25 cps.)
HECAP	Hydroxyethyl-cellulose acetate phthalate	Yoshitomi Pharmaceutical Industries (5)

All permeability data were determined as the mean of six observations at the same condition.

RESULTS AND DISCUSSION

Figure 1 shows the relationship between the pressure difference, Δp , and the moisture permeability, Q , across methylcellulose

Figure 2—Relationship between P and Δp . Temperature, 40° ; thickness of film, 0.2 mm.; $p_1 = 100\%$ R.H. = 55.3 mm. Hg; and $\Delta p = p_1 - p$.

(MC-25) film of 0.2-mm. thickness.

Application of Eq. 1 to this relationship gives the permeability coefficient P . The result is shown in Fig. 2.

$$Q = \frac{q}{At} = P \frac{p_1 - p_2}{l} = P \frac{\Delta p}{l} \quad (\text{Eq. 1})$$

where l = thickness of a film, A = permeation area of the film, t = time of permeation, p_1 = water vapor pressure at the side of higher humidity, p_2 = water vapor pressure at the side of lower humidity, P = permeability coefficient of moisture, Q = moisture permeability, and q = quantity of permeated moisture.

Figure 2 shows that the permeability coefficient is not a constant but a function of the humidity condition in which the film is placed. Each section that is rectangular to the direction of permeation across a film may have a certain differential permeability coefficient, depending upon the humidity condition in which the section is located. What is obtained in an experiment is permeability coefficient P , which corresponds to the integrated value of all differential permeability constants involved. This idea is expressed as follows:

$$P = \frac{1}{\Delta p} \int_{p_2}^{p_1} P' dp \quad (\text{Eq. 2})$$

where P' is the differential permeability coefficient.

Differentiating Eq. 2 gives Eq. 3:

$$P' = \frac{d(P \Delta p)}{dp} \quad (\text{Eq. 3})$$

Figure 2 gives the relationship between P and Δp (or p), which may produce P' with the help of Eq. 3. The process of this calculation is summarized in Table I. In this table, each P and Q has a suffix consisting of two letters. The first letter refers to the water-vapor pressure of the side of higher humidity; the second letter refers to the water vapor pressure of the side of lower humidity. For instance, Q_{p_1p} is the Q which is obtained by fixing the water vapor pressure on p_1 at the side of higher humidity and by varying the vapor pressure, p , at the side of lower humidity. In a like man-

ner, the correspondent permeability coefficient of moisture is expressed as P_{p_1p} .

The results shown in Table I were calculated from the data of Fig. 1, not from data of Fig. 2. Although the four values observed in Fig. 2 are converted from Fig. 1, the curve in Fig. 2 is not as accurate as that in Fig. 1, because the former is more sharply curved than the latter. As is understood from Eq. 3, even a small error in P will have a strong influence on the resulting P' . The results obtained in Table I show the relationship that corresponds to the function $P' = f(p)$ under a certain condition. Figure 2 shows the observed values corresponding to Eq. 4. Here, using the relation of $P' = f(p)$ of Table I, P_{pp_2} can be obtained (Eq. 5). P_{pp_2} is the permeability coefficient for varying vapor pressure at the side of higher humidity under constant vapor pressure at the lower side. Moreover, P_{pp_2} gives Q_{pp_2} according to Eq. 1.

$$P_{p_1p} = \frac{1}{p_1 - p} \int_p^{p_1} P' dp \quad (\text{Eq. 4})$$

$$P_{pp_2} = \frac{1}{p - p_2} \int_{p_2}^p P' dp \quad (\text{Eq. 5})$$

These calculations were made in accordance with Table II, and the results are shown in Fig. 3.

P_{p_1p} is considerably different from P_{pp_2} . This means that the moisture permeability will be different when the mean value of vapor pressure is not the same, even if the difference of pressure across the film is constant. The calculated P' values were considerably divergent as plotted in Fig. 3. This divergence was caused, as mentioned previously, by the fact that the values of P' were strongly influenced by the slightest errors of P (errors of observation and plotting). P' values used in Table II are the raw results from Table I, so the P_{pp_2} values obtained are divergent too. However, if the compensated values of P' obtained from the regression curve in Fig. 3 are used, a better curve can be obtained around P_{pp_2} . Rogers *et al.* (3) explained the two-sidedness of the permeability without calculating P' . Their idea shows that it is possible to obtain Q_{pp_2}

Figure 3— Δp -profile of P' , P_{p_1p} , and P_{pp_2} . Material, MC-25; thickness of film, 0.2 mm.; temperature, 40°; $p_1 = 100\%$ R.H. = 55.3 mm. Hg; and $\Delta p = p_1 - p$. P_{p_1p} = permeability coefficient observed by fixing the water vapor pressure on p_1 at the side of higher humidity and by varying the vapor pressure p at the side of lower humidity. P_{pp_2} = permeability coefficient calculated fixing the water vapor pressure on p_2 at the side of lower humidity and varying the vapor pressure p at the side of higher humidity. P' = differential permeability coefficient calculated.

Figure 4—Rogers' graphical method to obtain Q_{pp_2} from Q_{p_1p}

Figure 5—Graphical estimation of permeability (Q_c) of double-layer film composed of Material I (higher humidity side) and Material II (lower humidity side).

graphically, as shown in Fig. 4, if $Q_{p_1 p}$ is given. (This is, in principle, the same method as that used in Table I and/or II.)

Figure 5 gives the combination of $Q_{p_1 p}^I$ and $Q_{p p_2}^{II}$, where $Q_{p_1 p}^I$ means the moisture permeability across Film I when the vapor pressure p_1 , at the side of higher humidity, is constant with varying vapor pressure p at the lower side. $Q_{p p_2}^{II}$ is $Q_{p p_2}$ of Film II, which is obtained by the method shown in Fig. 4 using the data $Q_{p_1 p}^{II}$. Rogers *et al.* (3) indicated that Q_c in Fig. 5 corresponds to the moisture permeability of double-layer film made from I and II, where Film I faces the p_1 side and Film II faces the p_2 side. As a model, Fig. 6 (a and b) illustrates different combinations of films with different moisture permeability characteristics.

Rogers *et al.* (3) explained that the two-sided characteristic of the double-layer film results from the different Q around the intersect-

ing points C and D. When the thicknesses of Films I and II are the same, A, B, C, and D all correspond to the permeability across the films of the same thickness. The characteristics of these double-layer films are classified according to the order of magnitude of Q 's around A, B, C, and D as mentioned in an earlier report (1). Figure 6a belongs to group γ , and Figure 6b belongs to group α . Only if the actual data of $Q_{p_1 p}^I$ and $Q_{p p_2}^{II}$ are given can $Q_{p p_2}$ and $Q_{p_1 p}$ be determined graphically, where p_2 can be determined to be any value within a range of the mentioned data. For instance, the observed $Q_{p_1 p}$ for both ethylcellulose EC-50 of 0.1-mm. thickness and hydroxyethylcellulose acetate phthalate (HECAP) of 0.1-mm. thickness can produce Fig. 7.

Each intersecting point, A, B, C, or D, in Fig. 7 is plotted against humidity conditions to obtain Fig. 8. Figure 8 is utilized to compare the permeation property of the double-layer film with that of each of its single films, where the double-layer film is made from EC-50 and HECAP of 0.1-mm. thickness and single films are EC-50 and HECAP of 0.2 mm. The observed values corresponding to Fig. 8 were plotted in Fig. 9.

When the two graphs are compared, the shapes are seen to be similar, but the predicted graph (Fig. 8) seems to be more compressed in the direction of the ordinate than the observed ones (Fig. 9). These facts may be explained as follows. According to the method of Rogers *et al.* (3) shown in Fig. 4, the moisture permeability is halved when two films of the same kind with the same thickness are piled; that is, the thickness of the film is doubled. In other words, the moisture permeability is inversely proportional to the thickness of the film (or $1/Q$ is in direct proportion to l). Thus, Fig. 4b is obtained when Fig. 4a is turned over symmetrically around the line (parallel to the p ordinate) that passes through the point $1/2 \cdot Q$. However, as mentioned in an earlier report (1), the moisture permeability is not exactly in inverse proportion to the thickness but is slightly more than one-half, even if the thickness of the film is doubled. The main reason Fig. 8 differs from Fig. 9 may be attributed to the assumed inversely proportional relation.

Although the following processing method involves some theoretical inadequacies, it may be practically useful to estimate the two-sided property of the double-layer film.

1. The moisture permeability is measured at several Δp levels about single Films I and II, which may be combined to form a

Figure 6—Two-sidedness of double-layer films (Rogers' method).

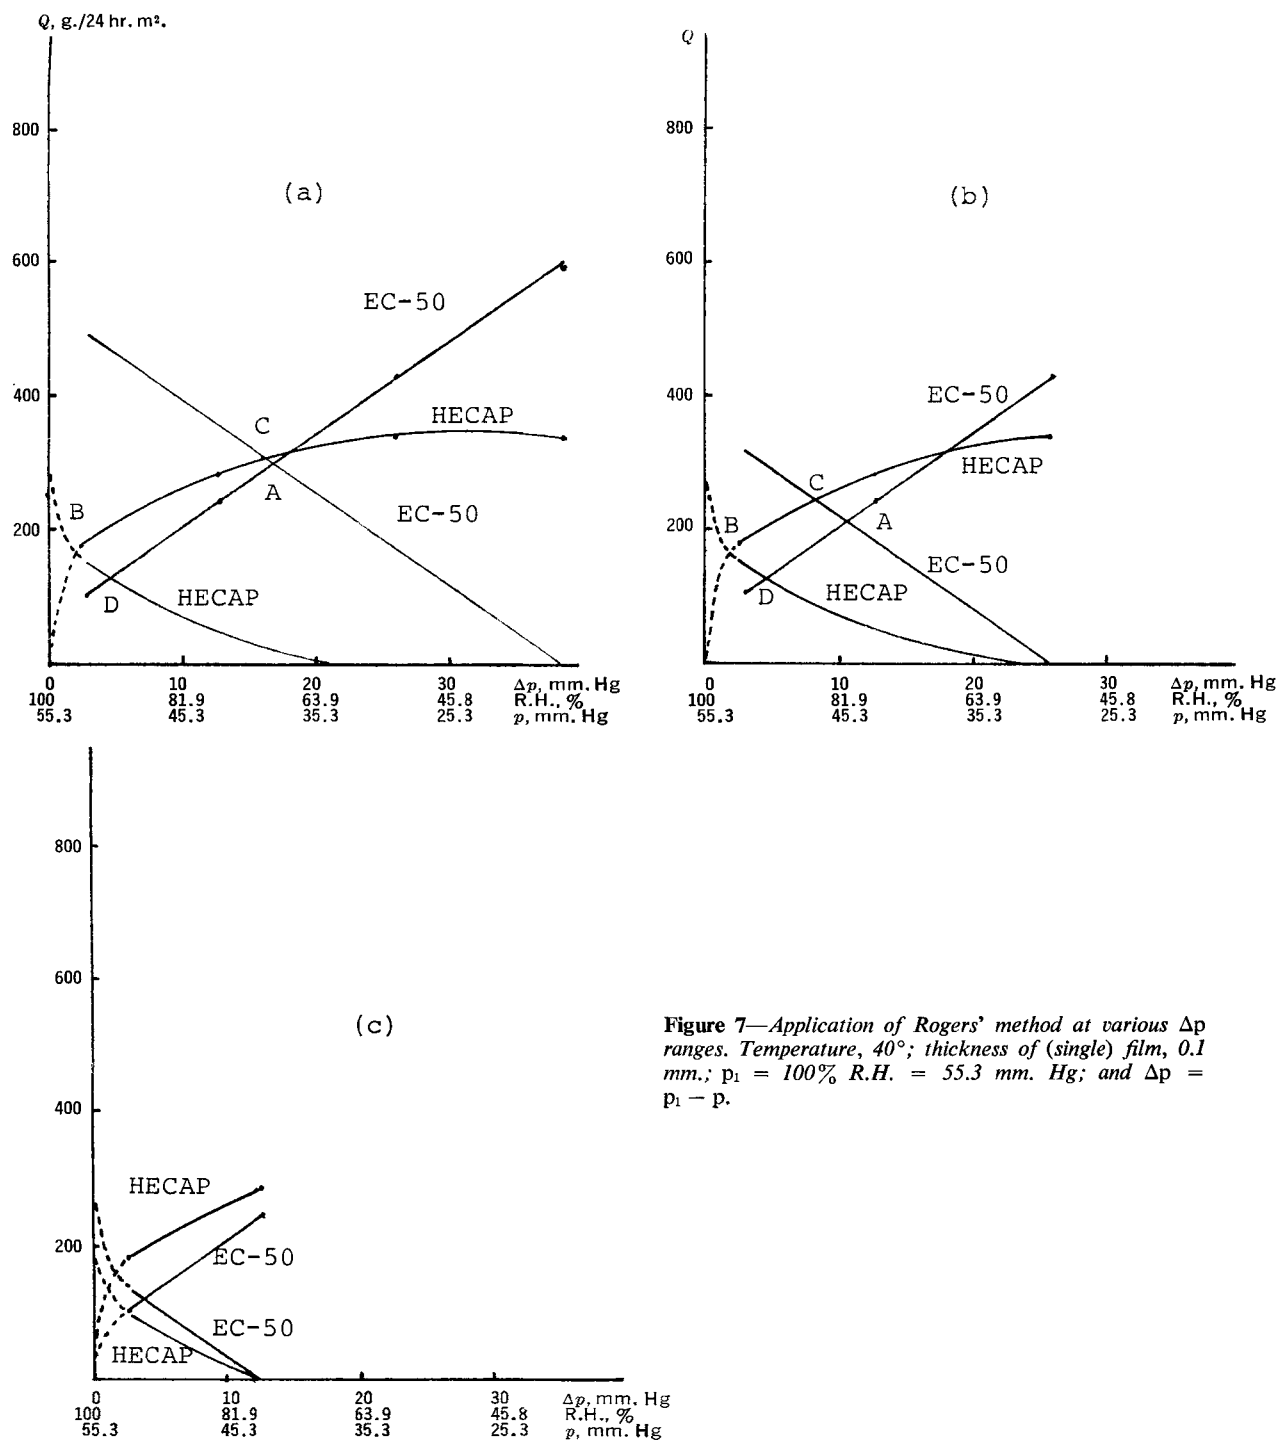

Figure 7—Application of Rogers' method at various Δp ranges. Temperature, 40°; thickness of (single) film, 0.1 mm.; $p_1 = 100\%$ R.H. = 55.3 mm. Hg; and $\Delta p = p_1 - p$.

double-layer film with several levels of thickness. (Although Δp can be set as either $p_1 - p$ or $p - p_2$, the following explanation is carried out using $\Delta p = p_1 - p$.)

2. The data are arranged in terms of: abscissa = l , ordinate = $1/Q$, and parameter = Δp , which afford a linear relationship. The graphs are obtained for I and II.

3. From the graphs obtained in Step 2, the figure is depicted for I and II in terms of: abscissa = Δp , ordinate = Q , and parameter = l . To evaluate the permeability of the double-layer film which consists of I and II when each elemental layer has thickness l_1 , the parameter is enough to be l_1 and $2l_1$. In other words, the Q - Δp (or $Q_{p_1 p}$) curve is obtained for both I and II with the thickness l_1 and $2l_1$, respectively.

4. The $Q_{p p_2}$ curve for a given p_2 is obtained by turning the $Q_{p_1 p}$ curve of a film with thickness l_1 symmetrically around the line that

passes through the point $Q_{p_1 p_2}$ of the film with thickness $2l_1$ and is parallel to the Δp axis. The four curves obtained, $Q_{p_1 p}^I$, $Q_{p p_2}^I$, $Q_{p_1 p}^{II}$, and $Q_{p p_2}^{II}$, are drawn in a graph as in Fig. 6.

In this method, different from that of Rogers *et al.* (3), the value of Q along the line of symmetry is not $1/2 \cdot Q_{p_1 p_2}$ for l_1 but $Q_{p_1 p_2}$ for $2l_1$. From the intersect points in the graph thus obtained, the two-sided characteristic of the double-layer film is evaluated. According to this method, the permeability of any combination of films can be determined only if the data for each single film are given, and the permeabilities of single films can be compared with each other under the same conditions on the any-accurate-thickness (l_1) basis (although it is very difficult to make a film with an exact l_1 thickness). Figure 10 is an example of the result thus obtained with a double-layer film made from EC-50 and HECAP.

Figure 8—Estimation of two-sidedness of moisture permeability. Temperature, 40°; $p_1 = 100\%$ R.H. = 55.3 mm. Hg; and $\Delta p = p_1 - p$. Materials: ①, HECAP (0.1 mm.) + EC-50 (0.1 mm.); ②, EC-50 (0.2 mm.); ③, HECAP (0.2 mm.); and ④, EC-50 (0.1 mm.) + HECAP (0.1 mm.).

Figure 10 closely resembles Fig. 9, indicating the usefulness of the method to predict the two-sided property. This graphical method does not necessarily match with the detailed facts. (For instance, $Q_{p_2 p_2}^I$ does not come to zero.) However, the Q values obtained from the intersecting points make it possible to determine the two-sided property of permeability of the double-layer film with tolerable accuracy.

The differential permeability coefficient can be utilized for another purpose. The $\Delta p/l$ in Eq. 1 is the gradient of vapor pressure across

Figure 9—Two-sidedness of moisture permeability observed. Temperature, 40°; $p_1 = 100\%$ R.H. = 55.3 mm. Hg; and $\Delta p = p_1 - p$. Materials: ①, HECAP (0.1 mm.) + EC-50 (0.1 mm.); ②, EC-50 (0.2 mm.); ③, HECAP (0.2 mm.); and ④, EC-50 (0.1 mm.) + HECAP (0.1 mm.).

Figure 10—Estimation of two-sidedness of moisture permeability. Temperature, 40°; $p_1 = 100\%$ R.H. = 55.3 mm. Hg; and $\Delta p = p_1 - p$. Materials: ①, HECAP (0.1 mm.) + EC-50 (0.1 mm.); ②, EC-50 (0.2 mm.); ③, HECAP (0.2 mm.); and ④, EC-50 (0.1 mm.) + HECAP (0.1 mm.).

the film. After permeation arrives at a steady state of condition, the moisture transmitting the cross section of the direction of permeation is of the same quantity as Q , passing through the film itself. Considering the cross section, Eq. 1 then can be written as Eq. 6:

$$Q = -P' \frac{dp}{dx} \quad (\text{Eq. 6})$$

where x is the distance from the surface of higher humidity to the aimed cross section of the direction of permeation. This equation may then be correlated to the equation of Fick's law (Eq. 7) on diffusion:

$$Q = -D \frac{\partial c}{\partial x} \quad (\text{Eq. 7})$$

Figure 11—Water vapor pressure distribution in film (calculated). Film material, MC-25; temperature, 40°; $p_1 = 4.53$ cm. Hg; and $p_2 = 1.03$ cm. Hg.

Figure 12—Water vapor pressure distribution (calculated) of double-layer film. Temperature, 40°; $p_1 = 5.03$ cm. Hg; and $p_2 = 1.53$ cm. Hg.

While the diffusion coefficient, D , in Eq. 7 is constant, the differential permeability coefficient, P' , in Eq. 6 is a function of the water-vapor pressure. Equation 8 is obtained when Eq. 6 is integrated in the range between $x = 0$ and $x = x$, i.e., between p_1 and p where p_1 = the water vapor pressure at the side of higher humidity, and p = the vapor pressure in equilibrium to cross section across the film ($p_1 > p > p_2$).

$$x = \frac{1}{Q_{p1p}} \int_p^{p_1} P' dp \quad (\text{Eq. 8})$$

The distribution of the vapor pressure across the film can be obtained from Fig. 10. Table III shows the calculation process which gives the relation of p to x . This calculation was carried out using the P' value which was calculated in Table I and revised in Fig. 3. These results produce Fig. 11.

The curve of the vapor pressure distribution in MC-25 (hydrophilic film) was concluded not to be linear, although it was linear in the case of a hydrophobic film. Gillespie (6) investigated the water concentration of each layer in some multilayer films and obtained similar results: the curve of water concentration distribution was linear on polystyrene (hydrophobic) and sigmoid on cellophane

(hydrophilic). Figure 11 supports this result, although it was not sigmoid. However, Fig. 11 shows the distribution of the vapor pressure; if the vapor pressure distribution is converted into the distribution of water concentration, it will give a sigmoid curve. The reason for this follows. Although the relation of the water vapor pressure, p , to the water concentration, c , which is in equilibrium with the pressure, follows Henry's law (Eq. 9) in general,

$$c = Sp \quad (\text{Eq. 9})$$

the relation given by Eq. 10 is valid, as shown by Henley (7) with the propane-polyethylene system, when p varies over a wide range:

$$S = ap + b \quad (\text{Eq. 10})$$

where both a and b are constants.

Substituting Eq. 10 into Eq. 9 gives Eq. 11:

$$c = ap^2 + bp \quad (\text{Eq. 11})$$

This indicates that c is a function of the second order of p . This has been also supported experimentally by Gillespie (6). The ordinate of Fig. 11 can be converted into the water concentration distribution by using Eq. 11, and then the obtained curve will be more similar to the sigmoid.

Table III—Calculation of Water Vapor Pressure Distribution in Film^a

p , cm. Hg	P' , g./sec. cm. cm. Hg	$\int_p^{p_1} P' dp$, g./sec. cm.	x , cm.

1.03	72×10^{-11}	709.1×10^{-11}	20.00×10^{-3}

^a $p_1 = 4.53$ cm. Hg, $p_2 = 1.03$ cm. Hg, $l = 0.02$ cm., $Q_{p1p2} = 1/l \int_{p_2}^{p_1} P' dp = \frac{709.1 \times 10^{-11}}{0.02} = 35.46 \times 10^{-3}$ (g./sec. cm.²) = 306 (g./24 hr. m.²).

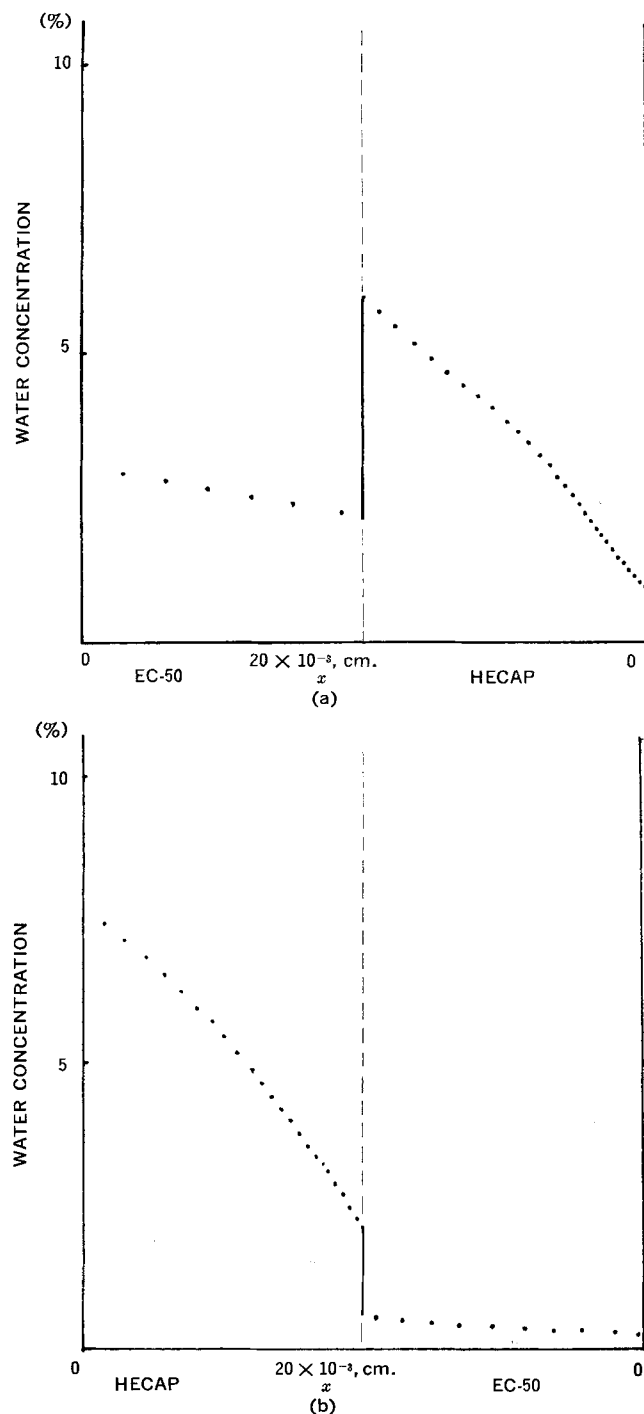

Figure 13—Water concentration distribution in double-layer film. x = film thickness.

For a double-layer film of EC-50 and HECAP, the distribution of the water vapor pressure can be shown as in Fig. 12 and the distribution of water concentration can be shown as in Fig. 13. These distributions change, depending upon which side faces the higher humidity atmosphere. In addition, Fig. 13a shows that moisture permeation can occur even against the gradient of water concentration in some cases, although it does not occur against that of the vapor pressure. The curve of the water concentration distribution is not so sharply S-shaped as observed by Gillespie. The difference may be caused mainly by the different experimental conditions between Gillespie's and the present study. Gillespie dealt with multilayer film having air layers between each elemental layer and, of course, the material of the film was different.

SUMMARY

The differential moisture permeability coefficient of a film was actually obtained by calculation. Using this coefficient, the permeability for any humidity condition, not only the condition in which the experiment was actually carried out, can be estimated. The authors introduced a graphical method to estimate the two-sided characteristic of moisture permeability for the double-layer film under changing humidity conditions. In addition, the distributions of both water vapor pressure and water concentration in a film were found to be determined by calculation, even in the case of very thin films for which other determination methods cannot be applied. In hydrophilic films, the curve of the water vapor pressure distribution was not linear. The distribution of the water vapor pressure within the double-layer film with a particularly remarkable two-sidedness was expressed by a specific figure, and the figure changed depending upon which side faced the higher humidity atmosphere. Across the interface of films, moisture permeation was found to occur possibly against the water concentration.

Accepted for publication April 22, 1970.

Abstracted from a thesis submitted by T. Kuriyama to the Graduate School, Kyushu University, in partial fulfillment of Doctor of Philosophy degree requirements.

Thanks are expressed to Prof. S. Iguchi for his interest in the work and useful discussions; also to Mr. M. Tasaka, Executive Director of Yoshitomi Pharmaceutical Industries, Ltd., for his encouragement and his kind permission to publish this paper.

Isolation of Diphenyl-Substituted Tetronic Acids from Cultures of *Paxillus atrotomentosus*

M. C. GAYLORD, R. G. BENEDICT, G. M. HATFIELD, and L. R. BRADY

Abstract □ Pigments which accumulated in surface cultures of *Paxillus atrotomentosus* (Batsch) Fr. were studied. The nutrient broth and mycelium of 2-month-old cultures were blended, and the pigments were partitioned into ether. Two pigments were isolated by dry-column chromatography using a silica gel adsorbent and ether saturated with concentrated HCl as a chromatographic solvent. The major pigment was identified as xerocomic acid, and the minor pigment was shown to be atromentic acid. Identification of these acids was based on UV and IR spectra, mass spectral fragmentation patterns, high-resolution mass spectroscopy, and properties of their acetyl derivatives. Examination of fresh carpophores of *P. atrotomentosus* failed to demonstrate detectable amounts of either of these tetronic acids. These pigments have been reported to occur in fresh carpophores of some species in the Boletaceae and Gomphidiaceae, but this is the first reported presence of any diphenyl-substituted tetronic acid in the saprophytic culture of a fungus.

Keyphrases □ Tetronic acids, diphenyl substituted—*Paxillus atrotomentosus* cultures □ Pigment formation—*P. atrotomentosus* cultures □ Column chromatography—separation □ Paper chromatography—identification □ Electrophoresis—separation monitoring

Diphenyl-substituted tetronic acids (pulvinic acid derivatives) have long been known to be characteristic constituents of certain lichens (1, 2). Experimental evidence (3) suggests that polyporic acid, a terphenylquinone present in basidiomycetes as well as in lichens, is a precursor of pulvinic acid lactone (I) and calycin in the thalli of the lichen *Pseudocyphellaria crocata*. A number of terphenylquinones are known to occur in basidiomycetes (4), especially in the Hydnaceae, but information on the occurrence of pulvinic acid derivatives in basidiomycetes is restricted essentially to recent reports on the presence of atromentic acid (II), gomphidic acid (III), variegatic acid (IV), and xerocomic acid (V) in carpophores of some species in the Boletaceae and Gomphidiaceae (Table I).

	R ₁	R ₂	R ₃	R ₄	R ₅
I, pulvinic acid lactone	H	H	H	H	H
II, atromentic acid lactone	H	OH	H	H	OH
III, gomphidic acid lactone	OH	OH	OH	H	OH

V, xerocomic acid lactone	OH	OH	H	H	OH

Pigmentation was noted in surface cultures of *Paxillus atrotomentosus* (Batsch) Fr., and studies were initiated to determine the identity of the pigments produced by vegetative mycelia of this agaric. Carpophores of *P. atrotomentosus* are known to contain the terphenylquinone, atromentin (9), but no information is available

in the literature on the pigments formed by vegetative growth of this species or on the occurrence of tetronic acids in carpophores of the fungus.

EXPERIMENTAL

Origin of Culture and Carpophores—A culture of *P. atrotomentosus* was used in this study.¹ Stock cultures were maintained on a recommended cherry agar and were transferred monthly.

Carpophores of this mushroom were obtained from the Quinault River area of western Washington during September 1969.²

Vegetative Growth of *P. atrotomentosus*—Liquid nutrient medium for surface cultivation of the fungus was prepared by steaming 1 kg. of pitted fresh, or unsweetened frozen, sour cherries in 1 l. of distilled water for 2 hr. Twenty milliliters of strained cherry decoction and 30 ml. of distilled water were added to each 500-ml. Roux bottle, and the nutrient solutions were autoclaved for 15 min. at 15 lb. pressure. Sterile nutrient solutions were inoculated immediately after preparation, using a homogenate obtained by removing the mycelium of *P. atrotomentosus* from 10–14-day-old agar-slant cultures and blending for 5 sec. with a small volume of sterile water.

Preliminary observations suggested that the best results were obtained when the cultures were incubated at 20°, that a pigment with chromatographic properties of atromentic acid was present in the cultures after 35 days, and that maximum pigment accumulation occurred between 50 and 60 days. Shortly after this optimal period, the cultures tended to undergo degradative changes, and pigments were no longer extractable with ether. Similar deteriorations occurred very rapidly in cultures incubated at 30° or exposed to intense light for a significant period. Thus, the cultures employed in this study were incubated routinely in the dark at 20° for 50–60 days.

Very little growth was evident in the cultures at the end of the 1st week. Fine vegetative mycelia gradually radiated from the submerged fragments of inoculum. Brown spherical aggregations began to appear in zonations around each growing point; after 21 days, scattered buff-colored tufts of aerial mycelium were developing from the dark-brown aggregations. In 38 days a yellowish-beige mycelial growth covered approximately one-half of the yellow-colored nutrient broth in the Roux bottles. Between 50 and 60 days, aerial mycelia became yellow-orange at the edges of the mycelial mats and fluoresced a bright orange under UV light. Microscopic examination

^a System A: silica gel G thin layer, methyl ethyl ketone–H₂O–formic acid (250:25:1); System B: silica gel G thin layer, ether saturated with concentrated HCl; System C: polyamide thin layer, methyl ethyl ketone–H₂O–formic acid (250:25:1); System D: kieselguhr G thin layer, benzene–methyl formate–formic acid (13:5:4); System E: Whatman No. 1 paper, *n*-butanol–acetone–H₂O (2:5:2); and System F: Whatman No. 1 paper, H₂O–methyl ethyl ketone–diethylamine (921:77:2).

of the aerial mycelia at this stage revealed the presence of specialized strand formations; these strands resembled the dark velvety hyphal structures found with numerous brown incrustations on the stipe of the mature carpophore of *P. atrotomentosus*.

Degradative changes in the cultures appeared to commence shortly after a complete mycelial mat was developed. These changes were associated with a rapid transition of mycelial color from yellow-orange to brown. The color of the nutrient broth also changed from yellow to brown.

Chromatographic Examination—Various chromatographic procedures were examined for their utility in detecting pigments in the cultures and in monitoring the isolation and purification manipulations. The four TLC and two paper chromatographic systems which offered the greatest value are listed in Table II. The silica gel G³ and kieselguhr G³ TLC plates were activated at 110° for 30 min. The polyamide⁴ system had been developed to examine fungal terphenylquinones (10), and the kieselguhr system had been used successfully with certain diphenyl-substituted tetronic acids (6, 8). The paper chromatographic systems were particularly useful for distinguishing atromentic and xerocomic acids.

The various pigments could be detected on the chromatograms without the use of any visualization reactions. However, observations of the chromatograms under longwave UV light provided some information which aided in distinguishing the various pigments. Atromentin, aurantiacin, polyporic acid, and thelephoric acid absorb UV light without fluorescing. The fluorescent colors noted with the other compounds were: atromentic acid, dull yellow; atromentic acid lactone and pulvinic acid, orange; pulvinic acid lactone, bright yellow; and xerocomic acid, dull orange.

Electrophoretic Examination—A paper electrophoretic procedure was also found to be useful in monitoring the isolation and purification manipulations. Samples were applied 20 cm. from the positive edge of 46 × 57-cm. sheets of Whatman No. 3 paper. The paper was then carefully dampened with a pH 2 buffer (formic acid–acetic acid–H₂O, 1:4:28). The dampened sheet was placed on a rack, covered, and run at 2500 v. and 100 ma. for 2 hr.; the sheet was covered with a crude fraction of nonane (b.p. approx. 100°), since the high voltage required the use of a cooling system.

Atromentic and xerocomic acids moved distances of 6.5 and 5.8 cm., respectively, toward the positive pole under the experimental conditions. Atromentic acid lactone and atromentin showed no migration in this electrophoretic system, and polyporic acid and pulvinic acid apparently were either eluted or ran off the sheet in the 2-hr. time interval.

Isolation and Purification of Pigments from *P. atrotomentosus* Cultures—Stability problems with some terphenylquinones and hydroxylated diphenyl-substituted tetronic acids and the suspected distribution of pigments in both the mycelium and culture broth suggested the desirability of extracting the total culture mixture without drying. The pooled mycelium and nutrient broth from 56-day-old cultures were blended in a large blender, and the mixture was extracted by shaking repeatedly with ether. Approximately 50 l. of ether was required to extract exhaustively the pigments from 50 Roux bottle cultures. The initial ether extract was dried over anhydrous Na₂SO₄. The ether solution was separated, and the sol-

vent was removed under reduced pressure at 32°. Most of the pigmented material in the resulting red residue was soluble in water; the pigments were dissolved in approximately 60 ml. of cold water and separated from less polar impurities by filtration. Pigments in the aqueous filtrate were partitioned into ether, and the ether was removed to give a crude pigment fraction. Precautions were taken during all of the purification manipulations to minimize exposure of the pigments to light.

The chromatographic and electrophoretic monitoring systems indicated the presence of one major pigment and one minor component in the crude pigment fraction. Dry-column chromatography (11) was selected for the separation of these substances. Silica gel was washed successively with water, methanol, and ether. The washed silica gel was dried at 140° for 24 hr. and then was equilibrated with 10% w/v water for 3 hr. in a ball mill. The crude pigment fraction was adsorbed on five times its weight of silica gel, and aliquots of this material were added to the top of approximately 1.8 × 30-cm. silica gel columns. Ether saturated with concentrated HCl was used as the chromatographic solvent system. The major and minor pigments, which were subsequently established to be xerocomic and atromentic acids, respectively, migrated at approximately R_f 0.51 and 0.60. These bands were removed from the columns, the pigments were eluted from the adsorbent with the HCl-saturated ether, and the pigment materials were rechromatographed individually on a second series of columns for ultimate separation. Each 100 mg. of the crude pigment fraction yielded 75 mg. of xerocomic acid and 2 mg. of atromentic acid. Some pigmented material could not be eluted from the adsorbent and remained at the top of the columns. No evidence of a pigment band was noted at R_f 0.80, the approximate migration of atromentin in the dry-column system.

Table III shows the relative weights of the various components found in 50 Roux-bottle cultures which were harvested at 56 days. After the blended cultures were extracted with ether, the mycelium and nutrient broth were separated and freeze-dried.

Identification of Xerocomic Acid⁵—The UV spectra of the major pigment, $\lambda_{\text{max}}^{\text{methanol}}$ 408 and 260 m μ , $\lambda_{\text{max}}^{\text{water}}$ 378 and 256 m μ , and $\lambda_{\text{max}}^{\text{0.01 M NaHCO}_3}$ 620, 362, 320 (sh), and 230 m μ , agreed with the published absorption properties of xerocomic acid (6) and a related tetronic acid (5). The IR spectrum (KBr pellet), with absorption peaks at 3190, 2882, 2558, 1739, 1675, 1600, and 1513 cm.⁻¹, was also in general agreement with the reported spectrum for xerocomic acid (6).

The mass spectral fragmentation of diphenyl-substituted tetronic acids has been studied (12), and the fragmentation patterns of some hydroxylated pulvinic acid derivatives have been confirmed (6, 8). Water is readily lost from these tetronic acids, and the molecular ions in the mass spectra correspond to the respective lactones. The tetronic acid lactones exhibit two basic fragmentation series. The first series involves successive elimination of small fragments; this established fragmentation series for xerocomic acid lactone is m/e 338 → 310 → 282 → 226. The second series involves cleaving the lactone into two equal or approximately equal ions and subsequent elimination of small fragments. Xerocomic acid lactone, an unsym-

⁵ UV and IR spectra were obtained with a Beckman UV spectrophotometer, model DB, and a Beckman IR spectrophotometer, model IR5A, Beckman Instruments, Inc., Fullerton, Calif. Mass spectra were determined with a Picker-AEI MS9 mass spectrometer, Picker Nuclear Division, White Plains, N. Y.

Table III—Weight of Culture Components and Pigment Fractions from 50 Roux Bottle Cultures of *P. atrotomentosus* Harvested at 56 Days

	Dry Weight, g.	Yield Based on Total Solids, %
Extracted mycelia	20.03	43.7
Solids from extracted nutrient broth	19.55	42.7
Initial ether extract	6.17	13.5
Partitioned crude pigment fraction	2.76	6.0
Xerocomic acid	2.07	4.5
Atromentic acid	0.055	0.001

metrical molecule, fragments initially into ions m/e 177 and 161, and these undergo the following fragmentations: m/e 177 \rightarrow 149 \rightarrow 121 \rightarrow 75 and m/e 161 \rightarrow 133 \rightarrow 105 \rightarrow 77.

The mass spectrum of the isolated pigment revealed ions at m/e 338, 310, 282, 226, 177, 161, 149, 133, 121, 105, 77, and 75. These observations agree completely with the known fragmentation patterns of xerocomic acid lactone. The high-resolution parent ion peak at m/e 338.0426, both observed and calculated for $C_{18}H_{10}O_7$, and other ionic fragments in the high-resolution mass spectrum further supported the identity of xerocomic acid lactone.

Confirmation of the identity of the major pigment as xerocomic acid was obtained by preparing an acetyl derivative, using an established procedure (6). The tetronic acid (50 mg.) was refluxed for 5 min. with 1 ml. of acetic anhydride and a trace of concentrated H_2SO_4 . The yellow needles of triacetyl xerocomic acid lactone, which separated upon cooling, were removed by filtration and recrystallized from glacial acetic acid. The properties of this acetyl derivative, m.p. 225° (lit. 221–223°), UV spectrum $\lambda_{max}^{acetone}$ 379 $m\mu$ and IR spectrum (KBr pellet) 1821, 1764, 1658, 1499, 1364, and 1205 cm^{-1} , were generally consistent with those reported previously (6). The mass spectrum of the acetyl derivative revealed a parent ion of m/e 464, an initial loss in mass equivalent to three acetyl groups to give fragments m/e 338 and 43, and fragmentation patterns of m/e 338 which were identical to those observed for xerocomic acid lactone.

Identification of Atromentic Acid—The UV spectra $\lambda_{max}^{ethanol}$ 391 and 257 $m\mu$, λ_{max}^{water} 375 and 258 $m\mu$, and $\lambda_{max}^{0.01 M NaHCO_3}$ 360 (sh), 320, and 238 $m\mu$ agreed with those of a reference sample of atromentic acid, the identity suggested for the minor pigment by the chromatographic and electrophoretic studies.

Atromentic acid lactone is symmetrical, and the mass spectral fragmentation patterns would be represented by m/e 322 \rightarrow 294 \rightarrow 266 \rightarrow 238 \rightarrow 210 and m/e 322 \rightarrow 161 \rightarrow 133 \rightarrow 105 \rightarrow 77. The mass spectrum of the isolated material was in complete agreement with these fragmentation patterns with ion peaks at m/e 322, 294, 266, 238, 210, 161, 133, 105, and 77. The high-resolution parent ion peak at m/e 322.1474, both observed and calculated for $C_{18}H_{10}O_6$, and other ionic fragments in the high-resolution mass spectrum provided additional evidence for the identity of atromentic acid lactone.

A crystalline acetyl derivative was not obtained due to the limited availability of the minor pigment, but a small quantity of the acetylated product was prepared and purified on a silica gel column using the ether-HCl solvent. The acetyl derivative was eluted from the chromatographic adsorbent, and this solution was used to obtain a mass spectrum. A parent ion was observed at m/e 406, as anticipated for diacetyl atromentic acid lactone. Fragments equivalent to two acetyl substituents were lost to give an ion peak at m/e 322, and the fragmentation patterns of this product were identical to those observed for atromentic acid lactone.

Examination of Carpophores of *P. atrotomentosus* for Tetronic Acids—Fresh carpophores (5 kg.) of the mushroom were placed in a blender and reduced to a pulpy slurry. Sufficient water was added to maintain the fluidity of the slurry. The blended mixture was extracted exhaustively by shaking with several portions of ether and then with cold methanol. The ether and methanol extracts were studied using the various chromatographic and electrophoretic procedures previously described. Atromentin was readily detected in the ether extract and was observed to be present in the

methanol extract. Using these experimental procedures, no evidence for the presence of pulvinic acid derivatives was noted in the limited quantity of mushrooms available.

RESULTS AND DISCUSSION

A temperature of 20° and an incubation period of approximately 2 months were selected as standard conditions for growing the vegetative mycelium of *P. atrotomentosus* in surface cultures. The cultures were grown in the dark to prevent any light-induced destruction or transformation of the pigments, and precautions were employed during all experimental manipulations to minimize exposure to light. Concern for stability also prompted extraction of the pigments from a blended mixture of the fresh mycelium and nutrient broth. A number of fungal terphenylquinones (10) and pulvinic acid derivatives (5–7) are known to present stability problems under certain conditions, and avoidance of a drying process would lessen the probability of artifact formation of the type that has recently been suggested for amitenone in carpophores of *Suillus bovinus* (13). Bovinone was obtained as the major pigment when fresh carpophores of *S. bovinus* were extracted without the application of heat, and the amitenone present in the dried mushroom may be of chemical rather than biologic origin.

No atromentin was detected in the cultures of *P. atrotomentosus*. The water-insoluble portion of the initial ether extract and the ether-exhausted slurry were treated with a $NaHCO_3$ solution and reextracted to exclude the possibility that atromentin was present as its leuco form, which is known to account for a significant percentage of this terphenylquinone in carpophores of this species (9).

Chromatographic, electrophoretic, and UV and IR spectral data all suggested and supported the conclusion that the pigments isolated from the cultures were diphenyl-substituted tetronic acids. The mass spectra and mass spectral fragmentation patterns of the acids and their acetyl derivatives established the number and distribution of hydroxyl substituents. The major pigment in the cultures was xerocomic acid, and atromentic acid was isolated in a considerably lower concentration. These observations provide the first established formation of pulvinic acid derivatives by the vegetative growth phase of a basidiomycete.

Several hydroxylated pulvinic acid derivatives are known to occur in the fresh carpophores of some mushrooms (5–8), especially members of the Boletaceae. The Boletaceae and the Paxillaceae are recognized as being closely related (14), and the possibility that pigments represent chemotaxonomic links between the two families has been noted (5). The recent report of atromentin in carpophores of *S. bovinus* (13) and the discovery of pulvinic acid derivatives in cultures of *P. atrotomentosus* provide further experimental support for such chemotaxonomic relationships and for the close relationship between terphenylquinones and pulvinic acid derivatives.

The distinctive metabolic capabilities of carpophores and vegetative growth of *P. atrotomentosus* raise a very interesting question of comparative biochemistry. The extremely limited information on the biosynthetic relationships of terphenylquinones and tetronic acids (3) suggests that atromentin is a precursor of atromentic acid; this sequence would imply that the vegetative phase of this species has a more complete biosynthetic capability than the specialized fruiting body. Experimentally controlled carpophore development of this species in the laboratory has never been achieved, but vegetative cultures may offer a tool for clarification of biosynthetic relationships and some biologic control mechanisms.

Application of Clearance and Volume of Distribution to the Plateau Principle of Drugs

SAMUEL A. CUCINELL* and WILLIAM PERL†

Abstract □ The concentration of drug in plasma after continuous administration (plateau concentration, C_{∞}) has been defined as the relationship of the dosage per unit time and the half-life of elimination ($t_{1/2}$) to the volume of distribution (V_d) of a drug. The C_{∞} determinants, V_d and $t_{1/2}$, have been determined in single-dose and continuous-infusion experiments. The data derived have been used to predict C_{∞} for a series of substances when administered by continuous intravenous infusion. Alterations in V_d and $t_{1/2}$ of a drug may occur under clinical situations. This is reflected in changes in the plateau concentration, despite a constant dosage per unit time. An experimental example of deoxycholic acid decreasing the volume of distribution of bromsulphophthalein is given.

Keyphrases □ Plateau principle—plasma drug concentration □ Deoxycholic acid effect—volume of distribution □ Volume of distribution—plasma concentration plateau □ Drug administration rate—plasma concentration plateau

Drugs are often administered by continuous or repeated administration over long enough periods so that a relatively constant, or plateau concentration, of drug in the plasma is achieved and maintained. This plateau concentration will, in large measure, determine the effectiveness or toxicity of a drug. Bishydroxycoumarin,¹ quinidine, the anesthetics, antibiotics, and digitalis depend on a constant drug level in plasma to maintain their desired clinical response. In many cases, the drug may be regarded as distributed in a so-called volume of distribution into which the drug is administered at a constant rate and out of which the drug is removed by first-order kinetics. This model leads to a relationship of the plateau concentration of the drug to its rate of administration, its volume of distribution, and its first-order rate constant of removal. This relationship has been called the plateau principle (1). The purpose of this paper is to report on various types of kinetic experiments which demonstrate the self-consistency and utility of the plateau principle.

THEORY

The basic formulas of the one-compartment model are summarized for convenience.

Drug is infused into the body at a constant rate, I (mg./min.). Upon entering the body, the drug is assumed to equilibrate "instantaneously" among the various body tissues, so the quantity $Q(t)$ (mg.) of drug in the body at time t (min.) is expressed as

$$Q(t) = V_d C_p(t) \quad (\text{Eq. 1})$$

where V_d (ml.) is by definition the constant volume of distribution and $C_p(t)$ (mg./ml.) is the concentration of drug in plasma at time t . The rate of removal $L(t)$ (mg./min.) of drug from the body, either as separation from the body or loss of identity within the body, is assumed expressible by the first-order expression

$$L(t) = GC_p(t) \quad (\text{Eq. 2})$$

where G (ml./min.) is by definition a constant clearance. The mass balance equation for the drug is, by Eqs. 1 and 2,

$$V_d(dC_p/dt) = I - GC_p(t) \quad (\text{Eq. 3})$$

which has the solution starting from zero drug plasma concentration (1)

$$C_p(t) = C_{p\infty} (1 - e^{-kt}) \quad (\text{Eq. 4})$$

In Eq. 4, the plateau concentration $C_{p\infty}$ (mg./ml.) is given by

$$C_{p\infty} = I/G \quad (\text{Eq. 5})$$

and the rate constant k (min.⁻¹) is given by

$$k = G/V_d \quad (\text{Eq. 6})$$

Equations 5 and 6 give

$$C_{p\infty} = I/kV_d \quad (\text{Eq. 7})$$

Substitution of the half-life $t_{1/2} = 0.693/k$ into Eq. 7 gives

$$C_{p\infty} = It_{1/2}/0.693V_d \quad (\text{Eq. 8})$$

If, after the plateau concentration is reached (to a given accuracy), the infusion is suddenly stopped, the decay of drug plasma concentration is described by Eq. 3, with $I = 0$, as

$$-V_d(dC_p/dt) = GC_p(t) \quad (\text{Eq. 9})$$

with solution

$$C_p(t) = C_{p\infty} e^{-kt} \quad (\text{Eq. 10})$$

Application of Clearance and Volume of Distribution to the Plateau Principle of Drugs

SAMUEL A. CUCINELL* and WILLIAM PERL†

Abstract □ The concentration of drug in plasma after continuous administration (plateau concentration, C_{∞}) has been defined as the relationship of the dosage per unit time and the half-life of elimination ($t_{1/2}$) to the volume of distribution (V_d) of a drug. The C_{∞} determinants, V_d and $t_{1/2}$, have been determined in single-dose and continuous-infusion experiments. The data derived have been used to predict C_{∞} for a series of substances when administered by continuous intravenous infusion. Alterations in V_d and $t_{1/2}$ of a drug may occur under clinical situations. This is reflected in changes in the plateau concentration, despite a constant dosage per unit time. An experimental example of deoxycholic acid decreasing the volume of distribution of bromsulphophthalein is given.

Keyphrases □ Plateau principle—plasma drug concentration □ Deoxycholic acid effect—volume of distribution □ Volume of distribution—plasma concentration plateau □ Drug administration rate—plasma concentration plateau

Drugs are often administered by continuous or repeated administration over long enough periods so that a relatively constant, or plateau concentration, of drug in the plasma is achieved and maintained. This plateau concentration will, in large measure, determine the effectiveness or toxicity of a drug. Bishydroxycoumarin,¹ quinidine, the anesthetics, antibiotics, and digitalis depend on a constant drug level in plasma to maintain their desired clinical response. In many cases, the drug may be regarded as distributed in a so-called volume of distribution into which the drug is administered at a constant rate and out of which the drug is removed by first-order kinetics. This model leads to a relationship of the plateau concentration of the drug to its rate of administration, its volume of distribution, and its first-order rate constant of removal. This relationship has been called the plateau principle (1). The purpose of this paper is to report on various types of kinetic experiments which demonstrate the self-consistency and utility of the plateau principle.

THEORY

The basic formulas of the one-compartment model are summarized for convenience.

Drug is infused into the body at a constant rate, I (mg./min.). Upon entering the body, the drug is assumed to equilibrate "instantaneously" among the various body tissues, so the quantity $Q(t)$ (mg.) of drug in the body at time t (min.) is expressed as

$$Q(t) = V_d C_p(t) \quad (\text{Eq. 1})$$

where V_d (ml.) is by definition the constant volume of distribution and $C_p(t)$ (mg./ml.) is the concentration of drug in plasma at time t . The rate of removal $L(t)$ (mg./min.) of drug from the body, either as separation from the body or loss of identity within the body, is assumed expressible by the first-order expression

$$L(t) = GC_p(t) \quad (\text{Eq. 2})$$

where G (ml./min.) is by definition a constant clearance. The mass balance equation for the drug is, by Eqs. 1 and 2,

$$V_d(dC_p/dt) = I - GC_p(t) \quad (\text{Eq. 3})$$

which has the solution starting from zero drug plasma concentration (1)

$$C_p(t) = C_{p\infty} (1 - e^{-kt}) \quad (\text{Eq. 4})$$

In Eq. 4, the plateau concentration $C_{p\infty}$ (mg./ml.) is given by

$$C_{p\infty} = I/G \quad (\text{Eq. 5})$$

and the rate constant k (min.⁻¹) is given by

$$k = G/V_d \quad (\text{Eq. 6})$$

Equations 5 and 6 give

$$C_{p\infty} = I/kV_d \quad (\text{Eq. 7})$$

Substitution of the half-life $t_{1/2} = 0.693/k$ into Eq. 7 gives

$$C_{p\infty} = It_{1/2}/0.693V_d \quad (\text{Eq. 8})$$

If, after the plateau concentration is reached (to a given accuracy), the infusion is suddenly stopped, the decay of drug plasma concentration is described by Eq. 3, with $I = 0$, as

$$-V_d(dC_p/dt) = GC_p(t) \quad (\text{Eq. 9})$$

with solution

$$C_p(t) = C_{p\infty} e^{-kt} \quad (\text{Eq. 10})$$

¹ Dicumarol.

Figure 1—Plasma BSP concentration with constant infusion.

Just after stoppage of the infusion, the time rate of change of $C_p(t)$ changes discontinuously from the value zero just before stoppage to the value given by Eq. 9 as

$$-V_d(dC_p/dt)_0 = GC_p(0) = GC_{p\infty} \quad (\text{Eq. 11})$$

Substitution of G from Eq. 5 and solving for V_d give

$$V_d = -I/(dC_p/dt)_0 \quad (\text{Eq. 12})$$

Equations 12 and 8 yield

$$C_{p\infty} = -(dC_p/dt)_0 t_{1/2} / 0.693 \quad (\text{Eq. 13})$$

The value of V_d from Eq. 12 applies only to a single-compartment model with monoexponential elimination. Although in practice this may be true for some drugs, additional compartments (multi-exponential) may be observed, yielding a low value of V_d from Eq. 12 compared to Eq. 8 (2).

In the present constant-infusion experiments, the experimental data were I (exp.), $C_{p\infty}$ (exp.), $(dC_p/dt)_0$ (exp.), and $t_{1/2}$ (exp.) from the slope of the semilogarithmic plot of the decay curve after stoppage of the infusion (Fig. 1). $C_{p\infty}$ (exp.) was compared with the theoretical $C_{p\infty}$ obtained by Eq. 13 from $(dC_p/dt)_0$ (exp.) and $t_{1/2}$ (exp.) (Table I). Equivalently, the theoretical V_d obtained by Eq. 12 from I (exp.) and $(dC_p/dt)_0$ (exp.) was compared with the theoretical V_d obtained by Eq. 8 from I (exp.), $C_{p\infty}$ (exp.), and $t_{1/2}$ (exp.).

A series of sudden-injection experiments was also performed. Theoretical first-order kinetics (3) predicts that the response to sudden injection is essentially the time derivative of the response to constant infusion. Hence, in the present model, if the amount Q_0

of drug is suddenly injected, the plasma concentration will be

$$C_p(t) = C_{p0} e^{-kt} \quad (\text{Eq. 14})$$

where the zero-time intercept C_{p0} yields the volume of distribution V_d by

$$V_d = Q_0/C_{p0} \quad (\text{Eq. 15})$$

and the rate constant k is given by Eq. 6. The experimental data in these experiments were the amount injected Q_0 (exp.), the zero-time intercept C_{p0} of the straight-line fit of the semilogarithmically plotted plasma concentration against time, and the half-life $t_{1/2}$ (exp.) = $0.693/k$ (exp.) from the slope of the semilogarithmic plot. Constant-infusion experiments on the same animals yielded the constant-infusion rate I (exp.) and the plateau concentration $C_{p\infty}$ (exp.). A comparison of theory and experiment was made by first calculating V_d by Eq. 15 from Q_0 (exp.) and C_{p0} (exp.) and then substituting this V_d and $t_{1/2}$ (exp.), I (exp.) into Eq. 8 to yield a $C_{p\infty}$ for comparison with $C_{p\infty}$ (exp.).

In some sudden-injection experiments, the plasma concentration decayed multiexponentially at first before becoming monoexponential (Fig. 2). In these cases the relation

$$V_d = Q_0/C_{p0}(1 + B) \quad (\text{Eq. 16})$$

was used instead of Eq. 15, where B is a correction derived in the Appendix.

In all experiments the clearance G was calculated by Eq. 6 (Table II).

If the drug is removed from the body primarily from one organ, then the rate of removal of drug can be expressed by the Fick principle as

$$L(t) = F[C_a(t) - C_v(t)] \quad (\text{Eq. 17})$$

where F (ml./min.) is the rate of blood flow through the organ, and $C_a(t)$ and $C_v(t)$ are the concentrations of drug, respectively, in the arterial blood inflow to and in the venous blood outflow from the organ. Equations 2 and 17 yield

$$G = \lambda EF \quad (\text{Eq. 18})$$

where

$$E = [C_a(t) - C_v(t)]/C_a(t) \quad (\text{Eq. 19})$$

is the so-called extraction ratio from whole blood and

$$\lambda = C_v(t)/C_p(t) \quad (\text{Eq. 20})$$

is the constant-partition coefficient of drug between whole blood and plasma.

EXPERIMENTAL

Mongrel dogs of both sexes were anesthetized intravenously with pentobarbital, 50 mg./kg. Polyethylene catheters were placed in the forepaw and in the femoral veins. Isotonic solutions of brom-sulphophthalein (BSP), antipyrine, *p*-aminohippuric (PAH) acid, and phenolsulphonphthalein (PSP) (all in saline) were used. In a constant-infusion experiment, the solution was infused into the paw vein at a constant rate by means of a Cambridge syringe pump. Blood was sampled from the catheter in the femoral vein into a heparinized syringe at intervals of 30 sec. for eight samples, every minute for the next four samples, and every 2 min. for the final four samples. The same schedule was followed for the single-injection experiments. There was never more than a 2% change in hematocrit throughout the experiment.

In those experiments in which two different infusions were made, the start of the second infusion was delayed until the plasma level of drug from the previous experiment had been zero for at least 2 hr. If this precaution was not taken, the BSP clearance often did not follow a first-order decay; instead the second infusion caused an almost linear rise in dye concentration throughout the 16-min. period of infusion. This suggests that the T_m for BSP had been exceeded and the rate of removal of BSP from plasma was no longer a first-order function but rather depended on liver capacity (4).

Values of V_d and k were obtained in each of six dogs by the single-injection technique. BSP (25 mg.), PSP (4.0 mg.), and PAH (500 mg.) were given intravenously as a single bolus in 5 ml. saline. Two

hours after the plasma level of the test drug had reached zero, a constant infusion of the same drug was started.

In the case of antipyrine, the constant-infusion study was done 1 week after the single injection of 500 mg. The blood in the case of antipyrine was drawn every minute for the first four samples, every 5 min. for the next four samples, and every 15 min. for the next six samples.

The BSP and PSP were analyzed by diluting serum (1:3) with 0.001 *N* NaOH and reading the absorbance in a DU spectrophotometer at 560 m μ . The PAH and antipyrine were analyzed by the methods of Smith (5) and Brodie and Axelrod (6), respectively.

RESULTS

The V_d and $t_{1/2}$ were determined for a series of representative substances by both the single-injection and the continuous-infusion techniques. Data from the continuous infusion of BSP are shown in Table I. The $C_{p\infty}$ calculated from these data are in fair approximation with the experimentally observed $C_{p\infty}$. The clearance G , or volume freed of drug per unit time, was determined by Eq. 5. The volume of distribution, V_d , determined from Eq. 12 was in fair agreement with that determined from Eq. 8.

To demonstrate the consistency of these equations, deoxycholic acid was added to the infusion of BSP (Fig. 1). This caused an increase in $C_{p\infty}$ for the same dosage of BSP in the same dog which had received BSP alone 2 hr. previously. This change in $C_{p\infty}$ could have been due, by Eq. 8, to an increase in $t_{1/2}$ or a decrease in V_d . It is seen from Table I that V_d , determined from the initial slope, decreased and $t_{1/2}$ remained the same. The G must decrease by Eq. 6. Now G is also equal to $F(C_a - C_v)/C_a$, Eq. 18, with $\lambda = 1$. Either the blood flow or the fraction of BSP extracted from plasma

must, therefore, have been depressed by deoxycholic acid to correspond with the depression of G . Since Demling (7), using a thermoelectric technique, was able to demonstrate that liver blood flow was not depressed by deoxycholate administration, the fraction of BSP removed from the plasma was probably decreased.

There is a tendency for the estimated $C_{p\infty}$ to be in excess of the experimental value (Table I). It may be that BSP has depots other than the plasma and liver which are more slowly filled. In this case the initial slope method, Eq. 12, would yield low values of V_d and, hence, by Eq. 8, too high values for $C_{p\infty}$.

In a similar manner, V_d and $t_{1/2}$ may be determined from Eqs. 14 and 15 by means of a single intravenous injection. Values of $C_{p\infty}$ predicted from Eq. 8, making use of V_d and $t_{1/2}$ obtained in this fashion, were in fair agreement with the $C_{p\infty}$ experimentally determined for BSP, PAH, PSP, and antipyrine by continuous infusion (Table II). The V_d and $t_{1/2}$ obtained from the single intravenous injection may be used to estimate the $C_{p\infty}$ of these substances during continuous administration. There is no consistent trend in the error of estimating $C_{p\infty}$ from the single-dose value of V_d and $t_{1/2}$.

Only in single-dose experiments with PAH was it necessary to correct for multiexponential kinetics by Eq. 16.

DISCUSSION

The clearance G determines, or is defined by, the plateau plasma concentration $C_{p\infty}$ in response to long-time, constant infusion of the drug at rate I (Eq. 5). It is clear that $C_{p\infty}$ can change, despite a constant I , if G changes. In the following, various pharmacological situations in which $C_{p\infty}$ changes are discussed in terms of G , V_d , and $t_{1/2}$. For convenience in visualization, the pair of fundamental parameters, G and V_d , may be replaced by the equivalent pair, $t_{1/2}$

and V_d , where by Eq. 6

$$t_{1/2} = 0.693 V_d/G \quad (\text{Eq. 21})$$

For convenience in interpretation, the pair $t_{1/2}$ and V_d are assumed to be independent variables experimentally as well as theoretically. This is probably rarely if ever qualitatively correct, but one or the other predominates quantitatively.

To illustrate the utility of the concept of volume of distribution, the displacement of drugs from plasma binding sites by competing substances in the plasma may be interpreted as an increase in volume. Sulfa drugs displacing bilirubin from plasma binding sites may precipitate kernicterus in the newborn at relatively low plasma concentrations of bilirubin (8). Phenylbutazone increases the antibacterial activity of the sulfa drugs (9). In these cases, the pharmacological activity or toxicity of the drug is increased while the plasma concentration is decreased. In terms of Eq. 15, V_d has increased, causing C_{p0} to decrease at constant Q_0 .

The volume of distribution may also be made to decrease. In this case, another drug may compete for binding sites in an organ other than the plasma. Thus, in Table I, deoxycholic acid when infused with BSP increased $C_{p\infty}$ and decreased V_d while $t_{1/2}$ remained unchanged. This implies (Eq. 21) a decrease in G which means that the drug is not being removed from the circulation as fast as the control, despite a constant $t_{1/2}$. Weiner *et al.* (10) have shown that methandrostenolone in man is capable of increasing the $C_{p\infty}$ of oxyphenbutazone while the $t_{1/2}$ remains unchanged. The implication that V_d is thereby decreased (Eq. 21) would indicate that methandrostenolone is capable of displacing oxyphenbutazone from extravascular binding sites. Norethandrolone and iopanoic acid appear capable of inhibiting liver storage and excretion of BSP in man (11). It is possible that this is a reflection of competition for liver binding sites. This is a case of V_d decreasing at constant I and $t_{1/2}$. Hence G is decreased (Eq. 21), which causes $C_{p\infty}$ to increase (Eq. 5).

Whereas V_d may be altered while the $t_{1/2}$ remains unchanged, the opposite may also occur. $C_{p\infty}$ may change with $t_{1/2}$ while V_d remains constant. The liver enzyme systems that metabolize a large number of drugs may be stimulated by phenobarbital or a number of other compounds (12). These enzymes will break down diphenylhydantoin, bishydroxycoumarin, and antipyrine at an increased rate after phenobarbital pretreatment. For example, an individual receiving an intravenous injection of a drug has a much longer $t_{1/2}$ before receiving phenobarbital than after receiving phenobarbital for a sufficient time. In terms of Eq. 21, G has increased.

It has been noticed that this effect is more readily demonstrated with a high dose of drug than with a low dose (13). The data in Table III demonstrate the differences observed in V_d and $t_{1/2}$ when a dog is given a 50-mg./kg. and a 20-mg./kg. dose of diphenylhydantoin intravenously. G at 20 mg./kg. was higher (2.6 l./hr.) than at 50 mg./kg. (1.5 l./hr.). Assuming that liver blood flow was not affected by the diphenylhydantoin, the fraction E of drug cleared from the blood was higher at the lower dose than at the higher dose (Eq. 18). After pretreatment of the dogs with barbiturates, the G for both dosage levels had increased (about 4 l./hr.), although the $t_{1/2}$ at the low dose was unchanged. This suggests that fraction E of the drug removed by the liver was no longer dose dependent. Also, it is clear that the induction of drug-metabolizing enzymes is prominent at low as well as high dosage levels in terms of an increase in G . The induction at the lower dose level manifests itself more as an increase in both V_d and G than as a decrease in $t_{1/2}$.

The $t_{1/2}$ may also be increased, forcing an elevation of $C_{p\infty}$, without an increase in I . Bishydroxycoumarin is capable of inhibiting the metabolism of diphenylhydantoin, thereby prolonging the $t_{1/2}$ and

potentiating the effect of the anticonvulsant (14). V_d tends to remain unchanged. Thus, there is a decrease in G (Eq. 21), which in turn would cause an increase in the level of $C_{p\infty}$ (Eq. 5).

SUMMARY

The plateau principle is experimentally described for BSP, PAH, PSP, and antipyrine in terms of the volume of distribution (V_d), the half-life of plasma decay ($t_{1/2}$), and the rate of administration (I).

The plasma concentration of a drug may be altered by changes in V_d or $t_{1/2}$ despite a constant I . Deoxycholic acid infusion increased $C_{p\infty}$ for BSP by decreasing the V_d , while $t_{1/2}$ remained constant. $C_{p\infty}$ may be predicted by prior determination of V_d and $t_{1/2}$ for drugs with approximately monoexponential decay kinetics.

APPENDIX

For a single-injection experiment, a better approximation of the volume of distribution than Eq. 15 is given by

$$V_d = \left\{ Q_0 - G_0 \int_0^{t_1} C_p(t) dt \right\} / C_{pi} \quad (\text{Eq. A1})$$

where C_{pi} is the drug plasma concentration at time t_1 on the final monoexponential portion of the plasma decay curve (Fig. 2). The numerator in Eq. A1 takes account of the drug which is lost from the body, by Eq. 2, at the actual (elevated) plasma concentration before the distribution of drug corresponding to the final monoexponential behavior has occurred. If the final monoexponential $C_{p0} e^{-kt}$ is added and subtracted to $C_p(t)$ in Eq. A1 and the integration

$$\int_0^{t_1} C_{p0} e^{-kt} dt = (C_{p0} - C_{pi})/k \quad (\text{Eq. A2})$$

is carried out, the result is

$$V_d C_{pi} = Q_0 - GA - G(C_{p0} - C_{pi})/k \quad (\text{Eq. A3})$$

where A is the area between the actual plasma decay curve and the monoexponential curve back-extrapolated to time zero (cross-hatched area in Fig. 2 measured on a linear plot). Substitution of Eq. 6 for G in Eq. A3 and solving for V_d yield

$$V_d = \frac{Q_0}{C_{p0} + kA} = \frac{Q_0}{C_{p0}(1 + B)} \quad (\text{Eq. A4})$$

where

$$B = kA/C_{p0} = 0.693A/t_{1/2}C_{p0} \quad (\text{Eq. A5})$$

Application of Molecular Sieve Technique in Solubilization Studies of Benzoic Acid in Solutions of Cetomacrogol 1000

M. DONBROW, E. AZAZ, and R. HAMBURGER

Abstract □ The applicability of a new technique in solubilization studies, using a molecular sieve, was tested on a system consisting of benzoic acid and cetomacrogol 1000 (cetostearyl ether of polyoxyethylene) in aqueous solutions. The data obtained are in good agreement with those found by other methods. Some advantages of the method are outlined.

Keyphrases □ Benzoic acid—solubilization study □ Cetomacrogol 1000 solution—benzoic acid solubility □ Micellar solubilization, benzoic acid in cetomacrogol 1000—quantitative determination □ Molecular sieve technique—solubilization study □ Spectrophotometry, UV, visual—analysis

The importance of theoretical and pharmaceutical aspects of micellar solubilization of drugs has been well recognized in recent years (1-4). Nevertheless, only three methods are available in routine practice for quantitative investigation of the phenomenon.

The conventional solubility method has been used by almost all investigators either as a basic tool or comparatively. Its main disadvantage is that it is limited to saturated systems; hence the dependence of solubilization on the concentration of the unbound solubilize cannot be studied by this method. Another major disadvantage lies in the fact that many additives decrease the cloud point (4, 5). This means that although turbidity is often used as a criterion for saturation with liquid solubilizes, it is not necessarily an indication of maximum solubility (6-10). Furthermore, the determination of the turbidimetric end-point is subject to error.

Equilibrium dialysis was first introduced into solubilization studies by Patel and Kostenbauder (11). This method solved the problems encountered in the solubility method. Although widely accepted, it is time consuming and requires preliminary work on the selection of a proper membrane for each system. Nylon mem-

branes used by Patel and Foss (12) are stated to swell and bind phenolic compounds; rubber membranes tried by Matsumoto *et al.* (13) varied in thickness; and methylcellulose membranes are attacked by certain surfactants (14).

Potentiometric titration was first used for solubilization studies of organic acids and bases by Donbrow and Rhodes (15-17). Although rapid and elegant enough to have been adopted for routine use (15-23), it is restricted to ionizing solubilizes in which only the unionized form undergoes micellar solubilization. It is thus unsuitable for studies on the solubilization of acids and bases of pronounced amphiphilic properties such as local anesthetics or acid derivatives of steroidal hormones, their ionized form, as well as the unionized, being solubilized (24).

In view of the increasing importance of studies on nonsaturated systems, additional methods of a more general nature and greater scope than potentiometric titration and quicker than equilibrium dialysis would be advantageous. Such methods would also be valuable for crosschecking.

A molecular sieve technique which promised to meet these needs, has in fact been applied to methyl *p*-hydroxybenzoate by Ashworth and Heard (25). Dextran gel, with a suitable degree of crosslinking, was used in a static way similar to a semipermeable membrane in dialysis. The small molecules (the solute) are distributed between the swollen gel and the external liquid, while the surfactant is unable to penetrate the internal gel phase and remains in the external liquid. The solute distribution normally follows a linear relation. (See also Eqs. 5 and 6 in *Results and Discussion*, and Eq. 1 in *Experimental*.)

The object of the present work is to broaden the applicability of this method by testing it on another

Application of Molecular Sieve Technique in Solubilization Studies of Benzoic Acid in Solutions of Cetomacrogol 1000

M. DONBROW, E. AZAZ, and R. HAMBURGER

Abstract □ The applicability of a new technique in solubilization studies, using a molecular sieve, was tested on a system consisting of benzoic acid and cetomacrogol 1000 (cetostearyl ether of polyoxyethylene) in aqueous solutions. The data obtained are in good agreement with those found by other methods. Some advantages of the method are outlined.

Keyphrases □ Benzoic acid—solubilization study □ Cetomacrogol 1000 solution—benzoic acid solubility □ Micellar solubilization, benzoic acid in cetomacrogol 1000—quantitative determination □ Molecular sieve technique—solubilization study □ Spectrophotometry, UV, visual—analysis

The importance of theoretical and pharmaceutical aspects of micellar solubilization of drugs has been well recognized in recent years (1-4). Nevertheless, only three methods are available in routine practice for quantitative investigation of the phenomenon.

The conventional solubility method has been used by almost all investigators either as a basic tool or comparatively. Its main disadvantage is that it is limited to saturated systems; hence the dependence of solubilization on the concentration of the unbound solubilize cannot be studied by this method. Another major disadvantage lies in the fact that many additives decrease the cloud point (4, 5). This means that although turbidity is often used as a criterion for saturation with liquid solubilizes, it is not necessarily an indication of maximum solubility (6-10). Furthermore, the determination of the turbidimetric end-point is subject to error.

Equilibrium dialysis was first introduced into solubilization studies by Patel and Kostenbauder (11). This method solved the problems encountered in the solubility method. Although widely accepted, it is time consuming and requires preliminary work on the selection of a proper membrane for each system. Nylon mem-

branes used by Patel and Foss (12) are stated to swell and bind phenolic compounds; rubber membranes tried by Matsumoto *et al.* (13) varied in thickness; and methylcellulose membranes are attacked by certain surfactants (14).

Potentiometric titration was first used for solubilization studies of organic acids and bases by Donbrow and Rhodes (15-17). Although rapid and elegant enough to have been adopted for routine use (15-23), it is restricted to ionizing solubilizes in which only the unionized form undergoes micellar solubilization. It is thus unsuitable for studies on the solubilization of acids and bases of pronounced amphiphilic properties such as local anesthetics or acid derivatives of steroidal hormones, their ionized form, as well as the unionized, being solubilized (24).

In view of the increasing importance of studies on nonsaturated systems, additional methods of a more general nature and greater scope than potentiometric titration and quicker than equilibrium dialysis would be advantageous. Such methods would also be valuable for crosschecking.

A molecular sieve technique which promised to meet these needs, has in fact been applied to methyl *p*-hydroxybenzoate by Ashworth and Heard (25). Dextran gel, with a suitable degree of crosslinking, was used in a static way similar to a semipermeable membrane in dialysis. The small molecules (the solute) are distributed between the swollen gel and the external liquid, while the surfactant is unable to penetrate the internal gel phase and remains in the external liquid. The solute distribution normally follows a linear relation. (See also Eqs. 5 and 6 in *Results and Discussion*, and Eq. 1 in *Experimental*.)

The object of the present work is to broaden the applicability of this method by testing it on another

Figure 1—Log-log plot of distribution of benzoic acid between Sephadex G25-fine and aqueous 0.005 N HCl at 25°. (See Eq. 1 in Experimental.)

system, benzoic acid in cetomacrogol solutions, for which data for comparison with other methods are available (18, 19, 21, 22, 26).

EXPERIMENTAL

Materials—Cetomacrogol 1000 BPC¹ was used (n_D^{60} , 1.451; n_D^{25} for 20% w/v solution, 1.360). The material, dried at 60° in vacuum, gave by combustion analysis the following results: C, 58.66; H, 9.62; O, 31.72. Assuming a molecular weight of 1300, this ratio fits the formula: $\text{CH}_3(\text{CH}_2)_{15}(\text{OCH}_2\text{CH}_2)_{24}\text{OH}$. Benzoic acid, analytical grade; dextran gel;² and Sephadex G25-fine² were also used. Water regain equalled 2.5 ± 0.2 g./g. dry gel. Particle size, 20–80 μ , was confirmed microscopically.

Procedure—*Determination of Internal Solvent Volume*—Ten milliliters of 0.1% solution of dextran blue 2,000,000² was added to about 3.5-g. samples of the gel swollen in 15 ml. 0.05 N NaCl. After the samples were shaken for 1 hr. at 25°, they were decanted and centrifuged. The concentration of the dye was determined by measuring the absorbance at 620 m μ directly, without further dilution. The water regain was measured on three samples of the gel. The mean value of a given batch was found to be 2.33 g./g. dry gel (± 0.05 g./g. dry gel).

Determination of K' (Distribution Coefficient of Benzoic Acid between Aqueous 0.005 N HCl and Sephadex G25-Fine)—Assuming a linear distribution of benzoic acid between the gel and the external phase (Eq. 1) and aiming at equal amounts of benzoic acid outside and inside the gel (Eq. 2), the optimal weight of dry gel for a given external volume was calculated from Eq. 3:

$$M = CK' \quad (\text{Eq. 1})$$

$$MW = CK'W = CV \quad (\text{Eq. 2})$$

or

$$W = \frac{V}{K'} \quad (\text{Eq. 3})$$

where M = mmoles of benzoic acid bound to 1 g. gel; C = concentration of the free acid in the external phase in mmoles; W = weight of the dry gel in grams; K' = the distribution coefficient in (mmoles acid/g. gel)/(mmoles acid/l.); and V = aqueous external volume in liters = $V_t - 2.33 W$ (where V_t is total aqueous volume and 2.33 g./g. dry gel is water regain of the gel).

Substituting K' of 0.0045 l./g., as approximated from the preliminary experiment, and external volume (V) of 0.002 l., suitable

Table I—Change in Concentration of Benzoic Acid Solution Shaken with Sephadex G25-fine at 25° with Time^a

Time, hr.	Benzoic Acid Concentration, mmoles
0	0.145 ^b
0.25	0.115
1	0.115
24	0.115
96	0.115
120	0.101
144	0.068
168	0.064
192	0.050
264	0.000

^a Total aqueous volume 50 ml., Sephadex about 3.5 g. ^b Hypothetical, calculated from total acid added.

quantities of Sephadex (W) were about 0.6 g. The samples were weighed accurately from weighing bottles into known volumes of aqueous 0.005 N HCl (thus minimizing moisture uptake from the air). This concentration of HCl was maintained in all subsequent stages of the work to suppress the ionization of benzoic acid. The gel was allowed to swell at room temperature for 3 hr. Solutions of benzoic acid of varying concentration were added and made up to constant volume of 0.004 l. (V_t). The samples were shaken at 25° for 1 hr.

After equilibration, aliquot portions of the external phase were decanted, diluted suitably with 0.005 N HCl, and centrifuged to remove any fine particles present. The absorbance was read spectrophotometrically at the 230 or 273-m μ maximum. Blanks were prepared using the same procedure but omitting the benzoic acid (Sephadex was found to release traces of UV absorbing materials.)

Distribution of Benzoic Acid between Cetomacrogol 1000 and Aqueous Solutions of 0.005 N HCl—The procedure and amounts were identical with those used in the previous stage, except that cetomacrogol 1000 as well as benzoic acid was added from stock solutions to the conditioned gel. The concentration of cetomacrogol in the samples was 2.3–2.6% (varying with the weight of dry gel). Equilibration and analysis were carried out as previously. At the dilutions of surfactant studied, Beer's law was observed. The λ_{max} and ϵ_{max} were as in water.

The optimum amount of dry gel (W) for a given external volume (V') in this case may be calculated from Eq. 4, aiming to equalize the amount of benzoic acid outside and inside the gel:

$$CWK' = CV' + CGK'' \quad (\text{Eq. 4a})$$

or

$$W = \frac{1}{K'} (V' + GK'') \quad (\text{Eq. 4b})$$

where C , K' , V , and W are as defined for Eq. 1; V' = external volume corrected for micelle partial volume (27) = $V - 0.84 G$; G = weight of micelles in sample in grams; and $K'' = K_1 K_2$ = apparent distribution coefficient of benzoic acid between cetomacrogol and

Figure 2—Adsorption isotherm of benzoic acid in 2% w/v cetomacrogol and 0.005 N HCl at 25°. (See text for description.) Key: —, experimental isotherm, $X = (K_1 K_2 C)/(1 + K_1 C)$; and ---, slope of the initial portion of the isotherm $X = K_1 K_2 C$.

water in l./g., neglecting its decreasing value with rising concentration (see *Results and Discussion*).

RESULTS AND DISCUSSION

From Fig. 1, plotted in log-log form for convenience, it is evident that the uptake of benzoic acid by Sephadex follows a linear relation over the range studied, and that the assumption made in Eq. 1 is valid.

The value of 4.46×10^{-3} l./g. found for K' , the distribution coefficient, was reproducible over a wide concentration range (1×10^{-2} – $1M$), provided that the equilibration time was limited. If the period of contact was extended above 96 hr. (Table I), benzoic acid reacted further with the gel. Such reactions have been observed for other aromatic and heterocyclic compounds (28).

With regard to the solubilization of benzoic acid in cetomacrogol 1000, some typical results are plotted in Fig. 2. These results clearly demonstrate that, as already reported (19, 22), there is a deviation from linear distribution.

The values of C and X (Fig. 2) were calculated from Eqs. 5 and 6, respectively:

$$C_0V = C_fV + K'CW \quad (\text{Eq. 5a})$$

$$C = \frac{(C_0 - C_f)V}{K'W} \quad (\text{Eq. 5b})$$

$$C_fV = CV' + GX \quad (\text{Eq. 6a})$$

$$X = \frac{C_fV - CV'}{G} \quad (\text{Eq. 6b})$$

where C , G , K' , V , V' , and W are as defined earlier (Eqs. 1–4b); C_0 = initial concentration of benzoic acid in mM; C_f = final total concentration of benzoic acid outside the gel in mM; and X = mmoles of benzoic acid bound/l g. micelles.

The results plotted in Fig. 2 may be represented by use of Langmuir's equation (Eq. 7):

$$X = \frac{K_1K_2C}{1 + K_1C} \quad (\text{Eq. 7})$$

where X = mmoles acid bound to 1 g. surfactant; C = concentration of free acid in mM; and K_1 and K_2 = adsorption parameters in l./mmoles and mmoles/g., respectively.

By means of the reciprocal form of Langmuir's equation (Eq. 8):

$$\frac{1}{X} = \frac{1}{K_2} + \frac{1}{K_1K_2C} \quad (\text{Eq. 8})$$

linearity was obtained over the full range (Fig. 3).

Unfortunately, the individual values of K_1 and K_2 could not be obtained by graphical methods. As can be seen from Fig. 3, the intercept ($1/K_2$) in the plot is very small and K_2 is subject to a very large error. This shortcoming has been pointed out previously (22).

Figure 3—Adsorption isotherm of benzoic acid in cetomacrogol at 25° from data obtained by different methods:

$$\frac{1}{X} = \frac{1}{K_2} + \frac{1}{K_1K_2C}$$

Key: ●, molecular sieve, present work; ▲, Donbrow and Azaz (21); □, Mitchell and Brown (18); and ○, Donbrow et al. (19, 22).

To overcome this difficulty, a X/C versus X plot was tried using the rearranged form of Langmuir's equation (Eq. 9):

$$X/C = K_1K_2 - K_1X \quad (\text{Eq. 9})$$

The slope was, however, very small, giving a large error in K_1 .

Values of K_1 and K_2 were, in fact, calculated statistically from a

^a Data were treated by the least-squares method using a Control Data Corp. computer to obtain the range of the individual runs. The means reported were combined parameters obtained by using all the individual results in the least-squares calculations. ^b The published data (19) were corrected for surfactant partial volume (27), replotted, and treated statistically. ^c These values were calculated from the potentiometric titration data of Mitchell and Brown (18) by changing the units and substituting into Langmuir's equation (Eq. 8). A plot of $1/X$ versus $1/C$ gave a straight line, from the slope of which the value of K_1K_2 was found to be 5.9×10^{-2} l./g. In the original publication, results were reported as distribution coefficients. The solubility method gave the lowest distribution coefficient (4.8×10^{-2} l./g.) as would be expected. Results within the same range were obtained by these authors by pH measurements (one point titration) and the equilibrium dialysis method. ^d The experimental procedure was similar to the one used previously (19, 22). ^e All repeated experiments were included.

very large number of results and will be reported (21). For the objective of this present work, the product of the two parameters $K_1K_2 = K''$, which can be determined accurately from either type of plot (Eq. 8 or 9), is sufficient to characterize the system. This combined parameter can be regarded as a linear distribution coefficient for a limited range of benzoic acid concentration in cetomacrogol 1000 solutions (Fig. 2, straight-line extrapolation from initial points). The concept of K'' as a distribution coefficient is derived from Eq. 7 which, at low values of the binding constant K_1 or low concentrations of adsorbate ($K_1C \ll 1$), approaches $X = K_1K_2C = K''C$.

Table II shows that the value of 6.05×10^{-2} for K'' by the molecular sieve method is of the same order as values obtained by other methods; the standard deviation, which falls within the range previously obtained, is acceptable. Since the method was found to be rapid and reproducible, it should prove to be suitable for routine solubilization studies, not only for benzoic acid in nonionic surfactants such as cetomacrogol 1000 but also for other unsaturated solubilized systems.

Some Factors Affecting Release and Availability of Drugs from Hard Gelatin Capsules

B. J. McGEE, D. R. KENNEDY, and G. C. WALKER

Abstract □ Acetylsalicylic acid, acetylsalicylic acid and lactose, and acetylsalicylic acid and dibasic calcium phosphate were administered orally in No. 3 and No. 4 hard gelatin capsules to rabbits, using a Latin square design. Plasma levels were determined at 1-, 2-, and 3-hr. intervals; an analysis of variance showed that at hour 3, there was a difference between the average for the No. 3 and No. 4 capsules, irrespective of excipient. The significantly better plasma levels obtained with the more tightly compacted No. 4 capsules may be due to the diffusion of gastric juice through the gelatin which created higher pressure within the capsules. Dissolution

determinations were made using the Levy beaker method and the oscillating tube method. The mean plasma levels at the end of 1, 2, and 3 hr. were lower than the concentrations obtained at the corresponding hours from the *in vitro* study, and direct correlation of the two sets of data could not be made. Hard gelatin capsules containing acetylsalicylic acid alone broke down slowly *in vitro*.

Keyphrases □ Capsules, hard gelatin—drug release, availability □ *In vivo-in vitro* release rates—drug from capsules □ Aspirin release, capsules—excipient effect □ Gelatin capsule size effect—aspirin release rates

Encapsulation remains a popular method for administering medication because of the general view that capsules readily break down upon ingestion to release the enclosed medicament (1). It was thought desirable to investigate the effects of two different excipients and the effects of two different pressures of

fill on the rate of absorption of acetylsalicylic acid (ASA) from hard gelatin capsules in the rabbit. tests were carried out to complement the *in vivo* work to determine if any correlation existed between the two sets of data.

METHODS AND PROCEDURES

ASA BP was used in all cases (British Drug Houses, 20-mesh crystals). The excipients were water-soluble α -lactose and the relatively water-insoluble dibasic calcium phosphate, both of which are used as fillers and diluents in capsules as well as tablets.

The rabbit was used as the test animal. Each rabbit received all four of the following combinations, as well as the control ASA at weekly intervals: ASA alone in a No. 3 capsule, ASA and lactose in No. 3 and No. 4 capsules, ASA and dibasic calcium phosphate in No. 3 and No. 4 capsules. Ten rabbits were used in two 5 × 5 Latin squares, and one rabbit died during the treatment schedule. An analysis of variance was carried out, ignoring the "week" as if the data were from a randomized block experiment and omitting Rabbit 5 from which two observations were missing.

It was determined that 200 mg. of ASA would produce measurable plasma salicylate levels and that 200 mg. of ASA and 66.6 mg. of excipient could be contained in both No. 3 and No. 4 empty gelatin capsules (Parke-Davis), thus affording a relatively greater compaction pressure in the No. 4 capsule. No. 3 capsules containing 200 mg. of ASA alone were also used, because it was felt that the same crystals without excipient or compaction would serve to point out any differences between excipients or compaction pressures. Ten capsules of each combination and size were selected at random and assayed individually according to the method of Routh and Dryer (2). The largest difference between the mean mixture weights of the combination variables was found to be 0.0003 g. For practical purposes the weights may be considered identical.

In Vitro Tests—Dissolution-rate studies were begun using the Levy and Hayes (3) "beaker method," so that the low agitation

intensity which Levy regards as important for *in vitro* dissolution-rate measurements to reflect *in vivo* conditions might be achieved (4). This method was found to be unsatisfactory for use with capsules; it was necessary to use the "oscillating tube" method which involves a relatively high agitation intensity as the dissolution fluid is forced through a 100-mesh screen on the bottom of a Plexiglas cylinder (4). Dissolution rates were determined for the No. 3 capsules containing ASA alone using the Levy and Hayes beaker method and the oscillating tube method with distilled water adjusted to pH 1.2 with hydrochloric acid as the dissolution medium. Dissolution rates for each combination variable were determined using the oscillating tube method and either gastric fluid, simulated test solution USP, or intestinal fluid, simulated test solution USP (5) as the dissolution medium. The intrinsic dissolution of the ASA crystals was determined in each simulated test solution using the oscillating tube method. The samples at the end of each time period were assayed by the method of Routh and Dryer (2) (Tables I-IV).

In Vivo Tests—The rabbit was mildly sedated using halothane. A gag was placed between the teeth, and the capsule was placed well back in the throat and washed down with a little water. Blood samples were withdrawn from the marginal ear vein at 1-, 2-, and 3-hr. intervals after administration of the capsule. The samples were collected in calibrated centrifuge tubes and centrifuged, and the liquid was used for analysis. Plasma blank values were subtracted from the sample values. The plasma was analyzed according to the method of Routh and Dryer (2).

RESULTS AND DISCUSSION

Table V and Figs. 1 and 2 show the mean plasma salicylate levels in mg./100 ml. obtained at 1, 2, and 3 hr. after administration of the capsule. The mean plasma salicylate values were low. A multiple regression analysis¹ (6), in which there was no detailed examination of differences among the five treatment means, showed no suggestion of week differences. An analysis of variance (Table VI) showed that by the 3rd hour, the highly compacted combinations in No. 4 capsules were producing better plasma levels than the No. 3 capsules, with or without excipients.

The better plasma salicylate levels obtained with the tightly compacted No. 4 capsules may be due to the diffusion of gastric juice through the gelatin, which created a higher osmotic pressure within the capsules, thereby leading to more rapid breakdown and absorption. It is difficult to explain the excellent *in vivo* performance of the ASA in a No. 3 capsule.

Under the low agitation conditions of the Levy beaker method, a No. 3 capsule containing ASA alone floated in the hydrochloric

acid-water solution for 2 hr. before settling to the bottom of the beaker. Figure 3 presents sketches of the appearance of the capsule at various times. The concentration of ASA was found to be 5.5 mg./100 ml. at the end of 4 hr. A small amount of pepsin was added to the beaker, and the thin gelatin bag broke within 1 min. The beaker method using distilled water, adjusted to pH 1.2 with hydrochloric acid, was felt to be unsatisfactory for dissolution determinations with capsules. A modified Levy-Hayes method, using weighted capsules to prevent floating, has been suggested for overcoming the results experienced in this study (7).

Using the oscillating tube method, the hard gelatin capsules showed distortion and did not appear to break down readily even in the presence of the digestive enzyme used and the relatively high agitation intensities of the oscillating tube method. The average concentration (three determinations) of ASA at the end of 4 hr. was 19.8 mg./100 ml. using hydrochloric acid-water (pH 1.2) as the dissolution medium and 20.0 mg./100 ml. after 3 hr. using gastric fluid, simulated test solution. Intrinsic dissolution determinations showed that ASA dissolves well when unencumbered by gelatin.

The mean plasma salicylate levels at the end of 1, 2, and 3 hr. were far lower than the concentrations obtained at the corresponding hours in the *in vitro* study, so that any attempt to correlate the

^a Significant at the 5% level. ^b Significant at the 1% level.

two sets of data was considered of little value. A rank order correlation may, however, be observed in that the mean plasma salicylate values, as well as dissolution values, are higher for the more highly compacted No. 4 capsules and in the case of dibasic calcium phosphate. The low plasma salicylate levels may be due to a failure to break down *in vivo*. The *in vitro* agitation intensities resulting from the dissolution medium being forced through the 100-mesh screen were reported by Levy (4) to be far greater than the agitation encountered in the stomach, a fact that could account for the widespread difference in concentration levels between the two studies.

In vitro observations showed that the ASA became moist; over a period of time the gelatin stretched and, together with the mechanical action of striking against the 100-mesh screen, assisted in the breakdown. The stretching effect was not as noticeable in the case of capsules containing excipients.

The low plasma salicylate levels obtained *in vivo* together with the *in vitro* behavior of the capsules would seem to indicate that the gelatin in the hard gelatin capsules had been modified in some manner, either by the acidity of the gastric juice, or by the acidity of the ASA (pK_a 3.5) within the microenvironment of the capsule, or by a combination of the two. If due to the weakly acidic drug alone or to a combination of drug and gastric juice, this could be of importance for other drugs of similar properties when encapsu-

lated. If due to the acidity of the gastric juice alone, it would appear that the release of any drug enclosed in hard gelatin capsules could be affected adversely. Gelatin is obtained by heat denaturation of collagen and is built of three strands, which are joined primarily by hydrogen bonding between the strands (8). It is possible that the stretching of these strands accounted for the appearance of the hard gelatin capsules in the *in vitro* tests and perhaps for the low plasma salicylate levels.

Factors Influencing Solvolysis of Corticosteroid-21-phosphate Esters

G. L. FLYNN and D. J. LAMB

Abstract □ The solvolysis of methylprednisolone-21-phosphate in dilute aqueous solution (<0.005 M) is qualitatively similar to that observed for methylphosphate and other simple monoalkyl phosphates, particularly in the pH range 3-8. In more concentrated solutions (>0.02 M), however, there is an acceleration of reaction velocities and marked deviation from the expected pH dependency. This change in chemical behavior is attributed to association colloid formation. Support for this mechanism is drawn from hydrolysis-rate data obtained as a function of concentration and independently determined critical micelle concentration values.

Keyphrases □ Corticosteroid-21-phosphate esters—solvolysis, micelle formation □ Solvolysis, corticosteroid-21-PO₄ esters—pH profile, activation energy, aggregation effect □ Critical micelle concentration determination—conductivity, surface-tension methods □ Phosphate, inorganic—analysis

The term phosphate ester is extremely ambiguous because it applies to several distinctly different classes of compounds, each characterized by unique chemical

behavior. Furthermore, chemistries in each phosphate ester class can be appreciably different both qualitatively and quantitatively, depending on the types and proximities of neighboring atoms within the molecule. Additional complexity arises from the biformity of the carbon-oxygen-phosphorus linkage. Solvolysis, for instance, may entail carbon-oxygen cleavage, phosphorus-oxygen splitting, or both, depending on the reaction conditions (1).

The hydrolyses of monoalkyl phosphates are characterized by these diversities. The prototype of this phosphate ester class is methylphosphate. It is a relatively simple molecule whose aqueous stability has been extensively studied (2). At pH values below zero, the conjugate acid species predominates, and the solvolysis takes place with both carbon-oxygen and phosphorus-oxygen splitting. The neutral molecule is the principal species in pH range 0-2, and it cleaves exclusively at the carbon-oxygen bond. Above pH 3, the monoanion,

Factors Influencing Solvolysis of Corticosteroid-21-phosphate Esters

G. L. FLYNN and D. J. LAMB

Abstract □ The solvolysis of methylprednisolone-21-phosphate in dilute aqueous solution (<0.005 M) is qualitatively similar to that observed for methylphosphate and other simple monoalkyl phosphates, particularly in the pH range 3-8. In more concentrated solutions (>0.02 M), however, there is an acceleration of reaction velocities and marked deviation from the expected pH dependency. This change in chemical behavior is attributed to association colloid formation. Support for this mechanism is drawn from hydrolysis-rate data obtained as a function of concentration and independently determined critical micelle concentration values.

Keyphrases □ Corticosteroid-21-phosphate esters—solvolysis, micelle formation □ Solvolysis, corticosteroid-21-PO₄ esters—pH profile, activation energy, aggregation effect □ Critical micelle concentration determination—conductivity, surface-tension methods □ Phosphate, inorganic—analysis

The term phosphate ester is extremely ambiguous because it applies to several distinctly different classes of compounds, each characterized by unique chemical

behavior. Furthermore, chemistries in each phosphate ester class can be appreciably different both qualitatively and quantitatively, depending on the types and proximities of neighboring atoms within the molecule. Additional complexity arises from the biformity of the carbon-oxygen-phosphorus linkage. Solvolysis, for instance, may entail carbon-oxygen cleavage, phosphorus-oxygen splitting, or both, depending on the reaction conditions (1).

The hydrolyses of monoalkyl phosphates are characterized by these diversities. The prototype of this phosphate ester class is methylphosphate. It is a relatively simple molecule whose aqueous stability has been extensively studied (2). At pH values below zero, the conjugate acid species predominates, and the solvolysis takes place with both carbon-oxygen and phosphorus-oxygen splitting. The neutral molecule is the principal species in pH range 0-2, and it cleaves exclusively at the carbon-oxygen bond. Above pH 3, the monoanion,

which cleaves exclusively at the phosphorus-oxygen bond, is formed and its concentration determines the reaction velocity well into the basic pH range.

Phosphates are of interest pharmaceutically because they provide a means of making soluble derivatives out of highly insoluble compounds. Additionally, some types of phosphate esters are sufficiently stable to allow the formulation of solutions with practical shelflives. These characteristics translated into biopharmaceutical terms mean instantaneous blood levels and facile parenteral administration. Most important or widely used of the pharmaceutical phosphate esters are the corticosteroid-21-phosphates. This report deals with their chemical behavior in aqueous solution as a function of concentration, pH, and other reaction conditions.

EXPERIMENTAL

Sample Preparation—In the kinetic studies, solutions were prepared at predetermined concentrations using distilled water and appropriate amounts of buffering agents and organic phosphate. In the pH 3–6 region, these were adjusted to pH at room temperature using either a concentrated solution of sodium hydroxide or concentrated hydrochloric acid. In the very low and high pH ranges, the samples were adjusted to pH at the temperature of the run. Initial concentrations were then determined by the Porter-Silber procedure (3, 4). After pH adjustment, the samples were filled in appropriately sized glass vials (usually 5 ml.) and placed in constant-temperature oil baths maintained within $\pm 0.1^\circ$ of the indicated temperatures. These were removed and analyzed on a suitable, predetermined schedule.

In the surface-tension determinations of critical micelle concentrations (CMC), a concentrated solution of the drug in distilled water was prepared and then diluted by 50 or 60% successively to levels far below the expected CMC. These were analyzed for surface tension as a function of concentration. Conductimetric studies were carried out on solutions prepared in a tight range around the expected CMC values ($1.5 \times 10^{-3} M$ to $3 \times 10^{-2} M$).

Equipment—Spectrophotometric determinations were performed on a Cary 11 recording spectrophotometer. The pH adjustments were monitored on either a Beckman model GS or a Corning expanded scale meter. The surface-tension measurements were done on a Cenco DuNoüy 70545 tensiometer and conductivity measurements on a Serrass conductivity bridge model RCM 15B1.

Inorganic Phosphate Procedure—**Chemicals**—All of the following chemicals were used without further purification: methylene chloride (distilled in glass); hydrochloric acid, reagent grade; potassium phosphate, monobasic, crystals A.R.; *N,N*-dimethylformamide (distilled in glass); ammonium molybdate A.R.; glacial acetic acid, reagent grade; cupric sulfate (anhydrous) A.R.; ascorbic acid USP; sodium acetate A.R., granular; stannous chloride, crystals A.R.; and sodium phosphate, dibasic (anhydrous) A.R.

Hydrocortisone-21-phosphate (disodium salt), prednisolone-21-phosphate (disodium salt), and dexamethasone-21-phosphate (disodium salt) were used as received.¹ Methylprednisolone-21-phosphate (M-21-P) (disodium salt) (Upjohn) was purified *via* continuous methylene chloride extraction for micellar kinetic studies. Otherwise, it was used as received.

Reagents—Originally the Mokrasch (5) procedure was employed. On later runs, a modified procedure with the following reagents was used:

1. Ammonium molybdate—2.0% $(\text{NH}_4)_6\text{Mo}_7 \cdot 4\text{H}_2\text{O}$ in double-distilled water.
2. Acetate buffer—310 ml. of glacial acetic acid, 49 g. of potassium acetate, and 48 mg. of cupric sulfate dissolved in double-distilled water and diluted to 1000 ml.
3. Ascorbic acid—2% ascorbic acid in distilled water.
4. Stannous chloride—20% stannous chloride in hydrochloric acid; 1 ml. diluted to 100 ml. with distilled water prior to use.
5. Standard inorganic phosphate solution—300 mg. (accurately weighed) of Na_2HPO_4 (dried 2 hr. at 110°) in 100 ml. of distilled

water; 10 ml. diluted to 200 ml. with distilled water (approximately $2 \times 10^{-4} M$). When buffer systems were used, the standard was prepared in them.

Procedure—Total sample was removed from the ampuls, placed in a 60-ml. separator, and extracted with two 25-ml. portions of methylene chloride to remove formed sterol. An aliquot of the extracted sample was then appropriately diluted. To separate 100-ml. volumetric flasks, the following were added: (a) 2 ml. of standard, q.s. to 10 ml.; (b) 2 ml. of standard and 2–5 ml. of sample q.s. to 10 ml.; (c) 2–5 ml. of sample [appropriate size varied from concentration to concentration but same amount of sample used in (b) and (c) in any case for given run]; and (d) 10 ml. distilled water (blank).

This was followed immediately for each solution with 50 ml. of acetate buffer, 5 ml. of ammonium molybdate solution, 5 ml. of ascorbic acid solution, and 5 ml. of stannous chloride solution, mixing well after each addition. These were then diluted to volume with acetate buffer and allowed to develop for 30 min. The absorbance of the samples at $740 m\mu$ against the blank was determined within 3 hr. using 1-cm. cells.

Calculations—

$$[M-21-P]_t = [M-21-P]^0 - [IP]_t \quad (\text{Eq. 1})$$

$$= [M-21-P]^0 - [S] \times \frac{A_{mp}}{A_s} \times \text{D.F.} \times \frac{\Delta A_{mp}^t}{\Delta A_{mp}^0} \quad (\text{Eq. 2})$$

where:

$[M-21-P]_t$ = molar concentration of methylprednisolone-21-phosphate with respect to time

$[M-21-P]^0$ = initial molar concentration of methylprednisolone-21-phosphate (independently determined); alternatively, the inorganic phosphate infinity value was used as material balance was good

$[IP]_t$ = inorganic phosphate molar concentration with respect to time

$[S]$ = molar concentration of phosphate standard

A_{mp} = absorbance of sample

A_s = absorbance of standard

D.F. = dilution factor

ΔA_{mp}^t = absolute difference in the spiked and nonspiked sample at time, t

ΔA_{mp}^0 = absolute difference in the spiked and nonspiked sample initially; equal to A_s

CMC Determinations—1. Surface-Tension Measurements—

These were made on the tensiometer at room temperature. Each dilution was read three times and the values were averaged. It was found that pH was relatively invariant at pH = 7.5, and no adjustments were made. Experiments run at lower pH were done on solutions that had been accurately pH adjusted.

2. **Conductimetric and Spectrophotometric Determinations**—These were run on solutions diluted to between 0.75 and 15 mg./ml. corresponding to $1.5 \times 10^{-3} M$ and $3 \times 10^{-2} M$, respectively. The conductimetric measurements were carried out in a jacketed-glass beaker in which the temperature was maintained within 0.1° of that indicated. The cell constant of the conductance probe was 1.0.

pKa Determinations—Solutions of M-21-P were prepared to contain 1.33 mg./ml. NaCl was added to give an ionic strength of 0.15. Titration curves were run on a radiometer titrator at the indicated temperature using 0.09823 *N* HCl as the titrant. The pK_{a2} values were read directly from the graph at the half-neutralization point. The pK_{a1} values were estimated from the one and one-half neutralization point and were corrected for water content of the phosphate sample. Equation 3 was used:

$$pK_{a1} = pH_1 - \log \frac{[A^- + H^+]}{[HA - H^+]} \quad (\text{Eq. 3})$$

THEORETICAL CONSIDERATIONS

From the beginning of these studies, it was realized that spurious, unquenchable reactions would be occurring simultaneously with the solvolytic reaction in the pH range of interest. To avoid the potentially serious complications resulting from these secondary decompositions, a method of monitoring the reaction, which was either sensitive to the presence of intact organic phosphate or capable of assessing formed inorganic phosphate, was sought. Two established analytical procedures, the Porter-Silber (3, 4) procedure

¹ Supplied by Merck & Co., Rahway, N. J.

Figure 1—Typical curves for the disappearance of M-21-P from aqueous media as a function of temperature at pH 5.42 and an ionic strength of 0.105.

and the Mokrasch (5) inorganic phosphate procedure, were deemed suitable. After some experimentation with each, the inorganic phosphate procedure was chosen. This procedure is based on the reduction of phosphomolybdate to form a colored product. It was developed expressly for the determination of inorganic phosphate in the presence of labile organic phosphate and thus was particularly suited to the investigation.

The removal of formed neutral species was found to be a necessary condition to the successful application of this technique. Otherwise, color development was erratic. In addition, each sample was assayed with a counterpart spiked with a known amount of inorganic phosphate. The procedure is similar to that used in scintillation counting where counting efficiency is determined by adding an exact quantity of unstable isotope (^3H , ^{14}C , etc.) to the sample after it has been counted for its unknown concentration. In both cases the known concentration corrects the value of the unknown for variances in the sensitivity of the assay. Thus, any tendency for color development to drift was offset by including the drift factor, $\Delta A_{mp}^t/\Delta A_{mp}^0$, in the calculations (Eq. 2). With these precautions the infinity time values by the inorganic phosphate method were within experimental error of the independently determined initial concentrations.

The solvolysis of M-21-P between pH 0 and 8 was expected to be pseudo-first-order based on literature reports (6, 7) for similar compounds:

$$\frac{d[\text{M-21-P}]}{dt} = -k_{\text{obs.}} [\text{M-21-P}] \quad (\text{Eq. 4})$$

where [M-21-P] stands for the instantaneous concentration of M-21-P and $k_{\text{obs.}}$ is the observed pseudo-first-order rate constant at a given pH, temperature, ionic strength, etc. The integrated form of this equation becomes the familiar

$$[\text{M-21-P}]_t = [\text{M-21-P}]^0 e^{-k_{\text{obs.}} t} \quad (\text{Eq. 5})$$

Since $[\text{M-21-P}]_t = [\text{M-21-P}]^0 - [\text{inorganic phosphate}]$, then

$$[\text{M-21-P}]^0 - [\text{inorganic phosphate}] = [\text{M-21-P}]^0 e^{-k_{\text{obs.}} t} \quad (\text{Eq. 6})$$

or, on a percentage basis:

$$\frac{[\text{M-21-P}]^0 - [\text{inorganic phosphate}]}{[\text{M-21-P}]^0} \times 100 = 100 e^{-k_{\text{obs.}} t} \quad (\text{Eq. 7})$$

Semilogarithmic plots of either intact M-21-P concentration or percent M-21-P remaining versus time should yield straight lines intercepting at $\log [\text{M-21-P}]^0$ (Eq. 6) or $\log 100$ (Eq. 7), respectively, with slopes of $k_{\text{obs.}}/2.303$.

RESULTS

The disappearance of M-21-P in reaction systems typical of those considered here is shown as a function of time and pH in Fig. 1.

Table II—Rate Constants at pH = 4.06 at 70° for Solvolysis of Several Corticosteroid-21-phosphate Esters

	k^{70° (days ⁻¹)
Methylprednisolone	0.151
Dexamethasone	0.148
Prednisolone	0.156
Hydrocortisone	0.148

This figure shows the residual percentage of the initial M-21-P in solutions consisting initially of 2×10^{-3} M M-21-P at several temperatures and pH = 5.42. The buffers used in the studies are from a paper by Bunton *et al.* (2) and are outlined in Table I.

As would be expected on the basis of Eq. 7, semilogarithmic plots of the residual percentage of M-21-P against time are linear. Typical pseudo-first-order curves are shown in Fig. 2 for the reaction at several temperatures and pH = 5.32. The solvolyses of prednisolone-21-phosphate, hydrocortisone-21-phosphate, and dexamethasone-21-phosphate proceeded in a similar fashion as shown by a single pH and temperature study summarized in Table II. These rates are indistinguishable within experimental error from one another.

The pH dependency of the reaction velocity is shown in Fig. 3. These data are for the reaction of solutions initially of 2×10^{-3} M concentration at 70°. Included with these data for later consideration are the 70° literature data of Marcus (8) for the solvolysis of hydrocortisone-21-phosphate and 101° data extrapolated to 70° for methylphosphate (2) using an activation energy of 30.6 kcal./mole.

The temperature dependency of the reaction was determined at multiple points above pH = 3. As predicted by the Arrhenius equation, plots of the log of the observed rate constant against the reciprocal of the absolute temperature yielded straight lines (Fig. 4). The lines representing different values of pH were also parallel. The activation energy values calculated from the slopes of these lines are tabulated in Table III. The average of these values, 27.5 kcal./mole, is assumed to be the best estimate of the activation energy.

Because of the striking diversity in these results and previous results on hydrocortisone-21-phosphate and the obvious structural

Figure 2—Semilogarithmic plots showing the disappearance of M-21-P as a function of temperature at pH 5.32 and an ionic strength of 0.100.

semblance between the corticosteroid phosphates and the surface-active bile acids (Structures I and II), studies attempting to relate the

I—cholic acid II—methylprednisolone-21-phosphate

observed differences to molecular aggregation effects were initiated. Typical results of surface-tension measurements of serially diluted solutions of M-21-P at room temperature and pH = 7.5 are shown in Fig. 5. These are plotted in the usual fashion as the surface tension *versus* the log of the molar concentration. Distinct breaks in the curves at approximately 0.02 *M* were observed. Because of the tedium of the procedure and interest in expanding the data to include surface-tension measurements as a function of pH and temperature, conductimetric studies supplanted surface-tension experiments. The data from a representative temperature experiment

Table III—Apparent Activation Energy as a Function of pH for the Solvolysis of M-21-P

pH	<i>E_a</i>
7.52	27.0
6.45	27.3
5.42	26.3
5.32	28.9
4.35	29.4
3.32	27.6

at pH = 7.5 are graphically presented in Fig. 6. It appears from this plot that there is a slight increase in the CMC with increasing temperature. CMC values fall between 0.01 and 0.02 *M*, which is in good agreement with the surface-tension studies. Neither method yielded sharply defined CMC's. Conductimetric studies were also performed at 25° and several pH values. At low pH, where the free acid predominates, the solubility of the compound was too low to make measurements. CMC's measured above pH = 3 were not distinguishable from one another.

With the amphiphilic character of the compound definitely established, studies were conducted to assess the effect of association colloid formation on the reaction. Unfortunately, in the pH range of maximum interest, the data gathered were only crudely quantitative due to an inability to control pH in bufferless systems. Therefore, the results will only be reported here in qualitative terms. The reaction rate was found to be invariant with concentration at pH = 4 in solutions ranging from 0.005 to 0.16 *M* (0.005, 0.01, 0.02, 0.04, 0.08, and 0.16 *M*). In these studies, pH drifts were found to be no more than several hundredths of a unit throughout the concentration range. However, on reactions run at pH = 7 and 7.5, a different behavior was observed for series of solutions of the same concentrations. For the dilute solutions, pH shifts to more acidic conditions exceeded a full pH unit. As the concentration increased, the pH drift narrowed to slightly over half a unit. The downward shift in pH would tend to accelerate the reaction. Despite this, the reaction in 0.16 *M* solutions was consistently observed to be 2–3 times more rapid than in 0.08 *M* solutions. There appeared to be little difference between 0.08 and 0.04 *M* solutions. Below 0.04 *M*, the pH shifts became exaggerated and there was an apparent increase in reaction rate.

DISCUSSION

Analysis of the pH-Rate Profile—The pH profile for all alkyl phosphates is a composite of the individual species profiles, and its shape is determined by their relative concentrations and rates (1). Four species are possible: the conjugate acid, the free acid, the monoanion, and the dianion. The conjugate acid is formed in highly acidic solution (pH < 1.0) and thus is only of marginal concern for the steroid-21-phosphates. In pH range 1–8, the instability of these compounds can be explained on the basis of the independent reactivities of the free acid and monoanion. An M-21-P species profile as a function of pH is given in Table IV. These data are calculated using averaged, independently determined p*K*_{a1} and p*K*_{a2} values of 2.55 and 6.04, respectively, and Eqs. 8–10:

$$C_N = \frac{[H^+]^2}{K_{a1}K_{a2} + K_{a1}[H^+] + [H^+]^2} \quad (\text{Eq. 8})$$

$$C_M = \frac{K_{a1}[H^+]}{K_{a1}K_{a2} + K_{a1}[H^+] + [H^+]^2} \quad (\text{Eq. 9})$$

$$C_D = 1 - [C_N + C_M] \\ = \frac{K_{a1}K_{a2}}{K_{a1}K_{a2} + K_{a1}[H^+] + [H^+]^2} \quad (\text{Eq. 10})$$

where *C* is the fractional concentration and subscripts *N*, *M*, and *D* refer to the neutral species, monoanion, and dianion, respectively.

Comparison of the pH profiles of methylphosphate and M-21-P between pH 0 and 2, where the neutral species prevails, indicates that the trough found for methylphosphate is leveled out for its corticosteroid counterpart (Fig. 3). Reaction rates at pH = 1.0 differ by approximately two orders of magnitude. Similar plateauing is observed in the profiles of α-D-glucose-1-phosphate (9) and monobenzyl phosphate (10). Unlike these two cases, the increased reactivity of the neutral species cannot be attributed to a change from an *S_N2* solvolytic displacement to an *S_N1* carbonium-ion mechanism. The carbonium ion of M-21-P would be even less energetically favored than that for methylphosphate due to the electron-withdrawing α-carbonyl. A probable explanation for the increased reactivity is stabilization of the transition state (*S_N2* mechanism with *sp*² hybridization) due to π-orbital overlap with the electron-rich neighboring oxygen atom (11). A similar effect of similar or greater magnitude for α-carbonyls has been noted in other solvolytic displacements (12). The plateau in the M-21-P profile suggests that the specific second-order rate constants for the cleavage of the neutral species and monoanion are of the same order of magnitude.

Figure 4—Arrhenius plots for the hydrolysis of M-21-P at several values of pH.

In the pH region of pharmaceutical interest, the principal degradative route for phosphate monoesters is the cleavage of the monoanion. The qualitative similarity of the reaction for M-21-P and methylphosphate above pH = 3 is readily apparent from Fig. 3. The reaction proceeds with P—O splitting. The specific requirements for the hydrolysis of the monoanion led Butcher and Westheimer (13) to postulate a mechanism in which an unstable monomeric metaphosphate-ion intermediate is formed. This mechanism is consistent with the relative rapidity of the hydrolysis, the requirement of protonation of one of the phosphate oxygens, P—O splitting, and the marked insensitivity of the hydrolytic velocity to the nature of the leaving group. At 70° the monoanion rate constant for M-21-P is just over seven times that found for methylphosphate. Because of an approximately 3-kcal./mole difference in observed activation energies, this factor shrinks as the temperature is lowered. Regardless, this difference is significant and likely attributable to electronic effects of the α -carbonyl on the strength of the P—O bond. An interesting fact discovered in these studies is that, in dilute solution, the nature of the steroid nucleus has little effect on the specific second-order monoanion instability constant for the corticosteroid-21-phosphates, at least insofar as hydrocortisone, methylprednisolone, dexamethasone, and prednisolone are different. This suggests that the overriding influence on the observed rate is the adjacent carbonyl and that the M-21-P data can be considered representative of the stability of related steroid phosphates.

Throughout the course of the kinetic studies at premicellar concentrations, there was no noticeable effect of buffers on the reaction rate. Buffers could be interchanged or changed in concentration without a measurable reaction velocity change. This is not too surprising because at low pH, the buffer species present are extremely poor nucleophiles. At high pH the mechanism precludes buffer involvement but, neglecting this, the reaction requirements are such that two negatively charged species must be brought together and this is energetically unfeasible.

Because of doubts regarding the relative validity of the available methods for following the progress of the reaction, the disappearance of M-21-P was also followed directly using the Porter-Silber procedure (3). Results by this procedure were comparable with those obtained following the appearance of inorganic phosphate. For instance, at 54.3° and pH = 5.4, the inorganic phosphate procedure yielded a value for k_{obs} of $1.45 \times 10^{-2} \text{ day}^{-1}$ while the value by the Porter-Silber procedure was $1.83 \times 10^{-2} \text{ day}^{-1}$. These results were obtained on ampuls from the same set. It was implicit in these studies that the formation of spurious products would have negligible effect on the principal reaction. In other

Figure 5—Determination of the CMC of M-21-P by surface-tension measurement. Each point is an average of three determinations.

words, it was assumed that changes in the molecule prior to solvolysis, if any, would not appreciably affect processes at the phosphate moiety. Products were assumed to be inert. The dominance of the solvolysis as the major instability, the linearity of plots, and the reproducibility of data by both of these methods attest to the credibility of these assumptions.

The dianion of M-21-P is virtually unreactive. Negative linear dependency on the pH is observed far into the high pH range, and this dependency parallels the concentration of the monoanion. Presumably, the concentration of the monoanion should eventually become negligible, resulting in a plateau in the pH profile. This point, if it is reached at all, is well above pH = 8 based on the observations in this study.

Micellization and Its Probable Influence on Reaction Rate—Strong evidence has already been presented for the formation of association colloids in these systems. In addition, slight but unmistakable deviations from Beer's law were observed above the CMC. Similarly, the solubility of methylprednisolone in solutions of M-21-P increases sharply as the CMC is exceeded.

The enthalpy for the formation of the micelles, ΔH_m , is calculable from the available data and Eq. 11:

$$\Delta H_m = -RT^2 \left(\frac{d \ln \text{CMC}}{dT} \right) \quad (\text{Eq. 11})$$

and was found to be approximately -1.0 kcal./mole at 40°. This is entirely consistent with the behavior of other systems (14). The significance of this value is that it indicates the marked temperature insensitivity of micellization. Over a narrow temperature range,

Figure 6—Determination of the CMC of M-21-P by conductance measurement. Each line represents a different temperature. In all cases, the apparent CMC fell between 0.01 and 0.02 M.

Table IV—M-21-P Species Concentrations of $f(\text{pH})^a$

pH	Free Acid (N)	Monoanion (M)	Dianion (D)

10	Negligible	Negligible	1.000

^a M-21-P total = 1.0.

the fraction of molecules participating in micelles to total surfactant molecules remains relatively constant. In other words, temperature effects parallel those of chemical equilibria rather than chemical reactions.

Another factor to be kept in mind is the salt effect or, more properly, the gegenion effect on micellization. Many investigators working with diverse systems have observed that the logarithm of the CMC changes linearly with the logarithm of the concentration of gegenion (14):

$$\ln \text{CMC} = -K \ln C_g + \text{constant} \quad (\text{Eq. 12})$$

In practical terms, this contraindicates the use of buffers in well-designed studies on micellar kinetics. It also suggests that the hydrocortisone-21-phosphate reaction systems of Marcus (8) were of significant micellar character. His working phosphate concentration was 0.02 M, slightly above the CMC, and his studies were performed in 0.20 M phosphate buffer providing as little as 0.2 M and up to 0.4 M concentration of positively charged ions (gegenions), depending on pH. The activation energy reported by Marcus for the solvolysis of hydrocortisone-21-phosphate is 17.0 kcal./mole, fully 10 kcal./mole less than that found for M-21-P and 13 kcal./mole less than the average for this entire class of compounds (1). A shifting micellar fraction with temperature can account for much of these substantial differences.

Controlling variables in micellar kinetic studies can be a difficult job. Not only do the usual parameters such as temperature and pH have to be controlled, but also gegenion concentration and impurities. Buffers can have a multiplicity of effects. Therefore, several studies at $\text{pH} \approx 4$ and $\text{pH} > 7.0$ were initiated in bufferless systems. There was definitely no micellar facilitation of the reaction at low pH. At high pH, it appeared as if the reactions were accelerated above the CMC, particularly when changing pH effects, which ran counter to the micellar effects, were taken into account. The insensitivity to micellization at $\text{pH} \approx 4$ is explicable when the peculiar requirements and mechanism of the phosphate monoanion decomposition are considered. The rate-determining step, the production of a metaphosphate anion, is a unimolecular reaction reflecting the intrinsic instability of a given molecule. With the exception of factors influencing protonation, the presence of neighboring molecules would not play a major role in the reaction.

It is implicit here that the pH at the micellar surface is not appreciably different from the bulk pH. This is not necessarily true at higher pH. The surface potential, ψ , is becoming increasingly negative. If the hydrogen ions are present in a Boltzman distribution represented by Eq. 13:

$$[\text{H}^+]_s = [\text{H}^+]_b \exp. - (|e|\psi/kt) \quad (\text{Eq. 13})$$

where $[\text{H}^+]_s$ and $[\text{H}^+]_b$ are the surface and bulk hydrogen-ion concentrations, respectively, then the pH at the micellar surface is expected to lag behind that of the bulk solution. This will change the ratio of phosphate monoanions to dianions relative to the bulk and, therefore, produce an apparent increase in rate. This factor and the gegenion effect together could help produce the rather unusual pH and temperature dependency observed by Marcus (8) in the pH range 5–8.

ACKNOWLEDGMENTS AND ADDRESSES

Received April 27, 1970, from the *Research Laboratories, The Upjohn Company, Kalamazoo, MI 49001*

Accepted for publication June 3, 1970.

Presented to the Basic Pharmaceutics Section, APHA Academy of Pharmaceutical Sciences, Washington, D. C. meeting, April 1970.

The authors express their appreciation to Mr. Russell Smith for his assistance in the work and to Mr. William Beyer, Upjohn Control Division, who improved the Mokrasch inorganic phosphate procedure. The improvements yield a procedure which is not encumbered with cloudiness and in which labile phosphates are more stable. Thanks are also extended to Drs. William Higuchi, Harry Kostenbauder, and Pasupati Mukerjee for helpful discussions.

Solute Fluxes in Fat Absorption

R. L. S. WILLIX

Abstract □ Diffusion rates of fatty acid (oleic and palmitic acids) in bile salt solution and in polyoxyethylene-polyoxypropylene copolymer solution depend on the amount of fatty acid solubilized and also on any physical restrictions to flow. Micelles of the two types of surfactant are significantly different in size. Assuming a passive process for the uptake of fatty acid, diffusion rates correlate with the observed uptake of fatty acid into everted intestinal sacs of the rat.

Keyphrases □ Fat absorption—solute fluxes, *in vitro* □ Diffusion cells—fat transfer □ Radioactive solute—fat transfer, diffusion cells □ Refractometry, differential—diffusion rates □ Scintillometry—analysis

The surface-active property of the natural surfactants, bile salts, in mediating lipolysis (1) and absorption by the small intestine of hydrophobic material, otherwise poorly soluble in an aqueous medium (2–4), is well accepted.

Synthetic nonionic surfactants, such as polyoxyethylene-polyoxypropylene copolymer,¹ also promote absorption of free fatty acids by everted intestinal sacs of the rat but less effectively than bile salts (5). They exert an effect *in vivo* from which conclusions are obscured due to the absence of a clear distinction between uptake from micellar solutions compared with uptake from emulsions (6).

Phase separation by ultracentrifugation has established that, for any one concentration of either surfactant and lipid composition, a fixed amount of fatty acid partitions between the micellar and emulsion phases (6); and for absorption *in vitro*, there is a clear relationship between the amount of fatty acid (oleic acid) solubilized and uptake into the everted intestinal sac (5).

If it is generally agreed that lipid is absorbed almost exclusively from the isotropic phase of intestinal content, micellar solubilization could promote uptake by increasing the chemical potential or effective concentration of lipid in the systems considered. An understanding of the mechanism, however, requires a knowledge of the dynamic nature of the physicochemical events in the absorptive process. Diffusion coefficients in the aqueous phase and the interfacial resistances to fatty acid movement between emulsion globules, micelles, and the surrounding aqueous medium are the kinetic quantities that provide the link between solubilization and uptake in this luminal stage of fat absorption.

The method involves the measurement of the fatty acid flux across a confined volume of solution, in practice a solution that is limited to the interior of a diaphragm and made less sensitive to gradients that lead to bulk flow in free solution. In addition, the use of diaphragms of different porosities provides data on

solute fluxes when the movement of fatty acid in one or more of its states of aggregation, monomers, micelles, or emulsion globules is restricted.

The method has been applied to lipids in a qualitative manner (7) and follows from studies (8, 9) on the effect of solubilizing agents in increasing the driving force for diffusion of water-insoluble dyes. The capacity of Millipore filters, under conditions of free filtration, in separating emulsion and micellar phases of lipid dispersed by bile salts has been previously demonstrated (10). Using Millipore and sintered-glass diaphragms, the present study provides quantitative data on the diffusive movement of fatty acid, specifically oleic acid, in lipid systems of bile salts and of polyoxyethylene-polyoxypropylene copolymer.

The validity of a diffusion-limited model for the luminal stage of fatty acid absorption implies the presence in the gut of a still layer near the absorptive cell. While this is not proven, the glycocalyx coat could well produce an unstirred layer of fluid of greater thickness than at a clean cell surface; the presence of microvilli with some of the characteristics of physical pores (11) improves the analogy with the physicochemical model, making the data on fatty acid movement in its different states of aggregation perhaps directly applicable to the biological situation.

An understanding of the luminal stage of the absorptive process through the comparison of different surfactants may then provide insight into the much more complicated *in vivo* problem where, as yet, few clearcut physicochemical parameters have emerged.

EXPERIMENTAL

Materials—Sodium taurocholate (NaTC) moved as a single spot on activated silica gel at room temperature with ethyl acetate-methanol-glacial acetic acid (70:20:10). It was used as supplied.²

Sodium taurodeoxycholate (NaTDC) was synthesized from tauroine and deoxycholic acid by the method of Norman (12) as modified by Hofmann (13). Bile salts were used in a 4:1 ratio with NaTC–NaTDC in all experiments.

Polyoxyethylene-polyoxypropylene copolymer (nominal molecular weight 8000) had a specific refractive index increment of 0.139 ml. g.^{−1} and was used as supplied.

Glycerol 1-monooleate (monoolein) was shown by TLC to contain small amounts (~5%) of diglyceride and free fatty acid. By GLC the fatty acid composition was C_{12:0} 1, C_{16:1} 5, C_{18:1} 85, C_{18:2} 5.

Oleic acid and palmitic acid were ~98% pure by GLC. Radiochemical purity of oleic acid-1-¹⁴C was certified³ as 95–98% pure C_{18:1} of which 7% was elaidic acid; 97% of the material was free fatty acid by TLC. Palmitic acid-9,10-³H was certified 96% pure; 94% of the activity was in the fatty acid band.

Sodium dihydrogen phosphate and monohydrogen disodium phosphate were used as supplied.⁴

Methods—Two types of diaphragm cells are described. One uses a sintered-glass disk of ~30-μ average pore diameter, 4.9 cm.²

Table I—Cell Constants

Diaphragm	Cell Constant β (cm. ⁻²)
Sintered glass (SG), 30 μ	0.25 \pm 0.02
Millipore (MP), 1.2 μ	9.54 \pm 1.1
Millipore, 0.010 μ	4.37 \pm 0.06

in area and 2 mm. thick, in the Stokes modification (14) of the Northrop-Anson (15) diffusion cell, in which stirring is effected by two polyethylene-encased⁶ metal bars mounted one on each side close to, but not in contact with, the diaphragm. The cell was filled by suction and the lower chamber was closed with a tightly fitting ground-glass stopper. A film of silicone grease was placed on the external joint, and the entire lower chamber port was enclosed in a small polyethylene bag. The cell was immersed vertically in the thermostat and held in a rigid clamp to minimize vibration.

When steady-state conditions prevailed in the diaphragm, the solution in the upper chamber was removed and replaced with the solution of interest, either a nonradioactive solution of lower concentration if a chemical concentration gradient was to be maintained across the diaphragm or a nonradioactive solution of the same lipid concentration if the system was to be at chemical (but not isotopic) equilibrium. The upper chamber was closed with a ground-glass stopper with a perforation to the atmosphere, and the run was commenced by activating the stirrer with rotating magnets. At the end of the diffusion period, the entire solution (24.2 ml.) from each chamber was removed for analysis. Radioactivity measurements were made on triplicate samples (refractive index measurements also were made if surfactant diffusion in concentration gradient experiments were being followed).

The other diaphragm cell utilized Millipore cellulose acetate filters (25 mm. in diameter, 0.15 mm. thick) of different porosities, mounted vertically to expose 2.90 cm.² to the solutions in each chamber (initially always 20 ml. in volume) and stirred by centrally located metal bars encased in Perspex and driven by rotating magnets mounted on the cell support platform. Solutions in both chambers were always of the same composition and concentration in lipid, i.e., at chemical but not isotopic equilibrium.

At timed intervals over the period of one experiment, 0.5-ml. samples (usually six in all) were removed from each chamber for radioactivity analysis, but the liquid level at the end of the diffusion period never fell below the top of the diaphragm. Before use the cell was tested for leaks with an impermeable barrier.

Cells were calibrated using KCl as the standard diffusing solute. Chloride ion in stock solutions and in each chamber at the experiment end was determined by AgCl turbidity in 50% ethanol-water (after dilution to reduce Cl⁻ concentration to a convenient level) according to the method of Luce *et al.* (16). The calibration curve at 350 m μ was linear up to 14 mcg./ml. Cl.

Where surfactant diffusion rates were monitored, differential refractometry (in 10-cm. cells) with a Hilger-Rayleigh interferometer was used. The instrument was calibrated with sucrose solutions of known refractive index to give drum readings with respect to the refractive index: $\Delta n/\Delta c = 4.81 \times 10^{-6}$. However, since the solute concentration term in the diffusion equation (discussed later) is independent of the unit of measurement, drum readings were later taken directly as measures of concentration. When such diffusion rates were followed in the presence of lipid, lipid concentrations were such that the refractive index measurement of $\Delta n/\Delta c = 0.140$ ml. g.⁻¹ polyoxyethylene-polyoxypropylene copolymer compared with 0.139 ml. g.⁻¹ polyoxyethylene-polyoxypropylene copolymer in the absence of lipid. From this it was concluded that, at these lipid concentrations, lipid contributed little to the refractive index and that refractive index changes were due mainly to the movement of surfactant.

For radiochemical assay, fatty acids were extracted with a 3:1 v/v quantity of a 1:1:1 v/v/v mixture of ethanol-heptane-diethyl ether. Two further extractions with the upper phase of ethanol-water-heptane-diethyl ether ensured that > 99% of the fatty acid was in the organic extract, the solvent was driven off under dry N₂, and the residue was counted in a liquid scintillation counter⁶ after dissolu-

Figure 1—Semilogarithmic plots of ¹⁴C and ³H isotopic concentration function $(C_{eq} - C)/(C_{eq} - C_0)$ versus time for 4:4:2 mM mono-olein-oleic acid-¹⁴C-palmitic acid-³H equilibrating through 10- μ MP. Key: mM 4:1 sodium taurocholate-sodium taurodeoxycholate: ●, 2.5; ▲, 5.0; ★, 7.5; ○, 10.0; and ■, 15.0.

tion in toluene containing 2,5-diphenyloxazole (4 g./l.) and 1,4-bis-2-(5-phenyloxazoly)benzene (0.05 g./l.) as scintillation solutes. Count times were such as to achieve 1% standard deviation. Corrections for quenching were made by the channels ratio method.

Solutions taken to be nonradioactive at the start of a diffusion period were tested for adventitious amounts of radioactivity.

Emulsions and micellar solutions of lipid were prepared by 5-min. ultrasonic irradiation (40 w. at 20 kc.) at constant anode current on a Branson sonifier.

Solubilization was determined by separation of emulsion and micellar phases by ultracentrifugation at 10⁷ g min. (~36°), at the end of which the lower aqueous micellar phase was sampled and analyzed for radioactivity.

All solutions were 0.15 M NaH₂PO₄/0.07 M Na₂HPO₄ in phosphate buffer at pH 6.4 \pm 0.1, and all experiments were performed at 37 \pm 1°.

RESULTS AND DISCUSSION

Diffusion Equation—The usual application of Fick's law of diffusion as applied to diaphragms (17) is followed:

$$\log \frac{C_{eq} - C}{C_{eq} - C_0} = -\bar{D}_T \left[\frac{A}{2.3l} \frac{V_P + V_Q}{V_P V_Q} \right] t \quad (\text{Eq. 1})$$

where A is the total area of the diaphragm pores exposed at right angles to the direction of flow, l the thickness of the diaphragm (and associated unstirred layers of solution), V_P and V_Q the volumes of

⁵ Polythene.

⁶ Nuclear Chicago.

Figure 2—Fatty acid equilibration rate $\bar{D}_T \beta$ as a function of the reciprocal of the bile salt concentration, 4:4:2 mM monoolein-oleic acid-palmitic acid, through 10- μ MP.

each compartment P and Q , C_{eq} , the concentration or specific activity of the diffusing solute at equilibrium, C_0 initially, and C at time t . \bar{D} is the average value of the diffusion coefficient for the concentration range of the experiment and is expressed as \bar{D}_T to allow for all states of aggregation of fatty acid.

The expression in square brackets is the cell constant β and is determined with KCl, given that $D_{KCl} = 2.45 \times 10^{-5} \text{ cm}^2 \text{ sec}^{-1}$ in 0.5 M solution at 37° (Table I). Three measurements with separate Millipore (MP) filters of each stated pore size were made for β , whereas β for the sintered-glass (SG) disk was obtained from nine separate determinations over the period of use (several months) to detect significant erosion. The 8% variability in β for the SG disk is higher than can be achieved with such diaphragms, but was considered satisfactory for the experiments described here. With SG diaphragms, diffusion coefficients were calculated from one experimental point. Since kinetic curves were not obtained, the results were more liable to error than in the MP procedure. This was partly offset by the duplication of experiments with the SG diaphragms.

Tortuosity and blocked capillaries in MP filters are serious limitations if such structural characteristics are a feature of many pores in the one filter and are not even approximately reproduced from filter to filter. However, the range in β for any one porosity suggested no gross irregularities.

Preliminary experiments established a rate of stirring above which the results were insensitive to stirring rate, *i.e.*, the "still" layers associated with the diaphragm were at their minimum thickness. In this respect, one limitation of the method is whether the dimensions of the unstirred layer are comparable for KCl and lipid solutes. When considered against the overall thickness of the diaphragm, the effect is likely to be small.

With MP filters, semilogarithmic plots of the concentration term-time give acceptable straight lines (Fig. 1). Correlation coefficients were never less than -0.95 . The gradients $\bar{D}_T \beta$, obtained

by regression analysis, were within 8% for both oleic acid and palmitic acid loss from one compartment and gain in the other compartment in any one experiment. Such parallelism in the rates of loss and gain suggest steady-state conditions in the diaphragm and the reasonable balance of activity-limited retention by the diaphragm.

Bile Salts—Effect of Solubilization—Figure 1 shows fatty acid, equilibration rates across a 0.010- μ MP where, in each experiment both chambers P and Q have the same lipid composition (4 mM oleic acid, 2 mM palmitic acid, and 4 mM monoolein), with one chamber containing ^{14}C - and ^3H -labeled fatty acids; bile salt concentrations alter from experiment to experiment. The effect of surfactant concentration on equilibration rate ($\bar{D}_T \beta$) is shown in Fig. 2.

Fatty acid solubilization in this system (Fig. 3a) suggests a CMC in the region 2.0–2.5 mM bile salts with total solubilization above 10.0 mM. When the gradient $\bar{D}_T \beta$ is expressed as a function of the reciprocal of the bile salt concentration (Fig. 2), no change in $\bar{D}_T \beta$ is apparent until the bile salt concentration reaches ~ 7.0 mM. This may be a result of pore blockage by fine globules, so appreciable transport rates are achieved only when there is near total solubilization. On the other hand, the solubilization curve reveals that only 30% of the fatty acid is solubilized at this bile salt concentration and that an increase in the solubilizing power, apparent from the change in the gradient of the solubilization curve, occurs in this region. A significant change in the flux is then to be expected near this surfactant concentration.

Furthermore, although all the lipid was solubilized near 10 mM bile salts, the diffusion function continued to increase with increasing surfactant concentration. At 10 mM bile salts and the stated lipid concentration, about 40 molecules of lipid are associated with each micelle on the basis of an even distribution of solubilizes and an aggregation number of ~ 40 for the bile salt micelle (discussed later). Given the tendency of lipid to swell micelles (18, 19), increasing the concentration of surfactant with the same overall lipid concentration would suggest the formation of more, and smaller, micelles. An increase in the rate of equilibration $\bar{D}_T \beta$ with increasing surfactant concentration is then understandable on the basis of micelle size. The reciprocal concentration plot is made to allow extrapolation to such high bile salt concentrations ($1/C = 0$), *i.e.*, so large a number of micelles that on the average the amount of lipid per micelle (at this fixed total lipid concentration) scarcely alters the dimension of the micelle. The extrapolated \bar{D}_T so determined is $1.7 \times 10^{-6} \text{ cm}^2 \text{ sec}^{-1}$.

Effect of Pore Size—The diffusion coefficient of oleic acid solubilized in bile salts and equilibrating through the SG diaphragm is $3.9 \times 10^{-6} \text{ cm}^2 \text{ sec}^{-1}$ (Table II). The difference between this figure and $1.7 \times 10^{-6} \text{ cm}^2 \text{ sec}^{-1}$ is probably due to the factor ~ 3 between micellar diameter ($\sim 30 \text{ \AA}$) and average pore size not being adequate for the process to approach that of diffusion in free solution, *i.e.*, with no geometrical limitations on movement. This fits with the observation that for the same lipid mixture in 10 mM bile salts equilibrating through a 1.2- μ MP, \bar{D}_T is $4.4 \times 10^{-6} \text{ cm}^2 \text{ sec}^{-1}$ (Table II).

The 20% lower \bar{D}_T when there is a chemical concentration dif-

ference (rather than just an isotopic concentration gradient) is outside the error limits for the experiments described.

For bile salt concentrations below the CMC, that is, lipid exists mainly in the emulsion phase, the kinetic constant is effectively the same when a 0.010- μ MP rather than a 30- μ SG diaphragm is interposed between the equilibrating systems; this figure is an order of magnitude lower than when the lipid is totally solubilized.

Polyoxyethylene-Polyoxypropylene Copolymer—Effect of Pore Size—When each chamber contains lipid of composition 4:4:2 mM in monoolein-oleic acid-palmitic acid and 2 mM polyoxyethylene-polyoxypropylene copolymer, equilibration rates over the MP porosity range from 0.010 to 1.2 μ are as shown in Fig. 4. The CMC for this nonionic surfactant is near 0.10 mM, based on solubilization data in Fig. 3b, and 2.0 mM polyoxyethylene-polyoxypropylene copolymer ensures better than 95% solubilization of fatty acid in the lipid system used. Hence, the interpretation is not complicated by the presence of an emulsion phase. Nevertheless, the equilibration rate is roughly constant over the MP porosity range from 0.010 to 0.200 μ and increases with larger pore sizes, even when variation in the cell constant β is allowed for (lower curve of Fig. 4).

In the lower porosity range, \bar{D}_T is 3.2×10^{-7} cm.² sec.⁻¹ and increases to 9.7×10^{-7} cm.² sec.⁻¹ for the 1.20- μ MP; from this

rate/reciprocal pore dimension display, $\sim 3 \mu$ is the MP dimension at which the diffusion coefficient of fatty acid in the 2.0 mM polyoxyethylene-polyoxypropylene copolymer system approaches that obtained with the SG diaphragm corresponding to free diffusion (Table III). Due to the steep nature of the plot in this region, this can only be an estimate; but the point emphasized is that although the fatty acid is solubilized, the flux is much reduced below 0.200 μ .

Effect of Solubilization—A detailed study of the effect of solubilization on equilibration rate was not carried out in the polyoxyethylene-polyoxypropylene copolymer system, since preliminary experiments suggested that similar effects to the bile salt system were being observed; that is, when micelles are freely transported and emulsion globules restricted in their movement, increased solubilization due to an increasing concentration of surfactant, at a fixed lipid composition, results in an increased flux. The difference is that these effects are observable in the 1- μ pore range compared with 100 times lower for the bile salt micelle.

This behavior is expected from the data in Fig. 5, which summarizes the throughput of fatty acid in ultrafiltration experiments, under a differential pressure of 60 cm. Hg. While only approximate at best, ultrafiltration does show that with increasing polyoxyethylene-polyoxypropylene copolymer concentration the proportion

Figure 4—Fatty acid equilibration rate $\bar{D}_T\beta$, upper curve, \bar{D}_T , lower curve, versus reciprocal of average pore dimension (MP): 4:4:2 mM monoolein-oleic acid-palmitic acid in 2.0 mM polyoxyethylene-polyoxypropylene copolymer.

Figure 5—Ratio of fatty acid, filtrate/unfiltered dispersion as a function of average pore dimension (MP): 4:4:2 mM monoolein-oleic acid-palmitic acid in polyoxyethylene-polyoxypropylene copolymer. Key: oleic acid mM, \bullet , 4.0; palmitic acid mM, \times , 2.0; —, filtration of emulsion-micellar dispersion; and ---, filtration of micellar solution obtained by ultracentrifugation of 2 mM polyoxyethylene-polyoxypropylene copolymer-lipid dispersion.

Table III—Diffusion Coefficients \bar{D}_T in Polyoxyethylene-Polyoxypropylene Copolymer (PPC) Solutions

PPC, mM	Chamber P		Chamber Q		Diaphragm	$\bar{D}_T \times 10^6$ (cm. ² sec. ⁻¹)	
	Lipid, mM	PPC, mM	Lipid, mM	PPC, mM		PPC	Oleic Acid
2.0 (16 mg./ml.)	—	0.1	—	—	30- μ SG	2.68	
2.0	1.0 OA, 1.0 MO	1.0	—	—	30- μ SG	1.83	2.20
						1.89	2.05
						2.63	2.01
						2.49	1.13

2.0	4.0 OA, 4.0 MO	2.0	4.0 OA, 4.0 MO	—	0.010- μ MP		0.32 \pm 0.04
2.0	4.0 OA, 4.0 MO	2.0	4.0 OA, 4.0 MO	—	1.20- μ MP		0.97 \pm 0.11

of fatty acid in the filtrate increases appreciably only with filters above 0.100- μ pore size. Moreover, while the bulk of fatty acid in polyoxyethylene-polyoxypropylene copolymer micellar solution is transmissible through 0.300- μ pores (Fig. 5), pore sizes in excess of 5.0 μ are necessary to recover all the fatty acid from a filtered polyoxyethylene-polyoxypropylene copolymer stabilized emulsion.

By contrast, a 0.010- μ MP under the same hydrostatic pressure retains no fatty acid from an emulsion stabilized with 2.0 mM bile salts.

The diffusion data in the polyoxyethylene-polyoxypropylene copolymer system are summarized in Table III.

Comparison of Micelles of the Two Surfactants—At 37°, pH 6.4, Na⁺ = 0.15 M, and in the absence of lipid, the micellar molecular weights (MMWs) of 4:1 NaTC-NaTDC is 2.0×10^4 (*i.e.*, aggregation number 40) and 5×10^5 for polyoxyethylene-polyoxypropylene copolymer from a light-scattering study made in conjunction with the present investigation. The former value is in fair agreement with $1.2-2.3 \times 10^4$ (depending on the sodium-ion concentration) for the taurodeoxycholate micelle at 25° (20). MMWs of the magnitude found for polyoxyethylene-polyoxypropylene copolymer are not unusual for nonionic surfactants (21).

From the Stokes relation, the diffusion coefficient D is inversely proportional to the radius. If the diffusing entities are roughly spherical and their densities about the same, D is inversely proportional to $\sqrt[3]{\text{MMW}}$. Also, if the two media have about the same viscosity,

$$\frac{D_{BS}}{D_{PPC}} \sim \frac{\sqrt[3]{5 \times 10^5}}{\sqrt[3]{2 \times 10^4}} = 2.9 \quad (\text{Eq. 2})$$

Above the CMC the apparent diffusion coefficient \bar{D}_T is the weighted mean of the coefficient for monomolecular and micellar species (22, 23):

$$\bar{D}_T C_T = D_{\text{mono.}} C_{\text{mono.}} + D_{\text{mic.}} C_{\text{mic.}} = L_1 X_1 + L_2 X_2 \quad (\text{Eq. 3})$$

where C 's are the concentrations (see *Appendix*).

If solubilization does not greatly alter the CMC, *i.e.*, the CMC of each surfactant in the absence of lipid solubilize is close to that in the presence of lipid, then from the observed values of the CMC by the solubilization method and the measured diffusion coefficients of monomeric and micellar surfactant:

$$\frac{\bar{D}_{BS}}{\bar{D}_{PPC}} = \frac{4.9 \times 10^{-6}}{1.6 \times 10^{-6}} \sim 3.0 \quad (\text{Eq. 4})$$

in fair agreement with the expected ratio.

Because of the necessarily lower concentrations of surfactants and the interferometric method of estimation, $D_{\text{mono.}}$ has low accuracy. However, the monomeric contribution to the total flux is relatively small, and relatively large errors in the determination of the diffusion coefficient of monomer result in relatively small changes in $D_{\text{mic.}}$

Correspondingly, using 6×10^{-6} cm.² sec.⁻¹ for the diffusion coefficient of monomeric oleic acid (24) and 4×10^{-6} M for its solubility (6), the diffusion coefficients of the lipid-containing (1.0 mM solutions) bile salt and polyoxyethylene-polyoxypropylene copolymer micelles are 3.9×10^{-6} cm.² sec.⁻¹ and 1.8×10^{-6} cm.² sec.⁻¹, respectively, based on the movement of radioactively labelled fatty acid.

CONCLUSIONS

An increase in the driving force for diffusion of lipid with an increase in solubilization is clearly apparent and, provided that events in the luminal stage determine the kinetics of absorption of fatty acid, this would account for the improved fatty acid uptake observed in everted sacs from micellar systems compared with emulsions (5).

Another factor that emerges from this study is the necessity for unrestricted movement of micelles if their maximum contribution to the diffusive flux is to be achieved. With bile salt micelles, the transport function approaches the diffusion coefficient in free solution for pore sizes somewhat in excess of 10 m μ ; whereas with polyoxyethylene-polyoxypropylene copolymer micelles, dimensions greater than 200 m μ are necessary for unhampered micellar movement.

The significance of these findings to fat absorption *in vivo* is not clearcut, but a reasonable expectation is that incomplete mixing in the gut preserves a layer of fluid near the absorptive cell in which diffusion-controlled processes dominate. Physical restrictions on the movement of micelles due to the microvilli and the associated glycocalyx coat are possible, but further experiments are required to assess their importance.

However, even neglecting the possible existence of a greater macroscopic barrier to the movement of the polyoxyethylene-polyoxypropylene copolymer micelle, the factor of 2 between the diffusion coefficients of the lipid-containing bile salt micelle compared with the lipid-containing polyoxyethylene-polyoxypropylene copolymer micelle would largely account for the difference of absorption rates in everted intestinal sacs observed for the two types of micellar systems.

APPENDIX

The usual application of irreversible thermodynamics is followed.

The flux of fatty acid (*e.g.*, oleic acid) in the systems described may be written

$$J_T = J_1 + J_2 + J_3 \quad (\text{Eq. A1})$$

where the subscripts 1, 2, and 3 refer to the contributions of monomers, micelles, and emulsion globules ("monomer" including all associated forms of fatty acid that exist outside the micelles and emulsions).

Flows and forces are related by

$$J_i = \sum_k L_{ik} X_k \quad \text{where } i = 1, 2, 3 \dots n \quad (\text{Eq. A2})$$

and L_{ik} is the coefficient that expresses the effect of the force X_k on the flow J_i . This set of n equations includes all possible interactions between flows and forces in the system.

In the absence of driving forces such as temperature and pressure gradients, the driving forces are equatable to chemical potential gradients or concentration gradients if the usual equivalence between thermodynamic activity and concentration, at low solute concentrations, is assumed.

Since the flux of surfactant can also be described as the sum of monomer J_I and micellar J_{II} fluxes, the fatty acid flux can be wholly described by

$$J_I = L_I X_1 + L_{II} X_2 + L_{I3} X_3 + L_{I1I} X_1 + L_{I1II} X_{II} \quad (\text{Eq. A3})$$

$$J_2 = L_2X_2 + L_{21}X_1 + L_{23}X_3 + L_{21}X_I + L_{21I}X_{II} \quad (\text{Eq. A4})$$

$$J_3 = L_3X_3 + L_{31}X_1 + L_{32}X_2 + L_{31}X_I + L_{31I}X_{II} \quad (\text{Eq. A5})$$

The first term in each equation is, as expected, an expression of Fick's diffusion law, $J_i = L_iX_i = -D(dc_i)/(dx)$. For example, in Eq. A3 the flux of monomer J_1 is related to the concentration of monomer X_1 through the diffusion coefficient L_1 , the second term takes into account "coupling" between monomer fatty acid and micellar fatty acid, and the third term takes into account coupling between monomer oleic acid and emulsified oleic acid. The last two terms in Eq. A3 allow for association between monomer oleic acid and monomer and micellar surfactant, respectively, and so on for J_2 and J_3 . These equations attempt to account for all associations between fatty acid and surfactant in their different aggregated forms (with the proviso that the presence of monoolein alters the description little).

From the reciprocal relation postulate of Onsager, $L_{12} = L_{21}$, $L_{13} = L_{31}$, etc. The near similarity of \bar{D}_T in an emulsified system when the movement of emulsion globules is, or is not, restricted by the diaphragm, e.g., 0.010- μ MP compared with SG, suggests that the flux of emulsion is small, i.e., $J_3 \sim 0$. Correspondingly and considering the relatively small interface of the emulsion, that is, molecules aggregated in the emulsion must interact less with fatty acid in free solution compared with the extent of interaction if the same amount of material was all dispersed in solution, coupling between emulsion and monomeric and emulsion and micellar fatty acid may be neglected. Then

$$J_1 = L_1X_1 + L_{12}X_2 + L_{11}X_I + L_{11I}X_{II} \quad (\text{Eq. A6})$$

and

$$J_2 = L_2X_2 + L_{21}X_1 + L_{21}X_I + L_{21I}X_{II} \quad (\text{Eq. A7})$$

are the only quantities of importance.

Coupling between surfactant and fatty acid movement should be apparent in the comparison of two systems, one where there is a net concentration gradient of surfactant and the other where chemical concentrations are the same in both chambers, but a difference exists only in the concentration of isotopic label. The identity (within the limits stated) of \bar{D}_T for oleic acid in polyoxyethylene-polyoxypropylene copolymer diffusing in sintered glass under the two conditions described suggests that

$$L_{1I} \sim L_{1II} \sim L_{2I} \sim L_{2II} = 0 \quad (\text{Eq. A8})$$

Considering the weights of monomers and micelles of bile salts compared with polyoxyethylene-polyoxypropylene copolymer, one may be led to expect that if interaction between the flows of fatty acid and surfactant were significant, a lesser effect would be observed with bile salts than with the nonionic surfactant. The reverse is the case, which is the justification for the application of Eq. A8 to the bile salt system.

The argument is somewhat complicated in a system with a solute concentration gradient by the movement of solvent (i.e., water) in the opposite direction to the flow of solute, which may reduce the observed (i.e., mutual) solute diffusion coefficient from the isotopic (\sim differential or thermodynamically ideal) value. However, this solvent flow effect is likely to be small when the chemical potential differences are as small as in the systems described here. The magnitude of solute concentrations in the present work also justifies comparisons between 1 mM and 4 mM lipid systems. Then,

$$J_T = L_1X_1 + L_2X_2 + L_{12}(X_1 + X_2) \quad (\text{Eq. A9})$$

from the mentioned equivalence of L_{12} and L_{21} . L_{12} is likely to be small. But since the extent of this coupling between monomer and micellar fatty acid is uncertain, Eq. A9 is best written

$$J_T = (L_1 + L_{12})X_1 + (L_2 + L_{12})X_2 = L_1'X_1 + L_2'X_2 \quad (\text{Eq. A10})$$

The measured diffusion coefficients L_1' and L_2' equal L_1 and L_2 , respectively, if L_{12} is negligibly small.

Inhibitors of Monoamine Oxidase VI: Effects of Substitution on Inhibitory Activity of 6(or 8)-Substituted β -Carbolines

BENG T. HO, KO-CHIN LI, K. E. WALKER, L. WAYNE TANSEY,
PATRICIA M. KRALIK, and WILLIAM M. McISAAC

Abstract □ A number of 6(or 8)-substituted aromatic β -carbolines were synthesized, and their inhibitory activities toward monoamine oxidase were compared with their tetrahydro congeners. A considerable difference in the effects of 6(or 8)-substitution on the inhibitory activities existed between these aromatic and tetrahydro- β -carbolines. Influence of 9-methyl substitution on activities was greater with the tetrahydro than the aromatic series; as a result, 9-methyltetrahydro- β -carbolines were generally much better inhibitors of the enzyme than the corresponding 9-hydrogen-tetrahydro- β -carbolines. An amino group at C₁ of β -carboline caused a fivefold decrease in inhibitory activity. This decrease was likely due to the steric hindrance by the bulk of the amino group. Aromatic β -carbolines were prepared by the palladium-on-charcoal catalyzed dehydrogenation of the corresponding tetrahydro- β -carbolines. Methylation of the N₉ of aromatic β -carboline was carried out with methyl iodide in the presence of sodium hydride. Nitration of β -carboline gave a mixture of two isomeric products, 6- and 8-nitro- β -carbolines, which were separated with hot chloroform. Catalytic reduction converted the nitro compounds to 6- and 8-amino- β -carbolines, respectively. The positions of the amino group was confirmed by NMR spectrometry.

Keyphrases □ Monoamine oxidase inhibitors—synthesis □ β -Carbolines, 6(or 8)-substituted—synthesis □ Structure-activity relationship—monoamine oxidase inhibitors □ NMR spectroscopy—structure □ UV spectrophotometry—structure

In the previous papers (1, 2) the monoamine oxidase inhibitory activity of several 6(or 8)-substituted tetrahydro- β -carbolines and their 9-methyl analogs has been reported. It was found that, in general, replacement of hydrogen on the C₆ position of tetrahydro- β -carboline (Ia) caused a slight reduction in inhibitory activity. An even greater decrease of activity resulted when the same position of 9-methyltetrahydro- β -carboline (Ib) was substituted (1). Introduction of a methyl group on C₈ of Ia and Ib, however, did not affect the activity of these two compounds. In the present study, a number of 6(or 8)-substituted aromatic β -carbolines (V–XV) were synthesized, and their inhibitory activities were compared with those of the tetrahydro series.

A considerable difference in the effects of 6(or 8)-substitution on the inhibitory activities existed between these aromatic β -carbolines and their tetrahydro congeners. Replacement of the C₆-hydrogen of II by a methoxy group resulted in nearly a 1.5 time decrease in activity (Table I, Compound VI), whereas a greater loss (fourfold) of activity was observed by a similar substitution in the tetrahydro series (Table II Compounds Ia and Ic). When the 9-methyl compounds of each series were compared, 6-methoxy substitution on the 9-methyltetrahydro- β -carboline (Ib) gave Compound Id, which was 10 times less active than Ib as an inhibitor; however, only less than a threefold decrease in activity of 9-methyl- β -carboline (III) resulted from

the conversion of III to 6-methoxy-9-methyl- β -carboline (VII). Substitution of chlorine on the C₆ position had less effect on both series, because X was equally as active as II, and Ie was only slightly less active than Ia. The greater (fourfold) loss of activity resulting from the methyl substitution of C₆ of II was unexpected in view of the similarity in sizes among CH₃, Cl, and OCH₃ and the weaker electron-donating nature of CH₃ than OCH₃.

It was reported earlier (1) that a methyl group on C₈ of Ia and Ib exerted little effect on the inhibitory activity (Table II, Compounds If and Ig). The same substitution on C₈ of the aromatic series, on the other hand, caused a reduction in the inhibition of the enzyme; XIII and XIV were, respectively, 2.5 and 2.0 times weaker inhibitors than II and III.

Effects of 9-methyl substitution were greater in the tetrahydro than in the aromatic series. For instance, a 34-fold increase in activity was achieved by the methylation of Ia to Ib, a 13-fold increase from Ic to Id,¹ and nearly a 24-fold increase from If to Ig (Table II). Introduction of a methyl group to N₉ of II gave only a threefold increase in inhibition; a 1.5 time increase was observed as a result of conversion of VI to VII, a 1.7 time increase from VIII to IX, and a 3.6 time increase from XIII to XIV (Table I). These data further indicated that if aromatic β -carbolines and their tetrahydro congeners were bound at the same site on monoamine

¹ The previously reported value of 3.6 mM (1) should be the I₅₀ for 2-methyl-6-methoxy-1,2,3,4-tetrahydro- β -carboline.

^a All data from References 1 and 2.

oxidase, it would appear to have different binding conformations for each series (3).

Decreases of 22- and 20-fold, respectively, in activity were found when an amino group was placed on either C₆ or C₈ of II (Table I, Compounds XI and XV). Such magnitude of reduction in activity, however, was not observed with the 6-methoxy compound (VI). Since the amino group is smaller in size than the methoxy group, the greater loss of activity found with XI and XV was, therefore, not due to the steric hindrance caused by the substituent on C₆ or C₈.

Replacement of C₁-hydrogen of II with an amino group resulted in about a fivefold decrease in activity. In view of the finding that V was an inhibitor of equal activity as 1-methyl-β-carboline (IV), this decrease was most likely attributed to the steric hindrance by the bulk of the amino or alkyl group (2).

CHEMISTRY

Aromatic β-carbolines, such as 6-methoxy-(VI), 6-methyl-(VIII), 6-chloro-(X), 8-methoxy-(XII), and 8-methyl-(XIII), were prepared by the palladium-on-charcoal (Pd-C) catalyzed dehydrogenation of the corresponding 1,2,3,4-tetrahydro-β-carbolines (I) in boiling xylene (Scheme I). The reaction would appear to require a

Scheme I

fresh and active catalyst; in a few instances when an old catalyst was used in the preparation of methoxylated β-carbolines, only the starting material was recovered. Due to the availability of 8-methyl-1-oxotetrahydro-β-carboline commercially, the preparation of XIII by the present method was simpler and more economical than by the method of Cook *et al.* (4) who utilized the condensation of 7-methyltryptophan with formaldehyde, followed by K₂Cr₂O₇ oxidation. The synthesis of 8-methyltetrahydro-β-carboline (If) has previously been reported (1).

The very low yield of Compound X was apparently attributed to the dehalogenation of the 6-chloro atom by Pd-C during the dehydrogenation; unsubstituted β-carboline (XVI) was isolated as a by-product. Attempts to prepare X by other methods were unsuccessful. Substitution of Raney nickel for Pd-C as the

Scheme II

catalyst resulted in the isolation of an equal amount of the unchanged 6-chlorotetrahydro-β-carboline (Ie) and the dehalogenated product II. No reaction took place when 1-oxo-6-chlorotetrahydro-β-carboline was refluxed with phosphorus oxychloride. This reagent has been reported to give 9-alkyl-β-carbolines from 1-oxo-9-alkyl-1,2,3,4-tetrahydro-β-carbolines (5). Chloranil (tetrachloro-*p*-benzoquinone) has been shown to be an excellent dehydrogenating agent for the preparation of carbazoles from tetrahydrocarbazoles (6). However, the use of *p*-benzoquinone in the dehydrogenation of 6-chlorotetrahydro-β-carboline failed to give X.

Methylation of VIII and XIII with methyl iodide in the presence of sodium hydride gave the dimethyl-β-carbolines IX and XIV, respectively (Scheme II). 1-Amino-β-carboline (V) was obtained from the treatment of β-carboline (II) with sodium amide according to the procedure reported in the literature (9) (Scheme III).

Scheme III

Nitration of β-carboline (II) and the reduction of the nitro-β-carboline to amino-β-carboline have been reported by Saxena (7). In his preparation, only one isomer was isolated. The position of the nitro group was not established other than to assume that it was the 6-nitro-β-carboline (XVI). No indication was given by Saxena on whether the 6-nitro-β-carboline prepared by him was free of contamination of other isomers. However, in carrying out the nitration of 1-methyl-β-carboline, Synder *et al.* (8) reported the isolation of two products. The higher-melting nitro compound (67% yield) was then reduced, diazotized, and converted to a bromo compound whose physical properties were identical with those of 6-bromo-1-methyl-β-carboline. The position of the nitro group in the lower-melting compound (20% yield) was assumed by them to be the isomer 8-nitro-1-methyl-β-carboline.

In the present work, two isomeric nitro-β-carbolines from the nitration of II (Scheme IV) were found to vary with their *R_f* values on TLC, retention times on gas chromatograms, as well as IR and UV spectra. Separation of these two isomers was achieved by the difference in their solubilities in hot chloroform. Reduction of the nitro group by Pd-C catalyst gave 6-amino-β-carboline (XI) and 8-amino-β-carboline (XV), respectively (Scheme IV). The authors chose to differentiate the positions of the amino group in the two products, XI and XV, by their NMR spectra; XI (60 Mc.p.s.): τ (D₂O-DCI),

Scheme IV

1.31 (singlet, H-1), 1.80 (doublet, $J = 6.0$ c.p.s., H-3), 1.89 (doublet, $J = 6.0$ c.p.s., H-4), 1.94 (doublet, $J = 2.0$ c.p.s., H-5), 2.27 (doublet of doublets, $J = 2.0$ and 8.7 c.p.s., H-7), 2.57 (doublet, $J = 8.7$ c.p.s., H-8). Due to the limited solubility of XV in D_2O -DCl, its NMR spectrum was run with a 100 Mc.p.s. spectrometer: τ (D_2O -DCl), 0.82 (singlet, H-1), 1.44 (doublet, $J = 6.3$ c.p.s., H-3), 1.55 (doublet, $J = 6.3$ c.p.s., H-4), 1.67 (doublet, $J = 7.9$ c.p.s., H-5), 2.07 (doublet, $J = 7.9$ c.p.s., H-7), 2.48 (triplet, $J = 7.9$ c.p.s., H-6). An earlier attempt to convert 6-nitrotetrahydro- β -carboline into XVI, which could then be used for further characterization of the 6-nitro isomer, was unsuccessful.

EXPERIMENTAL²

Preparation of Substituted Aromatic β -Carbolines from Tetrahydro- β -carbolines—A mixture of 20 mmoles of the corresponding substituted 1,2,3,4-tetrahydro- β -carbolines (1, 2) in 150 ml. of xylene and 500 mg. of 5 or 10% Pd-C catalyst was refluxed for 6 hr. or overnight and then filtered hot. The filtrate was cooled in ice; the deposited product was collected on a filter and recrystallized from a suitable solvent. Accordingly, the following compounds were prepared: 6-methoxy- β -carboline (VI), 45%, m.p. 206–207° (toluene); λ_{max} (EtOH) 217, 234, 249, 259 (s), 292, 299, 361, 371 μ .

Anal.—Calcd. for $C_{17}H_{10}N_2O$: C, 72.71; H, 5.09; N, 14.14. Found: C, 73.01; H, 4.77; N, 14.09.

6-Methyl- β -carboline (VIII)—27%, m.p. 190–191° (benzene); λ_{max} (EtOH) 220, 240, 255 (s), 265 (s), 285, 297, 357, 372 μ .

Anal.—Calcd. for $C_{15}H_{10}N_2$: C, 79.09; H, 5.53; N, 15.37. Found: C, 79.19; H, 5.55; N, 15.11.

6-Chloro- β -carboline (X)—0.9%, m.p. 270–271° (chloroform); λ_{max} (EtOH) 238, 249, 331, 345 μ .

Anal.—Calcd. for $C_{11}H_7ClN_2$: C, 65.20; H, 3.48; N, 13.82. Found: C, 65.49; H, 3.38; N, 13.96.

8-Methoxy- β -carboline (XII)—62%, m.p. 204–205° (xylene); λ_{max} (EtOH) 216, 243, 268, 278, 287, 343, 354 (s) μ .

Anal.—Calcd. for $C_{17}H_{10}N_2O$: C, 72.71; H, 5.09; N, 14.14. Found: C, 72.68; H, 5.11; N, 14.04.

8-Methyl- β -carboline (XIII)—90%, m.p. 233–234.5° (benzene); λ_{max} (EtOH) 217, 237, 338, 352 μ . A 229–230° m.p. has been reported for this compound, which was prepared by the treatment of 7-methyltryptophan with formaldehyde followed by potassium dichromate oxidation (4).

6-Methoxy-9-methyl- β -carboline (VII)—Ether-HCl was added to the xylene filtrate and the hydrochloride salt of VII was collected on a filter; yield, 83%, m.p. 254–257°. Recrystallization from EtOH gave 50%, m.p. 258–259°; λ_{max} (EtOH) 220, 235, 248, 270, 286 (s), 292, 299, 370, 380 μ . A 262–263° m.p. has been recorded for the hydrochloride salt of VII prepared by the treatment of the 1-oxo-6-methoxy-9-methyltetrahydro- β -carboline with $POCl_3$ (5).

Alkylation of Substituted β -Carbolines—8,9-Dimethyl- β -carboline (XIV)—To a stirred suspension of 0.2 g. (12 mmoles) of 8-methyl- β -carboline (XIII) in 20 ml. of dimethylformamide was added slowly 0.6 g. (17 mmoles) of sodium hydride (50% suspension in mineral oil). After stirring at room temperature for 4 hr., the mixture was cooled in ice, and 1.8 g. (13 mmoles) of methyl iodide was added. Stirring was continued overnight, and 150 ml. of chloroform was then added. The chloroform layer was washed with water (ten 100-ml. portions), dried (anhydrous sodium sulfate), and evaporated *in vacuo*, leaving an oil. When a solution of this oil in 150 ml. of dry ether was mixed with an excess of ether-HCl, a hydrochloride salt of the product precipitated. Recrystallization from ethanol gave 1.8 g. (65%), m.p. 298–300°.

Anal.—Calcd. for $C_{13}H_{12}N_2 \cdot HCl$: C, 67.10; H, 5.63; N, 12.04. Found: C, 66.75; H, 5.86; N, 11.98.

A small portion of this hydrochloride salt was neutralized with 10% sodium hydroxide to yield 8,9-dimethyl- β -carboline (XIV), m.p. 69–71°; λ_{max} (EtOH) 247, 292, 350, 364 μ . A 68–70° m.p. has been recorded for the compound prepared from 1,7-dimethyltryptophan and formaldehyde followed by oxidation of the condensation product with potassium dichromate (4).

6,9-Dimethyl- β -carboline (IX)—In a similar manner as the preparation of XIV, a mixture of 1.6 mmoles of 6-methyl- β -carboline

(VIII) in 10 ml. of dimethylformamide and 2.8 mmoles of sodium hydride was stirred for 30 min. Methyl iodide (2.8 mmoles) was added, and the stirring was continued for 1 hr. The product, m.p. 121–122°, was obtained in a 38% yield. Recrystallization from benzene-hexane did not raise the melting point; λ_{max} (EtOH) 220, 238, 255 (s), 265, 285, 297, 357, 367 μ .

Anal.—Calcd. for $C_{13}H_{12}N_2$: C, 79.56; H, 6.16; N, 14.27. Found: C, 79.73; H, 6.24; N, 14.13.

1-Amino- β -carboline (V)—This was prepared from β -carboline (II) and $NaNH_2$ according to the procedure of Snyder *et al.* (9), m.p. 200–201° (lit. m.p. 198–200°); λ_{max} (EtOH) 225, 243, 256 (s), 273 (s), 280, 290, 339, 353 μ .

Nitration of β -Carboline—A mixture of 4.96 g. (29 mmoles) of β -carboline (II) and 60 ml. of concentrated nitric acid was stirred at ice temperature for 2 hr. and then heated on a steam bath until the solid dissolved (approximately 15 min.). The hot solution was poured onto 30 g. of crushed ice, and the bright-yellow solid that precipitated was collected on a filter and washed several times with water. This nitrate salt was dissolved in a minimum amount of water (about 900 ml.). Upon neutralization with 10% sodium hydroxide, the free amine precipitated; yield 4.88 g. (78%). Both silica gel TLC [$CHCl_3$ -MeOH (9:1)] and gas chromatography (3% SE 30 on Varaport 30) showed that it was a mixture of two products.

The mixture was treated with about 4 l. of hot chloroform and then immediately filtered. The insoluble solid, 2.64 g. (42%) and with $R_f = 5.8$, was recrystallized 3 times from acetone to give 850 mg., m.p. 340–342°; λ_{max} (EtOH) 237, 267, 295, 350 μ .

Anal.—Calcd. for $C_{11}H_7N_3O_2$: C, 61.97; H, 3.31; N, 19.71. Found: C, 61.83; H, 3.39; N, 19.54. The assignment of 6-nitro- β -carboline (XVI) to this compound was based on the NMR spectrum of its reduction product, 6-amino- β -carboline (XI).

When this chloroform filtrate was evaporated *in vacuo*, 1.65 g. (26%) of bright-yellow solid was obtained. Two recrystallizations from a minimum amount of dimethylformamide gave 0.5 g., m.p. 320° dec.; $R_f = 7.3$. λ_{max} (EtOH) 228, 263, 292, 302 μ .

Anal.—Calcd. for $C_{11}H_7N_3O_2$: C, 61.97; H, 3.31; N, 19.71. Found: C, 62.01; H, 3.45; N, 19.68. On the basis of the NMR spectrum of its reduction product (XV), the compound was believed to be the 8-nitro- β -carboline (XVII).

6-Amino- β -carboline (XI)—A mixture of 0.85 g. (4 mmoles) of 6-nitro- β -carboline (XVI), 200 ml. of ethanol, and 0.5 g. of 5% Pd-C catalyst was shaken with hydrogen at an initial pressure of 3 atm. until the consumption of hydrogen ceased. After filtration, the solution was evaporated *in vacuo*, and the residue was twice recrystallized from ethanol yielding 0.33 g. (45%) of product, m.p. 302–303° [lit. (7) m.p. 268°]; λ_{max} (EtOH) 242, 296, 304, 381 μ . Silica gel TLC [butanol-acetic acid-water (4:1:1)]: $R_f = 4.5$.

Anal.—Calcd. for $C_{11}H_9N_3$: C, 72.11; H, 4.95; N, 22.94. Found: C, 71.81; H, 5.50; N, 22.69.

8-Amino- β -carboline (XV)—In a similar manner as described in the preparation of XI, the 8-nitro- β -carboline (XVII) was catalytically reduced. The product, 8-amino- β -carboline was recrystallized from ethanol-ether to yield 62%, m.p. 242° dec.; λ_{max} (EtOH) 232, 252, 292, 360 μ . Silica gel TLC [*n*-butanol-acetic acid-water (4:1:1)]: $R_f = 6.4$.

Anal.—Calcd. for $C_{11}H_9N_3$: C, 72.11; H, 4.95; N, 22.94. Found: C, 71.90; H, 5.11; N, 22.69.

Assay—Mitochondrial monoamine oxidase from beef liver was isolated and purified as previously described (2). All the stock solutions of inhibitors, except VIII and IX, were prepared in 0.01 N HCl. Compounds VIII and IX were dissolved in 0.02 N HCl. Incubation was carried out with tryptamine-2- ^{14}C hydrochloride according to the previously described procedure (2).

Kinetics and Mechanisms of Action of Drugs on Microorganisms XI: Effect of Erythromycin and Its Supposed Antagonism with Lincomycin on the Microbial Growth of *Escherichia coli*

EDWARD R. GARRETT, SAMUEL M. HEMAN-ACKAH, and GEORGE L. PERRY

Abstract □ The steady-state growth of *Escherichia coli* in broth cultures is inhibited by erythromycin with a new steady-state growth-rate constant (k_{app}), which is linearly related to drug concentrations in the range 0–10.0 mcg. ml.⁻¹ as $k_{app} = k_0 - k_E E$, where k_E is the inhibitory-rate constant for drug concentration E of drug-free rate constant k_0 . The k_{app} at $E > 10.0$ mcg. ml.⁻¹ adheres to a kinetic model, which implies the saturation of a limited number of receptor sites in accordance with the equation $k_{app} = k_0 - k_a E / (1 + k_b E)$, where k_a and k_b are constants of proportionality related to drug concentration partitioned into the biophase and its affinity for available receptor sites. The dependence of *E. coli* growth rate on drug concentrations is invariant with the organism population or broth concentrations. However, values for k_a increase 10-fold as the pH of broth is increased from 6.80 to 7.80 while k_0 remains constant. This indicates that the unprotonated fraction of the drug concentration contributes to the activity. Lincomycin in Phase I-affected growth has the same formal dependency on concentration as does erythromycin with a potency ratio of 6.68:1, erythromycin base to lincomycin base, on a weight basis. The combined effects of erythromycin and lincomycin in Phase I of its effect are not antagonistic on the growth rate of *E. coli* in the subinhibitory range and can be predicted on the basis of adding equivalent amounts in accordance with the coincident response-dose curves of erythromycin and lincomycin (Phase I).

Keyphrases □ Erythromycin effect—*Escherichia coli* steady-state growth □ Lincomycin growth, Phase I—erythromycin effect □ Reversibility—erythromycin antimicrobial activity □ Microbiological analysis—erythromycin action on *E. coli* □ Kinetics—erythromycin action on *E. coli*.

The mode of action of the macrolide erythromycin is generally ascribed to inhibition of protein synthesis (1–9). Erythromycin binds exclusively to the 50 S subunit of ribosomes from *Escherichia coli* (1, 4, 10), *Staphylococcus aureus* (11), *Bacillus subtilis* (6, 8, 12), *Bacillus megaterium* (2, 13), and *Bacillus stearothermophilus* (2) in reconstituted cell-free systems to inhibit polypeptide synthesis which has been stated to be a rapid and reversible process (8). Tanaka *et al.* (4) observed maximum binding of the 50 S ribosomal subunit of *E. coli* Q. 13 at very low concentrations of

erythromycin (~0.6 mcg. ml.⁻¹). Only about one-tenth of that amount was found to bind to the ribosomes of resistant mutants.

It has been speculated (8) that erythromycin competes with the transport RNA carrying the peptidyl radical involved in amino acid polymerization for a common binding site on the 50 S subunit of ribosomes. An alternative proposed model (12) for erythromycin's protein inhibition is that it inhibits a "translocase" factor which is necessary for the transfer of the peptidyl t-RNA elongated by a single aminoacyl residue from a ribosomal acceptor site to a donor site.

Conflicting views have been expressed about the modes of action of those antibiotics (*e.g.*, erythromycin, lincomycin, and chloramphenicol), which are supposed to have the common 50 S ribosomal binding site (7, 8, 10, 12). In fact, combinations of erythromycin and lincomycin have been claimed to be antagonistic (2, 3, 8, 10, 12), which would not necessarily follow from an assumption of similar modes of action.

The application of microbial kinetics to the quantification and prediction of antimicrobial action has been demonstrated (14–22). The effects of subinhibitory concentrations of drugs on the growth of bacteria have been studied in simple reproducible systems with *E. coli* strain B/r as the test organism to derive kinetic parameters that may characterize antibacterial action and drug-receptor interaction and to provide insight into the possible mechanisms of drug action.

This paper presents the results of such studies on the action of erythromycin on the growth of *E. coli*. It considers the formal dependence of the kinetic constants of growth inhibition on antibiotic concentration as affected by inoculum size, composition and pH of the media, and reversibility of the erythromycin concentrations. In addition, the actions of combinations of erythromycin and lincomycin on microbial growth, as compared with their *a priori* expectation, are considered.

The dependence of *E. coli* growth rate on drug concentrations is invariant with the organism population or broth concentrations. However, values for k_a increase 10-fold as the pH of broth is increased from 6.80 to 7.80 while k_0 remains constant. This indicates that the unprotonated fraction of the drug concentration contributes to the activity. Lincomycin in Phase I-affected growth has the same formal dependency on concentration as does erythromycin with a potency ratio of 6.68:1, erythromycin base to lincomycin base, on a weight basis. The combined effects of erythromycin and lincomycin in Phase I of its effect are not antagonistic on the growth rate of *E. coli* in the subinhibitory range and can be predicted on the basis of adding equivalent amounts in accordance with the coincident response-dose curves of erythromycin and lincomycin (Phase I).

Keyphrases □ Erythromycin effect—*Escherichia coli* steady-state growth □ Lincomycin growth, Phase I—erythromycin effect □ Reversibility—erythromycin antimicrobial activity □ Microbiological analysis—erythromycin action on *E. coli* □ Kinetics—erythromycin action on *E. coli*.

The mode of action of the macrolide erythromycin is generally ascribed to inhibition of protein synthesis (1–9). Erythromycin binds exclusively to the 50 S subunit of ribosomes from *Escherichia coli* (1, 4, 10), *Staphylococcus aureus* (11), *Bacillus subtilis* (6, 8, 12), *Bacillus megaterium* (2, 13), and *Bacillus stearothermophilus* (2) in reconstituted cell-free systems to inhibit polypeptide synthesis which has been stated to be a rapid and reversible process (8). Tanaka *et al.* (4) observed maximum binding of the 50 S ribosomal subunit of *E. coli* Q. 13 at very low concentrations of

erythromycin (~0.6 mcg. ml.⁻¹). Only about one-tenth of that amount was found to bind to the ribosomes of resistant mutants.

It has been speculated (8) that erythromycin competes with the transport RNA carrying the peptidyl radical involved in amino acid polymerization for a common binding site on the 50 S subunit of ribosomes. An alternative proposed model (12) for erythromycin's protein inhibition is that it inhibits a "translocase" factor which is necessary for the transfer of the peptidyl t-RNA elongated by a single aminoacyl residue from a ribosomal acceptor site to a donor site.

Conflicting views have been expressed about the modes of action of those antibiotics (*e.g.*, erythromycin, lincomycin, and chloramphenicol), which are supposed to have the common 50 S ribosomal binding site (7, 8, 10, 12). In fact, combinations of erythromycin and lincomycin have been claimed to be antagonistic (2, 3, 8, 10, 12), which would not necessarily follow from an assumption of similar modes of action.

The application of microbial kinetics to the quantification and prediction of antimicrobial action has been demonstrated (14–22). The effects of subinhibitory concentrations of drugs on the growth of bacteria have been studied in simple reproducible systems with *E. coli* strain B/r as the test organism to derive kinetic parameters that may characterize antibacterial action and drug-receptor interaction and to provide insight into the possible mechanisms of drug action.

This paper presents the results of such studies on the action of erythromycin on the growth of *E. coli*. It considers the formal dependence of the kinetic constants of growth inhibition on antibiotic concentration as affected by inoculum size, composition and pH of the media, and reversibility of the erythromycin concentrations. In addition, the actions of combinations of erythromycin and lincomycin on microbial growth, as compared with their *a priori* expectation, are considered.

EXPERIMENTAL

Organism—Replicate slants of *E. coli* strain B/r were used in all experiments. The slants had been prepared from a single colony and were stored in a refrigerator at 4°.¹

Culture Media—Bacto Antibiotic Medium 3² was rehydrated according to the specifications of the manufacturer to peptone broth USP. The media were filtered twice through Millipore 0.45- μ HA filters and autoclaved at 120° for 15 min. The pH of the media was 7.05 \pm 0.05, with the exception of those that were used to study the antibacterial activity as a function of pH. To obtain media with a pH in the range of 6.8–7.8, various amounts of Millipore-filtered 1.7 N HCl and 2 N NaOH, respectively, were added to the culture media aseptically after the sterilization.

Antibiotic—An assayed sample of erythromycin lactobionate³ (670 mcg. base eq. mg.⁻¹) was used and will be referred to here as erythromycin I. An assayed sample of lincomycin hydrochloride⁴ (895 mcg. base eq. mg.⁻¹) was also used. The references to concentrations of drugs throughout this paper refer to these samples of antibiotics.

Bacterial Cultures—An aliquot (5 ml.) of culture medium was inoculated from a fresh slant, and the culture was allowed to grow for 12 hr. at 37.5° in an incubator. A sample of 0.5 ml. was then diluted 100-fold into fresh medium. The growth of the culture was followed up to 2×10^7 *E. coli* ml.⁻¹. Samples of 0.5 ml. of this culture (undiluted or suitably diluted in broth) were finally added to replicate volumes of 49.0 ml. broth in loosely capped 125-ml. conical flasks. The growth of culture was followed to a desired inoculum size, and 0.5 ml. of drug was added. The cultures were maintained at 37.5 \pm 0.1° in a 50-gal. constant-temperature water bath equipped with a shaker. All pipets and media used for the dilutions of the cultures were prewarmed to protect the organisms from temperature shocks.

Total Count Method—The method has been previously described (16). Samples of 1.00 ml. were withdrawn at 20-min. intervals from the cultures. They were diluted to obtain counts within a range of 10,000–30,000 counts/50 μ l. on the Coulter counter, model B.⁵ The diluent used was a Millipore 0.45- μ HA-filtered aqueous solution of 0.85% NaCl and 1% formaldehyde. The instrument was equipped with a 30- μ orifice. The settings were: aperture current, 5; amplification, 8; gain, 10; lower threshold, 13; and upper threshold, maximum. The total counts were corrected for the background count of the particular batch of medium used and diluted in the same way as the sample. The background counts in general did not exceed 1000 counts/50 μ l.

Viable Count Method—Samples of 0.50 ml. were withdrawn from the cultures and appropriately diluted into sterilized 0.85% saline solution so that 50–150 colonies per plate would result. From these dilutions, aliquots of 1.00 ml. were pipetted onto each of three replicate agar plates. The plates were incubated for 48 hr. at 37.5°, and the colonies were counted on a Colony counter, model C-110.⁶

Effect of Antibiotic Concentration on Growth Rates—Fresh solutions of the respective antibiotics were aseptically prepared for each experiment. They were sufficiently diluted so that aliquots of 0.5 ml. added to 49.5 ml. culture volumes yielded the desired drug concentrations (Table I). The solutions were added to the cultures growing at 37.5° in the logarithmic phase at an organism population of 1.3×10^6 *E. coli* ml.⁻¹. Samples were withdrawn every 20 min. and counted by both the viable and total cell count methods. One culture without drug was studied in each experiment as the control to obtain the growth-rate constant in absence of the drug. The growth curves for 0–250 mcg. ml.⁻¹ at pH 7.05 were obtained (Fig. 1). A similar experiment was performed for 0–50 mcg. ml.⁻¹ erythromycin I, but counts were obtained by only the total cell count method (Fig. 2).

¹ The strain B/r of *E. coli* is an "in house" strain originally obtained from the Bacteriology Department of the University of Maine (Dr. D. B. Pratt) and has been used in both the Departments of Bacteriology and Pharmaceutics of this university for the last 10 years. In previous publications on "Kinetics and Mechanisms of Action of Drugs on Microorganisms I–X" (14–22), the authors have referred to this *E. coli* as strain B/r. A sample of this strain is being sent to the American Type Culture Collection for appropriate "official" numbering.

^a $n = 1$ for erythromycin; $n = 0.2$ for lincomycin, i.e., actual concentration of lincomycin is five times that stated. ^b Calculated from the slope of the plot of k_{app} versus concentration from 0 to 10 mcg. ml.⁻¹ erythromycin I or 0 to 100 mcg. ml.⁻¹ lincomycin HCl. ^c k_a , k_b , and k_a/k_b are estimated from the slopes and intercepts of $D/(k_0 - k_{app})$ versus D , where D is concentration of drug and k_0 is k_{app} at $D = 0$ for the expression $D/(k_0 - k_{app}) = D(k_b/k_a) + 1/k_a$ for erythromycin I > 10 mcg. ml.⁻¹ and lincomycin HCl in the steady-state Phase I > 100 mcg. ml. and for all studied lincomycin concentrations in the second steady-state Phase II that occurs after several generations of lincomycin-affected growth (22).

Effect of Broth Concentration on Drug-Affected Growth Rates—Various strengths of peptone broth USP, buffered at pH 7, were prepared so that the concentrations of broth ingredients were

Figure 1—Semilogarithmic plot of *E. coli*/ml. against time after broth inoculation in the presence of erythromycin I. Each curve is labeled in terms of micrograms per milliliter of erythromycin I. The open symbols are total counts obtained by the Coulter counter. The solid symbols are viable counts obtained by colony counts.

Figure 2—Typical semilogarithmic plots of *E. coli* growth by total counts (Coulter) in the presence of the labeled concentrations of erythromycin I in micrograms per milliliter at 37.5° and pH 7.05.

normal, halved, and doubled. Six replicate 49.5-ml. volumes of each kind were inoculated with 0.5 ml. culture containing 2×10^7 *E. coli* ml.⁻¹ in the logarithmic growth. They were maintained at 37.5°; when the cell concentration reached 10^6 ml.⁻¹, 0.5 ml. of drug solutions was added to achieve erythromycin I concentrations ranging from 5–80 mcg. ml.⁻¹ (Table II). The sixth replicate contained no drug. Coulter counts were obtained from samples withdrawn every 20 min.

Effect of Organism Population on Drug-Affected Growth Rates—Each flask of three sets of six replicate 49.5-ml. volumes of culture medium was inoculated with 0.5 ml. of appropriately diluted culture growing in the logarithmic phase. The three sets were allowed to grow at 37.5° to cell concentrations of 1.6×10^4 , 1.3×10^6 , and 1.1×10^6 *E. coli* ml.⁻¹, respectively. Aliquots (0.5 ml.) of drug solutions were added to achieve erythromycin I concentrations from 2.5–12.5 mcg. ml.⁻¹ (Table III). One culture in each set contained no drug. Coulter counts were obtained from samples withdrawn every 20 min.

Reversibility of Drug Action—A 49.5-ml. volume of broth was inoculated at zero time with *E. coli* to a cell concentration of 2×10^6 ml.⁻¹ (Figs. 3 and 4). The culture was allowed to grow at 37.5°

(Curves A). At 50 min., when the growth was in the logarithmic phase and the cell concentration was 10^6 *E. coli* ml.⁻¹, 0.5 ml. of a sufficiently diluted erythromycin I solution was added to achieve a final concentration of 50 mcg. ml.⁻¹ (Curves B). At 125 min., after the culture of Curve B had settled into a new steady-state growth, aliquots of 5 and 0.5 ml. were added to 45 and 49.5 ml. fresh broths, respectively, so that both organisms and drug concentrations were diluted 10-fold (Curve C, Fig. 3) and 100-fold (Curve D, Fig. 4). The drug-free culture of Curve A was likewise diluted 10-fold (Curve E, Fig. 3) and 100-fold (Curve F, Fig. 4). At the same time, aliquots of the cultures of Curve B (Figs. 3 and 4) were diluted 10-fold (Curve G, Fig. 3) and 100-fold (Curve H, Fig. 4), respectively, in broths containing enough erythromycin I so that the drug concentration was restored to 50 mcg. ml.⁻¹. Dilutions of the cultures of Curve B were also made 10-fold (Fig. 3) and 100-fold (Fig. 4) in broths (Curves I and J) containing enough erythromycin I to increase the drug concentration about 2-fold (i.e., 100 mcg. ml.⁻¹).

At 200 min., when the cultures of Curves C containing 5 mcg. ml.⁻¹ (Fig. 3) and 0.5 mcg. ml.⁻¹ (Fig. 4) of erythromycin I had emerged from the lag phase, 0.5-ml. aliquots of solutions containing enough erythromycin I were added to reestablish both drug concentrations to 50 mcg. ml.⁻¹ (Curves K, Figs. 3 and 4).

Whenever any variation was effected, samples of the broth culture were taken and counted on the Coulter every 10 min. for the first 30 min. and thereafter at intervals of 30 min.

Effect of pH on Drug-Affected Growth Rates—Sufficient amounts of 1 N HCl and 2 N NaOH were added to the broth to obtain pH values of 6.80, 7.05, 7.20, 7.60, 8.20, and 8.40 (Fig. 5). Six replicate 49.5-ml. volumes of each broth were inoculated with 0.5 ml. of appropriately diluted *E. coli* culture in the logarithmic phase of growth. They were maintained at 37.5° until the organism population reached 10^6 *E. coli* ml.⁻¹. Drug solutions (0.5 ml.) were added to five replicates to achieve the desired concentrations of antibiotic shown in Fig. 4. The sixth replicate in each set contained no drug. Coulter counts were obtained from samples withdrawn every 20 min.

Comparison of Growth Rates of Erythromycin-Affected Organisms with Lincomycin-Affected Organisms—Solutions (0.5 ml.) of erythromycin I were added to five replicate 49.5-ml. volumes of broth inoculated with *E. coli* in the logarithmic phase of growth and containing an organism population of 10^6 ml.⁻¹ at 37.5°. The final concentration of the drug achieved in the broths ranged from 2.5 to 50 mcg. ml.⁻¹ erythromycin I. This was repeated for concentrations of lincomycin HCl, from 12.5 to 250 mcg. ml.⁻¹ (Table I). Counts were obtained from samples withdrawn every 20 min. The relationships between the apparent growth-rate constants, $k_{app.}$, and drug concentrations are shown in Fig. 6.

Action of Erythromycin and Lincomycin Combinations—Replicate 49-ml. samples of cultures in the steady-state growth (Curve A, Fig. 7) with 10^6 ml.⁻¹ *E. coli* were treated with antibiotic solutions. Aliquots (0.5 ml.) of appropriately diluted erythromycin I or lincomycin HCl solutions were added to separate cultures of Curve A 50 min. after inoculation. The resultant plots are given as Curve B in Fig. 7 for final concentrations of 15.8 mcg. ml.⁻¹ of erythromycin I or 60 mcg. ml.⁻¹ of lincomycin HCl or as Curve D for final concentrations of 31.6 mcg. ml.⁻¹ of erythromycin I or 120 mcg. ml.⁻¹ of lincomycin HCl. Seventy-five minutes after the addition of the drug, when the culture had settled to a new steady-state growth, aliquots (0.5 ml.) of appropriately diluted lincomycin HCl or erythromycin I solutions were added to the replicate solution that had been treated previously with the alternate drug. The resultant curve

Figure 3—Semilogarithmic plots of reversibility studies of *E. coli* growth with time on addition of erythromycin I and 1:10 dilution of culture with broth. Curve A is without drug. Curve B is after addition of 50 mcg./ml. Curves C, E, F, and G are after 1:10 dilution of the Curve B culture and have final drug concentrations of 5, 50, 100, and 50 mcg./ml., respectively. The dilution broth contained the erythromycin I in the cases of Curves E and F. There was no drug in the diluent in the case of Curve C, and drug was added at 200 min. for Curve G. Curve D is after 1:10 dilution of the culture of Curve A with no drug added.

for both replicates, independent of the order of addition, was Curve C, Fig. 7. The final concentrations of the drugs in the cultures, represented by Curve C, were 15.8 mcg. ml.⁻¹ erythromycin I and 60.0 mcg. ml.⁻¹ lincomycin HCl. Coulter counts were obtained on samples that were withdrawn from the treated cultures every 20 min.

Effect of Mixtures of Graded Equipotent Concentrations of Erythromycin and Lincomycin—Equipotent solutions of 42.55 mcg. ml.⁻¹ erythromycin I and 200 mcg. ml.⁻¹ lincomycin HCl were prepared. They were then mixed in graded proportions using 100–0% of the lincomycin solution and the residual percentage of the erythromycin solution (Fig. 8). This was repeated to give nine graded equipotent mixtures for each of three antibiotic equivalent concentrations. Replicate 49.5-ml. cultures in steady-state growth that contained 10⁶ *E. coli* ml.⁻¹ were each inoculated with an aliquot (0.5 ml.) of one of the antibiotic mixtures. Coulter counts were obtained for samples withdrawn every 20 min.

RESULTS

The addition of graded concentrations of erythromycin to growing balanced cultures of *E. coli* strain B/r demonstrated a linear semilogarithmic plot (Figs. 1–4) shortly after the addition or dilution of the antibiotic concentration in accordance with Eq 1:

$$\ln N = k_{app}.t + \text{intercept} \quad (\text{Eq. 1})$$

where N is the number of organisms, t is time, and $k_{app.}$ is obtained from the slope of the appropriate plots in the steady-state growth. In the absence of antibiotic, $k_{app.}$ is k_0 and the intercept is the natural logarithm of the inoculum size, $\ln N_0$, at time zero.

Coincidence of Total and Viable Counts of Organisms—The coincidence of total (Coulter count) and viable (colony count) numbers of *E. coli* ml.⁻¹ in drug-free and in erythromycin-treated growing balanced cultures could not be denied for all erythromycin concentrations up to 150 mcg. ml.⁻¹ (Fig. 1). There is no significant evidence of kill in the time intervals studied at doses above the inhibitory concentrations. This evidence of the bacteriostatic action of erythromycin permits the use of total counts to determine the growth rates of organisms affected by subinhibitory concentrations of erythromycin.

Effect of Drug Concentrations on Growth Rates—The derived apparent growth-rate constants, $k_{app.}$ (Eq. 1), for various concen-

trations of erythromycin I were obtained from the slopes of the plots of Fig. 2 and are listed in Table I.

The extent of inhibition is directly proportional to the erythromycin I concentration, E , in the range 0–10 mcg. ml.⁻¹ in accordance with the expression:

$$k_{app.} = k_0 - k_E E \quad (\text{Eq. 2})$$

where k_E is defined as the specific inhibitory-rate constant. The $k_{app.}$ is not a linear function of increasing drug concentration when $E > 10$ mcg. ml.⁻¹, but it asymptotically approaches zero (Figs. 5 and 6). A plot of $E/(k_0 - k_{app.})$ versus E is reasonably linear for those concentrations >10 mcg. ml.⁻¹ but shows deviations at concentrations of 0–10 mcg. ml.⁻¹. This implies quantitative adherence of the action of erythromycin I on *E. coli* to a previously derived kinetic model (20, 22):

$$\frac{E}{(k_0 - k_{app.})} = E \left(\frac{k_b}{k_a} \right) + \frac{1}{k_a} \quad (\text{Eq. 3})$$

at erythromycin I concentrations, $E > 10$ mcg. ml.⁻¹. The k_a and k_b are constants of proportionality, which may be related to drug availability in the biophase and drug affinity to receptor or binding sites. The calculated values for the constants k_a and k_b were obtained from the slope and intercept of the linear portion of such a plot in accordance with Eq. 3. Typical plots are given for the data of Fig. 5 in Fig. 9.

Analysis of Culture Broth Variations—The apparent growth-rate constants, $k_{app.}$, obtained at different concentrations of erythromycin I at different concentrations of nutrients in broth are given in Table II. Variation of these growth-rate constants among the different broths is not significantly different from that observed in daily variation in organism growth rates. There is no significant inactivation or binding of the erythromycin by broth constituents at the nutrient concentrations studied.

Effect of Organism on Drug-Affected Growth Rates—The apparent growth-rate constants, $k_{app.}$, for *E. coli* obtained at various concentrations of erythromycin I for three different organism concentrations at the time of drug addition are given in Table III. There are no significant differences among the growth rates for the different organism concentrations at any drug concentration in the range studied. In the absence of any evidence for systematic influence of organism population on growth-rate constants, it is

Figure 4—Semilogarithmic plots of reversibility studies of *E. coli* growth with time on addition of erythromycin I and 1:100 dilution of culture with broth. Curve A is without drug. Curve B is after addition of 50 mcg./ml. Curves C, E, F, and G are after 1:100 dilution of the Curve B culture and have final concentrations of 0.5, 50, 100, and 50 mcg./ml., respectively. The dilution broth contained the erythromycin I in the cases of Curves E and F. There was no drug in the diluent in the case of Curve C, and drug was added at 200 min. for Curve G. Curve D is after 1:100 dilution of the culture of Curve A with no drug added.

Figure 5—Dependence of the apparent growth-rate constant, k_{app} , in sec.^{-1} , for *E. coli* on erythromycin concentration at various pH values and at 37.5° .

Figure 6—Demonstration of the coincidence of the dependencies of the apparent growth-rate constants, k_{app} , in sec.^{-1} , for *E. coli* at 37.5° and pH 7.05 on equipotent concentrations of erythromycin I and lincomycin HCl. Curve A represents this dependence, where the closed symbols are for erythromycin I and the open symbols for lincomycin HCl in its Phase I growth and where the actual concentrations of lincomycin HCl are five times the stated values. The dashed line, Curve B, demonstrates the linear dependency of k_{app} on drug concentration at low drug concentrations. Curve C represents the k_{app} dependence for Phase II steady state of lincomycin-affected microbial growth.

concluded that the drug is neither metabolized by the organisms nor depleted in the medium as a result of adsorption to cellular components, inactivation by excretory products of metabolism, and other interactions which may be functions of organism numbers. The effective drug concentrations may, therefore, be assumed to remain constant over the period of study.

Reversibility of Drug Action—The equilibrium of drug between the nutrient medium and the biophase in the microorganism is readily achieved. It took about 30–50 min. after drug addition for the culture to attain a new steady-state phase of growth (Figs. 1–3). The steady-state growth of *E. coli* inhibited by 50 mcg. ml.^{-1} erythromycin I (Curves B in Figs. 3 and 4) reverted to a new steady state when diluted 10-fold and 100-fold, respectively (Curves C in Figs. 3 and 4). The new growth-rate constants were coincident with those found in the presence of the resultant concentrations of the drug, i.e., 5 and 0.5 mcg. ml.^{-1} , respectively. The new steady state was attained after 20–30 min. of an apparent initial lag phase. Both drug-free (Curves D in Figs. 3 and 4) and drug-affected cultures (Curves C in Figs. 3 and 4) showed this initial lag period on dilution into fresh broth, so that this may be attributed to a possible need for cell rejuvenation before reestablishment of the new steady state or to a consequence of the shock of dilution.

Cultures inhibited by low concentrations of the drug, i.e., 5 and 0.5 mcg. ml.^{-1} erythromycin I, were further inhibited by addition of more drug to a final concentration of 50 mcg. ml.^{-1} , with predictable growth-rate constants (Curves G in Figs. 3 and 4). The time for equilibration of drug between the medium and biophase was also 20–30 min. Similarly, 10-fold and 100-fold dilutions of the culture of Curve B by fresh medium with the same concentration of drug (Curves E of Figs. 3 and 4) achieved similar steady-state growth rates after the same initial lag phase periods of 20–30 min. There were no significant changes in growth-rate constants. A similar dilution of the culture of Curve B into fresh medium containing high concentrations of the drug to increase the final concentration twofold (Curves F of Figs. 3 and 4) produced further inhibition and new steady-state growth rates were attained after 20–30 min. with predictable rate constants.

Thus it was concluded that the action of subinhibitory concentrations of erythromycin on intact *E. coli* cells is readily reversed in finite time intervals. Time lags introduced by dilution effects were the same in the presence or absence of erythromycin.

Effect of pH on Drug-Affected Growth Rates—The apparent growth-rate constants, k_{app} , obtained for *E. coli* in broth at pH values 6.80–8.40 in the absence and presence of graded erythromycin I concentrations are plotted in Fig. 5. Growth-rate constants for drug-free cultures are not significantly affected by pH; the values for drug-affected cultures are significantly decreased at

higher pH values for the same erythromycin concentrations (Fig. 5). Since it has been shown (22) that numbers of microorganisms in the

Figure 7—Nonsignificant effects of order of addition of equipotent erythromycin I and lincomycin HCl on growth rates of *E. coli*. Curve A is for growth of *E. coli* in the absence of drug. Curve B is for growth of *E. coli* in the presence of 15.8 mcg./ml. erythromycin I (closed symbols) or equipotent 60 mcg./ml. lincomycin HCl (open symbols). Curve C is when equipotent lincomycin HCl (60 mcg./ml.) is added to the erythromycin-affected culture of Curve B (closed symbols), or when equipotent erythromycin I (15.8 mcg./ml.) is added to the lincomycin-affected culture of Curve B (open symbols). Curve D is when 200 mcg./ml. lincomycin HCl (open symbols) and 31.6 mcg./ml. erythromycin I (closed symbols) are added to the culture of Curve A.

Figure 8—Effect of continuously varied erythromycin I and lincomycin HCl fractions in equipotent mixtures at three different potency levels on the apparent growth-rate constants, k_{app} , in sec^{-1} , of *E. coli* at pH 7.05 and 37.5° . Erythromycin I is presumed to be five times as potent as lincomycin HCl on a weight-to-weight basis.

Figure 9—Demonstration of saturation kinetics for the action of erythromycin I at higher concentrations, E , on the apparent growth-rate constants, k_{app} , of *E. coli* at 37.5° . The curves are labeled as to the pH values of the media and are plotted in accordance with the expression $E/(k_0 - k_{app}) = (k_b/k_a)E + 1/k_a$ where k_b/k_a and $1/k_a$ are the slopes and intercepts, respectively, and k_0 is the rate constant in the absence of drug.

Figure 10—Semilogarithmic plot of the apparent inhibitory-rate constant, k_a , for the effect of erythromycin I on the growth of *E. coli* at 37.5° . The drawn line is consistent with the expression $k_a = k_a^* (K_a/(K_a + [H^+]))$, where $k_a^* = 1.11 \times 10^{-3} \text{ ml./mcg.-sec.}$ is the intrinsic inhibitory-rate constant for the nonprotonated erythromycin I of $pK_a' 8.8$, and k_a is obtained from $k_{app} = k_0 - k_a E/(1 + k_b E)$.

growing culture have no significant effect on the pH of the medium up to 10^8 ml^{-1} organisms, the variations in growth-rate constants are attributed to variations in the initial pH values of the broths. The calculated values of k_a obtained from the intercepts of the plots of Fig. 9 in accordance with Eq. 3 are plotted as a function of pH in Fig. 10. The values of k_a increased about 10-fold for a unit increase in the pH over the range 6.80–7.60. The slope of the $\log k_a$ versus pH plot tended to lessen above that pH value.

Effect of Order of Addition of Lincomycin and Erythromycin on Microbial Growth—The dependence of the growth-rate constants of erythromycin-affected cultures on drug concentration is similar to that of lincomycin-affected cultures in Phase I of growth (22). The plot of k_{app} versus concentration (Fig. 6) for erythromycin I is coincident with that for lincomycin HCl when the actual lincomycin concentration is reduced by an average factor of 5.0. This implies that 5.0 weight units of lincomycin HCl are equipotent to 1.0 weight unit of erythromycin I, i.e., there is a molar potency ratio of 11.9. Aqueous solutions of erythromycin I lose potency during storage at refrigerator or room temperature. Consequently, the potency ratio between erythromycin I and lincomycin HCl may be far less than the figure quoted, unless freshly prepared aqueous solutions are compared.

There were no significant differences among the growth-rate inhibitions produced by $31.6 \text{ mcg. ml}^{-1}$ of erythromycin I (Curve D, Fig. 7), equipotent 120 mcg. ml^{-1} lincomycin HCl (Curve D, Fig. 7), and equipotent combinations of $15.8 \text{ mcg. ml}^{-1}$ erythromycin I and $60.0 \text{ mcg. ml}^{-1}$ lincomycin HCl (Curve C, Fig. 7) where Curves C and D had the same slopes. Also there was no significant difference in the effective inhibition by the combinations (Curve C, Fig. 7) when the equipotent amount of erythromycin I was added after 75 min. of lincomycin-affected growth (Curve B, Fig. 7) or when the equipotent lincomycin HCl was added after 75 min. of erythromycin-affected growth (also Curve B, Fig. 7). Thus, the order of addition of the antibiotics showed no significant difference in ultimate growth inhibition.

Effect of Mixtures of Graded Equipotent Concentrations of Erythromycin and Lincomycin—The growth-rate constants of cultures affected by mixtures of erythromycin and lincomycin are plotted in Fig. 8. The mixtures contained 100–0% erythromycin I and the residual percentage of equipotent lincomycin HCl solution. The mixtures were prepared so as to be *a priori* equipotent in their combined action on *E. coli* growth, in accordance with Fig. 6, at three different levels of action. The null slopes of the plots of the k_{app} for all the *a priori* equipotent mixtures demonstrate the lack of any significant bacteriostatic antagonism or synergism (23) in the subinhibitory range.

DISCUSSION

The steady growth rates of *E. coli*, as affected by concentrations of erythromycin, are unaffected by significant changes in the constituents of the nutritive media (Table II) and by organism population (Table III). The extent of inhibition of growth ($k_0 - k_{app.}$) is not directly proportional to drug concentration over the complete range (Fig. 6) in accordance with Eq. 2 and suggests that some saturable process, such as the binding of the drug to a limited number of receptor sites, may become rate determining at higher drug concentrations.

An operative kinetic model, similar to that which defined the kinetics of lincomycin action (22) on *E. coli*, may be applied:

where E , the erythromycin concentration in the culture medium, is in equilibrium with E_1 , the concentration within the cell or biophase, which reversibly binds to a free receptor site R to form a drug-receptor complex E_1R . On the basis of the assumption that the rate of increase in microbial numbers in a balanced culture is proportional to a net rate of protein synthesis above a minimum rate required for life-sustaining processes and is proportional to the number of organisms initially present in the culture, the following expression has been derived (18) to quantify the extent of inhibition of growth produced by the action of the drug:

$$k_0 - k_{app.} = \frac{k_a E}{1 + k_b E} \quad (\text{Eq. 5})$$

where k_0 is the growth-rate constant of the drug-free culture; $k_{app.}$ is the growth-rate constant of culture affected by the concentration, E , of erythromycin; $k_b = K_1 K_2$, the product of the partition coefficient, K_1 , and the affinity constant, K_2 , of Eq. 4; and $k_a = q K_1 K_2$, where q is a proportionality constant. It may be that at low drug concentrations ($0-10$ mcg. ml^{-1}), the inhibition of microbial growth is affected by reaction of the drug with only a small fraction of the available receptor sites. Thus K_2 , k_a , and k_b are small with $k_b E \ll 1$; Eq. 5 simplifies to Eq. 2, which is an expression for the observed linear dependence of the growth-rate constant on the drug concentration in this concentration range (Fig. 6 and Table I).

At higher drug concentrations, >10 mcg. ml^{-1} , it is possible that the already complexed receptor sites either reduce the availability of remaining sites by steric effects, configurational changes, protective colloid action, etc., or transform them to another type of reduced but constant affinity. Whatever the mechanism, it takes progressively greater concentrations of the drug to bind the remaining sites. Thus, the $k_{app.}$ does not remain linearly dependent on erythromycin concentrations. The arithmetic transformation of Eq. 5 is Eq. 3, so that the linear plots of $E/(k_0 - k_{app.})$ versus E for concentrations >10 mcg. ml^{-1} (Fig. 9) demonstrate adherence of the data to Eq. 5. The calculated value of $k_a/k_b = 117.25 \times 10^{-6}$ from such a plot (Table I) is approximately $2 k_0$, and it is the same with lincomycin (22).

The addition of the drug to a balanced culture results in inhibition of growth, with a new steady state of growth attained after 30-50 min. (Figs. 1-4). Dilution of drug-affected organisms into drug-free or drug-containing media established a new steady-state growth of the culture within similar time intervals. The rate transitions were no slower than those occurring on dilution of the drug-free culture into fresh media. Cultures inhibited by erythromycin reverted to growth rates coincident with those found in the presence of very small concentrations of the antibiotic when they were diluted into fresh broths. Conversely, cultures inhibited by low concentrations of the antibiotic were further and quickly inhibited by addition of more antibiotics to predictable growth-rate constants (Figs. 3-6). It is concluded that the action of erythromycin on bacterial culture is readily reversible.

Progressively larger amounts of erythromycin are needed to produce the same degree of inhibition of growth of *E. coli* as the pH is increased (Fig. 5). This confirms the literature (24, 25) that the minimum inhibitory concentration (M.I.C.) for erythromycin action on Gram-positive and Gram-negative organisms decreases with an increase in pH. Erythromycin base has a $\text{pK}_a = 8.8$ (25), and the enhanced antibacterial action observed at higher pH values may be assigned to the unprotonated fraction, f , of the total drug which contributes to the activity. If it is postulated that only the unprotonated species partitions into the microorganism (26), the

inhibitory-rate constant, k_a , of Eq. 5 should be a function of this unprotonated fraction, f , and then

$$k_a = k_a^* f = k_a^* \left(\frac{K_a}{K_a + [\text{H}^+]} \right) \quad (\text{Eq. 6})$$

where the intrinsic inhibitory-rate constant of the unprotonated species is $k_a^* = q K_1^* K_2$, K_1^* is the intrinsic partition coefficient between medium and microbial biophase for the uncharged species, $q K_2$ is invariant in that the biophase pH is considered constant, and f can be defined by the parenthetical expression of Eq. 6 (22).

A plot of $\log k_a$ versus pH must, therefore, approach a slope of unity when $[\text{H}^+] > K_a$, and the slope should tend to decrease as K_a becomes less than $[\text{H}^+]$, as in Fig. 10. The calculated value for k_a^* is $11.08 \pm 0.70 \times 10^{-4}$ (ml./mcg.-sec.), from which it is estimated that at pH 8.8 the activity of erythromycin will be 30-fold that at pH 7.0.

The coincidence of the plot of $k_{app.}$ against concentration for erythromycin I and lincomycin HCl in Phase I (22) (Fig. 6), when the latter is presumed to have one-fifth the potency of erythromycin on a weight basis, is not inconsistent with the same mechanisms of action for the two antibiotics. Antagonism would not be predicted for the action of combinations of these two antibiotics (23) on the premise of this same peculiar dependency of growth inhibition on dose (Fig. 6). This *a priori* prediction for *E. coli* is well verified by the fact that equipotent mixtures of lincomycin and erythromycin demonstrate the same inhibitory effect on the growth of *E. coli* at any magnitude of inhibition in the subinhibitory range (Fig. 8). Also, the sequence of addition of erythromycin and lincomycin produced no differences in growth-rate inhibition when the resultant drug combinations were equipotent (Fig. 7). For freshly prepared solutions, when the potencies of the antibiotic samples are taken into account, erythromycin base is 6.68 times as potent as the lincomycin base at 37.5° and pH 7.05 in the system against *E. coli*.

These observations are consistent with the facts that each of these compounds binds to the 50 S ribosomal subunit (2, 3, 7, 9, 10) in cell-free extracts and thus may inhibit polypeptide synthesis similarly in the intact living cell by interfering with the function of transfer RNA. If there is no peculiar or physicochemical interaction, the combined action of the two drugs should be predictable on the basis of the potencies determined from their individual dose-response relations (23) and assigned to their relative ability to compete for binding sites, where the relative potencies are functions of the products of their relative affinity for the receptor site, K_2 , and their partition into the biophase, K_1 , as per Eq. 4.

Since the *a priori* prediction and the kinetic results do not demonstrate antagonism, the problem is to reconcile this condition with the statements of supposed antagonism that exist in the literature (2, 3, 8, 10, 12). Most of these statements of antagonism are based on studies of protein synthesis in cell-free extracts, where the criteria of effect are degrees of amino acid incorporation (3, 8) where added erythromycin is supposed to reverse the inhibition of amino acid incorporation by lincomycin. It is apparent, however, that in balanced growth cultures of intact cells such as *E. coli*, no such antagonistic effects appear.

The present studies on such combinations were based on the Phase I lincomycin-affected steady state of *E. coli* growth (22). However, lincomycin has a second mode of action on a growing culture after prolonged contact with the cells. The $k_{app.}$ dependency on lincomycin concentration during this Phase II steady state of lincomycin-affected growth is different from that of the Phase I dependency and that of erythromycin-affected growth (Fig. 6). Thus, Phase II lincomycin effects may be expected to be different than erythromycin, and the observed cell-free antagonisms may be possible. The action of combinations of erythromycin and lincomycin in Phase II will be investigated further to test this hypothesis.

Biosynthesis of Deuterated Benzylpenicillins I: Solvent Deuterium Oxide Participation

BRUCE C. CARLSTEDT*, HENRY L. CRESPI, MARTIN I. BLAKE†, and JOSEPH J. KATZ

Abstract □ The 53-414 strain of *Penicillium chrysogenum* was cultured in a defined medium containing glucose, acetate, lactate, and phenylacetic acid as carbon sources and 99.8% deuterium oxide as solvent. Partially deuterated benzylpenicillin was isolated from the culture. The extent of solvent participation in the biosynthesis of the penicillin molecule was determined by analysis of the proton magnetic resonance spectra. Incorporation of deuterium appears almost complete at two positions: the C-3 position of the thiazolidine ring and the C-6 position of the β -lactam ring. A partial incorporation of deuterium at the C-5 position is also observed. The deuterium atoms in the C-5 and C-6 positions apparently arise during biosynthesis of the amino acid cysteine. The deuterium atom at the C-3 position apparently arises either in the biosynthesis of the amino acid valine or in the closing of the thiazolidine ring.

Keyphrases □ Deuterated benzylpenicillin—biosynthesis □ *Penicillium chrysogenum* cultures—benzylpenicillin deuteration □ Biosynthesis, deuterated benzylpenicillin—*P. chrysogenum* cultures □ Proton magnetic resonance—analysis, structure □ IR spectrophotometry—structure

A variety of organisms has been successfully cultured in pure deuterium oxide (D_2O) (1); in several instances, pharmacologically active principles containing deuterium have been isolated and studied. Nona *et al.* (2-4) studied the effects of D_2O on the growth of *Penicillium janczewskii*. Deuterated griseofulvin was isolated and its antifungal activity evaluated. Mrtek *et al.* (5, 6) cultured a strain of *Claviceps purpurea* in D_2O and examined the biosynthesis of deuterated clavine alkaloids isolated from the culture. Katz and Crespi (7) reviewed the literature on isotope effects in biological systems.

Shaffer *et al.* (8) observed the effects of D_2O on the growth rate and morphology of *Penicillium notatum*, but

penicillin production was not investigated. Mohammed *et al.* (9, 10) reported the effects of D_2O on the growth and antibiotic production of 13 low-producing strains of two species of *Penicillium* and three high-producing strains of *Penicillium chrysogenum*. Here again, deuterated antibiotic was not isolated. Behrens *et al.* (11) synthesized deuterophenylacetyl- ^{15}N -DL-valine and found the deuterophenylacetyl moiety was incorporated into the benzylpenicillin molecule. Demain (12) used partially deuterated benzylpenicillin, which contained five deuterium atoms in the benzene ring, to study the stability of penicillin during fermentation. Laskar and Mrtek (13) synthesized and studied the activity of a benzylpenicillin which was fully deuterated in the benzyl moiety. A reduction in antibiotic activity was reported.

In the present study, *P. chrysogenum* 53-414, a mutant of the Wisconsin Q-176 strain, was cultured in a defined medium containing D_2O as the solvent. Partially deuterated benzylpenicillin was isolated, and the degree of solvent participation in its biosynthesis was determined by proton magnetic resonance (PMR) analysis of this isotope hybrid compound.¹

EXPERIMENTAL

Preparation of Slants—*P. chrysogenum*, Wisconsin strain 53-414, was obtained from the American Type Culture Collection (number 12690) in the lyophilized form. Agar slants were prepared as described by Mohammed *et al.* (9). The lyophilized material was suspended in Difco nutrient broth, streaked on the surface of the agar

slants, and allowed to grow at room temperature for 5–7 days. The agar slants were stored at 5°; fresh slants were prepared every 4–6 months from lyophilized spores.

Preparation of Seed Culture—The seed culture medium was prepared according to the formula shown in Table I. The pH of the medium was adjusted to 6.9 with 25% KOH prior to the addition of CaCO₃. Fifty milliliters of medium was transferred into a series of 250-ml. conical flasks, and the flasks were autoclaved. Each flask was inoculated with a loopful of the aerial mycelium from an agar slant and placed on an Eberbach rotary shaker at 185–190 r.p.m. for 96 hr. The resulting inoculum, consisting of pellets ranging from 1 to 3 mm. in diameter, was recovered aseptically by collection on filter paper in a Büchner funnel. For H₂O cultures, the mycelial pad was washed with distilled water and stored in a sterile container. For D₂O cultures, the mycelial pad was rinsed once with distilled water, rinsed twice with D₂O, and stored in a sterile container.

Water Culture Techniques—The protio medium was prepared according to the formula shown in Table I. The pH was adjusted to 6.85 with 25% KOH (aqueous) prior to autoclaving. Three hundred and fifty milliliters of the medium was added to a series of 2-l. conical flasks and autoclaved. Twenty-eight grams (wet weight) of the seed culture mycelium was added to each culture flask by aseptic technique. All flasks were placed on an Eberbach rotary shaker at 185–190 r.p.m. for approximately 160 hr. at which time the cultures were harvested. Phenylacetic acid (PAA), as the potassium salt, was added as a sterile solution at the rate of 29.2 mg. PAA/350 ml. culture medium/day. Protio cultures were used as controls and for penicillin isolation studies.

Deuterated Culture Methods—A modified replacement technique was used for culturing *P. chrysogenum* in D₂O. The D₂O nutrient medium (Table II) differed from that of the protio cultures in the following ways: D₂O replaced water as the solvent, a vitamin mixture (Table II) was added, and a daily addition of carbohydrate was required. The D₂O nutrient medium was adjusted to apparent² pH (15) 6.9 with 25% KOH in D₂O; 50 ml. was transferred into 250-ml. conical flasks and autoclaved. One milliliter of the vitamin mixture was added to each flask. Each flask was inoculated with 4 g. (wet weight) of mycelial pad which had been previously rinsed with D₂O. The flasks were allowed to ferment on an Eberbach rotary shaker at 185–190 r.p.m. for approximately 160 hr. Anhydrous D-glucose, exchanged once with D₂O, was dissolved in sufficient D₂O to give a final concentration of 0.125 g./1.5 ml., transferred to a multiple-dose vial, and autoclaved.

PAA in D₂O was neutralized with 2.5% KOH in D₂O. The solution was diluted with D₂O to give a final concentration of 4.17 mg./0.5 ml., added to a multiple-dose vial, and autoclaved.

Daily addition of the D-glucose and PAA was accomplished with a sterile syringe and needle by injection through the cotton plug.

Bioassay Procedures—A 1-ml. aliquot of the culture medium was removed each day by means of a sterile disposable pipet and was placed in a 3-ml. test tube which was stoppered to reduce dilu-

Table II—Composition of D₂O Nutrient Culture Medium and Vitamin Mixture

D ₂ O Nutrient Culture Medium		Vitamin Mixture ^a	
Dextrose	1.00 g.	Biotin	0.005 g.
Standard salt mixture ^b	10.00 ml.	Inositol	0.005 g.
NH ₄ OH	0.55 g.	Ca pantothenate	0.005 g.
Acetic acid	0.273 g.	Pyridoxine HCl	0.005 g.

tion of the deuterium by atmospheric moisture. The aliquot was used for three analyses: pH or apparent pH, penicillin titer, and D₂O content where applicable. The USP XVII (16) bioassay procedure was employed, except that the test organism was *Sarcina lutea* (17), obtained from the American Type Culture Collection (number 9341). The organism was maintained on an agar slant of Difco Bacto Antibiotic Medium 1 and was reslanted every 7–10 days. A 10-ml. base layer of Difco Bacto Antibiotic Medium 2 and a 6-ml. seed layer of Difco Bacto Antibiotic Medium 1 were utilized. Sodium penicillin G³ was used as the reference standard. Microliter (10–100) portions of the aliquot were diluted to 10 ml. with 1% phosphate buffer, pH 6.0. Reference standard penicillin was included with each cup plate assay. The plates were incubated at 30° for 18–24 hr. A graph of inhibition zone diameter versus penicillin concentration was plotted. Titer values were read from the graph, multiplied by the dilution factor, and expressed as units per milliliter of culture medium. No correction factor was applied for the deuterated penicillin. All values of penicillin are in terms of sodium penicillin G reference.

Determination of pH—The pH of the protio cultures and the apparent pH of the D₂O nutrient cultures were determined daily on the aliquot removed from the culture medium.

Deuterium Analysis—D₂O content was determined daily by the spectrophotometric method of Crespi and Katz (18). Aliquots for analysis were centrifuged to yield a clear sample prior to determination.

Extraction Procedures—Centrifugation of the broth and mycelium and vacuum filtration on a Büchner funnel through double filter paper yielded a culture broth which contained essentially all of the penicillin produced in the fermentation. The extraction procedure was modified from a general solvent transfer method described by Chain (19). The method utilized amyl acetate, buffer, chloroform, and water as the four separate extraction steps. The method of Seifter and Richardson (20) involved amyl acetate, bicarbonate buffer, ether, and silica gel column with buffer elution as the four extraction steps. In the present study, butyl and/or amyl acetate were used as the nonpolar solvents. The broth was cooled to 3–5° in an ice-salt bath, acidified to pH 2.0 with phosphoric acid, and then shaken with cold (0–5°) 20% butyl acetate in amyl acetate saturated with water. Emulsions were broken by centrifugation. The butyl acetate-amyl acetate fraction was extracted with cold (0–5°) 3% pH 7 phosphate buffer. The buffer fraction was acidified to pH 2.0 and extracted with cold (0–5°) amyl acetate saturated with water. The amyl acetate fraction was extracted into distilled water with 2.5% KOH until the pH approached 7 as recorded on the pH meter. The water fraction was lyophilized, and the crude extract was stored in a vacuum desiccator.

Isolation and Identification of Penicillin—Initial purification of the crude extract was accomplished by recrystallization. The crude extract was dissolved in 85% acetone in water and kept cold in an ice-salt bath. Small flakes of penicillin formed upon addition of cold acetone. These flakes were isolated by centrifugation, dissolved in water, lyophilized, and the residue was stored in a vacuum desiccator. This proved to be sufficient purification for the protio penicillin, but further purification was required for the partially deuterated penicillin. The *N*-ethyl piperidine salt of the partially deuterated penicillin was prepared (21) and recrystallized, first from chloroform by additions of cold acetone and then from chloroform by additions of cold amyl acetate. The *N*-ethyl piperidine salt of a reference

² The apparent pH of a D₂O solution is that pH observed with a pH meter. The pH of a solution is the apparent pH plus 0.4 unit.

penicillin G was also prepared for comparative purposes. The IR spectrum of isolated material was obtained with a Beckman IR 7 spectrophotometer using a Nujol mull on Irtran II plates. The PMR spectra were obtained on a Varian HA 100 spectrometer (probe temperature at 31 °) after dissolving the sample in 0.01 M phosphate D₂O buffer (apparent pH 7.4) or in deuteriochloroform. The lock material was hexamethyldisiloxane (HMS), internally for deuteriochloroform solutions and as an external capillary for D₂O solutions. The chemical shifts for D₂O solutions (Table III) were referred to 3-(trimethylsilyl)-1-propanesulfonic acid sodium salt (DSS). The chemical shifts for the CDCl₃ solutions (Table IV) were referred to tetramethylsilane (TMS). Bioassays were performed on the partially deuterated penicillin as described under *Bioassay Procedures*.

RESULTS AND DISCUSSION

It has been demonstrated on numerous occasions that organisms cultured in media containing high concentrations of heavy water experience a severe inhibition in the biosynthesis of metabolic products. Experiences of the authors with ergot alkaloids (6), belladonna alkaloids (22), penicillin (9, 10), and griseofulvin (2) have been reported. Thus, poor yields of penicillin obtained in this study (Fig. 1) were not unexpected, nor does this represent a serious deterrent in studying the biosynthesis of this antibiotic.

Isolation of penicillin on a laboratory scale has been described (11) but does present certain difficulties, principally because of the extreme instability of penicillin at pH values below and above neutral. This is compounded in the present studies by low titer values imposed by the inhibitory effects of heavy water and by the necessity for developing a defined medium for biosynthetic studies.

Figure 1—Typical growth curves for *P. chrysogenum* 53-414 in D₂O nutrient medium. Key: ●, apparent pH profile; ○, penicillin titer; and △, D₂O dilution.

Knowledge of the composition of the medium and the availability of nutrient components and precursors in deuterated form is essential if the biosynthetic pathways are to be charted. Although optimal growth and penicillin production are achieved when corn-steep liquor is incorporated into the nutrient medium, its use here was precluded because of its unspecified composition. Further, the introduction of hydrogen atoms in this way would interfere with biosynthetic studies involving fully deuterated nutrient media needed for the production of fully deuterated penicillin.

The objectives of this study were: (a) to select a suitable strain of *Penicillium*, which would produce adequate amounts of penicillin under the constraints of a deuterated environment; (b) to develop an appropriate, defined, nutrient medium yielding maximum penicillin titers; (c) to isolate the antibiotic in a sufficiently pure state to permit identification, characterization, and analysis of deuterium distribution within the penicillin molecule; and (d) to determine the extent of participation of solvent D₂O in the biosynthesis of penicillin.

Five strains of *P. chrysogenum*, Q-176, 49-133, 51-20, 51-20 F3-64, and 53-414, were examined in preliminary studies for their ability to grow and produce antibiotic on a defined medium containing heavy water as solvent. The last two strains listed demonstrated the best performance in a series of growth and production studies. After further experimentation, the 53-414 strain was selected for the present work on the basis of higher penicillin titers (about 80 units per ml.).

For the protio cultures, the nutrient medium described by Singh and Johnson (23) was utilized. Cultures of the test organisms in this medium were used as controls, as a reference for establishing the appropriate medium and culture conditions for the D₂O nutrient cultures, and to provide a source material for the development of suitable extraction, isolation, and purification procedures. The composition of the protio culture media is shown in Table I. Since only one form of penicillin, benzylpenicillin, was desired in the fermentation broth, phenylacetic acid was added as a precursor to the nutrient.

In the development of an appropriate medium for the deuterio cultures, an attempt was made to include only those components that were also available in fully deuterated form. This was considered at this time since in subsequent studies the production of a fully deuterated penicillin was planned. The basic D₂O nutrient culture medium is listed in Table II and is an adaptation of the protio medium of Singh and Johnson (23). Lactose is a component of the protio medium, since it is slowly metabolized and represents a continuous source of glucose. Soltero and Johnson (24) demonstrated that increased penicillin titers resulted when cultures were fed glucose or sucrose on a continuous basis rather than only initially as a single addition of lactose which presumably has a similar effect as continuous or repeated additions of glucose. However, since deuterated lactose is not available at this time, the authors resorted to daily addition of glucose. Deuterioglucose is readily available from algae grown in heavy water.

The culturing procedure employed in this study is a modification of the replacement medium technique suggested by Halliday and Arnstein (25) for studying the metabolites in penicillin biosynthesis.

Table IV—Chemical Shifts (δ , p.p.m.) of Protio and Partially Deuterated *N*-Ethyl Piperidyl Benzylpenicillins in CDCl_3^a

Compound	Side-Chain Phenyl	Amide —NH—	β -Lactam CH—CH (<i>J</i> , c.p.s.)	Thiazolidine —CH—	Side-Chain —CH ₂ —	Thiazolidine (CH ₂) ₂
V. Benzylpenicillinic acid ^{b,c}	7.34	6.35d(8.5 c.p.s.)	5.52, 5.70d(4 c.p.s.) 5.49d(4 c.p.s.)	4.38	3.67	1.52, 1.45
VI. NEP-Benzylpenicillin ^{c,d}	7.37	6.22d(7.5 c.p.s.)	5.62, 5.69d(4 c.p.s.) 5.63d(4 c.p.s.)	4.35	3.70	1.63, 1.51
VII. NEP-Partially deuterated benzylpenicillin ^{c,e}	7.37	6.22	5.62	—	3.70	1.62, 1.52

^a d denotes doublet; *J* values in c.p.s. ^b Green *et al.* (28). ^c Referred to TMS. ^d Prepared as in *Experimental* section from reference benzylpenicillin. ^e Prepared from IV in Table III.

Nona *et al.* (3) and Mrtek *et al.* (6) used a replacement technique in culturing *P. janczewskii* and *C. purpurea*, respectively, in deuterated culture media. In their experiments the organism was allowed to mature in a protio medium and was then introduced into a D_2O medium containing only deuterated substrates. Hopefully the protio organism would synthesize deuterio metabolic products from the deuterated substrates. The technique was applied successfully for the production of deuterated griseofulvin and certain deuterated ergot alkaloids. It has not yet been successful for deuterated belladonna alkaloids when the method (26) is applied to a higher plant. The modification of replacement technique as applied in the present study involved the preparation of the seed culture in a protio medium. The mycelial pad from the protio seed culture was rinsed with D_2O and used as the inoculum for the deuterated culture.

The beneficial effect of a vitamin mixture addition on the culturing of organisms in a deuterated medium has been demonstrated by Mohan *et al.* (27) with *Torulopsis utilis*. Nona *et al.* (2) and Mrtek *et al.* (5) also reported the effects of adding selected vitamins to the culture medium. After preliminary experimentation the vitamin combination shown in Table II was found to enhance penicillin production.

Figure 1 shows the change in apparent pH, the dilution of deuterium by exchange with atmospheric moisture, and penicillin titer values for a typical D_2O nutrient culture over a 160-hr. study period. The apparent pH profile shows an expected immediate drop to an apparent pH 6.2 followed by a rise to a plateau value of apparent pH 8.6. If the fermentation was permitted to continue beyond that indicated in Fig. 1, the apparent pH would eventually drop. The data for the curves in Fig. 1 are based on the observations from thirty 50-ml. cultures. Maximum penicillin titers (70–80 units per ml.) are obtained after about 120 hr. of fermentation, at which point the apparent pH begins to plateau. At this apparent pH, autolysis begins and penicillin breakdown is evident. Over the course of study the D_2O content of the medium diminished at the rate of about 0.26% per day.

Because of the extreme lability of the penicillin molecule in solutions of low pH, caution was exercised during the processing of the fermentation broth. The primary problem in the extraction procedure was the formation of emulsions in the first step, which was overcome by centrifugation. After recovery of the crude extract in lyophilized form, the penicillin was recrystallized from 85% acetone in water by additions of cold acetone. The partially deuterated benzylpenicillin was found to be 60% pure by bioassay. The IR spectrum showed characteristic carbonyl absorptions at 1770, 1665, and 1608 cm^{-1} , which confirmed the presence of penicillin but also showed a broad shoulder between 1550 and 1575 cm^{-1} that indicated the possible presence of carbonyl groups other than those of the penicillin. The PMR spectrum showed additional peaks in the upfield region (0.70–2.30 p.p.m.) which were not due to the benzylpenicillin.

Chemical shifts for ordinary and partially deuterated benzylpenicillins are given in Tables III and IV. PMR spectrum for potassium benzylpenicillin in D_2O (II) shows a resonance at 7.38 p.p.m. for the five protons of the phenyl ring and two doublets at 5.53 and 5.43 p.p.m. due to the C-5 and C-6 protons (Structure I) of the β -lactam ring, respectively, in the downfield region. The amide proton is exchanged with the deuterium of the solvent and is not observed.

partially deuterated benzylpenicillin
I

In the upfield region of the spectrum, the C-3 proton of the thiazolidine ring is observed at 4.23 p.p.m. and the methylene protons of the benzyl side chain at 3.68 p.p.m. The two methyl groups on the thiazolidine ring appear as singlets at 1.58 and 1.51 p.p.m. The PMR spectrum for the isotope hybrid compound isolated in this study (IV) shows the same resonances for the phenyl, side-chain methylene, and thiazolidine methyl groups. The resonances at 4.22 and 5.43 p.p.m. are almost completely absent and a singlet is observed at 5.50 p.p.m. Interpretation of these spectra indicates the possibility of two points of full deuteration, which are surmised to be the C-3 position of the thiazolidine ring and the C-6 position of the β -lactam ring. Also, the C-5 position of the β -lactam ring appears to be partially deuterated.

C-3 Position—In accord with the assignments made by Green *et al.* (28), the resonance at 4.22 p.p.m. (Table III) is almost completely absent (5–10% normal value) and indicates extensive deuteration at the C-3 position.⁴ It has been shown that penicillin is biosynthesized from L-cysteine (29) and valine (30). The C-3 position of the thiazolidine ring arises from the α -carbon of valine, and an examination of the pathway for biosynthesis of valine (31) reveals that a deuterium atom from the solvent may be incorporated at the α -carbon by transamination. Arnstein and Crawhill (32) suggested a mechanism for the formation of the thiazolidine- β -lactam ring. In the final step for the thiazolidine ring closure, the suggested pathway allows for incorporation of a proton, or a deuterium atom, at the C-3 position, so that the deuterium atom evidenced here may be due either to previous incorporation into the valine or this last ring closure step.

C-5 and C-6 Positions—The assignments made by Green *et al.* (28) for potassium benzylpenicillin in D_2O (I) are in agreement with this work, except for the β -lactam ring protons at C-5 and C-6. They assigned the resonance at 5.43 p.p.m. to the C-5 proton and the resonance at 5.54 p.p.m. to the C-6 proton (Table III). In the partially deuterated benzylpenicillin isolated in this study, the doublet at 5.43 p.p.m. is essentially absent and the doublet at 5.53 p.p.m. is replaced by a singlet at 5.50 p.p.m. (Table III). The C-5 and C-6 positions of the β -lactam ring arise from the β - and α -carbon atoms, respectively, of cysteine (29). From an examination of the biosynthetic pathways for formation of cysteine (33), it is observed that a deuterium atom from the solvent may be incorporated at the α -carbon of cysteine (*i.e.*, the C-6 position of penicillin) by trans-

⁴ The presence of protons at these points might be due to the 3–5% water in the medium or a preferential isotope incorporation of the protons over the deuterium atoms during biosynthesis.

amination. This position should then be essentially fully deuterated. Thus, the observation of deuteration at the position which normally resonates at 5.43 p.p.m. indicates that this resonance represents the C-6 proton rather than the C-5 proton. The authors conclude, therefore, that the assignments by Green *et al.* (28) for the β -lactam protons are inverted. This observation is further confirmed by the data from Table IV in which chemical shifts for penicillin in organic solvents are listed.

The assignments of Green *et al.* (28) (V) are for benzylpenicillanic acid in CDCl_3 . The *N*-ethyl piperidyl salts of protio (VI) and partially deuterated (VII) benzylpenicillins were used in this study. Green *et al.* (28) assigned the resonance at 5.52 p.p.m. to the C-5 proton, the two doublets centered at 5.70 and 5.49 p.p.m. to the C-6 proton (which is coupled to the C-5 proton and the amide proton), and the doublet at 6.35 p.p.m. to the amide proton. Resonances observed for *N*-ethyl piperidyl protio-benzylpenicillin (VI) differ slightly but are in good agreement with these assignments. The spectrum observed for the *N*-ethyl piperidyl partially deuterated benzylpenicillin (VII) shows singlets at 6.22 and 5.62 p.p.m. The singlet observed at 5.62 p.p.m. is the same resonance as that assigned to the C-5 proton and indicates its presence in the partially deuterated benzylpenicillin. Agreement with the conclusion that the resonance observed in D_2O solutions at 5.50 p.p.m. (Table III) is due to the C-5 proton is thus retained. Also, if the protons had been present at the C-6 position, splitting of the amide resonance would have been observed. The change in assignments to 5.54 p.p.m. for the C-5 proton and 5.43 p.p.m. for the C-6 proton indicated by this study would involve only those assignments for potassium benzylpenicillin in D_2O solution.

The assignments made by Green *et al.* (28) for other penicillins or benzylpenicillins in other solvents or under different conditions than those examined in this study are assumed correct, since factors such as solvent or conformational effects could be influencing the chemical shifts. Incorporation of deuterium at the C-6 position is probably greater than 90%,⁴ since there is no observable splitting of the singlet peak at 5.50 p.p.m. (Table III). Partial deuteration at the C-5 position is estimated to be 50–75%. The amide proton in the CDCl_3 spectrum for VII (Table IV) was used as an internal reference. Saur *et al.* (34) observed isotopic exchange of deuterium in the β -carbon protons of phosphoenolpyruvate when examining deuterium isotope effects on fermentation of hexoses. Thus, deuterium may have been incorporated at the β -carbon of 3-phosphohydroxypyruvate during the biosynthesis of the cysteine (33). Arnstein and Crawhill (32) suggested that one of the β -protons of cysteine is retained during ring closure of penicillin biosynthesis and thus deuteration at the C-5 position would be observed.

Further studies will attempt to biosynthesize a fully deuterated benzylpenicillin, to examine its potency in relation to protio-penicillin, and to examine the fate of d_3 -acetate in the fermentation.

Interaction of Hexachlorophene with Human Epidermis I: *In Vivo* Bioelectrometric Study of pH Influence

ROLLAND I. POUST and VICTOR F. SMOLEN

Abstract □ The effects of pH and hexachlorophene on the net fixed-charge density of the colloids composing the epidermal surface were studied *in vivo* employing human subjects. The results are analogous to titration curves of amphoteric macromolecules. The study was performed over a pH range of 1.1–12.3 in the presence and absence of saturated concentrations of hexachlorophene. Both the control and hexachlorophene titration curves were nonhysteretic when initiated at either extreme of the pH range; this finding indicates reversibility of the observed pH and hexachlorophene-induced changes. The presence of hexachlorophene decreased the net fixed-charge density of the tissue surface below pH 5.6. Above pH 5.6, a net increase was consistently observed. Mechanistically, the hexachlorophene-induced alterations in fixed-charge density are hypothesized as resulting from allosterically effected changes in the dissociation constants of ionogenic protein side groups located vicinally to hexachlorophene interaction sites. The bioelectrometric method allowed the study to be performed without causing any injury or discomfort to the subjects. The results of the present study suggest a further utility for the bioelectrometric method in studies of the substantive antibacterial behavior of hexachlorophene on human skin.

Keyphrases □ Hexachlorophene interaction—human epidermis □ Epidermal surface colloids—acid-base binding properties □ Charge density, fixed—human epidermis □ Bioelectrometric study—pH effect, hexachlorophene—human epidermis interaction

Following transient exposure, the substantive effectiveness of a skin antibacterial such as hexachlorophene largely depends upon the extent of its deposition onto the colloids composing the stratum corneum as well as the manner in which it is subsequently available to affect microorganisms. Commonly employed experimental techniques do not always permit the substantive activity of skin antibacterials to be readily evidenced, particularly under conditions of actual product usage. The recovery and quantification of very small amounts of the antibacterial agents are often necessary. Some techniques require the excision of the treated skin and are, therefore, inapplicable for extended and routine use with human subjects. Techniques that involve the disintegration of the skin and fractionation of its constituents are further disadvantaged by the obvious difficulty of distinguishing and correcting for antibacterial bound to the colloid *in vivo* and that which becomes interacted *in vitro* through the activation of binding sites by the *in vitro* treatment of the tissue.

A bioelectrometric method, which has been successfully applied in studies of the interaction of other substances (1–5)—some of which have been phenolic (6)—could conceivably be applied to allow the detection of residual, bound quantities of hexachlorophene on human skin *in vivo* under realistic conditions of product usage, without any chance of injury resulting from the measurements.

The purpose of the present study was to determine the sensitivity of the bioelectrometric method in detecting changes in the net fixed-charge density of the epidermal

surface occurring in response to the interaction of hexachlorophene. The interpretation of the results of the investigation was anticipated to provide some mechanistic insight into the nature of observed phenomena.

METHOD

The application of the bioelectrometric method to the study of solute interaction with tissue surfaces is dependent on the detection of solute-induced changes in the net fixed-charge density of the surface colloids relative to suitable controls. The fixed charge originates from the dissociation of counterions from immobile ionogenic groups covalently bonded or otherwise sorbed onto the surface. The magnitude of the fixed-charge density, at any given composition of applied solution, determines the magnitude of the electrical potential difference developing across the colloid–aqueous boundary. The measurement of a potential, E_1 , includes this equilibrium phase boundary potential as well as all other potentials developed in the circuit. These extraneous potentials have been found to remain constant for the short period of time required to replace the initial solution in contact with the tissue surface with a dilution of this same solution, followed by the immediate recording of a second potential, E_2 .¹ The difference of these two measured potentials ($E_2 - E_1$), termed the dilution potential, E_d , is devoid of extraneous potentials and includes only those potential differences developed between the aqueous medium at the tissue surface and the bulk of the applied solution. This consideration allows the interpretation of E_d in terms of the familiar Donnan equilibrium (7) and its treatment as a diffusion potential (8). Under the conditions of its measurement, E_d is characteristic only of the tissue surface rather than reflecting the properties of the bulk or interior of the tissue phase.

General equations relating the dilution potential and fixed-charge density (f) have been presented in earlier reports (1, 2). Determinations of the fixed-charge density of tissue surfaces under conditions of varying pH resemble and are analogous to pH titration curves of amphoteric macromolecules (9) or insoluble colloids (10, 11) when plotted as a function of pH. The form of these curves is dependent upon the nature of the ionizing groups, the presence of interacting solutes, and the state of aggregation of the colloids composing the tissue surface. The fixed-charge density on tissue surfaces is often quite sensitive to interacting substances, as reflected in alterations in the shapes of titration curves. Such changes can often be interpreted to yield information concerning the extent and nature of the interaction.

Details of the experimental arrangement, preparation of the tissue surface, and precautions concerning how the measurements are to be performed have been reported earlier for human finger epidermis (2). Briefly, the experimental procedure consists of standardizing the condition of the skin by thorough cleansing and allowing the skin to become prehydrated by soaking in 0.15 *N* NaCl for approximately 15 min. This treatment also removes labile, water-soluble, ionogenic materials (12), which would otherwise be elutriated during the measurements. Such losses contribute to uncontrolled variations in the measured potentials. As shown in Fig. 1, the experimental finger and a saturated calomel electrode are placed together into a buffered isoosmotic solution, which may or may not contain the solute whose interaction with the surface is of interest. The reference finger is placed into another beaker containing 0.15 *N* NaCl solution along with another saturated calomel electrode. Neither the reference finger nor the electrode is further

¹ The solutions used for the measurement of E_2 were 10-fold dilutions with regard to all components except the hexachlorophene.

Figure 1—Diagram of experimental arrangement for the electro-metric study of hexachlorophene interaction with human finger epidermis. *P* = potentiometric device.

disturbed during the experiment.

The internal circuit between the experimental and reference fingers is completed by the body of the subject. The electrodes in the external circuit are connected to a potentiometric device used for the null point reading of the developed potentials. The potential, E_1 , is recorded until its observed variations become less than approximately 0.2 mv./min. When the epidermis is pretreated as previously described, this stability is usually achieved within 1 min. following immersion. Following the measurement of E_1 , the finger is removed and immersed in a 1/10 dilution of the same solution; the potential, E_2 , is immediately recorded. The finger is then removed from the 10-fold dilution and reimmersed in the previous solution. The potential, E_1 , is again measured and compared to the previously determined value to ensure that the extraneous potentials in the circuit have remained constant. Agreement within 1.0 mv. was taken as acceptable. The mean of the two measured values was used to obtain the dilution potential, E_d .

MATERIALS

Corning, miniature, fiber-junction, calomel reference electrodes were used in conjunction with a Heath pH electrometer-recorder. The potentials were read directly from the recorder chart. The potential measurements were performed on three male, human volunteers ranging from 20 to 25 years of age. All reagents were of analytical grade, except for hexachlorophene.²

The buffered solutions used for the determination of E_1 were each prepared to an ionic strength of 0.15 and a buffer capacity of 0.0288. This buffer capacity is approximately equivalent to that of a 0.05 M phosphate buffer at pH 7.21. The ionic strength is the same as that of isotonic sodium chloride. The compositions of these solutions are listed in Table I. Tenfold dilutions of these solutions, as well as of each of these solutions saturated with hexachlorophene, were also prepared and used in the experiment.

Calculations were performed with the aid of a CDC 6500 digital computer. Calibration curves, relating measured values of the dilution potential to corresponding theoretical values of the fixed-charge density, were constructed with a model 563 Calcomp digital incremental plotter.³ Representative curves, corresponding to several buffer solutions, are shown in Fig. 2. Figure 3 contains a corresponding nomograph. The verity of the calibration curves was tested experimentally through the *in vitro* measurement of E_d values corresponding to zero net fixed-charge density, i.e., E_d^0 values.

In the absence of fixed charge, the E_d^0 values are tantamount

to liquid junction potentials across a free diffusion-type boundary (8). Such boundaries may be conveniently formed using a filter paper bridge between each solution and its 10-fold dilution. However, an error can result in such measurements if a fixed charge resides on the filter paper. To determine whether an error is introduced from this source, diffusion potential measurements were performed with the formation of a liquid junction, between 0.1 and 0.01 N KCl solutions, within the filter paper. The measured potential had a mean value of 0.8 mv., indicating that the filter paper was effectively neutral and suitable as a matrix for the formation of free diffusion boundaries. Diffusion potentials measured in this manner have previously been found to agree generally within 1 mv. with values determined using free diffusion boundaries formed within glass capillaries (1).

The averages of six determinations of E_d^0 values are listed in Table II with their corresponding standard deviations. The agreement between experimental and calculated values is most often within 1 mv. and is considered acceptable. The presence of saturated concentrations of hexachlorophene in both the buffers and their 10-fold dilutions does not appear to influence the magnitude of the measured potentials.

To determine the influence of pH on the interaction of hexachlorophene with the epidermal colloids, the fixed-charge density of the tissue surface was determined at each of the 12 pH values de-

Figure 2—Plot of calibration curves for several buffered measuring solutions using the digital incremental plotter.

Figure 3—Alignment Chart relating experimentally observed values of the dilution potential to the corresponding density of fixed charge. To read the fixed-charge density, a straight line is passed to the left from the dilution potential, through the decimal point of the pH of the solution, and intersected with the fixed-charge density scale corresponding to the same solution pH.

scribed, both in the absence and presence of hexachlorophene. The use of the controls permitted the changes in fixed-charge density due to hexachlorophene interaction to be evidenced. Measurement of E_d values for the control points were made following the attainment of an apparent equilibrium of the solutions with the surface; usually only a few minutes were required. However, the measurements with hexachlorophene-containing solutions were made after 46 min. to allow time for complete interaction with the epidermal surface.

RESULTS AND DISCUSSION

Normal and Hexachlorophene-Displaced Titration Curves—

Figure 4 demonstrates the influence of pH on the net fixed-charge density of normal and hexachlorophene-treated human finger epidermis. The results resemble and are analogous to hydrogen-ion titration curves of proteins. A reversibility in the effects of pH and hexachlorophene on the fixed-charge density was indicated

by a lack of any systematic differences between titration curves, differing only in that the measurements were initiated at low and high pH. This conclusion was found to be further supported statistically by the results of a paired t test comparison performed between the up-curves and the down-curves; such curves were statistically the same in the case of both the control and hexachlorophene-treated skin. It was, therefore, concluded that the interactions of the solution components with the colloids constituting the epidermal surface are reversible.

Inspection of the curves reveals that, relative to the control curve below approximately pH 5, hexachlorophene induces a net decrease in the density of fixed positive charge on the epidermal surface and causes a small shift in the isoelectric point in the direction of a more acidic pH. In contrast, above the isoelectric point, near pH 5, a hexachlorophene-induced reduction in the fixed anionic charge density of the epidermal surface is observed. It is pertinent to note that, in excess of this pH, the proportion of hexachlorophene [pKa =

5.4 (12)] existing in solution as anions relative to unionized hexachlorophene increases very rapidly with increased alkalinity. It, therefore, appears that the reduction in net positive surface charge observed at low pH may be reasonably attributed to the results of the interaction of unionized hexachlorophene, while hexachlorophene anions are apparently responsible for the reduction of net negative charge in the less acidic and alkaline pH range. Although an interaction of anions with a negatively charged surface, which results in a reduction of negative charge density, may initially appear to be a rather unique phenomenon, it has previously been observed to occur in similar studies involving phenolic (6) and other anions (2, 4). The interaction of anions with proteins in solution above their isoelectric point has also been commonly reported (13).

Mechanism of Hexachlorophene Effects—Solute-induced changes in fixed-charge density, which result in the displacement of titration curves such as observed for the effects of hexachlorophene, can result from an irreversible loss of titrable groups from the surface or through the masking of their charge. Changes in the fixed-charge density, which might occur from the elutriative loss of charged materials from the skin (14, 15), are minimized by the treatment of the skin performed prior to the measurements. Any further elutriative losses, which could conceivably occur during the measurements, are apparently minimal as indicated by the previously described reversible nature of the effects. Since irreversible chemisorption is obviously also not a plausible mechanism, the hexachlorophene effects must be attributed to a masking of fixed surface charge.

Since at low pH the hexachlorophene is unionized and at high pH the interaction of anions lowers the anionic fixed-charge density, the observed phenomena must occur by a means other than a direct neutralization such as could result from salt binding of the hexachlorophene to the ionogenic fixed surface groups. Since hexachlorophene is a dihydric phenol, its mode of interaction with proteins may be expected to resemble that attributed to phenols in general. Kuntzel (16), in describing the action of phenols on collagen, suggested that their interaction with proteins occurs through hydrogen bonding of the phenols with the peptide linkages constituting the protein backbone. The affinity of the interacting molecules for the

protein is postulated to result from a polarity induced into their aromatic nuclei by the phenolic hydroxyl group; there results a development of activated CH groups with alternative net positive and negative partial charges. The CH group adjacent to the hydroxyl is postulated as the primary binding site within the molecule.

Pankhurst (17), on the other hand, suggested that the binding of phenolic molecules occurs directly by the formation of hydrogen bonds between the phenolic hydroxyl and the peptide nitrogen. Conceivably both sites may be operative and serve to complement one another; however, the direct hydrogen bonding of the hydroxyl appears to be more reasonable in providing the primary mode of interaction (18). In any event, only peptide linkages could occur in sufficient number to provide the binding sites for the extraordinarily large quantity of phenols commonly observed to be sorbed by proteins. That the sorption does not directly involve ionogenic groups is indicated by the mineral acid-binding capacity of collagen, for example, remaining unchanged (18). The degree of dissociation of ionogenic groups located vicinally to hexachlorophene-interacted peptide sites may, however, be influenced indirectly by hexachlorophene binding. Such influences can be propagated through space by direct electrostatic field effects or through the atoms constituting the protein itself through an inductive delocalization of electrons (19). Both mechanisms can operate to alter the acidic pK's of ionizable vicinal groups. The observed changes in fixed-charge density of the epidermal surface, therefore, can be postulated to occur as a consequence of an uptake or release of protons occurring concomitantly with the binding of hexachlorophene with peptide linkages vicinal to the affected ionogenic groups. Electron inductive effects have been shown to be effectively transmitted through as many as five saturated carbon atoms (20). Pauling (21) described the transmission of inductive effects through peptide linkages to be facilitated by the high polarizability, due to the partial resonance, of the peptide amide bond, which has been discerned to possess a transmissivity for inductive effects approximately tantamount to two methylene groups (22). Ling (22) and Szent-Györgi (23) convincingly postulated that such effects can be transmitted through hydrogen bonds to alter the reactivity of groups located in positions neighboring the binding sites of hydrogen bond-forming interactants.

Based on these considerations, the electronic mechanisms operative in the manifest effects of hexachlorophene on the epidermal fixed-charge density can be postulated to occur as diagrammatically described in Scheme I.

The influence of hexachlorophene at low pH must primarily be directed toward the fixed carboxyl groups, which are titrable within the pH range of 2–6 (9). Carboxyl groups are plentiful in the stratum corneum. It has been found (24) that aspartyl and glutamyl residues comprise approximately 21.7% of the weight of keratin, the major proteinaceous constituent of stratum corneum.

At low pH the hydrogen bonding of the electrophilic phenolic hydroxyl with the peptide linkage may be envisaged to induce a withdrawal of delocalizable electronic charge from the carboxyl group of a vicinal aspartyl or glutamyl side group, resulting in a lowering of the acidic pK of the groups. The accompanying release of protons into the milieu manifests as a reduction in the net positive fixed-charge density of the surface. The high density of carboxyl groups and their separation from the polypeptide backbone by only one or two methylene groups contribute to an expected high probability that such groups may be located within the inductive influence of bound hexachlorophene. The presence of the three electronegative chlorine atoms on the aromatic nuclei of the hexachlorophene molecule may be expected to contribute substantially to its electrophilic inductive efficacy.

At high pH the electrophilic character of the hexachlorophene can be considered as abrogated by the excess electrons resulting from the dissociation of protons from the phenolic groups. Scheme I also illustrates the electronic mechanism postulated as responsible for the observed lowering of fixed negative charge density of the epidermal surface at high pH. The groups primarily affected in the upper pH range are likely constituted by the ϵ -amino group of lysine, which together with the guanidyl group of arginine and the phenolic group of tyrosine comprises approximately 13% of the amino acid content of keratin (24). Delocalization of electronic charge originating in the bound hexachlorophene to groups normally dissociating their protons in the upper pH range is postulated to increase their acidic pK's and manifest in a lower net density of fixed charge on the surface. A similar increase in the pK's of titrable groups is apparently responsible for the reported anion-induced

Figure 4—Control (○) and hexachlorophene-displaced (●) titration curves of human finger epidermis. Each point is the average of six replicates on one subject.

Scheme I—Simplified diagrammatic representation of the postulated electronic inductive mechanisms of hexachlorophene-induced changes in the fixed-charge density of human epidermis

shifts in the position of hydrogen-ion titration curves of wool and soluble proteins in the direction of increased alkalinity along the pH axis (9, 10, 25). The proteins were reported to appear to combine stoichiometrically with both hydrogen ions and the anions inducing the shifts (26, 27).

The possibility of direct electrostatic salt binding between fixed cationic groups on the colloids and hexachlorophene anions cannot be entirely excluded. Such interactions would depend upon the availability of both fixed cationic groups and hexachlorophene anions. The interactions would be expected to manifest in a net reduction of fixed positive charge density and could possibly be contributing to the effects of hexachlorophene observed in the vicinity of pH below 5.7 in which imidazolyl and α -amino groups (9) can be expected to be involved. However, if salt binding of hexachlorophene is contributing to its observed effects, it cannot be resolved from the operation of the inductive mechanisms which have been postulated as primarily responsible.

SUMMARY AND CONCLUSIONS

The results of the present study clearly indicate that the bioelectrometric method is capable of detecting the influence of hexachlorophene on the acid-base binding properties of the colloids constituting the epidermal surface. The application of the method has revealed aspects of the interaction of hexachlorophene, which are undetectable by other more conventional experimental techniques. The mechanistic interpretation of the observed hexachlorophene-induced displacement of the titration curve of the epidermal surface,

although speculative, is in general agreement with related results previously reported and the postulations of other investigators.

The further utility of the electrometric method in the investigation of the kinetic and equilibrium interaction behavior of hexachlorophene with human skin *in vivo* and the manner in which the results relate to its substantive antibacterial properties are topics of subsequent reports in the present series.

Adsorption of Methylene Blue by Potato Starch: Effect of Methanol, Dioxane, Sucrose, and Urea in Aqueous Systems

ARVIND L. THAKKAR, WILLIAM L. WILHAM, and GEORGE ZOGRAFI*

Abstract □ Methylene blue is adsorbed by potato starch from aqueous solution as a monomer or dimer, depending upon its concentration. The adsorption phenomenon can be described by the Langmuir equation. The effect of methanol, dioxane, sucrose, and urea on methylene blue adsorption has been examined. These water-miscible additives shift the monomer-dimer equilibrium of the dye in the direction of the monomer and reduce the extent of methylene blue adsorption without significantly affecting the maximum possible adsorption. This appears to indicate that their effect is primarily on the effective concentration of the dye. At high concentrations, methanol and dioxane apparently further reduce adsorption by affecting the surface of potato starch.

Keyphrases □ Methylene blue—potato starch adsorption □ Starch, potato—methylene blue adsorption □ Methanol, dioxane, sucrose, urea effects—methylene blue adsorption □ Sucrose effect—methylene blue visible spectrum □ Colorimetric analysis—spectrophotometer

Enhanced adsorption of water-soluble certified dyes to various solid dosage form ingredients has been suggested as a means of overcoming the problems of dye migration during the drying of tablet granulations (1). During a study of anionic dye adsorption on various starches, significant adsorption was noted for all types of starch except potato starch (1, 2). Schoch and Maywald (3) observed also that Congo Red, a negatively charged dye, is not adsorbed by potato starch, presumably because of the presence of phosphate groups not ordinarily found in the other starches (4). In view of this negative charge, potato starch would be expected to adsorb cationic substances significantly. Schoch and Maywald (3) found that the cationic dye, methylene blue, strongly stains potato starch granules, but no quantitative studies on the adsorption of cationic substances by potato starch have appeared.

In the present study, methylene blue was chosen as a model dye in view of the information available concerning its state in solution (5-8). In dilute aqueous solutions, the dye exists principally in its monomeric form, while in concentrated solution the dimeric and multimeric forms predominate as a result of hydrophobic self-association. Since the monomer-multimer equilibria are sensitive to various polar additives (5), the effect of such substances on methylene blue adsorption was also investigated. The additives examined were dioxane, methanol, sucrose, and urea.

EXPERIMENTAL

Materials—Methylene blue USP and potato starch (purified powder)¹ were used as received. Water contents of the trihydrate

Figure 1—Effect of concentration upon the visible spectrum of methylene blue at room temperature. Key: A, 1.2×10^{-3} M, 0.1-mm. cells; B, 1.2×10^{-4} M, 1-mm. cells; and C, 1.2×10^{-5} M, 10-mm. cells.

dye and the starch were determined and were taken into consideration when recording their weights. Reagent grade dioxane, methanol, and sucrose and urea USP were used without further purification. Dye solutions for adsorption studies, with or without additives, were always freshly prepared using double-distilled water.

Spectral Studies—To illustrate the effect of concentration upon the visible spectrum of methylene blue, the following concentrations were employed: 1.2×10^{-3} M, 1.2×10^{-4} M, and 1.2×10^{-5} M; the cells used were of 0.1-, 1-, and 10-mm. light pathlengths, respectively. The effect of additives upon the spectrum of the dye was examined at constant dye concentration (1.2×10^{-4} M) and various additive concentrations, using 1-mm. cells. Spectra were recorded at room temperature on a spectrophotometer (Cary 15).

Adsorption Studies—All adsorption experiments were done at a controlled room temperature of $26 \pm 1^\circ$. Approximately 0.5 g. of potato starch was accurately weighed into each of a series of vials. Ten milliliters of a dye solution was added to each vial, and the vials were stoppered with butyl rubber closures. It was initially ascertained that these stoppers adsorbed no methylene blue. The adsorption vials were shaken occasionally over 4 hr. Preliminary experiments indicated that this time was more than sufficient for the various systems to attain equilibrium.

Upon equilibration, 1 ml. of clear, granule-free, supernatant dye solution was withdrawn from each vial. It was then suitably diluted with water, and its concentration was determined spectrophotometrically at 660 mμ. A spectrophotometer (Cary 15) and 1-cm. glass cells were used. When the systems contained additives, it was necessary to make sure that the dye solutions were diluted to a point where the additive concentrations were too low to interfere with the spectral procedure. This precaution precluded adsorption studies at relatively low equilibrium dye concentrations in the presence of additives. From the concentration of dye solutions before and after contact with starch, the amount of dye adsorbed was determined.

RESULTS

Spectral Properties of Methylene Blue—The changes in the visible spectrum of methylene blue, reflecting changes in the state of aggregation with increasing dye concentration, are shown in Fig. 1. The peak at ~ 660 mμ has been assigned to the monomeric form, which predominates in dilute aqueous solutions. The dimeric form absorbs at ~ 590 mμ; the population of this form increases as the dye concentration is increased. Possibility of higher multimers has been proposed for some time; recently, existence of a trimer was conclusively proven and a rather broad peak at ~ 580 mμ (not shown in Fig. 1) was ascribed to the trimer (8). Because of these spectral properties, the Beer's law relationship is applicable only in a limited concentration range, up to $\sim 1 \times 10^{-5}$ M, when absorbance cells of 1-cm. light pathlength are used.

Figure 2 illustrates the effect of increasing additive concentrations upon the spectrum of the dye. Relative effectiveness of these

additives in diminishing the self-association of methylene blue may be examined by considering the ratio of the absorbance of the monomer peak to that of the dimer peak. Plots of monomer/dimer ratio (M/D ratio) versus the concentration of additives are shown in

Figure 3—Relationship between additive concentration and absorbance ratio of the monomer and dimer peaks. Key: O, methanol; □, dioxane; ■, sucrose; and ●, urea.

Fig. 3. Sucrose is more effective than urea, on a molar basis, in reducing the self-association of the dye. This observation has an interesting parallel in the work of Emerson and Holtzer (9) who found that at equimolar concentrations, sucrose is more effective than urea in raising the CMC of dodecyltrimethylammonium bromide. Of the two organic solvents employed, dioxane is more effective than methanol at equal volume concentration.

Adsorption Studies—The Langmuir equation for adsorption from solution may be written in its linear form as follows:

$$\frac{C}{x/M} = \frac{C}{k_2} + \frac{1}{k_1 k_2} \quad (\text{Eq. 1})$$

where C is the concentration of the solute at equilibrium, x/M is the amount of solute adsorbed per unit weight of the adsorbent, and k_1 and k_2 are constants. The constant k_1 represents the tendency for adsorption to occur and may be considered as an equilibrium constant for the adsorption process; k_2 represents the maximum value of x/M at a given temperature determined by the number of available sites or the surface area of the adsorbent. If a system follows the Langmuir adsorption equation, then plots of $C/(x/M)$ versus C should be linear. The constants k_1 and k_2 may be calculated from the values of the slope and intercept of such Langmuir plots.

Figure 4 is a Langmuir plot for the adsorption of methylene blue on potato starch from water. The plot shows two linear regions of significantly different slopes. The lower region corresponds to dilute solutions in which methylene blue exists predominantly as the monomer; the higher region corresponds to solutions in which the dimers predominate. These regions are referred to hereafter as the monomer

Figure 4—Langmuir plots for adsorption of methylene blue on potato starch from water. A: Solid line and data points are for dimer range; dashed line is for monomer range. B: Solid line and data points are for monomer range; dashed line is for dimer range. The lines drawn are calculated least-squares lines.

Table I—Langmuir Constants for Adsorption of Methylene Blue on Potato Starch from Aqueous Solutions at 26°

Dye Concentration Range	Langmuir Constants		Correlation Coefficient of Linear Fit
	k_1 , l./mole	k_2 , moles/g.	
Low, predominantly monomer	0.466×10^4	2.18×10^{-5}	0.996
High, predominantly dimer	1.54×10^4	3.04×10^{-5}	0.998

and dimer regions, respectively. Since the trimer is formed at relatively high concentrations, it was assumed that within the dye concentration range employed in this study the fraction of trimer present was negligible.

The Langmuir constants calculated from the linear plot of Fig. 4, along with the correlation coefficients of the linear fits, are listed in Table I.

Effect of Additives—Figures 5–8 show, respectively, the effect of methanol, dioxane, sucrose, and urea upon the adsorption of methylene blue by potato starch. Over the dye concentration range employed, adsorption decreases with an increase in the additive content of the system. This finding is in agreement with previous observations made with dye–starch systems containing water-miscible organic solvents (2, 10, 11). In the experiments reported here, it was not possible to obtain valid results at low dye concentrations because the presence of additives gave rise to difficulties in the analytical procedure, as indicated in the *Experimental* section. The data obtained in the presence of additives, therefore, refer to relatively high dye concentrations (dimer range).

All the systems examined followed the Langmuir equation. Representative Langmuir plots, for the systems containing sucrose, are shown in Fig. 9. The Langmuir constants and the correlation coefficients for all the systems examined are listed in Table II. For comparison, the values of M/D ratio for these systems are also listed. The values listed in Table II make the following points apparent: (a) k_1 decreases with an increase in the additive content of the system; (b) k_1 decreases as the M/D ratio increases (or as the relative amount of dimer decreases); and (c) k_2 remains relatively unchanged (except at 10% volume concentration of methanol or dioxane).

DISCUSSION

Effect of Additives upon Self-Association of Methylene Blue—

All four additives employed in this study shift the monomer/dimer

Figure 5—Isotherms for adsorption of methylene blue on potato starch. Key: O, water; ■, 5% methanol; and □, 10% methanol.

Figure 6—Isotherms for adsorption of methylene blue on potato starch. Key: O, water; ■, 5% dioxane; and □, 10% dioxane.

equilibrium of methylene blue in aqueous solution toward the direction of the monomer. The organic solvents, methanol and dioxane, probably act this way by interacting with water and by lowering the dielectric constant of the system (12). However, it seems unlikely that the same mechanism is operative with urea and sucrose; urea increases the dielectric constant of water (13), whereas sucrose decreases it (14–16). Mukerjee and Ghosh (5) suggested that urea affects the monomer/multimer equilibrium of methylene blue by disrupting the structure of water. Uedeira and Uedeira (17) suggested that sucrose also diminishes self-association in some aromatic azo dyes by a similar mechanism.

Additionally, urea and sucrose are said to have opposite effects upon water structure (18); urea is believed to be a “structure breaker” and sucrose a “structure maker.” The terms structure maker and structure breaker, as applied to the action of urea on water, have been the subjects of recent controversies (19, 20) of both a mechanistic as well as a semantic nature. In view of such controversies, it is difficult to say what specific mechanisms are responsible for the actions of the four additives used in this study. However, these additives all have the potential for interacting with water and they all diminish self-association of methylene blue in aqueous solution.

Adsorption of Methylene Blue from Water—Giles *et al.* (21) and Giles (22) suggested that methylene blue is adsorbed as the dimer² on several nonporous adsorbents. The results of the present study show that, although at relatively high concentrations the dimer may be preferentially adsorbed, at very low concentrations, in which the monomer predominates, an appreciable amount of the dye is adsorbed on potato starch. It would appear that if adsorption experiments were performed with only relatively high concentrations of methylene blue, the monomer region might remain undetected. Additional evidence for the possibility of monomer adsorption comes from the

Figure 7—Isotherms for adsorption of methylene blue on potato starch. Key: O, water; ■, 0.5 M sucrose; and □, 1.0 M sucrose.

² The work of Giles *et al.* (21) and Giles (22) suggests that dimer adsorption of methylene blue involves adsorption of one molecule upon the adsorbent with the second molecule stacked lengthwise on top of the first. Dimer adsorption is not believed to involve side-by-side arrangement of two molecules on the surface of the adsorbent.

Table II—Langmuir Constants for Adsorption of Methylene Blue on Potato Starch from Aqueous Systems Containing Additives and M/D Ratios for These Systems

System	Langmuir Constants ^a			M/D Absorbance Ratio ^b
	k_1 , l./mole $\times 10^{-4}$	k_2 , moles/g. $\times 10^5$	Correlation Coefficient of Linear Fit

^a Determined at experimental temperature of $26 \pm 1^\circ$. ^b At methylene blue concentration = 1.2×10^{-4} M.

work of Iimura (23), who found that more methylene blue was adsorbed by some clays when the initial dye concentration in the system was high than when methylene blue was added in small successive amounts until the same total concentration was reached in the system. This observation may be interpreted as follows: When the initial concentration is high, methylene blue exists principally as the dimer, and it is adsorbed as a monolayer predominantly of dimers; when small successive amounts of methylene blue are added, it exists in the unaggregated (monomer) form which is adsorbed.

If the two regions of the Langmuir plot (Fig. 4) corresponded strictly to monomers and dimers, then one would expect that k_2 (dimer) should be twice as large as k_2 (monomer). Experimentally, such is not the case; k_2 (dimer) is only 1.39 times k_2 (monomer). This finding suggests that in neither the "monomer" nor the "dimer" region is there adsorption of only one dye species. The two regions of the Langmuir plot represent the predominant species.

Additionally, the specific surface area calculated from both of the k_2 values and a molecular area of 120 \AA^2 for methylene blue (22) do not agree with the specific surface area determined by porosity measurements (24). These values (in $\text{m}^2/\text{g}.$) are: 15.6 [from k_2 (monomer)], 11.0 [from k_2 (dimer)], and 0.2 (from porosity measurements).³ These much higher values from methylene blue adsorption measurements may be due to penetration and diffusion of the dye solution into the starch grain. Thus the actual area available for adsorption would be much greater than the outer grain surface. A similar lack of correlation between the specific surface area values obtained by different methods was found in a study of the adsorption of various anionic certified dyes by several starches (2). The structure and porosity of the starch grain are important factors to be considered in the study of adsorption by the grain; both the external and the internal surfaces of the grain probably participate when dissolved substances are adsorbed.

Adsorption in the Presence of Additives—The equilibria between various forms of methylene blue can be represented as shown in Scheme I:

Equilibrium 3 comes into the picture, apparently, only at very low dye concentration. Under the conditions employed in this study, dimer adsorption is predominant. The Langmuir constants listed in Table II refer to adsorption characteristics of methylene blue dimer.

The decreasing value of k_1 when the systems contain increasing amounts of additives indicates essentially what Figs. 5–8 show,

Figure 8—Isotherms for adsorption of methylene blue on potato starch. Key: \circ , water; \blacksquare , 0.5 M urea; and \square , 1.0 M urea.

i.e., the extent of adsorption decreases with an increase in the amount of additive. All the additives employed in this study shift Equilibrium 1 in the direction of the monomer, resulting in a decreased effective concentration of the dimer. The relative amount of dimer is still much greater than that of monomer and, since dimer is the predominant adsorbing species, decreased adsorption is reflected in lower k_1 values.

The relatively unchanged values of k_2 (or maximum possible amount of dye adsorbed) with increasing additive contents of the system indicate that the number of sites available for adsorption remains essentially unaltered. This observation indicates that the additives primarily affect the dye rather than the starch. However, at organic solvent concentrations of 10% (v/v) or higher, the starch is apparently affected. This is reflected in diminished values of both k_1 and k_2 . When the systems contained 50% or higher volumes of methanol or dioxane, dye adsorption was virtually eliminated. Starch is known to contain water of hydration as part of its grain structure. It is possible that organic solvents in excess shrink or dehydrate this hydrophilic polymer.

Apparent adsorption, as noted in this study for methylene blue, can also occur with a variety of cationic substances including drugs.

³ The cooperation of H. M. Rootare of the Department of Dental Materials, University of Michigan, in specific surface area determination is gratefully acknowledged.

In the case of dyes, enhanced adsorption is desirable for uniform coloring of solid dosage forms. However, in the case of drugs, adsorption to a seemingly inert excipient such as starch may affect their release and availability. Problems due to drug adsorption by excipients may also arise during *in vitro* evaluation of the solid dosage forms and during quantitative analysis for the active ingredient. This would be particularly true for potent drugs that have low effective doses. Adsorption studies during the preformulation stages in the development of a drug product can provide clues to such problems.

DRUG STANDARDS

Spectrophotometric Determination of Diphenhydramine Hydrochloride in an Antiallergic Cream

FABRIZIO De FABRIZIO

Abstract □ A specific method for the quantitative determination of diphenhydramine hydrochloride in a cream formulation has been developed. The method entails the extraction of diphenhydramine by chloroform, further purification of the extracted base by column chromatography using alginic acid, and its spectrophotometric determination in the eluate at 258 mμ.

Keyphrases □ Diphenhydramine cream—analysis □ Column chromatography—separation □ UV spectrophotometry—analysis

The isolation of a pharmacologically active ingredient from a pharmaceutical formulation containing surfactants is often difficult. Various authors have followed different procedures for the removal of unwanted ingredients. Jones (1) described a method for the determination of diethylstilbestrol in a water-dispersible suppository using column chromatography followed by TLC. Gottlieb (2) used refluxing with an organic solvent to break down the emulsion and subsequently recovered the active drug (which was also diethylstilbestrol) using an aluminum column. More recently,

Forman (3) developed an assay for dienestrol in a cream¹ using urea-inclusion chemistry to remove the excess of monostearin. The information obtained from any of these studies is valuable and may indicate a general approach to analysis employing the two basic steps of extraction and cleanup. However, each of them is a specific case which depends upon the physical and chemical properties of the active component.

Therefore, it is reasonable to assume that different methods of separation may be required for differing formulations containing the same active ingredients and for differing active ingredients contained in similar formulations. Diphenhydramine hydrochloride is found in various combinations in commercially available pharmaceutical preparations, and various assays for its determination have been reviewed (4-6). No procedure, however, has been reported involving the quantification of diphenhydramine hydrochloride in an

¹ The analysis was applied to a product containing 2% of diphenhydramine hydrochloride and marketed as "Allergin Cream."

In the case of dyes, enhanced adsorption is desirable for uniform coloring of solid dosage forms. However, in the case of drugs, adsorption to a seemingly inert excipient such as starch may affect their release and availability. Problems due to drug adsorption by excipients may also arise during *in vitro* evaluation of the solid dosage forms and during quantitative analysis for the active ingredient. This would be particularly true for potent drugs that have low effective doses. ^a The preparation also contains emulsifying wax, liquid paraffin, parabens, glycerin, water, color, and menthol. ^b Mean percentage recovery of diphenhydramine hydrochloride = 100.5%.

emulsified cream base. The procedure described in this paper is a modification of an analysis method for the determination of diphenhydramine hydrochloride in a cough mixture (6). The method entails the recovery of the diphenhydramine by chloroform extraction and further purification through an alginic acid column, followed by quantitative spectrophotometry at 258 m μ .

EXPERIMENTAL

Apparatus—A Beckman DB spectrophotometer and 4-cm. square, fused silica cells were used. A glass column, 30 \times 1.8 cm., with a stem, 5 cm., was fitted with a buret key.

Reagents—The following were used: cation-exchange resin, alginic acid, 40–100 mesh (available from British Drug Houses); 2 *N* hydrochloric acid in water; 0.1 *N* hydrochloric acid in water; 5% hydrochloric acid in water; 95% ethanol in water; and 80% ethanol in water. Except where otherwise specified, all reagents were of British Drug Houses' Analar quality.

Standard Solutions—The following solutions were prepared with suitable reference standards: (a) diphenhydramine hydrochloride, 2 g./100 ml. in 5% hydrochloric acid; and (b) diphenhydramine hydrochloride, 3.2 mg./100 ml. in 0.1 *N* hydrochloric acid.

Column Preparation—Alginic acid, about 4 g., was slurried in water and allowed to soak for 4 hr. The slurry was poured into a glass column which had been fitted with a cotton wool plug and allowed to settle. The column was washed with 2 *N* hydrochloric acid, until the absorbance of the eluate (pathlength 4 cm.) was less than 0.005 at 258 m μ , and then with distilled water until the eluate was neutral to litmus. Finally, 25 ml. of 80% ethanol was passed through the column.

Sample Treatment—An amount corresponding to approximately 2 g. of cream (about 40 mg. diphenhydramine hydrochloride) was accurately weighed into a 150-ml. separator. The cream was suspended in 6 ml. of 5% hydrochloric acid. The suspension was extracted with four successive portions of 15 ml. each of chloroform; each extraction was filtered through a pledget of cotton wool into a 100-ml. volumetric flask, and the solution was brought to volume. An aliquot of 20 ml. was pipetted into a 25-ml. volumetric flask. The chloroform was evaporated to dryness on a water bath with the aid of a current of air. The residue was dissolved in 95% ethanol, and the solution was brought to volume. An aliquot, 10 ml., was pipetted onto the prepared column, and the solution was allowed to pass through the column at a rate of 1 ml./min. The column was then washed with 50 ml. of 80% ethanol divided into two portions, also at a rate of 1 ml./min., and finally with 200 ml. of water at a rate of 4 ml./min. Diphenhydramine was subsequently eluted with 0.1 *N* hydrochloric acid at a rate of 1 ml./min. The first 5 ml. of eluate was discarded and the balance collected into a 100-ml. volumetric flask until 100 ml. was collected. The

Table II—Analysis of Diphenhydramine Hydrochloride in Eight Commercial Formulations

Preparation	Claim for Diphenhydramine Hydrochloride, g. %	Found, % of Claim
A	2	105.30
B	2	98.73

D	2	99.45
E	2	102.70
F	2	100.68
G	2	98.10
H	2	99.79

absorbance of the solution was then determined at 258 m μ , using 4-cm. cells and 0.1 *N* hydrochloric acid as blank.

RESULTS AND DISCUSSION

The cream examined was of the oil-water type. The oil phase contained menthol as a coolant. A nonionic emulsifying wax was used as the emulgent, as well as providing a cream of the required consistency. The aqueous phase contained diphenhydramine hydrochloride, parabens, red color, and glycerin as a humectant. In a preliminary study, attention was focused on the possibility of finding a combination of solvents which would help liquify the cream and at the same time facilitate the diphenhydramine extraction. The most suitable system found was chloroform-water. By initially acidifying the cream, the difficulty, which is normally encountered in alkaloidal extractions using chloroform-water systems, of extraction of the active ingredient favoring the aqueous phase instead of the chloroform phase is overcome. In addition to diphenhydramine, the chloroform extract contains menthol, liquid paraffin, parabens, and the emulsifying wax. For this reason, the residue after the evaporation of chloroform was dissolved in 95% ethanol instead of water which would have given a turbid solution. Although the alcoholic solution used does not dissolve the oily particles in the residue, these are easily eliminated by filtration of the solution through a pledget of cotton wool. When the procedure was followed to analyze eight synthetic mixtures of the cream (prepared in a manner similar to commercial formulation), the results in Table I were obtained.

When the method was applied to eight commercial products, the results in Table II were obtained.

The reasonable results obtained with commercial and empirical products establish the validity of this procedure.

Acetonitrile-Diatomaceous Earth Column for Corticosteroids

ROBERT E. GRAHAM*, PATRICIA A. WILLIAMS*, and CHARLES T. KENNER†

Abstract □ A column of acetonitrile on diatomaceous earth is used to hold the corticosteroid on the column during the wash of the column with *n*-heptane to remove decomposition products and interfering substances, after which the corticosteroid and acetonitrile are eluted from the column with chloroform. The recommended procedure significantly reduces or completely eliminates the interference of various substances and certain decomposition products in the blue tetrazolium, phenylhydrazine, isonicotinic acid hydrazide, and UV methods of determination. The column can be readily modified to include acidic, basic, or neutral aqueous-trap layers when necessary. There is no significant difference in precision between the proposed procedure and the normal precision of the determinative methods. Results on typical pharmaceutical preparations, some of which show evidence of extensive decomposition, are given.

Keyphrases □ Corticosteroid dosage forms—analysis □ Acetonitrile-diatomaceous earth column—corticosteroid separation □ Column chromatography—separation □ Blue tetrazolium, phenylhydrazine, isonicotinic acid hydrazide methods—corticosteroid analysis □ UV spectrophotometry—analysis

The determination of corticosteroids in many pharmaceutical preparations, other than those official in USP (1) and NF (2), can be difficult due to the interference of certain ingredients and because official methods do not always detect the presence of decomposition products of corticosteroids in the preparation. As a consequence, many "cleanup" procedures have been proposed to remove interferences and/or decomposition products before the actual final determinative step in the analysis of corticosteroids.

Levine (3) has reviewed the column partition chromatography of steroids and listed solka floc (4), silica (5, 6), siliconized diatomaceous earth (7), and diatomaceous earth (8) as the solid supports used. Jakovljevic *et al.* (9) used magnesium-silica gel¹ column chromatography with various solvent systems to remove the more polar interferences. Bracey *et al.* (10) utilized a column of methanol and water on acid-washed diatomaceous earth to remove interfering antibiotics from corticosteroid preparations.

This paper reports a new column partitioning chromatographic procedure which effectively traps the corticosteroid in an acetonitrile layer on a diatomaceous earth column while interferences are removed by washing with *n*-heptane. The acetonitrile and corticosteroid are then removed from the column with chloroform. The method may be modified readily for the removal of acidic, basic, and/or other water-soluble interferences.

EXPERIMENTAL

Apparatus—The following were used: Cary model 15 recording spectrophotometer; glass chromatographic columns, 2.2 × 25 cm. constricted at one end to 0.4 × 5 cm.; and aluminum tamping tool to fit chromatographic column.

Reagents—Solvents—All solvents were spectro, certified, analytical reagent, USP, or distilled-in-glass grade.

Acetonitrile, *n*-heptane, chloroform, methanol, and alcohol USP were used.

Acetonitrile-*n*-heptane (mutually saturated): mix 30 ml. of acetonitrile and 400 ml. of *n*-heptane in a separator. Agitate vigorously for at least 2 min. and separate when both layers are completely clear. These saturated solutions are to be used whenever *n*-heptane or acetonitrile is called for in these directions.

Chloroform (water saturated): add 50 ml. of water to 400 ml. of chloroform in a separator. Agitate vigorously for 2 min. and separate only when both layers are clear.

Diatomaceous earth,² acid washed, was used.

Standards—Hydrocortisone, hydrocortisone acetate, prednisolone, prednisolone acetate, prednisone (all USP reference standards); dexamethasone (NF reference standard); betamethasone (Schering Corp.); and flurandrenolone (Eli Lilly) were used.

All standard solutions were prepared as 1.00 mg./100 ml. in alcohol USP or as 100 mg./100 ml. in alcohol USP.

Reagents used in the determinative steps were prepared as specified in the method reference.

Proposed Column Procedure—Preparation of Column—Acetonitrile layer: insert a glass wool plug in the bottom of the chromatographic column. Thoroughly mix 4.0 g. of diatomaceous earth with 4.0 ml. of acetonitrile, transfer to the column, and pack firmly.

Aqueous trap layer: when it is necessary to remove water-soluble neutral impurities, an aqueous trap layer is used above the acetonitrile layer. Mix 2.0 g. of diatomaceous earth with 2.0 ml. of water, transfer to the column above the acetonitrile layer, and tamp firmly. If this type of trap is used, the chloroform must be saturated with water.

Aqueous basic trap layer: when it is necessary to remove water-soluble acidic interferences, a basic trap layer is used in the column above the acetonitrile layer. Mix 2.0 g. of diatomaceous earth with 2.0 ml. of either 8% (w/v) NaHCO₃ or 10% (w/v) Na₂CO₃, transfer to the column, and pack firmly above the acetonitrile layer. When this type of trap is used, the chloroform must be water saturated.

Aqueous acidic trap layer: when it is necessary to remove water-soluble basic interferences, both an aqueous layer and an acidic layer are used above the acetonitrile layer. Mix 1.0 g. of diatomaceous earth with 1.0 ml. of water and transfer to the column above the acetonitrile layer. Mix 2.0 g. of diatomaceous earth with 2.0 ml. of 1 *N* HCl, transfer to the column above the aqueous layer, and tamp firmly. Water-saturated chloroform is required in this case.

Sample layer: dissolve the sample residue, prepared as directed under *Sample Preparation*, in 1.0 ml. of acetonitrile and 2.0 ml. of *n*-heptane. Mix the solution thoroughly with 3.0 g. of diatomaceous earth, transfer to the column above the acetonitrile or other trap layer, and pack firmly. Dry wash the sample beaker with 1 g. of diatomaceous earth and with glass wool, both of which are transferred to the top of the column. Retain the sample beaker for washing with *n*-heptane and chloroform.

Elution of Column—Wash the sample beaker successively with six 25-ml. portions of *n*-heptane, which are transferred to the column. The liquid head should be maintained between 8 and 12 cm. above the column bed until the last wash, which is allowed to drain completely from the column. Wash the tip of the column with alcohol and discard the *n*-heptane and alcohol wash. Rinse the sample beaker with five 25-ml. portions of chloroform and pour each through the column, maintaining a liquid head of 8–12 cm. above the column bed until the last portion, which is allowed to drain completely from the column. Rinse the tip of the column with chloroform and add to the eluate. Evaporate the eluate carefully to dryness under air in the hood to ensure that the acetonitrile is evaporated completely and that fumes of acetonitrile are not generated in the open laboratory since acetonitrile vapors are toxic.

^a Compared to aliquots of the same sample determined identically but without going through the column procedure. ^b Calculated from the range by the method of Dean and Dixon (14).

Preparation of Sample Solution for Determinative Procedures—

Dissolve the residue from the chloroform eluate in alcohol USP and dilute accurately to a volume that will contain approximately 1 mg. of corticosteroid/100 ml. Use proper size aliquots of this solution for determination by one or more of the determinative procedures.

Determinative Procedures—Blue tetrazolium (BT) method: the procedure given in USP XVII (1) and NF XII (2) was followed, except that 10.0-ml. aliquots and 1.0 ml. each of the BT reagent and of the tetramethylammonium hydroxide reagent were used.

Phenylhydrazine (PH) method: the procedure of Silber and Porter (11) was followed without modification.

Isonicotinic acid hydrazide (INH) method: the procedure of Umberger (12) was used, except that the INH reagent was modified by using twice the recommended concentration of hydrochloric acid to increase the sensitivity of the reaction (13).

UV spectrophotometry: The alcohol USP solution was scanned directly in a 1-cm. cell.

Sample Preparation—Lotions, Creams, and Ointments—The sample size should be sufficient to contain approximately 5 mg. of the corticosteroid. For preparations declared on a weight-volume basis, transfer the selected volume to a beaker, using a pipet calibrated "to contain," and wash the contents of the pipet into the beaker with warm alcohol USP. For preparations declared on a weight-weight basis, weigh an accurate sample as rapidly as possible into a beaker. In either case, add warm alcohol USP up to a total volume of 30 ml. and heat on the steam bath with periodic agitation to incipient boiling. Cool in an ice bath until the residue solidifies and then decant the liquid into a 100-ml. volumetric flask. Repeat the extraction with three 20-ml. portions of warm alcohol, decanting each into the flask after cooling. Adjust to room temperature and dilute to volume with alcohol USP. Filter if necessary. Carefully evaporate a 20.00-ml. aliquot to dryness on the steam bath and continue as directed under "Sample Layer."

Drops, Injectables, and Suspensions—Accurately measure a volume of the sample containing approximately 1 mg. of cortico-

steroid into a beaker. Carefully evaporate to dryness under air on a steam bath and continue as directed under "Sample Layer."

Tablets—Weigh 20 tablets to obtain the average tablet weight. Grind the 20 tablets to pass a 60-mesh screen, mix thoroughly, and accurately weigh a sample containing approximately 1 mg. of corticosteroid into a beaker. Cover the sample with 1.0 ml. of methanol, swirl periodically during a 10-min. period, and add 1.0 ml. of water. Mix the solution thoroughly with 3.0 g. of diatomaceous earth; continue as directed under "Sample Layer" beginning with "...transfer to the column above the acetonitrile..." Use water-saturated chloroform in the elution step.

Buffered tablets that contain alumina or magnesium carbonate will not disperse properly under the conditions listed and must be dissolved by the following procedure. Prepare the column with the acetonitrile layer and an aqueous trap layer as directed previously. Add 1.0 ml. of dilute HCl to the accurately weighed sample and allow to stand for 5–10 min. to ensure complete solution of the oxide and/or carbonate. Add 2.0 ml. of water and 3.0 g. of diatomaceous earth and mix thoroughly. Transfer to the column; continue as directed under the "Sample Layer" beginning with "Dry wash the beaker..." Use chloroform saturated with water in the elution step.

Capsules—Weigh the net contents of 20 capsules to determine the average capsule content. Mix thoroughly and accurately weigh a sample containing approximately 1 mg. of the corticosteroid into a beaker. Proceed as directed under *Tablets* beginning with "Cover the sample with 1.0 ml. of methanol..."

METHOD DEVELOPMENT

Elution Curve—The column was prepared as directed under *Column Preparation*, including a sample of approximately 2 mg. of reference standard hydrocortisone. To ensure constant flow conditions, a 12-cm. liquid head was maintained in the column during elution by use of a separator. The 150-ml. *n*-heptane wash was evaporated to dryness, dissolved in alcohol USP, and scanned by UV. The spectrum showed no evidence of the presence of hydrocortisone. The chloroform eluate was caught in ten 10-ml. fractions and two 25-ml. fractions. Each fraction was taken to dryness,

dissolved in alcohol USP, and determined by UV spectrophotometry. The elution curve, shown in Fig. 1, indicates that the corticosteroid was completely eluted in the first 100 ml. of eluate. Since over 99.5% was eluted in the first 80 ml. of eluate, the use of 125 ml. of chloroform in the recommended procedure includes a definite safety factor.

Replication Studies—Six 2.00-ml. aliquots of a standard hydrocortisone solution containing 1.00 mg./ml. were determined by the suggested column procedure. Aliquots of the final alcohol solution were analyzed by all four determinative steps and compared to values obtained from aliquots of the same standard solution determined directly without being put through the column. The values are shown in Table I. The standard deviation, as calculated from the range by the method of Dean and Dixon (14), varies from 0.20%

for the UV method to 0.60% for the PH method, with an average of 0.50% for all four determinative procedures. This is approximately the same as the average standard deviation for six replicate 1.00-mg. samples of standard hydrocortisone which were dissolved in 100 ml. of chloroform, evaporated carefully to dryness, made to volume with alcohol USP, and determined by all four determinative procedures. The results, shown in Table II, have an average standard deviation of 0.61%.

Column Capacity Study—Samples of from 1.00 to 20.0 mg. of hydrocortisone were placed on and eluted from the column by the suggested procedure. The eluates were evaporated to dryness, dissolved in alcohol, and analyzed by UV spectrophotometry. The results were compared to identical samples which were not placed on and eluted from the column and are reported as percent recovery in Table III. Samples containing at least 20 mg. of corticosteroid can be determined safely by the suggested procedure.

Corticosteroid Applicability Studies—Since all of the method-development work utilized hydrocortisone, other corticosteroid standards were analyzed by the proposed column procedure utilizing the INH procedure and compared to identical standards which were not put on and eluted from the column. The results are shown in Table IV. The recoveries ranged from 97.6 to 101.7%, with an average recovery of 100.3% and a standard deviation calculated from the range by the method of Dean and Dixon (14) of 1.39%.

Interference Studies—The efficiency of the suggested procedure for the complete removal or reduction of interferences in the various determinative methods was investigated in sample preparations and by the addition of the interfering substances to hydrocortisone standards. In each case, the measurement was made on aliquots of the alcohol extract of the sample or of the extract of the standard plus the interfering substance. One aliquot was measured directly and the second was put through the column separation step before measurement. In the investigation involving the standard plus added interference, a standard without the interfering substance was also determined directly.

The results for two typical samples are shown in Table V. The values for the hydrocortisone cream show interference in both the BT and INH procedures, but none in the PH method when run directly. The interference in both BT and INH measurements was detected using the variation of absorbance with time method (15). The column separation procedure reduces the amount of interference in the BT method and completely removes the substances that interfere in the INH measurement.

Results for the buffered prednisolone tablets show the versatility of the suggested procedure in the detection and estimation of decomposition products in corticosteroid preparations. When run directly, interference was indicated only in the BT method, and this interference was not completely removed by the column procedure. Since the INH procedure depends upon conjugation in Ring A of the corticosteroid, and the BT and PH reagents react with the side chain at C₁₇ (15), the difference between the values by INH and PH when run directly indicates that the C₁₇ side chain in approx-

^a Average of duplicates. ^b Interfering substances present according to manufacturer's declared content: a, lanolin; b, magnesium stearate; c, parabens; d, salicylamide; e, sodium lauryl sulfate; f, sorbitan monostearate; g, stearic acid; and h, selenium sulfide. ^c Single determination. ^d Variation of absorbance with time indicates presence of unidentified interference. ^e ND, not determined by this method. ^f Salicylamide was removed by extraction of CHCl₃ eluate with 0.25 N NaOH before evaporation to dryness.

imately 40% of the declared amount of the corticosteroid had been oxidized to neutral or acidic products. The column procedure for buffered tablets of this type requires an aqueous trap layer to remove HCl from the chloroform, and this aqueous layer also removes any acidic decomposition products. The difference between the INH values before and after being put through the column indicates that approximately half of the decomposition products were acidic. The difference between the INH and PH results after being put through the column indicates that the other half of the decomposition products were neutral. These results also indicate that only 45% of the declared amount was actually present in the sample at the time of the analysis.

The results of the investigation using standards with added interfering substances are summarized in Table VI. The substances added have been reported to interfere in at least one of the determinative methods (15). The proposed procedure either eliminates the interference completely or greatly reduces it at the level shown. The first column of figures under each method is the absorbance for the standard alone run directly, the second column is the standard plus interference run directly, and the third column is the absorbance of standard plus interference after being separated by the proposed procedure. The differences in the values in the three columns indicate the extent of interference and the efficiency of removal.

RESULTS AND DISCUSSION

The results on typical undecomposed and partially decomposed corticosteroid preparations are summarized in Table VII. In each case in which there is significant disagreement between the BT and PH values, a study of the variation of absorbance with time indicates that some unidentified interfering substance is present. It is also apparent that such discrepancies are found more often in samples that have undergone decomposition, as indicated by significant differences between values obtained by the INH procedure and values obtained by the PH or BT method.

Diethyl ether was used instead of chloroform during part of this investigation for the removal of the corticosteroid from the column. It was found, however, that some bottles of ether contain ether peroxides, which cause decomposition of the corticosteroid during the evaporation step and also interfere with all four determinative methods. When ether is used, the column must be kept completely filled during the elution step to ensure that the corticosteroid is

completely eluted from the column. Since chloroform has none of these disadvantages, it is the solvent of choice for the elution step. Isooctane (2,2,4-trimethylpentane) was substituted for the *n*-heptane in several analyses but did not improve the results obtained.

The few minor limitations of the proposed procedure include the care that must be used in the evaporation of acetonitrile, because it is toxic and because any acetonitrile left unevaporated will cause gross interference in the BT procedure. Also, if the liquid head in the column is maintained above 12 cm. during the *n*-heptane wash, some acetonitrile will be stripped from the column. This could lead to some of the corticosteroid also being removed during the wash step.

Some substances, which interfere in one or more of the determinative steps, are sufficiently soluble in both water and chloroform to be removed from an aqueous trap layer in the elution step. If this occurs, the eluate is evaporated, redissolved in acetonitrile-*n*-heptane, and transferred to a new column without an aqueous trap layer. One example of an interfering substance of this type is a decomposition product of corticosteroids thought to be a glyoxal.

Preliminary work with the column indicates that it can be used to improve the analysis of other types of steroids and may be used to separate with ease certain important steroids occurring in pharmaceutical preparations. Investigative work is continuing on the use of the column for such separations.

Quantitative Determination of Butaperazine by TLC

A. J. KAPADIA, M. A. BARBER, and A. E. MARTIN

Abstract □ A method for the separation and determination of butaperazine in the presence of its degradation products is described. A sample is streaked onto a thin layer of silica gel G under a stream of nitrogen. The chromatogram is developed with isopropyl alcohol-ammonia (1 N) (4:1). The separated butaperazine is removed from the silica gel by elution with methanol and is determined quantitatively by UV spectroscopy. Details of the elution technique are described. Using the proposed method, quantitative recoveries are obtained from tablets and syrups.

Keyphrases □ Butaperazine in dosage forms—analysis □ TLC—separation □ UV spectrophotometry—analysis

The use of psychotropic drugs for the treatment of patients with emotional or mental disorders has led to widespread use of phenothiazine derivatives. One such derivative is butaperazine,¹ 2-(*n*-butyryl)-10-[3-(4-methyl-1-piperazinyl)-propyl]-phenothiazine.

The literature provides ample indication that several types of decomposition take place in these compounds. One type involves oxidation at the sulfur atom, leading to sulfoxide and eventually to sulfone (1). The quinonoid-type oxidation products of phenothiazine have been described (2–4). Huang and Sands (5, 6) studied the effect of UV irradiation on chlorpromazine solution under aerobic and anaerobic conditions. They found that under the former condition, oxidation prevails and the sulfoxide and *N*-oxide are formed; however, under the latter condition, the polymerization processes predominate.

The degree of deterioration and the type and amount of decomposition product pose difficult problems for the analyst. Consequently, for the purpose of establishing stability, it is necessary to devise a relatively simple but versatile separation, one that would be applicable to the quantitative determination of the phenothiazine derivative in experimental formulations.

Recently, Blazek (7) reviewed the procedures available for quantitative determination of phenothiazine derivatives. Included among the methods for these compounds are colorimetric (8), titrimetric (9), UV absorption spectrophotometric, and chromatographic procedures. One might choose any one of these except

for the following considerations. The first two procedures are not selective for the undegraded compound. The UV method (10, 11) is an accurate and convenient means of assaying formulations containing phenothiazine derivatives, but it is unsuitable in badly degraded formulations because of the presence of other UV absorbing species. A paper chromatography technique (12, 13) was not selected because of degradation and tailing occurring during analysis (14, 15). Gas chromatographic procedures have been used for phenothiazines, but the present authors observed that butaperazine, because of its high boiling point and low thermal stability, was too low in volatility to be eluted quantitatively without extensive thermal decomposition from the several columns that were tried. Thus, they eliminated GLC from further consideration.

Since its introduction by Stahl (16), TLC has assumed a position of analytical importance for both the separation and analysis of complex inorganic, organic, and biological mixtures. Several papers have been published which describe quantitative thin-layer techniques (16–19). These methods can be classified as direct or indirect.

In the direct method, the developed chromatogram is quantitatively evaluated by measuring spot size or area or by densitometry. Thus, measurement is accomplished without removing the sought-for substance from the support. An indirect method implies removal of the separated substance from the plate. This may be followed by elution of the sample from the adsorbent and analysis of the eluant, usually by spectrophotometry or colorimetry. Indirect methods have the advantage in that spectra of the samples are readily obtained as part of the analysis. These may provide important additional information concerning identity and purity (20). Spencer and Beggs (21) have pointed out certain precautions which must be taken if an indirect method is to give precise, accurate results.

The authors report an application of the indirect method, utilizing TLC for the physical separation of butaperazine from its degradation products and, subsequently, quantitative determination of butaperazine using UV spectroscopy. Possible sources of error in the method are examined. The initial steps in the oxidative decomposition of butaperazine are shown.

Thus, they eliminated GLC from further consideration.

Since its introduction by Stahl (16), TLC has assumed a position of analytical importance for both the separation and analysis of complex inorganic, organic, and biological mixtures. Several papers have been published which describe quantitative thin-layer techniques (16–19). These methods can be classified as direct or indirect.

In the direct method, the developed chromatogram is quantitatively evaluated by measuring spot size or area or by densitometry. Thus, measurement is accomplished without removing the sought-for substance from the support. An indirect method implies removal of the separated substance from the plate. This may be followed by elution of the sample from the adsorbent and analysis of the eluant, usually by spectrophotometry or colorimetry. Indirect methods have the advantage in that spectra of the samples are readily obtained as part of the analysis. These may provide important additional information concerning identity and purity (20). Spencer and Beggs (21) have pointed out certain precautions which must be taken if an indirect method is to give precise, accurate results.

The authors report an application of the indirect method, utilizing TLC for the physical separation of butaperazine from its degradation products and, subsequently, quantitative determination of butaperazine using UV spectroscopy. Possible sources of error in the method are examined. The initial steps in the oxidative decomposition of butaperazine are shown.

¹ Marketed as Repoise by A. H. Robins Co., Richmond, VA 23220

Figure 1—Elution assembly for quantitative recovery of sample.

EXPERIMENTAL

Apparatus—The following were used: Hamilton syringe, fixed needle, blunt tip, 100 and 250 μ l.; microbeaker, Pyrex, filter type with fine-porosity fritted disk; glass plates (20 \times 20 cm.); and Shandon Chromatank (Cat. No. SAB-2843) lined with solvent-saturated filter paper.

Chemicals—All chemicals and reagents used were analytical reagent grade. The chemical purity of standard butaperazine was checked by melting point and TLC. Solubility analysis gave further indication of the purity of the standard.

Phosphate Buffer Solution, pH 5.3—Sodium dihydrogen phosphate monohydrate ($\text{NaH}_2\text{PO}_4 \cdot \text{H}_2\text{O}$), 38.0 g., and 2.0 g. disodium hydrogen phosphate (Na_2HPO_4) were dissolved and diluted to 1 l. with water.

Preparation of Thin-Layer Plates—A slurry of silica gel G was prepared from 30 g. of Merck silica gel G, grain size 10–40 μ , and 60 ml. water. This was applied to glass plates with an appropriate spreader set at 250 μ . The plates were air dried for 15 min. and then activated at 105° and stored over anhydrous silica gel. Subsequent work has shown that the air-dried plates without activation yield the same type of separation.

Developing Solvent—The developing system consisted of 4 parts isopropyl alcohol and 1 part 1 N ammonia. The system was prepared just prior to use and used only once.

Preparation of the Standard—The standard solution of butaperazine phosphate or maleate was prepared in phosphate buffer solution (pH 5.3) such that it contained a concentration of the salt equivalent to 1.91 mg./ml. of the base. The solution was thoroughly mixed, and 10-ml. aliquots were transferred to a separator. The aqueous solution was extracted, using successively one 10-ml. and three 5-ml. portions of chloroform. The standard solution was prepared just prior to use.

Application of Drug and Development of Chromatogram—Using a precision syringe, a predetermined amount of chloroform extract was applied to a plate. The organic extract was transferred as a narrow streak 4 cm. long. An appropriate streak was achieved by applying successive 10- μ l. portions of the solution, evaporating each portion with a slow stream of nitrogen. This application was repeated until a total of about 0.1 mg. of butaperazine base was applied on the same streak. One hundred microliters of the standard solution previously described was applied as a single streak.

Another streak using the sample solution was applied in the same manner on the other side of the plate. The exact quantity applied depended, of course, on the expected sample concentration.

The prepared plates (two or more) were placed into separate chromatographic chambers. Each chamber was equilibrated for 2 hr.

and contained 150 ml. developing solvent. The chromatogram was allowed to develop in the dark and terminated when the solvent front ascended to a height of 15–16 cm. The developed plate was dried in a vacuum desiccator and was subsequently examined briefly under an UV lamp (254 $m\mu$) to locate the separated butaperazine. The butaperazine appeared as a bright-orange to pink fluorescent streak at R_f approximately 0.5. This area was carefully marked, taking care not to overlap any other fluorescent areas.

Quantitative Determination of Butaperazine—Quantitative determination was accomplished by carefully removing the portion of silica gel adsorbent containing the butaperazine. The powder was removed by scraping onto nonabsorbent paper and was then transferred to a microbeaker with the aid of a small funnel. Methanol (3 ml.) was added and, after mixing gently, the mixture was allowed to stand for 15 min. The methanolic extract was collected by filtration, using the filtration assembly shown in Fig. 1. Elution of butaperazine was continued, using two additional 3-ml. portions of methanol. The combined extracts were finally diluted to 10 ml. with

^a Corrected for analytical blank.

methanol and mixed. The UV spectrum of the methanolic solution was then recorded in 1.0-cm. cells, using methanol as the reference.

Assay of Experimental Preparations—Each formulation was treated individually because of differences in the concentration of butaperazine. The general procedure for film-coated tablets involved reducing several weighed tablets in a mortar to a fine powder and passing the grind through a No. 50 sieve. A weighed portion of the sieved grind was then transferred to a separator using phosphate buffer solution. After mixing thoroughly, the mixture was extracted completely with chloroform. Each portion of the chloroform extract was transferred through a pledget of chloroform-washed cotton into a flask. During the transfer, the withdrawal of any insoluble matter was avoided. The chloroform extract was either concentrated or diluted to volume, depending upon the concentration of butaperazine. It was then chromatogrammed and assayed. Usually the standard and sample were run concurrently; therefore, absorbance values of the butaperazine eluates were not corrected for adsorbent blank.

RESULTS AND DISCUSSION

To compare UV spectra, a standard butaperazine maleate solution was prepared and extracted with chloroform as described. One aliquot was diluted directly with methanol. An equal aliquot was chromatographed, the butaperazine was eluted, and the solution was finally diluted to volume with methanol. As seen in Fig. 2, absorbance spectra before and after TLC were essentially identical above 240 m μ . Below this wavelength, the spectrum of an unchromatographed sample exhibits a higher absorbance. This observed spectral difference reflects the presence of chloroform in the unchromatographed sample. Although 242 m μ could not be utilized as an analytical wavelength because of interferences, use of the absorbance maximum at 278 m μ provided a direct measure of intact butaperazine. At this wavelength, there is little interference in the analytical blank or from formulation excipients. The position of maximum absorbance and absorbancy coefficient did not change significantly above 240 m μ during chromatography. This observation indicates that the responsible chromophore is not modified during chromatography.

Two-dimensional TLC, using the same solvent system for development in both directions, confirmed the stability of butaperazine during chromatography. No evidence of decomposition or alteration of the butaperazine spot was noted.

The spectral absorbance of the silica gel was obtained by collecting portions of the surface layer in a region near the butaperazine

Table III—Recovery of Butaperazine in the Presence of Its Oxidation Products

120	0.389	0.290

spot and processing them in exactly the same manner as the sample. Absorbance of the filtrate was found to be 0.008 at 278 m μ , using a 1.0-cm. pathlength. This value is on the order of a few percent of the absorbance for the chromatographed samples.

Treatment of the eluant to remove most of the finely divided, insoluble particles of the adsorbent is an important step in improving the precision of the method. The 0.008 figure cited, which was repeatedly obtained, agreed closely with the published value of Spencer and Beggs (21).

A standard curve was prepared from aqueous solutions of butaperazine carried through the procedure described. At 278 m μ , a linear relationship exists between the absorbance and the amount of butaperazine in the range 45–123 mcg.

The precision of the method was established by measuring the absorbance at 278 m μ and calculating the absorptivity for known samples. Table I summarizes the precision data obtained for the whole procedure (including sample preparation, extraction, TLC, and elution). The experimentally determined mean absorptivity of a set of 10 assay runs on known samples was 51.3. The standard deviation (single measurement) was 0.56.

Experiments were conducted to determine the total recovery of butaperazine after TLC and elution (Table II). The average recovery (10 trials) was 98.3% (range 96–102%).

These high recoveries may be attributed partly to the method of elution chosen. Thus, butaperazine on the silica gel was exposed repeatedly to fresh solvent. Minimizing the volume of eluting solvent and filtering concurrently decreased losses from filtration and transfer.

To assess application of the method to degraded samples, mixtures of butaperazine, butaperazine sulfoxide, and sulfone were prepared so as to simulate various degrees of oxidation. These mixtures were assayed for intact butaperazine (Table III). As expected, recoveries were uniformly high, averaging better than 97%.

The assay method was further tested for its applicability in the presence of oxidative degradation products of butaperazine. Buffered aqueous solutions of butaperazine maleate were treated with 0.3 ml. and 0.6 ml. hydrogen peroxide (30%) for 30, 60, and 120 min. After each interval, the solutions were extracted with chloroform. The amount of butaperazine remaining was determined, using the procedures described (Table IV). In summary, hydrogen peroxide treatment causes a loss of butaperazine, which increases with time of exposure. Table III reveals that, as the amount of peroxide is increased, decomposition of butaperazine increases. Examination of TLC plates confirmed that the butaperazine spot became smaller and fainter with time and/or increasing peroxide concentration. The other change noted was in the sulfoxide spot, which increased in size and intensity with time. Thus, the sulfoxide appeared to be the major product for this oxidative degradation.

Table V—Assay of Butaperazine in Experimental Formulations: Application of TLC Method

Formulation	Storage Conditions	Labeled Amount of Butaperazine	Label Claim Found, %
Tablets	12 months at RT	51.3 mg./tablet	97.2
	12 months at 37°		99.4
	12 months at 50°		97.8
Syrup	Initial	5 mg./ml.	98.2
	12 months at RT		98.3
Injectables	3 months at RT	5 mg./ml.	96.8
	3 months at 37°		98.5
	3 months at 50°		99.0

Unbuffered aqueous solutions of butaperazine phosphate were placed in a commercial light-stability testing unit. After 7 and 15 days of exposure, the solutions were assayed. As expected, the butaperazine content had decreased by 16 and 22%, respectively.

Aqueous solutions of butaperazine buffered at pH 5.3 were sealed in glass ampuls and autoclaved at 115° for 30, 60, and 120 min. The ampuls were cooled, opened, and assayed for butaperazine. An initial 10% loss was noted, which did not increase with time. Atmospheric oxygen initially present in the vial and test solution was suspected. When consumed, no further oxidation occurred. This suspicion was confirmed by autoclaving ampuls in which oxygen was replaced with nitrogen. As predicted, these solutions did not show a significant loss of butaperazine.

Tablets, syrups, and injectables were assayed by the method described. These results are shown in Table V. The excipients, coloring agents, diluents, and fillers employed in the various formulations did not interfere.

It is evident that the formulations tested exhibited no significant decomposition. Storage at elevated temperatures (37 and 50°) for extended periods did not change this overall picture.

Several experimental factors were found to be critical in obtaining precise, accurate results. The area of the sample streak increases during development; therefore, care must be taken to keep the initial application narrow and uniform. Evaporation of the organic solvent must be accomplished quickly with a nonoxidizing drying agent. This precaution minimizes the size of the sample streak and prevents oxidative decomposition.

Use of the solvent system for more than one separation is not permissible, because decreased separation of butaperazine and decomposition products occurs and the R_f values change unpredictably.

Investigation was begun early to elucidate the major decomposition products of butaperazine and to compare them to those of other phenothiazines.

Chloroform solutions of butaperazine, its sulfoxide, and sulfone² were compared by TLC to the chloroform extract of degraded aqueous samples of butaperazine. These results showed that the sulfoxide and sulfone migrate slower than butaperazine in an isopropanol-NH₃ system. In addition, all were well resolved from butaperazine. In a degraded sample, one of the bands corresponded to the position of the sulfoxide streak. This band was eluted with methanol. The UV spectrum of the eluate was identical to that of the synthetic sulfoxide. The band corresponding to the synthetic sulfone could not be isolated by the techniques employed.

When a developed TLC plate was exposed for a few days to normal atmosphere, it was noted that the fluorescence of the butaperazine band changed with time. The resulting fluorescence was similar to that of a degraded sample.

TLC of grossly degraded samples often revealed the presence of products other than those described. Oxidative decomposition apparently is not the only degradation pathway, although, undoubtedly, the predominant one. Degradation apparently proceeds as follows: [butaperazine]...[sulfoxide]...[sulfone]...[other oxides].

Separation and Determination of Anhydrotetracycline, 4-Epianhydrotetracycline, Tetracycline, and 4-Epitetracycline in a Tetracycline Mixture

PETER P. ASCIONE and GEORGE P. CHREKIAN

Abstract □ A column chromatographic method for the determination of anhydrotetracycline, 4-epianhydrotetracycline, tetracycline, and 4-epitetracycline has been developed. The chromatogram involves the separation of these tetracyclines on a column of acid-washed diatomaceous earth treated with buffer consisting of 0.1 M ethylenediaminetetraacetic acid disodium salt at pH 7.0, glycerin, and polyethylene glycol 400, followed by a modified spectral determination of column eluates.

Keyphrases □ Tetracycline mixture—anhydrotetracycline, 4-epianhydrotetracycline, tetracycline, 4-epitetracycline determination □ Column chromatography—separation □ Colorimetric analysis—spectrophotometry

The method described in this paper was modified and adapted from previous studies (1, 2). Known tetracycline mixtures were determined with recoveries of 98.0 to 102.0% for anhydrotetracycline (ATC), 4-epianhydrotetracycline (EATC), tetracycline (TC), and 4-epitetracycline (ETC).

In the course of work in these laboratories on the stability of TC, it was necessary to find a specific and accurate method for the determination of degraded and nondegraded TC in crystalline and pharmaceutical preparations. The methods described by various workers (3–7) for separation of degraded TC from TC have been found workable and reproducible here, but they had the disadvantage of not determining all the components of a TC mixture on a single chromatogram.

TLC and column chromatographic methods were developed in these laboratories for the separation, examination, and determination of TC (1, 2). With modification of both the column chromatographic and spectrophotometric method, a specific and accurate method of assay for ATC, EATC, TC, and ETC, in TC mixtures, has been developed. This method allows a separate analysis for all components, thus providing a scheme for determining the column recovery quantitatively.

EXPERIMENTAL

Materials and Methods—Reagents, the preparation of diatomaceous earth¹ and chromatographic columns, and the apparatus have been described previously (2). A pH of 7.0 was maintained.

Determination of ATC, EATC, TC, and ETC—The general procedure, column preparation, and sample preparation for crystalline TC HCl or capsules and tablets were as described for demethylchlortetracycline HCl (2).

Sample Preparation—TC Neutral and Syrups—This was the same as described for demethylchlortetracycline neutral (2), except that

Table I—Analysis of Synthetic Mixtures of ATC, EATC, TC, and ETC

No.	Standard Mixtures	Amount Present, mg.	Amount Found, mg.	Recovered, %
1	ATC HCl	2.58	2.55	98.8
	EATC HCl	2.32	2.31	99.6
	TC HCl	19.01	18.98	99.8
	ETC HCl	0.51	0.50	98.0
2	ATC HCl	2.32	2.27	97.8
	EATC HCl	3.29	3.30	100.3
	TC HCl	18.91	18.98	100.4
	ETC HCl	0.50	0.51	102.0

20 mg. of TC neutral or 1.0 ml. of syrup equivalent to 20–25 mg. of TC was used.

Development of Column—Use a 25-ml. glass-stoppered graduate as the primary receiver under the column. Add 20 ml. of benzene to the column. When the solvent level reaches the top of the column packing, add 60 ml. of chloroform. After collecting 10 ml. (Cut 1), remove the primary receiver and replace with a 10-ml. graduate. Collect 5 ml. in this graduate and discard. Replace the 10-ml. graduate with another 25-ml. glass-stoppered graduate. After collecting 15 ml. (Cut 2), remove the second graduate and replace with a 50-ml. volumetric flask. Collect the eluate in this flask until the level of the solvent in the column again reaches the top of the packing. Replace the 50-ml. volumetric flask (Cut 3) with a 10-ml. graduate, and add 40 ml. of 50% *n*-butanol in chloroform to the column. When the volume of eluate in the graduate reaches 8 ml., replace the 10-ml. graduate (Cut 4) with a 50-ml. glass-stoppered graduate and collect all of the last solvent added to the column (Cut 5).

Assay of Column Cuts—Determine the absorbance of Cut 1 (ATC) and Cut 2 (EATC) in a 1-cm. cell against chloroform at a wavelength of 438 m μ on a suitable spectrophotometer.

To Cut 3 (TC), add Cut 4 and mix well. Add 2.0 ml. of alkaline methanol solution and dilute to volume with chloroform. Determine the absorbance of this solution in a 1-cm. cell against chloroform, at a wavelength of 366 m μ , on a suitable spectrophotometer within 10 min. after making the solution alkaline. To Cut 5 (ETC), add 2.0 ml. of alkaline methanol; adjust the volume to the nearest milliliter graduation with chloroform, mix, and record the volume. Determine the absorbance of this solution in a 1-cm. cell against chloroform, at a wavelength of 366 m μ , within 10 min. after making the solution alkaline.

RESULTS AND DISCUSSION

In earlier work (1, 2), the separation and determination of TC by TLC and column chromatography suggested the development of this column chromatographic technique. The effectiveness of the column for the separation of ATC, EATC, TC, and ETC was demonstrated by the use of TLC (1). The column eluates were collected in fractions of 5 ml. and examined by TLC. Figure 1 shows the chromatography of column eluates. According to the results of TLC, the TC was separated on a column of acid-washed diatomaceous earth treated with EDTA, polyethylene glycol 400 (PEG 400), and glycerin at pH 7.0, using benzene, chloroform, and butanol as the developing solvents. The ATC and EATC are visible yellow bands which can be seen during chromatography. The TLC shows the distribution of the TC components isolated on

¹ Celite 545, Johns-Manville Corp., New York, NY 10016

Figure 1—TLC of TC mixture column fractions: (1) ATC; (5) EATC; (9-11) TC; (19-20) ETC; and (21) reference standard mixture.

the column and having R_f values similar to those of standard test references.

Absorption Spectra—Absorption spectra in the region of 350–550 $m\mu$ were determined on a Cary model II recording spectrophotometer. Standard solutions of ATC and EATC, containing 0.25 mg./ml., were prepared by dissolving 25 mg. of standard in 10 ml. of methanol and diluting to 100 ml. with chloroform. Six

milliliters of the chloroform solution was transferred to a 25-ml. volumetric flask and then diluted to 25 ml. with chloroform. Figures 2 and 3 show the spectra of ATC and EATC with both maxima at 438 $m\mu$.

Through examination of the anhydro standards in these laboratories, the absorptivity for both ATC and EATC at 438 $m\mu$ was found to be 1.85×10^{-2} . The absorptivity is defined as the optical

Figure 2—Absorption spectrum of ATC.

Figure 3—Absorption spectrum of EATC.

density at the wavelength of each particular TC for a solution containing 1 mcg. of TC per milliliter, using a 1-cm. cell.

A standard calibration curve of ATC HCl was prepared in chloroform solutions. In the analysis of ATC HCl, a linear relationship over the range of 0.025–1.5 mg./50 ml. is obtained. The absorptivity for TC and ETC was determined in alkaline methanol at 366 m μ and found to be 3.29×10^{-2} as previously described (2). The determination of absorbances of the column chromatography eluates provided a quantitative spectrophotometric method for assaying ATC, EATC, TC, and ETC in solvent solutions when compared with standards treated in a like manner.

To test the accuracy of this column chromatographic procedure for TC mixtures, a known mixture was made of standards of ATC, EATC, TC, and ETC, which was analyzed by the column procedure with the recoveries shown in Table I.

In the two experiments performed, recoveries of 98.0–102.0% were obtained on TC mixtures. Quantitative analysis of synthetic mixtures of TC was achieved with high degree of accuracy (Table I) on the column of acid-washed diatomaceous earth treated with buffer consisting of 0.1 M EDTA, glycerin, and PEG 400 at pH 7.0. Therefore, this method has the advantage of determining the entire content of a TC mixture on a single chromatogram.

Spectrophotometric Assay of Potassium Permanganate Tablets (USP XVII)

A. MANCOTT and J. TIETJEN

Abstract ☐ Assay of potassium permanganate tablets (USP XVII) was accomplished by a spectrophotometric procedure. This method is comparable in accuracy to the USP XVII titrimetric procedure.

Keyphrases ☐ Potassium permanganate tablets—analysis ☐ Colorimetric analysis—spectrophotometer

The quantitative determination of potassium permanganate by a spectrophotometric method has been reported by Bastian *et al.* (1). The application of this method to the assay of USP XVII potassium permanganate tablets, as compared to the standard USP XVII titrimetric assay for potassium permanganate tablets (2), is reported in this article.

The spectrophotometric method reported here is comparable in accuracy to the USP XVII assay, but it is considerably simpler to do and results in an appreciable saving of time, labor, and materials.

EXPERIMENTAL

Apparatus—Spectra and absorbance measurements were made with a spectrophotometer¹ (slit width 5 Å). Matched cells with a 1-cm. optical path were used.

Reagents and Chemicals—Potassium permanganate solution (0.1 N)² was standardized against 0.1 N oxalic acid solution.³ Potassium permanganate tablets USP XVII (300 mg.)⁴ were assayed. All other reagents used were of the highest commercial grade available.

¹ Bausch and Lomb, model 505.

² Fisher Certified reagent.

³ Fisher Certified reagent.

60.059	0.939
63.220	0.988

Procedure—Standardized solutions of potassium permanganate were prepared and their absorbances measured. Twenty 300-mg. potassium permanganate tablets USP XVII were weighed and finely powdered. An accurately weighed portion of the powder, 50–55 mg., was dissolved in water and diluted to 1 l. The absorbance of the solution was measured at 526 m μ and compared with the standards to determine its concentration. The same samples were also assayed according to the USP XVII titrimetric procedure.

RESULTS AND DISCUSSION

Absorbance readings for the standardized potassium permanganate solutions in the concentration range of 44–64 mg./l. were obtained (Table I). A graph of absorbance *versus* concentration was linear with a slope of 0.0156.

The percent potassium permanganate in the sample used is found from:

$$\% \text{KMnO}_4 = \frac{A}{0.0156 \times W} \times 100 \quad (\text{Eq. 1})$$

where A = absorbance, and W = weight in milligrams of the KMnO₄ sample.

USP XVII standards for potassium permanganate tablets contain not less than 95% and not more than 105% of the labeled amount of KMnO₄ for tablets of 300 mg. or more, and not less

density at the wavelength of each particular TC for a solution containing 1 mcg. of TC per milliliter, using a 1-cm. cell.

A standard calibration curve of ATC HCl was prepared in chloroform solutions. In the analysis of ATC HCl, a linear relationship over the range of 0.025–1.5 mg./50 ml. is obtained. The absorptivity for TC and ETC was determined in alkaline methanol at 366 m μ and found to be 3.29×10^{-2} as previously described (2). The determination of absorbances of the column chromatography eluates provided a quantitative spectrophotometric method for assaying ATC, EATC, TC, and ETC in solvent solutions when compared with standards treated in a like manner.

To test the accuracy of this column chromatographic procedure for TC mixtures, a known mixture was made of standards of ATC, EATC, TC, and ETC, which was analyzed by the column procedure with the recoveries shown in Table I.

In the two experiments performed, recoveries of 98.0–102.0% were obtained on TC mixtures. Quantitative analysis of synthetic mixtures of TC was achieved with high degree of accuracy (Table I) on the column of acid-washed diatomaceous earth treated with buffer consisting of 0.1 M EDTA, glycerin, and PEG 400 at pH 7.0. Therefore, this method has the advantage of determining the entire content of a TC mixture on a single chromatogram.

Spectrophotometric Assay of Potassium Permanganate Tablets (USP XVII)

A. MANCOTT and J. TIETJEN

Abstract ☐ Assay of potassium permanganate tablets (USP XVII) was accomplished by a spectrophotometric procedure. This method is comparable in accuracy to the USP XVII titrimetric procedure.

Keyphrases ☐ Potassium permanganate tablets—analysis ☐ Colorimetric analysis—spectrophotometer

The quantitative determination of potassium permanganate by a spectrophotometric method has been reported by Bastian *et al.* (1). The application of this method to the assay of USP XVII potassium permanganate tablets, as compared to the standard USP XVII titrimetric assay for potassium permanganate tablets (2), is reported in this article.

The spectrophotometric method reported here is comparable in accuracy to the USP XVII assay, but it is considerably simpler to do and results in an appreciable saving of time, labor, and materials.

EXPERIMENTAL

Apparatus—Spectra and absorbance measurements were made with a spectrophotometer¹ (slit width 5 Å). Matched cells with a 1-cm. optical path were used.

Reagents and Chemicals—Potassium permanganate solution (0.1 N)² was standardized against 0.1 N oxalic acid solution.³ Potassium permanganate tablets USP XVII (300 mg.)⁴ were assayed. All other reagents used where of the highest commercial grade available.

¹ Bausch and Lomb, model 505.

² Fisher Certified reagent.

³ Fisher Certified reagent.

Quantitative Separation of Free Estrogens by Liquid Partition Chromatography

G. J. KROL, R. P. MASSERANO, J. F. CARNEY, and B. T. KHO

Abstract □ A mixture of structurally related estrogens containing estrone, equilin, equilenin, 17 α -estradiol, 17 α -dihydroequilin, and 17 α -dihydroequilenin was separated by a partition column chromatographic system based on a lipophilic polydextran stationary support and a composite organic solvent. The chromatographic column yielded 25 theoretical plates per centimeter of column height at 0.6 ml./min. flow rate; column efficiency was studied as a function of solvent flow rate, and an inverse relationship between the two parameters was observed. Since the complete separation of the six estrogens required 10 hr., the column was shortened to yield a 3-hr. elution, which separated completely four of the estrogens with only partial overlap between estrone and equilin. The overlap between estrone and equilin was resolved quantitatively by specific colorimetric and fluorometric determinations. The method may be scaled up for preparative purposes, it is applicable to other steroids that are too labile for gas chromatography, and the same chromatographic column can be used repeatedly.

Keyphrases □ Estrogens, free—quantitative separation □ Chromatography, liquid partition—separation □ Fluorometry—analysis □ Colorimetric analysis—spectrophotometer □ UV spectrophotometry—analysis

The separation and quantitative determination of estrogens were studied by a number of investigators. The problem was already approached by gas chroma-

tography (1, 2), TLC (3), and liquid chromatography (4-6). However, no quantitative chromatographic method applicable to an estrogen mixture containing closely related structures such as estrone, equilin, equilenin, estradiol, dihydroequilin, and dihydroequilenin was reported in the literature. Although this study is based only on the analysis of an arbitrary mixture of these synthetic free estrogens, the sulfate esters of these free estrogens are the principal ingredients of the naturally occurring estrogenic hormones (7, 8).

Another consideration was the need for a chromatographic procedure that would be applicable to the separation of structurally related free estrogens for preparative purposes. Liquid column chromatography is ideally suited for this purpose. Furthermore, such a system may also be applicable to the analysis of other steroid structures that are too labile for gas chromatography. For example, Vandenheuvel and Horning (9) observed that gas chromatography of C-21 steroids containing an α -ketol side chain led to side-chain cleavage. Other internal rearrangements of C-21 steroids were observed by Brooks (10). Such rearrangements could lead to complications in the quantitation and the

Figure 2—Separation of estrone (ES), equilin (EQ), equilenin (EQN), estradiol (ED), dihydroequilin (DHEQ), and dihydroequilenin (DHEQN) on Sephadex LH-20 (0.9 × 45-cm. column) with cyclohexane–benzene–methanol (500:150:75) solvent. Flow rate: 1.6 ± 0.1 ml./min.

degree of specificity of the gas chromatographic separation.

The chromatographic approach selected in this study was based on the need for a selective separation system which would be applicable to both analytical and preparative purposes. The choice of a partition chromatographic system involving a lipophilic polydextran gel support and a nonaqueous solvent system was suggested by the work of Nystrom and Sjoval (11) and Seki (12) with other steroids. However, the previous work (11, 12) was not quantitative and not directly applicable to the present requirements.

The chromatographic system reported in this paper yielded 3020 theoretical plates and separated the six estrogens. However, the complete separation required 10 hr. Since the rate-determining step is the separation of estrone and equilin, the authors decided, for practical considerations, to base the quantitative analytical method on a less time-consuming chromatographic system which separates all of the estrogens except estrone and equilin. The short column separation required 3 hr. Furthermore, the partial overlap between estrone and equilin was resolved quantitatively by three independent nonchromatographic procedures. One procedure depended on a colorimetric reaction which was specific for equilin (13). The other two depended on a relatively higher specific fluorometric (14) and colorimetric response of estrone as compared to equilin after heating in a sulfuric acid–methanol–water solution. The latter procedures were modified to enhance the selectivity for estrone.

Since the chromatographic solvent selected for the complete separation of the estrogen mixture was relatively volatile and inert, the separation may be adapted to preparative purposes. An analogous chromatographic system was also found applicable to C-21

steroid structures containing labile side chains and to steroids that are prone to dehydration under gas chromatographic conditions (15).

EXPERIMENTAL

Apparatus—All chromatographic separations were carried out in 0.9-cm. (i.d.) and 50–125-cm. columns.¹ Chromatograms were obtained with a flow-cell² and recording spectrophotometer³ system. A pulseless pump⁴ was used to vary the elution flow rate. A spectrofluorometer⁵ was used for the fluorometric analyses. UV and colorimetric determinations were carried out with a recording spectrophotometer.⁶

Reagents and Materials—The following solvents were used: reagent grade glacial acetic acid, benzene, methanol, concentrated sulfuric acid, toluene, triethylamine, trimethylamine, xylene, and spectroquality cyclohexane;⁷ reagent grade benzene was redistilled prior to use. Free estrogen samples were of reference standard purity.⁸ The commercially available lipophilic gel⁹ was used without pretreatment.

Preparation of Column—The gel was suspended in the chromatographic solvent (200 ml. of solvent/10 g. of gel), and the resulting slurry was equilibrated by shaking for at least 2 hr. The gel was allowed to settle, excess solvent was decanted, and a fresh portion of solvent was added. This procedure was repeated three times. The final slurry was transferred to the column by gravity feed and packed at elution pressure to the desired length.

Chromatography—An aliquot (0.5–1 ml.) containing a mixture of free estrogens (50–200-mcg. amounts) in a given chromatographic solvent was applied quantitatively to the column. The column was eluted with the aid of a pulseless pump at flow rates ranging from 0.4–2 ml./min. The elution patterns were recorded by the flow-cell spectrophotometer system, and fractions were collected at appropri-

ate elution volumes. A 100-ml. fraction free of any estrogens was collected for a blank in UV determinations.

Quantitation—Each fraction was evaporated to dryness at 50° under nitrogen. The estrogen fractions were reconstituted quantitatively with methanol in a 5-ml. volumetric flask. The 100-ml. blank fraction was reconstituted in a 10-ml. volumetric flask. Each fraction was scanned by a recording spectrophotometer against methanol and an appropriate blank, which was prepared from the 100-ml. fraction. Aliquots of each fraction were then withdrawn for the fluorometric and colorimetric analyses.

The fluorometric analysis was applied only to the fraction containing estrone and equilin. The determination required approximately 2–4 mcg. of estrone, which was contained in 50–100 μ l. of methanol. The solution was pipeted into a 10-ml. volumetric flask, which was made up to volume with concentrated sulfuric acid, water, and methanol (8:1:1 parts by volume). The volumetric flasks were heated at 80° for 15 min. After cooling to room temperature, the fractions and standard reference solutions were analyzed spectrofluorometrically by activating at 273 $m\mu$ and reading the emission at 470 $m\mu$.

By increasing the concentration range of the estrogens by a factor of 10–20, the fluorometric procedure was adapted to colorimetric analysis of estrone, equilin, equilenin, estradiol, 17 α -dihydroequilin, and 17 α -dihydroequilenin. After heating and cooling, the sulfuric acid solutions were scanned by a recording spectrophotometer from 700 to 420 $m\mu$.

The chromatographic fractions containing estrone and equilin were also analyzed by a modified Kober test which is specific for equilin (13).

RESULTS AND DISCUSSION

Chromatography—The efficiency of the chromatographic system was studied as a function of solvent composition, column height, and flow rate. Table I presents the column plate numbers, the peak elution volumes, and the volumes of estrogen fractions as a function of the solvent system. Figures 1 and 2 illustrate representative elution patterns obtained with the selected solvent system.

These data and preliminary data indicated that a combination of a short-chain alcohol, cyclohexane, and an aromatic solvent yielded the most effective separation. Such a combination not only facilitated the miscibility of the first two components but also introduced selective interactions between the steroid molecules and the mobile phase. The selectivity of this system was apparently enhanced by

the favorable partition coefficients resulting from marked contrast between the polarity of the methanol-solvated stationary phase and the relatively low polarity of the mobile phase. The structure and the relative ratio of the aromatic component to cyclohexane have been found to be rather critical. A somewhat favorable effect was also observed on addition of tertiary amines. This effect could be attributed to "masking" of the common phenolic group, which has a predominant effect on the polarity and solubility of estrogens, and subsequent enhancement of less significant structural variations between different estrogen structures. However, the somewhat favorable effect of tertiary amines was offset by the odor of the resulting solvent mixtures and complications in the quantitation procedure; thus, for quantitative analytical purposes, the amines were omitted from the solvent mixture.

Although the chromatographic system studied separated estrogens that differed only by one double bond, it did not separate the α - and β -isomers of estradiol, dihydroequilin, and dihydroequilenin. Table II reflects the results of the column height study. As anticipated, the degree of separation and the column plate number increased with increasing column height. However, due to practical considerations such as flow rate, there was a natural limitation to the height of the column. Increasing the pressure to increase the flow rate tended to compress the gel phase and thus increase the resistance to solvent flow.

Increasing the flow rate also led to decreasing column efficiency (increasing height of the theoretical plate). At higher flow rates, the operation is at nonequilibrium, and the diffusion-dependent mass transfer C_v term of the Van Deemter equation (16) is directly proportional to the square of the thickness of liquid film (d_f) on the support and inversely proportional to the diffusion coefficient of a solute in the solvent phase (D_s). Since in the chromatography system investigated, d_f is rather large while D_s is rather small, the C_v term made a relatively large contribution to the Van Deemter equation and thus led to the inverse relationship between column efficiency and solvent flow rate. These effects are apparent in Table III.

Quantitation—Since the system selected for quantitation did not yield complete separation between estrone and equilin, additional specificity was built into the quantitation procedure. The UV determination is suitable for quantitation of equilenin, estradiol, dihydroequilin, and dihydroequilenin which are separated from each other. However, the UV spectra of estrone and equilin are identical; thus the UV determination of the combined estrone and equilin fraction gives only the sum of their concentrations. Combining the result of the UV determination with a fluorometric and a colorimetric procedure, which is relatively selective for estrone,

Figure 3—Relative emission intensity of estrone (ES) and equilin (EQ) at 273-m μ activation wavelength and 470-m μ emission wavelength. Key: \square , equilin (EQ); \circ , estrone (ES); Δ , 0.2 mcg. of ES + 0.2 mcg. of EQ; and \blacktriangle , 0.4 mcg. of ES + 0.2 mcg. of EQ.

and a modified Kober procedure, which is selective for equilin, gives three independent methods for individual determination of the estrone and equilin mixture.

The fluorometric procedure adopted in this study is based on a method developed by Bates and Cohen (14). However, the authors have observed that a mixture of sulfuric acid, methanol, and water yields a greater response than the sulfuric acid and water solution recommended by Bates and Cohen (14). By utilizing a spectrofluorometer rather than a fluorometer, a significant gain was also obtained in the specificity of estrone determination. The relative response ratio of estrone to equilin, observed by Bates and Cohen (14) with a filter fluorometer, was 4:1, while the ratio observed in the present study with the aid of a spectrofluorometer was 10.8:1 (Fig. 3). Given this relative response ratio and the total concentration of the two estrogens in an unknown mixture, one can postulate the following equations, which resolve the composition of the unknown mixture:

$$R = R'Es + R''Eq \quad (\text{Eq. 1})$$

$$R'' = \frac{R'}{10.8} \quad (\text{Eq. 2})$$

where R = observed fluorescence response of the estrone and equilin fraction; Es = mcg. of estrone in the sample; Eq = mcg. of equilin in the sample; R' = the fluorescence response for estrone (in response units per mcg. of estrone); and R'' = the fluorescence response for equilin (in response units per mcg. of equilin).

Note that concentrations are not involved since all samples are in the same volume.

Table IV—Observed Maximum Absorption Wavelength and Absorptivity in the Acid-Induced Colorimetric Determination

Estrogen	Maximum Absorption Wavelength, m μ	Absorptivity ($a \times 10^{-2}$)
Estrone	453	14.5
Equilin	453	7.0
Equilenin	480	11.6
Estradiol	455	4.0
17 α -Dihydroequilin	490	19.0
17 α -Dihydroequilenin	455	5.1

Figure 4—Colorimetric absorbance of estrone (ES, at 453 m μ), equilin (EQ, at 453 m μ), equilenin (EQN, at 480 m μ), estradiol (ED, at 455 m μ), 17 α -dihydroequilin (DHEQ, at 490 m μ), and 17 α -dihydroequilenin (DHEQN, at 455 m μ).

From UV determination:

$$Eq = C_T - Es \quad (\text{Eq. 3})$$

where C_T = total mcg. of estrone and equilin in the mixed fraction.

By substitution:

$$Es = 1.10 \frac{R}{R'} - 0.102 C_T \quad (\text{Eq. 4})$$

Equation 4 was applied to the analysis of several fractions containing estrone and equilin, and quantitative results were obtained. However, some chromatographic fractions, which apparently contained an unknown impurity that had a significant quenching effect, yielded values considerably lower than expected. These fractions were analyzed by the colorimetric procedure which, although less sensitive than the fluorometric analysis, was considerably more reliable. A set of equations analogous to those already listed was also applied to the colorimetric analysis of the fraction containing both estrone and equilin. The relative colorimetric response ratio of estrone to equilin was observed to be 2:1. As an independent check of the determination of equilin in the combined estrone and equilin fraction, a modified Kober test was utilized (13).

The colorimetric analysis was also applied to the determination of the remaining estrogen fractions. In this application, no blank correction was necessary; since there was no overlap between the remaining estrogens, the directly observed absorbances were used in the determination. Table IV summarizes the absorptivities and the wavelengths of maximum absorbance observed in the colorimetric determination. Figure 4 illustrates the relative colorimetric responses of the six estrogens. It is of interest to note the differences in the relative response of each of the estrogens. Jones and Hähnel (17) postulated a carbonium-ion mechanism for the formation of an acid-induced steroid chromophore. Since the double bond in Ring B of the equilin structure could affect adversely the carbonium-ion formation, this mechanism could explain the observed decrease in the absorptivity of equilin as compared to estrone. However, the

Table V—Comparative Recovery Data

^a A and B values correspond to different elutions.

observed relative magnitude of absorptivities of other estrogens is not as readily explained and thus merits further investigation.

Table V summarizes the quantitative results observed in this study.

SUMMARY AND CONCLUSIONS

The partition chromatographic system investigated was found to be sufficiently selective to separate completely six estrogens which are characterized by only minor differences in the molecular structure. The chromatographic column used for this purpose yielded 3020 theoretical plates, 25 theoretical plates per centimeter of column height at 0.6 ml./min. flow rate. However, this separation required 10 hr. and, due to a relatively large contribution of the mass transfer factor to column efficiency, it was not possible to increase the efficiency of the system by increasing the solvent flow rate. This limitation was compensated by selecting a shorter column (800 theoretical plates) and resolving the partial overlap between estrone and equilin by specific fluorometric and colorimetric reactions. Since the elution volumes were reproducible, columns could be monitored manually without elaborate instrumentation. However, the separation procedure requires 3 hr. and thus is still relatively impractical. To reduce the elution time, the authors are now investigating the possibility of further optimization of their chromatographic system.

Received June 16, 1969, from the Analytical Development Department, Ayerst Laboratories Inc., Rouses Point, NY 12979

Accepted for publication May 11, 1970.

Presented to the Pharmaceutical Analysis and Control Section, APHA Academy of Pharmaceutical Sciences, Montreal meeting, May 1969.

The authors wish to thank Dr. D. Beall, Dr. W. Hausmann and Mr. P. Neil for their interest, helpful discussions, and assistance in the preparation of this manuscript. They also thank Miss H. Archibald for the colorimetric analyses and Dr. G. Schilling for supplying the estrogen reference compounds.

Factors Affecting Dose Variation in Meter Valves

AVINASH M. CONTRACTOR, M. DAVID RICHMAN*, and RALPH F. SHANGRAW

Abstract □ Dose variation in commercial meter valves appears to be within acceptable pharmaceutical limits. Changes in delivered dose weights were found to occur during container emptying due to formulation fractionation. A more serious problem results from failure of the meter chamber to fill uniformly when the container is almost empty (~15% remaining). Three valves were found to be superior to others in overcoming this problem. Storage position influenced drainback in meter valves, particularly at later stages of container emptying.

Keyphrases □ Aerosol meter valves—dosage weight variation □ Propellant, formulation effects—aerosol dosage weight □ Fractionation—aerosols □ GLC—analysis

The need for official standards for weight variation of doses obtained from aerosol meter valves has long been recognized. The Chemical Specialties Manufacturers Association is attempting to draw up safe and reasonable specifications. Although much data on meter valves have been generated by the pharmaceutical industry, little has been published. Notable exceptions to this lack of published data are found in articles by Porush *et al.* (1), Young *et al.* (2), Grim *et al.* (3), and Contractor *et al.* (4). These authors have emphasized the importance of uniformity in delivery from meter valves as indispensable in dependable pharmaceutical preparations. Limits of $\pm 15\%$ of the calculated dose have been suggested. However, no articles have addressed themselves to dose variations arising from such critical factors as formulation pressure, container emptying, long standing of containers between actuations, and valve design. Comparison between commercially available meter valves, using identical formulations and evaluation methods, was undertaken with the hope that data would be generated upon which reasonable standards for meter valve performance and dose variation could be based.

EXPERIMENTAL

Valves—Meter valves for use with pharmaceuticals are available in sizes of 200, 100, and 50 μl ., the last being the most common. The meter valves employed in this study are listed in Table I. All valves studied, except valve R 50I, contained acetel resin¹ stems with rubber stem seals supported by stainless steel gaskets. The R 50I valve was similar but the stem was made of stainless steel. The resin has replaced stainless steel in many valve stems due to the lower cost and a greater flexibility in design. Valves R 50I-EC and S 50I-EC have an emptying cup to assist in complete product removal from the container. Valve V 50I-DA has such a design that the last traces of product drain into the valve.

Formulations—The same four formulations used in the previous study and listed in Table II, representing various types of products, were employed (4). Since the purpose of the study was to investigate factors affecting dose variation under various conditions, the formulations tested were kept as simple as possible, with no active ingredient in them.

Testing Procedures—Ten replicates of each valve and each formulation were used to provide data in the following areas:

1. Dose-to-dose variation at four levels of container emptying: initial, 10, 50, and 80%.
2. Maximum amount removable before dose became substandard and erratic.
3. Effect of storage position and time on dose.
4. Effect of formulation on dose uniformity.
5. Effect of container emptying on the ratio of formulation components.

The functionality of valves covering dose variation within and between valves has been presented in an earlier paper (4). The testing procedures and parameters measured were the same, except for the quantitative measurement of the ratio of propellant blends before and during container use. Gas chromatography utilizing new sampling procedures was used for the quantitative determination of propellant blends.

The instrument employed was an Aerograph (model A-700 Atuoprep) gas chromatograph with thermal conductivity detection. The column was of stainless steel, 6.09 m. \times 0.95 cm. (20 ft. \times 0.375 in.), containing 30% SE 30, 60–80-mesh diatomaceous earth.² The columns were conditioned at 150° for 24 hr. with a helium flow of 6 ml./min. Analysis was performed isothermally with column temperature at 55°, injector block temperature at 130°, and detector temperature at 190°. The carrier gas, helium, was at an inlet pressure of 50 p.s.i. and a flow rate of 200 ml./min., and the filament current was maintained at 150 ma. A Honeywell recorder (Electronic 15) was employed at a speed of 1.01 cm./min. (0.4 in./min.).

Sampling Technique—A 3.81-cm. (1.5-in.) 25G regular point hypodermic needle³ was attached to the top of the stem of a 50- μl . valve, using a piece of polyethylene tubing as packing. The needle was carefully introduced into the injector block, and the valve was actuated by pressing the container against the injector block. A sample of about 50 μl . was thus injected through the needle. The pressurized container acted as a pressure syringe and delivered about a 50- μl . sample every time the valve was actuated. By comparing the ratio of the peak heights, proportions of components were calculated, because the volumes of samples were about and not exactly 50 μl . Initial sample composition served as a standard control for comparing subsequent sample compositions at various levels of container emptying.

RESULTS AND DISCUSSION

The mean dose delivered from each valve for each formulation at various levels of container emptying can be seen in Tables III and IV. Since the doses were measured in milligram³, there is a significant difference in dose between formulations due to the differences in densities of the various propellant and propellant-alcohol blends. Although the differences between the same size valves of different types and manufacturers were considerable, these differences are not of importance in determining the precision of

each type of valve. They are, however, of great importance in terms of product development departments, because each formulation must be tailored to each specific valve, even though the valves are labeled to contain equal volumes (*i.e.*, 50 or 100 μ l.).

The precision of meter valves is extremely good and would certainly compare favorably to other dosage forms when limited to a single formulation and a single level of container emptying. The precision exhibited by inverted valves is generally better than that of the upright valves.

It would appear from Tables III and IV that the precision was influenced by formulation. Formulation IV gave an unusually

high level of precision, while Formulation III generally exhibited low precision. These results indicate possible container-emptying effects due to fractionation. Formulation IV, containing only propellant C 318, could not fractionate. On the other hand, Formulation III, containing propellants and alcohol with significantly different densities and vapor pressures, would be most prone to show fractionation effect. The result of this fractionation is proportionally higher vaporization of component with higher vapor pressure, thereby leaving the liquid phase gradually more and more concentrated in the component with lower vapor pressure as the level of container emptying increases. To confirm this container-emptying effect due to fractionation, Formulations I, II, and III were subjected to quantitative analysis, using gas chromatography. Figures 1 and 2 are the plots of data obtained by quantitative analysis of the liquid phase at various levels of container emptying. These figures confirm the fractionation effect.

Although container-emptying effects are not large, they are real and should not be ignored. Formulations that minimize these effects would appear to be preferable. Fractionation effects in themselves are not critical in regard to dose of active ingredient as the formulation is measured by volume in the metering chamber. Vaporization of the propellant into the headspace would tend to concentrate any active ingredient during container use. However, persons evaluating aerosols should be aware that weights will change in most formulations with container emptying. Even when

these effects are included, individual doses fall well within $\pm 15\%$ of mean for most of the valves and formulations.

Although the weight variation of doses delivered from meter valves would appear in most cases to meet USP and NF weight variation standards for capsules and small weight tablets, other areas of concern do exist. One major problem with most meter valves is the determination of the point at which the dose falls below acceptable limits. Using the arbitrary end-point of two successive individual doses being at least 10% less than the previous dose, the percent remaining in the aerosol package with each type of valve was determined. These values are shown in Table V. The results, to say the least, are disturbing, with the exception of three valves

(V 50I-DA, R 50I-EC, and S 50I-EC). A significant quantity remains in the container beyond the point where doses fall below acceptable limits. In most cases the patient is not able to determine either visually or audibly that any change in dose has occurred. Such a phenomenon is not or would not be tolerated in any other dosage form. Its acceptance in aerosols becomes particularly questionable when it is obvious that valves do exist that effectively eliminate the problem. The apparent formulation effect which indicates that Formulation III is better than I or II is only a result of product densities. Approximately the same number of doses remains in the container for all formulations tested. The end-point for the upright valves is a function of the length of the dip

Figure 1—Effect of container emptying on ratio of propellents 12/114.

Figure 2—Effect of container emptying on proportion of P-12/P-114 ethanol.

tube and is generally more variable than that found in inverted valves.

The fact that initial doses from meter valves after a period of nonuse are often low has long been recognized. In many cases it was believed that the time necessary to cause a significant decrease in the weight delivered was longer than would ordinarily be encountered in practice. The data presented in Tables VI-VIII indicate

that a problem does exist under ordinary use conditions for some valves. As can be seen in Table VI, no significant difference appears to exist with upright valves between the dose obtained after a 16-hr. storage and those obtained at 45-min. intervals. These data were collected from containers stored in the upright position. Observation of the bottles and dip tubes indicates that the liquid remains in the dip tube in contact with the bottom of the valve stem at all times, preventing drainback.

Inverted valves appear to exhibit a problem as can be seen in Table VII. Doses obtained from inverted valves after 16-hr. storage in the upright position showed a significant loss in weight, with the exception of only one valve (R 50I-EC). In addition, this loss of weight is even larger at later stages of container emptying, amounting to from one-third to one-half of the dose obtained from 45-min. actuations. Of equal importance is the fact that when inverted valves are stored in the inverted position, no significant differences occur, as can be seen from the data for valves R 50I, V 50I-DA, R 50I-EC, and S 50I-EC.

To verify the importance of storage position and eliminate any variations due to fractionation, valves E 50I, V 50I, V 50I-DA, R 50I-EC, and S 50I-EC were studied in both upright and inverted storage conditions, using Formulation IV. The results of the study are shown in Table VIII. These data show conclusively that drainback does occur in inverted valves without efficient emptying cups and that this drainback is a function of storage position. Although the cause is not obvious, container emptying accentuates the drainback problem. Unfortunately, data were not collected at intermediate levels of container emptying in such a form to indicate when this effect first begins to occur. At least one manufacturer has designed an inverted valve, which effectively decreases drainback, by adding a chamber around the lower tank opening. At least one commercial product avoids the problem because packaging and labeling are designed so that containers are customarily stored in the inverted position. It would appear that all producers using inverted valves might well adopt this policy.

SUMMARY AND CONCLUSIONS

1. Container-emptying effects resulting from propellant fractionation and causing changes in the weights of doses delivered do occur in inhalation formulations.
2. A new simple technique is described to measure the extent of fractionation, using a gas chromatograph.
3. A significant decrease in dose weights at the latter stages of container emptying is a serious problem in metered aerosols. Three valves appear to be significantly superior to all others in minimizing variation of dose through the latter stages of container emptying.
4. Doses delivered from inverted meter valves after standing all night in an upright position are significantly lower than those delivered at 45-min. intervals. These effects are magnified at latter stages of container emptying. The problems can be solved by designing packaging and labeling so that containers with inverted valves are stored in an inverted position.

Bentonite-Cellulose Systems: Flow Behavior of Mixed Dispersions and Mechanical Properties of Composite Films

HANS SCHOTT

Abstract □ Bentonite and microcrystalline cellulose are used as thickening agents and binders; their interaction was studied in suspension and in the solid state. Mixtures of the two solids covering the whole range of compositions were prepared by blending their aqueous suspensions under high shear. The rheological behavior of the mixed suspensions and the mechanical properties of composite films prepared by drying thin layers of these suspensions were investigated as a function of composition. Based on the volume-percentage of the dry components, bentonite was about five times more effective in increasing the viscosity of aqueous suspensions than cellulose. Cellulose tended to produce yield values. Bentonite formed strong films when its aqueous suspensions were dried; neither pure cellulose nor a mixture containing 88 vol. % cellulose formed coherent films. In the range of 0–77 vol. % cellulose, the in-plane and perpendicular tensile strengths of the composite films decreased only moderately with increasing cellulose content.

Keyphrases □ Bentonite-cellulose systems—flow behavior, mechanical properties □ Cellulose-bentonite systems—flow behavior, mechanical properties □ Films, bentonite-cellulose—relative composition effect □ Rheological behavior, bentonite-cellulose suspensions—relative composition effect

Bentonite and finely dispersed cellulose are used as thickening agents and binders in suspensions, ointments, and tablets (1, 2). The rheology of aqueous bentonite dispersions (3–5) and cellulose suspensions (6, 7), as well as the film-forming ability of sodium bentonite (8), has been reported. The present work deals with the flow behavior of mixed dispersions, containing varying proportions of cellulose and clay, and with the mechanical properties of films prepared therefrom. The purpose was to determine whether there is any synergism in thickening and binding; for instance, whether partial replacement of bentonite by cellulose boosts the viscosity of bentonite suspensions, or whether the presence of cellulose increases the strength of solid bentonite. The interaction between clays and cellulose is described in previous work (9, 10).

EXPERIMENTAL

Materials—Microcrystalline cellulose¹ is manufactured by acid hydrolysis of wood pulp with a high α -cellulose content to the "level-off degree of polymerization," followed by mechanical disintegration (11, 12). Suspensions were made by dispersing the powder in water with a Waring blender. They were permitted to hydrate 24 hr. before admixing clay dispersions.

Sodium bentonite² was slurried in a Waring blender with water for 10 min. at top speed and was decanted from settled out grit and heavy particles. This reduced the clay concentration from 28 to 21 g./l. The supernatant dispersion was passed through a column of a commercial cation-exchange resin³ in the sodium form. The pH of a dispersion containing 21 g./l. was 9.8. Since the micro-

crystalline cellulose is partly soluble in alkaline media, the pH of the clay dispersion was adjusted to 5–7 as follows: a small amount of the sodium bentonite dispersion was passed through a column of the cation-exchange resin in the hydrogen form, which reduced its pH to 2.2. It was then mixed immediately with enough of the sodium form to obtain the desired pH.

The water was twice distilled. Neither bentonite nor cellulose contained water-soluble impurities. Mixed suspensions were prepared by combining the required amounts of clay dispersions and cellulose suspensions of known concentrations and stirring together in a Waring blender, followed by two passes through a hand homogenizer. Lower viscosities and yield values were found if homogenization was omitted. The total solids content of dispersions was sometimes determined by drying at 125° to ensure against concentration changes due to evaporation of water. The nominal and actual compositions always agreed within $\pm 0.01\%$, expressed as solids content.

After viscosity measurements, the suspensions were concentrated, spread into thin layers on metal or glass trays, and dried in a forced-circulation oven. As a routine precaution, the composition of a few films was determined from the ash content at 600°. The difference between nominal and actual composition was always below 0.1% in terms of percentage composition values. This shows that preferential settling out of bentonite or of cellulose from the suspensions during handling did not occur.

Methods—Viscosity measurements were made with a rotational Synchro-Lectric viscometer,⁴ using chiefly the No. 1 and occasionally the No. 2 spindle. The instrument was used at 2, 4, 10, and 20 r.p.m. with the guard in place. The 650-ml. samples were measured in 800-ml. beakers. All measurements were made at 22–23.5°.

Because the viscosity of suspensions containing cellulose rose very rapidly even after short rest periods, the flow measurements had to be restricted to those observable after elimination of thixotropic thickening. Reproducible results were obtained when the suspensions were stirred for 10 min. with a magnetic stirrer at top speed immediately before measuring viscosities. Sometimes, thixotropic increases in viscosity occurred even during viscosity measurements. In those cases, the suspensions were stirred between readings as often as was necessary to obtain reproducible values.

Flow curves were drawn as revolutions per minute (rate of shear) versus scale divisions of torque (shear stress); the full scale was 500 divisions. Yield values, Y , are reported as scale divisions for No. 1 spindle at the point where the extrapolated flow curve intersected the shear stress axis. They are only approximate values, particularly for those systems where rapid thixotropic buildup of viscosity introduced some uncertainty in the readings at 2 r.p.m.

There are two convenient and representative ways of defining the viscosity of shear-thinning liquids, some of which have yield values. The first, "differential viscosity," is defined here as the reciprocal slope of the secant to the flow curve at the points for 10 and 20 r.p.m. Since the instrument had only four speeds, this was more reproducible than drawing the tangent to the flow curve at a given r.p.m. and using its reciprocal slope (13, 14). The differential viscosities, η_{dit}^* , in centipoises (cps.), were calculated as

$$\eta_{dit}^* = K(\Delta \text{ div.} / \Delta \text{ r.p.m.}) \quad (\text{Eq. 1})$$

which became

$$\eta_{dit}^* = 1.96 \left[\frac{\text{div. (20 r.p.m.)}}{1.06} - \text{div. (10 r.p.m.)} \right] \quad (\text{Eq. 2})$$

³ Amberlite IR-120, Rohm & Haas Co., Philadelphia, Pa.

⁴ Model RVF, Brookfield Engineering Laboratories, Inc., Stoughton, Mass.

for the No. 1 spindle, and

$$\eta_{dl}^* = 8.2 \left[\frac{\text{div. (20 r.p.m.)}}{1.17} - \text{div. (10 r.p.m.)} \right] \quad (\text{Eq. 3})$$

for the No. 2 spindle; div. (20 r.p.m.) is the number of scale divisions on the torque scale ranging from 0–500 at the speed of 20 r.p.m. The numerical constants were determined by calibrating the instrument with a 60% sucrose solution (48 cps. at 23.2°).

A second way of describing the flow behavior is as “apparent plastic viscosity” (15), by analogy to plastic and pseudoplastic liquids (16). Apparent plastic viscosities, η_{pl}^* , in cps., for the No. 1 spindle were calculated as

$$\eta_{pl}^* = \frac{\text{div. (20 r.p.m.)}}{1.06} - Y \quad (\text{Eq. 4})$$

This is the reciprocal slope of the secant to the flow curve at the point of 20 r.p.m. and the yield value or, if $Y = 0$, at the origin. Such computations are necessary because, while the suspensions containing only cellulose gave nearly linear flow curves above the yield value between 4 and 20 r.p.m., many of the suspensions containing clay gave flow curves that were convex toward the shear stress axis, and the two kinds of curves must be compared. For Newtonian liquids, differential viscosity and apparent plastic viscosity are identical with the Newtonian viscosity.

The mechanical properties of the films were measured after conditioning at 23° and 50% relative humidity, using a recording stress-strain tester equipped with strain gauges.⁵ Tensile strength in the plane of the film (x - y direction) was determined on strips 1.27 cm. (0.5 in.) wide and with a 2.54-cm. (1.0-in.) distance between the clamps, which were elongated at the rate of 2%/min. To compensate for differences in density, the tensile strength is expressed as breaking length, *i.e.*, the smallest length of film sufficient to cause it to break under the load of its own weight. The tensile strength perpendicular to the plane of the film (z -direction) was determined by gluing a 2.54 × 2.54-cm. (1 × 1-in.) film specimen with epoxy cement between two cubic aluminum blocks of 2.54-cm. (1-in.) side length, attaching one to the upper jaw of the tensile testing machine and the other to the crosshead, and lowering the latter at the rate of 0.025 cm./min. (0.01 in./min.). The z -direction tensile strength represents resistance to delamination. The epoxy cement did not appreciably penetrate the clay film because, except for the layer immediately adjoining the aluminum surface, the ruptured films swelled and dispersed freely in water.

RESULTS

Flow Properties—Typical flow curves are shown in Fig. 1. Differential and apparent plastic viscosities and approximate yield values are listed in Table I. Compositions are expressed as volume percent of dry material, with a density of 1.5 g./cm.³ for cellulose, 2.8 g./cm.³ for clay, and 1.0 g./cm.³ for water. Yield values are expressed as scale divisions for the No. 1 spindle, full scale being 500 divisions. As indicated by Table I, clay tends to build up viscosity faster than cellulose, and cellulose tends to produce yield values faster than clay with increasing concentration.

The effect on the differential viscosity of gradually replacing clay with microcrystalline cellulose while maintaining the total concentration of suspended solids constant at 1.64 vol. % of dry material is shown in Fig. 2. Also shown is the effect of concentration on the differential viscosity of dispersions of pure clay. The abscissa scale representing clay concentration is the same for both curves. Therefore, the upper, broken curve refers to compositions containing a concentration of cellulose equal to 1.64 vol. % minus the indicated clay concentration.

If the two curves coincided, microcrystalline cellulose would have the same thickening effect on clay dispersions as water, *i.e.*, none. If the broken curve representing the viscosity of mixed suspensions at constant total concentration was a straight horizontal line located at the differential viscosity of a pure clay dispersion containing 1.64 vol. %, namely 135 cps., cellulose would have the same thickening effect on clay dispersions as an equal volume of additional clay. The broken curve was only slightly above the solid

curve, indicating that microcrystalline cellulose exerts only a modest thickening effect on clay dispersions.

The reverse situation is shown in Fig. 3. Starting with a cellulose suspension of 3.430 vol. % and replacing small but increasing amounts with clay at a constant volume fraction of dry solids caused

Figure 2—Differential viscosity of clay dispersions as a function of clay content, and the effect of replacing clay with cellulose. Key: ●—●, clay only; and ○—○, gradual replacement of clay with cellulose at a constant solids content of 1.64 ± 0.02 vol. %.

a rapid increase in differential viscosity. In the range of compositions studied, this increase amounted to about 170 cps./vol. % replaced. If the increase in viscosity per volume percent was the same for cellulose as for clay, the broken curve would be a straight horizontal line located at the differential viscosity of the 3.430 vol. % cellulose suspension, namely 10 cps. The rapid divergence of the two curves shows that for suspensions of microcrystalline cellulose, bentonite is a far more effective thickening agent than are additional amounts of cellulose. Similar plots and the same conclusions can be obtained with apparent plastic viscosities.

The following numerical examples show how the relative thickening efficiency of clay and that of cellulose were compared. From Fig. 2, it is seen that a suspension containing 0.47 vol. % clay and $1.64 - 0.47 = 1.17$ vol. % cellulose has the same differential viscosity as a 0.80 vol. % clay dispersion. Therefore, $0.80 - 0.47 = 0.33$ vol. % clay is approximately equivalent in thickening power to 1.17 vol. % cellulose, or 1 vol. % clay is equivalent to 3.55 vol. % cellulose. From Table I, a 4.0-vol. % cellulose suspension is seen to have the same differential viscosity as the interpolated value for a 0.98-vol. % clay dispersion, and a 3.8-vol. % cellulose suspension the same as a dispersion containing 0.73 vol. % clay. The equivalent

of 1 vol. % clay is, therefore, 4.08 and 5.20 vol. % cellulose, respectively. The values obtained by this kind of calculation, based on differential viscosities, ranged from 1:3.0 to 1:9.0, with a mean equivalent thickening ratio of 1:4.5 vol. % dry clay–vol. % dry cellulose. Similar calculations for apparent plastic viscosities gave a range of 1:3.2–1:10.8 for equivalent thickening ratios of clay–cellulose and a mean of 1:4.9. The large spread in the values may be due to the fact that the structural mechanism by which bentonite thickens a cellulose suspension is different from the one operative in a dispersion of pure bentonite. The 4.5 and 4.9 ratios are only meaningful as an order of magnitude.

According to Einstein's law, the viscosity of dispersions is determined only by the total volume fraction of the dispersed phase and not by its particle size. The present systems are strongly non-Newtonian; even the viscosity of very dilute bentonite dispersions was found to be 70 times larger than that predicted by Einstein's law, owing to the interaction between particles (5). This interaction is responsible for the pronounced thickening observed. Thickening, i.e., high viscosities and yield values, results from three-dimensional networks formed by particle–particle association. Small particle sizes, as shown by high specific surface areas, and highly asymmetric particle shapes are conducive to thickening (Reference 13, p. 338; Reference 14, p. 180). The increase in viscosity with de-

Figure 5—Effect of microcrystalline cellulose on the breaking length of Na^+/H^+ bentonite films.

Figure 6—Effect of microcrystalline cellulose on the elongation to break of Na^+/H^+ bentonite films.

creasing particle size has also been attributed to a solvation shell surrounding the particles, which increases their effective volume (17).

The kind of bentonite used here has stacks of 3–4-lattice layers as primary particles. These swell in water by inserting three layers of water, each 3 Å thick, between adjacent clay layers (5, 18). Neglecting the lateral area, the specific surface area corresponding to the basal planes is 240 m^2/g . The primary particles in microcrystalline cellulose, which had been stirred for 10 min. at top speed in a Waring blender and given two passes through a hand homogenizer, were rods or laths with a median length between 4.5 and 6.5 μ and a median diameter or width between 1.0 and 1.6 μ when wet. According to these microscopic measurements, the specific surface area of the water-swollen particles was about 3 m^2/g .

The bentonite lamellas are far more asymmetrical than the rods of microcrystalline cellulose. The higher specific surface area of the clay particles compared to the cellulose particles, and their greater asymmetry, should produce an equivalent thickening ratio far greater than 1:4.5 or 1:4.9. This may indicate the existence of some specific effects which enhance the thickening power of the microcrystalline cellulose or reduce that of bentonite. Hydrogen-bond formation resulting in more and stronger particle-to-particle attachments for cellulose is unlikely to be responsible for the smaller than expected difference in thickening, because bentonite particles can adhere to cellulose surfaces by hydrogen bonds (as proton acceptors) as readily as two cellulose surfaces adhere to each other (9). There seems to be no reason why the hydration shell surrounding a cellulose particle should be substantially deeper than that around a clay particle of the same size. Perhaps electrostatic effects, specifically the repulsive component of the interaction between the more highly charged clay particles, are involved. Another possible explanation is that the mechanical shearing to which the microcrystalline cellulose was subjected, like the beating of paper-making pulp, frazzled the rods, rendering their surface fuzzy. Microfibrils emanating from the rods need not be visible at the magnification of 500 \times used in these microscopic observations, yet they could increase the surface area of these rods and considerably enhance their ability to form three-dimensional networks in suspension. This would also explain why the rods seemed to occur in clumps.

Film Properties—Neither pure microcrystalline cellulose nor a mixture containing 88 vol. % cellulose formed coherent films when their aqueous suspensions were dried without external pressure. For the remaining range of compositions, the apparent densities of the conditioned films, d , i.e., the weight divided by length \times width \times thickness, increased with increasing weight % clay (% CL) according to the equation

$$d = 0.544 + 0.0134\% \text{ CL} \quad (\text{Eq. 5})$$

Using 1.5 and 2.8 g/cm^3 as bulk densities of cellulose and clay, the equation indicates that the void volume of the films increased with increasing cellulose content, from 30% for pure clay films to 44% for films containing 77.6 vol. % cellulose. The high void volume associated with microcrystalline cellulose is useful for the

Figure 7—Effect of microcrystalline cellulose on the z-direction tensile strength of Na^+/H^+ bentonite films.

absorption of oils and pharmaceuticals in tablets or gels (2).

The mechanical properties of films of pure clay were found to improve with increasing thickness (Fig. 4). This runs counter to the usual observation of increasing strength of films and fibers with decreasing cross-sectional area owing to the reduced probability of finding flaws. For this reason, only films of thickness between 0.010 and 0.015 cm. were tested in later work. As can be seen from Fig. 4, the proportionality between tensile strength and thickness cannot extend to films much thinner than those studied in the present work. Otherwise, extrapolation of the least-squares line based on films in the thickness range of 50–150 μ would result in a tensile strength of nearly 30 kg/cm^2 for a film of zero thickness. The correlation coefficient between tensile strength (dependent variable) and film thickness for the data of Fig. 4 is 0.909. At 26 degrees of freedom, this corresponds to a level of significance better than 0.1%.

In Figs. 5–7, each point is the average of at least eight measurements, and the bars represent \pm the standard deviation of the averages. The initial 15 vol. % cellulose had no noticeable effects on breaking length and elongation. Higher loadings of cellulose reduced the former by approximately 30% to a nearly constant level independent of cellulose loading. Except for the film containing 77.6 vol. % cellulose, the z-direction tensile strength decreased only very slightly with increasing cellulose content (note the expanded ordinate scale of Fig. 7).

The fact that finely dispersed cellulose lowered the strength of sodium bentonite or hydrogen bentonite films only moderately indicates that the adhesion of cellulose to clay is of the same order of magnitude as the adhesion of clay to itself. The strength of the pure bentonite films indicates that the latter is considerable. Mixed cellulose–bentonite films swelled freely and disintegrated readily in water over the entire range of compositions.

NOTES

Cautions Regarding the Physical Interpretation of Statistically Based Structure-Activity Relationships

ARTHUR CAMMARATA*, RICHARD C. ALLEN*, J. K. SEYDEL†, and E. WEMPE†

Abstract □ The distinction between the use of multiple regression analysis as a predictive tool and as a means of investigating controlling physical characteristics in structure-activity studies often is unrecognized. Three examples of complications that can arise with either of these goals in mind are discussed. The first is an illustration of a "false" parabolic dependence of activity on lipophilicity; the second deals with unrecognized interrelationships between certain physical parameters; and the third is a situation where a number of statistically significant correlations can be presented, each of which may be given a differing physical interpretation.

Keyphrases □ Structure-activity relationships—precautions concerning interpretation □ Multiple regression analysis—use, misuse

Within the past few years, multiple regression analysis has been exploited as a statistical tool for the evaluation of structure-activity data. One goal of these analyses is the derivation of a regression equation which will provide estimates of the biological potencies for additional structural entities within a series. A second goal is the determination of the physical and chemical properties of a given series of compounds which are most influential in affecting the observed biological potencies. It is often not recognized that each of these goals represents a separate problem, because the multiple regression approach usually makes use of physically meaningful parameters. As a consequence, any regression equation that correlates structure-activity data can be given a physical interpretation. At times, however, a quirk within a set of structure-activity data can lead to a statistically significant regression equation which provides a poor, if not erroneous, reflection of the physical factors affecting biological potency. At other times, a physical interpretation becomes difficult because a number of correlations can be presented for the same data, each of which involves one or more parameters that could be given a differing physical interpretation. Three examples to illustrate these complications are discussed in this report.

EXAMPLE 1

The minimum inhibitory concentrations against *Escherichia coli* for a variety of congeneric sulfanilamides have been correlated linearly with the Hammett σ -value or with the pKa for the compounds (1, 2). Other congeneric sulfanilamide series have been found (3) which require the addition of π or of π and π^2 terms in a multiple regression model in order to gain a correlation with their bacteriostatic activities. A π term in combination with σ or pKa in a regression equation indicates that lipophilic and electronic factors, respectively, are controlling biological potency. When both π and π^2 appear in a regression equation, the biological activities are parabolically related to the lipophilicities of the compounds; *i.e.*, there is an optimal lipophilicity to observe a maximum biological response within the series.

A reasonable approach to follow if regression equations are to be used as a guide to further syntheses is first to synthesize and test a relatively few compounds which vary over a wide range with respect to their expected electronic (σ) or lipophilic (π) characteristics. If the subsequent regression analysis requires the addition of a physical parameter other than that chosen as an initial criterion to correlate the activity data, it could be said that the additional parameter (or parameters) reflects a real physical requirement for the system under study. Following this approach, *N*¹-benzoylsulfanilamides having substituents covering extremes in Hammett σ -values (Compounds 1-7; Table I) are found to have their bacteriostatic potencies correlated by the equation

$$\log (1/C) = -0.81 (\pm 0.16)\sigma + 1.18 (\pm 0.31)\pi \quad (\text{Eq. 1})$$

(-4.99)	(3.74)		
-1.19	(\pm 0.35)\pi^2 + 5.10		
(-3.38)			
N	s	R	F(3,3)
7	0.12	0.98	34.67

In Eq. 1, the standard error for the estimate of a coefficient appears in parentheses after the coefficient; in parentheses below the coefficient is the *t* test. The statistics for the equation are the standard error of the estimate *s*, the multiple correlation coefficient *R*, and the *F*-ratio.

Based on Eq. 1, it may be concluded that electronic and lipophilic factors control the bacteriostatic activities for this series of sulfanilamides and that there is an optimum lipophilicity for the series. If the latter conclusion is true, a regression equation based on the activities for a larger number of *N*¹-benzoylsulfanilamides should retain the π and π^2 terms as found in Eq. 1, since the lipophilicities for the additional compounds should lie on the same parabola as is found for the smaller series. In this particular instance, an extension

Abstract □ The distinction between the use of multiple regression analysis as a predictive tool and as a means of investigating controlling physical characteristics in structure-activity studies often is unrecognized. Three examples of complications that can arise with either of these goals in mind are discussed. The first is an illustration of a "false" parabolic dependence of activity on lipophilicity; the second deals with unrecognized interrelationships between certain physical parameters; and the third is a situation where a number of statistically significant correlations can be presented, each of which may be given a differing physical interpretation.

Keyphrases □ Structure-activity relationships—precautions concerning interpretation □ Multiple regression analysis—use, misuse

Within the past few years, multiple regression analysis has been exploited as a statistical tool for the evaluation of structure-activity data. One goal of these analyses is the derivation of a regression equation which will provide estimates of the biological potencies for additional structural entities within a series. A second goal is the determination of the physical and chemical properties of a given series of compounds which are most influential in affecting the observed biological potencies. It is often not recognized that each of these goals represents a separate problem, because the multiple regression approach usually makes use of physically meaningful parameters. As a consequence, any regression equation that correlates structure-activity data can be given a physical interpretation. At times, however, a quirk within a set of structure-activity data can lead to a statistically significant regression equation which provides a poor, if not erroneous, reflection of the physical factors affecting biological potency. At other times, a physical interpretation becomes difficult because a number of correlations can be presented for the same data, each of which involves one or more parameters that could be given a differing physical interpretation. Three examples to illustrate these complications are discussed in this report.

EXAMPLE 1

The minimum inhibitory concentrations against *Escherichia coli* for a variety of congeneric sulfanilamides have been correlated linearly with the Hammett σ -value or with the pKa for the compounds (1, 2). Other congeneric sulfanilamide series have been found (3) which require the addition of π or of π and π^2 terms in a multiple regression model in order to gain a correlation with their bacteriostatic activities. A π term in combination with σ or pKa in a regression equation indicates that lipophilic and electronic factors, respectively, are controlling biological potency. When both π and π^2 appear in a regression equation, the biological activities are parabolically related to the lipophilicities of the compounds; *i.e.*, there is an optimal lipophilicity to observe a maximum biological response within the series.

A reasonable approach to follow if regression equations are to be used as a guide to further syntheses is first to synthesize and test a relatively few compounds which vary over a wide range with respect to their expected electronic (σ) or lipophilic (π) characteristics. If the subsequent regression analysis requires the addition of a physical parameter other than that chosen as an initial criterion to correlate the activity data, it could be said that the additional parameter (or parameters) reflects a real physical requirement for the system under study. Following this approach, *N*¹-benzoylsulfanilamides having substituents covering extremes in Hammett σ -values (Compounds 1-7; Table I) are found to have their bacteriostatic potencies correlated by the equation

$$\log (1/C) = -0.81 (\pm 0.16)\sigma + 1.18 (\pm 0.31)\pi \quad (\text{Eq. 1})$$

(-4.99)	(3.74)		
-1.19	(\pm 0.35)\pi^2 + 5.10		
(-3.38)			
N	s	R	F(3,3)
7	0.12	0.98	34.67

In Eq. 1, the standard error for the estimate of a coefficient appears in parentheses after the coefficient; in parentheses below the coefficient is the *t* test. The statistics for the equation are the standard error of the estimate *s*, the multiple correlation coefficient *R*, and the *F*-ratio.

Based on Eq. 1, it may be concluded that electronic and lipophilic factors control the bacteriostatic activities for this series of sulfanilamides and that there is an optimum lipophilicity for the series. If the latter conclusion is true, a regression equation based on the activities for a larger number of *N*¹-benzoylsulfanilamides should retain the π and π^2 terms as found in Eq. 1, since the lipophilicities for the additional compounds should lie on the same parabola as is found for the smaller series. In this particular instance, an extension

Table I—*In Vitro* Activities against *Escherichia coli* of *N*¹-Benzoylsulfanilamides

Compound Number	Benzoyl Substituent	σ	π	Activities, ^a log (1/C)
1	4-OMe	-0.27	0.08	5.40
2	4-Me	0.17	0.42	5.40
3	H	0.0	0.0	5.25
4	4-Cl	0.23	0.87	5.10
5	3-CF ₃	0.42	1.07	4.65
6	4-NO ₂	0.78	0.02	4.50
7	4-CN	0.63	-0.31	4.05
8	3-Me	-0.07	0.52	5.40
9	4-iso-Pr	-0.15	1.40	5.40
10	4-Et	-0.15	0.92	5.62
11	4- <i>n</i> -Pr	-0.15	1.42	5.18
12	3,4-Me	-0.24	0.94	5.40
13	3-Me, 4-MeO	-0.44	0.60	5.25

^a These activities were determined in the laboratories of J. K. S. and have been reported in previous discussions by J. K. Seydel and E. Wempe, *Arzeim.-Forsch.*, **14**, 705(1964), and by A. Cammarata, *J. Med. Chem.*, **11**, 1111(1968).

of the series (Compounds 1-13, Table I) eradicates the π , π^2 dependence:

$$\log(1/C) = \begin{array}{l} -0.88 \ (\pm 0.19)\sigma + 0.59 \ (\pm 0.32)\pi \\ (-4.51) \quad (1.81) \\ -0.39 \ (\pm 0.24)\pi^2 + 5.04 \\ (-1.62) \end{array} \quad (\text{Eq. 2})$$

The equation correlating the total set of data is, therefore,

$$\log(1/C) = -1.06 (\pm 0.17)\sigma + 5.15 \quad (\text{Eq. 3})$$

N	s	R	$F(1, 11)$
13	0.22	0.87	36.10

which indicates that only electronic factors influence the activities of these compounds.

With Eq. 3 as a guide, it is readily found that Compound 7 alone led to the π , π^2 dependence found in Eq. 1. This compound represents a terminal point displaced relative to the overall linear trend of activity with σ which holds for the other compounds (Compounds 1–6). When Compound 7 is deleted from the set used to derive Eq. 1, the resultant regression equation becomes

$$\log(1/C) = \frac{-0.84}{(-5.73)} (\pm 0.14)\sigma + \frac{0.57}{(1.07)} (\pm 0.53)\pi \quad (\text{Eq. 4})$$

The statistics for the coefficients in Eq. 4 clearly indicate that the π and π^2 terms should be deleted.

For the 13 *N*-benzoylsulfanilamides considered, a linear correlation between their bacteriostatic potency and their Hammett σ -values is suitable for directing later syntheses. An eventual π , π^2 dependence will most probably be found as a wider variety of multiple substitutions are made on the *N*-benzoyl moiety. In this event, it is likely that the optimum lipophilicity found will differ substantially from the optimum lipophilicity calculated on the basis of Eq. 1.

EXAMPLE 2

In testing alternative physical indexes in attempted correlations of structure-activity data, the rationale commonly used is to attribute physical significance only to those terms that appear as statistically significant in the derived regression equation. For example, if the use of the Hammett σ -constant does not lead to a regression equation in which this index is shown to be statistically significant, the inference that may be drawn is that an alternative electronic index, such as

group polarizability P_E or group dipole moment μ , might be more suitable. These alternative indexes are often considered as measures of electronic properties not encompassed by the Hammett σ -value. Seldom, however, are these more specific electronic indexes investigated with respect to the general electronic index they are intended to displace. The result of this type of an investigation can considerably complicate the physical interpretation of a regression equation for a given body of structure-activity data.

Certain pharmacological agents have been indicated as having their effect on a biological system more adequately interpreted in terms of the group dipole moments, μ , than of the Hammett σ -values for the substituents (4-6). An investigation of the relation between the group dipole moments and the Hammett σ -values for the substituents found in Table II, however, reveals a significant correlation between the two indexes:

$$\mu = \frac{-4.162}{(-9.16)} (\pm 0.454)\sigma - 0.969 \quad (\text{Eq. 5})$$

Thus, a correlation of biological potency which involves μ or σ should be similarly interpreted. If, in two respective regression

4-NO ₂	1.827	1.27	0.50	-0.468
4-SO ₂ NH ₂	1.841	0.91	-1.16	-0.745

^a From the results of Hückel molecular orbital calculations reported by A. Perault and B. Pullman, *Biochim. Biophys. Acta*, **66**, 86(1963).

^b From the data reported by K. B. Jacobson, *J. Biol. Chem.*, **236**, 343 (1961).

analyses, it is found that μ contributes significantly, whereas σ does not, or the converse, this finding alone is not sufficient to warrant an alternative interpretation. The compounds considered may have biological potencies that more closely parallel the order of one index than they do the other, but the indexes are not sufficiently independent, on the basis of Eq. 5, to make a distinction between the two possible physical interpretations.

Recently, viral neuraminidase inhibition potencies have been reported (6) for the compounds shown in Table III. The regression equation correlating these data was given (6) by

$$\log (1/C) = 0.271 (\pm 0.031)\pi + 0.061 (\pm 0.036)\mu_v \quad (\text{Eq. 6})$$

(8.78) (1.68)

$$+ 0.029 (\pm 0.010)\mu_v^2 + 2.551$$

(2.95)

N	s	R	$F(3,12)$
16	0.079	0.927	28.96

A more appropriate representation of the correlation, based on the statistics for the coefficients of Eq. 6, is expressed as

$$\log (1/C) = 0.265 (\pm 0.032)\pi + 0.014 (\pm 0.003)\mu_v^2 \quad (\text{Eq. 7})$$

(8.11) (3.67)

$$+ 2.548$$

N	s	R	$F(2,13)$
16	0.081	0.916	36.89

Equation 7 indicates that these compounds have their potencies determined by lipophilic factors and by the component of the group dipole moment, μ_v , which is directed along the 1,4-axis of the substituted moiety.

Upon comparing the electronic index μ_v^2 to its analog σ^2 , as is suggested by Eq. 5, it is found that these indexes are related:

$$\mu_v^2 = 30.235 \sigma^2 - 1.048 \quad (\text{Eq. 8})$$

N	s	R	$F(1,14)$
16	2.115	0.925	83.89

A much improved correlation can be obtained by using the unresolved group dipole moments:

$$\mu^2 = 29.659 \sigma^2 - 0.205 \quad (\text{Eq. 9})$$

N	s	R	$F(1,14)$
16	1.483	0.960	164.16

Since the quantity σ^2 has been indicated as having a variety of possible origins (7) and has been shown to correlate with a free-radical index E_r (8) and a charge-transfer index E_{LEMO} (9), it is found that at least three differing physical interpretations can be presented for the electronic term found in Eq. 7. The resolution of the possible alternatives is, therefore, seen as a problem separate from the use of Eq. 7, or related forms, as a predictor of new agents. The most convenient equation to use for guiding the synthesis of new compounds may contain physical parameters which only obliquely reflect the actual factors controlling the observed response.

EXAMPLE 3

Another illustration of the potential complications attending the physical interpretation of derived regression equations is provided

by the data found in Table IV. A more limited statistical analysis of the enzymatic acylation rates for this system has been reported (10). Here the authors would like to point out that at least five different statistically significant regression equations will correlate the data:

$$\log A = -0.028 (\pm 0.004) \mu^2 + 0.012 \quad (\text{Eq. 10})$$

N	s	R	$F(1,4)$
6	0.111	0.952	38.58

$$\log A = 0.085 (\pm 0.024) \mu + 0.216 (\pm 0.063) \pi \quad (\text{Eq. 11})$$

(3.54) (3.40)

$$\log A = -0.112$$

N	s	R	$F(2,3)$
6	0.112	0.963	24.88

$$\log A = -0.335 (\pm 0.022) \sigma^- + 0.252 (\pm 0.015) \pi \quad (\text{Eq. 12})$$

(-15.27) (16.94)

$$\log A = -0.155$$

N	s	R	$F(2,3)$
6	0.028	0.997	399.2

$$\log A = 18.169 (\pm 2.021) q_N + 0.290 (\pm 0.024) \pi \quad (\text{Eq. 13})$$

(8.99) (12.16)

$$\log A = -33.82$$

N	s	R	$F(2,3)$
6	0.048	0.993	140.7

$$\log A = -0.272 (\pm 0.039) \sigma^2 + 0.264 (\pm 0.031) \pi \quad (\text{Eq. 14})$$

(-6.96) (8.41)

$$\log A = -0.179$$

N	s	R	$F(2,3)$
6	0.061	0.989	85.96

There is little doubt that a charge-related property is affecting the enzymatic acylation rates, according to these correlations, and it is also likely that the lipophilicity of the compounds contributes an effect. An explicit description of the electronic interaction mechanism is difficult, however, because of the various physical significances that can be attributed to the different electronic indexes. In this particular case, Eq. 13 may be preferred as a basis for interpretation, since the charge density on the aniline nitrogen is the most fundamental of the electronic indexes that can be used.

CONCLUSIONS

From the examples presented, it is clear that a physical interpretation for a correlation of biological activities with some combination of physical parameters should be made with caution. It is also evident that the ability of a regression equation to act as a predictor for the biological activities of compounds within a series cannot be presented in full support of the interpretation lent to the terms appearing in the regression equation.

At present, a safe approach to follow if the intent is to gain insight into physical factors influencing the action of drug agents is: (a) investigate a correlation for internal consistency, as may be illustrated by *Example 1*; (b) establish whether the use of fundamental linear free energy (σ , π) and molecular orbital (q , S^E , S^N) indexes lead to essentially equivalent conclusions, e.g., Eqs. 12 and 13 complement one another; and (c) when indexes having little precedent in correlating the rates and equilibria of simple chemical systems become involved in a correlation—viz., μ , μ^2 , and σ^2 , investigate compounds designed specifically to distinguish between alternative physical interpretations. In the latter instance, since Hammett σ -values are simply additive, whereas group dipole moments are vectorially additive, it might be expected that multi-substituted compounds should provide the more appropriate test of dipole control of a biological response.

Solubilization of Some Steroid Hormones in Aqueous Solutions of Bile Salts

ARVIND L. THAKKAR

Abstract □ Solubilities of testosterone propionate, methyltestosterone, and 19-nortestosterone in aqueous sodium cholate and deoxycholate were determined. Solubilizing capacity values show that deoxycholate is a better solubilizer than cholate and that both bile salts solubilize more 19-nortestosterone than other testosterone derivatives. A possible mode of solubilization is discussed.

Keyphrases □ Steroid hormones—solubilization, aqueous solutions, bile salts □ Testosterone derivatives—solubilizing effect of sodium cholate, deoxycholate □ UV spectrophotometry—analysis

The ability of bile salts to enhance the water solubility of steroid hormones was noted as early as 1944 by Cantarow *et al.* (1). Since that time, micellar solubilization of steroids has been studied extensively by Ekwall (2) and Sjöblom (3). However, bile salt solubilization of hormonal steroids appears not to have been examined in detail. This study was undertaken to examine the solubilization of testosterone propionate, methyltestosterone, and 19-nortestosterone by the anionic surfactants, sodium cholate and sodium deoxycholate, and is part of a larger study of the solubilization of steroidal hormones by steroidal surfactants. A recent report from this laboratory (4) dealt with the solubilization of some androgenic steroids by ethoxylated cholesterol, a non-ionic surfactant.

EXPERIMENTAL

Materials—Sodium cholate,¹ sodium deoxycholate,¹ methyltestosterone NF, testosterone propionate USP, and 19-nortestosterone² were used as received. Moisture contents of the bile salts, determined by drying overnight *in vacuo* at 110°, were taken into consideration when recording their weights. Bile salt solutions, prepared with distilled water, were not buffered; their pH ranged from 7.0 to 7.8 for cholate and from 7.2 to 8.6 for deoxycholate.

Solubility Determinations—Solubilities were determined by equilibration of several concentrations of bile salt solutions with the steroids, followed by spectrophotometric analyses of suitably di-

Figure 1—Solubility of steroids in aqueous solutions of sodium cholate at 30°. Key: ●, 19-nortestosterone; ■, methyltestosterone; and ▲, testosterone propionate.

luted aliquots, as described previously (4). For solutions in which enhancement of steroid solubility was minimal, dilution with 50% (v/v) methanol was still necessary to lower the bile salt concentration to a point where it would not interfere with the UV spectrophotometric analytical procedure. In such cases, cells of 5-cm. pathlength were used. 19-Nortestosterone, which was not included in the previous study, has maximum absorbance in 50% (v/v) aqueous methanol at 244 mμ, with a molar absorption coefficient of 17.3×10^3 .

RESULTS AND DISCUSSION

Figures 1 and 2 show the relationship between solubility of the steroid solubilizes and the concentration of sodium cholate and sodium deoxycholate, respectively. At low concentrations of bile salts, only a marginal change in steroid solubility is observed. After these initial stages, up to 1.0×10^{-2} M for sodium cholate and $\sim 6.0 \times 10^{-3}$ M for sodium deoxycholate, steroid solubility increases linearly with bile salt concentration. This behavior conforms well to the general features of micellar solubilization, but it is at variance with the report of Lach and Pauli (5) who found that the solubility of testosterone increased at a higher rate below the apparent critical micelle concentration (CMC) of deoxycholate than above it. In a comprehensive paper dealing with the solubiliza-

Table I—Solubilizing Capacity of Bile Salts for Steroids at 30°

Steroids	Solubilizing Capacity, ^a —(Mole Steroid/Mole Bile Salt) × 10 ³ —		Reciprocal of Solubilizing Capacity, —Mole Bile Salt/Mole Steroid—	
	Sodium Cholate	Sodium Deoxycholate	Sodium Cholate	Sodium Deoxycholate
Testosterone propionate	6.61	34.19	151	29
Methyltestosterone	16.20	30.49	62	32
19-Nortestosterone	62.11	163.2	16	6

^a These values are calculated by the method of least squares from the linear plots, above the apparent CMC, in Figs. 1 and 2. Correlation coefficients of the linear relationships were higher than 0.90 in all the cases.

tion of bile acids, cholesterol, and several other lipoidal substances by bile salts, Ekwall (2) has shown that micelle formation in aqueous bile salt solutions takes place in a number of discrete stages. In the present work, the bile salt concentration ranges in which the rather sharp increases in steroid solubility commence are in reasonably good agreement with the "first concentration limits," $1.3\text{--}1.8 \times 10^{-3} M$ for cholate and $5\text{--}6 \times 10^{-3} M$ for deoxycholate, reported by Ekwall (2), and also with the CMC values reported by Bates *et al.* (6), using other solubilizes.

The solubilizing capacities of the bile salts for the steroids examined are listed in Table I. It is evident from Table I that deoxycholate is a better solubilizer than cholate. This is in agreement with previous findings (2, 6) with other solubilizes. Table I also shows that both bile salts solubilize 19-nortestosterone to the greatest extent. Water solubilities (in moles/liter at 30°) of the steroids examined are in the following order: 19-nortestosterone (9.59×10^{-4}) > methyltestosterone (1.02×10^{-4}) > testosterone

propionate (0.06×10^{-4}). The ability of 19-nortestosterone to become solubilized to the greatest extent may be due to its inherently high affinity for water. Sjöblom (3) has also reported similar data for solubilization of 19-nortestosterone in aqueous solutions of polysorbate 20. In the concentration range examined, both of the bile salts solubilized more methyltestosterone than testosterone propionate. However, as Table I shows, the solubilizing capacity of deoxycholate for testosterone propionate is greater than that for methyltestosterone. These results and those of a previous study (4) thus show that there is no apparent relationship between the water solubility of a steroid and its property of becoming micellarly solubilized.

A closer examination of Figs. 1 and 2 shows that significant increases in the solubility of 19-nortestosterone take place before the apparent CMC's of the bile salts are exceeded. This may be due to formation of mixed micelles of the bile salt and 19-nortestosterone, or it may be that the bile salts increase the solubility of 19-nortestosterone by cosolvation effects. It is interesting that 19-nortestosterone, a steroid molecule without one angular methyl group, is considerably more hydrophilic than other testosterone derivatives.

Recently, Small *et al.* (7, 8) proposed that cholate and deoxycholate micelles are formed by hydrophobic association of the hydrocarbon backs of the rigid steroid nuclei in such a way that the hydrophilic sides, containing the hydroxyl groups and the negatively charged ionic groups, are exposed to water. In the absence of excess counterion concentration, as in this study, these micelles remain small in comparison with classical detergent micelles, their aggregation number ranging from 2 to 9 (7). Upon examining space-filling (Stuart-Breiglib) molecular models, Small has suggested that up to 9 or 10 cholate molecules may associate hydrophobically.

Small and Admirand (9) have shown that at 30° about 6–9 moles of bile salt will solubilize 1 mole of lithocholate. The reciprocal solubilizing capacity values for 19-nortestosterone determined in this study are similar to those for lithocholate. There is a structural similarity between lithocholate and 19-nortestosterone; both have polar groups at each end of their molecules. These observations suggest that the mechanism responsible for the solubilization of these two steroids may be similar. Working with space-filling molecular models (Corey–Pauling–Koltun), it is possible to surround one molecule of either 19-nortestosterone or lithocholate by bile salt molecules in such a way that the hydrophobic parts of the molecules are in contact and the polar functions are exposed to the surroundings. The number of bile salt molecules required for this purpose is consistent with the reciprocal solubilizing capacity values.

For methyltestosterone and testosterone propionate, the solubility data do not permit postulation of the solubilization mechanism. It seems reasonable, however, to expect that the effective average micelle size and volume would change when these solubilizes are incorporated, regardless of the mechanism, in micellar solutions of bile salts. Light scattering, viscosity, and ultracentrifugation studies would reflect such changes and might, therefore, provide useful clues for understanding these solubilized systems.

Alkaloids of *Tylophora* I: Isolation of Six New Alkaloids

KOPPAKA V. RAO*, RICHARD WILSON, and BERNICE CUMMINGS

Abstract □ *Tylophora crebriflora* (N. O. Asclepiadaceae) is a slender vine found chiefly in northeastern Australia. In a detailed examination of the plant, six alkaloids have been isolated which have not previously been shown to be present in this genus. The methods for their isolation and their physical characteristics are described.

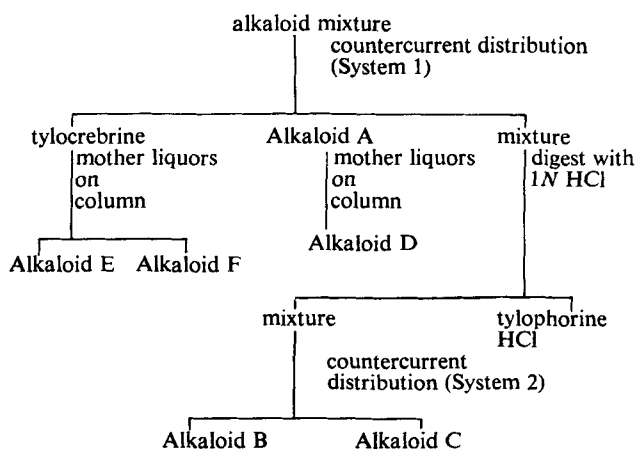

Keyphrases □ *Tylophora crebriflora*—separation, isolation, physical properties, six alkaloids □ IR spectrophotometry—structure, identification □ UV spectrophotometry—structure, identification

In a series of papers during the 1950's, Govindachari *et al.* (1-5) described the isolation, structure, and synthesis of two alkaloids, tylophorine and tylophorinine, present in the Indian plant *Tylophora indica*. These alkaloids are built up of a dibenzo[*f,h*]-pyrrolo[1,2*b*]-isoquinoline skeleton. From a related Australian plant, *Tylophora crebriflora*, Gellert *et al.* (6) described the isolation of a third member named tylocrebrine, together with a minor amount of tylophorine. The two were shown to be isomeric, differing in the arrangement of the methoxyl groups. During routine screening by the Cancer Chemotherapy National Service Center (CCNSC), it was observed that tylocrebrine showed significant antileukemic activity. At the request of CCNSC to provide tylocrebrine for possible clinical trials, these studies were initiated.

EXPERIMENTAL

The dried plant, *Tylophora crebriflora*, was obtained from Australia.¹ The total alkaloid fraction could be readily isolated by the following steps: (a) extraction with 1% methanolic acetic acid;

¹ The plant material used in this study was collected, identified, and supplied by the Department of Forestry of Queensland, Brisbane, Queensland, Australia, in 1964. (A voucher specimen was preserved at Chas. Pfizer & Co., Inc., Maywood, N. J.)

Scheme I—Separation of the alkaloids of *Tylophora crebriflora*. System 1: 3% aqueous acetic acid-chloroform-ethyl acetate (10:7:3) System 2: 3% aqueous acetic acid-chloroform-*n*-butanol (5:4:1)

(b) concentration; (c) partition between ethyl acetate and 0.2 N HCl (aq.); and (d) extraction of the aqueous layer at pH 9-10 with chloroform. The crude mixture of alkaloids represented a yield of approximately 0.15%.

The mixture was separated into its components by the use of countercurrent distribution and chromatography on a commercial adsorbent,² as indicated in Scheme I. In addition to the two known members, tylocrebrine and tylophorine, the extracts yielded six new alkaloids.

Tylocrebrine and Alkaloid A are the major components, each being present to the extent of about 40% of the total. Next in abundance are tylophorine and Alkaloids B and C, which account for approximately 4-5% each. The rest is made up of the other three members, Alkaloids D, E, and F.

The analytical data and physical properties of the new members are shown in Tables I and II. In general, Alkaloids A-E show

Dermophilic Insect Repellents with Perdurable Efficacy

RONALD P. QUINTANA*, ANDREW LASSLO*, LORRIN R. GARSON*,
CARROLL N. SMITH†, and IRWIN H. GILBERT†

Abstract □ The synthesis of the monohexanoate, monopropionate, and monobenzoate esters of dihydroxyacetone is reported; the compounds were designed to provide long-lasting insect-repellent efficacy. The insectifugal properties of these compounds and those of the corresponding monoundecanoate ester are also described. While several of the compounds exerted significant repellency, the perdurable effect of dihydroxyacetone monohexanoate (II) was particularly noteworthy.

Keyphrases □ Dihydroxyacetone—synthesis of monohexanoate, -propionate, -benzoate esters □ Insect repellents, dermophilic, long-lasting—dihydroxyacetone monohexanoate, -propionate, -benzoate, -undecanoate esters, evaluation □ Synthesis—dihydroxyacetone monohexanoate, -propionate, -benzoate esters, insect-repellent activity

This approach to the development of dermophilic¹ insect repellents with prolonged activity involves the synthesis of compounds, designed for topical application, incorporating an insect-repellent component along with a component capable of anchoring to the skin; the respective entities are linked together by chemical bonds, constituting the so-called "precursor molecule" (1–4). The specifics of the rationale have been discussed in detail relatively recently (3). While the precursor molecule may be an effective repellent *per se*, it is the gradual breakdown of the precursor molecule, anchored to the epidermis, that is expected to provide long-lasting protection by means of the sustained release of the repellent component.

In two preceding communications (3, 4), the authors reported the preparation of dihydroxyacetone monoundecanoate (I). Based upon the effects elicited by I and upon the observations of Drake and Melamed (5), it was felt that structural designs inherent in the monohexanoate, monopropionate, and monobenzoate esters of dihydroxyacetone (II, III, and IV, respectively) should contribute substantially to the elucidation of relationships between chemical constitution and insect repellency (6). These compounds, like I, derive their dermophilic properties from the α -hydroxymethyl ketone moiety (7), retaining the hydroxyacetone ester function known to enhance susceptibility substantially to the hydrolytic process (8). In addition to the synthesis and the insectifugal efficacies of Compounds II, III, and IV, the insect repellency of I is reported here for the first time.

Compounds II–IV were prepared by procedures patterned after the direct acylation employed in the synthesis of I (4). Their properties are summarized in Table I. Compound II was also prepared by the method utilizing the diazoketone intermediate (3);

however, the former method of preparation turned out to be a much more feasible one. The conditions associated with monomer and dimer formation in a monoester of dihydroxyacetone were discussed earlier (4); the physicochemical characteristics of Compounds II–IV parallel those observed in the referenced communication. Since the formulation used in the insect-repellent tests assured conversion to the sought monomeric state in each instance (4), circumstances did not warrant characterization of the monomers and dimers of the three new compounds.

The repellency of Compounds I–IV against *Aedes aegypti* mosquitoes is summarized in Table II. Compound II completely prevented biting at the 4- and 8-hr. test intervals and effected a dramatic reduction in biting at the 26-hr. test interval compared to the corresponding control. It is important to note the similarity in effects produced by Compounds I and II at the 22- and 26-hr. intervals; in both cases there was a resurgence of repellent effects from the 22-hr. test to that at 26 hr.

The test 22 hr. after application (after the overnight period) tends to coincide with the point following a period of limited exertion and limited perspiration, while that at 26 hr. appears to coincide with a 4-hr. active period following the overnight hours. If these premises are accepted, the results may be interpreted in terms of enhanced hydrolytic release of the repellent component prior to the 4-, 8-, and 26-hr. testing points. The repellency level of Compounds I and II with respect to the USDA standard deet, at the 26-hr. interval, is also noteworthy, particularly that of Compound II.

In addition to the tests summarized in Table II, Compound II was subsequently evaluated at additional time intervals; the treated subjects remained in a warm, humid room for a 3-hr. period immediately prior to the evaluation. Under these conditions, Compound II provided essentially complete protection 16 and 20 hr. after application to the skin [biting at 16 hr., 1.9% (control 64%, $LSD_{0.05}$ 10.8); biting at 20 hr., 9.7% (control 64%, $LSD_{0.05}$ 10.8)].

The repellent efficacy of Compound III is also apparent; the latter provided almost complete protection 4 and 8 hr. after application. The fact that it exerted no repellency at the subsequent test intervals can be interpreted in terms of a comparatively increased rate of hydrolysis normally associated with propionic acid esters with respect to those of substantially larger aliphatic acids. The relatively higher volatility of the released propionic acid with respect to the larger homologs also could be a contributing factor.

The specific contributions of the precursor molecules' intrinsic repellency and of the released acid-components have not been ascertained. It is apparent, however, that hydrolytic release of the latter is associated with maximum protection.

¹ Dermophilic properties include all those chemical and physical characteristics of an organic molecule that contribute to its affinity for the skin.

Table I—Esters of Dihydroxyacetone

No.	R	B.p. (mm.)	M.p.	Yield, %	Formula	Anal., %	
						Calcd.	Found
II	<i>n</i> -C ₅ H ₁₁	114–116°(0.25)	...	52.0	C ₉ H ₁₆ O ₄	C, 57.43 H, 8.57	C, 57.57 H, 8.43
III	C ₂ H ₅	80–82°(0.10)	...	21.2	C ₆ H ₁₀ O ₄	C, 49.31 H, 6.90	C, 49.52 H, 6.92
IV	C ₆ H ₅	...	86.7–89.2° ^a	25.4	C ₁₀ H ₁₀ O ₄	C, 61.85 H, 5.19	C, 61.86 H, 5.18

^a The analytical sample was obtained by recrystallization from ethanol after the more insoluble dihydroxyacetone dibenzoate (V) had been removed by crystallization from this solvent. The latter was obtained in 6% (crude) yield; the analytical sample (Anal.—Calcd. for C₁₇H₁₄O₅: C, 68.45; H, 4.73. Found: C, 68.34; H, 4.68.) melted at 123.6–124.1°; Romo (9) reports m.p. 118–119°.

The lack of insectifugal activity observed with Compound IV is somewhat surprising when one considers that the two closely related analogs, 1-hydroxy-2-propanone benzoate (VI) and 1,3-propanediol monobenzoate (VII), are effective repellents (10).

These findings constitute the results of exploratory work involving structural designs, with gradual changes in chemical constitution or physical properties or both, which enabled correlations between molecular configuration and biological response in terms of concepts reasonably well established in contemporary theoretical chemistry. The work currently in progress leads to the anticipation of even more encouraging results; some of these are expected to be reported in the authors' next communication.

EXPERIMENTAL

Synthetic Work²—The esters of dihydroxyacetone, listed in Table I, were prepared by the procedure reported in the authors' preceding communication (4). The hexanoyloxyacetic acid (VIII) used in the earlier cited alternate method (3) for the preparation of dihydroxyacetone monohexanoate (II) distilled at 130–132° (1.8 mm.), m.p. 30.7–33.9°, $\nu_{\text{max}}^{\text{CHCl}_3}$ 1745 cm.⁻¹ (carbonyl), and was obtained in a 46.0% (59.6 g.) yield.

Anal.—Calcd. for C₈H₁₄O₄: C, 55.16; H, 8.10. Found: C, 55.37; H, 8.04.

The latter (VIII) was converted through 1-hexanoyloxy-3-diazoacetone (IX) to Compound II, b.p. 100–102° (0.1 mm.).

Anal.—Calcd. for C₉H₁₆O₄: C, 57.43; H, 8.57. Found: C, 57.52; H, 8.69.

Evaluation of Insect-Repellent Activity—Female *Aedes aegypti* mosquitoes, 7–8 days old, were confined in small cylindrical cages (4 × 12 cm.). The sides of the cages were clear plastic; one end was covered with gauze and the other end was fitted with a plastic slide closure. Mosquitoes in stock cages were immobilized by exposure to a low temperature, and six females were placed in each small cage. The cages were then held in a warm room for at least 1 hr. to permit the mosquitoes to recover before tests were begun. Three squares, each 25 cm.², were outlined on the skin of each

Table II—Percent of Mosquitoes (*Aedes aegypti*) Biting Forearms of Human Volunteers at Various Intervals after Topical Application

^a Application rate 20 mg./cm.², applied in ethanol solution. ^b Least significant difference at the 0.05 level. ^c Average of three tests on each of three subjects with six mosquitoes per test. ^d In addition, one subject received no bites when exposed to a stock cage (containing 1000–1500 mosquitoes) for 3 min. ^e *N,N*-Diethyl-*m*-toluamide; application rate 3 mg./cm.².

forearm of three subjects, and each square was treated with 20 mg./cm.² of the repellent. The latter was applied as an ethanol solution heated on a steam bath for 30 min. prior to application. Tests were made by placing the end of the cage equipped with the slide in contact with a treated area on a human arm and by opening the slide to give the mosquitoes direct access to the treated skin for a period of 1 min. In each test period, cages of mosquitoes were exposed to untreated areas of the skin to provide checks on the percentage biting. Three tests on each of three subjects were employed in determining average values.

In the tests reported in Table II, the treated subjects remained in a room maintained at 27.7° (82°F.) and 78–80% relative humidity during the 8-hr. workday. In the subsequent evaluations conducted on Compound II, the subjects remained in the temperature- and humidity-controlled room only for 3 hr. immediately prior to the repellency test.

Interactions of Drugs with Proteins I: Binding of Tricyclic Thymoleptics to Human and Bovine Plasma Proteins

H. J. WEDER* and M. H. BICKEL

Abstract □ Data on the binding of imipramine, desipramine, and 3-chlorodesmethylimipramine to plasma proteins have been obtained over a wide range of ligand concentration using a modified equilibrium dialysis technique. Plasma proteins other than albumin do not appreciably contribute to complex formation with the drugs studied. Fifty-nine percent imipramine is bound to albumin in the plasma level range reached under therapeutic conditions. However, the association constants of the complex is low. Species differences in the binding capacity of albumin were observed. Apparently, atypical binding behavior was disclosed for desipramine and 3-chlorodesmethylimipramine. A binding model is discussed, and values of binding parameters are given.

Keyphrases □ Thymoleptics, tricyclic—binding to human, bovine plasma proteins □ Proteins, human, bovine plasma—imipramine, desipramine, 3-chlorodesmethylimipramine, interaction, binding, model

These studies on the binding of drugs and other compounds to plasma proteins are aimed at gaining insight into the following problems:

1. Possible influence on the pharmacokinetics of a drug by its interactions with proteins.
2. Mechanism of interactions between drugs or model compounds and proteins and physicochemical interpretation.
3. Critique of methods used in the study of drug-protein interactions.

Part I contains data on the complex formation of imipramine, its active metabolite desipramine (desmethylimipramine), and 3-chlorodesmethylimipramine with bovine albumin and human albumin, γ -globulin, plasma, and serum in concentration ranges including the one met with under therapeutic conditions. The first two drugs are used clinically; the latter is a metabolite of the clinically used 3-chloroimipramine accumulating in rats (1) and human (2).

Imipramine (IP) is one of the few drugs about which much of the metabolic and pharmacokinetic data is known (3–8). In addition, physicochemical data of all its major metabolites have been reported (9). Sensitive methods exist for determining imipramine, desipramine, and 3-chlorodesmethylimipramine (5, 6, 10, 11).

Data on IP binding to plasma proteins were published by Tinao and Gomez-Guillen (12) in 1963. Data and species differences in the binding of desipramine to plasma proteins have recently been reported by Borgå *et al.* (13). Earlier, Gillette (14, 15) reported on the binding of imipramine to liver microsomes, which presumably is the reason for the high concentrations of imipramine and related drugs in lung, liver, or kidney tissue in the rat *in vivo* (5, 8). Beside many reports on interactions between thymoleptics and membranes [reviewed by Glowinski and Baldessarini (16)], an interaction between imipramine and the outer membrane of blood platelets has also been reported (17).

EXPERIMENTAL

Materials—The hydrochlorides of imipramine,¹ desipramine¹ (DMI), and 3-chlorodesmethylimipramine¹ (CDMI) were used.

Also used were 10,11-¹⁴C-imipramine hydrochloride² (8.05 mc./mmole) and ³H-acetic anhydride² (in benzene, 500 mc./mmole). Gas chromatographic (11) and spectrophotometric tests showed

These studies on the binding of drugs and other compounds to plasma proteins are aimed at gaining insight into the following problems:

1. Possible influence on the pharmacokinetics of a drug by its interactions with proteins.
2. Mechanism of interactions between drugs or model compounds and proteins and physicochemical interpretation.
3. Critique of methods used in the study of drug-protein interactions.

Part I contains data on the complex formation of imipramine, its active metabolite desipramine (desmethylimipramine), and 3-chlorodesmethylimipramine with bovine albumin and human albumin, γ -globulin, plasma, and serum in concentration ranges including the one met with under therapeutic conditions. The first two drugs are used clinically; the latter is a metabolite of the clinically used 3-chloroimipramine accumulating in rats (1) and human (2).

Imipramine (IP) is one of the few drugs about which much of the metabolic and pharmacokinetic data is known (3–8). In addition, physicochemical data of all its major metabolites have been reported (9). Sensitive methods exist for determining imipramine, desipramine, and 3-chlorodesmethylimipramine (5, 6, 10, 11).

Data on IP binding to plasma proteins were published by Tinao and Gomez-Guillen (12) in 1963. Data and species differences in the binding of desipramine to plasma proteins have recently been reported by Borgå *et al.* (13). Earlier, Gillette (14, 15) reported on the binding of imipramine to liver microsomes, which presumably is the reason for the high concentrations of imipramine and related drugs in lung, liver, or kidney tissue in the rat *in vivo* (5, 8). Beside many reports on interactions between thymoleptics and membranes [reviewed by Glowinski and Baldessarini (16)], an interaction between imipramine and the outer membrane of blood platelets has also been reported (17).

EXPERIMENTAL

Materials—The hydrochlorides of imipramine,¹ desipramine¹ (DMI), and 3-chlorodesmethylimipramine¹ (CDMI) were used.

Also used were 10,11-¹⁴C-imipramine hydrochloride² (8.05 mc./mmole) and ³H-acetic anhydride² (in benzene, 500 mc./mmole). Gas chromatographic (11) and spectrophotometric tests showed

¹ Supplied by Geigy Ltd., Basel, Switzerland.

² Acquired from Radiochemical Centre, Amersham, England.

Figure 1—Fraction of IP, DMI, and CDMI bound to HA, pH 7.4, 20°. HA 4% = $6.15 \cdot 10^{-4}$ M. % $c_{s(b)}$ = fraction of ligand bound. $c_{s(T)}$ = total molar ligand concentration.

purities of >99% for all compounds. The radiochemical purities were >98%.

Demineralized crystallized bovine albumin³ (BA), electrophoretically pure human albumin⁴ (HA), and γ -globulin⁴ (HGLO) were used. All reagents used were of analytical purity.

Normal human plasma (NHP) and serum (NHS) were pooled and stored at -15° for no longer than 1 week.

The ligands (IP, DMI, and CDMI) were dissolved in 0.01 M phosphate buffer containing 0.9% NaCl, at pH 7.4 ± 0.05 and ionic strength of 0.19. The proteins (BA, HA, and HGLO) were dissolved in the same medium by gentle agitation.

Methods—Unbound and total ligand concentrations were determined after equilibrium dialysis. The dialysis chamber was developed in this laboratory and will be described in a subsequent paper (18).

Analytical Methods—¹⁴C-IP in aqueous solutions was measured by direct liquid scintillation counting. Protein quenching was corrected for by the channel ratio method. DMI and CDMI were determined by the isotope derivative method described by Hammer and Brodie (10). In all cases, a Packard Tri-Carb 314 E scintillation spectrometer and the following scintillation system were used: 4 g./l. 2,5-bis-[5'-*tert*-butylbenzoxazolyl(2')]-thiophene (BBOT) and 40 g./l. naphthalene in dioxane-xylene-ethyleneglycol monomethyl ether (3:1:3, v/v).

RESULTS

Table I shows the fraction of the total concentrations of IP, DMI, and CDMI bound to HA, HGLO, BA, serum, and plasma. The values for two total concentrations are given for each ligand, the first concentration representing the range of plasma levels observed in therapy (2, 19, 20). The albumin concentrations of the sera showed a mean value of 4.1%.

The fractions of IP, DMI, and CDMI bound in a 4% HA solution as a function of total ligand concentration in the range of 0.1–20 μ M are depicted in Fig. 1. Whereas a typical curve results with IP, the curves obtained with DMI and CDMI represent apparently atypical cases.

IP in the concentration range of 0.2 μ M (0.06 mcg./ml.)–3 μ M (0.95 mcg./ml.), i.e., in the therapeutic range, is bound at a fraction of $58.9 \pm 2.8\%$. A further increase of the total ligand concentration up to 17.2 μ M (54.5 mcg./ml.) leads to a gradual decrease to a bound fraction of $10.5 \pm 1.9\%$.

The DMI fraction bound shows a sharp increase from $23.5 \pm 2.1\%$ to $61.2 \pm 2.4\%$ in the (therapeutic) concentration range 0.27 μ M (0.08 mcg./ml.)–3 μ M (0.91 mcg./ml.). With a further increase to 19.3 μ M (5.85 mcg./ml.), the fraction bound remains constant.

An analogous atypical curve is obtained with CDMI; from $35.2 \pm 1.8\%$ to $84.2 \pm 3.1\%$ are bound in the range of 0.3 μ M (0.1 mcg./ml.)–3 μ M (1.0 mcg./ml.), the fraction bound again remaining

constant at higher concentrations. Thus, 3 μ M represents a critical concentration in the atypical cases of DMI and CDMI.

DISCUSSION

An interaction between albumin and the ligands IP, DMI, and CDMI is demonstrated by the results. The experiments did not reveal an influence on the binding affinity of HA by other plasma proteins. It must be concluded that albumin is the only complexing partner for these ligands in plasma. Species differences are observed for all three ligands, the binding affinity being significantly higher with bovine than with HA.

The therapeutic treatment of patients with IP or DMI leads to plasma levels of 0.005–0.3 mcg./ml. (2, 19, 20). Similar concentrations are observed with other tricyclic drugs, although the absolute values are very low compared with many other classes of drugs. According to the results, up to 70% of IP, DMI, and CDMI in plasma are bound to albumin in the therapeutic concentration range, leaving a free concentration of 30% or more. These data are of little help for the estimation of a possible influence on the pharmacokinetics and pharmacodynamics of the drugs by their interactions with plasma albumin. In this respect, a far better key is provided by the absolute values of the binding affinity, i.e., the association constant, because only the stability of these complexes can possibly be related with pharmacological phenomena. Therefore, information should be obtained on the main forces responsible for drug-protein complexes and not merely on their stabilizing factors.

The following model allows the estimation of the association constant of the IP-HA complex under the experimental conditions used. The c_p ($6.15 \cdot 10^{-4}$ M) is the concentration of albumin P , where each molecule P can bind n ligand molecules S . Thus P has n binding sites. If all the n binding sites are occupied with ligands, the total binding capacity per liter solution is $c_p \cdot n$. This capacity, however, can only be reached if the concentration of the free ligands, $c_{s(f)}$, is infinite. With relatively low ligand concentrations, the binding sites are only partially occupied in a statistical manner. A correlation between the number of occupied and unoccupied binding sites can be derived under the assumption that the reactivity of all binding sites is equal and that no interactions occur between binding sites. If A is a binding site of albumin, S a ligand molecule, and AS an occupied binding site, then the association or affinity constant k for the binding reaction $A + S \rightleftharpoons AS$ is

$$k = \frac{c_{AS}}{c_A \cdot c_{s(f)}} \quad (\text{Eq. 1})$$

If, under the experimental conditions, r out of n binding sites are occupied, then

$$c_{AS} = c_p \cdot r \quad (\text{Eq. 2})$$

and

$$c_A = c_p \cdot n - c_p \cdot r \quad (\text{Eq. 3})$$

Thus, Eq. 1 becomes

$$k = \frac{c_p \cdot r}{(c_p \cdot n - c_p \cdot r) c_{s(f)}} \quad (\text{Eq. 4})$$

or

$$c_p \cdot r = \frac{c_p \cdot h}{1 + [1/(k \cdot c_{S(f)})]} \quad (\text{Eq. 5})$$

Figure 2 shows the plot of the free ligand concentration $c_{S(f)}$ against the total ligand concentration $c_{S(T)} = c_p \cdot r + c_{S(f)}$. A curve is thereby obtained for each albumin complex with the three ligands used. Curves 4 ($k = 0$) and 5 ($k = \infty$) represent the cases of total lack and of infinitely high binding affinity, respectively. Thus, the sequence of the association constants for the complexes in the concentration range 1–11 μ M is $k_{\text{CDMI}} > k_{\text{DMI}} > k_{\text{IP}}$. Only IP fits the binding model introduced, whereas the atypically behaving DMI and CDMI do not. However, with all three ligands, no deviation from the ideal binding curve can be observed in the lowest concentration range (0–1 μ M). In this range the sequence of binding affinities is $k_{\text{IP}} > k_{\text{CDMI}} > k_{\text{DMI}}$ (Table I).

Graphical determination of the binding capacity of HA for IP leads to a value of about 5.1 μ M (Fig. 2). By calculation, an association constant of $k_{\text{IP}} = 0.5 \cdot 10^4 \text{ M}^{-1}$ is obtained. According to Fig. 2 the binding capacities of albumin for DMI and CDMI must be much higher than for IP. A hypothetical explanation of the atypical curves of DMI and CDMI could be a conformational change of the protein by a primary interaction, which then results in an increase of available binding sites, possibly of higher reactivity.

It is unlikely that at therapeutic concentrations the binding of IP to plasma albumin exerts an appreciable influence on pharmacokinetics and thus pharmacodynamics, since the association constant of the IP–HA complex is less than 10^4 M^{-1} (21, 22).

Figure 2—Free ligand concentration $c_{S(f)}$ as a function of total concentration $c_{S(T)}$. For conditions, see Fig. 1. Key: 1 = IP, 2 = DMI, 3 = CDMI, and 4 and 5 = theoretical binding curves for $k = 0$ and $k = \infty$, respectively.

Further results on the binding mechanism as well as thermodynamic data will be presented and discussed in a subsequent report (18).

Use of Tetraphenylethylene in Quantitative GLC of Hyoscyamine and Scopolamine

BANG-LING WU CHU and EDWARD S. MIKA

Abstract □ Hyoscyamine and scopolamine as free bases were simultaneously quantitated by GLC, using tetraphenylethylene as an internal standard. A linear relationship was found between the ratios of the integrated peak areas of alkaloid to the internal standard and the actual weight ratios of alkaloid to the internal standard for both hyoscyamine and scopolamine. Pure compounds and extracts from *Hyoscyamus niger* Linne powder were analyzed. The combined precision of the extraction procedure of plant materials with the GLC procedure was determined.

Keyphrases □ Tetraphenylethylene, internal standard—quantitative GLC of hyoscyamine, scopolamine □ GLC, hyoscyamine, scopolamine, quantitative—tetraphenylethylene, internal standard □ Hyoscyamine—simultaneous GLC quantification with scopolamine using tetraphenylethylene as internal standard □ Scopolamine—simultaneous GLC quantification with hyoscyamine using tetraphenylethylene as internal standard

Brochmann-Hanssen and Svendsen (1) successfully separated a large number of alkaloid mixtures from various plant sources by GLC. Solomon *et al.* (2) reported quantitative determination of atropine and scopolamine by GLC. No information was available pertaining to the use of a proper compound as an internal standard for the quantitation of the two major tropane alkaloids. Furthermore, no estimate of the combined precision of the alkaloid extraction procedure involving plant materials with the GLC procedure has been reported. Recently, Zimmerer and Grady (3) described an assay procedure of hyoscyamine, atropine, scopolamine, and phenobarbital in unit doses of tablets and elixirs, using homatropine as an internal standard.

The importance of using an internal standard to obtain reproducible quantitative results in any assay procedures by GLC has been emphasized by various investigators (4–9). This paper reports the quantitative determination of hyoscyamine and scopolamine simultaneously as pure compounds and from plant extracts, using tetraphenylethylene (TPE) as an internal standard by employing both isothermal and programmed temperature GLC.

EXPERIMENTAL

Equipment—A linear programmed temperature gas chromatograph (Perkin-Elmer model 881), equipped with a hydrogen flame-ionization detector and a 1-mv. recorder (Sargent model SR, S-72180-20) with a chart speed of 1 in./min. and 1-sec. full-scale response, was used. A pH meter (Beckman zeromatic), centrifuge, and flash evaporator were used for the extraction of plant powders.

Materials—The carrier gas was helium. Hydrogen and air were used in the flame-ionization detector. Dual borosilicate glass columns, 1.83-m. (6-ft.) \times 0.19-cm. (0.075-in.) inside diameter, were packed with 2.5% of methyl silicone gum rubber¹ on diatomite aggregate,² DMCS 80/100 mesh. The prepared packing material

(Perkin-Elmer Co.) was introduced into the columns under reduced pressure with uniform vibration. A minimum of Pyrex glass wool was used to hold the packing material in place in the column. The columns were conditioned and maintained by the injection of Silyl-8³ into the chromatograph once every 2 weeks before any sample analysis was made. Seeds of *Hyoscyamus niger* Linne (Solanaceae), annual variety, were used.⁴ Macroscopic and microscopic examination of aerial organs of flowering plants in this laboratory confirmed identity as *hyoscyamus* NF XI (henbane). Plants which were field grown, oven-dried at 50°, and ground to 40 mesh served as the standard plant powder. Hyoscyamine⁵ and scopolamine⁶ free bases, as well as their hydrobromide salts,⁷ were used. TPE was also used.⁶ All other chemicals used were analytical reagent grade.

Operating Conditions—The sample was chromatographed isothermally at 200° for 6 min., followed by programmed temperatures from 200 to 290° at the rate of 6°/min. The injector temperature was maintained at 300°. The helium flow rate was 100 ml./min., with an inlet pressure of 24 psig. Air and hydrogen inlet pressures were 48 and 24 psig., respectively. Attenuations of \times 100, \times 50, \times 20, and \times 10 were used.

Standard Curves—Nine separate chloroform solutions were prepared by weighing out known amounts of hyoscyamine, scopolamine, and the internal standard, TPE, into 10-ml. volumetric flasks. The solutions were chromatographed, and the integrated peak areas of hyoscyamine, scopolamine, and TPE were obtained. A standard curve was then established by plotting the ratio of peak areas of hyoscyamine to TPE *versus* the weight ratio of the two compounds. A similar curve was obtained for scopolamine. On alternate days during this study, fresh solutions of the two alkaloids and the internal standard were used to determine the reproducibility of the standard curves.

Quantitation of the Alkaloids of *Hyoscyamus* Powder—**Extraction Procedure**—Hyoscyamine and scopolamine were extracted from standard *hyoscyamus* powder as total alkaloids by the procedure previously described (10).

Preparation of Sample Solution—A stock solution was prepared by dissolving a known amount of TPE in chloroform. A definite volume of this standard TPE solution was added to an aliquot of the plant extract by means of a lambda pipet and thoroughly mixed. The mixed solution was then chromatographed. The usual sample size injected was approximately 2 μ l. Pure hyoscyamine and scopolamine as free bases were used to check the reproducibility of the procedure each day that plant extracts were analyzed.

Calculations—The amounts of hyoscyamine and scopolamine in *hyoscyamus* powder were determined by computing the alkaloid to TPE peak area ratio from the chromatogram, obtaining the cor-

^a Consists of 3.01 mg. hyoscyamine and 5.09 mg. scopolamine which was added volumetrically to each plant sample, alkaloid content of which was calculated from data in Table II.

responding weight ratio of alkaloid to TPE from the standard curve, and multiplying by the weight of TPE in the sample. The value so obtained was then converted to alkaloid concentration in mg./100 g. dry weight of powdered plant specimen.

Recovery Studies—A solution of hyoscyamine hydrobromide and scopolamine hydrobromide as a mixture was prepared by dissolving known amounts of the two alkaloid salts in 10 ml. distilled water. An aliquot of this solution was added to a weighed *hyoscyamus* powder sample and extracted and analyzed by this method to estimate the recovery of the added pure alkaloids.

RESULTS AND DISCUSSION

For accurate quantitative analysis, the internal standardization technique was used. The virtues of using an internal standard have been well established (3–9).

Figure 1 is a typical gas chromatogram of a mixture of pure hyoscyamine and scopolamine, with TPE added as an internal standard. Extracts of *Hyoscyamus niger* L. with TPE added showed

similar chromatographic characteristics. The three compounds were well separated from one another with no overlapping, and TPE was found in the proximity of hyoscyamine and scopolamine. Therefore, in these studies, TPE can be used as an internal standard for each pure alkaloid individually, as a mixture, or in plant extracts. Moreover, TPE is readily available commercially, does not exist in plant extracts, remains stable in chloroform solution for relatively long periods of time, and does not decompose within this operating temperature range of GLC. Various other compounds such as acetanilid, pilocarpine, and pilocarpine hydrochloride were investigated in this study for their ability to serve as an internal standard; however, TPE proved to be the most satisfactory.

Brochmann-Hanssen and Svendsen (1) separated hyoscyamine and scopolamine from *hyoscyamus* leaf extract by GLC at 200° isothermally. Solomon *et al.* (2) reported a GLC procedure involving temperature programming only from 150 to 275° at the rate of 6°/min. for the separation of these two alkaloids from plant extracts. During initial experimentation, both procedures were compared using certain root extracts of *H. niger* as the sample. Data obtained showed the presence of a few compounds eluted between the solvent

Figure 1—Typical gas chromatogram of a mixture of pure hyoscyamine and scopolamine bases in chloroform to which TPE was added as the internal standard. Extracts of *Hyoscyamus niger* L. with TPE added showed similar chromatographic characteristics.

Figure 2—Standard curves for hyoscyamine and scopolamine with TPE as the internal standard.

peak and the hyoscyamine peak, resulting in chromatograms that did not afford the desired resolution. A technique was desired where the two alkaloids in question would have greater retention times and also greater differences in retention time so as to minimize or eliminate any possible interfering effect of the solvent and/or any other substances on the quantitation of hyoscyamine and scopolamine. A combination of both isothermal and programmed temperature GLC yielded well-separated symmetrical peaks (Table I). The number of theoretical plates suggested high column efficiency. The resolution factors (8) between hyoscyamine and scopolamine and between scopolamine and TPE were 2.2 and 2.4, respectively, indicating complete resolution.

A linear relationship was established between the weight ratios of the alkaloid to the internal standard and the integrated area ratios of the two. Figure 2 shows the standard curves for hyoscyamine and scopolamine with TPE as the internal standard. Maximum precision

and accuracy were obtained when the integrated peak area ratio of alkaloid to TPE was near unity. Each value shown in Fig. 2 is the average of three independent determinations. The standard curves thus obtained were checked and redetermined with fresh standard solutions. The use of an internal standard greatly simplified the analytical procedure and calculations.

Samples of hyoscyamus powder were analyzed by this method, and the results are shown in Table II. The combined precision of the liquid-liquid extraction technique with the GLC procedure was examined by adding known amounts of the two alkaloid salts to hyoscyamus powder. The results obtained from the recovery studies are presented in Table III. In all cases, quantitative recoveries of the added alkaloids were obtained.

Brochmann-Hanssen and Svendsen (1) pointed out that the amount of glass wool placed on top of the column packing was closely associated with the degree of decomposition or dehydration of the alkaloids. Special care was taken in using only the minimum amount of glass wool practicable during column packing. As shown in Fig. 1, no additional peaks apparently due to decomposition were present when pure alkaloids or henbane extracts to which TPE was added were chromatographed. The treatment of columns by injection of Silyl-8, which is a mixture of three trimethylsilyl donors, also aids in enhancing the column efficiency and preventing breakdown of sensitive compounds.

It should be emphasized that under the conditions employed, GLC did not differentiate between hyoscyamine and atropine. Zimmerer and Grady (3) arrived at the same conclusion and thus used the term "hyoscyamine-atropine" in their discussion.

The results obtained in this study clearly demonstrate that TPE is an excellent internal standard in the quantitative GLC determination of hyoscyamine and scopolamine, irrespective whether present as authentic free bases, mixtures, or in plant extracts.

Aspirin-Induced Occult Gastrointestinal Blood Loss: Local *versus* Systemic Effects

JACK R. LEONARDS* and GERHARD LEVY†

Abstract □ The purpose of this study was to determine if occult gastrointestinal blood loss produced by therapeutic doses of aspirin in man is a local or systemic effect. The daily oral administration of from 3.9 to 5.2 g. aspirin in tablets for 8 days increased the average daily blood loss from 0.3 to 6.4 ml. in nine normal subjects. Intravenous administration of from 2.7 to 3.4 g. aspirin as the sodium salt per day for 3 days to the same subjects caused no measurable gastrointestinal blood loss above control values. The average bleeding time increased from a control value of 2.6 to 4.5 min. during oral aspirin administration and to 4.1 min. during intravenous administration of the drug. The absence of gastrointestinal bleeding due to intravenous aspirin and the similarity in the degree of prolongation of bleeding time by both oral and intravenous aspirin indicate that gastrointestinal bleeding is a local effect of the drug and is not related to changes in the bleeding time.

Keyphrases □ Aspirin—induced gastrointestinal blood loss, local *versus* systemic effects □ Gastrointestinal bleeding—aspirin-induced, local, systemic effects

The mechanism of aspirin-induced gastrointestinal blood loss has been the subject of considerable discussion. Some investigators believe that it is a local¹ effect (1, 2), while others consider it due to a systemic action of aspirin (3, 4). It has been suggested that the prolongation of bleeding time produced by aspirin may possibly play a role in the causation of gastrointestinal blood loss (5). The study described here was initiated for the purpose of assessing the degree of gastrointestinal blood loss caused by the relatively large oral doses of aspirin used for the relief of rheumatism and arthritis, and to compare this with that produced by intravenous aspirin. Bleeding times were determined during a control period and during oral and intravenous aspirin administration to establish the possible relationship between this effect and gastrointestinal blood loss.

METHODS

Nine healthy, ambulatory subjects (sex, age, and weight listed in Table I) had their red blood cells labeled with ⁵¹Cr as described in a previous paper (6). They collected their stools over a 35-day period for the determination of fecal blood loss (6). The first 8 days served as a control period. From 3.9 to 5.2 g. aspirin as 0.3-g. tablets (Bayer) were taken daily, in four equal doses, for the next 8 days. After a rest period of 11 days, 2.7–3.4 g. aspirin as sodium acetylsalicylate dissolved in 250 ml. of normal saline was injected intravenously at a constant rate over a 1–2-hr. period each day for 3 days.

Bleeding times were obtained on the last 2 days of the control and oral aspirin periods and on each day of the intravenous aspirin period at the end of the injection. At least six stab wounds (three on each arm) were made on each day, and the reported bleeding times are averages of 12 to 36 individual determinations. The stab wounds were made with a disposable lancet (Dade Hemolet) with a blade 4

Figure 1—Average daily occult gastrointestinal blood loss in nine normal subjects during a control period, during oral administration of 3.9–5.2 g. aspirin in tablet form per day, during postdrug periods, and while receiving 2.7–3.4 g. aspirin intravenously for 3 days. Vertical bars are standard deviations.

mm. long and 1.4 mm. wide at the base, which was attached to a specially modified spring-type automatic lancet holder.

RESULTS

The results of the study are summarized in Table I. Oral administration of aspirin caused a pronounced and statistically significant increase in average daily blood loss (ADBL), which persisted for at least 6 days after the last day of drug ingestion. The total average blood loss due to aspirin was 59 ml. above control values, based on the bleeding observed from the 10th to the 23rd day of the study. One individual lost 129 ml. of blood during this period, or 117 ml. in excess of the control value. Intravenous administration of aspirin did not cause any measurable bleeding under the experimental conditions. There was no statistically significant difference (by paired *t* test) in the ADBL during the intravenous aspirin period and the initial control period. The time course of ADBL in the various control, treatment, and rest periods is shown in Fig. 1.

The average bleeding time was 2.6 min. in the control period. There was a statistically significant ($p < 0.01$) increase in bleeding time to 4.5 min. during oral aspirin administration and to 4.1 min. in the period when aspirin was given intravenously (Table I).

¹ In this discussion, "local effect" refers to the topical exposure of the gastrointestinal mucosa to ingested aspirin.

^a Average daily blood loss.

DISCUSSION

The relatively large oral doses of aspirin tablets employed in this study caused appreciable gastrointestinal blood loss. The ADBL of 6.4 ml. observed in this study during daily administration of 4.5 g. aspirin on the average may be compared to an average of 2.3 ml. in 15 subjects who received daily doses of only 2.6 g. of the same aspirin tablets in a previous study (7). Gastrointestinal bleeding due to aspirin is, therefore, of increasing significance when relatively high doses of the drug are used.

No bleeding was observed during intravenous administration of aspirin to the subjects in this study, although the same or larger doses caused significant gastrointestinal blood loss when given orally (7). The period of oral administration of aspirin (8 days) was considerably longer than the period of intravenous administration (3 days). However, comparison of the ADBL of the nine subjects during the first 3 days of oral administration of aspirin (5.7 ml.) with that during the 3 days of intravenous administration (0.45 ml.) yields essentially the same results as those listed in Table I for the longer time periods. Both sets of data show statistically significant ($p < 0.01$ by paired t test) blood loss during oral administration of aspirin and no evidence of aspirin-induced bleeding when the drug was given intravenously. Due to technical problems, intravenous aspirin was always given after a period of oral aspirin administration rather than in a crossover fashion, but it has already been shown (6, 7) that the bleeding response to aspirin is not affected by previous aspirin administration when followed by an 8-day rest period.

The results of this study are consistent with those of Anderson (1) and Davison *et al.* (2) who did not detect any gastric erosions or bleeding after parenteral administration of aspirin to guinea pigs, rabbits, and dogs in doses that caused significant gastric damage when given by the oral route. Simultaneously with the preliminary report of this study (8), Cooke and Goulston (9) recently reported that intravenous infusion of 1 g. aspirin twice daily for 3 days did not increase the fecal blood loss in 15 healthy human subjects above control levels. However, they did not challenge their subjects with oral aspirin.

The paper by Grossman *et al.* (3) has been cited frequently in support of the contention that aspirin-induced gastrointestinal blood loss in man is a systemic effect. These investigators reported a barely statistically significant increase in ADBL from intravenous aspirin administration, but it should be noted that most of the subjects had peptic ulcer; some had bled within 2 weeks of the study, and much more bleeding was observed when the same dose of aspirin was administered orally (2.1 ml. versus 0.8 ml./day in excess of control values). There has been a number of reports of gastric hemorrhage following parenteral administration of aspirin to rats (10, 11) and

cats (12), but the doses used were massive (300 to 1300 mg./kg.) and often lethal. It is unrealistic to extrapolate the results obtained under these extreme conditions to the therapeutic doses used in man. Brodie and Chase (13) recently reported a statistically significant increase in the incidence of gastric hemorrhage in rats given 64 mg. aspirin/kg., either orally or intraperitoneally. They noted, however, that hemorrhage was much less severe and the lesions were smaller when the drug was given intraperitoneally. Since the serosal side of the stomach is exposed directly to aspirin particles when the drug suspension is injected intraperitoneally, this effect could well have been a local one.

The prolongation of bleeding time during aspirin administration observed in this study is in agreement with the reports of other investigators (5). The prolonged bleeding time during intravenous aspirin administration was not a carryover from the oral aspirin period, since the bleeding times determined in several of the subjects just prior to the first intravenous dose of aspirin was similar to their control times. The rigid standardization of the stab wound (due to the use of an automatic lancet) and the large number of determinations accounted for the very small variability of the bleeding times.

The results of this study show that gastrointestinal blood loss in normal human subjects receiving therapeutic doses of aspirin is a local effect and that it is not related to the prolongation of bleeding time produced by aspirin. It is, therefore, reasonable that the gastrointestinal bleeding liability of aspirin preparations can be reduced or even eliminated (7, 14, 15) by appropriate pharmaceutical formulation designs. Such preparations would be particularly important for the treatment of rheumatoid arthritis, which usually requires relatively high doses of aspirin. Unfortunately, none of the presently available preparations is ideally suitable for this purpose, mainly because of the high sodium content or limited buffer capacity. The feasibility of developing more suitable preparations for this purpose is now being explored.

Effect of Micelle Formation on Optical Rotatory Dispersion of β -D-Octyl Glucoside

P. MUKERJEE, J. PERRIN, and E. WITZKE

Abstract □ The optical rotatory dispersion of a nonionic surfactant, β -D-octyl glucoside, has been investigated in aqueous solutions in the UV region. The rotatory dispersion curves at any concentration can be represented by a one-term Drude equation. The specific rotation at any wavelength shows an increase at the CMC, which can be determined reliably from this change in specific rotation. The rotatory dispersion curve for the surfactant in micellized form has been derived and compared with that of the nonmicellized surfactant below the CMC. The change is small and can be ascribed to a "medium" effect, arising from the difference in the local refractive index at the micelle surface, as compared to the bulk solvent. This interpretation is compatible with the currently accepted ideas on the fluid nature of the micelle core and suggests a lack of any conformational restraint at the micellar interface.

Keyphrases □ Optical rotatory dispersion, β -D-octyl glucoside—micelle formation effect □ β -D-Octyl glucoside—optical rotatory dispersion, micelle formation effect □ Micelle formation, effect—optical rotatory dispersion, β -D-octyl glucoside

Many chemical and biochemical reactions and interactions of interest occur at interfaces, e.g., monolayers, micelles, enzymes, or membranes. The local molecular environment at an interface and the presence of an asymmetry and other peculiarities in dielectric properties (1) are factors of considerable importance in understanding the properties of molecules at interfaces. It has been pointed out recently that for studying many such interactions, the interface between a micelle and the solution provides a convenient locus whose composition is capable of a considerable controlled variation (2, 3). The use of optically active surfactant monomers or solubilized molecules offers the possibility of using optical activity as a probe for studying properties of interfaces and of understanding the effect of the interface composition on the optical activity itself. The present paper reports what appears to be the first such study on a simple model surfactant system, β -D-octyl glucoside.

β -D-Octyl glucoside has a CMC in aqueous solution of 0.024–0.025 *M* at 25° (4, 5). The micelles probably contain about 30 monomers (6), the hydrocarbon chains forming a spheroidal core. The glucoside head groups presumably remain exposed to water both in the monomeric and micellar forms. This, by itself, would

suggest that there should be no change in their optical activity. In fact, however, the packing of the chains produces a high effective concentration of the head groups in the interfacial layer (2), which interact strongly enough with each other to counter the micelle-forming tendency of the aliphatic chain rather substantially. This is apparent from the following comparison.

Recently the CMC of a hypothetical octyl chain, unencumbered by any head group, was estimated to be about 3×10^{-3} *M* (3). The CMC of octyl glucoside is higher by a factor of about 8. The head group self-interaction thus makes the standard free energy of micelle formation for octyl glucoside more positive by $kT \ln 8$ or about $2kT$'s per monomer, where k is the Boltzmann constant and T the absolute temperature (3). The glucoside groups at the micelle surface are thus in a considerably different local environment when compared to the free monomers.

EXPERIMENTAL

Materials—The octanol used was a Baker analyzed reagent, which was purified further by vacuum distillation, the middle one-third portion being collected.

β -D-Octyl Glucoside—Glucose, on acetylation followed by bromination (7), yielded acetobromoglucose, m.p. 89°. The bromo compound was reacted with octanol in dry absolute ether in the presence of silver oxide to give β -tetraacetyl octyl glucoside, m.p. 63–64°. After deacetylation in sodium methylate solutions, β -D-octyl glucoside was obtained. It was recrystallized twice from ethyl acetate, washed with Skelly-A, and dried under vacuum. The compound melts over a wide range, 65–99° (8). The intermediate compounds were purified by recrystallization before proceeding to the next step of the preparation.

Anal.—Calcd. for C, 57.5; H, 9.7. Found: C, 57.8; H, 9.5.

Apparatus and Experimental Procedure—The optical rotatory dispersion (ORD) measurements were carried out in a Cary model 60 spectropolarimeter. The cell compartment was thermostated at $25 \pm 0.2^\circ$. Five-centimeter cells were used. All solutions were optically clear, and double-distilled water was used. The ORD measurements were made in the 250–370- $m\mu$ region.

RESULTS

Figure 1 shows the variation of the observed rotation at 320 $m\mu$ as a function of concentration. To magnify the small differences observed, a deviation plot is presented. The data show the usual curvature near the CMC. If the CMC region is excluded, the data

Effect of Micelle Formation on Optical Rotatory Dispersion of β -D-Octyl Glucoside

P. MUKERJEE, J. PERRIN, and E. WITZKE

Abstract □ The optical rotatory dispersion of a nonionic surfactant, β -D-octyl glucoside, has been investigated in aqueous solutions in the UV region. The rotatory dispersion curves at any concentration can be represented by a one-term Drude equation. The specific rotation at any wavelength shows an increase at the CMC, which can be determined reliably from this change in specific rotation. The rotatory dispersion curve for the surfactant in micellized form has been derived and compared with that of the nonmicellized surfactant below the CMC. The change is small and can be ascribed to a "medium" effect, arising from the difference in the local refractive index at the micelle surface, as compared to the bulk solvent. This interpretation is compatible with the currently accepted ideas on the fluid nature of the micelle core and suggests a lack of any conformational restraint at the micellar interface.

Keyphrases □ Optical rotatory dispersion, β -D-octyl glucoside—micelle formation effect □ β -D-Octyl glucoside—optical rotatory dispersion, micelle formation effect □ Micelle formation, effect—optical rotatory dispersion, β -D-octyl glucoside

Many chemical and biochemical reactions and interactions of interest occur at interfaces, e.g., monolayers, micelles, enzymes, or membranes. The local molecular environment at an interface and the presence of an asymmetry and other peculiarities in dielectric properties (1) are factors of considerable importance in understanding the properties of molecules at interfaces. It has been pointed out recently that for studying many such interactions, the interface between a micelle and the solution provides a convenient locus whose composition is capable of a considerable controlled variation (2, 3). The use of optically active surfactant monomers or solubilized molecules offers the possibility of using optical activity as a probe for studying properties of interfaces and of understanding the effect of the interface composition on the optical activity itself. The present paper reports what appears to be the first such study on a simple model surfactant system, β -D-octyl glucoside.

β -D-Octyl glucoside has a CMC in aqueous solution of 0.024–0.025 *M* at 25° (4, 5). The micelles probably contain about 30 monomers (6), the hydrocarbon chains forming a spheroidal core. The glucoside head groups presumably remain exposed to water both in the monomeric and micellar forms. This, by itself, would

suggest that there should be no change in their optical activity. In fact, however, the packing of the chains produces a high effective concentration of the head groups in the interfacial layer (2), which interact strongly enough with each other to counter the micelle-forming tendency of the aliphatic chain rather substantially. This is apparent from the following comparison.

Recently the CMC of a hypothetical octyl chain, unencumbered by any head group, was estimated to be about 3×10^{-3} *M* (3). The CMC of octyl glucoside is higher by a factor of about 8. The head group self-interaction thus makes the standard free energy of micelle formation for octyl glucoside more positive by $kT \ln 8$ or about $2kT$'s per monomer, where k is the Boltzmann constant and T the absolute temperature (3). The glucoside groups at the micelle surface are thus in a considerably different local environment when compared to the free monomers.

EXPERIMENTAL

Materials—The octanol used was a Baker analyzed reagent, which was purified further by vacuum distillation, the middle one-third portion being collected.

Apparatus and Experimental Procedure—The optical rotatory dispersion (ORD) measurements were carried out in a Cary model 60 spectropolarimeter. The cell compartment was thermostated at $25 \pm 0.2^\circ$. Five-centimeter cells were used. All solutions were optically clear, and double-distilled water was used. The ORD measurements were made in the 250–370- $m\mu$ region.

RESULTS

Figure 1 shows the variation of the observed rotation at 320 $m\mu$ as a function of concentration. To magnify the small differences observed, a deviation plot is presented. The data show the usual curvature near the CMC. If the CMC region is excluded, the data

Figure 1—Variation in optical rotation at 320 $m\mu$ with concentration of octyl glucoside at 25°. The ordinate records the difference between the observed rotation, ϕ , and that calculated as $0.587 C$, C being the concentration of octyl glucoside in grams per 100 ml.

can be represented by two straight lines, one below and one above the CMC, whose point of intersection corresponds to the CMC. The value observed, 0.70% or 0.024 mole/l., is in good agreement with the value of 0.024–0.025 M obtained from surface-tension measurements (4, 5). ORD measurements are thus capable of determining CMC's for some optically active surfactants. The technique should be of some value for naturally occurring optically active surfactants such as bile salts.

To determine the nature and extent of the change in the ORD curves, the rotation data were analyzed by using the simple Drude equation:

$$[\alpha]_{\lambda} = A/(\lambda^2 - \lambda_0^2) \quad (\text{Eq. 1})$$

in which $[\alpha]_{\lambda}$ is the specific rotation measured at the wavelength λ . A and λ_0 are constants (9). For exhibiting the changes observed on micelle formation on a magnified scale, Eq. 2, which is a rearranged form of Eq. 1, was used, as suggested by Heller (10):

$$\frac{1}{[\alpha]_{\lambda}\lambda^2} = \frac{1}{A} - \frac{\lambda_0^2}{A\lambda^2} \quad (\text{Eq. 2})$$

Figure 2—Plots of specific rotation-wavelength data for octyl glucoside at 25° according to Eq. 2. Key: \circ , below the CMC (monomeric); and \square , micellar (see text).

A plot of $1/[\alpha]_{\lambda}\lambda^2$ versus $1/\lambda^2$ should yield a straight line if Drude's equation is obeyed. From the intercept and the slope, A and λ_0 can be determined.

The upper curve in Fig. 2 shows the data below the CMC. Each point is a mean of three measurements at three different concentrations. This curve represents the monomer. To obtain the curve representing the optical rotatory power of octyl glucoside in the micellar form, the change in the observed rotation, $\Delta\phi$, at a particular wavelength was determined from the difference in ϕ between two concentrations, one considerably above and one slightly above the CMC. From this $\Delta\phi$ and the corresponding difference in concentration, ΔC , after a suitable correction for the pathlength of the cell, $[\alpha]_{\lambda}^m$, the specific rotation of the surfactant in the micellar form was obtained. The rationale behind this method of calculation is the well-founded assumption that above the CMC the monomer concentration changes very little with the total concentration. Here, also, the plotted points are the means of three sets of calculations of $[\alpha]_{\lambda}^m$, using three different combinations of concentrations. The average variation in the specific rotations estimated at different concentrations was 0.2–0.3%.

Figure 2 shows that the data are linear within experimental error; thus the simple Drude equation is obeyed. The values of A obtained from the least-squares fitted straight lines are 9.32×10^6 and 10.08×10^6 (degree $^{-1}$ cm. $^{-4}$ g.) for the monomeric and micellar forms, respectively, while the corresponding values of λ_0 are 1525 and 1531 Å. Thus, the change in the ORD on micelle formation arises mainly from a change of about 8% in A , the change in λ_0 being barely significant.

DISCUSSION

Although this analysis shows that the simple Drude equation is obeyed and that the primary change on micelle formation is in A rather than λ_0 , an unequivocal interpretation is difficult; the apparent simplicity of the Drude equation may be misleading.

For regions far from optically active absorption bands, the specific rotation can be written as (11)

$$[\alpha]_{\lambda} = \left(\frac{n^2 + 2}{3} \right) \left(\frac{9600\pi cN}{Mh\lambda^2} \right) \sum_i \frac{R_i}{\nu_i^2 - \nu^2} \quad (\text{Eq. 3})$$

where n is the refractive index of the medium, c is the velocity of light, N is Avogadro's number, M is the molecular weight of the substance, h is Planck's constant, ν is the frequency of incident light, ν_i is the frequency characterizing the electronic transition to an excited state, and R_i is the "rotatory strength" of the transition. Replacing the frequencies by the corresponding wavelengths, and condensing several quantities into the new variable A_i , yield

$$[\alpha]_{\lambda} = \left(\frac{n^2 + 2}{3} \right) \sum_i \frac{A_i \lambda_i^2}{\lambda^2 - \lambda_i^2} \quad (\text{Eq. 4})$$

Although Eq. 4 has the form of the Drude Eq. 1, it clearly shows that λ and A in Eq. 1, where A includes the refractive index factor, are complicated averages.

By considering the physical realities of the situation at a micellar interface, however, it is possible, qualitatively, to ascribe at least a part of the difference in A between free and micellized monomers to the Lorentz correction factor, $(n^2 + 2)/3$. At the micellar interface, the glucose moieties are present at a high concentration, roughly 3 molal or 35% by weight (3), and close to the hydrocarbon core of the micelle. The refractive index, at the sodium D line (5893 Å), of a 35% by weight solution of glucose is estimated to be 1.390 (12),¹ as compared to 1.3330, the value of water. This, by itself, can increase the Lorentz factor by 4%. The actual effect may be substantially higher because of two additional factors. The frequency dependence of the refractive index (dispersion) is expected to be substantially higher for glucose than for water and, therefore, the refractive increment for glucose solutions should be higher at the lower wavelengths at which the ORD measurements were made,

¹ Experimental values of the refractive index of D-glucose solutions at such high concentrations were not available. The refractive increments of D-glucose and sucrose up to 10% concentrations are very similar, however. Therefore, the authors used the value for a 35% solution of sucrose, 1.3902. D-Fructose has a very similar value, also.

2500–3700 Å. The proximity of the hydrocarbon core of the micelle may also be a contributory factor, because of the higher refractive index of octane ($n_D = 1.3975$) as compared to water. Thus, although no firm conclusion is possible, the change in optical rotation on micelle formation is not incompatible with a “medium” effect, operating through the Lorentz factor, and no conformational restraints at the micelle surface need be invoked. This tentative conclusion is in accord with the accepted fluid nature of the micelle core (3). It should clearly be of some interest to study monomers or solubilized species in micelles containing optically active absorption bands in experimentally accessible wavelength regions.

Finally, note the observed curvature near the CMC in Fig. 1. This is another piece of evidence against the phase-separation model for micellization, the arguments against which have been summarized recently (3).

2-Amino-2-oxazoline Formation by Cyclization of 1-(2-Hydroxyethyl)-2-methyl-2-thiopseudoureas

DANIEL L. KLAYMAN, ROBERT J. SHINE*, and ARLESS E. MURRAY, Jr.

Abstract □ 1-(2-Hydroxyethyl)-3-substituted-2-methyl-2-thiopseudourea hydriodides, when heated in polar solvents, were found in many instances to result in the formation of 2-amino-2-oxazoline derivatives with the simultaneous evolution of methyl mercaptan. The rate of the reaction is apparently influenced by the group substituted in the 3-position of the thiopseudourea. Similarly, the 5,6-dihydro-4*H*-1,3-oxazine ring system could be prepared by starting with a 1-(3-hydroxypropyl)-2-thiourea.

Keyphrases □ 2-Amino-2-oxazoline formation—using thiopseudoureas, cyclization □ Thiopseudoureas—in formation of 2-amino-2-oxazoline □ IR spectrophotometry—identity

An investigation of the influence of the degree of *N*-substitution of *S*-methylthiopseudoureas, which are subjected to alkaline hydrolysis, on the rate of methyl mercaptan evolution was reported earlier (1). In the course of that study the preparation of the *S*-methyl derivative of 1-(2-hydroxyethyl)-3-benzoyl-2-thiourea (If), a potential antiradiation agent, was attempted. It was found that methyl mercaptan was readily evolved when the *S*-methyl derivative (II*f*) was heated in polar organic solvents such as acetonitrile, alcohols, and acetone, even in the absence of base. Methyl mercaptan was formed as a consequence of the intramolecular displacement of the methylthio group by the hydroxyl group to give 2-benzamido-2-oxazoline hydriodide (III*f*) in 73% yield.

To examine further this interesting reaction, a number of other 1-(2-hydroxyalkyl)-2-thioureas were prepared and subsequently treated with methyl iodide (Scheme I).

Scheme I

Simply heating the 2-methyl-2-thiopseudourea hydriodides in polar solvents in several cases led to methyl mercaptan evolution. The rate of this evolution, which reflects the extent of the cyclization reaction, was found to be strongly influenced by the R group of the 1-(2-hydroxyalkyl)-2-thiourea (I). Oxazoline formation proceeds smoothly when there is a benzoyl group in the 3-position of a 1-(2-hydroxyalkyl)-2-thiourea. 1-(2-Hydroxypropyl)-3-benzoyl-2-thiourea (II), on heating with methyl iodide in ethanol, gave 2-benzamido-5-methyl-2-oxazoline hydriodide (III*l*). When 1-(3-hydroxypropyl)-3-benzoyl-2-thiourea was used (II*k*), the cyclization reaction gave the six-membered heterocycle—*viz.*, 2-benzamido-5,6-dihydro-4*H*-1,3-oxazine hydriodide (III*k*), in good yield.

The evolution of methyl mercaptan was slower when the *S*-methyl derivatives of 1-(2-hydroxyethyl)-3-phenyl-2-thiourea (II*d*) and 1-(2-hydroxypropyl)-3-phenyl-2-

2500–3700 Å. The proximity of the hydrocarbon core of the micelle may also be a contributory factor, because of the higher refractive index of octane ($n_D = 1.3975$) as compared to water. Thus, although no firm conclusion is possible, the change in optical rotation on micelle formation is not incompatible with a “medium” effect, operating through the Lorentz factor, and no conformational restraints at the micelle surface need be invoked. This tentative conclusion is in accord with the accepted fluid nature of the micelle core (3). It should clearly be of some interest to study monomers or solubilized species in micelles containing optically active absorption bands in experimentally accessible wavelength regions.

Finally, note the observed curvature near the CMC in Fig. 1. This is another piece of evidence against the phase-separation model for micellization, the arguments against which have been summarized recently (3).

2-Amino-2-oxazoline Formation by Cyclization of 1-(2-Hydroxyethyl)-2-methyl-2-thiopseudoureas

DANIEL L. KLAYMAN, ROBERT J. SHINE*, and ARLESS E. MURRAY, Jr.

Abstract □ 1-(2-Hydroxyethyl)-3-substituted-2-methyl-2-thiopseudourea hydriodides, when heated in polar solvents, were found in many instances to result in the formation of 2-amino-2-oxazoline derivatives with the simultaneous evolution of methyl mercaptan. The rate of the reaction is apparently influenced by the group substituted in the 3-position of the thiopseudourea. Similarly, the 5,6-dihydro-4*H*-1,3-oxazine ring system could be prepared by starting with a 1-(3-hydroxypropyl)-2-thiourea.

Keyphrases □ 2-Amino-2-oxazoline formation—using thiopseudoureas, cyclization □ Thiopseudoureas—in formation of 2-amino-2-oxazoline □ IR spectrophotometry—identity

An investigation of the influence of the degree of *N*-substitution of *S*-methylthiopseudoureas, which are subjected to alkaline hydrolysis, on the rate of methyl mercaptan evolution was reported earlier (1). In the course of that study the preparation of the *S*-methyl derivative of 1-(2-hydroxyethyl)-3-benzoyl-2-thiourea (If), a potential antiradiation agent, was attempted. It was found that methyl mercaptan was readily evolved when the *S*-methyl derivative (II*f*) was heated in polar organic solvents such as acetonitrile, alcohols, and acetone, even in the absence of base. Methyl mercaptan was formed as a consequence of the intramolecular displacement of the methylthio group by the hydroxyl group to give 2-benzamido-2-oxazoline hydriodide (III*f*) in 73% yield.

To examine further this interesting reaction, a number of other 1-(2-hydroxyalkyl)-2-thioureas were prepared and subsequently treated with methyl iodide (Scheme I).

Scheme I

Simply heating the 2-methyl-2-thiopseudourea hydriodides in polar solvents in several cases led to methyl mercaptan evolution. The rate of this evolution, which reflects the extent of the cyclization reaction, was found to be strongly influenced by the R group of the 1-(2-hydroxyalkyl)-2-thiourea (I). Oxazoline formation proceeds smoothly when there is a benzoyl group in the 3-position of a 1-(2-hydroxyalkyl)-2-thiourea. 1-(2-Hydroxypropyl)-3-benzoyl-2-thiourea (II), on heating with methyl iodide in ethanol, gave 2-benzamido-5-methyl-2-oxazoline hydriodide (III*l*). When 1-(3-hydroxypropyl)-3-benzoyl-2-thiourea was used (II*k*), the cyclization reaction gave the six-membered heterocycle—viz., 2-benzamido-5,6-dihydro-4*H*-1,3-oxazine hydriodide (III*k*), in good yield.

The evolution of methyl mercaptan was slower when the *S*-methyl derivatives of 1-(2-hydroxyethyl)-3-phenyl-2-thiourea (II*d*) and 1-(2-hydroxypropyl)-3-phenyl-2-

thiourea (Ij) were used than with the comparable benzoyl derivatives described previously. 2-Anilino-2-oxazoline (III*d*) and 2-anilino-5-methyl-2-oxazoline (III*j*) hydriodides were obtained in good yield after several hours of refluxing in ethanol. The *S*-methyl derivative of 1-(3-hydroxypropyl)-3-phenyl-2-thiourea (Ii), in contrast to its benzoyl analog, failed to cyclize to any appreciable extent, as was further indicated by only a meager evolution of methyl mercaptan.

S-Methyl derivatives of 1-(2-hydroxyethyl)-2-thioureas, which were substituted in the 3-position by methyl (Ib), *tert*-butyl (Ic), and phenethyl (Ie), on refluxing in acetonitrile or ethanol gave only trace quantities of methyl mercaptan, indicating failure of the

cyclization reaction to occur. The thiopseudoureas could be isolated from the reaction mixture. When the *S*-methyl derivatives of 1,1-di(2-hydroxyethyl)-3-phenyl-2-thiourea (Ih) and 1-(2-hydroxyethyl)-3-methyl-3-phenyl-2-thiourea (Ig) were refluxed in the usual polar solvents, considerably less than one equivalent of methyl mercaptan was evolved, resulting in their limited conversion to oxazolines. Compound IIIg could be isolated in poor yield, however, when the reaction was performed in water.

In an attempt to make the difficultly accessible 2-amino-2-oxazoline hydriodide (IIIa), the previously unknown 1-(2-hydroxyethyl)-2-thiourea (Ia) was prepared by the reaction of benzoylisothiocyanate with 2-aminoethanol. The resultant compound, If, was hydrolyzed with dilute sodium hydroxide, giving Ia in good yield. The *S*-methyl derivative of this thiourea failed to cyclize to any appreciable extent. A successful synthesis of 2-amino-2-oxazoline (isolated as the picrate salt) was achieved, however, by removing the benzoyl group of IIIf by hydrolysis with 1:1 hydrochloric acid for about 2 hr. Its homolog, 2-amino-5,6-dihydro-4*H*-1,3-oxazine picrate, was prepared similarly from its benzamido derivative (IIIk).

^a Derived from the thiourea indicated by the same letter in Table I. ^b Reaction was run in water to give a complex mixture of products which included the amino-oxazoline. ^c 2-Benzamido-5,6-dihydro-4*H*-1,3-oxazine hydriodide.

Adcock *et al.* (2) reported the use of 2.5 equivalents of sodium ethoxide in boiling ethanol to effect the cyclization of certain 1-(2-hydroxyethyl)-2-methyl-2-thiopseudoureas. However, it appears that base is not necessary if the R groups of II are sufficiently activating. The resultant increase in the net positive charge on the carbon atom bearing the methylthio group facilitates the attack by the hydroxyl oxygen atom.

While this investigation was in progress, Budde and Salerni (3) in a related reaction reported the cyclization of the S-ethyl derivative of 1-(2-hydroxyethyl)-1-(2-

acetamidoethyl)-3-phenyl-2-thiourea to give a 2,3-disubstituted oxazoline.

EXPERIMENTAL¹

Melting points were determined on a Fisher-Johns melting point apparatus and are uncorrected. IR spectra were determined on a

¹ Microanalyses were performed by Mr. Joseph F. Alicino, Metuchen, NJ 08840

Beckman IR-5 or Perkin-Elmer 221 spectrophotometer as KBr pellets.

Hydroxyalkyl-2-thioureas—To 0.2 mole of an alkyl or arylisothiocyanate in 100 ml. of ethanol was added portionwise 0.2 mole of an amino-alcohol, and the resultant solution was heated for 0.5 hr. on a steam bath. In some cases, the hydroxyalkyl-2-thioureas crystallized from the cooled solution; in other instances, the solutions were concentrated or evaporated to dryness to induce crystallization.

1-(Hydroxyalkyl)-3-benzoyl-2-thioureas—These compounds were prepared essentially by the method of Douglass and Dains (4). To 44.6 g. (0.55 mole) of sodium thiocyanate dissolved in 500 ml. of acetonitrile or acetone was added slowly 70.3 g. (0.50 mole) of benzoyl chloride, and the resulting mixture was heated on a steam bath for 10 min. The mixture was then cooled, and the amino-alcohol (0.50 mole) was added with constant stirring. The resultant mixture was heated on a steam bath for 15 min. and poured into a large volume of water. The oily layer generally crystallized on cooling to give the 1-(hydroxyalkyl)-3-benzoyl-2-thiourea (Table I).

1-(2-Hydroxyethyl)-2-thiourea (Ia)—To 22.4 g. (0.1 mole) of 1-(2-hydroxyethyl)-3-benzoyl-2-thiourea was added 100 ml. of 6% NaOH solution, and the resulting solution was heated on a steam bath for 10 min. The cooled solution was then made slightly acidic with 6 N H₂SO₄; the benzoic acid, which separated, was removed by filtration. The filtrate was adjusted to neutrality with dilute NaOH solution. The solvent was removed under reduced pressure, giving a residue which was extracted with three 100-ml. portions of hot CH₃CN. The CH₃CN extracts were evaporated to dryness, and the Ia was recrystallized (Table I).

Reaction of Hydroxyalkyl-2-thioureas with Methyl Iodide—To 1-(hydroxyalkyl)-2-thiourea (0.05 mole) dissolved in 40 ml. of acetonitrile or ethanol was added methyl iodide (0.06 mole), and the solution was heated under reflux. When methyl mercaptan evolution was very faint or not detected within 0.5 hr., the solution was refluxed for 2 hr. and cooled or concentrated under reduced pressure to give the S-methylthiopseudourea hydriodide. The latter gave a positive nitroprusside test (1) when heated with base (Table II).

When a copious evolution of methyl mercaptan was detected within the first 0.5 hr. of refluxing, heating was continued until methyl mercaptan evolution virtually ceased, generally within 6–12

hr. The solution was cooled or concentrated, causing separation of the 2-amino-2-oxazoline derivative (or 2-amino-5,6-dihydro-4H-1,3-oxazine derivative) as the hydriodide salt. The IR spectra of these compounds showed a characteristic peak at 5.9–6.1 μ (C=N) (Table III).

2-Amino-2-oxazoline (IIIa)—A mixture of 1.0 g. (0.0031 mole) IIIf in 10 ml. of 1:1 HCl was agitated and heated under reflux for about 2 hr. until solution was complete. The benzoic acid, which separated on cooling, was removed and the filtrate was concentrated several times with water to remove the excess acid. The syrup was treated with a saturated ethanolic solution of picric acid to give 0.45 g. (46%) of 2-amino-2-oxazoline picrate as fine needles (from water), m.p. 192–195° [lit. (5) m.p. 186–188°].

2-Amino-5,6-dihydro-4H-1,3-oxazine—2-Benzamido-5,6-dihydro-4H-1,3-oxazine hydriodide (IIIk, 1.0 g., 0.0030 mole) was treated as described previously to give 0.37 g. (37%) of 2-amino-5,6-dihydro-4H-1,3-oxazine picrate as fine needles (from water), m.p. 207–208° [lit. (6) m.p. 200°].

Comparison of Effects of 1,8-Dihydroxyanthraquinone and 1,5-Dihydroxyanthraquinone on Different Segments of Rabbit Gastrointestinal Tract

THEODORE H. EICKHOLT, LAWRENCE J. DANNA*, LYNN J. VERZWYVELT*, GERALD P. WAGUESPACK*, JOHNNY L. BUNCH*, and DANIEL D. WINSLOW*

Abstract □ Using an isolated muscle bath technique, five different segments of the rabbit gastrointestinal tract (duodenum, jejunum, ileum, and ascending and descending colon) were used to record the effects of two doses of 1,5-dihydroxyanthraquinone. Transducer-recorded tracings were made of contractions per minute, interval between contractions, and amplitude of contractions. The results were evaluated; statistical tests among comparisons of the three parameters between the two drug doses, control values, and previous

values for 1,8-dihydroxyanthraquinone again indicated the parameter of interval between contractions to be a statistically significant measurement of activity. No statistically significant differences in effects were shown between the two drugs.

Keyphrases □ 1,8- versus 1,5-Dihydroxyanthraquinone—effect on gastrointestinal tract, rabbit □ Gastrointestinal tract, rabbit—effects, 1,8- versus 1,5-dihydroxyanthraquinone

^a Significantly different from normal averages at $p = 0.05$.

recorded tracings indicated that the parameter of interval between contractions was a statistically significant measurement of activity.

Therefore, the purposes of this study were to observe the effects of 1,5-dihydroxyanthraquinone on the different segments of the rabbit gastrointestinal tract and to compare these statistically with the previous normal and 1,8-dihydroxyanthraquinone figures to determine the value of the parameter of interval between contractions as a significant measurement of activity for drug-effect studies.

EXPERIMENTAL

Adult albino rabbits were anesthetized with ether, and 2–3-cm. segments of duodenum, jejunum, ileum, and ascending and descending colon were expediently removed and maintained in oxygenated Tyrode's solution in the same manner as in the previously delineated standards and 1,8-dihydroxyanthraquinone studies (1, 2).

As in the previous studies, the Tyrode's solution in glass distilled water again contained sodium chloride, 0.8%; potassium chloride, 0.02%; calcium chloride, 0.02%; magnesium chloride, 0.01%; sodium bicarbonate, 0.1%; sodium diphosphate, 0.005%; and glucose, 0.1%; 15 ml. was used to bathe the intestinal segment in the isolated muscle bath chamber (1, 2).

Similar to the standard and 1,8-dihydroxyanthraquinone studies, the temperature was maintained at 38°, and the preparation was oxygenated using an air flow slowly (2–3 bubbles/sec.) bubbled through the solution (1, 2). The segment was attached to the muscle hooks, and the intestinal activity was again recorded *via* transducer (E & M isotonic myograph) and physiograph recorder (E & M) (1, 2).

The segments were allowed to acclimate to the muscle bath environment, following which normal intestinal activity for the different segments was recorded. Six different rabbits were used to provide six different samples of duodenum, jejunum, ileum, and ascending and descending colon for each of the two doses of the 1,5-dihydroxyanthraquinone in the same manner as in the 1,8-dihydroxyanthraquinone studies (2).

The anthraquinone was 1,5-dihydroxyanthraquinone.¹ The drug was placed in Tyrode's solution so as to provide 0.1 and 0.2% concentrations, providing 15 and 30 mg./15 ml. isolated muscle bath chamber, respectively, for the low and high doses.

The effects of each dosage were recorded for a minimum of 15 min. for each of the six different samples of the five different seg-

ments and were completely repeated at the second dosage for six different samples of the five different segments, identical to the design of the 1,8-dihydroxyanthraquinone studies (2).

From each recording of each individual gut segment, amplitude of contraction, interval between contractions, and contractions per minute were measured and averaged as in the two previous studies (1, 2).

Standard deviations were calculated; analyses of variance with *F* test and Scheffe's *S* method tests were made between combinations of treated and control intestinal segments (3).

RESULTS

Table I summarizes the averages and standard deviations of the amplitude of contraction, interval between contractions, and contractions per minute obtained with the low dose (15 mg.) of 1,5-dihydroxyanthraquinone.

Table II summarizes the averages and standard deviations of the amplitude of contraction, interval between contractions, and contractions per minute obtained with the high dose (30 mg.) of 1,5-dihydroxyanthraquinone.

Table III summarizes the similar parameters obtained with the low dose (15 mg.) of 1,8-dihydroxyanthraquinone, and Table IV summarizes those obtained with the high dose (30 mg.) of 1,8-dihydroxyanthraquinone.

Table V summarizes the averages and standard deviations of the amplitude of contraction, interval between contractions, and contractions per minute obtained with the normal untreated intestinal segments.

Of the 150 possible comparisons of the three parameters between drug-treated and normal averages, 31 were significantly different statistically at $p = 0.05$, including the 15 from the 1,8-dihydroxyanthraquinone (2).

All 10 comparisons of the interval between contractions for both the 15 and 30 mg. 1,5-dihydroxyanthraquinone and normal averages were significantly different statistically at $p = 0.05$. There were no significant differences between any of the comparisons between the 15- and 30-mg. doses of 1,5-dihydroxyanthraquinone; there was one significant with the 1,8-dihydroxyanthraquinone, the ileum comparisons of amplitude of contractions (2).

The remaining six significant comparisons were jejunum *versus* jejunum amplitude of contractions between 30-mg. dose and normal averages (this is compared to the 15-mg. dose of the 1,8-dihydroxyanthraquinone which was significant); ileum *versus* ileum amplitude of contractions between both treatments and normal averages; ascending colon *versus* ascending colon contractions per minute between both treatments and normal averages; and the descending colon *versus* descending colon contractions per minute between 30-mg. dose and normal averages.

SUMMARY AND CONCLUSIONS

Five different segments of the rabbit intestinal tract—duodenum, jejunum, ileum, and ascending and descending colon—were utilized in recording the activity of these segments in response to 15- and 30-mg. doses of 1,5-dihydroxyanthraquinone, using an *in vitro* isolated muscle bath technique.

Contractions per minute, interval between contractions, and amplitude of contraction were recorded, determined, and averaged; standard deviations were calculated; and analyses of variance with *F* test and Scheffe's *S* method tests were performed on segment combinations between the 1,5-dihydroxyanthraquinone-treated and normal segments and the 1,8-dihydroxyanthraquinone-treated segments.

Of the 150 comparisons of the three parameters between drug-treated and normal averages, 31 were significantly different statistically at $p = 0.05$ and included all comparisons of interval between contractions for both drug treatments and normal averages.

Comparing the actual figures (averages) of the three parameters for the five segments of the high dose of the 1,5-dihydroxyanthraquinone and the normal averages, 5/5 values for interval between contractions for the high dose were less than the normal figures and all showed statistically significant differences.

Comparing the actual values of the three parameters for the five segments of the low dose of the 1,5-dihydroxyanthraquinone and the normal averages, 5/5 values for interval between contractions for the low dose were less than the normal figures and all again showed statistically significant differences.

Comparisons of effects between the high and low doses of 1,5-dihydroxyanthraquinone on the three parameters showed no

statistically significant differences. Comparisons of the activity between the high doses of both drugs on the three parameters and comparisons between the low doses of the two drugs showed no statistically significant differences.

The statistical tests between figures of both drugs *versus* normal show considerable agreement in the numbers of statistically significant differences and agree much of the time with specific segments.

The results from this *in vitro* study and their statistical comparisons show again the parameter of interval between contractions to be a statistically significant measurement of activity.

New Compounds: Some 3,4,5-Trimethoxyphenyl Analogs of Analgesics

VASANT G. TELANG* and CHARLES I. SMITH†

Abstract □ Starting from 3,4,5-trimethoxybenzoic acid, the syntheses of the 3,4,5-trimethoxyphenyl analogs of meperidine hydrochloride and ketobemidone hydrochloride are described.

Keyphrases □ Meperidine HCl, 3,4,5-trimethoxyphenyl analogs—synthesis □ Ketobemidone HCl, 3,4,5-trimethoxyphenyl analogs—synthesis □ NMR spectrometry—structure □ IR spectrophotometry—structure

A number of naturally occurring compounds having action on the CNS possess a 3,4,5-trimethoxyphenyl group. For the past 15 years, a considerable amount of work on 3,4,5-trimethoxyphenyl compounds of possible psychotropic activity has been done (1). Many of these compounds have little chemical relationship except the possession of 3,4,5-trimethoxyphenyl groups. One laboratory reported previously on the synthesis of some 3,4,5-trimethoxyphenyl analogs of antihistamines (2) and anticonvulsants (3). Since analgesics are known to have a distinct effect upon the CNS, the drugs selected for the present studies were the important synthetic substitutes for the narcotic analgesic morphine. They are meperidine hydrochloride¹ and ketobemidone hydrochloride.²

The synthetic routes are shown in Scheme I. The 3,4,5-trimethoxybenzoic acid (I) was reduced to the corresponding alcohol according to the procedure reported by DiFazio (4). This alcohol was converted to 3,4,5-trimethoxybenzyl chloride (II) following the procedure of Drake and Tuemmler (5). It remained stable without any change in color in an evacuated desiccator over sodium hydroxide pellets for more than 6 months at room temperature, in contrast to a previous report by Tsao (6) that this product slowly darkens even when stored in the refrigerator. Acetone has been reported (4, 7) to be the best of several solvents tried for the conversion of II to 3,4,5-trimethoxyphenylacetone nitrile (III). By reaction in dimethyl sulfoxide (DMSO) at 55–60°, the desired nitrile was obtained in approximately the same yield but the reaction time was decreased from 10 days (acetone) to 3 hr. Alkylation of III followed by treatment of the resulting product with hydrogen chloride gave α,α -bis(2-dimethylaminoethyl)-(3,4,5-trimethoxyphenyl)acetone nitrile dihydrochloride (IV). Pyrolysis of IV at its melting point to cause evolution of trimethylamine and give the cyclized product V failed. Only a black residue which did not melt when tested up to 350° was obtained. Therefore, III was alkylated with 2,2'-dichloro-*N*-methyldiethylamine to obtain the

cyclized product V. Sodium amide or *n*-butyllithium worked equally well as the base for this condensation reaction.

Hydrolysis of V according to the method reported by Eisleb (8) failed. Several attempts, using either acid or alkali at elevated temperatures under pressure, did not yield the desired product. Finally, refluxing V with an excess of 2.2 *M* ethanolic sulfuric acid for 4 days and then hydrolyzing the imino ester gave the desired ethyl ester VIII. It is known that the carboxyl group on a quaternary carbon atom reacts sluggishly, probably because the alkyl groups dominate so much space in the neighborhood of the carboxyl group that they tend to block the intermediate ionic addition complex (9). Similar steric hindrance of the 4-cyano group in V is the probable reason for the failure in facile hydrolysis of the nitrile. Compound VIII was also prepared by condensation of 2,2'-dichloro-*N*-methyldiethylamine with ethyl 3,4,5-trimethoxyphenylacetate (VII) in the presence of sodium ethoxide.

Compound V reacted with ethylmagnesium bromide only at low temperatures. Addition of ethylmagnesium bromide at 0° and then stirring the reaction mixture at 20° for 24 hr. gave the intermediate ketimine, which finally was hydrolyzed to the corresponding ketone by warming with dilute acid. Similar trials at higher temperatures did not yield any product. It appears, therefore, that the intermediate magnesium adduct of the ketimine is unstable above 20°. A similar observation was reported recently by Muren (10).

EXPERIMENTAL

All melting points were determined with a Thomas-Hoover melting-point apparatus and are uncorrected. IR spectra were recorded with Beckman model 8 or Perkin-Elmer 237B grating IR spectrophotometers. NMR spectra were determined with Varian Associates A-60 and A-60D instruments, using tetramethylsilane or 3-(trimethylsilyl)propanesulfonic acid sodium salt as the internal standard. Unless otherwise specified, all NMR spectra were obtained with approximately 15% concentrations; s refers to singlet, d to doublet, t to triplet, q to quadruplet, and m to multiplet. Microanalyses were performed by Micro-Analysis, Inc., Wilmington, Del., and M-H-W Laboratories, Garden City, Mich.

3,4,5-Trimethoxyphenylacetone nitrile (III)—3,4,5-Trimethoxybenzyl chloride (II) was prepared according to the method reported by Drake and Tuemmler (5). A mixture of 2.18 g. (0.0101 mole) of II, 0.49 g. (0.010 mole) of sodium cyanide, and 190 ml. of DMSO was heated with magnetic stirring for 3 hr. at 55–60°. Subsequently, the mixture was cooled, diluted with four times its volume of water, and then extracted with three 100-ml. portions of ether. The combined pale-yellow ethereal extracts were washed with 6 *N* hydrochloric acid and with water, and then they were dried over anhydrous magnesium sulfate. Removal of the ether under vacuum yielded a pale-yellow oil, which crystallized upon cooling to provide 1.2 g. (58%) of yellow needles, m.p. 75–76°.

α,α - Bis(2 - dimethylaminoethyl) - (3,4,5 - trimethoxyphenyl)acetone nitrile dihydrochloride (IV)—Sodium amide was freshly prepared, starting with 7.5 g. (0.33 g. atom) of sodium and about 400

¹ Marketed as Demerol hydrochloride by Winthrop Laboratories, N. Y.; 4-carbethoxy-1-methyl-4-phenylpiperidine hydrochloride.

² Named Cliradon hydrochloride and used experimentally as an analgesic; ethyl 4-(*m*-hydroxyphenyl)-1-methyl-4-piperidyl ketone hydrochloride.

Scheme 1

ml. of anhydrous liquid ammonia, according to the procedure of Hancock and Cope (11). The ammonia was allowed to evaporate as the reaction flask achieved room temperature. Then 150 ml. of dry benzene and 15 g. (0.072 mole) of III were added. The mixture was stirred with heating for 1 hr. and then was cooled. Next, 21 g. (0.14 mole) of 2-chloro-*N,N*-dimethylethylamine hydrochloride was added with stirring, and the reaction mixture was stirred and heated at reflux for 24 hr. It was cooled, 100 ml. of water was added, and the two layers were separated. The aqueous layer was extracted with benzene. The combined benzene extracts were dried, and the solvent was removed under vacuum to yield a red residue, which was dissolved in anhydrous ether. Dry HCl gas was bubbled into the ethereal solution, whereupon a copious pale-yellow solid precipitated; yield 18.4 g. (60.6%). Decolorization with activated carbon³ and four recrystallizations from hot absolute ethanol gave a white solid, the dihydrochloride, m.p. 270°.

Anal.—Calcd. for $C_{19}H_{31}N_2O_3 \cdot 2HCl$: C, 54.03; H, 7.87; Cl, 16.79; N, 9.95; O, 11.36. Found: C, 54.27; H, 7.79; Cl, 16.47; N, 9.83; O, 11.51.

4-Cyano-4-(3,4,5-trimethoxyphenyl)-1-methylpiperidine (V)—A mixture of 2.07 g. (0.0100 mole) of III, 1.07 g. (0.0274 mole) of sodium amide,⁴ and 1.92 g. (0.0100 mole) of 2,2'-dichloro-*N*-

methyldiethylamine hydrochloride (12) in 50 ml. of toluene was refluxed for 12 hr. with stirring. It was cooled and decomposed with water. The organic layer was separated and extracted with three 20-ml. portions of 10% hydrochloric acid. The acidic extracts were combined, made alkaline with 40% aqueous sodium hydroxide solution, and then extracted with ether. After the ethereal layer was dried over magnesium sulfate, the ether was removed under vacuum to obtain 1.5 g. (52%) of V as an oily residue. This was redissolved in ether, and dry hydrogen bromide gas was bubbled in to precipitate a dark solid. This solid was separated and recrystallized four times from hot absolute ethanol with decolorization (Norite) to yield a white granular powder, the hydrobromide of V, m.p. 244.5°. The IR spectrum showed a broad ammonium band (2700–2250 cm^{-1}) and a nitrile peak (2242 cm^{-1}). The NMR spectrum (D_2O) showed peaks of δ values: 2.45 (t, 4 β H, piperidine ring); 3.18 (s, 3H, N—CH₃); 3.60 (t, 4 α H, piperidine ring); 4.0 (d, 9H, methoxys); and 7.05 (s, 2H, aromatic).

Anal.—Calcd. for $C_{16}H_{22}N_2O_3 \cdot HBr$: C, 51.76; H, 6.24; Br, 21.52; N, 7.55; O, 12.93. Found: C, 52.42; H, 6.43; Br, 21.36; N, 7.48; O, 12.85.

4-Carboethoxy-4-(3,4,5-trimethoxyphenyl)-1-methylpiperidine (VIII)—*Method A*—To an ice-cold solution of 2.9 g. (0.010 mole) of V in 210 ml. of absolute ethanol, previously dried according to the procedure of Vogel (13), was added dropwise 30 ml. of concentrated sulfuric acid. This reaction mixture was stirred mag-

³ Norite, American Norite Co., Jacksonville, Fla.

⁴ Gray powder, Fisher Scientific Co., Fairland, N. J.

netically and heated at reflux for 4 days. After being cooled, it was poured upon 300 g. of ice and the resulting aqueous solution was boiled for 5 hr. and cooled. The solution was made alkaline with 40% aqueous sodium hydroxide solution, and the resulting turbid solution was extracted with ether. The ethereal extract was dried over magnesium sulfate and the ether was removed under vacuum to obtain 1.7 g. (50%) of an oily residue (VIII). The IR spectrum (film) of this oil showed a strong peak for ester carbonyl (1718 cm^{-1}), ester C—O—C stretch (1316 and 1066 cm^{-1}), and complete absence of any nitrile peak. The NMR spectrum (CCl_4) showed peaks of δ values: 1.18 (t, 3H, C—CH₃); 2.34 (m, 11H, 8 piperidine ring and 3 N—CH₃); 3.75 (d, 9H, methoxys); 4.12 (q, 2H, CH₂ of ethyl); and 6.64 (s, 2H, aromatic). This oily free base (VIII) was dissolved in dry ether, and dry HCl gas was bubbled in to produce a white granular precipitate. This hydrochloride was separated, decolorized (Norite), and recrystallized twice from absolute ethanol and ether, m.p. 198–199°.

Anal.—Calcd. for $\text{C}_{18}\text{H}_{27}\text{NO}_5 \cdot \text{HCl}$: C, 57.82; H, 7.55; Cl, 9.48; N, 3.75; O, 21.40. Found: C, 57.83; H, 7.47; Cl, 9.58; N, 3.91; O, 21.28

Method B—Sodium ethoxide was prepared by reacting 1.5 g. (0.065 g. atom) of sodium with 100 ml. of absolute ethanol. Most of the alcohol was distilled and 100 ml. of dry toluene was added, of which 50 ml. was distilled to ensure complete removal of ethanol. Then 7.6 g. (0.030 mole) of ethyl 3,4,5-trimethoxyphenylacetate (VII) was added, and the reaction mixture was warmed for 1 hr. and cooled. Next 4.7 g. (0.030 mole) of 2,2'-dichloro-*N*-methyl-diethylamine was added, and the mixture was stirred and heated for 24 hr. under an atmosphere of dry nitrogen. The contents were cooled and diluted with water. The organic layer was separated and extracted with dilute hydrochloric acid. The acidic aqueous layer was made alkaline with 40% sodium hydroxide solution and extracted with ether. The ethereal extract was dried over sodium sulfate, and the ether was evaporated to obtain 3.5 g. (35%) of oily residue (VIII). The IR spectrum of this oil was identical with that of the oily free base obtained by Method A.

Ethyl 4-(3,4,5-Trimethoxyphenyl)-1-methyl-4-piperidyl Ketone (IX)—A solution of 0.58 g. (0.0020 mole) of V in 20 ml. of dry benzene was added to a solution of ethylmagnesium bromide prepared by reacting 0.44 g. (0.0040 mole) of ethyl bromide with 0.096 g. (0.0040 g. atom) of magnesium in 10 ml. of dry ether under an atmosphere of dry nitrogen. During the addition, the reaction was maintained at 0° and, after the addition, was stirred for 24 hr. at 20°. The reaction mixture was decomposed with 10 ml. of 3 *N* hydrochloric acid and heated for 1 hr. on a steam bath while the organic layer was allowed to evaporate. The mixture was cooled and made alkaline with 3 *N* sodium hydroxide solution. The resulting turbid solution was extracted with chloroform. The combined extracts were dried and the chloroform was evaporated. The residual oil, on TLC examination (basic alumina; ethyl acetate–benzene, 7:3, as the developing solvent), showed two distinct spots. The spot with the lower R_f value proved to be the desired ketone

(IX), which was isolated by chromatography using ethyl acetate–benzene (7:3) on a basic alumina⁵ column. The eluting solvents were evaporated under reduced pressure; the residual oil, 0.27 g. (42%), was dissolved in minimal ether and treated with ethereal HCl. The precipitate obtained was decolorized (Norite) once and recrystallized twice from chloroform–hexane so as to yield a white fluffy powder, m.p. 226–228° (dec.). The IR spectrum of this hydrochloride showed a broad ammonium band, complete absence of a nitrile band, and the presence of a carbonyl band (1699 cm^{-1}). The NMR spectrum of the hydrochloride salt (CDCl_3) showed peaks of δ values: 0.93 (t, 3H, CH₃); 2.55 (m, 13H, 8 piperidine ring, 3 N—CH₃ and 2 CH₂ of ethyl); 3.86 (d, 9H, methoxys); and 6.44 (s, 2H, aromatic).

Anal.—Calcd. for $\text{C}_{18}\text{H}_{27}\text{NO}_4 \cdot \text{HCl}$: C, 60.41; H, 7.89; N, 3.91. Found: C, 60.56; H, 7.88; N, 4.01.

Lidocaine: Evidence for the *trans*-Configuration

Keyphrases □ Lidocaine—*trans*-configuration □ NMR spectroscopy—structure □ IR spectrophotometry—structure

Sir:

A recent communication (1) gave IR data which purported to show that lidocaine was an unusual example of an acyclic secondary amide possessing the *cis*-configuration. The bases for this spatial assignment were: (a) the amide II band situated at a lower frequency (1494 cm^{-1}) than that usually associated with *trans*-amides ($>1500 \text{ cm}^{-1}$), and (b) an invariance with dilution of the single N—H stretching band at 3312 cm^{-1} , presumably arising from *cis*-dimeric association.

Entirely different conclusions were reached in recently published studies regarding spatial properties of some closely related acetanilides (2) and α -haloacetanilides (3, 4), including the immediate precursor of lidocaine (5), 2-chloro-2',6'-acetoxylicide (I).

The strong dependence of both the NMR spectra and chemical reactivity of the α -halogen on the spatial configuration of these anilides was amply demonstrated. It was shown that *ortho*-substituted tertiary α -haloacetanilides could exist in two rotameric forms, the predominant isomer, A, being spatially constituted with the α -methylene group *cis* and orthogonal to the anilide ring. In this configuration, the α -halogen was quite unreactive and its chemical properties contrasted sharply with the other rotomer, B, possessing the α -methylene group in a much less constricted environment, *i.e.*, *trans* and away from the anilide ring.

Moreover, secondary (*N*-hydrogen) α -haloacetanilides were shown to be entirely constituted with the α -methylene *trans* and away from the anilide ring; their NMR spectral properties and chemical reactivity thus closely resembled the B rotomers of the tertiary anilides. This was consistent with the usual *trans*-

assignment (amidic proton *trans* to carbonyl oxygen) for most secondary amides, although contrasting slightly with findings for similar, hindered, secondary α -unsubstituted acetanilides (2), where, for instance, 2',6'-acetoxylicide (II) is only 74% rather than all *trans* (B configuration).

Relevant to this communication was the finding, substantiated in other systems (2, 6, 7), that the *cis*- or *trans*-spatial configuration strongly and consistently influenced the NMR resonance of selected groupings in the amide. Thus, the α -methyl or α -methylene and nucleophilic groups attached thereto, which were constituted *trans* and away from the aromatic ring, were deshielded and absorbed at a lower field than rotomers that possessed the α -methylene *cis* and orthogonal to the ring. Likewise, in tertiary amides the N—CH₃ *cis* to the carbonyl oxygen was upfield from the *trans*-N—CH₃ group.

Moreover, the ability to separate tertiary α -haloacetanilide rotomers A and B into pure form given sufficient *ortho*-bulk (*i.e.*, *ortho-tert*-butyl) provides a convenient means, by simple nucleophilic displacement, for preparing new compounds of known spatial configurations. Under controlled conditions, reactive rotomer B can alkylate a nucleophile many times faster than its equilibration to A. Thus, a new compound with configuration B may be prepared, and its equilibration to an equilibrium mixture of A and B may be observed and measured.

Therefore, confirmation of the *cis*- or *trans*-configuration of lidocaine can be ascertained from a comparison of its spectra with selected materials, including rotomers of known configurations. Accordingly, Table I compiles pertinent NMR and IR absorptions for lidocaine; I; II; the tertiary anilide homolog of lidocaine, *N*-methyl-2-diethylamino-2',6'-acetoxylicide (III); 2-chloro-2'-*tert*-butyl-6'-ethylacetanilide (IV); 2-diethylamino-2'-*tert*-butyl-6'-ethylacetanilide (V); and the A and B forms of its *N*-methyl homolog, 2-diethylamino-*N*-methyl-2'-*tert*-butyl-6'-ethylacetanilide (VI).

Examination of the tertiary anilides, III and VI, shows that the B isomer is present at equilibrium, as in the α -halo series, only in minor amounts; hence, substitution of halogen by diethylamino does not produce any unusual change in rotomer distribution. It could be reasonably questioned then why such an unusual departure from normal *trans*, as recently claimed (1), would take place with secondary α -amino-acetanilides, such as lidocaine.

The *trans*-tertiary amides (carbonyl oxygen *cis* to anilide ring), VIB and IIIB, as predicted, have resonance absorptions for N—CH₃ downfield from those for VIA and IIIA. Moreover, the α -methylene and N—(CH₂CH₃)₂ groups also are downfield from these more highly shielded groups in VIA and IIIA. The resonance absorptions for these latter two moieties in lidocaine, positioned between IIIA, VIA and IIB, VIB, are of little use for structural determinations. Compelling, however, is the consistent position of the N—(CH₂CH₃)₂ triplet. Materials possessing the α -methylene and, hence, diethylamino *cis* and over the anilide ring have this moiety well within the aromatic shielding zone (6) and therefore at a higher field (δ 0.8 p.p.m.) than the δ 1.1 observed for materials constituted with the α -methylene *trans* to the anilide ring.

In contrast, the position of the amide II band does not appear to be a reliable criterion for spatial assignments, a conclusion previously reached (8). As was found for similar compounds (9, 10), *trans*- α -chloroacetanilides I and IV absorb very close to 1500 cm.⁻¹, at considerably lower frequencies than the amide II band normally found in *trans*- α -unsubstituted acetamides. (Note that II, predominately *trans*, has a prominent amide II band at about 1540 cm.⁻¹.)

Assignment of the *trans*-configuration to lidocaine can be reconciled with the observed single, solvent invariant N—H stretch and lower than usual amide II band by reference to the internally bonded structure shown for *trans*-lidocaine. Ample precedent for this type of hydrogen bonding has been noted in *trans*- α -halo- and α -alkoxy acetamides (9, 10). Such internal bonding could produce a single solvent invariant ν N—H; the ν N—H found for lidocaine at even 100 cm.⁻¹ lower frequency than the same function in α -halo-substituted amides is a tribute to the strong amido-amino (N—H...N) association in this amide (11).

As suggested for similar association in α -haloacetanilides (9), such bonding could force an equilibrium shift to a wholly *trans*-configuration (as contrasted with some minor *cis* in materials such as II). Finally, the amide II band near 1500 cm.⁻¹ found for lidocaine (and related *trans*-materials, I, IV, V) could arise from a lesser amount of intermolecular association. As shown earlier (10), α -substitution and steric hindrance to intermolecular association cause a frequency drop in this band. Protonation of the amino group would lessen the internal bonding, and the spectral characteristics presumably found for lidocaine hydrochloride (1) could revert more closely to those of "normal" *trans*-amides.

The assignment of the *trans*-associated structure for lidocaine is further strengthened by its behavior to vapor phase osmometric measurements in benzene. In this nonbonding solvent, as well as carbon tetra-

trans-lidocaine

chloride, lidocaine over a 0.1–0.005 *M* concentration range shows no evidence of intermolecular association and is strictly monomeric. In contrast, certain authentic *cis* and dimerically bonded amides such as 2-pyridone have been shown to give a corresponding multiple of its molecular weight under these conditions (12).

Extrinsic Optical Activity from a Micellar Solution

Keyphrases ☐ Micellar solutions—extrinsic optical activity ☐ Sulfathiazole—betaine-induced optical activity ☐ Polarimetry—analysis

Sir:

Extrinsic optical activities have been observed following the interaction of macromolecules with suitable small molecules (1–3) and following the interaction of optically active solvents with solutes (4, 5). We now report optical activity induced into a symmetrical molecule by an optically active surfactant in the micellar form. L- and D-*N*-decyl-*N,N*-dimethylalanine hydrobromides (betaines) were used as the surfactants; their

Figure 1—Extrinsic circular dichroism curves for 7.0×10^{-4} M SETD in an 8.9×10^{-2} M aqueous betaine solution. Key: O, D-betaine; □, L-betaine; and S/N ratio = 20:1. All measurements were made in a 0.1-cm. cell.

CMC's, measured by optical rotatory dispersion and circular dichroism, have been found to be approximately 1×10^{-2} M at 25° (6, 7). Sulfaethidole (SETD) was used as the optically inactive molecule; this drug has been found to become optically active when bound to bovine serum albumin (8), giving peaks in ellipticity at 280 (negative) and 257 mμ (positive) which are consistent with the UV spectra.

All measurements were made in a 6002 attachment to a Cary 60 spectropolarimeter¹ at 25° . Under the experimental conditions, the betaine showed no optical activity above 240 mμ (7), and the SETD alone showed no activity at any wavelengths. Figure 1 shows the optical activity induced in the SETD molecules by the L- and D-betaines at concentrations considerably above their CMC. Peaks of opposite sign are seen at wavelengths of 288 and 255 mμ. We have not observed any induced optical activities at concentrations of betaine below the CMC.

Figure 2 shows the effect of betaine concentration on the ellipticity at 285 mμ with the SETD concentration constant. These ellipticities are small, as is the signal-noise (S/N) ratio, but it appears that the plot cuts the betaine concentration axis at approximately the CMC. At a concentration of 6.0×10^{-2} M, the ellipticity seems to have reached a plateau. This is probably the result of all the SETD being solubilized by the micellar betaine, so that subsequent additions of betaine can cause no further interaction. These extrinsic effects probably are due to the interaction of the hydrophobic core of the

Figure 2—Plot of observed ellipticity at 285 mμ against D-betaine concentration for a constant SETD concentration of 7.0×10^{-4} M. S/N ratio = 20:1 at largest ellipticities and 4:1 at the lowest. All measurements were made in a 0.2-cm. cell.

perature on the dissolution of a polyethylene maleic anhydride-phenylpropanolamine interaction system that was recently devised (4). Samples of the interaction system were prepared at 27, 40, 45, 50, 55, 60, 80, and 100°; aqueous solutions of the polymer and drug were mixed in a 1:1 stoichiometric ratio at each indicated temperature. The solutions were evaporated to dryness, and the powder was compressed into 1-g. nondisintegrating disks on a laboratory press using a 1.6-cm. (0.63-in.) punch and die set. Dissolution studies were then performed using a refractometric method previously described (5). In addition, 10-ml. samples from a stock solution containing 16.40 mg./ml. of polymer-drug in a 1:1 ratio were oven dried to constant weight at the stated temperatures to determine bound moisture.

The results of these experiments are summarized in Tables I and II. It is apparent from an examination of Table I that the dissolution rates of the polymer-drug are essentially the same between the temperature range of 27–55°, with the higher rate at 27°. However, an abrupt, approximately 10-fold, decrease in rate is shown at 60 and 80°, with another significant drop in rate at 100°. These results clearly indicate that temperature has a pronounced effect on some physicochemical property of the polymer-drug system during preparation.

The data in Table II summarize the temperature effect on bound moisture in the polymer-drug system. There is a continuous decrease in bound moisture with an increase in drying temperature, the percent being approximately equal from 40 to 50° and from 55 to 80°. This table shows a rank order correlation with the data in Table I, because both dissolution rate and bound moisture decrease with an increase in temperature. In both studies, 55° appears to be the inflection point at which temperature has the most pronounced effect on dissolution and bound moisture.

Moisture, it appears, is a factor contributing to this dissolution phenomenon. Therefore, water associated with the molecules of the polymer-drug system influences the dissolution mechanism of this polymeric material. Prior to polymer dissolution, solvent imbibition and hydration must occur to form a swollen gel; subsequently, gel disintegration must occur for dissolution to proceed. This situation suggests a dynamic system which encompasses several rate phenomena such as solvent penetration, hydration, swelling, and gel disintegration, all of which determine the dissolution

rate of the polymer. The state of hydration, therefore, has an apparent influence on the dynamics of polymer-drug dissolution as suggested by this report.

Other factors, which may contribute to a change in dissolution characteristics when a polymer-drug system is prepared at different temperatures, are stability of the individual components comprising the system and the type of interaction system formed.

The effect of preparation temperature on dissolution could not be attributed to instability of the components of the system studied. The integrity of the pure polymer was confirmed, since no change in dissolution rate was found when a solution of pure polymer was dried at 27 and 100° and then tested. In addition, polyethylene maleic anhydride was reported by the supplier to be stable to any rupture of molecules and does not break down into smaller units at temperatures below 200° (6). The spectra for phenylpropanolamine did not change when a solution of the drug at the concentration used for interaction system preparation was heated at 100° for 2 days, the time required for preparation of the polymer-drug systems.

Ethylene maleic anhydride hydrolyzes in water to form the free acid, each monomer containing two carboxyl groups. Dicarboxylic acids form salts or amides with amines depending upon the reaction temperature (7). It is, therefore, proposed that the polymer and drug may interact at the lower and intermediate temperatures to form a salt. As the temperature increases, a greater proportion of the interaction system formed may be the amide form. The salt form, being more hydrophilic, would have a greater affinity than the amide for bound water. The amide, being more hydrophobic, would show a lesser degree of attraction for moisture. One would, therefore, have a lower rate of hydration and subsequent dissolution, which are consistent with the experimental data.

I am presently engaged in studies to elucidate further the mechanism of this dissolution phenomenon and to determine the effect of preparation temperature on drug release from the polymer.

Identification of *p*-Nitrophenyl Glucoside as a Urinary Metabolite

Keyphrases ☐ *p*-Nitrophenol-2,6-¹⁴C urinary metabolites—determination ☐ Paper chromatography—separation, identification ☐ Rechromatography procedure—separation, identification

Sir:

In 1969, Gessner and Vollmer (1) reported that mouse liver microsomes fortified with uridine diphosphoglucose (UDPG) can effect glucosylation of *p*-nitrophenol (PNP) to *p*-nitrophenyl glucoside (PNPG). The pathway appeared to be about 5 times less active than glucuronidation of PNP when carried out by the same microsomal preparations fortified with uridine diphosphoglucuronic acid (UDPGA). In view of the fact that glucosides of phenols have not been previously detected among mammalian metabolites, it was of interest to test whether the pathway manifests itself at all *in vivo*. We found PNPG in the urine of PNP-treated mice. The metabolite was characterized chromatographically by employing a novel technique, which permits a chromatographic sample to be subjected to consecutive chromatography in several solvent systems without elution of the material. The method is described below.

Male, Albany Swiss mice, weighing 23–30 g., were injected intraperitoneally with a 50 mg./kg., 0.145 mc./kg., dose of radioactive PNP¹ in a quantity of isotonic saline which was equivalent to 25 ml./kg. per dose. Urine from six mice was pooled and subjected to lyophilization. The residue of lyophilization was dissolved in distilled water; the concentrate thus obtained was used for chromatography. Descending chromatography was carried out on Whatman No. 1 paper strips in the solvents listed in Table I. Authentic reference compounds, PNP, PNPG, *p*-nitrophenylglucuronic acid (PNPGA), and *p*-nitrophenylsulfate (PNPS) were chromatographed contemporaneously for comparison of the *R_f* values of metabolites with those of authentic compounds. The compounds were detected on chromatograms with the aid of UV light; they appeared as quenching spots. Radioactive metabolites were located by scanning chromatographic strips with the aid of the Nuclear Chicago 4 pi chromatogram scanner, model 1002. In this manner, *R_f* values of the metabolites were located and compared to the *R_f* values of the authentic compounds. The presence of a radioactive peak at the *R_f* of PNPG on the initial chromatogram was interpreted as an indication of the possible presence of PNPG. The hypothesis was further tested by subjecting the chromatographically separated radioactive metabolite to chromatography in other solvents.

A novel method of rechromatography was developed, one that does not require elution of the substance under investigation. Verbal report of the method was made in 1969 in conjunction with the identification of PNPG as an *in vitro* metabolite (1). The method is suitable for

Table I—Comparison of the Chromatographic Mobility of a Urinary Metabolite with that of Authentic *p*-Nitrophenylglucoside

Solvent System	<i>R_f</i> ^a of PNPG	<i>R_f</i> ^a of Metabolite
I <i>n</i> -Butanol-pyridine-water (14:3:3)	0.63	0.63
II Benzene-acetic acid-water (125:72:3)	0.48	0.44
III <i>n</i> -Propanol-ethyl acetate-water (7:1:2)	0.73	0.74
IV Methanol-formic acid-water (16:3:1)	0.68	0.66
V 1 <i>N</i> Sodium formate-formic acid (200:1)	0.77	0.77

^a Chromatography was carried out on Whatman No. 1 paper strips in a consecutive manner as described in the text.

consecutive chromatography in several solvents and permits purification and characterization of an unknown substance by its chromatographic mobility. The paper chromatogram is developed in the usual manner, and the region with the *R_f* range under investigation is cut out as a strip. The cutout strip is then pinned at two opposite ends (using rustless pins) to two strips of chromatographic paper; a short leader-strip is for dipping into the solvent, and a long strip is for the development of the chromatogram. Thus assembled, the chromatogram is developed in the usual manner. Again the region with the *R_f* value of interest can be cut out from the chromatogram and subjected to chromatography in another solvent. The process can be repeated several times with little loss of the original material, and data from several solvents can be obtained from experiments on a single chromatographic sample of a substance.

The method of consecutive chromatography was used for the detection of PNPG in the urine of PNP-treated mice as follows. The concentrate described previously was chromatographed in Solvent I, *n*-butanol-pyridine-water (14:3:3), and the radioactive peak with the *R_f* of PNPG was cut out and subjected to chromatography in Solvent II, benzene-acetic acid-water (125:72:3). Again the chromatogram that was developed in Solvent II was cut up, and the radioactive peak with *R_f* of PNPG was subjected to chromatography in Solvent III, *n*-propanol-ethyl acetate-water (7:1:2). The process was repeated with the chromatogram from each solvent in turn. Chromatography in Solvent III was followed by chromatography in Solvent IV, methanol-formic acid-water (16:3:1), and then by chromatography in Solvent V, 1 *N* sodium formate-formic acid (200:1). The *R_f* values of the reference PNPG and radioactive metabolite were noted in each solvent, and the results are summarized in Table I.

Thus, the presence of PNPG in the urine of PNP-treated mice was established by consecutive chromatography in five solvent systems. Data in the table show that in each solvent system the radioactive peak of metabolite behaved like PNPG. Our experiments showed that in the first solvent system, PNPG overlapped with PNPS. However, the two components separated out in the second solvent system and, thereafter, a single radioactive peak with the mobility of PNPG was detectable on chromatograms. The chroma-

¹ *p*-Nitrophenol-2,6-¹⁴C from Tracerlabs, Waltham, Mass.

tographically pure PNPG was present in a small quantity and accounted for about 1–2% of the urinary metabolites. We also noted from our experiments that 24–50% of the administered PNP was excreted in urine in the form of metabolites of PNP in the first 5 hr., and that PNPGA and PNPS were the major products detectable on chromatograms at that time. The two metabolites accounted for about 95% of the urinary metabolites. This observation is in accord with an earlier work of Robinson *et al.* (2). In the 5-hr. urine, PNPGA and PNPS appeared to be present in equal amounts.

The fact that PNPG was present only in small amounts in the urine explains why the metabolite eluded detection in the past. However, low urinary excretion need not necessarily imply low production of this metabolite at all times in the body, but may be related to the fact that PNPG is not sufficiently acidic for extensive renal excretion. *In vitro*, the glucosylation pathway appears quite active (1). In this context perhaps it is significant that *N*-acetylglucosamine conjugation of steroids is also a pathway that appears to be very active *in vitro* (3), but such metabolites are detected with difficulty in mammalian urine (4).

I

by a 14-step procedure and an alternate 16-step procedure.

In the shorter synthesis, we started with the preparation of *O*-benzylvanillin, which was condensed with hippuric acid to yield 5-keto-2-phenyl-4-(4'-benzyloxy-3'-methoxybenzylidene)-4,5-dihydrooxazole. The latter then was hydrolyzed with barium hydroxide to give 3-methoxy-4-benzyloxyphenyl-pyruvic acid, which was readily oxidized with hydrogen peroxide to provide the desired 3-methoxy-4-benzyloxyphenylacetic acid, m.p. 114–116° [lit. (2) m.p. 116°]. This acid was converted to its acid chloride with thionyl chloride prior to reaction with β -methoxy- β -(3-benzyloxy-4-methoxyphenyl)ethylamine, which was obtained by treating the nitromethane adduct of *O*-benzylisovanillin with sodium methoxide, according to Rosenmund *et al.* (3), to give 1-methoxy-1-(3-benzyloxy-4-methoxyphenyl)-2-nitroethane, m.p. 100–102°, which was then reduced with lithium aluminum hydride. The resulting amide, m.p. 96.5–98.5°, was then submitted to Bischler-Napieralski cyclization (4) with phosphorus oxychloride to give 1-(3'-methoxy-4'-benzyloxybenzyl)-6-benzyloxy-7-methoxyisoquinoline, m.p. 146–147°.

Another route to this isoquinoline was achieved by dehydrogenation of the known 1-(3'-methoxy-4'-benzyloxybenzyl)-6-benzyloxy-7-methoxy-1,2,3,4-tetrahydroisoquinoline (5) with 10% palladium-on-carbon and rebenzylation of the resulting phenolic isoquinoline with benzyl chloride according to Lee and Soine (6). This route also served to confirm the identity of the isoquinoline from the first method. The tetrahydroisoquinoline was prepared, according to Tomita and Kunimoto (5), by condensation of 3-methoxy-4-benzyloxyphenylacetyl chloride with β -(3-benzyloxy-4-methoxyphenyl)ethylamine. Subsequent Bischler-Napieralski cyclization with phosphorus pentachloride gave 1-(3'-methoxy-4'-benzyloxybenzyl)-6-benzyloxy-7-methoxy-3,4-dihydroisoquinoline hydrochloride. The latter, on reduction with sodium borohydride in aqueous methanol, provided the desired tetrahydroisoquinoline.

The isoquinoline obtained by either of the two methods then was quaternized with methyl iodide and reduced with sodium borohydride in pyridine, according to Barton *et al.* (7), to yield 1-(3'-methoxy-4'-benzyloxybenzyl)-2-methyl-6-benzyloxy-7-methoxy-1,2-dihydroisoquinoline, m.p. 61–64°. Acid cyclization of this product, by the method of Battersby and Binks (8), gave (\pm)-bisnorargemonine, m.p. 231.5–232.5°. Except for melting point and rotational differences, the natural and synthetic compounds were shown to be identical. The identity of natural and synthetic materials was established by comparative UV, IR, NMR, and mass

Total Synthesis of (\pm)-Bisnorargemonine

Improved Method for Measuring Output Potential of Specific Ion Electrodes

Keyphrases □ Ion electrodes, specific—output potential measurement □ pH meter, expanded scale—ion electrode potential output determination

Sir:

Since Frant and Ross (1) announced the invention of a single crystal lanthanum fluoride electrode for the determination of fluoride-ion activity, numerous articles have appeared in the literature describing applications of the device. It has been used to determine fluoride in bone (2), urine (3), chromium plating baths (4), tungsten (5), toothpaste (6), and numerous other samples.

In these methods, either an expanded scale analog or digital pH meter was used to measure fluoride-ion activity electrode potential. When using an expanded scale pH meter, it is possible to read electrode potentials to about ± 1 mv. According to the report of Lingane (7), this would represent an error of ± 0.017 pF unit, or a relative accuracy of $\pm 1.7\%$. With a digital pH meter, it is possible to measure potentials to ± 0.1 mv., with a correspondingly greater relative accuracy.

When determining the fluoride content of some pharmaceutical preparations without a digital pH meter, it was necessary in the authors' laboratory to devise a method of measuring the electrode potential more ac-

curately than can be done directly with an expanded scale analog instrument. This was accomplished by using an expanded scale pH meter as an electrometer coupling between the electrode and a variable range strip-chart recorder, which involves simply connecting the recorder into the appropriate electrical output jacks of the meter. By so doing, and by choosing the proper input range of the recorder, it is possible to expand almost any portion of a standard curve [*i.e.*, almost any millivolt range of the plot: $\log(\text{concentration } F^-)$ versus millivolts] to full-scale deflection on the chart.

The most convenient way is to operate the pH meter in the pH (expanded scale) mode. This is done to keep the calibration circuit of the meter activated.

For the present work, a Corning model 10 expanded scale pH meter was used. While some of its characteristics (*i.e.*, deactivation of the calibration circuit when operated in the millivolt mode) may not be common, simple modifications of this procedure should make it applicable to individual needs.

After choosing the desired concentration range for the standard curve, the fluoride and reference electrodes are placed in the least concentrated standard sample. The calibration knob of the pH meter is then adjusted to bring the recorder pen to zero. Thus, at this concentration, the recorder will sense a zero potential from the electrode. The electrodes are then placed in the most concentrated standard, and the span control of the recorder is adjusted to bring the pen to fullscale deflection. To do this, the span control of the recorder must be infinitely variable between any two coarse span settings. One or two standards of intermediate concentrations are then used, and the pen deflection is noted.

When this is done, the numbers read from the chart become arbitrary units, not millivolts. However, the relationship, $\log(\text{concentration } F^-)$ versus recorder reading, is still linear. The concentration range is chosen on the basis of a compromise between a range narrow enough to allow sufficient accuracy and one wide enough to suppress electronic noise from the electrode. In the authors' laboratory, a three or fourfold concentration range was found reasonable. This range requires the recorder to have a fullscale deflection of about 1.5 mv.

In addition to a high degree of accuracy, several advantages are realized with the use of the recorder:

1. It provides a superb method of determining when the electrodes reach equilibrium; one need only note the point at which the needle ceases to drift. In extremely dilute solutions, equilibration time may be 30–45 min.

2. As reported by Strinivasan and Rechnitz (8), the electrode was found to drift, necessitating frequent recalibration. Because the slope of the calibration curve did not change, recalibration could be accomplished in a few minutes by adjusting the reading of one of the standard solutions to its original value on the recorder with the calibration knob of the pH meter.

3. The recorder gives a graphic presentation of the electronic noise produced by the electrode. This can be significant when the recorder is operated in the 1–2 mv. range. With the recorder, one can read potentials in spite of noise.

While work using this procedure in the authors' laboratory was conducted with a fluoride electrode, the

spectral analyses. Such criteria left no doubt that the original structural assignment (1) was correct.

Improved Method for Measuring Output Potential of Specific Ion Electrodes

Keyphrases □ Ion electrodes, specific—output potential measurement □ pH meter, expanded scale—ion electrode potential output determination

Sir:

Since Frant and Ross (1) announced the invention of a single crystal lanthanum fluoride electrode for the determination of fluoride-ion activity, numerous articles have appeared in the literature describing applications of the device. It has been used to determine fluoride in bone (2), urine (3), chromium plating baths (4), tungsten (5), toothpaste (6), and numerous other samples.

In these methods, either an expanded scale analog or digital pH meter was used to measure fluoride-ion activity electrode potential. When using an expanded scale pH meter, it is possible to read electrode potentials to about ± 1 mv. According to the report of Lingane (7), this would represent an error of ± 0.017 pF unit, or a relative accuracy of $\pm 1.7\%$. With a digital pH meter, it is possible to measure potentials to ± 0.1 mv., with a correspondingly greater relative accuracy.

When determining the fluoride content of some pharmaceutical preparations without a digital pH meter, it was necessary in the authors' laboratory to devise a method of measuring the electrode potential more ac-

curately than can be done directly with an expanded scale analog instrument. This was accomplished by using an expanded scale pH meter as an electrometer coupling between the electrode and a variable range strip-chart recorder, which involves simply connecting the recorder into the appropriate electrical output jacks of the meter. By so doing, and by choosing the proper input range of the recorder, it is possible to expand almost any portion of a standard curve [*i.e.*, almost any millivolt range of the plot: $\log(\text{concentration } F^-)$ versus millivolts] to full-scale deflection on the chart.

The most convenient way is to operate the pH meter in the pH (expanded scale) mode. This is done to keep the calibration circuit of the meter activated.

For the present work, a Corning model 10 expanded scale pH meter was used. While some of its characteristics (*i.e.*, deactivation of the calibration circuit when operated in the millivolt mode) may not be common, simple modifications of this procedure should make it applicable to individual needs.

After choosing the desired concentration range for the standard curve, the fluoride and reference electrodes are placed in the least concentrated standard sample. The calibration knob of the pH meter is then adjusted to bring the recorder pen to zero. Thus, at this concentration, the recorder will sense a zero potential from the electrode. The electrodes are then placed in the most concentrated standard, and the span control of the recorder is adjusted to bring the pen to fullscale deflection. To do this, the span control of the recorder must be infinitely variable between any two coarse span settings. One or two standards of intermediate concentrations are then used, and the pen deflection is noted.

When this is done, the numbers read from the chart become arbitrary units, not millivolts. However, the relationship, $\log(\text{concentration } F^-)$ versus recorder reading, is still linear. The concentration range is chosen on the basis of a compromise between a range narrow enough to allow sufficient accuracy and one wide enough to suppress electronic noise from the electrode. In the authors' laboratory, a three or fourfold concentration range was found reasonable. This range requires the recorder to have a fullscale deflection of about 1.5 mv.

In addition to a high degree of accuracy, several advantages are realized with the use of the recorder:

1. It provides a superb method of determining when the electrodes reach equilibrium; one need only note the point at which the needle ceases to drift. In extremely dilute solutions, equilibration time may be 30–45 min.

2. As reported by Strinivasan and Rechnitz (8), the electrode was found to drift, necessitating frequent recalibration. Because the slope of the calibration curve did not change, recalibration could be accomplished in a few minutes by adjusting the reading of one of the standard solutions to its original value on the recorder with the calibration knob of the pH meter.

3. The recorder gives a graphic presentation of the electronic noise produced by the electrode. This can be significant when the recorder is operated in the 1–2 mv. range. With the recorder, one can read potentials in spite of noise.

While work using this procedure in the authors' laboratory was conducted with a fluoride electrode, the

method should be equally applicable to all other specific ion electrodes.

BOOKS

REVIEWS

Editor's Note: While it is not usual Journal practice to run more than one review on a particular book, "The Theory and Practice of Industrial Pharmacy" appeared to warrant a broader approach as it is an initial attempt to produce a textbook in the area of industrial pharmacy. For this reason, we are providing the opinions of two reviewers in the book reviews which follow.

The Theory and Practice of Industrial Pharmacy. Vol. 1. Edited by LEON LACHMAN, HERBERT A. LIEBERMAN, and JOSEPH L. KANIG. Lea & Febiger, Philadelphia, PA 19106, 1970. xii + 811 pp. 15.5 × 23 cm. Price \$24.50.

In their preface, the editors state that a good textbook on industrial pharmacy has been sorely needed. This is indeed the case and this book represents the first modern comprehensive treatment of industrial pharmacy to be published in the English language.

The book has three coeditors and thirty-eight contributors. As a result some chapters are truly outstanding and others are distinctly disappointing.

The book is written in four sections. These sections deal with the principles of pharmaceutical processing, dosage forms, quality control, and industrial pharmaceutical law and structures of pharmaceutical companies.

The first third of the book deals with principles of pharmaceutical processing and is written from a unit operations standpoint. Unit operations which are of particular importance in pharmaceutical processing are covered in separate chapters and include drying, mixing, milling, dispersion, clarification and filtration, compaction and compression, heat transfer, and fluid flow. Other specialized pharmaceutical processes treated are sterilization and tablet coating. One of the most outstanding chapters in the entire book appears to be very much out of place in the pharmaceutical processing or unit operations section and that is the chapter on biopharmaceutics. This chapter which was contributed by Professor Gibaldi is perhaps the most outstanding single chapter on the subject of biopharmaceutics to have been written to this date.

Section two treats on an individual chapter basis all of the various major classes of pharmaceutical dosage forms, including tablets, capsules, liquids, emulsions, semisolids, suspensions, suppositories, sterile products, aerosols, and sustained-release products. This section is entitled in the table of contents, "Dosage Forms: Design and Evaluation." Unfortunately dosage form design principles and drug product evaluation are either inadequately treated or are virtually missing from many of the chapters in this section. For example, in the chapter on capsules, no mention is made of the importance of availability studies or methods of characterizing *in vitro* availability. In most of the chapters in this section mechanical methods of manufacture are stressed. In the approximate 40% of the book dealing with dosage forms the chapter on sustained-action dosage forms by Eriksen, the chapter on sterile products by Avis, and the chapter on aerosols by Sciarra are outstanding in organization and content. The chapter on pilot plant scale-up techniques by Michelson is also

well done, but seems strangely out of place, not to have been located in part one of the book dealing with pharmaceutical processing.

The nearly 100 pages of the book dealing with quality control contain two chapters coauthored by Dr. Lachman, one dealing with kinetic principles of stability testing and the other with quality assurance. These are very well written and represent a significant textbook compilation on these subjects to the literature.

In the design, organization, and writing of their book the editors have overlooked one important aspect of industrial pharmacy today. That aspect is the role of preformulation research and the application of physical-chemical principles in a systematic manner for the rational design of pharmaceutical drug products and dosage forms. It is obvious from the examination of the table of contents that the authors were at some loss as to the location of the section on biopharmaceutics. This excellent chapter together with a section on preformulation, its implications in drug product design, and the components of a total preformulation system would have provided a very good foundation for the dosage form section of the book. Unfortunately the preformulation concept is not treated by the book, making the foundation for the following dosage form section inadequate, and accentuating the lack of total information on basic principles of dosage form design and evaluation.

Even though this book contains some obvious omissions, quite often is incomplete on the subjects of dosage form design principles and evaluation, and is questionably organized in two instances, the book does represent a creditable and laudable effort to cover a broad and very difficult area. This book is recommended as a textbook for any advanced pharmaceutics or manufacturing graduate course. The book warrants consideration for elective undergraduate manufacturing pharmacy courses. It is doubtful that the book will find wide-scale acceptance as an undergraduate text based on the specialized subjects treated and the nature of the material being covered. The book should, however, have a prominent place on the shelf of every pharmacy school and pharmaceutical laboratory library. It will also undoubtedly be a valuable contribution to the working bookshelf of many industrial and development pharmacists.

The Theory and Practice of Industrial Pharmacy. Vol. 1. Edited by LEON LACHMAN, HERBERT A. LIEBERMAN, and JOSEPH L. KANIG. Lea & Febiger, Philadelphia, PA 19106, 1970. xii + 811 pp. 15.5 × 23 cm. Price \$24.50.

The preparation of this first attempt at a text on industrial pharmacy was undoubtedly difficult. The very scope of the subject must have given rise to many hard decisions finally arrived at with much hesitation, breadth *versus* depth alone being one of the most weighty of these.

All in all, the book is an excellent beginning and the editors are congratulated in obtaining the consistently good help of so many competent contributors.

But there are serious omissions in a text that by its title claims exposition of both theory and practice, and there are inclusions that seem a bit unnecessary here, however necessary and important as ancillary materials that have been very properly treated in other works.

As to the latter, it seems that for the most part the chapters on heat transfer, momentum transfer, and fluid flow have been well treated elsewhere and need not have been included here, however well done. In actual practice an engineering department would or should function competently in these areas.

It is interesting to note that the technological details of dosage form development in the various areas are never tied in with control and production in the sense that in a well-run outfit development should issue detailed specifications for the finished job and assume the responsibility for the accuracy of these regardless of the degree of control and production involvement during the planning stages of new drug design. The chapter on pilot plant scale-up techniques is well done technically, but needs the finishing touch of stress on the responsibilities to be assumed and by whom. This is the important connecting link between development and production and is an extremely important administrative factor in the pursuit of industrial pharmacy. Interestingly, it is often disregarded in practice as it is disregarded in this text.

Little if any reference is made to the construction and control of labeling information, to include both label and package circular, yet these are grave responsibilities that come much earlier in the scheme of things than the mechanical control of finished labeling.

In the chapter on quality assurance, reference is made to a zero-defect concept. It is unfortunate that this widely used term is repeated here since it is a physical and psychologic anomaly. Yet the notion, as developed by Sinotte and others, is a most interesting approach to quality control because it deals with the fallibilities of the human which, after all is said and done, constitute the fundamental need for control. But the term "zero defect" should be replaced with one of greater semantic digestibility. Personnel may and should be qualified not only by training, experience, and the like, but also by their emotional attitudes toward the job after training and motivational incentives have been applied. The applicable paragraph on page 715 could and should be greatly expanded by competent psychological treatment. It is not too difficult to calculate a standard deviation, but a human can ruin its importance.

The control of bulk raw material is well spiced with general statements such as "adequate systems," "appropriate records," and our old friend "careful handling." A few pages later these are followed by a quite satisfactory handling of statistical quality control for the purposes of this text, but in neither case nor in any other area of this volume is much attention given to how samples are taken, and where and when, and by whom. It is one thing to give a blessing to Military Standards sampling plans, but quite another to show how these are not complete and practical answers to the requirements of practice. The reader should like to know who trains the sampler or his supervisor and how this is done and what responsibilities reside in these operators. Often no one else sees what they do, or how they do it.

Automated sampling and assay procedures have already solved many problems in quality control, as this reviewer prophesized many years ago, and as this volume gives adequate description, but we need more definitive treatment of hand sampling and bench assay operation in a text on industrial pharmacy too, it would seem. The day is somewhat in the future when relatively small pharmaceutical operations will have disappeared. These need specific and truly applicable help in these areas of quality control far more than their more sophisticated counterparts.

This reviewer is impelled once again to point out that it seems almost axiomatic that authors in this field must use terms such as, "carefully," "adequate," "absolutely correct," "proper," "suitable," "reasonable," and the like. This volume has far too many such terms. As a text it needs none of them, or at the most, few. But it does need definitive statements in these applicable areas.

In no place was there found any statement as to the organizational responsibilities and authorities of the director of quality control. This matter has been so avoided or mishandled in the industry generally that a careful discussion of it would seem to be in order.

The statement in the last paragraph on page 748 is good, but it is altogether too general for a text without more detailed support.

The matter of patents is well discussed and is quite informative to those of little experience in the field, which is as it should be. It would have been most helpful however, if some discussion of the manner in which ideas are developed in the group research that pertains today, and the difficulty of assigning the proper credit to individuals who participate in invention. These are the very facts of life to directors of development, or should be. Patents protect and provide incentive, but they are not the research "thing" itself. The "thing" itself is the heart and soul of industrial pharmacy.

But this is an excellent "first try" in the elaboration of a text that has been long sorely needed. Careful revision will make it into a most valuable resource. Such revision will surely follow its use as a text, a use which is recommended.

European Pharmacopoeia. Vol. 1. Published under the direction of the Council of Europe (Partial Agreement) in accordance with the Convention on the Elaboration of a European Pharmacopoeia. Maisonneuve S. A., 57-Sainte-Ruffine, France, 1969. i + 401 pp. 15.5 × 24.5 cm. (English and French versions available)

The publication of the *European Pharmacopoeia* represents a significant step toward greater cooperation across national boundaries in the field of public health. The European Pharmacopoeia Commission was established by a Convention signed in September 1964 by the following countries: Belgium, France, Federal Republic of Germany, Italy, Luxembourg, the Netherlands, Switzerland, and the United Kingdom.

For the past five years, some hundred scientists, representing these eight countries, have been preparing this compilation. Application of the standards established in this volume must be made before January 1, 1972, with this volume gradually replacing the traditional national pharmacopoeias.

This volume contains general methods of analysis as well as 51 monographs on specific basic medicinal substances. A second volume of this compendium containing biological substances such as hormones, vaccine serum, and antibiotics is scheduled for publication next year.

Pharmacology and Patient Care. By SOLOMON GARB, BETTY JEAN CRIM, and GARF THOMAS. Springer, 200 Park Ave. So., New York, NY 10003, 1970. x + 597 pp. 14 × 21.5 cm. Price \$8.95 (hard cover), \$6.75 (soft).

This, the third edition of *Pharmacology and Patient Care*, is somewhat broader than the first two editions. Garf Thomas, Chief Hospital Pharmacist, University of Missouri Medical Center, has been added as a coauthor, in an attempt to give this book, originally published as a textbook for nurses, a more interdisciplinary, paramedical approach.

This edition contains several new chapters, with all the chapters from the preceding editions being updated. Of particular interest are the chapters on "Drug Interaction and Incompatibilities" and "Pharmaceuticals and Society."

Staff Review ■

This is the important connecting link between development and production and is an extremely important administrative factor in the pursuit of industrial pharmacy. Interestingly, it is often disregarded in practice as it is disregarded in this text.

Little if any reference is made to the construction and control of labeling information, to include both label and package circular, yet these are grave responsibilities that come much earlier in the scheme of things than the mechanical control of finished labeling.

In the chapter on quality assurance, reference is made to a zero-defect concept. It is unfortunate that this widely used term is repeated here since it is a physical and psychologic anomaly. Yet the notion, as developed by Sinotte and others, is a most interesting approach to quality control because it deals with the fallibilities of the human which, after all is said and done, constitute the fundamental need for control. But the term "zero defect" should be replaced with one of greater semantic digestibility. Personnel may and should be qualified not only by training, experience, and the like, but also by their emotional attitudes toward the job after training and motivational incentives have been applied. The applicable paragraph on page 715 could and should be greatly expanded by competent psychological treatment. It is not too difficult to calculate a standard deviation, but a human can ruin its importance.

The control of bulk raw material is well spiced with general statements such as "adequate systems," "appropriate records," and our old friend "careful handling." A few pages later these are followed by a quite satisfactory handling of statistical quality control for the purposes of this text, but in neither case nor in any other area of this volume is much attention given to how samples are taken, and where and when, and by whom. It is one thing to give a blessing to Military Standards sampling plans, but quite another to show how these are not complete and practical answers to the requirements of practice. The reader should like to know who trains the sampler or his supervisor and how this is done and what responsibilities reside in these operators. Often no one else sees what they do, or how they do it.

Automated sampling and assay procedures have already solved many problems in quality control, as this reviewer prophesized many years ago, and as this volume gives adequate description, but we need more definitive treatment of hand sampling and bench assay operation in a text on industrial pharmacy too, it would seem. The day is somewhat in the future when relatively small pharmaceutical operations will have disappeared. These need specific and truly applicable help in these areas of quality control far more than their more sophisticated counterparts.

This reviewer is impelled once again to point out that it seems almost axiomatic that authors in this field must use terms such as, "carefully," "adequate," "absolutely correct," "proper," "suitable," "reasonable," and the like. This volume has far too many such terms. As a text it needs none of them, or at the most, few. But it does need definitive statements in these applicable areas.

In no place was there found any statement as to the organizational responsibilities and authorities of the director of quality control. This matter has been so avoided or mishandled in the industry generally that a careful discussion of it would seem to be in order.

The statement in the last paragraph on page 748 is good, but it is altogether too general for a text without more detailed support.

The matter of patents is well discussed and is quite informative to those of little experience in the field, which is as it should be. It would have been most helpful however, if some discussion of the manner in which ideas are developed in the group research that pertains today, and the difficulty of assigning the proper credit to individuals who participate in invention. These are the very facts of life to directors of development, or should be. Patents protect and provide incentive, but they are not the research "thing" itself. The "thing" itself is the heart and soul of industrial pharmacy.

But this is an excellent "first try" in the elaboration of a text that has been long sorely needed. Careful revision will make it into a most valuable resource. Such revision will surely follow its use as a text, a use which is recommended.

European Pharmacopoeia. Vol. 1. Published under the direction of the Council of Europe (Partial Agreement) in accordance with the Convention on the Elaboration of a European Pharmacopoeia. Maisonneuve S. A., 57-Sainte-Ruffine, France, 1969. i + 401 pp. 15.5 × 24.5 cm. (English and French versions available)

The publication of the *European Pharmacopoeia* represents a significant step toward greater cooperation across national boundaries in the field of public health. The European Pharmacopoeia Commission was established by a Convention signed in September 1964 by the following countries: Belgium, France, Federal Republic of Germany, Italy, Luxembourg, the Netherlands, Switzerland, and the United Kingdom.

For the past five years, some hundred scientists, representing these eight countries, have been preparing this compilation. Application of the standards established in this volume must be made before January 1, 1972, with this volume gradually replacing the traditional national pharmacopoeias.

This volume contains general methods of analysis as well as 51 monographs on specific basic medicinal substances. A second volume of this compendium containing biological substances such as hormones, vaccine serum, and antibiotics is scheduled for publication next year.

Pharmacology and Patient Care. By SOLOMON GARB, BETTY JEAN CRIM, and GARF THOMAS. Springer, 200 Park Ave. So., New York, NY 10003, 1970. x + 597 pp. 14 × 21.5 cm. Price \$8.95 (hard cover), \$6.75 (soft).

This, the third edition of *Pharmacology and Patient Care*, is somewhat broader than the first two editions. Garf Thomas, Chief Hospital Pharmacist, University of Missouri Medical Center, has been added as a coauthor, in an attempt to give this book, originally published as a textbook for nurses, a more interdisciplinary, paramedical approach.

This edition contains several new chapters, with all the chapters from the preceding editions being updated. Of particular interest are the chapters on "Drug Interaction and Incompatibilities" and "Pharmaceuticals and Society."

REVIEW ARTICLE

Syntheses and Biological Activity of 5-Aminoimidazoles and 5-Triazenoimidazoles

Y. FULMER SHEALY

Keyphrases □ 5-Aminoimidazoles—methods of synthesis □ Triazenoimidazoles—synthesis, stability □ Antineoplastic activity—triazenoimidazoles □ Microbiological activity—triazenoimidazoles □ Clinical studies—5-(3,3-dimethyl-1-triazeno)imidazole-4-carboxamide, 5-[3,3-bis(2-chloroethyl)-1-triazeno]imidazole-4-carboxamide

I. INTRODUCTION

In 1945, Stetten and Fox (1) isolated a heterocyclic amine that accumulated (1, 2) during sulfonamide bacteriostasis of *Escherichia coli* and also detected this compound in sulfonamide-inhibited cultures of other bacteria. Shive *et al.* (3), proceeding from the hypothesis that purine biosynthesis had been affected, showed that the heterocyclic amine was 5-aminoimidazole-4-carboxamide¹ (I) (AIC²), an imidazole

that had been synthesized more than 20 years earlier by Windaus and Langenbeck (4) as a potential intermediate for the chemical synthesis of purines (5). Shive *et al.* (3) correctly postulated that AIC "functions as a precursor of purine bases or is formed from a precursor of purines" and that a *p*-aminobenzoic acid "coenzyme [formyltetrahydrofolic acid] functions in combining a single carbon unit into the pyrimidine ring." Subsequent studies of purine biosynthesis revealed that the 1-(β -D-ribofuranosyl) 5'-phosphate derivatives of AIC and of four other imidazoles constitute the middle group of steps in the biosynthetic pathway to purine ribonucleotides. All imidazole moieties of these compounds have an amino group (or its formyl derivative) at the 5-position of the imidazole ring; all, save the first, have a carboxyl or a carboxamide group at the 4-position.

¹ When a nitrogen atom of the imidazole ring has an exocyclic substituent, that nitrogen atom is assigned position 1. Prior to 1967, the subject indexes of *Chemical Abstracts* listed Compound I as 5(or 4)-aminoimidazole-4(or 5)-carboxamide, because the position (which should be number 1) of the labile ring proton cannot be fixed. This nomenclature convention, in which the number of the alternative numbering sequence is included in parentheses, had been employed for similar imidazoles that have a proton on a ring nitrogen and substituents at positions 4 and 5. In recent subject indexes, Compound I is named 5-aminoimidazole-4-carboxamide, and this simplified nomenclature is also employed for similar imidazoles. In agreement with later *Chemical Abstracts* usage and for the sake of simplicity, a single number, without the parenthetical alternative numbering system, will be used throughout this review to designate positions 4 and 5. In the structures of compounds, such as AIC, having the labile proton instead of another substituent (alkyl, ribofuranosyl, *etc.*) on a nitrogen atom, the proton is generally placed on the nitrogen atom that corresponds to the point of attachment of the ribofuranosyl group of the biosynthetic imidazoles.

² The letter designations AIC and AICA are both employed in the literature for Compound I. Since either abbreviation could also be logically used for 5-aminoimidazole-4-carboxylic acid, the ribonucleotide of which is a precursor of the ribonucleotide of I, neither is specific. The shorter abbreviation will, therefore, be used in this article.

Other imidazole derivatives possess various types and varying degrees of biological significance. The physiological and pharmacological importance of histidine and histamine is well known, and the literature relating to these compounds, their derivatives, and their analogs is extensive. Certain imidazole structures are reported to display antiprotozoal, antifungal, antibacterial, monoamine oxidase-inhibitory, her-

bicidal, and other types of activity. The following examples are illustrative: the activity of imidazole-4,5-dicarboxamide and some of its derivatives against coccidiosis in poultry (6, 7); the activity of 1-(2-hydroxyethyl)-2-methyl-5-nitroimidazole (metronidazole) (8-10) and other nitroimidazoles (e.g., 10-15) against *Trichomonas vaginalis*, other *Trichomonas* species, *Entamoeba histolytica*, and other protozoa; and the broad-spectrum antibacterial and antiprotozoal activity of 2-amino-5-(1-methyl-5-nitro-2-imidazolyl)-1,3,4-thiadiazole and related structures (16). The antiprotozoal activity of metronidazole is clinically important in the oral treatment of trichomoniasis (14, 17-19) and amoebiasis (14, 20, 21).

However, to limit the scope of this review, it deals, first, with chemical syntheses and biological properties of 5-aminoimidazoles related to those in the biosynthetic pathway to purine ribonucleotides, the principal emphasis being on imidazoles bearing a member of the carboxylic acid family of groups (carboxyl, ester, amide, thioamide, amidine, nitrile, etc.) *ortho* to the amino group. Secondly, it summarizes the chemical and biological properties of triazenoimidazoles related to the imidazoles mentioned.³ An excellent review of the entire imidazole field covers the period from 1919 to 1950 (22). Recent reviews (23, 24) differ from the present review in that: (a) they were limited to nucleosides and nucleotides of imidazoles, and (b) consideration of these types of derivatives was not confined to 5-aminoimidazoles.

II. SYNTHESSES OF 5-AMINOIMIDAZOLES^{4, 5}

Chemical syntheses of 5-aminoimidazole derivatives are presented by describing the basic methods for forming the imidazole ring with an amino group (or a precursor group) at position 5 rather than by structural type (amide, ester, nitrile, etc.). To preserve the continuity of certain synthetic sequences, further transformations of the structures obtained from a basic route are also frequently included in the section in which the basic method is described.

³ Triazenoimidazoles and aminoimidazoles are included in the same review because of the derivation, structures, and biological activity of the former. There is no intention to imply that inhibition of biochemical reactions involving aminoimidazoles is the primary mechanism of action of the triazeno derivatives (Part IV).

⁴ To minimize both the number of letter designations and the number of long systematic names, three abbreviations will be employed in Parts II and III, with some exceptions in Part III where commonly accepted letter designations are shown with the structures. The three are AI for 5-aminoimidazole, AIC for Compound I, and AICAR for the ribonucleotide of Compound I. Admittedly, the latter two are not consistent; but there is no reason to change the generally accepted AICAR, and the reasons for choosing AIC are explained in Footnote 2. These three letter designations are employed in combination with the formulas of functional or protecting groups and in combination with names of groups or substituents to designate certain derivatives. For brevity, the terms ribofuranoside or ribonucleoside and ribonucleotide will be used for imidazoles bearing the β -D-ribofuranosyl and the β -D-ribofuranosyl 5'-phosphate groups at the position of these groups in the biosynthetic imidazoles (i.e., adjacent to the amino group). This shorthand nomenclature method is illustrated by the following examples: 2-methyl-AIC ribonucleotide for 5-amino-2-methyl-1-(β -D-ribofuranosyl)imidazole-4-carboxamide 5'-(dihydrogen phosphate) (LXd); 1-cyclohexyl-AI-COOH for 5-amino-1-cyclohexylimidazole-4-carboxylic acid (XXXVII; $R' = R_2 = H$, $R_1 = \text{cyclohexyl}$); and AI-COOCH₃ for 5-aminoimidazole-4-carboxylic acid methyl ester (IX).

⁵ For convenience, carboxyl, amino, and phosphoric acid groups are depicted in their unionized forms throughout this review. However, ionic species are present in the biochemical environments in which imidazole derivatives having these groups are biosynthesized and transformed, and they are usually the forms isolated from chemical reactions.

Scheme 1

The synthetic methods of Sections B, C, and D are related and, in some of their variations, may include similar or common intermediates. However, they were developed at different times by different investigators; to simplify the presentation, they are treated separately.

A. Reduction of the Nitro Group (Windaus-Langenbeck and Sarasin-Wegmann Routes)—Because of its importance in aromatic chemistry, reduction of a nitro group (or an arylazo group) naturally received initial attention as a method for preparing 5-aminoimidazoles. These early efforts to synthesize 5-aminoimidazole (AI) and its methyl derivatives met with difficulties

owing to the instability of the products under the conditions of the chemical reductions (25–27, *cf.*, 28). Yields were low or nil because of degradation by ring-opening, but both AI (29) and its 4-methyl derivative (30) were subsequently obtained (as dihydrochlorides) in moderate yields by chemical reduction of the corresponding nitro compounds. The examples of prime interest in the present context have a carboxamide, a carboxyl, or similar group at position 4. During the period that difficulties were being experienced in preparing the simple aminoimidazoles, Windaus and Langenbeck (4) succeeded in synthesizing AIC and AI-COOCH₃⁴ (IX) by a route that began with 4-methylimidazole (II) and terminated in the reduction of a nitro group (Scheme I). A nitration (25), an aldol-type condensation, and oxidation of the resulting styryl derivative (IV) yielded the key intermediate, 5-nitroimidazole-4-carboxylic acid (V), which had been obtained earlier by a less productive method (31). The nitro amide (VII) (4, 32) was prepared from the ester (VI) and reduced catalytically to AIC (4). Further studies and modifications of the route to V and IX were made by Allsebrook *et al.* (33), who also used the method to prepare the two nitro acids (XIIIb and XVIIb) having a methyl group on a ring nitrogen atom. The route was employed by Shive *et al.* (3) to prove the structure of AIC isolated from bacterial cultures; by Rabinowitz (34) to prepare (in weakly basic solution) 5-aminoimidazole-4-carboxylate (VIII), a catabolite of xanthine formed by extracts of *Clostridium cylindrosporum*; by Allsebrook *et al.* (33) to prepare 5-ureidoimidazole-4-carboxylic acid and its methyl ester for purine synthesis; by Taylor *et al.* (35) to prepare 5-aminoimidazole-4-carboxyhydroxamic acid; and by Robinson and Shepherd (36) to prepare 5-nitroimidazole-4-carboxylic acid hydrazide.

Kulev and Gireva (37) and Gireva and Dobychina (38) described an improved synthesis of the nitro acid (V); 4-(hydroxymethyl)imidazole (X), prepared from invert sugar, was nitrated and 4-(hydroxymethyl)-5-nitroimidazole (XI) was oxidized in high yield to V in the nitration mixture. These authors and others have reported the preparation of several esters (XIIa) of V (38–42), the reduction of some of the nitro esters to esters (XIIb) of 5-aminoimidazole-4-carboxylic acid (38, 40, 41), the preparation of acyl and sulfonyl [including bis(2-chloroethyl)aminobenzoyl and bis(2-chloroethyl)aminobenzenesulfonyl] derivatives of the amino group of XIIb (R = C₂H₅) (43), and the synthesis of *N*-aryl carboxamide analogs of VII (44, 45).

A synthesis (*cf.*, Parts IIB and IIE) of AIC ribonucleoside (XVIa) based on the nitro acid (V) was accomplished by Baddiley *et al.* (32, 46). Glycosidation of the silver or chloromercury salt of methyl 5-nitroimidazole-4-carboxylate (VI) with 2,3,5-tri-*O*-benzoylribofuranosyl chloride evidently gave a mixture of ribofuranosides (XIVa and XVIIIa tribenzoates) that was transformed by ammonia to a mixture of the nitro amides (XVa, XIXa), which were separated. Catalytic reduction of each isomer gave AIC ribonucleoside (XVIa) and its isomer, 4-amino-1-(β-D-ribofuranosyl)imidazole-5-carboxamide (XXa). Methylation of the silver salt of the nitro amide (VII) gave the 1-methyl derivative (XVb)

(32, 33) and its isomer (XIXb), which was also prepared from XVIIIb (32); catalytic reduction of XVb afforded 1-methyl-AIC (XVIb).

Several findings on alkylation of these nitroimidazoles are germane to aminoimidazoles because of their potential or actual precursor role. Methyl 1-methyl-4-nitroimidazole-5-carboxylate (XVIIIb) was the only reported product of methylation of the silver salt of VI (32, 33); the nitro styryl derivative (IV), like VII, gave a mixture of *N*-methyl isomers (32), and alkylation of the sodium salts of IV and its 2-methyl derivative gave mixtures of isomers (15). Ikehara *et al.* (47) isolated XVIIIa tribenzoate as the main product of glycosidation of the chloromercury derivative of VI with 2,3,5-tri-*O*-benzoylribofuranosyl chloride and, in contrast, 4-methyl-5-nitro-1-β-D-ribofuranosylimidazole tribenzoate as the main product (44%) of glycosidation of 4-methyl-5-nitroimidazole (III). These results suggest either that the position of attack varies with the type of nitroimidazole substrate, the alkylating agent, and the conditions or that the methods of isolation or detection sometimes failed to reveal a second isomer.

In another synthesis of aminoimidazole nucleosides *via* glycosidation of nitro derivatives, more conclusive evidence of the position of predominant attack was obtained. Rousseau *et al.* (48, 49) employed an acid-catalyzed fusion procedure to glycosidate VI and 4-bromo-5-nitroimidazole with tetra-*O*-acetyl-β-D-ribofuranose. The *O*-triacetyl derivative of XVIIIa was obtained in 83% yield, and the isomer could not be detected chromatographically. Although 4-bromo-5-nitroimidazole is not a product of the Windaus–Langenbeck route, it may be appropriate at this point to note that benzylation of this compound in solution (DMF) afforded a 78% yield of the derivative (XXIa) with the alkyl group adjacent to the bromo group⁶ (50) and that 5-bromo-4-nitro-1-(2,3,5-tri-*O*-acetyl-β-D-ribofuranosyl)imidazole (XXIb) was isolated in 72% yield from the acid-catalyzed fusion procedure (49), whereas less than a 5% yield of the isomeric ribofuranoside could be isolated. The amino derivatives, XXIIIa (50) and XXIIIb (48, 49), were obtained in yields of 99 and 87%, respectively, by catalytic hydrogenation of the nitro derivatives (XXII); similarly, XXa was obtained in high yield from XVIIIa triacetate by the sequence consisting of amination of the ester group, deacetylation, and catalytic hydrogenation (49).

Another synthesis of aminoimidazolecarboxylic acid derivatives originated soon after the Windaus–Langenbeck route and produces structures related to those just discussed. In a sequence (Scheme II) of high-yielding steps (XXIV–XXVII, XXX), Sarasin and Wegmann (51) converted 5-chloro-1-methylimidazole (XXIV, R₁ = R₂ = H) to 4-amino-1-methylimidazole-5-carboxamide (XXX, R = R₁ = R₂ = H). The total synthetic route begins with the Wallach imidazole-ring formation (52, 53) from an *N,N'*-dialkyloxamide (XXXIII) and results in the introduction of a substituent on the imidazole-ring nitrogen adjacent to the car-

⁶ Benzylation of the sodium salt gave a mixture of approximately equal amounts of the isomers.

boxyl-type group (*cf.*, XVII–XX, XXII, XXIII) rather than at the position of the ribofuranosyl group in the biosynthetic imidazoles. In its most general form, the route is represented by XXIV–XXXII (Scheme II). Although hydrolysis of the amides (XXVII) to acids (XXVIII) is difficult, Mann and Porter (54) introduced a modification that gave high yields of the carboxylic acids (XXVIII) (*cf.*, 55). From the acids, *N*-substituted amides (XXXI, R_1 and $R_2 = H$ or CH_3) (54–56), nitro esters (54), and a hydroxamic acid (57) have been prepared *via* acid chlorides. Originally, the nitro group of XXVI and XXVII was reduced chemically (tin and hydrochloric acid) (51, 55, 58, 59), but catalytic reduction to amino amides (XXX) (54, 56, 60–62), esters (XXXII, $R_1 = R_2 = H$) (54), and carbonitriles (XXIX) (60) is superior. However, incomplete reduction of the nitro group of 1-methyl-4-nitroimidazole-5-carbonitrile (XXVI, $R_1 = R_2 = H$) to an hydroxyl-amino group has been observed (63). The aminoimidazole derivatives resulting from most of these investigations (51, 54, 56, 58–64) were employed as intermediates for the synthesis of *N*-alkylpurines.

Recent investigations (61, 62, 65, 66) have extended the scope of and have clarified the reaction of oxamides with phosphorus pentachloride, the initial step of the overall synthesis of the amino amides (XXX). The isomers isolated have always been the 5-chloroimidazoles (51, 58, 61, 62, 67). In the recent study of several products by Trout and Levy (62), vapor-phase chroma-

In XLV–XLIX, $A = H, CH_3, C_6H_5, -COOC_2H_5$, or $-CONH_2$ and $R_1 = H, CH_3, C_6H_5, -COC_6H_5, -COOC_2H_5$, but not in all possible combinations.

Scheme IV

tography and TLC failed to reveal any of the 4-chloro derivatives. An unsymmetrical oxamide (XXXIII) (Scheme III) gave two separable 5-chloro-1,2-dialkylimidazoles (XXXIV and XXXV) (61). Several 4-amino-1,2-dialkylimidazole-5-carboxamides (XXX) were prepared by the Sarasin–Wegmann route (XXIV–XXVII, XXX)

in the course of these studies (61, 62) and used for the synthesis of purines (64).

5-Chloro-1-methyl-4-nitroimidazole (XXV, $R_1 = R_2 = H$) (51, 67) has also served as a starting point for the synthesis of some 4-amino-1-methylimidazole-5-sulfonamides (68, 69).

B. From α -Aminonitriles (Cook-Heilbron and G. Shaw Methods)—Synthetic routes that begin with α -aminonitriles were pioneered by Cook, Heilbron, G. Shaw, and coworkers and have proved to be exceptionally important in syntheses of 5-aminoimidazoles (XXXVI–XLII), including the nucleotides of the biosynthetic pathway (Part III). In the first route (Scheme IV) (70–75), reactions of isothiocyanates (XLV) with α -aminonitriles (XLVI) produce 2,5-diaminothiazoles (XLVIII) *via* thioureas (XLVII), which may or may not be isolated. Under the influence of mild aqueous base, these 5-aminothiazoles rearrange to 5-amino-2-mercaptoimidazoles (XLIX, or the tautomeric 5-amino-2-thioxoimidazolines). The group (R_1) at position 1 is derived from the isothiocyanate, whereas the substituent (A) at position 4 is that present on the α -carbon atom of the aminonitrile. When an acylisothiocyanate is one of the reactants, the acyl group appears on the 5-amino group of the imidazole derivative (L). Presumably, the 1-acylimidazole is first formed, and then acyl migration occurs under the influence of the basic conditions of the thiazole \rightarrow imidazole rearrangement (70). The mercapto (or thioxo) substituent at position 2 may be removed by Raney nickel desulfurization (71–73), or it may be alkylated to afford compounds such as 2-(methylthio) and 2-(benzylthio) derivatives (75, 76). This synthetic route has produced 5-aminoimidazoles devoid of a functional substituent at position 4 (71–73), 5-aminoimidazole-4-carboxylic acid esters (73), or 5-aminoimidazole-4-carboxamides (73–75) with (XLIX, L) or without (LI, XXXVI–XXXVIII with $R_2 = H$) a sulfur function at position 2. Treatment of a thiazole ester (XLVIII; $A = COOC_2H_5$, $R_1 = CH_3$) with ammonia and subsequent desulfurization also gave amides, 1-methyl-2-mercapto-AIC and 1-methyl-AIC (XVIb or XXXVIII; $R_1 = CH_3$, $R_2 = R' = H$) (73). Recently, 2-mercapto-AIC was prepared by the route XLV–XLIX (77) (see last paragraph of this section).

In a second route (Scheme V) (70, 74, 78, 79) based on α -

Scheme V

aminonitriles, the imidazole ring is formed by interaction of an amidine (LIIa), an imidic acid ester (imide) (LIIb), or an imidic acid thioester (thioimide) (LIIc) with an appropriate α -aminonitrile (XLVI). This type

of reaction produces 2-substituted derivatives and may be visualized as proceeding through an intermediate amidine (LIII). Again, the 5-amino group and the 4-substituent are furnished by the α -aminonitrile; the substituent at the 2-position is determined by the structure (LII) of the amidine or imidic acid derivative. This method was responsible for an early synthesis (74) of AIC from formamidine (LIIa, $R_2 = H$). Soon after its role in purine biosynthesis had been discovered, AIC labeled at the 5-position with ^{14}C was prepared (80, 81) (*cf.*, Part IIC) from ethyl formimide (LIIb, $R' = C_2H_5$) and labeled 2-aminocynoacetamide (XLVI, $A = CONH_2$). Thioimide (LIIc) hydrochlorides were considered (79) to give more satisfactory results in this type of synthesis, and they were utilized in the preparation of a considerable number of 5-aminoimidazoles (XXXVI; $R_1 = H$, $R = \text{hydrogen, alkyl, or aryl}$) (79, 82, 83), 5-aminoimidazolecarboxylates (XXXVII; $R_1 = H$, $R' = C_2H_5$) (79, 82, 83), and 5-aminoimidazole-4-carboxamides (XXXVIII; $R_1 = R' = H$) (74, 84) with several different substituents at position 2. Several reported observations are of interest in the light of subsequent syntheses of this type: (a) the imidates (LIIb) were used as free bases (79–81); (b) the thioimide (LIIc) hydrochloride sometimes failed to give imidazoles (or gave low yields) owing, apparently, to replacement by the α -aminonitrile of the imino group rather than the thioether group (82, 83); and (c) an intermediate imide (LIV; $R_2 = C_6H_5CH_2-$, $A = -COOC_2H_5$), rather than an imidazole, was obtained when an equivalent of acid was present during the reaction of ethyl aminocynoacetate with a starting imide (LIIb; $R_2 = C_6H_5CH_2-$, $R' = C_2H_5$).⁷ More recently, bicyclic compounds that are 1,2-disubstituted AIC derivatives by virtue of ring fusion at positions 1 and 2 of the imidazole ring have been synthesized from cyclic imidates and aminocynoacetamide (85–90). These reactions of *N*-substituted imidates were usually performed in the presence of a catalytic amount of acid.

By preparing intermediate linear imidates (LIV), either in the isolated form or in solution, G. Shaw and coworkers (91–95) added an extra dimension of versatility to this method of synthesis. The general route (Scheme VI) is shown by Structures LIIb, XLVI,

Scheme VI

LIV, and XXXVI–XLII. As before, the starting imide supplies the carbon atom at position 2 with its sub-

⁷ Observations by Abraham, Baker, Bartrop, Chain, Waley, and Robinson cited in Reference 79.

stituent, but a primary amine (LV), or ammonia, then completes the imidazole ring by furnishing the nitrogen atom at position 1 with its substituent. The amidine (LVI) may be assumed to be an intermediate in this process (Scheme VI). Thus, appropriate choices of α -aminonitriles, imidates, and primary amines permit, in the absence of complications in specific cases consequent to the use of such sensitive intermediates, the introduction of various substituents at positions 1, 2, and 4 of 5-aminoimidazoles. From such linear imidates (LIV) and primary amines or ammonia, 1-alkyl and 1,2-dialkyl 5-aminoimidazoles (XXXVI, $R = H$) (92), 1-substituted and 1,2-disubstituted derivatives of AIC (XXXVIII, $R' = H$) and of its *N*-methylamide analog (XXXVIII, $R' = CH_3$) (91, 92, 96, 97), and 1-substituted 5-aminoimidazole-4-carboxylic acid esters (XXXVII, $R_2 = H$) (95) have been synthesized. Included among the AIC derivatives prepared by the Shaw method were 1,1'-bis derivatives (97) joined by an alkylene chain. When the primary amines were replaced in the synthetic sequence by hydrazine, a substituted hydrazine (LV, $R_1 = R''R'''N-$), or a semicarbazide, then 1,5-diaminoimidazoles (XL, XLI) were obtained (94, 97). Moreover, beginning the sequence with α -aminocyanothioacetamide (XLVI, $A = -CSNH_2$) produced thioamide analogs of AIC (XXXIX) (93), which have also been prepared by thiation of amides or addition of hydrogen sulfide to nitriles (Part IIF). The synthesis of the thioamides was sometimes frustrated by thiazole formation and other complications, but these difficulties could be circumvented by choosing specific esters of imidic acid hydrochlorides as reactants with aminocyanothioacetamide. Thus, benzyl acetimidate hydrochloride produced 2-methyl derivatives (XXXIX, $R_2 = CH_3$), whereas isopentyl formimidate (but not certain other formimidic acid esters) gave thioamides unsubstituted ($R_2 = H$) at position 2. (However, in a nonaqueous solvent the isopentyl ester gave a thiazole.) The formation of 5-amino-2-methylimidazole-4-thiocarboxamide (XXXIX; $R_1 = H$, $R_2 = CH_3$) from ethyl acetimidate free base is consistent with earlier observations (79) that imidate free bases and α -aminonitriles form 5-aminoimidazoles without a requirement for added ammonia. Only recently, after aminomalononitrile (XLVI, $A = CN$) became available as a result of studies related to prebiological syntheses (Part IID), has a carbonitrile (XLII) been synthesized by this route (96).

Representatives and derivatives of the general structures XXXVI-XLIV were synthesized during the course of these studies from aminoimidazoles obtained from the basic routes. Thus, carbonitriles (XLII) were also prepared by dehydration of some 1-alkyl- and 1,2-dialkyl-AIC derivatives with pyrophosphoryl chloride (96). Earlier, representatives of XLII had been obtained by treating thioamides (XXXIX) with mercuric chloride and methylamine (93). 1-Cyclohexyl derivatives of XXXVIII (1-cyclohexyl-AIC and some of its *N*-alkyl derivatives), as well as an analogous *N,N*-disubstituted amide, were synthesized from 1-cyclohexyl-AI-COOH by the active ester, mixed anhydride, or dicyclohexylcarbodiimide methods of peptide syn-

thesis (98, 99). Since the ultimate aim of much of the earlier work on the routes from α -aminonitriles was the synthesis of purines, further transformations of the initially obtained aminoimidazole derivatives were directed toward that end. Conversion of the amino group to ureido and to thioureido groups with isocyanates and isothiocyanates, respectively, afforded urea and thiourea derivatives (XLIII, XLIV) (70, 73, 75, 78, 79, 82, 83, 100-102) for cyclization to purines. Alkylation of the imidazole ring with diazomethane, methyl iodide, or methyl sulfate gave some 1-methyl-4-aminoimidazoles (XLIV, $X = H$) (101, 102) for the preparation of *N*-alkylpurines *via* urea or thiourea derivatives.

The linear imidates (LIV, $A = COOCH_3$ or $CONH_2$) derived from methyl α -aminocynoacetate or α -aminocynoacetamide served not only as sources of alkyl and aryl derivatives but also as precursors of the biosynthetic ribonucleotides (Part III) and the corresponding ribonucleosides. Interaction of the appropriate linear imidate and 2,3,5-tri-*O*-benzoylribofuranosylamine (LVIIa) (103) gave, after removal of protecting groups, AIC ribonucleoside (XVIa) (92) and the methyl ester of AI-COOH ribonucleoside (95, 104). Although 5-aminoimidazole-4-carboxylic acids readily undergo decarboxylation in the acid form, AI-COOH ribonucleoside could be obtained as its calcium salt (95) or the pyridine salt of its isopropylidene derivative (LVIIIa) (98) after alkaline hydrolysis of derivatives of the ethyl or methyl esters. AIC ribonucleoside was also prepared (105) by amidation of the isopropylidene derivative (LVIIIb) (95, 104, 105) of AI-COOCH₃. The ribofuranoside analogs, 1-galactosyl-2-methyl-AI and 2-methyl-1-xylopyranosyl-AIC, were synthesized from glycosylamines and linear imidates (LIV) (92).

The ribonucleotides were first synthesized *via* the linear imidate method (*cf.*, Part IIE) by phosphorylating the 5'-hydroxyl group of isopropylidene derivatives of the nucleosides with 2-cyanoethylphosphate and dicyclohexylcarbodiimide (106) or with pyrophosphoryl chloride (107). Thus, phosphorylation of the isopropylidene derivative (LVIIIb) of AI-COOCH₃ ribonucleoside and subsequent removal of protecting groups led to the isolation of AI-COOH ribonucleotide (Part III) (95, 104) and its methyl ester (105) in the form of their barium salts. Succino-AICAR (Part III) was then synthesized in 15% yield from LVIIIb by a sequence of operations consisting of coupling the pyridine salt of LVIIIa with dimethyl aspartate in the presence of dicyclohexylcarbodiimide, phosphorylation, removal of protecting groups, and purification by ion-exchange methods (98, 108). Subsequently, this sequence of steps was employed for the preparation of analogs of succino-AICAR in which the aspartyl moiety is replaced by other amino acid residues (LIX) (109); a similar sequence of steps that began with the pyridine salt of LVIIIa and proceeded *via* active esters—the 2,4-dinitrophenyl and the pentachlorophenyl esters (LVIIIc, LVIIId)—also produced succino-AICAR (99). From nucleosides obtained by the linear imidate method, AICAR (Part III) was prepared by the following methods (99, 105) (including the usual deblocking and purification operations): (a) phosphorylation of

b, X = S

LVIIIb followed by amidation (40–50% yield) of the ester group with ammonia; (b) phosphorylation of the 2',3'-O-isopropylidene derivative of AIC ribonucleoside; (c) amidation of the pyridine salt of LVIIIa with ammonia in the presence of dicyclohexylcarbodiimide; and (d) phosphorylation of the active ester LVIIIc followed by amidation. Method *a* is apparently superior to the other three methods. Subsequently, it was found (96) that the major product of phosphorylation of isopropylidene AIC ribonucleoside with pyrophosphoryl chloride is, after deblocking, AI-CN ribonucleotide (LXIa) formed by concomitant dehydration of the amide group. As mentioned, alkyl derivatives of AIC were similarly dehydrated to nitriles. The last method (*d*) applied in the reverse order, *i.e.*, amidation followed

by phosphorylation, also yielded the *N*-methyl (LXIb) and *N,N*-diethyl (LXIc) analogs of AICAR (99).

After some of these syntheses of ribonucleotides from ribofuranosides had been performed, 2',3'-O-isopropylideneribosylamine 5'-phosphate (LVIIIb) was synthesized (110, 111) and used for syntheses of imidazole ribonucleotides directly from the linear imidate intermediates. The ribonucleotides of AIC and AI-COOCH₃ were obtained from reactions of LVIIIb with LIV (A = —CONH₂ or —COOCH₃) (110, 111), and 2-methyl-AIC ribonucleotide (LXIc) was similarly formed in very low yield (111).

A synthesis of 2-hydroxy-AIC (or the tautomeric 5-amino-2-oxoimidazoline-4-carboxamide, LXIIa) and of ¹³C-labeled LXIIa is similar to the thiourea-thiazole method of Cook, Heilbron, and coworkers. The urea (LXI) obtained from aminocynoacetamide (XLVI, A = —CONH₂) cyclized in aqueous base to LXIIa (112). The analogous 2-mercapto-AIC (LXIb), mentioned previously, was formed from XLVI and potassium thiocyanate in acidic solution without identification of intermediates (77).

C. From Aminomalonic Acid Derivatives (E. Shaw Method)—Soon after AIC had been identified as a biologically significant compound, E. Shaw and Woolley (113) devised a new synthesis (Scheme VII) that is also applicable to similar aminoimidazoles. The basic intermediate is a three-carbon unit, typified by malonamimidine (LXIII, X = O), obtainable from nitriles such as ethyl cyanoacetate and malononitrile. The 2-amino group is introduced by coupling an aryldiazonium salt at the active methylene group of LXIII and reducing the resulting azo derivative (LXIV). Reduction with zinc in formic acid affords a formamide derivative (LXVI, R₂ = H) that can be thermally cyclized to the imidazole (LXVII). In this way, AIC was synthesized (Scheme VII) from malonamimidine (LXIII, X = O) (113), and the analogous carboxamidine (LXVII; R₂ = H, X = NH) was prepared from malonodiamidine (LXIII, X = NH) (114). Both gave formyl derivatives (LXVIII) on treatment with formic acid and acetic anhydride (114). Similarly, from ethyl chloroformate and aminomalonodiamidine (LXV, X = NH), which was isolated by substituting hydrochloric acid for formic acid in the reduction of the phenylazo derivative (LXIV), 5-amino-2-hydroxyimidazole-4-carboxamidine (LXVII; R₂ = OH, X = NH) was obtained (Scheme VII) (115), and radioactive AIC labeled with ¹⁴C at position 5 was synthesized (116) by the E. Shaw route (see Part IIB for labeled AIC). The phenylazo derivative (LXIV) can also be reduced catalytically (117), and the cyclization of LXVI (R₂ = H, X = O) is more conveniently effected in refluxing formic acid (117) or with triethyl orthoformate (118, 119). 5-Formamidoimidazole-4-carboxamide (LXVIII, X = O) obtained by the first modification of the procedure is easily hydrolyzed to AIC.

The adaptability of the method for the introduction of other substituents was demonstrated with syntheses of *N*-benzyl-AIC from *N*-benzyl cyanoacetamide *via* LXIX with R₁ = H and R = benzyl (120); 2-methyl-AIC *via* LXVI (R₂ = CH₃) by substituting acetic acid for formic acid in the reduction (121); and the

Scheme VII

N-benzylamidine (LXIX; R = H, R₁ = benzyl) analog of LXVI. Intermediates of the latter type can cyclize to either a 1-substituted AIC (LXX) or to an AIC substituted on the amino group (LXXI). Either of the two benzyl AIC derivatives could be obtained as the major product by properly choosing the reaction conditions (122). A further modification by Richter *et al.* (118) yields 2-substituted AIC derivatives. The reaction of aminomalonamidine dihydrochloride (LXV, X = O) (112, 113) with a molar equivalent of an orthoester gives a 2-substituted AIC derivative (LXVII); an excess of the orthoester produces an alkoxy alkyl (or aryl) methyleneamino derivative (LXXII), which can

Scheme VIII

be cyclized to a purine or hydrolyzed to the AIC derivative (LXVII).

Another route (Scheme VIII) (123, 124) to AIC that begins with malononitrile and proceeds through oximinomalonodiamidoxime (LXXIII) (125) is essentially a variation of the E. Shaw method. Nitrosation, rather than azo coupling, provides the precursor group at the 2-position, and reaction of hydroxylamine at the nitrile groups then gives the three-carbon unit (LXXIII) similar to LXIV. Reduction of LXXIII with zinc and formic acid gives formyl-AIC (LXVIII). Alternatively, the furazan (1,2,5-oxadiazole) (LXXIV) (125) may be prepared from LXXIII and aqueous base (or from malononitrile without isolating LXXIII) and converted to formyl-AIC by treatment with formic acid and reduction with zinc-formic acid (123). Reduction of other furazans or furazanopyrimidines obtained from LXXIV also gave 5-formamidoimidazole-4-carboxamide (LXVIII) (123).

D. From Hydrogen Cyanide—Interest in prebiotic synthesis of purines stimulated investigations of simple precursor molecules that give rise to adenine (126, 127). Oró and Kimball (128) proved that AIC and 5-aminoimidazole-4-carboxamide (LXVII; X = NH, R₂ = H) (AI-amidine), as well as formamidine, were among products formed from hydrogen cyanide and aqueous ammonia. They proposed (128, 129) a multi-step route to these compounds which included formamidine and 2-aminomalononitrile, a hydrogen cyanide trimer. Ferris and Orgel (130, 131) succeeded in preparing the long-sought (*e.g.*, 75, 132) aminomalononitrile (LXXV) and showed that interaction of this compound with formamidine in ethanol did, indeed, give an imidazole, 5-aminoimidazole-4-carbonitrile (LXXVI, AI-CN), which was isolated in 35% yield⁸ (Scheme IX). This imidazole can be hydrolyzed to AIC

Scheme IX

(131, 133, 134) or prepared from it by dehydration with thionyl chloride in pyridine (130, 131) or with phosphorus oxychloride (135).

However, aminomalononitrile also reacted with cyanide in aqueous solution (130, 131) to give the more stable hydrogen cyanide tetramer, diaminomaleonitrile

⁸ This reaction is the same type as the Cook-Heilbron synthesis of AIC (74) (Part IIB).

(LXXVII) (136–138 and references cited), and both the tetramer and AI-CN were stated to be among the products of Oró's hydrogen cyanide–aqueous ammonia reactions (130, 131). Further studies (133, 139) showed that the yields of AI-CN were 5–50%, depending on reaction conditions, from formamidine and aminomalononitrile in *aqueous* solutions; that reaction of the latter compound with cyanide to the tetramer (LXXVII), however, was faster and proceeded in yields of 60–80%; that the tetramer also produced very low yields of AI-CN, AIC, and AI-amidine by reaction with formamidine; and that formation of the tetramer and its subsequent reaction with formamidine could be responsible for AI-CN, AIC, and the amidine formed in solutions of HCN and aqueous ammonia. In dilute aqueous solutions, the tetramer was converted photochemically *via* its *trans*-isomer (139, 140) to AI-CN in yields as high as 80% (139). (However, AI-CN is subject to photochemical degradation, and the yields quoted were determined by analytical methods.) As a result of these studies, the proposed steps in the pathway from hydrogen cyanide and ammonia to imidazoles and purines were revised to place greater emphasis on the role of the tetramer (LXXVII) (139, 141, 142).

Since the aim of these studies was to demonstrate the formation of purines under postulated primitive earth conditions, much of the work was performed with dilute aqueous solutions; yields were only of secondary importance. Wakamatsu *et al.* (143) and Yamada *et al.* (144, 145) then found, however, that anhydrous solutions of ammonia and hydrogen cyanide (or sodium cyanide and ammonium chloride) yield adenine and imidazole-4,5-dicarbonitrile (LXXVIIIa) in addition to the tetramer (144) and a pyrimidopyrimidine (146). Yields of LXXVIIIa, determined analytically, under optimal conditions were only about 20% (144), but the starting materials are simple. In anhydrous ammonia, the formation of LXXVIIIa from the tetramer was attributed to reversion of the tetramer to aminomalononitrile (146).

Prior to these studies of either the aqueous or the anhydrous ammonia–hydrogen cyanide systems, the tetramer (LXXVII) had been converted to imidazole-4,5-dicarbonitriles (LXXVIIIa–c) with triethyl orthoesters (147), to the 2-oxoimidazoline (LXXVIIId, OH-tautomer) with phosgene (148), and to LXXVIIIb with ethyl acetimidate (149). The relevance of the formation of dinitriles from hydrogen cyanide or its oligomers to aminoimidazoles is that AI-CN and AIC were prepared from LXXVIIIa in good yields by the following sequence of steps: partial hydrolysis to the monoamide (LXXIX) (150, 151), a Hofmann hypobromite reaction to AI-CN (150, 152), and alkaline hydrolysis to AIC (150 and references already cited). AI-CN, LXXVIIIa and its 1-substituted derivatives, and other dicarbonitriles derivable from hydrogen cyanide or its oligomers are potential precursors of other aminoimidazole derivatives (153–155).

E. By Ring Cleavage of Purines—Much of the early work on 5-amino-4-substituted imidazoles was motivated by plans to form a pyrimidine ring from the substituents and, thereby, to produce purines. The reverse process, cleavage of the pyrimidine ring of purines, has

furnished 5-aminoimidazole-4-carboxylic acid derivatives and has become increasingly important as a route to these compounds. Imidazoles obtained by this method have sometimes been formed inadvertently during studies of purines, sometimes as a means of establishing the structure of certain purines, and sometimes by design. The formation of imidazoles from purines is part of the larger area of pyrimidine-ring cleavage and rearrangement reactions of fused pyrimidine heterocycles such as pteridines, quinazolines, 8-azapurines, and thiadiazolopyrimidines. The products of cleavage of these ring systems are usually similar in structure to the aminoimidazolecarboxylic acid derivatives under consideration here. Correlation of findings from these areas is obviously beyond the scope of this review. The following discussion simply narrates the historical highlights and attempts to record most of the known examples of formation of derivatives of the aminoimidazolecarboxylic acid-type from purines.⁹

The action of barium, sodium, or potassium hydroxide solutions on the methylated purines (caffeine, theophylline, and theobromine) provided the first

⁹ Demonstrations of the formation of imidazoles by ring opening of purines have not always included isolation, nor have the yields always been of practical significance.

examples of this method of synthesis. Caffeidine [1, *N*-dimethyl-4-(methylamino)imidazole-5-carboxamide] (LXXXa) was obtained from caffeine (LXXXIII, R₂ = H) (156–158 and earlier references cited in these publications) and from 8-carbamoylcaffeine (LXXXIII, R₂ = CONH₂) (159). The initial products resulting from alkaline degradation of caffeine, 8-carbamoylcaffeine, and 1-ethyltheobromine (160) were believed to be the carbamic acids (LXXXIIa) (158, 161). Later, thiocaffeine and theophylline (LXXXIV, R₁ = R₂ = H) were degraded by alkaline conditions to thiocaffeidine (LXXXb) (162) and to theophyllidine (LXXXIa) (163), respectively. More recently, some isocaffeines (LXXXIV, R₁ = CH₃) were similarly cleaved to 1, *N*-dimethyl-5-(methylamino)imidazole-4-carboxamides (LXXXIb) (164), and some 7- and 8-substituted theophyllines produced (165) 1-substituted *N*-methyl-4-(methylamino)imidazole-5-carboxamides (LXXXIIb) and a 2-substituted theophyllidine (LXXXIc), respectively (165). Certain 2-substituted theophyllidines (LXXXId) (165) were also obtained from 2-nitrotheophyllidine. Methylation (55, 158, 166) and ethylation (156) of caffeidine gave dialkylamino derivatives (LXXXIIc), and the methylamino group of LXXXa was converted to benzoyl, urea, and nitroso derivatives (158). Caffeidine has also been transformed to its methyl ester analog *via* the formyl derivative of its methylamino group and the nitroso derivative of its amide group (167).

Purines not substituted on the ring-nitrogen atoms are ionizable in alkaline media. The anion formed is then stabilized to attack by nucleophiles. In the methylated derivatives just discussed, the two carbonyl groups in the pyrimidine ring, as well as the *N*-alkyl substituents,

contribute to labilization of the purine system. During the year that the degradation of theophylline was recorded, the initial reports (120, 168) of the extensive investigations of purine *N*-oxides by Brown (169) and coworkers and of the purposeful labilization of the purine ring by E. Shaw appeared. These series of publications served to emphasize the potential utility of purines substituted on ring-nitrogen atoms for imidazole formation. Prior evidence, to be presented, by Baker and Joseph (170) of the increased susceptibility of nitrogen-substituted purines to ring opening may have gone unrecognized because of the specialized (cyclonucleoside) structure.

E. Shaw synthesized (Scheme X) AIC ribonucleoside (*cf.*, Parts IIA and IIB) from inosine (LXXXV; R = R₂ = H, R₁ = β-D-ribofuranosyl) or its triacetate by first labilizing the pyrimidine ring by placing a substituent (R) at position 1. The first method (120) consisted of alkaline ring cleavage of 1-benzylinosine and removal of the benzyl group of *N*-benzyl-AIC ribonucleoside (LXXXVIa) with sodium and liquid ammonia. The overall yield suffered because of the difficulty of the debenzylation step. The second method (171) consisted of tosylation of inosine triacetate, alkaline ring opening of 1-(*p*-toluenesulfonyl)inosine triacetate, hydrazinolysis of the resulting *N*-(*p*-toluenesulfonyl)-AIC ribonucleoside (LXXXVIb), and reductive fission of the acid hydrazide (LXXXVIc) to the amide (AIC ribonucleoside). A third method (172) gave AIC ribonucleoside from inosine triacetate and AICAR from the di(*p*-nitrophenyl) ester of the 2',3'-*O*-isopropylidene derivative of inosinic acid [inosine 5'-(dihydrogen phosphate) or IMP, Part III] as follows: the methoxymethyl group was introduced at position 1, the pyrimidine ring was again opened under alkaline conditions, the labilizing methoxymethyl group was simultaneously removed hydrolytically from the carboxamide group of LXXXVIa and of the dinitrophenyl isopropylidene derivative of LXXXVIe, and the protecting groups were removed. This method constituted the first chemical synthesis of AICAR. The β-alanine analog (LXXXVIg) of succino-AIC ribonucleotide was similarly prepared by employing the principle of ring labilization (173). Inosinic acid was alkylated with propiolactone at position 1 by careful control of the pH; alkaline ring opening of 1-(2-carboxyethyl)inosinic acid then gave LXXXVIg.

Other aminoimidazolecarboxamides have been formed by alkaline cleavage of substituted hypoxanthines—mostly 1-substituted derivatives—as follows: 1, *N*-dibenzyl-AIC (LXXXVIg) (174) from 1,9-dibenzylhypoxanthine (LXXXV; X = O, R = R₁ = benzyl, R₂ = H); 4-amino-1, *N*-dibenzylimidazole-5-carboxamide (LXXXIIId) from 1,7-dibenzylhypoxanthine (175); the ethoxymethylene derivative of *N*-methyl-AIC ribonucleoside (LXXXVIh) (176) from the corresponding 1-methylinosine; several glucopyranosyl-AIC derivatives (LXXXVIIi, LXXXIIe) (175) from various glucopyranosylhypoxanthines; and 5-(methylamino)imidazole-4-carboxamide (LXXXIIIf) (177) from 3-methylhypoxanthine, 3-methyladenine, or 6-(dimethylamino)-3-methylpurine. The last two purines may have been converted to 3-methylhypoxan-

thine prior to ring opening. Cleavage of hypoxanthinium salts is outlined near the end of this section (IIE).

In addition, ring opening of certain purine-6(1*H*)-thiones (LXXXV, X = S) (6-mercaptapurines) has resulted in imidazole formation. 1-Benzyl-9-β-D-ribofuranosylpurine-6(1*H*)-thione, the sulfur analog of 1-benzylinosine, was cleaved to AI-CSNHCH₂C₆H₅ ribonucleoside (LXXXVIj) (178); 1-methylpurine-6(1*H*)-thione (LXXXV; R = CH₃, R₁ = R₂ = H) gave AIC on treatment with aqueous ammonia (179); and 5-formamido-1-β-D-ribofuranosylimidazole-4-thio-carboxamide 5'-(dihydrogen phosphate) (formyl-thio-AIC ribonucleotide, LXXXVIk) was reported (180) to be formed from 6-mercaptapurine ribonucleotide pyridinium salt.

As mentioned, initial investigations of purine *N*-oxides and 1-substituted hypoxanthines were reported almost simultaneously. Although the isolation of 4-guanidinoimidazole after vigorous acidic hydrolysis of guanine (181) and of AIC after treatment of hypoxanthine with zinc and sulfuric acid (182) has been reported, acidic ring cleavage of the common purines unsubstituted on ring-nitrogen atoms usually results in extensive degradation (183, 184 and references cited). However, under milder, but still strenuous, conditions, it was possible to isolate 5-aminoimidazole-4-carboxamide (LXXXVIIa) in 10% yield by acidic hydrolysis of adenine (183). In contrast, the oxide of adenine prepared by Stevens and Brown (168) was cleaved under much less vigorous conditions to 5-aminoimidazole-4-carboxamidoxime (LXXXVIIIa) in yields in excess of 75% (168, 185). This reaction established the structure of the oxide as adenine 1-*N*-oxide (LXXXIXa); catalytic reduction of the carboxamidoxime produced the amidine (LXXXVIIa) (*cf.*, Parts IIC and IID), and hydrolysis gave AIC. Formation of the amidoxime by acidic ring opening of 2-methyladenine 1-*N*-oxide (LXXXIXb) (186) and of the 2', 3', and 5'-phosphates of adenosine 1-*N*-oxide (LXXXIXc) (with the expected concomitant loss of the ribofuranosyl group) was also demonstrated (187). Ring cleavage of adenosine 1-*N*-oxide and its 2', 3', and 5'-phosphates by aqueous sodium hydroxide produced, respectively, the ribonucleoside (LXXXVIIIb) and the 2', 3', and 5'-phosphates of LXXXVIIIb (187).

Cleavage of 1-*N*-oxides by acetic anhydride apparently proceeds through the initial acetylation of the *N*-oxide group (186). Adenine 1-*N*-oxide and 2,6-diaminopurine 1-*N*-oxide were cleaved by refluxing acetic anhydride, and an oxadiazole ring was formed by the reagent; the product was a 3-(5-acetamidoimidazol-4-yl)oxadiazole (XCa), which was obtained also from LXXXVIIIa and acetic anhydride. The 2-acetoxy derivative (XCb) was likewise formed from 8-hydroxyadenine 1-*N*-oxide. Under milder conditions the product obtained from adenine 1-*N*-oxide was the formamide (XCc), and XCc was evidently formed from it by an acyl-exchange reaction. Both XCc and XCb were hydrolyzed under acidic conditions to the 5-aminoimidazole derivatives (XCd and XCe) (186). In other studies of purine oxides, 4-acetyl-5-aminoimidazole was obtained by acid hydrolysis of 6-methylpurine

1-*N*-oxide (188); the amidoxime (LXXXVIIIa) and AIC were minor components of the acid hydrolysate of 1-hydroxyisoguanine (189); 5-chloro-AIC was one of several products of the action of hydrochloric acid on hypoxanthine 3-*N*-oxide (190); and 1-β-D-ribofuranosyl - 5 - ureidoimidazole - 4 - carbonitrile (XCIIa) was one of the products isolated, in low yield, after photolysis of adenine 1-*N*-oxide (191).

Syntheses of imidazoles from purine *N*-oxides and from purines having an alkyl group on a ring-nitrogen atom converged when the *N*-oxide group was alkylated to 1-alkoxy derivatives (XCI) (192, 193). As 1-substituted adenine derivatives, such compounds are highly susceptible to the well-known rearrangement, generally believed to involve ring opening and reclosure, that results in placing the 1-substituent on the 6-amino group. This reaction was, indeed, observed to occur with 1-alkoxyadenines (192). However, the substituted imidazolecarboxamidoxime (LXXXVIIIc) could be isolated in high yield by cleavage of XCIa in neutral solution at low temperature (192). Likewise, 1-benzyl-oxyadenosine (XCIIb) was cleaved in methanolic ammonia to a substituted imidazolecarboxamidoxime (LXXXVIIId) (193). Reductive removal of the benzyl-oxy group gave the amidine analog (LXXXVIIb) of AIC ribonucleoside, and diazotization of LXXXVIIb

Scheme XI

purines that can form such tricyclic compounds (XCVII, XCIII). Temple *et al.* (201–203), in a series of publications, described the synthesis of 4-aminoimidazol-5-yl-*s*-triazoles (XCVIII), 5-aminoimidazol-4-yl-*s*-triazoles (XCIX), and aminoimidazolyltriazoles (C and CI) by acid- or base-catalyzed ring cleavage. The presence of a benzyl group on one of the imidazole ring-nitrogen atoms may aid, but is not necessary for, opening of the pyrimidine ring. The aminoimidazoles represented by XCVIII and XCIX (201, 203) were obtained from appropriately substituted *s*-triazolo[3,4-*i*]purines (XCIV, XCV) or from the isomeric *s*-triazolo[5,1-*i*]purines (XCVI). Furthermore, the 6-hydrazinopurines from which the *s*-triazolo[3,4-*i*]purines were prepared also underwent ring cleavage to derivatives of type XCVIII or XCIX. When formic acid, diethoxymethyl acetate, or phosgene was the reactant, cyclization to an *s*-triazolo[3,4-*i*]purine may have preceded ring opening. But, when 7-benzyl-6-hydrazinopurine was converted to XCVIII ($R = \text{benzyl}$, $R_1 = X = \text{H}$) with mineral acid, prior formation of a tricyclic system was not possible. Similarly, the 5-[amino (or formamido)imidazoly]tetrazoles (C and CI) (202) were isolated in good yields by acidic or basic cleavage of the tetrazolopurines (CII), which are in tautomeric equilibrium with the 6-azidopurines (CIII) (Scheme XI).

Quaternized purines, positively charged in the purine ring, may be expected to be even more susceptible

provided a convenient synthesis of 2-azaadenosine. [2-Azaadenine 1-*N*-oxide and 2-azaadenosine 1-*N*-oxide had also been prepared (194) by diazotizing the amidoximes LXXXVIIIa, LXXXVIIIb.] At this point it may be recalled that ring fission of adenine 1-*N*-oxide by acetic anhydride, discussed previously, evidently proceeds *via* a 1-acyloxy derivative (186) analogous to the 1-alkoxyadenines.

Although 1-alkyladenines readily rearrange in basic media to 6-(alkylamino)purines, they may undergo cleavage to carboxamidines in acidic solutions. Brookes and Lawley showed that 5-amino-*N*-methylimidazole-4-carboxamide (LXXXVIIc) (195) and the *N*-benzyl derivative (LXXXVIIId) (196) are formed by acidic cleavage of 1-methyladenine and 1-benzyladenine, respectively. Acidic degradation of 1-methyladenosine and 1-benzyladenosine removed the ribofuranosyl group and gave the same carboxamidines (LXXXVIIc, LXXXVIIId) (196).

Cleavage of the pyrimidine ring of a cyclic adenine derivative (XCIIIa), formed from *N*⁶-glycyladenine, also occurs under acidic conditions (197). The ring-cleavage products isolated—and probably formed *via* 1-carboxymethyladenine (197, 198)—were the *N*-substituted amidine LXXXVIIe and AIC. Acidic hydrolysis of the related cyclic intermediate (XCIIIb) from *N*⁶-glycyl-9-methyladenine produced, among other products, a small amount of 1-methyl-AIC (XVIb) (199). An earlier acidic cleavage of *N*-(purin-6-yl)aspartic acid, the aglycone of adenylosuccinic acid (Part III), resulted in the formation of AIC and was postulated to involve a cyclic intermediate (200).

5-Aminoimidazol-4-yl heterocycles that are structurally similar to the imidazolyloxadiazoles (XC) already described have been obtained from purines to which a heterocyclic ring is fused at positions 1 and 6 (tricyclic heterocycles) (XCIV–XCVI, CII) or from

to nucleophilic opening of either the pyrimidine or the imidazole ring than are uncharged species. The studies of puromycin provided an example of pyrimidine-ring opening of a quaternary derivative. As mentioned, Baker and Joseph (170) found that the cyclonucleoside (CIVa) (Scheme XII) was easily cleaved by dilute base to CVa ($R_1 = CHO$). Further, mild basic treatment hydrolyzed the amidine and the formamide groups, yielding an AIC ribonucleoside analog (CVIa). Michelson (204) mentioned the formation of a similar amidine (CVb, $R_1 = H$) from the cyclonucleoside of 2',3'-isopropylideneadenosine (CIVb); Montgomery *et al.* (174) observed the formation of an *N*-benzyl-AIC ribonucleoside analog (CVIb) by facile ring cleavage of the isopropylidene-protected cyclonucleoside of 1-benzylinosine, a hypoxanthinium salt. Kusashio and Yoshikawa (205) isolated small amounts of CVIc and carbonitrile analogs of CVIc ($R_1 = CHO$ and H) during studies of the phosphorylation of 2',3'-*O*-isopropylideneinosine with phosphorus oxychloride containing a small quantity of water or with pyrophosphoryl chloride. These imidazoles were presumably formed from the cyclonucleoside of inosine. Montgomery and his coworkers (174, 206) also found that derivatives of aminoimidazolecarboxamides were formed from quaternary salts under mild conditions as follows: CVIIa and LXXXIIg from 1,3-dibenzyl- and 1,3,7-tribenzylhypoxanthinium bromides, respectively; and CVIIc from 3,9-dibenzyl-6-(dimethylamino)-purinium bromide (CIVd). Compounds CVIIb and CVIIc were prepared from CVIIa and CVIIc, respectively. Cleavage of the dimethylaminopurinium derivative (CIVd) might have proceeded by initial hydrolysis at position 6 to 3,9-dibenzylhypoxanthine; however, its similarity to cyclonucleosides (CIVa, CIVb) (Scheme XII), which first yielded the amidines (CVa, CVb), is evident, and ring opening could have preceded hydrolytic removal of the dimethylamino group. Furthermore,

Marsico and Goldman (207) found that alkaline degradation of 6-(diethylamino)-3,9-dimethylpurinium iodide (CIVc) produced the amidine CVc ($R_1 = H$); further degradation yielded the nitrile (XCIIb) and finally 1-methyl-5-(methylamino)imidazole-4-carboxamide (CVIIe), which was independently synthesized by lithium aluminum hydride reduction of formyl 1-methyl-AIC. Although the foregoing studies were not designed to determine relative facility of ring opening, it appears that, in general, the quaternized derivatives yielded imidazoles under milder conditions than uncharged, ring-nitrogen-substituted derivatives.

Other reported examples of imidazole formation by ring opening include the interception of 1-methyl-4-ureidoimidazole-5-carbonitrile during the alkaline hydrolysis of 2-chloro-7-methyladenine (208); isolation of 2-(methylsulfonyl)AIC ribonucleoside (or a derivative) after treatment of 8-(methylsulfonyl)guanosine with *tert*-butoxide ion in dimethyl sulfoxide (209); and the nonenzymatic formation of AI ribonucleoside from adenosine, a ketopentose, cupric ions, and pyrophosphate (210).

Finally, an interesting acid-catalyzed ring opening of 6-(methylthio)purines was recently reported by Albert (211) and afforded the first imidazole thiol esters (CVIII), one of which was converted by ammonia to AIC.

At the beginning of this section, it was stated that ring-opening and rearrangement reactions of purines are related, but the transitory formation of imidazole derivatives during rearrangement reactions has not been treated here. During such reactions, facile reclosure of a pyrimidine ring to a more stable purine may preclude ring opening as a source of imidazoles. Likewise, the fact that the imidazole, rather than the pyrimidine, ring of purines is sometimes cleaved has not been discussed, but this fact is relevant to ring opening as a method of imidazole synthesis.

F. Miscellaneous Methods—1-Substituted-4-aminoimidazoles, which belong to the structural type furnished by the Sarasin-Wegmann method, are formed by a route (Scheme XIII) that begins with *N*-cyanoimino-dithiocarbonic acid esters (CIX) (212). The imidazole

Scheme XIII

ring is formed (CXI) by base-catalyzed cyclization of the intermediate isothiureas (CX). The thioether group at position 2 may be removed with Raney nickel (CXII).

Approaches to 1-substituted derivatives of AI and AI-COOH (VIII) similar to the steps in the biosynthesis of inosinic acid have been studied by Shaw and co-workers (*cf.*, Part III). The 1-cyclohexyl and ribonucleotide derivatives of AI, the latter in admixture with formylglycinamide ribonucleotide (FGAM), were obtained by decarboxylation of the amino acids under careful control to minimize ring opening (213). The influence of metal ions, pH, and other factors on the decarboxylation has been studied (214). Conversely, carboxylation of these two AI derivatives with bicarbonate gave the amino acids (215), and cyclization of the *N*-cyclohexyl derivatives of glycinamide (with ethyl formimidate) and formylglycinamide gave small amounts of 1-cyclohexyl-AI (213, 215).

Interconversions of carboxamide and carbonitrile and of thiocarboxamide and carbonitrile groups are potential sources of derivatives of all three types. Dehydration of AIC to AI-CN (LXXXVI) and hydrolysis of the latter compound to AIC were described in Part IID; hydrolysis of nitrile products of the Sarasin-Wegmann method to amides was depicted in Part IIA; and conversion of some 1-alkyl-5-aminoimidazole-4-carboxamides and -thiocarboxamides to the corresponding nitriles was mentioned in Part IIB. The thiocarboxamide analog (AI-CSNH₂) (XXXIX, R₁ = R₂ = H) of AIC was first prepared by thiation of AIC with phosphorus pentasulfide (47, 216) and by the linear imidate method of Shaw and Butler (93) (Part IIB). Recently, thiation of AIC has been improved (217, 218), but conversion of the nitrile to AI-CSNH₂ with a methanolic alkaline solution of hydrogen sulfide proved to be superior (217, 219). Treatment of AI-CSNH₂ with formic acid and sodium formate yielded the 5-formamidoimidazole-4-thiocarboxamide (LXVIII, X = S).

These reactions have been extended to include the syntheses of the thioamide analogs of AIC ribonucleoside and ribonucleotide (217, 219). 5-Amino-1-(2,3-*O*-isopropylidene- β -D-ribofuranosyl)imidazole-4-carbonitrile (CXIIIa), obtained by dehydrating AIC

isopropylidene group furnished the thioamide analog of AIC ribonucleoside (CXIVa), which reverted to the nitrile upon treatment with methyl iodide and base. Phosphorylation of CXIIIb by the phosphorus oxychloride-trimethyl phosphate method, removal of the isopropylidene group, and application of the usual ion-exchange purification procedures yielded the thiocarboxamide analog (CXIVb) of AICAR.

Other interconversions and further transformations of functional groups, many of which have been mentioned in the preceding sections, provide access to desired derivatives. Some examples involving the amino group are its conversion by orthoesters to alkoxyanils (50, 93, 94, 221, 222) exemplified by LXXII; the preparation of 5-formamido derivatives (93-95, 114, 117, 217), which are of potential interest because a derivative of this type is the immediate biosynthetic precursor of inosinic acid; and the formation of ureido, thioureido, and guanidino derivatives (167, 212, 223, 224, and references cited in Parts IIA and IIB).

Investigations of the biosynthesis of aminoimidazole ribonucleotides by bacteria were an integral part of fundamental studies of purine biosynthesis. Microbiological synthesis has become an important source of AIC ribonucleoside (225-232), AIC ribonucleotide (227, 233-235), and succino-AIC ribonucleotide or the analogous ribonucleoside (227, 236) as a result of the use of bacterial species, mutant strains, or yeasts that accumulate these compounds. Microbiological synthesis has provided these compounds in quantities sufficient for the employment of AIC ribonucleoside as a starting material for the synthesis of purine ribonucleosides (224, 237) and for consideration of AICAR and succino-AICAR as food-seasoning agents (Part III).

III. BIOCHEMISTRY AND BIOLOGICAL ACTIVITY OF 5-AMINOIMIDAZOLES⁴

AIC and its ribofuranosyl derivatives, alone or in combination with other metabolites or antimetabolites, have been the subjects of many biochemical, microbiological, pharmacological, and other biological investigations. These studies are too numerous to be recounted here; rather, the purpose of items 1-7 of Part III is to point out several known biological roles of aminoimidazoles in order to emphasize their importance in metabolic processes.

1. The prominent role of ribonucleotides of aminoimidazoles in the biosynthesis of purines is now well known. The postulated (3) association of AIC, or a derivative, with purine biosynthesis came during a period when studies designed to identify the ultimate sources (*e.g.*, glycine and formate) of the individual atoms of the purine ring and when investigations probing the role of folic acid in one-carbon metabolism were being intensively pursued. The identification of AICAR, rather than AIC itself, as a true precursor of purines resulted from the discoveries, along with other findings, of the precursor role of inosinic acid (IMP) for hypoxanthine (238) and of the accumulation of AIC ribonucleoside (XVIa) (239-243) and AICAR (240, 244) during sulfonamide bacteriostasis. The convergence and integration of these studies of simple

ribonucleoside with *p*-toluenesulfonylchloride in pyridine (220), was transformed by the hydrogen sulfide procedure to isopropylidene AI-CSNH₂ ribonucleoside (CXIIIb). The usual mildly acidic removal of the

reactions of Scheme XIV,^{5, 10, 11} the principal emphasis being, of necessity, on the actions of purines and purine analogs on the initial and the late steps.

The prominent role of aminoimidazole ribonucleotides in purine synthesis *de novo* is evident from Scheme XIV. Only certain salient aspects (arbitrarily selected) of the synthesis *de novo* of inosinic acid will be mentioned. (a) Glutamine plays a donor role in two steps (PRPP → PRA and FGAR → FGAM), and tetrahydrofolate derivatives insert a one-carbon unit in two of the steps (GAR → FGAR and AICAR → FAICAR). (Glutamine is not the only nitrogen source for PRPP → PRA. Interference with *N*¹⁰-formyltetrahydrofolate metabolism was responsible for blocking the formylation of AIC ribonucleotide and its resulting accumulation during sulfonamide bacteriostasis.) (b) The formation of PRA is subject to feedback inhibition by purine derivatives and purine analogs. (c) Salvage pathways for the utilization of preformed purines, AIC, AIC ribonucleoside, and purine ribonucleosides are available to certain cells and organisms. (d) The transformations of succino-AICAR to AICAR and of adenylosuccinic acid to AMP are apparently effected by the same enzyme, adenylosuccinase (253, 254). (e) Biotin apparently does not participate directly in the carboxylation of AIR; impairment of aspartate synthesis was probably responsible for evidence of biotin-deficiency inhibition of this step (255).

In addition to these selected fragments of biochemical information, the following chemical findings are relevant to the role of aminoimidazoles in purine biosynthesis. (a) Evidence for the nonenzymatic formation of PRA from ribose 5-phosphate and aqueous ammonia has been presented (256), and derivatives of PRA have been employed in chemical syntheses of imidazole nucleotides (Part IIB). (b) 5-Aminoimidazole-4-carboxylic acids are easily decarboxylated to the corresponding aminoimidazoles, which are likewise unstable. Decarboxylations of AI-COOH (VIII) (34), its ribonucleoside (214), its ribonucleotide (C-AIR) (213,

CXIV

CXIX

Scheme XV

214, 257), and its 1-cyclohexyl derivative (XXXVII; R₁ = C₆H₁₁, R₂ = R' = H) (95, 213, 214) occur in mildly acidic or neutral media; certain metal ions have a stabilizing influence (214). (c) Using AI-COOH ribonucleotide and 1-cyclohexyl AI-COOH (as a model compound), Franks *et al.* (213) have further shown that the steps from GAR to C-AIR may be caused to proceed nonenzymatically in the reverse direction simply by varying the pH and by heating. (d) By these degradative methods and by synthetic procedures, the open-chain precursors (GAR, FGAR, and FGAM) and the analogous cyclohexyl derivatives have been formed by purely chemical means (110, 111, 213, 258). (e) Nonenzymatic carboxylation of AIR with bicar-

¹⁰ Abbreviations used in Scheme XIV are: ATP = adenosine triphosphate = adenosine 5'-(tetrahydrogen triphosphate)*; AMP = adenosine monophosphate = 5'-adenylic acid*; THF = tetrahydrofolate; PRPP = 5-phosphoribosylpyrophosphate = ribofuranose 5-(dihydrogen phosphate) 1-(trihydrogen pyrophosphate)*; PRA = 5-phosphoribosylamine = 2-amino-2-deoxyribose 5-(dihydrogen phosphate)*; GAR = glycylamide ribonucleotide = 2-amino-*N*-β-D-ribofuranosylacetamide 5'-(dihydrogen phosphate)*; FGAR = formylglycylamide ribonucleotide = 2-formamido-*N*-β-D-ribofuranosylacetamide 5'-(dihydrogen phosphate)*; FGAM = formylglycylamide ribonucleotide = 2-formamido-*N*-β-D-ribofuranosylacetamidine 5'-(dihydrogen phosphate)*; AIR = 5-aminoimidazole ribonucleotide = 5-amino-1-β-D-ribofuranosylimidazole 5'-(dihydrogen phosphate)*; C-AIR = 5-amino-4-carboxylimidazole ribonucleotide = 5-amino-1-β-D-ribofuranosylimidazole-4-carboxylic acid 5'-(dihydrogen phosphate)*; FAICAR = 5-formamidoimidazole-4-carboxamide ribonucleotide = *N*-(5-amino-1-β-D-ribofuranosylimidazol-4-yl)carboxylaspartic acid 5'-(dihydrogen phosphate)*; AICAR = 5-aminoimidazole-4-carboxamide ribonucleotide = 5-amino-1-β-D-ribofuranosylimidazole-4-carboxamide 5'-(dihydrogen phosphate)*; succino-AICAR or SAICAR = 5-amino-4-imidazole-*N*-succinocarboxamide ribonucleotide = *N*-(5-amino-1-β-D-ribofuranosylimidazol-4-yl)carboxylaspartic acid 5'-(dihydrogen phosphate)*; AICAR = 5-aminoimidazole-4-carboxamide ribonucleotide = 5-amino-1-β-D-ribofuranosylimidazole-4-carboxamide 5'-(dihydrogen phosphate)*; SAMP = adenylosuccinic acid = *N*-(9-β-D-ribofuranosyl-9*H*-purin-6-yl)aspartic acid 5'-(dihydrogen phosphate)*; XMP = 5'-xanthylic acid*; GMP = 5'-guanylic acid*. (*Chemical Abstracts names.)

¹¹ See References 247-249 for the enzyme, metal-ion, and ATP or GTP requirements for these steps and for other species (phosphate, ADP, and water) either required for or produced in the various steps. Systematic enzyme names are given in *Report of the Commission on Enzymes of the International Union of Biochemistry*, Pergamon Press, New York, N. Y., 1961.

bonate at 85° has been demonstrated (215). (f) Cusack *et al.* (215) have pointed out that most of the forward reactions to inosinic acid and most of those that are enzymatically reversible have been performed chemically under relatively mild conditions, and they have suggested a possible relevance of these findings to primeval synthesis.

2. AICAR is a coproduct of an intermediate in histidine biosynthesis (*e.g.*, 259, 260 and references cited). Adenosine triphosphate is glycosidated at position 1 by PRPP; a ring opening, analogous to one of the chemical methods of synthesis previously described, then produces an AIC ribonucleotide derivative (CXV) (Scheme XV). In several steps, AICAR and 4-imidazolylglycerol phosphate (CXVI) are formed, the latter arising from the ribofuranosyl group of PRPP, the nitrogen atom at position 1 of ATP, and nitrogen donated by glutamine. Histidine is formed from CXVI in several additional steps. It is interesting to note certain biochemical interrelationships: (a) AICAR may be recycled to ATP *via* IMP and AMP, and (b) biodegradation of histidine in several steps *via* urocanic acid yields formiminoglutamic acid, a one-carbon donor for tetrahydrofolate (261).

3. The pyrophosphate (CXVIIa) of AICAR and AMP is formed from AIC and nicotinamide adenine dinucleotide (NAD) in the presence of NAD glycohydrolase from beef spleen (262–265). Enzymatic conversion of the dinucleotide (CXVIIa) to the pyrophosphate of IMP and AMP and incorporation of the imidazole moiety into nucleic acids have been demonstrated. Evidence has also been presented for the transfer of a deoxyribofuranosyl group from pyrimidine deoxyribofuranosides to AIC by bacterial enzymes (266, 267).

4. Xanthine is degraded by extracts of certain species of *Clostridia* to 5-aminoimidazole-4-carboxylic acid (VIII) (34). The amino acid is formed *via* 4-ureidoimidazole-5-carboxylic acid (CXVIII) (268) and undergoes further degradation to 5-aminoimidazole (34). Again, it is interesting for correlative purposes to note that the latter compound is further degraded to formiminoglycine, which is a one-carbon source for tetrahydrofolic acid (THF). The sequential formation of 5-formimino-THF, 5,10-methenyl-THF, and 10-formyl-THF is effected by enzymes from *C. cylindrosporum* extracts (269). Thus, interrelationships among purines, aminoimidazole derivatives, and folic acid coenzymes may be found in catabolic, as well as anabolic (Scheme XIV), processes.

5. AIC has been identified as a urinary excretion product of healthy human beings and of animals (270–275). It is normally excreted by adult human beings in quantities of about 1 mg. per day (271, 273, 276, 277), and for most individuals it is comparable to creatinine in the constancy of its excretion (273, 276). The excretion levels may be elevated in abnormal circumstances such as during acute leukemia (276, 278); after oral administration of adenine, glycine, or AIC (279); or during folic acid deficiency (280). More recently, AIC ribonucleoside has been identified as one of several ribonucleosides excreted by normal subjects and by patients with leukemia or gout (281).

6. A compound believed to be 5-aminoimidazole-4-carboxamide 5'-S-homocysteinylriboside {5-amino-1-[5-S-(3-amino-3-carboxypropyl)-5-thio-β-D-ribofuranosyl]imidazole-4-carboxamide} (CXVIIb) has been isolated from the urine of patients with homocystinuria (282, 283).

7. In studies with mutants of *Salmonella typhimurium*, Newell and Tucker (284, 285) showed that purines and the pyrimidine moiety (CXIX) of thiamine share the early parts of their biosynthetic pathways. The evidence indicates that this pyrimidine is formed from AIR. The transformation of AIR to the pyrimidine requires the loss of the ribofuranosyl group and the addition of one carbon atom in the ring and the two carbon atoms in the exocyclic groups.

In addition to their involvement in these metabolic processes, aminoimidazolecarboxylic acid derivatives have displayed certain types of biological activity. 5-Amino-2-thioxoimidazoline-4-carboxamide (LXIIb or, in the thiol tautomeric form, 2-mercapto-AIC) was reported to be moderately inhibitory to Ehrlich ascites carcinoma in mice (77). However, imidazoline-2-thione (2-mercaptoimidazole) and several of its derivatives that do not have the functional groups of the biosynthetic imidazoles appear to be more active against this neoplasm; some of these same compounds—LXIIb was not included—are also effective in inhibiting solid rodent neoplasms (77, 286). Imidazoline-2-thione and some related compounds inhibited thymidine uptake by ascites cells (77). The activity of LXIIb in the Ehrlich ascites test may, therefore, be unrelated to its formal resemblance to AIC.

Among 15 analogs or derivatives of AIC and of AIC ribonucleoside tested against Nakahara-Fukuoka sarcoma (a tumor especially sensitive to 6-mercaptopurine and related compounds), only 5-formamidoimidazole-4-thiocarboxamide (LXVIII, X = S) and 5-amino-1-β-D-ribofuranosylimidazole-4-thiocarboxamide (CXIVa) were active (287). Further evaluation (288) of these two compounds against seven mouse tumors and leukemias showed that they are inhibitory to adenocarcinoma 755, Ehrlich carcinoma (ascites), sarcoma 180 (ascites), leukemia L-1210, C1498 leukemia, SR-61 leukemia, and Nakahara-Fukuoka sarcoma. 6-Mercaptopurine and its ribonucleoside, employed as reference compounds in these tests, were also active against the same mouse neoplasms. A subline of SR-61 leukemia resistant to these two purine anticancer agents was also resistant to the two imidazole derivatives. These results, the fact that the structures of the two imidazoles suggest that they are potential precursors of 6-mercaptopurine, and the observation (289) that 6-mercaptopurine is excreted after administration of the two compounds to mice suggest that the observed activity may be due to 6-mercaptopurine formed *in vivo* rather than to the two imidazoles *per se*. The thiocarboxamide analog (XXXIX, R₁ = R₂ = H) of AIC was reported to be weakly active against the Ehrlich ascites carcinoma and adenocarcinoma 755 (288); however, in an earlier test, it did not significantly increase the lifespan of animals with Ehrlich ascites carcinoma (290).

Inhibition of the growth of a rat sarcoma by ethyl 5-aminoimidazole-4-carboxylate (XIIb, R = C₂H₅) and its *p*-[bis(2-chloroethyl)amino]phenylsulfonyl derivative has also been reported (43).

The activity of 8-azaguanine against mouse leukemia L-1210 was found to be potentiated by AIC (291). This effect resulted from inhibition by AIC of the enzyme guanine deaminase (292). Inhibition of adenylosuccinase by an analog of succino-AICAR also represents activity at the enzyme level and deserves mention because of its potential importance for further investigation. Burrows *et al.* (109) found that the *L*-threo- β -methylaspartic acid analog of succino-AICAR is a competitive inhibitor of the enzyme.

AICAR is reported to possess potent activity in enhancing the flavor of a wide variety of food products (227, 233, 293). It is also claimed that succino-AICAR has flavor-enhancing activity (227).

IV. TRIAZENOIMIDAZOLES AND RELATED COMPOUNDS

Interest in triazenoimidazoles began with the prototype, 5-(3,3-dimethyl-1-triazeno)imidazole-4-carboxamide (NSC-45388, DIC), which was synthesized by Shealy *et al.* (294) for evaluation as a potential anticancer agent. Initial biological evaluation revealed activity in prolonging the survival time of mice with lymphoid leukemia L-1210 and in inhibiting the growth of the solid tumors adenocarcinoma 755 (Ca755) and sarcoma 180 (S180) in mice (295). This evidence of activity against more than one type of neoplasm led to pharmacological studies and clinical trials under the auspices of the Cancer Chemotherapy National Service Center (CCNSC). The chemistry and the biological properties of this compound and of related triazenoimidazoles are discussed in this section. There is no intention to imply that biological activities of the types to be mentioned are confined to imidazole triazenes.

Diazotization of 5-aminoimidazoles, followed by the addition of a coupling agent, such as 1- or 2-naphthol or the Bratton-Marshall reagent [*N*-(1-naphthyl)ethylenediamine] (296), usually produces intensely colored solutions. This property has frequently been exploited in characterizing 5-aminoimidazoles (e.g., 26, 27, 30, 73, 82, 92) and is the basis for an assay procedure for excreted AIC (273). Diazotization of AIC (Scheme XVI) initially gave 2-azahypoxanthine¹² (CXXI) (1, 297), the product of intramolecular coupling of the diazo group with the adjacent amide nitrogen atom. Later, an intermediate in the formation of 2-azahypoxanthine was isolated and characterized as 5-diazoimidazole-4-carboxamide (CXX) (298). [The substance that initially precipitated from one of the earlier diazotizations (297) might have been CXX.] This compound readily cyclizes to 2-azahypoxanthine over a wide range of pH values, particularly at pH 7 and in basic solutions. Despite this propensity for intramolecular coupling, which is amply preceded in the formation of benzo-*v*-triazines (299), intermolecular

Scheme XVI

coupling with aromatic compounds and with amines was sufficiently competitive to permit isolation (usually in good yields) of the resulting arylazo (CXXII) (294), dialkyl- or arylalkyl-triazeno (CXXIII) (294, 300), and monoalkyl- or monoaryl-triazeno (CXXIV) (301, 302) derivatives.

In the initial studies (294), representative disubstituted-triazeno derivatives (CXXIII) (including DIC) in phosphate buffer (pH 7), as well as DIC in 0.1 *N* hydrochloric acid, were shown by UV spectroscopy to be essentially unchanged in the dark during the periods of observation (limited to 1–2 days). Exposure of these solutions to ambient light resulted in the formation of 2-azahypoxanthine (CXXI). The disubstituted-triazeno derivatives (CXXIII) were evidently dissociated by certain wavelengths of light to CXX and the secondary amine (RR'NH), and CXX then cyclized to CXXI. Further observations (300) by TLC of the dimethyl-triazeno (DIC) and the butylmethyltriazeno (CXXIII; R = CH₃, R' = C₄H₉) derivatives in 50% aqueous methanol or ethanol showed that the formation of 2-azahypoxanthine is rapid in sunlight or in 365-m μ light (*cf.*, 303), slow under fluorescent lighting, and very slow or negligible under incandescent lighting.¹³

¹³ These qualitative observations simply indicate a trend and should not be interpreted to be applicable to all lighting situations involving sunlight and artificial lighting. They indicate that suitable precautions should be exercised in handling solutions of triazenoimidazoles. It cannot be emphasized too strongly that the behavior of solutions of these and similar compounds will depend on the wavelengths of light to which they are exposed and on the intensity of the sensitizing light that reaches these solutions. Since the intensity of light decreases rapidly with distance at rates that depend on the geometrical arrangement of the solution and the light source, relatively small differences in the distance of a solution from a light source (e.g., a 365-m μ lamp) catalyzing decomposition can make considerable differences in the apparent rate of decomposition. [The intensity of light from a germicidal lamp was found to be inversely proportional to distance at short distances and roughly inversely proportional to the square of the distance at greater distances (304). The Inverse Square Law applies to a point source of light.] For these reasons, exact comparisons of the rates of change of a compound in different solutions or of the rates of change of different compounds cannot be made unless the solutions are exposed under comparable conditions to light of the same wavelength and intensity. Comparisons of stability of different compounds might also be made at the light wavelengths that are optimal for the decomposition of each compound. Obviously, much effort would be needed to acquire the data necessary for precise comparisons.

¹² Chemical Abstracts names: 4*H*-imidazo[4,5-*d*]-*v*-triazin-4-one, 3,7-dihydro-; 7*H*-imidazo[4,5-*d*]-*v*-triazin-4-ol.

Loo and Stasswender (303, *cf.*, 305, 306) developed a colorimetric method for determining DIC in biological material, based on the deliberate dissociation of DIC, by exposing solutions containing both this compound and the Bratton-Marshall reagent to UV light in the 365-m μ range. Taken together, these studies indicated that DIC is stable in the dark for at least 24 hr. in phosphate buffer (294), for at least 4–7 days in 50% alcohol (300), and for at least 1 month in refrigerated 0.1 *N* hydrochloric acid solutions (303). Considerable (and various degrees of) dissociation of several disubstituted-triazeno derivatives (CXXIII) in Krebs-Ringer phosphate buffer (pH 7.4) within 20 hr. has been reported (307) but protection from light was not mentioned. In agreement with the observations at pH 7, Skibba *et al.* (306) recently reported DIC to be stable for at least 24 hr. in the dark in lactated Ringer's solution (pH 6.5).¹⁴

In contrast, it was found (Scheme XVII) that simple

Scheme XVII

monoalkyltriazeno derivatives (CXXIV) are unstable in aqueous and alcoholic solutions even in the dark, that AIC is formed during the decomposition of these derivatives, and that the decomposition follows first-order kinetics (302). Within the series consisting of CXXIV with R = methyl, ethyl, *n*-butyl, cyclohexyl, and *tert*-butyl, stability appeared to decrease in the order in which these compounds are listed. This decomposition was assumed to be similar to deamination of primary amines by nitrosation. Deamination *via* decomposition of triazenes of the benzenoid series is known to occur in organic solvents (308, 309) or in aqueous acids (310–312). Although the mechanistic details of deamination reactions are complex (313–315), they suggested that the simple monoalkyltriazenoimidazoles dissociate, in essence, in accordance with the equations shown (302), producing the unstable alkyl diazonium ion (CXXV) in addition to AIC. The alkyl diazonium ion, in turn, evolves nitrogen and forms a carbonium ion (CXXVI). Some form¹⁵ of the carbonium ion or the alkyl diazonium ion may rearrange (R'), form an alkene, or react with nucleophiles available *in vitro* or *in vivo* (water; hydroxyl, amino, or thiol groups; electron-rich centers of heterocycles; *etc.*). Certain monosubstituted-triazeno derivatives (CXXIV), in which the substituent is an aryl group or a more complex alkyl moiety, are more stable (302); the mode of decomposition may be different or may yield a more stable diazo derivative.

In the initial synthesis (294) of 5-(3,3-disubstituted-1-triazeno)imidazole-4-carboxamides (CXXIII), the sub-

stituents on the triazeno group included straight-chain alkyl, cyclic alkyl, aralkyl, and aryl groups, and the number of carbon atoms in the straight-chain groups was doubled [from the dimethyltriazeno (DIC) to the

dioctyltriazeno derivative]. Because of the antileukemic (L-1210) activity of DIC, its *v*-triazole analog (316), and some methyltriazenes of the benzenoid series (317), one of the alkyl substituents in a later group of dialkyltriazenoimidazolecarboxamides was a methyl group (300). Routine screening of the dialkyltriazeno derivatives against mouse neoplasms indicated that those derivatives in which at least one of the alkyl substituents is a methyl group are the most effective against L-1210.¹⁶ Thus, in addition to DIC, the methyl propyl (NSC-76418), methyl butyl (NSC-70874), methyl isobutyl (NSC-83113), methyl pentyl (NSC-87981), methyl cyclohexyl (NSC-83111), and methyl 2-hydroxyethyl (NSC-83112) derivatives all caused an increase in lifespan (ILS) of treated leukemic mice, as did 5-(3-methyl-1-triazeno)imidazole-4-carboxamide (MIC) (302). The maximum values of the ILS observed in preliminary tests of these compounds fall within the range 40–70% (Reference 300 and additional tests on NSC-83112). By way of comparison, preliminary test of DIC against L-1210 indicated the ILS to be about

¹⁴ In the author's laboratories, there was no significant decrease in the absorbance of DIC in Krebs-Ringer buffer during 24 hr. in the dark and only a small decrease during 4 days.

¹⁵ Summaries of theories on the nature of the carbonium ion (hot, nonsolvated, vibrationally excited, solvent-caged) from deamination reactions and the roles of the alkyl diazonium ion and the counterion may be found in References 309 and 313–315.

¹⁶ Since doses in some of the L-1210 tests were determined by prior results from S180 and Ca755 tests, more detailed testing might reveal some activity among derivatives that failed the preliminary L-1210 tests.

50–60% (295); further, extensive evaluation has given values of the ILS of 60–90%, depending on the dose and on the route and frequency of administration (318). Activity by methyltriazeno derivatives was also found among the analogous triazenoimidazole-carboxylic acid esters; methyl 5-(3,3-dimethyl-1-triazeno)imidazole-4-carboxylate (NSC-87982) increased the lifespan of leukemic mice by 60% (319). At dose levels determined by the L-1210 primary screening protocols, other (but not all) methylalkyltriazenoimidazole esters (CXXVII) have likewise caused some increase in the lifespan of treated leukemic mice (320).

Antineoplastic activity of triazenoimidazoles is not confined to leukemia L-1210. DIC is active against other leukemias and inhibits the growth of solid rodent tumors (295, 318), and most of the aforementioned methylalkyl derivatives also inhibit Ca755 and S180 (300). Derivatives of this group selected for tests against intramuscular Walker carcinosarcoma 256 (IMW256) in rats inhibited tumor growth (300), and an initial test of MIC against the subcutaneous form of this tumor suggested modest inhibition (302). Inhibition of solid tumor growth was frequently accompanied by loss of weight by the host animals. The apparent association of L-1210 activity with at least one methyl group may not apply to other tumors. Modest inhibition of S180 by triazenoimidazolecarboxamides lacking a methyl group was observed (300). Furthermore, certain monoaryltriazeno derivatives of the imidazole-carboxylate variety (CXXVII) that did not inhibit L-1210 in primary screening did display modest inhibition of IMW256 (320). Such derivatives, of course, cannot form a methyl or alkyl carbonium ion; rather, nonenzymic dissociation should produce a diazoimidazole, an aryldiazonium ion, or both. (Aryldiazonium ions are more stable than the alkyl variety, and their coupling properties are well known.) In addition, Hano *et al.* (307) described some dialkyl- and monoalkyltriazenoimidazolecarboxamides (CXXIII and CXXIV) in addition to those mentioned and evaluated the new and some of the old derivatives against the Ehrlich carcinoma. Within the series of derivatives of CXXIII in which R and R' were identical and comprised of one to five carbon atoms, the dipropyltriazene and DIC were considered to be the most active against the solid form of the tumor (321). The butyl methyl and the methyl propyl derivatives were subsequently shown to display similar activity (307). None of the dialkyltriazeno derivatives inhibited proliferation of the ascites form of the Ehrlich carcinoma, but two monosubstituted-triazeno derivatives (CXXIV, R = ethyl or hydroxyethyl) were reported to increase lifespan. The potentiating effect (322) of MIC on the activity of 8-azaguanine against Ehrlich ascites is probably due to AIC, which is known (301, 302, 307) to be formed, as previously explained, from the triazene and which is known to potentiate the activity of 8-azaguanine by inhibiting guanine deaminase (see Part III).

The uncertainties of the association of structural elements with activity are emphasized by the fact that the most effective derivative in the L-1210 test system is one that does not bear a methyl group; namely, 5-[3,3-bis(2-chloroethyl)-1-triazeno]imidazole-4-carbox-

amide (NSC-82196) (323, 324). At *certain* dose levels and dosage schedules, a majority of leukemic mice treated with this compound survived until tests were discontinued after long periods (2–8 months) (323, 325). In addition to these encouraging effects in the standard L-1210 test, Hoffman *et al.* (325) demonstrated the effectiveness of NSC-82196 in advanced L-1210 leukemia. Intraperitoneal administration produced a high proportion of 60-day survivors on certain treatment schedules; oral administration was less effective. Knowledge of the L-1210 test system gained from correlations of inoculum size to average lifespan and from cell-kill kinetic studies (326) indicates that leukemic cells had been completely eradicated from the long-term survivors of the L-1210 tests. Using spleen-colony and host-survival criteria, Wodinsky *et al.* (327) showed that the activity of both NSC-82196 and DIC against L-1210 extends also to an L-1210 line resistant to 6-mercaptopurine. This study indicated a low level of crossresistance of the 6-MP-resistant line to NSC-82196 but not to DIC. Additionally, Tyrer *et al.* (328) developed a strain of L-1210 resistant to NSC-82196 and showed that the resistant variant is crossresistant to DIC and to nitrosoureas; but, interestingly, it is sensitive to certain nitrogen mustard derivatives such as cyclophosphamide and melphalan.

Unfortunately for purposes of handling and administration, this compound is beset by problems of instability. In addition to its susceptibility to light-catalyzed dissociation, it undergoes an internal alkylation to an ionic transformation product in solution and even, slowly, in the solid state (323, 324), but it can be preserved in the solid form at low temperatures. The *v*-triazolinium salt structure (CXXVIII), the most likely among several candidate structures, was identified as the structure of the ionic isomer by an X-ray crystal structure analysis (329). The quality of specimens of NSC-82196 was originally estimated from distinctive differences in the IR spectra of the two compounds. Determinations of NSC-82196 based on a microbiological assay (330), light-catalyzed dissociation to 5-diazoimidazole-4-carboxamide (303, 305), a UV absorption method (331), and titrimetric determination of the ionic isomer (332) have been described. The latter method also provided information on the rate of change of NSC-82196 in solution. A nonaqueous titration procedure developed by Sternglanz (333) provides a direct determination of NSC-82196 and other triazenoimidazole amides and esters.

Bis[3,3-(2-fluoroethyl)-1-triazeno] derivatives of the imidazole (CXXIII and CXXVII) and pyrazole (CXXX) types have likewise demonstrated activity against L-1210, but they are, thus far, more toxic and less active than NSC-82196 (334a). The association of L-1210 activity with methyltriazenes also applies, as mentioned previously, to the *v*-triazole analog (CXXIX) (316) of DIC and to certain triazenopyrazole-carboxylic acid esters (CXXXa) (334b) and triazenopyrazolecarboxamides (CXXXb) (334b, 335). The triazeno-*v*-triazoles (316) and the triazenopyrazoles (334b, 335) appear¹³ to be more stable to light than the triazenoimidazoles.

In addition to the antineoplastic effects produced by certain triazenoimidazoles, antimicrobial activity has also been demonstrated. Methyl 5-(3,3-dimethyl-1-triazeno)imidazole-4-carboxylate (NSC-87982) (319) is strongly inhibitory *in vitro* to a broad spectrum of Gram-positive and Gram-negative bacteria, mycobacteria, yeasts, filamentous fungi, and algae (319, 336, 337). Strains of *Escherichia coli* and *Streptococcus faecalis* resistant to various antibiotics and antimetabolites were not crossresistant to NSC-87982 (338). Activity *in vivo* was demonstrated against *Staphylococcus aureus* in mice (336), and significantly high blood levels and detectable concentrations in several mouse tissues were found after administration by various routes (337). It has also been shown that a number of related 5-(disubstituted-triazeno)imidazole-4-carboxylic acid esters have broad-spectrum antimicrobial activity *in vitro* (320). Additionally, from among a number of bacteria sensitive to DIC, a strain of *E. coli* resistant to glutamic acid γ -hydrazide (and sensitive to DIC at a concentration of 5 mcg./ml. in the disk-plate method) was selected for a microbiological method of assay of DIC in blood and tissues (339). Recently, inhibition of *E. coli* B (340) by DIC and several of its homologs (at concentrations of about 10 mcg./ml.) and inhibition of *Bacillus subtilis* (341) by DIC were reported. Although the antimicrobial activity of the 3,3-bis(2-chloroethyl)-1-triazeno derivative (NSC-82196) is minimal, inhibition of two species of *Mycobacteria* and of drug-resistant *E. coli* strains at high concentrations was observed (330).

Pharmacological studies of DIC have been conducted in the dog (342-344), rat (305, 345), mouse (339), monkey (305), and man (306, 342, 343, 345, 346); DIC and some of its homologs have also been studied in rabbits and cats (347). NSC-82196 has been subjected to pharmacological and clinical evaluation (305, 348). In clinical trials, DIC (NSC-45388) has brought about objective remissions of malignant melanoma in some of the treated patients (306, 349). Objective responses by several other cancers have also been observed in patients treated with DIC (349).

The discussion, thus far, has dealt with triazenoimidazoles. Although 5-diazoimidazole-4-carboxamide (CXX, diazo-IC, NSC-22420), the precursor of the carboxamides, is an unstable compound in solution, there are reports that it also has various types of biological activity; these findings have possible relevance to the question of the mechanism of action of triazenoimidazoles prepared from it. Reports of antineoplastic activity include inhibition of human epidermoid carcinoma (H.Ep.-2) cells in culture (298), subcutaneous Walker carcinoma 256 (298), and Ehrlich ascites carcinoma (298, 321). Antimicrobial activity by diazo-IC (or, because of the instability of CXX, a mixture of diazo-IC and 2-azahypoxanthine) in the form of inhibition of *Mycobacterium tuberculosis* has been reported (350). Furthermore, diazo-IC completely inhibits *E. coli* *in vitro* (290, 340) at low concentrations and is strongly inhibitory to *B. subtilis* (341). A third type of activity is represented by the potent inhibition of xanthine oxidase by the diazo compound and by two thioazo derivatives prepared from it (351).

At this time, there are unanswered questions concerning both the relationship of structure to activity and the mechanism of action of triazenoimidazoles and related compounds. Several potential mechanisms of action may be considered, and these are not necessarily mutually exclusive. The structural relationship to, and chemical derivation from, the imidazole moieties of the imidazole ribonucleotides suggested *a priori* that the triazenoimidazoles or diazo-IC might interfere in some way with imidazole and purine metabolism (295, 298). A second possibility that was also considered (295) is that the triazenes may be latent forms of the active agent—the corresponding diazo compound for disubstituted-triazeno derivatives or, in the case of NSC-82196, the diazo compound and bis(2-chloroethyl)amine. A third possibility is that the *monosubstituted*-triazeno derivatives are carrier forms (302) of a reactive species (an alkyl diazonium ion or a carbonium ion) and, on the basis of recent findings (345), that the disubstituted-triazeno derivatives may act similarly after *N*-dealkylation.

In what is, of necessity, a speculative vein, a number of findings may be brought to bear on the question of mechanism of action without, at this time, providing a definitive answer. Some observations tend to place the triazenoimidazoles in the class of chemically reactive anticancer drugs (“biological alkylating agents”) such as alkylating agents and diazo compounds. Studies by Wilkoff *et al.* (352) of the cell-kill kinetics of DIC and NSC-82196 in cultures of leukemia L1210 cells indicate that these drugs are probably not cell-cycle-stage specific agents. Their behavior in this system, therefore, is similar to that of certain chemically reactive drugs. The crossresistance to nitrosoureas of the L-1210 variant that is resistant to NSC-82196 (328) is consistent with the reactive species idea, but the lack of crossresistance to other drugs having a bis(2-chloroethyl)amino group is not. The earlier findings of Pittillo and Hunt (338) that sulfur-containing amino acids reversed the inhibition of *E. coli* ATCC9637 and of *Saccharomyces cerevisiae* by NSC-87982 and the inhibition of another *E. coli* strain by NSC-82196 suggested (along with observations of crossresistance) involvement of a chemically reactive species as one, but not the sole, mechanism of action (330). Subsequently, Yamamoto (340) reported that cysteine abolished the inhibitory action of diazo-IC on *E. coli* B and suggested that this compound might be the active form for inhibition of this organism by dialkyltriazenoimidazolecarboxamides. More direct evidence in this connection is the discovery by Saunders and Saunders (341) that the inhibitory action of DIC on *B. subtilis* is markedly increased by exposing cultures growing in the presence of the compound to light and that a strain resistant to DIC is also resistant to the diazo compound. These studies in bacteria also indicated that RNA and protein synthetic processes are inhibited by NSC-87982 in *E. coli* (338), that DNA synthesis is inhibited in *E. coli* B by diazo-IC (340), and that DNA synthesis in *B. subtilis* is inhibited by DIC (341).

In the studies of Pittillo and Hunt (330), the partial protection to NSC-82196 inhibition of an *E. coli* strain

afforded by AIC suggested the involvement of purine metabolism. The observations in these studies of NSC-82196 and of NSC-87982 of collateral sensitivity of bacteria resistant to certain purine analogs (330, 337, 338) and of partial crossresistance to 8-azaguanine and to 2,6-diaminopurine of an *E. coli* strain resistant to NSC-82196 (330) also tended to implicate purine metabolism. In this connection, the low level of crossresistance to NSC-82196 by 6-mercaptopurine-resistant L-1210 cells (327) should be recalled. The statement made at the outset that potential mechanisms of action should not be considered mutually exclusive is illustrated by the report of Peters and McGeer (290) that diazo-IC, as well as some related compounds, showed inhibitory effects on the incorporation of glycine into hypoxanthine by pigeon liver homogenates.

A mechanism involving some form of alkyl diazonium ion or carbonium ion must be considered for the mono-alkyltriazenoimidazoles because of their demonstrated behavior *in vitro*, as explained previously. Housholder and Loo (353) and Skibba *et al.* (345) reported that patients given DIC excrete large amounts of AIC; the latter investigators found that DIC is *N*-demethylated by rat liver microsomes to formate and AIC. It is appropriate to recall at this point that MIC not only forms AIC in solution but also has antineoplastic activity. If metabolic *N*-demethylation results in the formation of MIC, then a mechanism involving some form of an alkyl diazonium ion or a carbonium ion must also be considered for DIC and other disubstituted triazenoimidazoles. By analogy with organic deamination reactions, some form of these highly reactive species should be generated and should react with nucleophilic centers such as those listed earlier in this section. Recently, Preussmann *et al.* (354), in a comprehensive paper on the mechanism of carcinogenesis of phenyltriazenes, reported that formaldehyde and aniline are formed by incubation of 3,3-dimethyl-1-phenyltriazenes with rat liver or lung microsomal fractions in the presence of oxygen and an NADPH-generating system, that formaldehyde or acetaldehyde are formed similarly from certain other carcinogenic dimethyl- or diethyltriazenes of the phenyl and pyridyl series, and that 3-methyl-1-phenyltriazenes is a potent carcinogen. Their proposed mechanism of carcinogenesis consists of oxidative dealkylation of a 3,3-dialkyl-1-aryltriazenes *in vivo* to an aryl monoalkyltriazenes, decomposition of this intermediate to a carbonium ion, and alkylation by this species of "biopolymers, probably nucleic acids." (The authors mention certain, as yet, unexplained phenomena such as the failure to observe tumors in the liver or lungs.) The later stages of their mechanism are essentially those proposed (302) for the dissociation of 5-(3-alkyl-1-triazeno)imidazole-4-carboxamides (CXXIV), and their findings are similar to those of Skibba *et al.* (345), except that formate was identified in the latter study. Whether *N*-dealkylation is the basis of a mechanism of action or simply a catabolic process remains to be seen. One may speculate that the particular mechanism by which a triazene acts (such as reversion to a diazo derivative, interference in purine metabolism, oxidative *N*-dealkylation, or combinations

of these processes) may depend on the biochemical environment in which it is placed or to which it is transported.¹⁷

¹⁷ Addendum added in proof—The following publications dealing with the mechanism of action, metabolism, and biological effects of DIC and NSC-82196 appeared since this manuscript was completed:

- (1) C. L. Vogel, V. T. De Vita, R. P. Lisak, and M. W. Kies, *Cancer Res.*, **29**, 2249(1969).
- (2) J. L. Skibba, D. D. Beal, G. Ramirez, and G. T. Bryan, *ibid.*, **30**, 147(1970).
- (3) C. L. Vogel, C. Denham, T. P. Waalkes, and V. T. De Vita, *ibid.*, **30**, 1651(1970).
- (4) P. P. Saunders and G. A. Schu'tz, *Biochem. Pharmacol.*, **19**, 911 (1970).
- (5) J. L. Skibba, G. Ramirez, D. D. Beal, and G. T. Bryan, *ibid.*, **19**, 2043(1970).

- (36) B. Robinson and D. M. Shepherd, *J. Pharm. Pharmacol.*, **14**, 9(1962).
- (37) L. P. Kulev and R. N. Gireva, *Zh. Prikl. Khim.*, **30**, 811 (1957); through *Chem. Abstr.*, **51**, 17897a(1957) [*J. Appl. Chem. USSR*, **30**, 858(1957)].
- (38) R. N. Gireva and N. S. Dobychina, *Izv. Tomsk. Politekh. Inst.*, **102**, 108(1959); through *Chem. Abstr.*, **59**, 1622d(1963).
- (39) L. P. Kulev and A. M. Rozhkov, *Zh. Obshch. Khim.*, **27**, 1389(1957) [*J. Gen. Chem. USSR*, **27**, 1470(1957)].
- (40) L. P. Kulev and V. R. Koroleva, *ibid.*, **29**, 2401(1959) [*J. Gen. Chem. USSR*, **29**, 2366(1959)].
- (41) V. R. Koroleva, *Izv. Tomsk. Politekh. Inst.*, **111**, 23(1961); through *Chem. Abstr.*, **57**, 14594b(1962).
- (42) R. N. Gireva, V. E. Golubev, T. A. Boldyreva, and V. E. Chistyakov, *Sin. Prir. Soedin., Ikh Analogov Fragmentov, Akad. Nauk SSSR, Otd. Obshch. Khim.*, **1965**, 54; through *Chem. Abstr.*, **65**, 2158d(1966).
- (43) R. N. Gireva, G. A. Aleshina, L. F. Mal'tseva, T. V. Mikhailova, and O. I. Petrova, *Khim.-Farm. Zh.*, **2**, 39(1968).
- (44) R. N. Gireva, N. N. Gavrilov, and V. M. Mar'yanovskii, *Khim. Geterotsikl. Soedin., Sb. 1: Azotsoderzhashchie Geterotsikly*, **1967**, 119; through *Chem. Abstr.*, **70**, 96709g(1969).
- (45) R. N. Gireva, N. N. Gavrilov, G. A. Aleshina, A. V. Evseeva, and N. V. Nikitina, *ibid.*, **1967**, 123; through *Chem. Abstr.*, **70**, 96710a(1969).
- (46) J. Baddiley, J. G. Buchanan, and J. Stewart, *Proc. Chem. Soc.*, **1957**, 149.
- (47) M. Ikehara, N. Nakazawa, and H. Nakayama, *Chem. Pharm. Bull.*, **10**, 660(1962).
- (48) R. J. Rousseau, L. B. Townsend, and R. K. Robins, *Chem. Commun.*, **1966**, 265.

ACKNOWLEDGMENTS AND ADDRESSES

Received from the Kettering-Meyer Laboratories, Southern Research Institute, Birmingham, AL 35205

The author is grateful to Mrs. Joan K. Whitworth for preparing the manuscript and for assistance with source materials; to Mr. Vladimir Minic for assistance with literature compilations; and to Chemotherapy, National Cancer Institute, National Institutes of Health, U. S. Public Health Service, Contracts PH43-64-51 and SA-43-ph-1740, and to the C. F. Kettering Foundation for support of investigations cited from these laboratories.

Corneal Absorption Reinforcement of Certain Mydriatics

EUNICE S. N. WANG and E. ROY HAMMARLUND*

Abstract □ By using a prebuffer technique or by adding buffer and/or viscolizer to certain dilute mydriatic solutions, similar physiological effects were obtained as were given by unbuffered solutions that were 10 times more concentrated. Isotonic, sterile, 2.6% sodium borate solution was found to be an effective buffer for the following solutions: 0.1% homatropine HBr, and 1% phenylephrine HCl plus 0.1% cyclopentolate HCl. These concentrations provided adequate dilation for routine eye examinations. The addition of 0.5% hydroxypropyl methylcellulose, 4000 cps., to buffered mydriatic solutions did not show any further increase in pupil size of Caucasians compared to the same buffered solutions without viscolizer. However, when used similarly in the eyes of Orientals, the viscous solutions produced a more marked dilating effect. No eye irritation was reported by any of the human test subjects for any of the dilute experimental eye drops tested. The results of the animal experimentation indicated that the several biological buffers tested [tromethamine, 2-(*N*-morpholino)ethanesulfonic acid, and *N,N*-bis(2-hydroxyethyl)glycine] were not as effective as sodium borate for increasing the corneal absorption of the medicinal agents used. The pKa value of cyclopentolate HCl, determined by titration, was found to be 7.93.

Keyphrases □ Mydriatics—corneal absorption reinforcement □ Corneal absorption, mydriatics—reinforcement □ Buffer effect—corneal absorption □ pH effect—mydriatic activity □ Cyclopentolate HCl—pKa determination

Good therapy involves the efficient use of a drug so that the body encounters minimal chemical challenge to achieve the desired effect. In the case of ophthalmic solutions, modification of the vehicle must be continuously studied since it has the potential for improving therapy.

Because the cornea of the eye is more permeable to lipid-soluble than to water-soluble substances, the nonionized form of a drug, which is more lipid soluble, will be absorbed through the cornea more rapidly than the lipid-insoluble ionized form. The degree of dissociation of a drug in tears (normal pH 7.4), predictable from its pKa, and the capacity of tear buffers to overcome the buffer effect of the drug play vital roles in corneal drug absorption. The short-term alteration of pH also may affect the rate of corneal uptake.

Since the physiological effect of alkaloidal eye drops results from an absorption of the free base portion of the alkaloid, greater response should be obtained if the drugs are administered in alkaline media. However, due to the instability of many alkaloids in alkaline solution, this procedure is not usually possible. Previous studies by Boberg-Ans *et al.* (1) have shown that pretreatment of the eye with a drop of sterile, isotonic, 2.6% sodium borate solution (pH 9.2) can markedly reduce the

dose required for an alkaloidal drug to produce a mydriatic or miotic response in the eye.

In 1966, Good *et al.* (2) described a series of organic buffers, called "biological buffers," for use in biological systems. No report has appeared on the effect of these biological buffers on the corneal absorption of ophthalmic drugs.

The objective of this study was to investigate some related aspects of prebuffering the eye or of buffering certain mydriatic eye drops with various alkaline buffers along with the utilization of some viscolizers in order to obtain increased physiological response in both rabbit and human eyes.

Since Howard and Lee (3) and others have shown that there is a difference in mydriatic response between persons of different races, both Oriental and Caucasian subjects were included in this study. In addition, the previously unreported dissociation constant for cyclopentolate HCl was determined experimentally.

EXPERIMENTAL AND RESULTS

Subjects and Materials—The experimental subjects employed were Caucasian and Oriental humans, both male and female, and New Zealand white rabbits, female, weight 2–2.5 kg. The mydriatics used were cyclopentolate HCl,¹ homatropine HBr USP,² and phenylephrine HCl USP.³ The buffers utilized were sodium borate decahydrate,⁴ *N,N*-bis(2-hydroxyethyl)glycine,⁵ 2-(*N*-morpholino)ethanesulfonic acid,⁶ and tromethamine.⁷ The viscolizers employed were hydroxypropyl methylcellulose 4000 cps.⁸ and polyvinyl alcohol.⁹

Preparation of Aqueous Solutions of Mydriatics and Buffers—All aqueous drug and buffer solutions (without viscolizer) were prepared and sterilized by filtration through sterile membrane filters¹⁰ (0.45 μ) into sterile dropper bottles; subsequent transfers were made with sterile pipets. Adjustment of the tonicity of the test solutions was not considered. All eye drops prepared were stored in 0.5-oz., light-resistant, sterile, all-glass dropper bottles. To standardize the size of the drops instilled, only droppers that delivered 71–74 drops of water to give exactly 4 ml. when dropped vertically into a small cylindrical graduate were used.

Preparation of Ophthalmic Vehicles Containing Viscolizers—A double concentrated solution of each viscolizer, *i.e.*, 1% hydroxypropyl methylcellulose and 2.8% polyvinyl alcohol, was prepared

and autoclaved at 15 p.s.i. for 30 min. After cooling, a clear dispersion resulted. Equal volumes of the doubly concentrated sterile stock viscolizer solution and the doubly concentrated sterile aqueous mydriatic solution were mixed together before instillation, thereby giving the desired final experimental concentration. The final viscolizer concentrations of 0.5% hydroxypropyl methylcellulose and 1.4% polyvinyl alcohol were selected because those concentrations are often employed commercially.

Measurement of Pupil Size—Rabbits were placed on top of empty rabbit cages, the height of which subdued them sufficiently so that no further restraint was necessary; humans were seated in an evenly lighted room. A ruler with a millimeter scale was held firmly against the face, and the horizontal diameter of the pupil was estimated to the nearest 0.5 mm. in a similar manner in all cases. The pupil diameters were measured before the initial instillation of drops and at various time intervals thereafter. The results are presented as the average millimeter of increased diameter of at least two human or three rabbit subjects in each case.

Although statistical analysis could have been used in this study, it would contribute little. The range of values from which the averages were derived for the controls did not overlap those for the test subjects in any instance.

Determination of Threshold for Mydriatics in Rabbits—Before undertaking the mydriatic study in rabbits, it was necessary to ascertain the proper concentration of drug to give the desired response in rabbit eyes. The threshold concentration sought was the minimum concentration that would give a measurable mydriatic response but which was still small enough so that any increase in response brought about by any adjuvant would be apparent. The rabbit threshold concentrations were found to be 0.0075% for

homatropine HBr and 0.02 and 0.002%, respectively, for the combination phenylephrine HCl and cyclopentolate HCl solution.

Comparison of Effects of Combination Solution of Phenylephrine HCl and Cyclopentolate HCl in Different Concentrations, Both with and without Sodium Borate Prebuffering—The combination solution of 10% phenylephrine HCl and 1% cyclopentolate HCl, which is used routinely in many eye clinics, is designated as "concentrated dilating solution," and a combination solution of exactly one-tenth this concentration is designated as "dilute dilating solution" throughout this study. The mydriatic effect and relative amount of eye irritation of both solutions were tested on human subjects. One drop of the concentrated dilating solution was instilled in one eye of the test subject, and one drop of the dilute dilating solution was instilled immediately in the other eye. Measurements of the pupil size were taken immediately before and every 10 min. after instillation for 1 hr. Figure 1 shows that the dilute dilating solution gave a weaker response than did the concentrated solution. The test subjects reported that the concentrated dilating solution was quite painful to the eye but that the dilute dilating solution was not.

In another series of experiments, one drop of sterile 2.6% sodium borate solution (pH 9.2) was first instilled in one eye of the test subject. After a few seconds, any excess buffer solution on the eye lid was wiped off with soft tissue, and this prebuffered eye received one drop of the dilute dilating solution while the unbuffered eye received one drop of the concentrated dilating solution. Figure 1 shows that there was a similar mydriatic response in both eyes, with both pupils reaching the same maximum diameter at about the same time. The degree of dilation of both eyes was confirmed by an ophthalmologist at the eye clinic as being adequate for any routine eye examination; the borate prebuffer solution gave no eye irritation.

The foregoing experiments were first carried out on rabbit eyes using the previously mentioned threshold concentration of the combination dilating solution. The results on rabbits corresponded to those reported in Fig. 1 for humans.

Use of Combination 1% Phenylephrine HCl and 0.1% Cyclopentolate HCl Solution in a Sodium Borate Buffered Vehicle, Both with and without Viscolizer—To lessen the number of drops that must be given a patient, an attempt was made to combine the borate buffer solution (both with and without viscolizer) and the dilute dilating solution so that the technique of prebuffering the eye was unnecessary. The buffered drops had a pH of 9.2. A brief study of the stability of the agents in aqueous, viscous and nonviscous, alkaline solutions was in order.

Comparison tests of the degree of mydriasis obtained were conducted first with rabbit eyes and then with a series of humans, using freshly prepared, dilute dilating solution in sodium borate buffer *versus* similar solutions which were 8 and 24 hr. old. All tests were made by instilling in a like manner one solution in one eye while the solution to which it was being compared was instilled in the other. The results for the average of three humans for each solution are presented in Fig. 2. The rabbit tests gave

similar responses. Clinically satisfactory and practically identical mydriatic and cycloplegic effects were obtained from the prebuffered solution and the freshly prepared and the 8-hr. old alkaline solution, but the 24-hr.-old alkaline solution produced slightly less mydriatic effect than did the others. No irritation to the eye was felt by any of the subjects receiving any of these alkaline, dilute dilating solutions. There was no change in physical appearance of the 24-hr.-old alkaline solution. However, after standing at room temperature for 3 days, the solution turned slightly yellow.

The addition of 0.5% hydroxypropyl methylcellulose to the freshly prepared sodium borate buffered, dilute dilating solution did not produce any increased mydriasis in the eyes of Caucasians because they were already at maximum dilation. However, when this viscous, dilute dilating solution was compared in Oriental eyes to the same solution without viscolizer, an increase in the degree of mydriasis in Oriental eyes was produced by the more viscous solution (Fig. 3). Since Oriental eyes are known to be more difficult to dilate than those of Caucasians, it was not surprising that one drop of the buffered, viscous, dilute dilating solution did not produce a completely satisfactory dilation, as shown in Fig. 3. It was necessary to instill a second drop 15 min. later into the eyes of Orientals to effect comparable dilation; these results are shown in Fig. 4 along with a one-drop dose of concentrated dilating solution. Comparison with Fig. 1 shows how much less effective one drop of concentrated dilating solution is for Orientals (Fig. 4) than for Caucasians (Fig. 1).

Effect of Various Prebuffers on Rabbit Corneal Absorption of Certain Mydriatics—In this study on rabbits, the enhanced mydriatic effect produced by using 2.6% sodium borate solution as a prebuffer was compared to the effect given by use of the following three biological buffers: 0.2 M *N,N*-bis(2-hydroxyethyl)glycine, 0.2 M 2-(*N*-morpholino)ethanesulfonic acid, and 0.2 M tromethamine for aqueous homatropine HBr solutions. The tests were all made in a similar manner, with sodium borate prebuffer solution being instilled in one eye of each rabbit and one of the biological buffer solutions dropped in the other eye prior to the instillation of the mydriatic solution. The diameter of the pupils was measured every 15 min. thereafter for 2 hr. and represented the average given by three or more rabbits in all cases. The results, shown in Fig. 5, indicate that the largest increase in mydriatic effect was given by the buffer with the higher pH and the smallest increase was given by the buffer with the lowest pH. A similar test on rabbits was made using sodium borate prebuffer solution in one eye and no buffer in the other eye to find out how much the mydriatic effect of a combination solution of phenylephrine HCl and cyclopentolate HCl is increased in rabbit eyes by prebuffering with sodium borate. The results, shown in Fig. 6, indicate that prebuffering markedly reinforces the mydriatic effect of phenylephrine and cyclopentolate solution in rabbit eyes.

Effect of Viscolizers on Rabbit Corneal Absorption of Homatropine HBr Solution—A series of rabbits received one drop of aqueous 0.0075% homatropine HBr solution in one eye and one drop of the same homatropine solution prepared in either 1.4% polyvinyl

Figure 5—Effect of various prebuffer solutions on rabbit corneal absorption of 0.0075% homatropine HBr solution. Key: Δ, with sodium borate prebuffer (pH 9.2); ●, with no buffer or with *N,N*-bis(2-hydroxyethyl)glycine prebuffer (pH 8.4) or with tromethamine prebuffer (pH 8.3); and ○, with 2-(*N*-morpholino)ethanesulfonic acid prebuffer (pH 6.2).

alcohol or 0.5% hydroxypropyl methylcellulose in the other eye. Single-drop doses rather than measured volumes were used, because when the droppers were calibrated, the sizes of the drops were found to vary less than 6% whether or not they contained a viscolizer. The procedure was carried out in the same manner as described previously; the measurement of the pupil diameters was taken every 15 min. for 2 hr. The results are shown in Fig. 7 and indicate that both viscolizers reinforce the mydriatic effect of homatropine HBr solution but that the increase given by hydroxypropyl methylcellulose was much greater than that given by polyvinyl alcohol. This increased mydriatic effect produced by the drops containing 0.5% hydroxypropyl methylcellulose paralleled the somewhat greater viscosity that it had, i.e., 13.2 cps. versus 2.3 cps. for the drops containing 1.4% polyvinyl alcohol.

Determination of pKa of Cyclopentolate HCl—An aqueous solution of known concentration of cyclopentolate HCl was neutralized with a stoichiometric quantity of standardized NaOH solution to liberate free cyclopentolate. A titration curve of the free cyclopentolate was obtained by titrating the neutralized solution with standardized dilute HCl, using a Beckman Zeromatic pH meter. The midpoint of the titration curve was ascertained, and the pKa value of cyclopentolate HCl was determined by finding the pH value that corresponded to this midpoint. In this way the pKa of cyclopentolate HCl was found to be 7.93, as shown in Fig. 8.

DISCUSSION AND CONCLUSIONS

The experimental data obtained from this investigation indicate that the physiological response of several mydriatic eye drops can be enhanced by proper utilization of certain buffers and viscolizers, with 2.6% sodium borate solution being the most effective buffer and 0.5% hydroxypropyl methylcellulose being the most effective viscolizer of those tested.

A comparison of the amount of the free base portion of an amine ophthalmic drug present at pH 9.2 (the pH of 2.6% sodium borate

Figure 6—Mydriatic effect on rabbits of combination solution of 0.02% phenylephrine HCl and 0.002% cyclopentolate HCl, both with and without borate prebuffer. Key: ○, with sodium borate prebuffer; and ●, without sodium borate prebuffer.

solution) and at pH 7.4 (the pH of normal tear fluid) by using the pKa of the particular drug can be used to predict whether or not buffering the eye to pH 9.2 would enhance the corneal absorption of this drug. For example, with phenylephrine HCl, which has a pKa of 8.86, the amount of free base present at pH 9.2 would at maximum be about 22 times greater than that present at pH 7.4; in a similar manner for homatropine HBr (pKa 9.7), the free base form would be about 48 times greater at pH 9.2. In the case of pilocarpine HCl with a pKa of only 6.85, the concentration of the free base portion at pH 9.2 is only about 1.3 times greater than that present at pH 7.4. This increase in quantity of free base is too small an amount to show any measurable increase in miotic effect. A study of pilocarpine HCl showed no measurable decrease in pupil diameter due to the prebuffer treatment with sodium borate.

Since the pH on the surface of the eye may fluctuate due to the loss of carbon dioxide and sometimes become as high as 8 (rather than 7.4), and since the pH of the mixed sodium borate solution and tear fluid which is continuously being diluted with more tears will decrease and be lower than 9.2 for much of the time after its initial instillation, the actual ratio of the free base molecules of instilled amine drops on buffered and unbuffered eyes will be considerably smaller than the theoretical calculated value. This study showed that the mydriatic effect of the combination solution of phenylephrine HCl and cyclopentolate HCl and of homatropine HBr each was increased about 10-fold when the sodium borate prebuffer method or borate-buffered drops were used. If the theoretical optimum buffering conditions could have prevailed, the mydriatic solutions should have given physiological responses of 2-4 times the experimental findings.

Although the most appropriate pH for eye drops is usually reported as being 7.4 for maximum eye comfort, Trolle-Lassen (4) and others have found that the eye can tolerate an isotonic solution up to about pH 9.7 as long as it has no other irritating properties. Therefore, the sterile, isotonic, 2.6% sodium borate solution is a suitable nonirritating buffer for ophthalmic use whenever the

therapeutic drug has a sufficiently high pKa value for its effect to be appreciably enhanced.

Recommended Diluting Solutions for Routine Eye Examination—The following two rather dilute mydriatic preparations will give a physiological response equal to that of the frequently used more concentrated dilating solution composed of 10% phenylephrine HCl and 1% cyclopentolate HCl:

1. If the administration of a drop dose of each of two separate solutions presents no problem, it is recommended that one drop of sterile, 2.6% aqueous sodium borate solution be first instilled in the eye, followed immediately by one drop of a sterile, aqueous, combination solution of 1% phenylephrine HCl and 0.1% cyclopentolate HCl. This is the so-called prebuffering technique.

2. If it is desired to have the total medication in a single drop, as it might be for children, one drop of a special solution should be instilled which is prepared by mixing together equal volumes of the aqueous mydriatic and viscous buffer solutions not more than 8 hr. prior to their use. The buffer solution is composed of double concentrations of sodium borate, 5.2%, and hydroxypropyl methylcellulose, 1.0%, and has been sterilized in an autoclave. The mydriatic solution consists of double concentrations of phenylephrine HCl, 2%, and cyclopentolate HCl, 0.2%, and has been sterilized by filtration. Equal volumes of these two solutions, each in a sterile bottle, are mixed by pouring the viscolizer and buffer solution into the dropper bottle containing the mydriatic solution and shaking the contents well for a few seconds to effect complete mixing. The resulting solution will have the recommended concentration of 1.0% phenylephrine HCl, 0.1% cyclopentolate HCl, 0.5% hydroxypropyl methylcellulose, and 2.6% sodium borate, and it should not be used more than 8 hr. after being mixed.

While the use of the buffered solution has the advantage of requiring the instillation of only a single drop, it also has the obvious disadvantage of requiring that the two separate solutions must be mixed together daily since the mixture is only stable for 1 day. Also, when using the prebuffer technique, if there is any excess buffer solution on the cornea or lids following its instillation, it should be wiped off gently with tissue before instillation of the mydriatic drops. Otherwise, due to the occasional limiting capacity of the cul-de-sac of the eye, a portion of the medicinal drop will flow out from the eye and down the cheek. The partial loss of the drop will cause a deficient response. Use of the preparation with both medicament and buffer combined in one solution will avoid this disadvantage.

For use on races other than Caucasian, it is recommended for either buffering method that a repeat instillation be made about 15 min. after the first one to ensure adequate dilation.

Duration of Activity and Decreased Side Effects—All of the dilute mydriatic solutions used with prebuffer or with both buffer and viscolizer studied in this investigation gave mydriatic effects which were of considerably shorter duration than those given by the more concentrated dilating solutions used without buffer, although the duration of action of the various solutions is not being specifically reported in these results. Since it has been found that angle closure glaucoma can be precipitated by dilating the pupil (5), the shorter duration of mydriasis should be a decided advantage for using a dilute mydriatic solution with a buffer rather than a nonbuffered, more concentrated one.

Carpenter (6) states that cyclopentolate in its usual and more concentrated dosage has been found to produce disorientation, hallucinations, apprehension, and cerebral disfunction in some cases, lasting for as long as 11 months in one instance. Another report (7) concludes that cyclopentolate is a strong enough hallucinogen to produce symptoms similar to those of LSD in some persons. Since an appreciable amount of any instilled eye drops descends through the nasolacrimal duct into the nasopharynx and is eventually swallowed or absorbed through the pharyngeal mucosa, a 10-fold less concentration of any therapeutic agent instilled into the eye—if it produces an acceptable therapeutic response—should have the added advantage of producing considerably less side effects.

Figure 8—Titration curve of cyclopentolate.

Interactions of Drugs with Proteins II: Experimental Methods, Treatment of Experimental Data, and Thermodynamics of Binding Reactions of Thymoleptic Drugs and Model Dyes

H. J. WEDER* and M. H. BICKEL

Abstract □ The binding to bovine albumin of the model dyes and drugs—bromocresol green, eosin, imipramine, and desipramine—has been studied using equilibrium dialysis, ultracentrifuge sedimentation, and difference spectrophotometry. An improved apparatus for equilibrium dialysis has been developed. Bromocresol green interacts with two types of binding sites: four ligands are bound by H-bonds, electron-donor-acceptor (and possibly hydrophobic) forces stabilized by electrostatic forces, and three to four ligands are bound by electrostatic forces only. Eosin is bound by van der Waals' forces and electron-donor-acceptor forces to three binding sites and by electrostatic forces to six binding sites. Imipramine interacts with only one type of binding site by van der Waals' and possibly hydrophobic forces, stabilized by dipole-dipole forces and involving tyrosyl residues. There are $n = 6$ binding sites, and the intrinsic association constant $k = 5 \times 10^5 M^{-1}$. Desipramine binding exhibits a more complicated mechanism, probably involving exposure of additional binding sites upon a drug-induced conformational change. Given concentrations of drug and protein yield the free-drug concentration and degree of binding as experimental values. From these the following parameters for each type of binding site have been determined by computer: n , k , free-enthalpy change, enthalpy change, and entropy change. From these parameters, as well as from spectral shifts and dependence on pH, ionic strength, and temperature, the modes and forces of interaction have been deduced according to previously discussed binding models and methods. Identical results are obtained by dialysis and ultracentrifugation if pH, ionic strength, and temperature are kept constant.

Keyphrases □ Plasma protein—drugs—interactions □ Thymoleptics, dyes—bovine albumin binding □ Dyes, thymoleptics—thermodynamics, bovine serum binding □ Thermodynamics—drugs—albumin binding □ Dialysis, equilibrium—albumin binding □ UV spectrophotometry—analysis

It is generally assumed that a small molecule interacting with a biopolymer induces a conformational change which is responsible for the action of the small molecule (drug). Similar interactions or binding of drugs also occur with biopolymers not involved in pharmacological action, *i.e.*, with unspecific receptors such as plasma proteins.

The binding of a small molecule can influence the chemical reactivity at different sites of the macro-

molecule. These phenomena are mainly due to long-range electrostatic forces, to shorter range specific interactions such as hydrogen and hydrophobic bonds (1), and finally to proton dispersion forces; the latter obey the same laws as London dispersion forces (2). In addition, primary drug-protein complexes are often stabilized by charge transfer forces. These forces, however, should not be used to estimate the overall complex stability, since the interactions are mainly due to van der Waals-London forces. The stability of a drug-protein complex is expressed by its association constant, which is also important for the pharmacokinetic behavior of the drug.

Numerous methods are currently used for the study of drug-protein interactions (3). Thermodynamic methods and optical rotatory dispersion (ORD) or circular dichroism measurements are tools for the detection of drug-induced conformational changes of a biopolymer. Equilibrium dialysis and ultracentrifugation, as well as spectroscopy in the visible and UV range, allow the determination of association constants. The resulting energy and entropy effects are useful parameters for the interpretation of the mechanism of interaction. Difference spectra in the 220–310-m μ range yield information on conformational changes in the environment of phenylalanyl, tyrosyl, and tryptophyl residues. High resolution NMR spectroscopy is a powerful tool for the study of primary binding sites and of drug atoms interacting with the macromolecule. Information on the mobility of the interacting groups can, in this way, be obtained by the determination of relaxation times.

In this paper, the authors present the results of experiments with triphenylmethane dyes and bovine albumin designed to test methods used in the study of drug-protein interactions. Some of these methods were used in the earlier study of tricyclic thymoleptic drugs (4). This paper also contains additional data on the thermodynamics and binding mechanism of the drugs mentioned.

Numerous methods are currently used for the study of drug-protein interactions (3). Thermodynamic methods and optical rotatory dispersion (ORD) or circular dichroism measurements are tools for the detection of drug-induced conformational changes of a biopolymer. Equilibrium dialysis and ultracentrifugation, as well as spectroscopy in the visible and UV range, allow the determination of association constants. The resulting energy and entropy effects are useful parameters for the interpretation of the mechanism of interaction. Difference spectra in the 220–310-m μ range yield information on conformational changes in the environment of phenylalanyl, tyrosyl, and tryptophyl residues. High resolution NMR spectroscopy is a powerful tool for the study of primary binding sites and of drug atoms interacting with the macromolecule. Information on the mobility of the interacting groups can, in this way, be obtained by the determination of relaxation times.

In this paper, the authors present the results of experiments with triphenylmethane dyes and bovine albumin designed to test methods used in the study of drug-protein interactions. Some of these methods were used in the earlier study of tricyclic thymoleptic drugs (4). This paper also contains additional data on the thermodynamics and binding mechanism of the drugs mentioned.

EXPERIMENTAL

Materials—The purity of the dyes, bromocresol green (BKG) and eosin (EOS),¹ was checked by TLC. All other compounds used were described previously (4). The buffer solutions are indicated in the respective tables and figures.

Spectrophotometry—All measurements were carried out at $20 \pm 2^\circ$ with a Unicam UV spectrophotometer SP 800 and a 1-cm. cell. The following molar extinction coefficients have been determined for BKG (ϵ_{616}^{20}) and EOS (ϵ_{515}^{20}), respectively: 2.93×10^4 and 5.94×10^4 (pH 7.0 phosphate buffer, 0.01 M), 2.04×10^4 and 5.50×10^4 (pH 5.0 disodiumcitrate buffer, 0.05 M), and 1.32×10^4 and 3.26×10^4 (pH 3.5 citric acid-phosphate buffer 0.05 M). The relative errors were $<3\%$.

To use a spectral change for the determination of the free and protein-bound dye, the following conditions must be fulfilled:

1. There is no absorbance of the protein in the spectral range used.
2. Free and bound ligands obey Beer's law in the concentration range used.
3. Extinction coefficient (ϵ) of bound ligand is independent of degree of binding (r).
4. There is the appearance of an isosbestic point ($\epsilon_{free} = \epsilon_{bound}$).

Calculations of association constants can be carried out according to Benesi and Hildebrand (6) or Hammes and Schimmel (7). The molar ratio of an interaction can be determined by extrapolation of the difference spectrophotometric titration curve at saturation ($r = n$) obtained by varying the concentration of either ligand or protein.

Equilibrium Dialysis—The fraction of a ligand bound to a protein can be determined by measuring the free ligand concentration in the protein-free compartment. Membrane effects can be controlled if the ligand concentration can be determined in both compartments. Under certain conditions (8), the Donnan effect must be corrected for (9, 10). The devices used for equilibrium dialysis range from simple cellophane bags (11–13) to specially designed apparatus (14, 15). The one developed by the authors contains two cells (3.0 ml., 0.27-cm. width), separated by a regenerated cellulose membrane of a medium pore size of 3–5 μ m

and a weight of 12.8 g./m.². The vertically positioned wheel-shaped double cell is rotated at 100 r.p.m. Each cell contains two metal tubes in opposite position. They are used for filling and emptying the cells and are connected by a plastic tube during dialysis. Further details are shown in Fig. 1. The main advantages (14) of this device, as compared to others, are a constant solution volume (pressure compensation), minimal dilution effects, short equilibration times, and low risk of denaturation.

To suppress Donnan effects, the buffer solutions contained 0.9% NaCl. The dialyses were carried out at 20 ± 1 and $4 \pm 1^\circ$, respectively. The experimentally determined equilibration times were in the 2–3 hr. range for all ligands used [imipramine (IP), desipramine (DMI), BKG, and EOS]. Addition of these ligands to the buffer cell or to the protein cell led to identical results. In the latter case, an incubation time of 30 min. was allowed before dialysis. The binding reactions have been found to be reversible. The weak adsorption of IP and DMI to the membrane has been controlled by measuring the equilibration concentrations in both cells. The concentrations were determined either by measurement of radioactivity (4) or spectrophotometry.

Ultracentrifugation—In a strong gravitational field, sedimentation of proteins and protein-ligand complexes can be obtained whereas the free ligand concentration remains unchanged. The method described by Steinberg and Schachman (16, 17) has been used.
