Normal and Promoted Gastrointestinal Absorption of Water-Soluble Substances I: Induced Rapidly Reversible Hyperabsorptive State in the Canine Fundic Stomach Pouch

W. W. DAVIS, R. R. PFEIFFER, and J. F. QUAY

Abstract □ Certain surface-active agents placed in a Thomas canine fundic pouch in buffered solutions influence the absorption of soluble drugs (antibiotics). Such agents induce a rapidly reversible hyperabsorptive state of the organ, resulting in blood levels of absorbed drug many times greater than control values. Effective surface-active agents may be nonionic, anionic, or zwitterionic. The influence of the surface-active agent is upon the organ and not upon the drug, as evidenced by the efficacy of the absorption promoter when it is employed and removed before the drug is introduced.

Keyphrases □ Absorption, antibiotics—surfactant effect □ Surfactant effect—antibiotic absorption □ Gastric fundus pouch, dog—absorption, antibiotics □ Plasma levels—antibiotics □ Microbiological analysis—plasma, antibiotic concentration

Detergents and bile salts interfere with the normal barrier to the movements of Na^+ , K^+ , and H^+ in the gastric mucosa (1). Many other reports in the literature describe examples of surface-active agents having a marked effect, either positive or negative, on passage of molecules through physiologic barriers (2–8).

Most of these observations, however, deal with translocation of substances under conditions complicated by insolubility of the compound (6), involvement of active transport processes (7, 8), or interaction of the surface-active agent with the penetrating species (4, 5). These complications prevent formulation of conclusions concerning the general nature of the influence of surfactants on the absorption of drugs from the gastrointestinal tract.

This and subsequent reports present observations regarding the general nature of the effects of surfactants on the absorption of drugs from the gastrointestinal tract. By restricting these studies to soluble drugs, the authors avoid variability due to differences in wetting, solubilization, and dispersion. In this initial study, the gastric fundic mucosa was used as a test membrane to confine the observations to a relatively simple system. By sometimes exposing the tissue first to surfactant and subsequently to the drug, the authors were able to separate the effects of surfactant-membrane interactions from those of surfactant-drug interactions.

Parenteral antibiotics were chosen for specific study because this class of drugs is readily detected in the blood by known quantitative methods. These compounds, furthermore, are ordinarily not well absorbed from the gastrointestinal tract. Their absorption in significant amounts would therefore be easier to demonstrate and be of greater practical interest than if the enhanced absorption of an already well-absorbed drug was the subject of study.

EXPERIMENTAL

Dogs were surgically prepared with Thomas-type pouches of the gastric fundus several months prior to the experimental period. Catheter access to the pouch permitted ready introduction and removal of solutions containing conditioning agents and drugs, either together or separately.

Dogs were fasted overnight before use so that observed gastric acid secretion was minimal. The secretory state, in addition to causing undesirable fluctuations in the pouch contents, was observed to oppose absorption where such absorption had been previously observed in the absence of secretion. In the early experiments, whenever the pouch contents were observed to be acidic, the animal was made nonsecreting by giving it 3 mg. of an anticholinergic drug¹ orally 30 min. before the experiment. This treatment had no apparent effect on either control or experimental results. To prevent the occasional inconsistencies attributable to the secretory state and to reduce the number of experimental variables, the treatment was subsequently made routine.

Solutions of sodium cephalothin² in pH 7.0 sodium phosphate buffer, with varying amounts of POE-24-cholesterol ether,³ were placed in the pouch of a dog and replaced at approximately 40-min. intervals with a fresh solution. Heparinized samples of peripheral venous blood, removed periodically by venipuncture, were centrifuged; the plasma was assayed for microbiological activity of cephalothin by standard disk-plate tests.⁴

RESULTS AND DISCUSSION

Absorption of cephalothin from the gastric pouch was promoted by the presence of POE-24-cholesteryl ether. The plasma antibiotic level achieved was dose responsive to the pouch concentration of this nonionic surface-active agent (Fig. 1a) at constant antibiotic concentration.

Absorption of cephalothin from the gastric pouch under the same conditions was also promoted by many, but not all, other surface-active agents (Table I). The absorption of cephalothin was dose responsive to the concentration of coadministered sodium lauryl sulfate (Fig. 1b), but with the limitations to be discussed.

The absorption of cephaloridine,⁵ an antibiotic related to cephalothin but amphoteric in nature, was also promoted by the presence of POE-20-oleyl ether⁶; the extent of absorption was again dependent on surfactant concentration (Fig. 1c).

The relationships between surfactant concentration and rate of drug absorption in these experiments illustrate an important aspect of the action of the surface-active agents. The critical micelle concentration (CMC) of sodium lauryl sulfate under comparable conditions is about 0.035% (12, 13), corresponding to the concentration at which the absorption response to increased surfactant concentra-

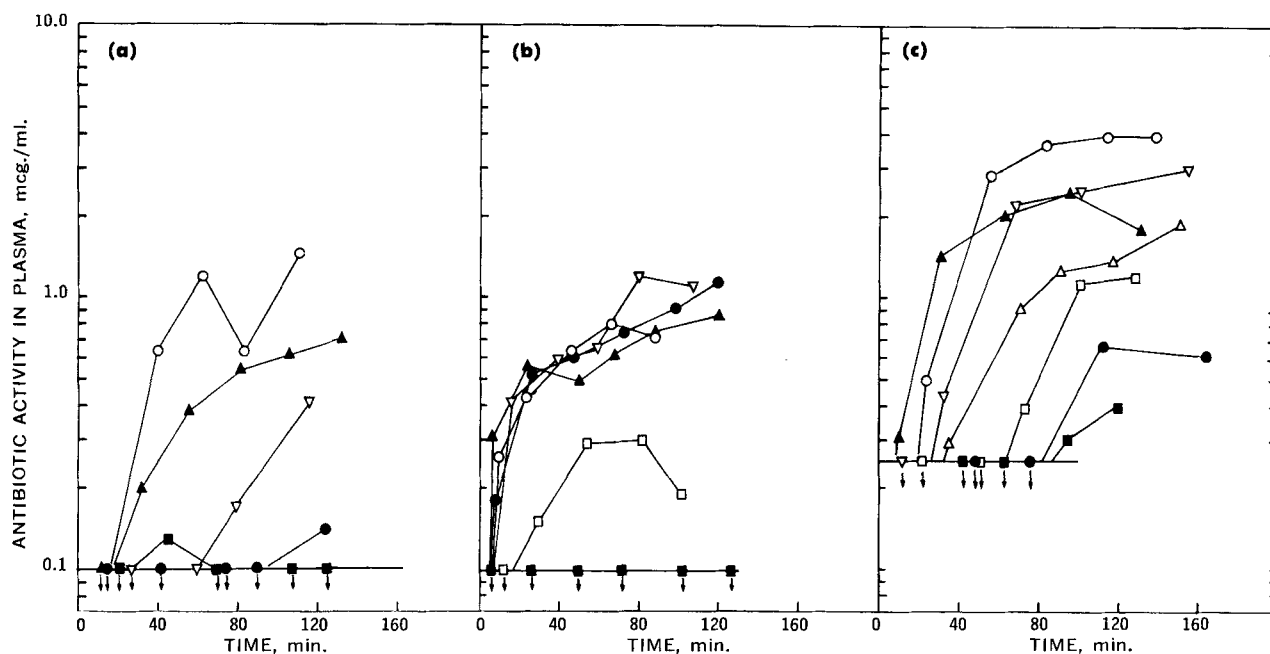

Figure 1—Effect of surfactant concentration on the absorption of cephalosporin antibiotics from the dog fundic pouch. Pouch contents: 25 ml. 1% antibiotic and indicated concentration of surfactant, dissolved in isosmolar sodium phosphate buffer, pH 7.0. The horizontal lines are drawn at the minimum detection limit of the assay. Key: (a) Absorption of cephalothin promoted by POE-24-cholesteryl ether; surfactant concentration, w/v: ■, 0.0%; ●, 0.025%; ▽, 0.05%; ▲, 0.1%; and ○, 0.5%. (b) Absorption of cephalothin promoted by sodium lauryl sulfate; surfactant concentration, w/v: ■, 0.0%; □, 0.025%; ●, 0.05%; ▽, 0.2%; ▲, 0.4%; and ○, 0.8%. (c) Absorption of cephaloridine promoted by POE-20-oleyl ether; surfactant concentration, w/v: ■, 0.0%; ●, 0.15%; □, 0.031%; △, 0.062%; ▽, 0.125%; ▲, 0.25%; and ○, 0.5%.

tion terminates. Therefore, the absorptive response to surfactant concentration develops only throughout the range in which the concentration of molecularly dispersed sodium lauryl sulfate is increasing. The absorptive response to nonionic surfactants (Figs. 1a and 1c) occurs over a wider range of surfactant concentration, in keeping with the continued increase in concentration of the molecularly dispersed species above the CMC which is a characteristic of nonionic surfactants. This dose response to molecularly dispersed surfactant is in contrast to the ability of surfactants to solubilize water-insoluble substances, which depends on and is proportional to the amount of surfactant in the micellar phase.

To characterize the onset of the hyperabsorptive state as a result specifically of contact of the stomach with the absorption promoter, POE-24-cholesteryl ether in buffered solution was placed in the pouch for periods from 5 to 60 min. and then removed. The pouch was rinsed several times with buffer (requiring about 5 min.), and then a solution of cephalothin (in buffer) without surfactant was introduced into the pouch. The resulting plasma levels of antibiotic activity rose more rapidly and to higher peak values as the duration of pretreatment with promoter was increased, demonstrating the gradual appearance of the hyperabsorptive state of the pouch with increasing time of exposure to the surfac-

Table I—Effect of Various Promoters on the Absorption of Several Antibiotics from the Dog Fundic Pouch

Figure 2—(a) Effect of duration of contact between POE-24-cholesteryl ether solution and the dog fundic pouch upon the subsequent absorption of cephalothin. Sequence of pouch contents: (1) 25 ml. 0.5% POE-24-cholesteryl ether in isosmolar sodium phosphate buffer, pH 7.0, for the indicated time of contact; (2) three rinses with 25 ml. buffer; (3) 25 ml. 1% cephalothin in isosmolar sodium phosphate buffer, pH 7.0 (without POE-24-cholesteryl ether), for 120 min. Plasma activity was followed for 120 min. Each point is the mean \pm SEM of the maximum levels from the number of experiments shown in bold numerals performed on each of two 21-kg. dogs. The horizontal line is the minimum detection limit of the assay. (b) Effect of recovery time on the hyperabsorptive state of the dog fundic pouch, the absorption of cephalothin after various time intervals between removal of POE-24-cholesteryl ether and introduction of cephalothin. Sequence of pouch contents: (1) 25 ml. 0.5% POE-24-cholesteryl ether in isosmolar sodium phosphate buffer, pH 7.0, for 40 min.; (2) three rinses with 25 ml. buffer; (3) pouch empty for indicated time; (4) 25 ml. 1% cephalothin in isosmolar sodium phosphate buffer, pH 7.0 (without POE-24-cholesteryl ether), for 120 min. Plasma activity was followed for 120 min. Each point is the mean \pm SEM of the maximum levels from the number of experiments shown in bold numerals performed on each of two 21-kg. dogs. The horizontal line is the minimum detection limit of the assay.

tant. The effect increased with time of exposure to this promoter at this concentration up to about 40 min., as seen in the plot of peak antibiotic plasma levels against time of contact (Fig. 2a). This graph also shows that as little as 5 min. of contact with 0.5% POE-24-cholesteryl ether solution resulted in some promoted absorption.

To quantitate the rate at which the fundic pouch loses the hyperabsorptive state after removal of the surface-active solution, 0.5% buffered POE-24-cholesteryl ether solutions were maintained in the pouch for 40 min. and then rinsed out with buffer. Then a time was permitted to elapse before the cephalothin solution without surfactant was introduced (Fig. 2b). As the elapsed time between removal of promoter and introduction of antibiotic increased, the maximum resulting blood levels declined rapidly. The peak plasma

level obtained fell to one-half when the elapsed time was 25 min., and it fell below the detection limit when the elapsed time was 2 hr.

This rapid recovery of normal absorptiveness, suggesting the rapid restoration of a normal barrier to diffusion, is in contrast to the persistent hyperpermeability associated with damage to the gastric mucosa caused by fatty acids and acetylsalicylic acid at low pH, as reported by Davenport (14).

In addition to the observation that peak plasma levels of drug reach lower levels as the recovery time increases, other observations provide evidence of the rapid reversal of the hyperabsorptive state and the return to a normal absorptive state after removal of the promoter. When the drug is placed without promoter in the preconditioned pouch, blood levels decline rapidly after an initial

sharp rise, implying that absorption continues only briefly in the absence of promoter in the pouch contents.

The complete reversibility of this induced hyperabsorptive state and the absence of permanent damage in the Thomas pouch dogs used for almost daily experiments are indicated by the fact that they lost neither their characteristic control response nor their reactivity to promoters over the course of several years.

These experiments clearly show that the surface-active agent acts on the organ rather than on the drug. The effect of surface-active agents in rendering the stomach hyperabsorptive toward water-soluble drugs is thus distinguished from the reported effects of similar agents on the absorption of poorly soluble drugs, which is commonly attributed to improved physical dispersion or rate of dissolution.

All agents that the authors found to possess the ability to promote gastric absorption of drugs are surface-active agents, but not all surface-active agents are effective at the concentrations employed.

The phenomenon of promoted absorption is not limited by the specific molecular nature or charge of the soluble drug (Table I). It also can be observed at low pH and is seen in presence of citrate or phosphate buffers of a range of concentrations and with isotonic sucrose when these solutions are used to dissolve the drug and promoter.

The effectiveness of the surfactants in promoting gastric absorption of cephalothin is poorly correlated with the hydrophile-lipophile balance of the surface-active agent and is not proportionate to the ability of the agent to lower the surface tension at an air-water interface. A general correlation was observed, however, between the effectiveness of a surface-active agent in promoting gastric absorption and its ability to lyse erythrocytes *in vitro*. This lytic action, to which erythrocytes are notoriously sensitive, is generally regarded as due to the accumulation of the surfactant molecules in the lipid membrane of the cell wall in a manner that causes loss of functional or physical integrity of the membrane.

A high degree of order on a monomolecular or bimolecular leaflet level (15) is generally pictured as having an essential role in the maintenance of a barrier to passive diffusion across cell walls. The reversible changes in gastric absorption reported in the present paper are, the authors believe, the consequences of reversible alterations of this highly ordered barrier that accompany the addition or removal of surfactant as described in these experiments.

The hyperabsorptive state of the stomach epithelium is thus regarded as one in which interference with the diffusion barrier permits increased absorption of a wide variety of water-soluble substances placed in the organ. However, the net absorption (or excretion) of a substance by active transport processes may simultaneously suffer from this reduction of the barrier to free diffusion, since the barrier is presumably operative in both directions and lowering it would lend advantage to the flux opposite to the active transport. Indeed, some compounds used here as promoters have elsewhere been found to inhibit active transport processes (8, 17).

In this study, convenience of measurement has prejudiced the choice of drugs to antibiotics, and the authors have dealt with absorption from the dog fundic pouch only. The observations of

promoted absorption of other drugs in the intact gastrointestinal tract, as well as in ligated segments of the gastrointestinal tract, of the dog and other animal species have confirmed the more general implications of this work to drug absorption.⁷ Such studies will be reported in following communications.

Effects of a Tranquilizer and Two Antidepressants on Learned and Unlearned Behaviors

HARRY M. GEYER, III, NATHAN WATZMAN*, and JOSEPH P. BUCKLEY

Abstract □ The dose-response effects of chlorpromazine, imipramine, and thiazesim were investigated on unlearned behaviors (spontaneous motor activity, eating, drinking, mouse-killing, self-grooming, and forced motor activity) and learned behavior using the rat pole-climbing unit. Three or four doses of each drug were used in the study of each parameter, and ED_{50} values were calculated from the generated log dose-response line. Ratios of the forced motor activity ED_{50} divided by the ED_{50} 's of the various behavioral tests were used to determine whether the blockades of the behavioral parameters occurred at debilitating or nondebilitating doses. The tranquilizer, chlorpromazine, required a debilitating dose to block four of the five unlearned behaviors. The antidepressant, imipramine, disrupted three of these at nondebilitating doses; the antidepressant, thiazesim, blocked all unlearned behaviors at nondebilitating doses. All compounds required debilitating doses to block the learned behavior, a conditioned avoidance response. The results generally support the hypothesis that antidepressants selectively block unlearned behaviors which are not blocked by tranquilizers until debilitating doses are used.

Keyphrases □ Tranquilizer, antidepressant effects—learned, unlearned behavior □ Chlorpromazine, imipramine, thiazesim—comparative effects, learned, unlearned behavior □ Behavioral response, learned, unlearned—antidepressants, tranquilizer effects

Although two major classes of psychotherapeutic agents, tranquilizers and antidepressants, are quite different in their clinical applications, often the assignment of a compound into either of these classifications must await clinical evaluation since the difference is not readily assessable by preclinical animal testing. Tranquilizers and antidepressants have been reported to have qualitatively similar electroencephalographic effects (1-4). Herr *et al.* (5) reported the lack of qualitative differences when these compounds were compared in various toxicological and behavioral studies. Horovitz *et al.* (6) reported a possible method for a preclinical differentiation. These authors reported that antidepressants, but not tranquilizers, given to rats at nondebilitating doses had a blocking action on mouse-killing, an unlearned behavior described by Karli (7). Horovitz *et al.* (6) also reported that this difference between tranquilizers and antidepressants was not found in the comparison of drug effects on a learned avoidance response.

The present study was an attempt to determine if other nonlearned behaviors in rats show the "selective" blocking action by antidepressants.

MATERIALS AND METHODS

Subjects—The subjects were Sprague-Dawley male rats (519) and female rats (82) weighing 200-350 g. The subjects were maintained in individual wire-mesh cages on a 12-hr. light-dark cycle at ambient temperatures between 23.9 and 25.5° (75 and 78°F). Purina laboratory chow and tap water were available *ad libitum* for all subjects except those used in the studies of food and water consumption. All subjects were used only once except in the study of muricide. Maternal behavior and muricide were tested

in the light portion of their light-dark cycle. All other studies were performed during the dark portion of the cycle; in the testing of self-grooming and forced motor activity, the subjects were illuminated by two 1.5-m. (5-ft.) fluorescent red light bars approximately 0.9 m. (3 ft.) from the cage and between the investigator and the subjects.

Drugs—The prototype tranquilizer selected was chlorpromazine hydrochloride, and the antidepressants were imipramine hydrochloride and thiazesim hydrochloride. All drugs were dissolved in distilled water, with concentrations adjusted to enable intraperitoneal injection in volumes of 1 ml./250 g. of body weight. The various testing procedures were performed during peak drug effect which occurred 30 min. after chlorpromazine, 40 min. after imipramine, and 30 min. after thiazesim administration (8). The saline subjects (0.9% NaCl) were tested 30 min. after saline administration. The doses used were as follows: chlorpromazine, 1, 2, and 4 mg./kg.; imipramine, 8, 16, and 32 mg./kg.; and thiazesim, 10, 20, and 40 mg./kg., i.p. In the experiments with self-grooming, mouse-killing, and conditioned avoidance response, an additional dose of chlorpromazine, 8 mg./kg., was included. In the study of water consumption, an additional dose of 5 mg./kg. of thiazesim was included, and imipramine was used in doses of 4, 8, and 16 mg./kg.

Forced Motor Activity (FMA)—Forced motor activity was evaluated by the use of a revolving wooden rod, 5.08 cm. (2 in.) in diameter, as described by Watzman *et al.* (9). The rod first revolved at 7.8 r.p.m., and the speed was increased by 4.5 r.p.m. every 30 sec. The amount of time the subjects remained on the rod was used as the measure of motor activity. The subjects, 81 male rats, were given five consecutive training trials both in the morning and afternoon of the 1st day, four consecutive trials in both the morning and afternoon of the 2nd day, and three consecutive trials on the morning of the 3rd day. The rotarod performance was found in preliminary trials to be stable by the 3rd day. The drugs and saline were administered in the afternoon of the 3rd day, and the subjects were given three consecutive test trials at the time of peak drug effect. The test trials were averaged for each subject, and the groups receiving the experimental compounds were compared with the saline controls.

Spontaneous Motor Activity (SMA)—Spontaneous motor activity was tested in four circular, 6-beam photocell activity cages (Actophotometer, Metro Industries, Inc., New York, N. Y.), using a single subject per cage. The drugs, doses, saline controls, and cages were arranged in a modified factorial design. The testing was performed on 3 consecutive days. There were three experimental subjects and one saline control at each testing session, and each drug-dose group was compared with its appropriate saline controls. The subjects, 95 male rats, were introduced at the time of peak drug effect; their activity counts were recorded at the end of 30 min.

Food Consumption—In this study, 68 male rats were deprived of food for 24 hr. but water was available *ad libitum*. At the end of the deprivation period, the subjects were treated with drugs or saline and, at the time of the peak effect, were given a preweighed amount of Purina laboratory pellets. At the end of 1 hr., the remaining pellets and spillage were collected and weighed. The recorded data were both the weight eaten and the weight of the subject just prior to testing.

Water Consumption—The subjects used in the study of drinking (75 male rats) were deprived of water for 3 days and then placed at the time of peak drug effect in a compartment, 25.4 × 26.6 × 27.9 cm. (10 × 10.5 × 11 in.), which had a drinking spout attached to a drinkometer apparatus. The number of licks recorded in 30 min. was used as the measure of water consumption.

Maternal Behavior—Maternal behavior was studied 1 to 4 days postparturition. The subjects (82 female rats) were removed from their home cages momentarily, the wood floors were cleared, and a new supply of the nesting material and all pups were deposited on

Figure 1—Effects of chlorpromazine, imipramine, and thiazesim on spontaneous (right side) and forced motor activity (left side). Key: ■—, chlorpromazine; ▲ . . ., imipramine; and ● —, thiazesim.

the side of the cage opposite the previously noted nesting site. The subjects were then returned to their cages and rated on the 5-point scale of 0, 1, 2, 3, and 4 according to approximate percents of the nesting material retrieved to the nesting site: 0, 25, 50, 75, and 100%. Simultaneously, the subjects were scored according to the percent of young retrieved. Each session was 8 min. in duration; 24 hr. later the testing procedure was repeated at the time of peak drug action. The experimental subjects were compared with saline controls, and the preliminary trial (saline injection) was used to eliminate the few subjects not completing both nest-building and young-retrieval within 4 min.

Mouse-Killing—An albino mouse, 25 to 30 g., was introduced in the rat's home cage for 5 min.; if the rat killed the mouse, it was retested at least once a day for 5 days. The latter tests were 30 min. after saline injection, and a 60-sec. time limit was imposed. Only those rats (36 males) that killed in all of the predrug trials were used in this study. The animals received drug injections and were tested on four to six occasions. There were always at least 1 week and one saline test between drug administrations. The total number killing within 60 sec. was recorded for each drug and dose.

Self-Grooming—The 84 male rats used in this study were immersed in a sample of rat urine to wet the forepaws, hind paws, and undersides. They were immediately returned to their home cages, and the total time spent grooming was measured over a 5-min. period. Twenty-four hours later, the subjects were weighed and injected and the same procedure was repeated. The time spent grooming each day was recorded.

Conditioned Avoidance Response (CAR)—This was studied in automated pole-climbing units (25.4 × 26.6 × 35.5 cm.) (10 × 10.5 × 14 in.) (10). A 15-sec. tone was followed by an electrical shock (300 v., 2 mamp.) from the grid floor with a maximum duration of 45 sec. The tone was continued through the shock period, and this was followed by a 2-min. intertrial period. Pole-climb latencies during tone alone (shock avoidance) and during the shock cycle (shock escape) were recorded on a pen polygraph (Lehigh Valley Electronics No. 1321-4).

The subjects, 80 male rats, were trained to a minimum of 75% avoidance in three to five 1-hr. sessions. The training sessions were once daily on consecutive days, and the animals were retested at peak drug effect 24 hr. after the training session in which they reached the 75% avoidance criterion. The number of avoidances made by the drugged subjects were compared with the appropriate saline controls.

RESULTS

Forced Motor Activity (FMA)—All drugs produced dose-dependent decrease in motor performance, and chlorpromazine and imipramine produced a decrement exceeding 50%. Thiazesim did not quite reach the 50% level at the highest dose, 40 mg./kg. (Fig. 1). This was the maximum dose used because pilot studies indicated that both 50 and 60 mg./kg. could produce convulsions. The data were calculated and presented as the percent of saline scores.

Spontaneous Motor Activity (SMA)—The SMA data (Fig. 1) depict the drug actions as dose-dependent decreases in activity and are reasonably straight lines for chlorpromazine and thiazesim. The imipramine effects appear biphasic in this and in several other measures in this study. This biphasic action will be discussed later. The ED₅₀ value for imipramine was calculated with only the low and medium doses because the latter approaches the 50% level (51.8%).

Food Consumption—The data on this parameter produced a fairly linear dose-dependent decrease in food consumption by each drug (Fig. 2). The results depicted are percent control values and are calculated as the amount eaten, divided by the subject's weight. The subject's weights did not differ significantly between groups; however, the within-group weights varied up to 100 g. For this reason the results were weighted in relation to subject's size. This weighting of scores assumed that larger subjects would eat more, even under the experimental conditions. This was substantiated by the overall mean Pearson correlation coefficient of +0.48 for the weight of food eaten per gram of body weight.

Water Consumption—The inhibitory effects on water consumption produced by the three compounds are summarized in Fig. 2. Although the linearity of chlorpromazine and thiazesim results is clear, imipramine again shows a biphasic response. The two low doses, one on either side of the 50% level, were used to calculate the ED₅₀ value.

Maternal Behavior—The results summarized in Fig. 3 failed to show a clear log dose-response relationship in most cases. Although rough approximations of the respective ED₅₀ values do agree with the proposed hypothesis, the lack of clear dose-response relationships is considered ample reason for deletion of these parameters from further considerations. The cause of this discrepancy is not clear, although there is the possibility that the home cages [20.3 × 21.6 × 27.9 cm. (8 × 8.5 × 11 in.)] may not have been of sufficient size to stimulate the maternal behaviors tested. That is, pups,

8 to 10 in. away in the home cage, may have been an inadequate stimulus to induce retrieval behavior in some of the animals.

Mouse-Killing—The data summarized in Fig. 4 indicate that the drugs produced a linear log dose-response relationship. The ability of chlorpromazine to block muricide, even at the high dose (8 mg./kg.), is, however, open to question. The test sequences were only 60 sec. and, at the highest dose, chlorpromazine appeared to induce the expected sedation. To clarify this, after the end of their test sequence, some sedated rats were manually jostled and the mice were immediately killed by the aroused rat. This was found in

eight of the nine subjects receiving 8 mg./kg. of chlorpromazine, although the same procedure did not induce killing when used with six of the subjects receiving 32 mg./kg. of imipramine or six of the subjects receiving 40 mg./kg. of thiazesim. The tranquilizer, therefore, appeared to block mouse-killing mainly due to its sedative action.

Self-Grooming—The results depicted in Fig. 4 show the log dose-response relationship for the compounds investigated. Of interest is the evident increase in grooming induced by 2 mg./kg. of chlorpromazine, although this difference was short of statistical sig-

nificance ($p > 0.05$). These results are in agreement with the report of Silverman (11), which gave data indicating that low doses of chlorpromazine significantly increase unstimulated self-washing of the face and forepaws. An increase in any behavior after chlorpromazine administration is of interest because of this compound's general depressant action.

Conditioned Avoidance Response (CAR)—The results shown in Fig. 5 are for the most part in agreement with those reported

Figure 5—Effects of chlorpromazine, imipramine, and thiazesim on the rat pole-climbing conditioned avoidance response. Key: ■—, chlorpromazine; ▲. . ., imipramine; and ●—, thiazesim.

by Horovitz *et al.* (6), although these investigators found imipramine to be more potent in CAR disruption. This causes no change in direction of the ratio values employed by these investigators, only an insignificant change in magnitude.

ED₅₀ Values—The ED₅₀ values were calculated from the best fitting straight lines as established by the method of least squares (Table I). Exceptions to this method of analysis were the aforementioned cases involving the biphasic imipramine action in SMA and water consumption. In these cases, the line between the lower doses transversed or approached the 50% level, and the ED₅₀ was calculated from this line. The ED₅₀ for the thiazesim effect on drinking was calculated after deletion of the lowest of the four doses.

Ratio Values—The ratio values presented in Table II are the ED₅₀ values of the experimental compounds in the FMA divided by their respective ED₅₀ values in the behavioral parameters investigated. The ratio values for CAR are listed as <1.0, since the ED₅₀'s for imipramine and thiazesim were greater than the maximum doses used. Ratio values greater than unity are, therefore, indicative of a "selective" blocking action, a disruption of specific behaviors at nondebilitating doses. Ratio values less than 1 show that the behavior was blocked by debilitating doses.

DISCUSSION

The biphasic aspects of the imipramine action were troublesome in analyzing the data. The possibility of multiple experimental

errors was not considered likely; as in the study of SMA, eight subjects were used at each dose, including saline controls, and a prior pilot study measuring SMA with two subjects per activity cage yielded similar results. A close examination of the literature revealed that this biphasic effect is not uncommon. Furguele *et al.* (12) reported a biphasic imipramine response in SMA testing that was parallel to that observed in the present experiment. The biphasic imipramine action has also been reported on bulboapnine and paraldehyde depression of motor control (13, 14). Osborne and Sigg (15) and Schaeppi (16) reported that the pressor responses to epinephrine and norepinephrine injections were potentiated by low doses of imipramine and blocked by high doses. This biphasic imipramine action in the adrenergic system may be related to its effect on drinking, since Grossman (17) and Hutchinson and Renfrew (18) have reported that adrenergic stimulation in several areas of the brain can greatly modify drinking behavior. In addition, Furguele *et al.* (12) also reported a biphasic imipramine effect on SMA increased by a compound with adrenergic activity. The work of Thoenen *et al.* (19) may well explain the biphasic imipramine action. These investigators studied the perfused cat spleen and induced contractions by stimulation of the postganglionic splenic nerve. Their data indicate that imipramine, in low doses, augments adrenergic responses by inhibiting reuptake of the transmitter; in high doses the adrenergic response is inhibited in a manner resembling α -adrenergic blockage. Although extrapolation of data from actions on isolated tissue to the behavioral responses of the whole organism is hazardous at best, the wealth of information relating imipramine to adrenergic activity, the reports of biphasic imipramine actions, and the desire for explanations of obtained results all make the extrapolation possible.

The present study provides evidence that there is a qualitative difference between the effects of a tranquilizer and antidepressant compounds on unlearned behaviors. The antidepressants appear to block selectively unlearned behaviors which were blocked by chlorpromazine only at debilitating doses. The ratio values (Table II) show that 12 of the 15 pairings of the three experimental compounds could have been predicted on this basis. As discussed previously, the biphasic imipramine action in drinking and SMA did create some problem in the determination of the ED₅₀ values. It should be noted that these two parameters are the only ones

that did not show an imipramine block at nondebilitating doses. The use of only one tranquilizer and two clinically classified antidepressants does make generalizing the results to include the two classes quite speculative. However, Horovitz (20) reported at least six tranquilizers and six antidepressants had the ratio values of FMA ED₅₀/muricide ED₅₀ characteristic of their respective classes, and this suggests that the generalization may be warranted.

Laboratory Evaluation of Aggressive Behavior of the Grasshopper Mouse (*Onychomys*)

HENRY F. COLE* and HAROLD H. WOLF

Abstract □ The genetically predisposed aggressive behavior of two species of grasshopper mouse, *Onychomys leucogaster* and *O. torridus*, was evaluated in an experimental paradigm involving isolation-induced aggression. *O. leucogaster* exhibited considerably more aggression than did *O. torridus*. When aggression was provoked in *Onychomys* by isolation, the behavior could not be suppressed by pentobarbital nor by chlordiazepoxide. Indeed, chlordiazepoxide increased the amount of time spent fighting. Chlorpromazine was able to depress fighting behavior in *torridus* but not in *leucogaster*. The results obtained support the contention that an animal's behavioral predisposition may markedly alter the organism's response to drugs.

Keyphrases □ Grasshopper mouse—aggressive behavior □ Aggression—genetic predisposition, mice □ Chlorpromazine HCl, chlordiazepoxide, Na pentobarbital effect—aggression □ Genetic predisposition effect—pharmacological tests

The effects of tranquilizers and other central nervous system depressants on the aggressive behavior of albino mice have been studied by many investigators (1-7). Such investigations reveal that aggressive behavior of most albino mice is mild and relatively unstable. This is not surprising because albino mice have been bred for hundreds of generations for docility and tolerance to high-population densities. Moreover, in laboratory colonies, two major causes of aggression, competition for food and competition for territory, are removed. Under these conditions, a high level of aggressiveness becomes an undesirable trait, to be removed from the population.

In view of the relative docility of albino mice, the authors felt that an aggressive animal might serve as a more appropriate subject for studies on aggression. One such animal is the northern grasshopper mouse, *Onychomys leucogaster*. These grasshopper mice are predatory and carnivorous. In their natural habitat, they stalk and quickly kill other small rodents by gnawing into the base of the victim's brain (8). Ingles (9) estimates that small mammals and insects form 90% of *Onychomys*' natural diet. In the laboratory, the fighting behavior of *O. leucogaster* is readily elicited, quite stable, and easily quantified (10). When given the opportunity, *leucogaster* will quickly and vigorously attack a victim mouse. When given regular opportunities to fight, they may become so adept at expressing this behavior that the victim is killed as quickly as 20 sec. after its exposure to the aggressor (10).

The highly stereotyped and invariable method of killing by gnawing through the base of the skull exhibited by *leucogaster*, as well as the ease with which the behavior is elicited, even in naive subjects several generations removed from the wild, strongly suggests that this behavior is primarily genetically determined rather than learned. Therefore, the authors thought it worthwhile to investigate the genetically predisposed ag-

gressive behavior of these grasshopper mice in an experimental paradigm involving isolation-induced aggression.

Members of a second species, *O. torridus*, the southern grasshopper mouse, were also included in this investigation. Because the authors are unaware of any studies concerned with the behavior of *torridus* under laboratory conditions, they felt valuable behavioral data could be provided by the inclusion of this species.

EXPERIMENTAL

A commonly employed method of producing aggressive behavior in albino mice is to subject them to extended periods of social isolation. Since such isolation-induced aggression has been frequently employed in drug studies (1, 2, 4, 6), the authors also utilized this method in their investigations of the aggressive behavior of *Onychomys*.

The *O. leucogaster* ranged in weight between 24 and 41 g., were derived from a colony previously maintained at the University of Utah College of Pharmacy, and were approximately 6 to 10 generations removed from the wild. The *O. torridus* were first-generation offspring of mice trapped by The Pet Corral, Tucson, Arizona, and weighed 20-32 g. *Onychomys* were segregated according to sex and were housed in groups of at most three mice to a standard 43 × 25 × 12-cm. plastic cage. When it became necessary to employ female subjects, care was taken to ensure that pregnant females were excluded. Purina Lab Chow and water were continually available in the cages. This diet was periodically supplemented with sunflower seeds, wheat, or small quantities of canned dog or cat food. Results were statistically analyzed by means of the following specific procedures; except where otherwise indicated, differences were considered to be significant at $p < 0.05$.

The drugs employed in these studies, chlordiazepoxide HCl (CDP), chlorpromazine HCl (CPZ), and sodium pentobarbital (PTB), were administered intraperitoneally in aqueous solution in such concentration that 1 ml./100 g. body weight contained the appropriate dose. Dosage and time of peak drug effect (TPE) were based on a roller-rod test slightly modified from that previously described (11) in that a speed of 4 r.p.m. was employed. The time at which the greatest number of mice were unable to remain on the rod for at least 30 sec. in any one of three trials (minimal neurological deficit) was taken as the time of peak drug effect (TPE). Employing this TPE, the dose of each drug producing evidence of minimal neurological deficit in 50% of the mice (TD₅₀) was calculated by the method of Litchfield and Wilcoxon (12). All further drug-behavior studies were carried out at the TPE using a dose level of $\frac{1}{2}$ TD₅₀. The TPE's and TD₅₀'s for the drugs employed are presented in Table I.

Four male and two female adult *leucogaster* and five male and two female adult *torridus* were caged individually and then tested at intervals of every 2 or 3 days until they would consistently attack a small albino victim mouse introduced into the aggressor's cage for a 5-min. period. Isolation periods as short as 3 or 4 days were usually sufficient to evoke this behavior in *leucogaster*, whereas *torridus* required as much as 2 to 3 weeks of isolation. When attack behavior was consistently displayed by *Onychomys*, the drug studies were initiated. Mice were randomly assigned to receive each of four treatments (control, CPZ, CDP, and PTB) in a unique sequence. Mice were injected with the appropriate treatment; at the TPE listed in Table I, a small (10-14 g.) victim albino mouse was placed in the cage of the *Onychomys* for a maximum of 5 min. The latency to the first attack by the aggressor and total amount of time spent engaged in aggressive activity were recorded. Mice not observed to attack the

^a Median toxic dose, mg./kg. ^b Time of peak drug effect, min. ^c 95% fiducial limits.

victim within the 5-min. test period were assigned a latency of 300 and a fighting duration of 0 sec. If a victim was killed before the end of the 5-min. test period, the time was noted and the victim was removed immediately.

Mice were given one of the four treatments no more than once every 5 days. On the day immediately preceding that on which a treatment (drug or control) was administered, each mouse was injected with distilled water and tested at the TPE of the treatment to be given the following day. Thus, each mouse received five control (distilled water) treatments over the duration of the study. This paradigm allowed each treatment to be compared to the immediately preceding control treatment and, furthermore, allowed an evaluation of the stability of the behavior with respect to time and exposure to the fighting situation. Moreover, this schedule permitted each animal to serve as its own control.

The results, unless otherwise indicated, were analyzed with the Wilcoxon matched-pairs signed-ranks test or with the Friedman two-way analysis of variance (13).

RESULTS

The effects of $\frac{1}{2}$ TD₅₀ of chlorpromazine, chlordiazepoxide, and pentobarbital and of the combined control treatments on the amount of time spent engaged in aggressive activity after isolation are displayed in Figs. 1 and 2 for *leucogaster* and *torridus*, respectively. None of the drugs significantly depressed fighting time in *leucogaster*. Indeed, CDP significantly increased the duration of fighting in this species. The fighting time of *torridus* was also slightly, but significantly, prolonged by this drug, while CPZ significantly decreased the duration of fighting time of *torridus*.

The time that the victims survived on exposure to either species of *Onychomys* after the various treatments is tabulated in Table II. None of the drugs significantly altered the time either species re-

quired to kill a victim. However, as Table III reveals, CPZ did significantly increase the latency of *torridus* to attack a victim.

A statistical analysis of differences in performance between each of the five control treatments for either species revealed no significant changes in latency to attack, survival time of the victim, or fighting time. Thus, levels of aggression remained constant over the entire experimental period. Moreover, a given treatment had no appreciable lasting effect on subsequent fighting performance.

A Mann-Whitney "U" test comparison (13) of control performances of *torridus* and those of *leucogaster* revealed that *torridus* exhibited significantly longer latencies to attack and significantly shorter fighting durations than did similarly treated *leucogaster*. Although no significant difference was found between the survival times of *leucogaster*'s and *torridus*'s victims, *leucogaster* did kill a significantly ($p < 0.01$) greater number of their victims (58%) than did *torridus* (40%) as determined by the Fisher exact probability test (13).

DISCUSSION

Under the conditions employed in these studies, the *torridus* appeared to be somewhat less aggressive than *leucogaster*. In the isolated subjects, *torridus* displayed longer latencies to attack, shorter fighting times, and made fewer kills than did *leucogaster*. Moreover, in an unpublished study conducted in this laboratory, it was observed that a conditioned aggressive response which was readily acquired by *leucogaster* could not be reliably reproduced in *torridus*. Studies to date from this laboratory have not provided an apparent explanation for the quantitative discrepancy in aggression exhibited by the two species of *Onychomys*, and the authors are unaware of any studies comparing the aggressive behavior of these two mice either in the laboratory or the field. Nevertheless, it should be emphasized that both species of *Onychomys*, especially when

^a Significantly longer than control latencies ($p < 0.05$).

isolated, were found to display a markedly greater degree of aggressive behavior than would albino subjects under similar conditions.

To evoke aggressive behavior in albino subjects, weanlings are typically isolated for periods of a month or longer (1, 7, 14). In contrast, the genetically predisposed aggressive behavior of *torridus* could be evoked in half this time and *leucogaster* would consistently attack victim mice after periods of isolation as short as 3 or 4 days. Moreover, less than 70% of a population of albino mice subjected to extended periods of social isolation can be expected to display even a minimal amount of aggressive behavior (1, 4, 7), while each of the *Onychomys* vigorously and consistently attacked the victim mice after the isolation period. Furthermore, an analysis of the latencies to attack, fighting times, and killing times for each of the five control treatments which every *Onychomys* received revealed no change for either species over the entire course of this study (eight opportunities to display aggressive behavior). In contrast, in a similar experimental paradigm, half of a population of albino mice failed to display a minimal amount of aggressive behavior after as few as six exposures to a victim (1). It should be mentioned also that while albino mice are commonly isolated while relatively young, the *Onychomys* employed in these studies were placed in isolation as adults, a time when isolation is much less effective in producing aggression (14).

The aggressive behavior of albino mice is characterized by sparring and nipping, components of mild rather than severe fighting. The injury to the victim is only superficial and the authors have never observed an albino aggressor kill a victim, even though exposure periods of up to 15 min. were employed (1). On the other hand, *torridus* and *leucogaster* killed 40 and 58%, respectively, of their victims.

Differences between the aggressive behavior of isolated albino mice and *Onychomys* are also apparent with regard to drug effects. For example, CPZ has been shown to depress the isolation-induced aggressive behavior of albino mice in small, nontoxic doses (1–3, 6). In contrast, a dose of CPZ as large as $\frac{1}{2}$ TD_{50} was ineffective in suppressing significantly the isolation-induced aggressive behavior of *leucogaster*. Although the less aggressive *torridus* did respond to CPZ, this effect might be at least partially due to a nonselective depression of the central nervous system, since at this dose the animals appeared to be somewhat sedated. Clark (10) also found the aggressive behavior of *leucogaster* to be quite resistant to suppression by this drug. He further reported that aggression was increased on the day following CPZ treatment. However, the experiments reported here were not designed to investigate such late alterations of behavior.

CDP has been reported to possess unique taming properties (15) and to be effective in calming aggressive or vicious albino mice and rats, dogs, cats, and monkeys (5, 15). The authors have found it effective in suppressing the isolation-induced aggressive behavior in albino mice in doses as low as $\frac{1}{8}$ TD_{50} (1). However, in both *leucogaster* and *torridus*, a much higher dose of CDP was not only ineffective in suppressing aggression, but indeed significantly increased the amount of time the aggressor spent engaged in fighting

activities. This increase in fighting time could not be attributed to a decrease in fighting efficiency due to neurotoxicity, since both the latency to attack and survival time of the victims remained essentially unchanged.

Pentobarbital was not found to alter significantly the aggressive behavior of either species of *Onychomys*. Similarly, this nonselective central depressant is ineffective in altering the aggressive behavior of albino mice except in severely debilitating doses (1, 3, 4, 6).

It should be reemphasized that *Onychomys* are predatory rodents. In their natural habitat, survival probably depends in large part on the ability of these mice to track and kill victims for food. Moreover, this behavior appears to be genetically predetermined since individuals several generations removed from the wild will readily attack and kill victims in their typical stereotyped pattern. Taken in light of these factors, the experimental results reported here demonstrate how markedly the aggression of albino subjects differs from that of *Onychomys*. The relatively mild, difficult to elicit, and unstable aggressive behavior of albino subjects contrasts sharply with the genetically predisposed, predatory nature of *Onychomys*. Thus, the results the authors have reported support and extend their earlier contention (16) that the genetic predisposition underlying an animal's behavior may qualitatively and quantitatively influence the results obtained in pharmacological and behavioral investigations and must not be ignored.

Polymorphism in Sulfanilamide-d₄

HWAING OU LIN and J. KEITH GUILLORY

Abstract □ Thermal behaviors of four crystalline forms of sulfanilamide and of sulfanilamide-d₄ have been examined. Heats of transition and fusion have been determined. The deuterated modifications exhibit smaller heats of transition and heats of fusion than the corresponding undeuterated forms. There is, however, a difference in the magnitude of this decrease in the case of the heats of transition.

Keyphrases □ Sulfanilamide-d₄—polymorphism □ Polymorphic forms—sulfanilamide-d₄ □ Differential thermal analysis—identity □ IR spectrophotometry—identity □ NMR spectroscopy—identity

Polymorphic forms of the same compound exhibit a number of divergent physical properties including crystal structure, rate of dissolution, density, solubility, and refractive index. Differences in dissolution rate have been noted in such widely used drugs as aspirin (1) and chloramphenicol palmitate (2). These differences in solution properties can be expected to result in variations in therapeutic blood levels and therapeutic efficacy.

In spite of the fact that polymorphism is a widespread phenomenon among organic compounds, in general, and among pharmaceuticals, in particular, very little progress has been made toward an understanding of the factors that permit some compounds to exhibit and prevent others from exhibiting polymorphism. The availability of commercial instrumentation which makes thermodynamic data concerning heats of transition and fusion more readily accessible encouraged the authors to study a group of structurally related compounds, the sulfonamides (3). Polymorphism has been detected in some sulfonamides but not in others.

One sulfonamide that has been studied extensively is sulfanilamide. The existence of polymorphic forms of the compound was first reported by Zyp in 1938 (4). He observed that sulfanilamide appeared in several crystal forms when crystallized from a drop of water and examined under the microscope. Watanabe (5, 6) conducted an X-ray diffraction study of sulfanilamide crystallized from various solvents, and he determined that the compound could crystallize in at least three polymorphic modifications designated as α -, β -, and γ -forms. Yakowitz (7), in his report, confirmed Watanabe's discovery that sulfanilamide is polymorphic, with at least three phases, and reported refractive indexes and heats of solution of these forms. McLachlan (8), in his book on X-ray crystal structure, mentions four polymorphic forms of sulfanilamide, designated as β -, γ -, δ -, and ϵ -forms.

The techniques of neutron diffraction and X-ray diffraction have been employed in the elucidation of the crystal structures of some polymorphic forms of sulfanilamide. O'Connor and Maslen have determined the structures of α -sulfanilamide (9) and of β -sulfanil-

amide (10), and Alleaume and Decap have determined the structures of β - and of γ -sulfanilamide (11–14). The present investigation was undertaken to obtain thermodynamic data on heats of transition and fusion of sulfanilamide and sulfanilamide-d₄.

EXPERIMENTAL

Materials—Sulfanilamide-d₄ was prepared by repeated recrystallization of sulfanilamide from monodeuteroethanol, monodeuteromethanol, or deuterium oxide. The progressive exchange of D for H in the amino and amide groups of sulfanilamide was observed in the IR spectrum of the material. After five or six recrystallizations, the exchange was virtually complete. The isotopic purity of sulfanilamide-d₄ was further confirmed by NMR spectroscopy using dimethyl-d₆-sulfoxide as the solvent. Monodeuteromethanol and monodeuteroethanol were prepared by the method described by Greive and Sporek (15). Monodeuterobutanol was obtained by repeated isotopic exchange of *n*-butanol with deuterium oxide (Merck, AG, 99.75% isotopic purity) in the presence of deuterium chloride as the catalyst. Acetone-d₆ (Mallinckrodt) had a stated isotopic purity of not less than 99.5%.

Methods and Instrumentation—Polymorphic forms of sulfanilamide and sulfanilamide-d₄ were prepared by recrystallization from appropriate solvents. Distilled water, ethanol, methanol, butanol, and acetone were used as solvents in the recrystallization of sulfanilamide, while deuterium oxide, monodeuteroethanol, monodeuteromethanol, monodeuterobutanol, and acetone-d₆ were used in the recrystallization of sulfanilamide-d₄, which had been prepared as described. The α -, β -, and γ -forms of sulfanilamide were obtained by methods described by Watanabe and Kamio (5). The δ -form was obtained by recrystallization of sulfanilamide from hot, saturated butyl alcohol. Deuterated solvents, analogous to those used for obtaining the four forms of sulfanilamide, were employed in the preparation of the four deuterated modifications.

The Du Pont 900 differential thermal analyzer (DTA), equipped with a standard cell, was employed to detect polymorphic transitions and melting in the various forms of sulfanilamide and sulfanilamide-d₄. Thermograms, plots of differential temperature as a function of the sample temperature, were obtained. In each case the sample was heated from room temperature to a temperature several degrees above fusion, at a uniform rate of 10°/min. Samples of approximately 2 mg. were employed in ordinary glass capillary tubes, 2 mm. in diameter. Nitrogen gas was flushed through the standard cell during the heating procedure to minimize oxidative decomposition. The reference used in these experiments was glass beads. Temperatures of phase transitions were obtained from the thermograms and were corrected for nonlinear temperature response of the chromel/alumel thermocouple.

Quantitative measurements of the heats of transition and fusion of the compounds were obtained using the Du Pont 900 differential thermal analyzer equipped with a calorimeter cell. While the Du Pont standard cell provides useful qualitative information concerning polymorphic transitions, the geometry of the cell precludes its use for quantitative determinations of heats of transition and fusion. The calorimeter cell was designed for this purpose. Samples of approximately 5 mg. were employed in measurements of heats of fusion, and samples of approximately 7 mg. were employed in measurements of heats of transition. These were weighed on a Cahn electrobalance to the nearest 0.002 mg. The samples were placed in cups fashioned from aluminum foil, and the cups were fitted into the silver sample holder of the calorimeter cell in such a way as to obtain good contact with the bottom of the sample holder. Neither aluminum liner nor reference material was used in the reference cup. Thermograms incorporating the temperature ranges of interest were recorded using the chart recorder of the

Table I—Thermal Behaviors of Sulfanilamide and Sulfanilamide-d₄

Polymorphic Forms	Solvents Used for Recrystallization	Phase Transition Temperature	Heat of Transition, cal./mole $\times 10^{-2}$	Fusion Temperature	Heat of Fusion, cal./mole $\times 10^{-3}$

DTA instrument. The areas of the transition and fusion peaks were obtained by drawing a line from the point at which the thermogram first departed from the baseline to the point at which the baseline was reestablished. Area measurements were performed using a polar planimeter (Keuffel & Esser No. 62005). The area of the peaks obtained in DTA calorimetry is proportional to the heat of transition, and the value of ΔH can be obtained by calculation based on the use of a calibration curve. This curve is constructed from data on the areas of the fusion peaks of materials with known heats of fusion, including gallium, tin, indium, and zinc. The procedure is described in more detail in a paper by Guillory (16). The calibration was found to be accurate to within 2.1% when checked with samples of silver nitrate and benzoic acid. Heats of transition and fusion reported in Table I are average values of six or more determinations. The average deviations from the mean for these measurements are also given.

IR spectra of crystals of sulfanilamide and sulfanilamide-d₄ were taken as potassium bromide pellets. The pellets were prepared using a Beckman potassium bromide dye and a Pasadena Hydraulics, Inc., press at a pressure of 20 tons. The sample–potassium bromide ratio employed was 1:200. Some samples were obtained using the Wilks Mini-Press with a sample–potassium bromide ratio of 0.7:120. Both methods resulted in identical IR patterns. Spectra were obtained on a Beckman IR-10 IR spectrophotometer. The instrument employs two precision replica gratings in a single monochromator. The first operates from 4000 to 600 cm.⁻¹, and the second grating operates from 650 to 300 cm.⁻¹. Polystyrene film was used to calibrate the wavelength axis.

As an independent check, observations of phase transitions were carried out on the Koefer micro hot stage. A small amount of sample was placed between a slide and cover glass, and the slide was placed on the hot stage. The sample was observed through a microscope as it was heated at a constant rate (10°/min.) up to fusion.

X-ray diffractograms of the polymorphic forms were recorded by the powder diffraction method.¹ These diffractograms are reproduced elsewhere (17).

RESULTS AND DISCUSSION

Four polymorphic modifications of sulfanilamide and sulfanilamide-d₄ were obtained by recrystallization from the solvents listed in Table I. These modifications were subjected to DTA, IR spectroscopy, and DTA calorimetry. Forms I, II, and III of undeuterated sulfanilamide are analogous to the α -, β -, and γ -forms of Watanabe and Kamio (5). The deuterated polymorphic forms are named by analogy to the corresponding undeuterated forms.

The commercially available form of sulfanilamide is the β -form. The three other forms of sulfanilamide also remain stable at room temperature. DTA reveals that the α -, β -, and δ -forms are transformed to the γ -form prior to melting. The γ -form, then, is the only polymorph that melts without undergoing a polymorphic transformation. The deuterated forms of these four polymorphs behave in a precisely analogous fashion.

In 1961, Inoue and Saito (18) reported the use of DTA in the study of polymorphic transitions occurring in sulfanilamide. Two thermograms appear in this paper, and an explanation of the thermograms is given by the authors. Two transition peaks are observed in the thermogram of what the authors refer to as the α -form of sulfanilamide. They associate these two peaks with transformations from the α - to the β -form and from the β - to the γ -form, respectively. The latter peak is substantially smaller in area than the former. In the second thermogram, the transition peak is identified as being associated with the β - to γ -transition.

In the present investigation (Figs. 1 and 2), repeated experiments have failed to produce two transition peaks when the α -form is heated from room temperature to fusion. An examination of the data obtained from DTA calorimetry (Table I) reveals that the magnitude of the heat of transition in the case of these two forms is virtually the same. If the α -form did indeed transform to the β -modification at 108°, one would expect to find a transition peak of approximately the same area at 131–141°, the transition temperature range of the β -form. The fact that Inoue and Saito (18) found only a small peak in this range indicates that their sample of the α -form was contaminated with some β -form. The authors of this study believe

Figure 1—DTA thermograms of four polymorphic forms of sulfanilamide.

Figure 2—DTA thermograms of four polymorphic forms of sulfanilamide- d_4 .

that Watanabe and Kamio (5), who reported from thermomicroscopic observations a transition from α to β occurring at temperatures near 90° , made a similar error. According to their account, when suction was used to dry crystals of the α -form, they were converted to the β -form. The authors have found that a similar transition occurs on trituration of the α -modification. Inoue and Saito (18) do not describe the δ -to γ -transition which was detected in this study, nor did they estimate the heats of transition of the polymorphic changes.

Data obtained from DTA calorimetry are listed in Table I. Heats of transition are reported for the α -, β -, and δ -forms. These three forms are converted to the γ -form, which melts without undergoing polymorphic transition. Since three forms are converted to the γ -form prior to fusion, all four forms are expected to exhibit the same heat of fusion. This is found to be true, within the limits of experimental error, for both the nondeuterated and the deuterated forms.

An examination of the heats of transition for the three polymorphs which undergo transition reveals that the δ -form requires the greatest amount of energy to affect its transition to the γ -form. The α - and β -modifications apparently have similar internal energies. This may explain why conversion from the α -form to the β -form occurs so readily. Simple trituration will bring about this change (although heating from room temperature to fusion will not, as pointed out previously).

Hydrogen bonding plays an important role in the crystalline structure of sulfanilamide. Apparently the two hydrogens of each amide group are engaged in $\text{NH}\cdots\text{O}$ bonding with oxygens on two adjacent sulfanilamide molecules. Similarly, the two hydrogens on each amine function participate in similar hydrogen-bonding interactions. It is interesting to note that X-ray diffraction studies (9–14) suggest that the hydrogen bonds in the α - and β -forms are, on the average, very nearly the same length, but those of the β -modification are slightly longer. This observation is in line with the heats of transition determined in this study (*i.e.*, higher heat of transition for the form with shorter bonds).

The γ -form, which does not exhibit a polymorphic transition, forms hydrogen bonds that are, on the average, somewhat longer than those of the α - and β -forms. Data are not available for the

lengths of the hydrogen bonds in the δ -form, but results of this investigation suggest that, on the average, the hydrogen bond lengths in this form will be considerably shorter than those of the α - and β -forms.

The heat of fusion of the deuterated γ -form is approximately 5% less than that of the undeuterated modification, although the melting point is decreased only about 1° by deuteration. Substitution of deuterium for hydrogen apparently lengthens the hydrogen bonds in the crystal lattice (19), and this accounts for the lower heat of fusion.

In the case of the three modifications that exhibit phase transitions prior to fusion, deuteration diminishes the magnitude of the energy required for conversion to the γ -form. The degree of reduction of the heat of transition is approximately the same for the α - and δ -forms as the reduction in the heat of fusion measurements. The β -form, however, shows anomalous behavior, with a reduction in heat of transition of approximately 25%. Apparently, isotopic substitution affects the bond lengths and bond strengths of the hydrogen bonds of these crystals to a different degree.

When the X-ray diffraction patterns obtained for the four modifications of sulfanilamide and sulfanilamide- d_4 are compared (17), it is seen that the crystal structures appear to have similar molecular arrangements in the case of the deuterated and undeuterated β - and δ -forms. There are, however, significant differences in the molecular arrangements in the α - and γ -forms following deuteration. This implies that, at least in some cases, substitution of deuterium for hydrogen in sulfanilamide does more than simply expand the crystal lattice. Deuteration may, or may not, affect the lattice structure.

Figures 3 and 4 show IR spectra of sulfanilamide and sulfanilamide- d_4 , respectively. In Fig. 3 it can be seen that the spectra for the α - and β -forms are virtually identical. In preparing samples for IR analysis, grinding and pressing operations are employed which can be expected to bring about a transformation from the α -form to the β -form. Therefore, the first two spectra shown are both of the β -modification. A comparison of the spectra for the deuterated sulfanilamides reveals that three of the forms exhibit essentially identical spectra. Ito and Sekiguchi (20), in a paper on the formation of a molecular compound of sulfanilamide and sulfathiazole, reported that they had examined three deuterated forms of sul-

Figure 3—IR spectra of four polymorphic forms of sulfanilamide.

Figure 4—IR spectra of four polymorphic forms of sulfanilamide- d_4 .

fanilamide and found that: "spectral differences between the three polymorphic forms . . . (were) comparatively few." In the present investigation, minor differences in the spectra were noted in the —NH_2 stretching regions but not in the —ND_2 stretching regions. Similar differences can be seen in spectra published by Novak *et al.* (21).

The study of polymorphism in sulfanilamide is complicated by the large number of possible hydrogen bonding sites in the molecule; by the formation of hydrogen bonds of various lengths; by the fact that in some forms the unit cell is made up of eight, and in others, of four molecules; and by the fact that the crystal structure of the δ -form has not yet been elucidated. Additional information is

required before the mechanisms of the polymorphic transitions occurring in this compound can be understood.

Distribution, Excretion, and Metabolism of ^{14}C -Labeled Quaternary Ammonium Salt of Perphenazine in Rats

C. L. HUANG, G. M. MIR, and J. Z. YEH

Abstract □ Urinary excretion was the major route of excretion of intraperitoneally administered perphenazine dimethiodide- ^{14}C in rats. Peak blood level was observed at 0.5 hr. after the administration of the compound, and brain level was above the detectable level at the same period of time. Antimicrobial activities were demonstrated. The toxicity of quaternary ammonium salt of perphenazine on mice is higher than perphenazine.

Keyphrases □ Perphenazine dimethiodide- ^{14}C —synthesis □ Distribution, metabolism, excretion—perphenazine dimethiodide- ^{14}C □ Antimicrobial activity—perphenazine dimethiodide- ^{14}C □ UV spectrophotometry—analysis □ Paper chromatography—radio scanning

Perphenazine is a phenothiazine derivative which differs chemically from prochlorperazine only with respect to the substitution of a hydroxyethyl group for the methyl group of the latter drug. Perphenazine is approximately twice as potent dosagewise as prochlorperazine and exhibits clinical effects and side actions similar to those of chlorpromazine (1–3).

Symchowicz *et al.* (4, 5) have reported the tissue distribution of ^{35}S -perphenazine in rats after the subcutaneous injection of 0.3 mg./kg. of the compound. High concentrations were found in the lungs, adrenals, liver, kidneys, spleen, and pituitary, while the brain had only a residual activity. Blood levels were consistently low. High levels of radioactivity were found in the pituitary gland after 48 hr. and remained relatively high even after 6 days. Over 80% of the administered activity was excreted during the 24-hr. period, of which 64% was found in the feces and only 16% in the urine.

Huang and Kurland (6), who focused their attention on identification and quantitative determination of the major metabolites of perphenazine, found that unlike chlorpromazine (7, 8) the rate of excretion of perphenazine metabolites was low; approximately 44% of the administered dose was recovered in man during a 7-day period. Perphenazine glucuronides were found to be the major metabolites, representing approximately 69% of the total urinary metabolites. Perphenazine sulfoxide was found to be approximately 13% of the administered dose, and the unchanged perphenazine was usually undetectable.

It has been demonstrated that toxic properties of phenothiazine neuroleptics do not diminish by quaternization of the side-chain nitrogen but rather increase in most cases (trifluoperazine, mepazine, and promethazine). The excretion of the majority of the administered activity of quaternary derivative of mepazine, promethazine (9), and trifluoperazine (10) was consistent with predominantly fecal excretion.

Absorption of these compounds from the intraperitoneal cavity was rapid, which is reflected in a rapid increase of blood levels in rats in 0.5 hr. Brain levels were generally

low and were either trace or insignificant against the background activity. All these compounds seemed to have a particular affinity for the bone, since significant activities were recorded in the bone after 5 days. No radioactivity was found in the calcium carbonate formed from the carbon dioxide collected in the expired air from the animals placed in metabolic jars, which indicated that demethylation of these quaternary compounds did not occur *in vivo*. Antimicrobial activities were also demonstrated. High intestinal activity appeared to be due to the secretory process of these drugs *via* bile. As indicated in a previous communication (10), trifluoperazine, one of the potent phenothiazine neuroleptics with a piperazinyl side chain, is excreted unchanged. It would be of interest to see how a compound of this series with a primary alcohol function on the side chain would behave *in vivo*. In this report, distribution and elimination of perphenazine dimethiodide- ^{14}C in rats are described.

METHODS¹

Synthesis of Perphenazine Dimethiodide (PPZ-DMEI)—Perphenazine dihydrochloride (0.53 g., 1.1 mmoles) was dissolved in water. The solution was adjusted to pH 10 and extracted several times with ether. The combined ether extracts were dried over anhydrous sodium sulfate and the solvent removed *in vacuo*. The oil (0.42 g., 0.97 mmole) remaining in the container was dissolved in 10 ml. of acetone, and methyl iodide (0.71 g., 5 mmoles) was added. The mixture was left at room temperature for 1 hr., and about 10 ml. of anhydrous ether was added to precipitate the quaternary ammonium salt. The precipitate was collected and recrystallized from methanol-ether to yield 0.36 g. (50%) of a white crystalline powder with m.p. 207–209°; λ_{max} , 218 and 256 m μ ; R_f = 0.50.

Anal.—Calcd. for $\text{C}_{23}\text{H}_{32}\text{ClIN}_3\text{OS}$: C, 40.12; H, 4.65; N, 6.10; S 4.65. Found: C, 40.38; H, 4.76; N, 6.11; S, 4.87.

Synthesis of Perphenazine Dimethiodide- ^{14}C (PPZ-DMEI- ^{14}C)—The free perphenazine base (121 mg., 0.3 mmole) was dissolved in 5 ml. of acetone, and 85.5 mg. (0.6 mmole) of ^{14}C -methyl iodide (11.7 $\mu\text{C}/\text{mg}$. in 5 ml. of acetone) was added. About 300 mg. of unlabeled methyl iodide was added as a carrier. The container was stoppered and left standing at room temperature for 24 hr. Then ether was added to precipitate the product. The crude material was recrystallized from ethanol-ether to yield 104 mg. (50%) of the final product with m.p. 207–209° and specific activity 3.27 $\mu\text{C}/\text{mg}$. Mixed melting point with PPZ-DMEI above did not show depression (207–209°). The authenticity and radiochemical purity of the product were established by paper chromatography coupled with a radiochromatogram scanner, Actigraph III. The physical properties of this compound were found to be identical with PPZ-DMEI. The scheme of the synthesis of this compound is shown in Scheme I.

¹ Melting points were taken in a Fisher-Johns apparatus and were corrected. UV absorption spectra were recorded on a Perkin-Elmer model 202 spectrophotometer. Elemental analysis was performed by Galbraith Laboratories. Paper chromatograms were developed in a solvent system, *n*-butanol-ethanol-water (5:2:2), and in the case of radiochromatogram, an Actigraph III (Nuclear-Chicago) was used to record the activity. Radioactivity in the tissues was recorded in a G-M counter (Tracerlab, model TGC-2), with the efficiency of 9%. All of the recordings were carried out at a constant geometry, and corrections for self-absorption were made for the thick-layer preparations.

Scheme 1—Synthesis of Perphenazine Dimethiodide-¹⁴C

Tissue Distribution Studies—PPZ-DMEI-¹⁴C (1 mg.) was dissolved in 1 ml. of water and injected intraperitoneally into five Holtzman rats (one rat for each time period) weighing 175–250 g. The animals were sacrificed at various intervals of 0.5, 1, 2, 4, and 8 hr. after the injection. The liver, kidneys, spleen, heart, lungs, intestines, stomach, muscle, bone, and brain were isolated, rinsed with normal saline solution, and briefly dried, and their weights were recorded. The whole organ (except blood and bone) was homogenized with water 10 times its weight. An aliquot (0.5 ml.) was measured and evaporated to dryness in a planchet and the activity of the residue was recorded. The blood specimen (0.1 ml.) was measured and dried directly in a planchet, and a portion (0.1 g.) of the bone (femur, dried and ground to a powder) was placed in a planchet to record the activity.

Urinary and Fecal Excretion Studies—One milliliter of the aqueous solution of PPZ-DMEI-¹⁴C (1 mg./ml.) was injected intraperitoneally into four Holtzman rats weighing 175–250 g. The animals were maintained in metabolic cages with free access to food and water. The urine and feces were collected separately every 8 hr. An aliquot (0.5 ml.) of the urine specimens was measured in a planchet and dried for recording activity. Since it was a thin-layer preparation, no correction for self-absorption was required. The feces were dried and powdered. A fraction (0.1 g.) was weighed out in a planchet to record the activity. Corrections for self-absorption were made for the preparation.

Biliary Excretion Studies—Holtzman rats weighing about 300 g. were anesthetized by a subcutaneous administration of 70 mg./kg. of pentobarbital sodium. An incision was made on the abdominal wall, and the common bile duct was cannulated with a polyethylene tube, PE50 (Clay-Adams). About 1 ml. of the test solution (1 mg./ml.) was placed directly into the intraperitoneal cavity and the incision was closed. Bile specimens were collected at the intervals of 0.5, 1, and 2 hr. All animals were sacrificed at the end of the 2-hr. period; intestines and urine in the bladder were collected and the activities were recorded.

Metabolic Studies—To study the *N*-demethylation *in vivo*, two rats were injected intraperitoneally with PPZ-DMEI-¹⁴C and placed in a large metabolic jar with a constant flow of air to remove carbon dioxide produced by the animals. The air was passed through a gas washing bottle containing 40% sodium hydroxide solution. The carbon dioxide collected in the gas washing bottle was precipitated by adding 50% calcium chloride solution; the calcium carbonate thus formed was collected and dried and the activity was recorded.

Paper chromatographic technique was used to determine metabolites of PPZ-DMEI-¹⁴C in urine and feces. Pooled urine (10 ml.) from three rats after the intraperitoneal administration of PPZ-DMEI-¹⁴C was condensed to 1 ml. and centrifuged to remove solid precipitate. An aliquot of 0.5 ml. of the supernatant liquid was placed linearly on Whatman 3 MM paper, and the chromatogram was developed in the solvent system previously mentioned. A reference PPZ-DMEI-¹⁴C was used as a control. The chromatogram was scanned in a radiochromatogram scanner, Actigraph III, and the *R_f* values of the corresponding spots were calculated.

Feces collected over a 3-day period after the administration of PPZ-DMEI-¹⁴C were extracted with ether in a continuous extrac-

Table I—Recovery of Radioactivity^a from Urine and Feces of Four Rats after Intraperitoneal Administration of 1 mg. (1 ml.) of Aqueous Solution of Perphenazine Dimethiodide-¹⁴C

Time, hr.	Urine, %	Feces, %
8	13.0 ± 4.05	0.03 ± 0.00
16	14.0 ± 3.01	0.03 ± 0.00
24	3.4 ± 0.60	0.48 ± 0.04
32	2.5 ± 0.21	9.12 ± 2.32

tion apparatus for 2 days to remove fatty substances. The ether extracts which did not show radioactivity nor color reaction with 50% sulfuric acid were discarded. The residue in the continuous extraction apparatus extractor was extracted with methanol for 3 days. The methanol extracts were evaporated to 1–2 ml. under reduced pressure, and an aliquot of 0.1 ml. was chromatographed on Whatman 3 MM paper and treated in the same manner described for the analysis of urinary metabolites.

Acute Toxicities—A series of dilutions of aqueous solution of PPZ-DMEI was administered intraperitoneally to a group of 10 male albino mice (Southern Animal Farms, Prattville, Ala.). Each animal was placed in an individual cage with free access to water. Acute toxicity was observed and the mortality recorded. LD₅₀ was calculated according to the method of Litchfield and Wilcoxon (11).

Antimicrobial Activities—Antibacterial and antifungal activities of PPZ-DMEI were tested by using a diffusion method in which a short glass cylinder containing 0.3 ml. of the test solution was placed on a solid culture medium which was previously seeded with a test organism. After incubation at 37° for an optimum growth period for the organism, the diameter of the clear zone surrounding the glass cylinder was taken as the measure of the inhibitory effect of the drug against the organism. In this test, *Staphylococcus aureus* and *Escherichia coli* were chosen to represent a Gram-positive microorganism and a Gram-negative microorganism, respectively. Brain heart infusion agar (Baltimore Biological Laboratory, Baltimore, Md.) was used as the culture medium.

Saccharomyces carlbergensis and *Aspergillus niger* grown on Sabouraud dextrose agar medium were used in the test for antifungal activity.

RESULTS

In contrast to the excretion pattern of trifluoperazine methiodide-¹⁴C, the major route of excretion of PPZ-DMEI-¹⁴C was

^a Expressed in terms of percent of specific activity of organ (c.p.m./g. of wet weight) against specific activity of whole body (administered activity/g. of body weight).

consistent with predominantly urinary excretion as indicated by the cumulative excretion data shown in Table I. About 55% of the administered activity was recovered during the 112-hr. period, of which 41% was found in the urine and only 14% in the feces. In all cases, urinary excretion was rapid; nearly 70% of the recovered activity appeared in the urine during the first 16-hr. period. However, fecal excretion was somewhat slow; that is, only a small amount of feces specimen was collected within the first 24-hr. period and a large amount of specimen was obtained between 24 and 32 hr. The slow fecal excretion was apparently due to the decreased intestinal motility associated with the sedative effect of the drug. The ratio of the activity between the urine and feces was 2.8:1.

The distribution pattern of radioactivity of this compound is presented in Table II. Radioactivity in the kidneys and liver prevailed over other organs 0.5 hr. after the administration. Rapid absorption of the compound was indicated by a rapid decline in the activity of the recovered abdominal washings, and it was further reflected by the high blood level with a peak at 0.5 hr. after the injection. The blood level decreased thereafter; however, the activity remained above the detectable level after 8 hr. The kidney level was almost parallel to the urinary level, which started to increase at 2 hr. and reached its peak at 4 hr. An average of 6% of the administered activity was found in the liver and 5% in the intestines during the 8-hr. period. The brain level was low but above the significant level. Activity in the brain accumulated slowly but steadily, reaching its peak at 8 hr. In other organs, the radioactivity was in the descending order of stomach, spleen, lungs, and heart during the 8-hr. period.

The overall recovery of the administered activity was between 54 and 66% in these animals. A considerable amount of the material apparently was retained in the fat and skin of the animals, because an average of 4.2 and 9.3% of the injected activity was found in the fat and skin tissues, respectively (digested with hyamine hydroxide and dried in a planchet or activity recording), of two rats (used in the excretion study) 6 days after the administration of PPZ-DMEI- ^{14}C .

In contrast to chlorpromazine methiodide- ^{14}C , only a low radioactivity (0.45% of the injected dose) of PPZ-DMEI- ^{14}C was recovered in the bile collected from the common bile duct at 8 hr. This may be due to a weak affinity of this compound for the hepatic transport mechanism, because a compound which is not actively taken up by liver cells is not actively secreted into the bile through the liver. Activity in the intestinal content from the bile duct-cannulated animals was low (4%) but above the significant level, which suggested an active secretion of the compound to the in-

testinal lumen by the glands of the intestinal mucosa. Urinary excretion during the same period of time was 8% of the administered activity.

When these data were interpreted in terms of percent per unit wet weight of organs or tissues, a remarkable change in the ratio of activity between the organ was observed. The relative specific activity in the brain was higher than that in the muscles 2 hr. after the administration of the compound (Table III).

A comparative rate of biliary, intestinal, and urinary excretion of PPZ-DMEI- ^{14}C and chlorpromazine methiodide- ^{14}C in the rats 2 hr. after the intraperitoneal administration of these compounds is shown in Table IV.

The calcium carbonate, obtained by collecting the carbon dioxide produced by the rat after PPZ-DMEI- ^{14}C administration, did not show a significant activity. This indicated that *N*-demethylation and degradation of this compound did not occur *in vivo*. However, this does not rule out the possibility that *N*-methyl exchange with neuroamines such as catecholamines might have occurred *in vivo*.

Paper chromatographic technique coupled with radiochromatogram scanner revealed that there were at least three metabolites present in the urine. One of the substances with R_f 0.50 was identified to be the unchanged PPZ-DMEI- ^{14}C . A trace of the metabolite with R_f 0.66 was found to be its sulfoxide by cochromatography with an authentic perphenazine sulfoxide. Fecal metabolites are currently under investigation.

When LD₅₀ (18.2 mg./kg.) was administered, the principal signs of toxicity were clonic and tonic convulsions; respiratory depression occurred between 5 and 30 min. after the intraperitoneal injection. At lower doses, respiratory depression as well as cyanosis was observed. Dosagewise, PPZ-DMEI- ^{14}C (LD₅₀, 18.2 mg./kg., i.p.) appears to be more toxic than its parent compound, perphenazine (LD₅₀, 64 mg./kg., i.p.). On a molar basis, PPZ-DMEI- ^{14}C has a higher toxicity than the quaternary methiodide of its analog, such as chlorpromazine and trifluoperazine.

PPZ-DMEI- ^{14}C showed an inhibitory effect against the Gram-positive bacteria, *Escherichia coli*, at 10 γ /ml. No remarkable effect was observed on the yeast and fungus tested.

CONCLUSION

Intraperitoneally administered perphenazine dimethiodide- ^{14}C was well absorbed by the rats. The majority (40%) of the drug was accumulated in the kidneys and was excreted in the urine; only 14% of the drug was excreted by the intestines. The ratio of the urinary to fecal excretion was 2.8:1. Peak blood level was observed 0.5 hr. after the administration of the drug. Perphenazine dimethiodide- ^{14}C seemed to have a particular affinity for the bone. The activity in the bone started to rise in 0.5 hr. and reached its peak level in 1 hr. Brain level was low but above the detectable level at 0.5 hr.

Excretion of the activity of perphenazine dimethiodide- ^{14}C was fairly rapid; almost 70% of the activity excreted in urine and feces was recovered in the first 32-hr. period. The quaternary ammonium salt of this compound has a toxicity higher than the parent compound, perphenazine. Antibacterial activities against Gram-positive and Gram-negative bacteria were demonstrated.

Dissolution of Slightly Soluble Powders under Sink Conditions I: Development of an Apparatus and Dissolution Studies of Salicylic Acid Powders

ISMAT ULLAH* and DONALD E. CADWALLADER†

Abstract □ A three-compartment apparatus was developed for dissolution studies of slightly soluble powders under sink conditions. The apparatus was designed to accommodate up to three phases to provide sink conditions. The apparatus could accommodate a barrier in the dissolution medium to prevent floating powders from entering and dissolving directly into the sink phase. Dissolution studies were conducted with several particle size grades of salicylic acid under nonsink as well as sink conditions. Effects of the rate of agitation and methods of introducing samples (dry or wetted suspensions) were also investigated. The data indicated that under diffusion-controlled rate of agitation, using the appropriate placement of propellers, it was possible to establish a rank order for *in vitro* dissolution times of different particle size salicylic acid powders.

Keyphrases □ Powders, slightly soluble—dissolution, sink conditions □ Particle-size effect—powder dissolution □ Diagram—powder dissolution apparatus □ UV spectrophotometry—analysis

In recent years, much attention has been focused on the problem of drug availability from solid dosage forms. The importance of *in vitro* dissolution-rate studies for solid dosage forms in determining the drug availability has been recognized (1–5), but it is now generally accepted that the *in vitro* results should be correlated to some physiologic parameter. It has been shown that unless appropriate sink conditions are maintained in certain cases, *in vitro* dissolution studies might bear little relationship to *in vivo* dissolution results (6).

Recently, several methods have been developed (3–17) to study the *in vitro* dissolution rates of drugs from solid dosage forms; however, most of these methods lack sink conditions. Only a few methods (6, 15) have been reported for dissolution studies under sink conditions, but these are not suitable for powders. Due to flotation and flocculation of slightly soluble powder, the determination of a rank order in the dissolution rates of slightly soluble powders is a problem even under nonsink conditions. Unless these floating

floccules could be broken up, and the powders distributed in such a way that the relative surface areas of different particle-size powders would be available for dissolution, a rank order in the dissolution rates would not be possible. Finholt *et al.* (18, 19) encountered these problems in their attempt to study the effect of particle size on dissolution rates and while comparing the dissolution rates of powders with granules and tablets. Lin *et al.* (20) also found similar problems in the rank order in the dissolution rates of different particle-size powders.

Because certain properties of drug powders play an important part in their dissolution rates from the dosage forms, it is important that the dissolution behavior of powders be studied. An apparatus, which could give a rank order in the *in vitro* dissolution rates of powders and could also accommodate sink phases, would be of value in the development and evaluation of dosage forms where control of certain powder characteristics is important.

The objectives of this investigation were to develop an apparatus which could be used to carry out dissolution studies of slightly soluble powders under sink conditions, and to demonstrate the utility of this apparatus by obtaining an appropriate rank order in the dissolution rates of different particle-size powders of a model drug.

EXPERIMENTAL

Chemicals and Materials—The salicylic acid¹ used was USP grade. The different particle-size grades were obtained by sieving twice through Ro-Tap testing sieve shaker, using U. S. standard sieves. Isopropyl myristate² and polysorbate 80³ were used. All other chemicals were reagent or certified ACS grade.

Figure 1—Dissolution apparatus.

Apparatus—The dissolution apparatus developed for this study is illustrated in Fig. 1, a schematic diagram of the assembly is shown in Fig. 2, and the dismantled apparatus is given in Fig. 3. The basic parts of the apparatus consist of a main frame; two glass bowls; a pair of Teflon gaskets; a screen or a filter membrane-holding frame; two controlled speed stirrers with stirring shafts, propellers, and impellers; and a sample injector.

The main frame was fabricated from stainless steel. When the glass bowls were clamped to the main frame, the apparatus consisted of three compartments. The main frame served as the compartment (Compartment C) for an organic sink phase.

The glass bowls were 9.0 cm. in diameter with round bottoms. The bowl for Compartment A was 7.3-cm. deep, and the bowl for Compartment B was 9.1-cm. deep.

The Teflon gaskets had 9.1-cm. open diameter. One gasket was 2.0-cm. thick, while the other was 0.16 cm. The screen-holding frame, to which a screen was secured, was 0.3-cm. thick, had four support arms, and had a central hole for a stirrer shaft. As seen in Fig. 3, this screen-holding frame was combined with the sample entrance tube through which samples being studied could be introduced directly into the dissolution medium. To prevent injecting air below the screen when introducing the samples, a side tube was affixed to the sample entrance tube to vent the air. The level of this air vent tube corresponded to the level of the liquid in the apparatus. A 200-mesh screen⁴ was used as the barrier throughout these studies. This screen was selected on the basis of transport and equilibrium studies carried out using various membranes and screens as barriers. The results of these studies will be reported in a forthcoming paper.

Two propellers were attached to the left-hand stirrer shaft. A three-blade propeller, 1.9 cm. in diameter, was positioned 2.5 cm. from the bottom of the glass bowl in Compartment B. A three-blade turbine impeller, 2.6 cm. in diameter, was used in the organic phase and positioned 0.9 cm. above the interface in Compartment B.

Two, three, or four propellers were attached to the right-hand stirrer shaft. A three-blade propeller, 1.9 cm. in diameter, was placed 2.2 cm. from the bottom of the glass bowl in Compartment A. A three-blade turbine impeller, 3.0 cm. in diameter, was attached 0.2 cm. above the screen. Other additional impellers were used, depending on the particular experimental conditions, and will be described in detail under other headings.

The sample injector is shown in Fig. 4 and consists of a syringe-like assembly made of Teflon. A Teflon piston was attached to a stainless steel rod, which could be unscrewed to clean the assembly. A Teflon disk or Whatman No. 1 filter paper disk was used to cover the tip of the injector assembly. The fitting of these disks was such that they could be ejected with a slight pressure but would remain intact while the samples were being introduced.

Dissolution of Salicylic Acid Powders under Nonsink Conditions—These experiments were carried out in Compartment A with the

apparatus immersed in a $37 \pm 0.5^\circ$ water bath. A 600.0-ml. volume of 0.2 *M* Clark-Lubs pH 2.0 buffer containing 0.05 % polysorbate 80 (dissolution medium), which was previously equilibrated⁵ at 37.0° , was poured into Compartment A through the sample entrance tube with the help of a separator⁶ (there was approximately 145 ml. of dissolution medium above the screen). The stirrer, which was previously set at 55 r.p.m., was started. One gram of salicylic acid powder of desired mesh size was placed in the sample injector. The closed end of the injector was gently tapped three times on a firm surface to give uniform packing. The piston rod was pushed to bring the powder to the tip of the injector, and a Whatman No. 1 filter paper disk was placed over the opening. The sample injector was then introduced into the aqueous phase through the sample entrance tube with the lower tip of the injector placed 4.5 cm. above the bottom of the glass bowl; the sample was then slowly injected into the aqueous phase over a 30-sec. period. One-milliliter samples were removed from the solution above the screen at appropriate intervals. The samples were diluted with pH 2.0 buffer and assayed spectrophotometrically at 302 $m\mu$ using a Beckman DU-2 spectrophotometer. A volume of the buffer used for dissolution (37.0°) equal to the sample volume removed was replaced immediately after each sample was taken. Using this method, the effect of particle size on dissolution of salicylic acid was investigated.

Dissolution of Salicylic Acid Powders under Sink Conditions—Three different methods were used for these experiments. In Compartment A, three propellers were used for Methods A and B while four propellers were used for Method C. The third propeller was a three-blade turbine-type impeller, 2.2 cm. in diameter, and was placed 0.6 cm. above the interface. The fourth propeller was also a three-blade turbine-type impeller. This impeller was 4.3 cm. in diameter and was attached 0.1 cm. below the screen-holding frame.

Method A—A 600.0-ml. quantity of dissolution medium was poured into Compartment A as described earlier. A 480.0-ml. volume of 0.2 *M* Clark-Lubs pH 7.4 buffer was used in Compartment B, while 300.0 ml. of isopropyl myristate was placed above the two aqueous phases. The stirrers were started and the three phases allowed to equilibrate for 45 min. The stirrer for Compartment B was adjusted to 100 r.p.m., while the Compartment A stirrer was varied for different experiments as indicated in the particular experiment. One gram of salicylic acid powder of desired particle size was packed and introduced into the dissolution medium as described earlier. One-milliliter samples were removed from each phase⁷ at appropriate intervals, and the sample volume was replaced immediately with the appropriate solvent. The samples from Compartments A, B, and C were diluted, respectively, with pH 2.0 buffer, pH 7.4 buffer, and isopropyl myristate and assayed spectrophotometrically at 302, 297, and 306 $m\mu$ using a Beckman DU-2 spectrophotometer. Using this method, the effects of various particle sizes and two Compartment A agitation rates (55 and 100 r.p.m.) on the dissolution rate of salicylic acid powder were studied.

Method B—These experiments were carried out as described under Method A except that the samples were introduced as suspensions. A suspension of 1.0 g. of salicylic acid powder and 1.5 ml. of the dissolution medium was made in the sample injector by stirring with a melting point capillary tube. The piston rod was moved to bring the suspension level up to the tip of the injector, and a Teflon disk was placed over the opening. The samples were then shaken vigorously before introducing them into the dissolution medium in Compartment A. The suspensions were slowly injected into the dissolution medium over a 30-sec. period, and samples from each phase were removed at appropriate intervals and assayed spectrophotometrically as described earlier.

Method C—With this method the experiments were carried out as described under Method A, with the exception that an additional three-blade impeller, as described earlier, was attached to the stirrer shaft below the screen in Compartment A. An agitation rate of 30 r.p.m. in Compartment A was used in these experiments.

⁵ This was necessary so that dissolved air in the buffer would not be evolved and block the screen.

⁶ The separator had a 20.0-cm. long stem which, when introduced through the sample entrance tube, would rest on the bottom of the glass bowl. There was no formation of foam below the screen when the dissolution medium was introduced in this manner.

⁷ The samples from aqueous phases were removed by dipping pipets into the respective phases through the organic phase. The sides of these pipets were wiped off before delivering the samples.

⁴ This screen was obtained from Cambridge Wire Cloth Co. The screen had twilled weave, 68.6- μ pore size and was made from a 58.42- μ diameter wire.

Figure 2—Schematic diagram of the dissolution apparatus.

The sample injector was positioned just below the lower edge of the screen-holding frame, so the lower impeller would scrape off the powder sample as it was slowly introduced into the dissolution medium over a 30-sec. period.

Figure 3—Dissolution apparatus dismantled.

RESULTS AND DISCUSSION

Dissolution of Salicylic Acid Powders under Nonsink Conditions—The apparatus used for these studies, as described under *Experimental*, was essentially a modified form of Levy's beaker stirrer assembly. Using this apparatus, the dissolution studies of different particle size salicylic acid powders under nonsink conditions (Fig. 5) show a good rank order for the dissolution rates of medium particle size range powders (40/60, 60/80, and 100/120). The method however, fails to give relative dissolution rates for coarser (20/30) or finer (120/140) powders. Figure 5 shows that after about an hour, there is a higher dissolution rate for 20/30-mesh powder as compared to 40/60 mesh. Similar discrepancies have been reported by other workers (18-20). This might be due to the packing characteristics of different particle-size powders. The 20/30-mesh powder, being coarser, may not pack as tightly as the 40/60-mesh powder and thus might allow a greater movement of the dissolution medium through its particles, resulting in a higher dissolution rate. It was

Figure 4—Sample injector.

Figure 5—Effect of particle size on dissolution of salicylic acid under nonsink conditions at 55 r.p.m. and 37°. Key: ○, 120/140 mesh; △, 100/120 mesh; □, 60/80 mesh; ▲, 40/60 mesh; and ■, 20/30 mesh.

observed that a small portion of the 40/60-mesh powder was dispersed over a larger surface area at the bottom of the vessel than the 20/30-mesh powder, and this could be the reason for higher initial dissolution rates for the finer powder.

Figure 5 also shows a lower than expected dissolution rate for 120/140-mesh powder. This lower dissolution rate is due to the greater tendency of this size powder to agglomerate because of greater surface energy and electrostatic charges (21). In these studies, the powder remained mainly as a single large mass against the bottom of the screen, which resulted in a much lower effective surface area for dissolution. This mass slowly, but not uniformly, disintegrated during the dissolution period. After about 2 hr., there was a slight increase in the dissolution rate due to the breakup of the floating mass into smaller particles.

The flotation problem could still be seen with fine powders, even though the dissolution medium used in the studies contained 0.05% polysorbate 80. In these studies, 20/30 and 40/60-mesh powders sank rapidly; but 60/80-mesh powder floated for about 2 min., 100/120-mesh powder floated for about 20 min., and 120/140-mesh powder remained floating during a 3-hr. experimental run. The preliminary experiments showed that in the absence of polysorbate 80, the flotation problem was much greater even in relatively much coarser powders, and a 120/140-mesh powder did not completely disintegrate and sink even after 24 hr. under similar experimental conditions. The presence of the surfactant in the gastrointestinal contents (22–24) and its use in the dissolution studies have been shown (24). In these studies, the presence of surfactant in the dissolution medium does not completely solve the flotation problem; however, it does substantially decrease its magnitude.

Dissolution of Salicylic Acid Powders under Sink Conditions—The studies under sink conditions show that the dissolution rates (Fig. 6) are generally higher than those under nonsink conditions (Fig. 5). However, a close comparison shows that the differences are small. This is due to the fact that after 3 hr. the dissolution medium is never more than 35% saturated for any mesh size salicylic acid powder, even under nonsink conditions.

Figure 6—Effect of particle size on dissolution of salicylic acid under sink conditions at 55 r.p.m. and 37°. Key: ○, 120/140 mesh; △, 100/120 mesh; □, 60/80 mesh; ▲, 40/60 mesh; and ■, 20/30 mesh.

Figure 7—Dissolution and partitioning of 100/120-mesh salicylic acid powder using Method A at 55 r.p.m. and 37°. Key: ○, pH 2.0 buffer; △, isopropyl myristate; and □, pH 7.4 buffer.

It is apparent from these studies that the failure to obtain a rank order in the dissolution rates of salicylic acid powders under nonsink conditions was not due to the lack of sink conditions but to the packing, agglomerating, and floating characteristics of the powders. Under these circumstances, the presence of a sink condition would not be expected to make a qualitative change in the dissolution results. The method, however, does demonstrate the technique for using sink conditions and the necessity for a screen barrier to prevent the floating powders from entering directly in the organic phase under sink conditions. The experiments also did not indicate any emulsification at the interface.

Figure 7 shows the partitioning of 100/120-mesh salicylic acid powder as the dissolution takes place. The development of concentration in the pH 7.4 buffer seems to be a little slow and could possibly be increased by using a higher pH buffer; however, no such attempt was made because the purpose of these studies was mainly to demonstrate the use of a three-phase sink system and not necessarily to develop a perfect sink system which, of course, would be different from product to product.

Dissolution studies at 100 r.p.m. under sink conditions (Fig. 8) show that, at this rate of agitation, it is possible to have a large rank order difference between coarser powders (20/30 and 40/60). This could be due to a greater distribution of 40/60-mesh powder under the force of agitation. Figure 8, however, shows a decrease in the difference of the dissolution rates of the finer (60/80 and 100/120) powders. This could be due to the fact that, at this rate of agitation,

Figure 8—Effect of particle size on dissolution of salicylic acid under sink conditions at 100 r.p.m. and 37°. Key: ○, 120/140 mesh; △, 100/120 mesh; □, 60/80 mesh; ▲, 40/60 mesh; and ■, 20/30 mesh.

Figure 9—Effect of particle size on dissolution of salicylic acid under sink conditions using suspension samples at 55 r.p.m. and 37°. Key: ○, 200/230 mesh; △, 120/140 mesh; □, 60/80 mesh; ●, 40/60 mesh; and ▲, 20/30 mesh.

the finer powders cannot remain distributed on the lower sides and bottom of the vessel but are forced into the central vortex, where there is less surface area exposed to the dissolution medium. The 120/140-mesh powder shows an initial lower dissolution rate even at this high rate of agitation. The floating mass is wetted and completely disintegrated after about an hour, resulting in an increased dissolution rate. Although the flotation of powders was partially reduced with the increase in the rate of agitation, the problem of powder distribution was aggravated due to vortexing; the rank order problem was not solved by this experimental method.

Dissolution of Salicylic Acid Powders Using Suspension Samples—Since the problem of rank order in the dissolution rates could be attributed mainly to flotation, flocculation, and poor distribution, it was thought that if prewetted powder samples could be properly distributed, a rank order might be possible. Dissolution studies using samples as wetted suspensions (Method B) did not show any significant difference in the dissolution profiles of powders having particle sizes higher than 40/60 mesh (Fig. 9). A rapid settling of the powders was observed and there was no flotation and flocculation. Due to rapid settling of the powders, however, it appeared that the particles could not be distributed well enough to expose relatively different surface areas; different dissolution rates for different particle size powders above 40/60 mesh did not occur.

A similar phenomenon was observed by Finholt *et al.* (18), who could not differentiate dissolution rates of different particle size acetylsalicylic acid powders in 0.1 N HCl containing 0.2% polysorbate 80. These workers mentioned the possibility of a complex formation between acetylsalicylic acid and polysorbate 80 as

Figure 10—Effect of particle size on dissolution of salicylic acid under sink conditions using four propellers at 30 r.p.m. and 37°. Key: ○, 200/230 mesh; △, 120/140 mesh; □, 60/80 mesh; ●, 40/60 mesh; and ▲, 20/30 mesh.

being responsible for this unusual behavior. They did not introduce the samples as suspensions, but the powders were spread over the dissolution medium. An alternative explanation for their observation might be that the powders were wetted rapidly and, under the slow rate of agitation used, were not distributed enough in the dissolution vessel to give relatively different surface areas for dissolution.

In the present studies, a lower concentration of polysorbate 80 (0.05%) was used. This low concentration is not enough to complex a major fraction of the sample used and probably does not explain the results. Since good differentiation in the dissolution rates of some powders was achieved using the same concentration (0.05%) of polysorbate 80 (Figs. 5 and 6), it would appear that some other factor is responsible for the lack of differentiation in this case. The most likely factor that would explain the lack of differentiation is the rapid settling of the powders. Figure 9 also shows relatively lower dissolution rates as compared to Fig. 6. This difference can also be explained on the basis of rapid settling and poor distribution of the powders.

Dissolution of Salicylic Acid Powders under Sink Conditions Using Additional Lower Impeller—The preceding studies on dissolution of salicylic acid powders showed that the apparatus was adequate for dissolution studies under sink conditions; however, a rank order in the dissolution rates of different particle size powders could not be obtained. The failure was probably due to a lack of mechanism to wet and disintegrate rapidly the large floating powder masses (in the case of fine powders) and to inadequate distribution of the particles in the dissolution medium. An increase of rate of agitation or prewetting of the samples also did not overcome the problems. Consideration of the previous results indicated that an additional lower impeller just below the barrier might solve these problems. A rate of agitation of 30 r.p.m. was selected on the basis of preliminary equilibrium and dissolution studies using the additional lower impeller.

Dissolution profiles of various particle size salicylic acid powders, using an additional lower impeller (Method C), are shown in Fig. 10. The profiles show a good rank order for the different particle size powders studied. The dissolution profiles do not give conventional linear rate order plots, but this is not surprising since a multi-particulate system is very complex.

Table II—Reproducibility of Dissolution Method C for the Dissolution of 120/140-Mesh Salicylic Acid Powder at 30 r.p.m. and 37°

Dissolution Time, min.	Mean Weight ^a (mg.) in Solution	SD ± mg.	Percent SD

			Mean = 2.31

^a Each value is an average of six experiments.

Since these studies show a rank order for the dissolution of different particle-size powders and the studies were conducted under sink conditions using a diffusion-controlled rate of agitation, it might be possible to correlate such studies with some physiological parameter.

Since the main difference in the dissolution Methods A and C was the presence of an additional lower impeller in the latter method, the achievement of the rank order in the dissolution rates of different particle-size powders can be attributed to the effect of this impeller. This impeller runs very close (0.1 cm.) to the lower end of the sample entrance tube where it scrapes off the powders as they are introduced into the dissolution medium and distributes them evenly on the bottom and sides of the dissolution vessel. In this way, even coarser powders are not allowed to drop to the bottom in the form of small piles but are distributed relatively more widely, resulting in higher dissolution rates as compared to the rates of Method A (Figs. 5 and 6). Since the smaller particle-size powders require relatively longer times for settling, they are distributed differently and relatively more widely by the action of the lower impeller. Another very important effect of the lower impeller on very fine powders (120/140 and smaller), which tend to float, is the slight impact it has on the floating masses due to its proximity (upper edge of this impeller is 0.4 cm. below the screen). Under this gentle impact, the floating masses were rapidly disintegrated and settled evenly on the lower sides of the dissolution vessel.

Figure 10 shows that after about 80% of the sample weight has been dissolved, the dissolution profiles of finer powders converge. This could be due to the fact that in the case of very fine powders (120/140 and 200/230), some glomerates are not completely disintegrated before settling on the bottom portion of the dissolution vessel. After the major portion of the powder has been dissolved, these small glomerates remain at the bottom of the vessel and their surface area is about the same as the large-size powders. However, this does not seem to be a serious problem since it occurs after a major portion (above 80%) of the sample has been dissolved.

Although a fine powder (120/140 mesh) was used for dissolution studies with Method C as compared to a relatively coarser powder (100/120 mesh) for Method A, the comparison of the data in Tables I and II shows that Method C with an additional lower impeller is much more reproducible as compared to Method A which does not have this lower impeller. The mean percent standard deviation is more than 6 times greater than for Method C. Student's *t* test conducted on percent standard deviation gave the value of 15.95, which shows that Method C is significantly better than Method A even at 99.9% confidence limits. This can be explained on the basis that in the case of Method C, the lower impeller distributes the powders uniformly each time, while in its absence (Method A), the powders disintegrate and distribute in a haphazard and non-uniform fashion.

Release, Uptake, and Permeation Behavior of Salicylic Acid in Ointment Bases

MASAHIRO NAKANO* and NAGIN K. PATEL†

Abstract □ *In vitro* release of salicylic acid from ointments was investigated by a diffusion technique employing a silicone rubber membrane. The advantages of this membrane over a cellophane membrane are discussed. Release of salicylic acid from five ointment bases indicated that emulsion-type ointment bases are superior to oleaginous and polyethylene glycol ointment bases. Uptake of salicylic acid by polyethylene glycol ointment from the solution was much faster than that by others, indicating a fairly strong affinity of this drug for the polyethylene glycol base. The permeation of salicylic acid from the aqueous solution through ointment bases to another aqueous solution was studied with a three-compartment diffusion cell to examine the relative importance of the factors involved in the process. Dimethyl sulfoxide and dimethylacetamide facilitated the release of salicylic acid from the ointments. Di-*n*-butylpropionamide was found to increase both the release of salicylic acid from the ointment and permeation through the ointment base. The *in vitro* release pattern from various bases is in agreement with the *in vivo* data reported in the literature.

Keyphrases □ Ointment bases—salicylic acid □ Salicylic acid in ointment—release, uptake, permeation □ Release rates—salicylic acid, ointment bases □ Silicone rubber membrane—salicylic acid transfer □ UV spectrophotometry—analysis

Physiological availability of a topically applied drug depends on both the rate of release from the vehicle and the permeability through the skin. The former is physicochemical in nature, whereas the latter may be called physiological. The role of the physicochemical factor in the overall availability of a drug has not been fully understood. To explore this point, the behavior of a drug in ointment bases was examined with a diffusion cell and a silicone rubber membrane instead of the commonly used cellophane membranes (1, 2). Since an *in vitro* study using an excised skin (3) and a number of *in vivo* studies (4–6) deal with salicylic acid, this agent was selected for the present study.

Some of the special features and objectives of the present work are as follows. (a) The feasibility of the use of silicone rubber membranes in availability studies *in vitro* was investigated. (b) The very slow rate of release of salicylic acid from polyethylene glycol ointment prompted the authors to investigate the affinity or interactive nature of the drug for the ointment base by measuring the uptake of the drug from the solution by the ointment base. (c) To ascertain whether the diffusivity of the drug through the ointment or the solubility of the drug in the ointment base (7) plays the major role in the release characteristics of salicylic acid, the rate of permeation¹ of the drug from the solution to another solution through an ointment-base layer was determined with the use of a three-compartment cell. (d)

Figure 1—Diagrams of apparatus used in: (a) release study, (b) uptake study, and (c) permeation study. Key: 1. salicylic acid incorporated in an ointment base; 2. sodium hydroxide solution; 3. ointment base; 4. salicylic acid solution; and m, dimethyl polysiloxane membrane. An arrow indicates direction of transfer of salicylic acid.

The effect of dimethyl sulfoxide and two amides on the release and permeation of the drug was also investigated, since these organic solvents have received considerable attention with regard to their effect on membrane permeability (8).

EXPERIMENTAL

Materials—Reagent grade salicylic acid² was used throughout. Dimethyl polysiloxane³ sheeting in a labeled thickness of 5 mil was used. Dimethyl sulfoxide,⁴ *N,N*-dimethylacetamide,⁵ and *N,N*-di-*n*-butylpropionamide⁶ were used without further purification. Polyethylene glycol ointment, hydrophilic petrolatum, and hydrophilic ointment were prepared according to USP XVII. Water-in-oil and oil-in-water bases were prepared according to the method of Whitworth (9).

Apparatus—The polymethyl methacrylate⁶ diffusion cell described by Patel and Foss (11) was used. The diameter of the available area for diffusion was 34 mm. A three-compartment cell designed for permeation studies consisted of the mentioned diffusion components and a thin plastic⁶ plate (1.8 mm. in thickness) with a central opening, 34 mm. in diameter.

Procedure—Finely powdered salicylic acid (final concentration = 3%) was levigated with 10 drops of liquid petrolatum and incorporated into an ointment base by means of a mortar and pestle. Organic solvent (final concentration = 5%) was blended with the ointment base using a mortar and pestle prior to incorporation of the drug.

Three types of experiments performed in the present investigation: (a) release, (b) uptake, and (c) permeation, are illustrated diagrammatically (not to scale) in Fig. 1 and the procedure is given for each experiment.

Release from Ointment—One compartment of the diffusion cell was filled with an ointment and the excess was removed with the edge of a spatula to produce an even surface. The silicone rubber

⁵ Distillation Products Industries, Division of Eastman Kodak Co., Rochester, N. Y.

⁶ Plexiglas, Rohm & Haas Co., Philadelphia, Pa. This material has recently been shown to absorb some nonelectrolytes from the solution (10). Salicylic acid may also be absorbed to a certain extent.

¹ In this communication the following terminology is used. Diffusion is designated as the transport of a material within a medium, whereas permeation is defined as the transport of a material from one aqueous medium to another aqueous medium through a semisolid phase which separates the two aqueous media, since in the latter both diffusion and partition take place.

Figure 2—Release of salicylic acid from ointments at 30°. Key: ●, oil-in-water ointment; □, hydrophilic ointment; ▽, water-in-oil ointment; △, hydrophilic petrolatum; and ○, polyethylene glycol ointment.

membrane was then placed on it and carefully pressed to ensure complete contact of the membrane with the ointment. The other compartment of the cell was then placed on the membrane. The cell was assembled and tightly secured with bolts and wing nuts. The unit was brought up to a temperature of 30° by keeping it in a constant-temperature incubator.⁷ A 10-ml. portion of prewarmed 0.01 *N* NaOH was placed in the empty compartment. Sodium hydroxide was added to maintain the effective concentration of permeable species to a value of zero in solution. The entire assembly was agitated on a shaker⁸ in the incubator at a constant temperature of 30°. A 0.5-ml. aliquot of the aqueous solution was withdrawn at a definite interval and diluted to 10 ml. with 0.02 *N* HCl to suppress the dissociation of salicylic acid. The concentration of salicylic acid was determined spectrophotometrically⁹ at 302 μ .

Uptake by Ointment Base—The general procedure is the same as just described with the exception that the ointment base was packed in one compartment and a 10-ml. portion of a 10 mM salicylic acid solution in 0.01 *N* HCl was placed in the opposite compartment. Decrease in the salicylic acid content of the aqueous phase was determined spectrophotometrically.

Permeation through Ointment Base—The plastic plate with a circular opening was placed on the silicone rubber membrane and the opening was filled with an ointment base. The second membrane was then placed on it and pressed down to ensure complete contact with the ointment base. This unit was then placed between the two halves of the diffusion cell and the cell was assembled. The cell was brought up to 30° by placing it in the incubator. A 10-ml. portion of prewarmed 0.01 *N* NaOH was placed in one compartment, and an equal amount of prewarmed 10 mM salicylic acid in 0.01 *N* HCl was pipetted into the opposite compartment. The cell was agitated at a constant temperature; the increase in the drug concentration of the alkaline solution at definite time intervals was followed spectrophotometrically.

RESULTS

Release of Salicylic Acid from Ointments—The release characteristic of salicylic acid from various ointment bases over a 2-hr. period is illustrated in Fig. 2. The increase in the drug concentration of the aqueous phase at varying time intervals was used to

assess the rate of drug release from the ointments. The emulsion-type ointments were superior to either hydrophilic petrolatum or polyethylene glycol ointment bases in salicylic acid release. Among the emulsion-type bases investigated, the oil-in-water type bases gave a better release than the water-in-oil type. Although not shown in the figure, the rate of release of salicylic acid from white petrolatum was slower than that from hydrophilic petrolatum; whereas the drug release from Base II, a polyethylene glycol base containing cetyl alcohol (12), was comparable to that from the polyethylene glycol base. Results are in agreement with those published in the literature (4) with the exception of the release data from polyethylene glycol bases, which are in direct contrast with those reported earlier (13). A possible explanation is offered under *Discussion*. Three official ointment bases, *i.e.*, hydrophilic ointment (an emulsion base), hydrophilic petrolatum (an absorption base), and polyethylene glycol base (a water-soluble base), were further examined in the uptake and permeation studies.

Uptake of Salicylic Acid by Ointment Bases—The drug uptake from aqueous solution by the ointment bases, separated by the silicone rubber membrane, was measured to evaluate the relative affinity of the drug for the bases. The data for this part of the study are plotted in Fig. 3. The figure shows that only 8% of the drug remained in solution after a 24-hr. period in the case of polyethylene glycol base, thus demonstrating a comparatively rapid rate of uptake by this base. The uptake by hydrophilic ointment was fairly rapid, whereas it was very slow for hydrophilic petrolatum.

Permeation of Salicylic Acid through Ointment Bases—Figure 4 illustrates the permeation profile of salicylic acid from the acidic solution to the alkaline solution through various ointment bases. Here the drug concentration of the alkaline solution is plotted as a function of time. The permeation of salicylic acid through hydrophilic ointment was comparatively rapid, whereas very little drug permeated through polyethylene glycol base within a 10-hr. period, with hydrophilic petrolatum as an intermediate. Even though only a small fraction of salicylic acid permeated through polyethylene glycol base into the alkaline solution, there was a large decrease in the drug content of the acid solution, thus indicating a significant accumulation of salicylic acid in the base.

Effects of Some Organic Solvents on the Release and Permeation—The data on the influence of dimethyl sulfoxide and two amides for the release of salicylic acid from hydrophilic petrolatum are presented in Fig. 5. The rate of drug release was dependent upon the nature of the organic solvent. Di-*n*-butylpropionamide exhibited the greatest enhancing effect, followed by dimethylacetamide and dimethyl sulfoxide in decreasing order. Similar enhancing effects of these solvents were observed with polyethylene glycol and hydrophilic ointments.

Figure 6 illustrates the effects of the solvents on the rate of drug permeation through hydrophilic petrolatum. Permeation through the vehicle was accelerated in the presence of di-*n*-butylpropionamide, but the effect due to dimethylacetamide was not very pronounced. Polyethylene glycol ointment showed a similar behavior with the solvents; however, the magnitude of acceleration was less

marked. These solvents had little effect on the permeation of the drug through hydrophilic ointment.

DISCUSSION

As illustrated in Fig. 2, the release characteristics of salicylic acid from five physically different ointment bases through a silicone rubber membrane over a period of 2 hr., indicate that the membrane of a thickness of 5 mil provides reasonably fast rates of release to be of practical use for investigations of release of drugs from ointments. The linearity of the plots appears to indicate that the release of salicylic acid follows apparent zero-order kinetics, although this is not always the case (Fig. 5). The release pattern obtained using a silicone rubber membrane is in agreement with the *in vivo* data of Stolar *et al.* (4). Their ranking of the ointment bases for percutaneous absorption of salicylic acid was: hydrophilic ointment > hydrophilic petrolatum > polyethylene glycol.

Billups and Patel reported that cellophane membrane gave unusually rapid release of salicylic acid from the polyethylene glycol-cetyl alcohol base (Base II), although it was satisfactory for emulsion- and oleaginous-type bases (13). This is in direct contrast to the poor percutaneous absorption of salicylic acid from polyethylene glycol base (4). Cellophane membrane is freely permeable to water. In the case of an ointment base with high affinity for water, such as polyethylene glycol, the base attracts water, thus forming a solution and thereafter allowing the drug to permeate from the aqueous solution rather than from the base.

The mechanism of transfer of salicylic acid through the silicone rubber membrane is possibly governed by the partitioning of the drug into and diffusion through the membrane (14). The partition coefficient of the drug between the membrane and the ointment base thus plays an important role. In overall availability, this factor may be desirable because of the similarities in the physical properties of the membrane with those of skin. The skin barrier is generally considered to be lipid in nature, although the exact mechanism of percutaneous absorption is not fully understood (15). Silicone rubber membranes are known to be permeable to nonionic drug molecules; and because of their lipidlike properties, they are claimed to be of value in the investigation of the drug transport through lipid barriers (14, 16, 17). Based on the agreement of *in vitro* release pattern with *in vivo* data (4), a silicone membrane appears to be ideal for investigating drug release from diverse bases.

The very slow release of salicylic acid from polyethylene glycol ointment observed in this study was also noted by Loveday using excised pig skin (3) and by Stolar *et al.* from the measurement of the blood level in the rabbit (4). This slow release is most likely due to the affinity of salicylic acid for polyethylene glycol. This was demonstrated by the fairly rapid uptake of salicylic acid by the polyethylene glycol base from the solution (Fig. 3) and the drug accumulation

Figure 5—Effect of dimethyl sulfoxide and amides on the rate of release of salicylic acid from hydrophilic petrolatum at 30°. Key: ▽, with di-n-butylpropionamide; ○, with dimethylacetamide; □, with dimethyl sulfoxide; and △, without organic solvent.

within the ointment base in the permeation studies (Fig. 4). Hydroxybenzoic acids and phenols form molecular complexes with polyethylene glycol (18, 19) through hydrogen bonding. Due to complexation, salicylic acid is held up by the vehicle, thus retarding its release. Drugs which do not complex with polyethylene glycol would be expected to show better drug release than the acid. Loveday observed superior release of methyl salicylate from polyethylene glycol ointment (3). Methyl salicylate would not be expected to complex with polyethylene glycol because of the lack of the carboxylic acid group and involvement of the hydroxy group in intramolecular hydrogen bonding.

For diffusion to occur, the medicinals should be dissolved in the ointment base; this factor is of considerable importance for poorly soluble drugs. The three-compartment cell was used to examine the permeability characteristics of the drug in each ointment base without complications from the difference in the solubilities of the drug in various bases. In this experiment the initial concentration of salicylic acid in one compartment was kept constant, and the drug was allowed to permeate through varied bases into another

Figure 6—Effect of amides on the rate of permeation of salicylic acid through hydrophilic petrolatum. Key: ▽, with di-n-butylpropionamide; ○, with dimethylacetamide; and △, without amide.

compartment. Under these conditions the partition coefficient of the drug between the ointment base and membrane, as well as its diffusivity in the ointment base, would influence the rate of permeation and consequently the rate of release. The overall similarity of the release and permeation profile of the drug from hydrophilic ointment, hydrophilic petrolatum, and polyethylene glycol indicates that the solubility factor is not of overwhelming importance and the contribution from other factors, such as the diffusivity of the drug in the ointment base and possibly the partition characteristics of the drug between the base and the membrane, also have a significant bearing upon the release characteristics of the drug.

In the absence of specific interaction between the drug and the ointment base, as was the case with salicylic acid and polyethylene glycol ointment base, the base that takes up the drug fast appears to release the drug fast (Figs. 2 and 3). The rate of uptake of the acid by the ointment base from a solution through the silicone rubber membrane depends upon both the partition coefficient between the ointment base and the membrane and the diffusivity through the ointment base. Diffusivity through the ointment base may be the rate-limiting factor for ointments with poor drug release. This can be explained on the basis of uptake data for hydrophilic ointment and hydrophilic petrolatum. The greater uptake of drug by hydrophilic ointment than by hydrophilic petrolatum can be related to faster diffusion of salicylic acid through hydrophilic ointment. Water, being a continuous phase in hydrophilic ointment, is more mobile than the continuous oil phase of hydrophilic petrolatum and this, in turn, would favor diffusion of salicylic acid through hydrophilic ointment. The partition factor, on the other hand, should have a favorable effect upon hydrophilic petrolatum over hydrophilic ointment, since salicylic acid is roughly five times more soluble in oils and fats than in water (20).

Accelerated release of salicylic acid from white petrolatum and water-in-oil-type emulsion base in the presence of organic solvents has been reported by Whitworth (9). The results of the present study showed that the *in vitro* release of salicylic acid from hydrophilic petrolatum, polyethylene glycol base, and hydrophilic ointment was also increased in the presence of dimethyl sulfoxide and the amides. The reported increased percutaneous absorption of salicylic acid in the rabbit in the presence of dimethyl sulfoxide (21) may be attributed to the increased drug release from the ointment (Fig. 5) rather than merely to the change in the skin permeability by the sulfoxide. The increased solubility of salicylic acid in the ointment base containing organic solvents would be expected to increase the rate of release. The reason for attributing the increased release of salicylic acid mainly to the increased solubility of the drug in the base, rather than to change in membrane permeability, comes from the fact that the effect of dimethyl sulfoxide and dimethylacetamide on the rate of permeation was not so pronounced as that on the release rate. In addition, these two organic solvents have been shown not to partition to an appreciable extent into the silicone rubber membrane (22). These solvents, therefore, may not have a significant influence on the silicone rubber membrane itself, although the possibility of this effect may exist with biological membranes. The greater enhancing effect of di-*n*-butylpropionamide compared to dimethylacetamide may be due in part to the greater solubility of the former in the membrane. Di-*n*-butylpropionamide partitions into the membrane from the ointment, and it can form hydrogen bonds with salicylic acid which, in turn, facilitates the transfer of salicylic acid from the ointment into the

membrane. This interaction is expected to accelerate the permeation of salicylic acid (22).

Comparative Evaluation of Various Dissolution Apparatus for Capsule Dosage Forms

SONG-LING LIN, JOHANNE MENIG, and CHARLES J. SWARTZ

Abstract □ The dissolution profiles of experimental diuretic and antidiabetic compounds in capsules were investigated by bead, plate, blade, holder, basket, disintegration time, and proposed USP dissolution methods. The apparent initial dissolution rate and the extent of drug released within the testing period were used as parameters in comparative evaluation of these seven methods. The influence of the size of the stirrer, the volume of dissolution medium, and the size of screen cloths for making the basket on the dissolution profile was studied and discussed. The Reynolds number of the fluid is introduced to explain the influence of the size of the stirrer on the dissolution rate. Due to the small screen (40 mesh) employed in the proposed USP dissolution method, the visual observation of the behavior of the capsule is impaired, and the chance of clogging the screen by the granules is greater than the self-designed (8 mesh) basket used in the basket method. The dissolution profiles obtained with the disintegration time method provide the fastest rate and the greatest extent of dissolution for both experimental diuretic and antidiabetic compounds.

Keyphrases □ Capsule dosage forms—dissolution apparatus □ Dissolution apparatus, comparison, evaluation—capsule dosage forms □ Stirring rate effect—capsule dissolution □ UV spectrophotometry—analysis

The majority of drugs today are formulated and marketed as tablets and capsules. For slightly and poorly water-soluble compounds, the effective absorption process is generally controlled by the disintegration time of the dosage form and the rate and extent of the subsequent dissolution at which the drug goes into and remains in the solution state. Thus, for a drug contained in a solid dosage form to be absorbed, the following illustrated sequence must occur (Scheme I):

Scheme I

The usefulness and importance of developing suitable dissolution apparatus and procedures in product research and development have been recognized for several years. In the product research area, dissolution testing is commonly employed as a means of evaluating and selecting the crystalline or amorphous forms, polymorphic or solvate forms, or the eutectic or com-

plex forms of the compound. On the other hand, dissolution testing is generally accepted in the product development area for studying the drug-release patterns of the conceptual dosage forms, for investigating the formulation and process factors in the development of dosage forms, and for facilitating the selection of certain preliminary formulations for preclinical *in vivo* efficacy studies of the formulation. In general, when the correlations between the *in vitro* dissolution data and the *in vivo* clinical or pharmacokinetic evidence have been established, the dissolution method may be incorporated in the specification of the dosage form as a quality control tool. Therefore, the standardization of test apparatus and methodology is extremely important in the evolution of drug standards, and proper comparative evaluations play a significant role in such standardization.

Dissolution characteristics of solid dosage forms such as tablets or capsules may be determined by various apparatus employing various dissolution media, agitation intensities, and sampling methods for assaying the drug content in solution. Many *in vitro* techniques appear in the literature for the evaluation of drug-release patterns from solid dosage forms (1-24). The applicability and reliability of these apparatus and procedures are, in general, more suited for tablets than for capsules. It is the purpose of this article to evaluate comparatively the dissolution profiles attainable by various devices which are shown to be practical and reproducible for investigating the release pattern of the compound from the capsule.

EXPERIMENTAL

Materials—The diuretic compound was dried at 100° for 8 hr. The chemical identity was confirmed by elemental analysis and IR spectra. The moisture content, as determined by the Karl Fischer method, was about 1%. Analysis by a nonaqueous titrimetric method showed a purity of better than 99% which was substantiated by TLC analysis. The equilibrium solubility at 37° in phosphate buffer at pH 7.3 was about 1 mg./ml. Using U. S. standard sieves, the fraction of the diuretic compound passing through 40 mesh but retained in 100 mesh was collected and used throughout this investigation.

The antidiabetic compound was dried at 80° under vacuum for 12 hr. The moisture content, as determined by the Karl Fischer method, was negligible. The chemical purity was found to be better than 99.5%. The equilibrium solubility at 37° in double-distilled water was approximately 2%. The samples were sieved through U.S. standard sieves, and fractions of 20/100-mesh particles were collected for use in this investigation.

Determination of Dissolution Profile—Approximately 100 mg. of the sieved sample of the diuretic or antidiabetic compound was accurately weighed and carefully introduced into No. 1 clear gelatin capsules with as little compaction as possible. The capsule was then placed in one of the several devices, as depicted in Fig. 1, for obtaining the dissolution profile. The devices or apparatus employed are as follows: (a) The capsule is weighted down to the

Figure 1—Photograph illustrating the various devices employed for the investigation of capsule dissolution profile. bottom of the dissolution flask by inserting two glass beads at both ends of the capsule (bead method) prior to the filling of the drug into the capsule. (b) The capsule sinks to the bottom of the dissolution flask by affixing the capsule to a 2 × 2-cm. stainless steel plate (plate method) with the aid of water-repellant glue. (c) The capsule is affixed to one of the three blades of the stirrer (blade method) with the same water-repellant glue. (d) The capsule is positioned into the orifice of a plastic capsule holder (holder method) specifically designed for a No. 1 gelatin capsule. (e) The capsule is placed in a self-fabricated basket (basket method) made from a stainless steel metal screen. (f) The capsule is placed in the USP proposed basket (proposed USP method) designed to be one of the official dissolution testing apparatus in the future.

The dissolution studies were performed using 300 ml. of dissolution medium at 37° in a pyrex beaker of 800-ml. capacity. The bottom face of the beaker was converted into a convex shape. The agitation of the dissolution medium was achieved by an overhead stirrer operated at 60 r.p.m. and placed at the center of the beaker. The agitation mechanism and the volume of dissolution fluid employed for each method are indicated in Table I. In all cases, the top surface of the agitation mechanism, such as the stirrer or basket, was immersed 2 cm. below the surface of the dissolution medium. The dissolution media employed for the diuretic and antidiabetic compounds were phosphate buffer at pH 7.3 and double-distilled water, respectively. At zero time, the capsule was introduced into the dissolution medium maintained at 37°. At prescribed time intervals, sample aliquots were withdrawn and replaced immediately with the same volume of fresh medium maintained at 37°. The aliquot was immediately filtered through 0.45-μ pore size Millipore filter paper. The clear filtrate was properly diluted with an appropriate solvent and assayed spectrophotometrically at 282 mμ for the diuretic compound and 347 mμ for the antidiabetic compound. Beer's law curves were constructed previously in the solvent systems employing 50% aqueous methanol and distilled water. A cumulative correction was made to account for the previously removed samples in determining the total amount of drug dissolved at any specific time. An average of at least three determinations was performed for

each method investigated in this study. The gelatin capsule in the diluted sample aliquots was found not to interfere with the spectrophotometric assay at the aforementioned wavelengths.

RESULTS AND DISCUSSION

The experimental conditions employed to obtain dissolution profiles, together with their apparent agitation mechanism, are summarized in Table I. Numbers appearing in the first column of Table I correspond to the number designated for the curves in Figs. 2–6. Whenever the device investigated was suitable for studying the effect of the size of the stirrer on the release rate of drug from the capsule, two kinds of three-bladed stirrers were employed. The small stirrer used was 2.0 cm. in diameter and the angle of the blade to the horizontal plane was 45°, whereas the large stirrer employed was 4.3 cm. and the blade was perpendicular to the horizontal plane. It was suggested by Levy (15) that, using a stirring rate of 30 to 60 r.p.m., the agitation intensity is sufficient to obtain a homogeneous solution for sampling purposes yet low enough to preserve the microenvironment of the tablet being tested. Consequently, the constant stirring rate of 60 r.p.m. was employed throughout the study unless otherwise specified.

The plot in Fig. 2 depicts the dissolution profiles of the diuretic and antidiabetic compounds, using the bead method with the small and large stirrers. It is evident from the plot that a lag time does exist prior to the dissolution of drug from its encapsulated form into the dissolution medium. The existence of the lag time is explained by the dissolution of gelatin capsules prior to the leaching or releasing of the drug from the capsule. The lag time is about 5 min. for gelatin capsules under the experimental conditions employed. In general, the capsule breaks initially from both ends that are in contact with the glass beads, and this is soon followed by the melting of gelatin from the middle portion of the capsule. Comparison of the dissolution profiles of the two compounds investigated shows that the higher the aqueous solubility of the compound, the faster the initial rate of dissolution and the greater the extent of drug released. This finding is in accord with the Noyes-Whitney equation.

Although the stirring speed was kept constant at 60 r.p.m., it is conceivable that the larger the diameter of the stirrer, the greater the driving force and the better the efficiency of the dissolution fluid impacting on the capsule to release the drug. The increased dissolution rate could be correlated qualitatively to the Reynolds number, a dimensionless group of importance in fluid dynamics.

Figure 2—Dissolution profiles of the diuretic (open symbols) and antidiabetic (solid symbols) compounds by bead method at 60 r.p.m. Key: 1, small stirrer; and 2, large stirrer.

The Reynolds number (N_R) of the fluid having been agitated at constant speed (r) is related to the diameter of the stirrer (D) through the following equations:

$$N_R = kD^2 \quad (\text{Eq. 1})$$

$$k = \frac{r\rho}{\eta} \quad (\text{Eq. 2})$$

where ρ and η represent the density and viscosity of the fluid, respectively. Assuming that the ρ and η of the dissolution fluid are macroscopically independent of stirrer dimension, k will remain as a constant when the fluid is stirred at constant speed, r . Then, it follows from Eq. 1 that the ratio of Reynolds numbers obtained with larger versus smaller stirrers employed in this study are:

$$\frac{N_R^1}{N_R^2} = \frac{D_1^2}{D_2^2} = \frac{(4.3)^2}{(2.0)^2} = 4.6 \quad (\text{Eq. 3})$$

Therefore, as expected, the larger the stirrer size, the greater are the initial dissolution rate and the extent of the dissolution of the diuretic and antidiabetic compounds (Fig. 2). For the diuretic compound, the initial dissolution rate is increased about threefold, and the extent of dissolution within a 2-hr. period is approximately doubled when the smaller stirrer (Curve 1, open symbol, Fig. 1) is replaced with the large stirrer (Curve 2, open symbol, Fig. 1). Quantitative study of the effect of N_R on dissolution rate is in progress (25).

In the plate method, the capsule is affixed to a 2×2 -cm. stainless steel plate in such a way that the contact area between the capsule and the metal plate is minimized by applying as little as possible of the water-repellant glue. The dissolution data obtained with the plate method are illustrated in Fig. 3 for the diuretic compound (open symbols) and the antidiabetic compound (solid symbols). It is clearly demonstrated again that the rate and extent of dissolution are increased with the intensity of agitation and the size of the stirrer. The general characteristics of these four curves of Fig. 3 are very similar to the corresponding curves illustrated in Fig. 2.

For the diuretic compounds (the lower two curves of Figs. 2 and 3), the apparent initial rate and the extent of dissolution are slightly greater for the bead method than for the plate method when small stirrers are employed; the similar apparent initial rate but a greater extent of dissolution is observed for the bead method than for the plate method when a large stirrer is used. The situation is somewhat different for the antidiabetic compound (the upper two curves of Fig. 3). Using a small stirrer, the identical apparent initial release rate is observed and the extent of dissolution is found to be slightly greater for the plate method than for the bead method when a larger stirrer is employed.

The data obtained with the blade method and the holder method are summarized together as depicted in Fig. 4. For the antidiabetic compound, the dissolution profiles obtained with either large or small stirrer using either blade or holder method are nearly superimposable. Therefore, the resulting dissolution profiles are illustrated representatively by the upper curve of Fig. 4. The effect of the size of the stirrer on the dissolution profile of the antidiabetic compound was not discernible for both the blade method and the holder method. This finding differs from that obtained with either the bead method or the plate method, in which the rate as well as the extent of dissolution is enhanced with increasing agitation intensity by replacing the small stirrer with the large stirrer.

The dissolution profile of the diuretic compound is not affected by the size of the stirrer used in the blade method (Curves 5 and 6, open symbol, Fig. 4) but is slightly altered in the holder method (Curves 7 and 8, open symbol, Fig. 4). Comparison of dissolution profiles of the diuretic compound in Figs. 2-4 indicated that, using a small stirrer, the apparent initial dissolution rate and the extent of drug release are decreased in the following order: blade method > holder method > bead method > plate method. However, no significant difference in the apparent initial dissolution rate is observed when the large stirrer is employed among the blade, holder, bead, and plate methods. It is interesting to note that the scattering of the dissolution profiles of the diuretic compound obtained among blade, holder, plate, and bead devices is greatly minimized by substituting the small stirrer with the large stirrer. It appears that the larger the stirrer operating at the same rotating

Figure 3—Dissolution profiles of the diuretic (open symbols) and antidiabetic (solid symbols) compounds by plate method at 60 r.p.m. Key: 3, small stirrer; and 4, large stirrer.

Figure 4—Dissolution profiles of the diuretic (open symbols) and antidiabetic (solid symbols) compounds by blade (Curves 5 and 6) and holder (Curves 7 and 8) methods at 60 r.p.m. Key: 5 and 7, small stirrer; and 6 and 8, large stirrer.

speed, the smaller variation of dissolution profiles is obtained among various devices. It was found in preliminary experiments with the blade methods that the difference in dissolution profiles of the diuretic compound is negligible when the capsule investigated is affixed at the bottom of the stirring shaft, at the face of the blade opposite to the direction of the flow, or at the face of the blade facing the same direction of the flow as shown in Fig. 1.

With blade or holder method, the majority of the drug is fairly well dispersed in the testing fluid at 60 r.p.m., although a small fraction of drug falls to the bottom of the dissolution vessel. The observation of the relative degree of drug dispersion in the dissolution fluid, together with the determination of dissolution profile, could be employed as a fast and useful means for screening the dosage forms. In general, if the large particulate agglomerates are visually observed to swell or sink in the dissolution flask, an unsatisfactory dissolution profile is expected. The poor dispersion effect may be taken as a possible early warning of drug-availability problems from the absorption viewpoint.

One common characteristic among the blade, holder, plate, and bead methods is that a certain segment of the capsule is physically in contact with supporting devices such as the stirring blade, plastic holder, metal plate, or glass bead, respectively. To prevent the physical contact and to alleviate the common problem of floating of the capsule on the surface of the dissolution medium, a self-designed basket was employed. The basket is labeled E in Fig. 1. The basket consists of a stainless steel cylinder 4.5 cm. in height and 2.3 cm. in diameter. The sides and bottom of the basket are No. 8 mesh stainless steel cloth. The bottom wire is welded together. The wire at the top of the cylinder is welded to a stainless steel ring which, in turn, is welded to an inverted T-shaped stainless steel attachment. The top of this cylindrical assembly has an orifice to be affixed to the bottom tip of the stirring shaft.

With this cylindrical basket, the dissolution profiles of the diuretic and the antidiabetic compounds were investigated. The results obtained are illustrated as Curves 9–12 in Fig. 5. When the agitation of dissolution fluid is provided by the rotational movement of the basket alone, the dissolution profile of the diuretic compound

(Curve 9, open symbol, Fig. 5) closely resembles the profiles obtained with the plate—large stirrer (Curve 4, Fig. 3), holder—large stirrer (Curve 8, Fig. 3), and blade—small or large stirrer (Curves 5 and 6, Fig. 4) systems.

For evaluating the influence of the stirrer on the dissolution profile of the diuretic compound, it is necessary to increase the volume of dissolution fluid to accommodate the stirring assembly. As the volume is doubled from 300 to 600 ml. (Curves 9 and 10, Fig. 5), the rate and the extent of dissolution are enhanced when the basket alone is rotated at 60 r.p.m. to supply the agitation. By keeping the volume of dissolution fluid at 600 ml., the dissolution profiles (Curves 10–12, Fig. 5) show that the apparent initial dissolution rate and the extent of drug released are increased with the increase of the stirrer dimension.

Since the disintegration time (D.T.) apparatus, as described in USP XVII, is commonly employed in assessing the dissolution profile of a solid dosage form, this apparatus was incorporated in this investigation with the following slight modifications: a round-bottom dissolution flask of 800-ml. capacity was employed and one capsule was introduced to any one of the six compartments of the basket rack assembly. The assembly, agitated at 30 c.p.m., was allowed to descend to 1 cm. from the bottom of the dissolution flask on the downward stroke. The disk was used, and the volume of dissolution fluid was 700 ml. The data obtained for the diuretic compound are shown as Curve 13 (open symbol) in Figs. 5 and 6. The extent of the diuretic compound released within the testing period of 1 hr. is greatly enhanced with the D.T. method as compared with the basket, blade, holder, plate, or bead methods. This may be attributed to the stronger turbulent flow and the greater impacting force exerted on the capsule and the particulate aggregates by the D.T. method. Therefore, the percentages of drug released within 5 and 10 min. are already at the level of about 33 and 50%, respectively. However, the shape of the dissolution profile of the diuretic compound obtained by the D.T. method is similar to the following systems: (a) bead—large stirrer system (Curve 2, Fig. 2); (b) plate—large stirrer system (Curve 4, Fig. 3); (c) blade—small or large stirrer system (Curves 5 and 6, Fig. 4); (d) holder—large stirrer system (Curve 8, Fig. 4); and (e) basket—no stirrer system (Curve 9, Fig. 5).

The dissolution profiles obtained for the antidiabetic compound are depicted in Fig. 5 as circular and inverted-triangular solid symbols for basket and D.T. methods, respectively. It appears that the change of the volume of the dissolution fluid and the addition

Figure 5—Dissolution profiles of the diuretic (open symbols) and antidiabetic (solid symbols) compounds by basket (Curves 9–12) method at 60 r.p.m. and D.T. (Curve 13) method at 30 c.p.m. See Table I for detailed experimental conditions.

of a small or large stirrer to the basket have not caused any detectable alteration in the dissolution profile of the antidiabetic compound. Consequently, the results are plotted collectively as solid circles of Curves 9–12 of Fig. 5. With the D.T. method, the dissolution profile is nearly superimposable to that obtained by the basket method.

Toward the completion of this investigation, a similar basket as was employed in this study was advocated by the USP as a tentative apparatus for investigating the dissolution of tablet and capsule dosage forms. Therefore, the suggested USP basket was purchased and incorporated in this study. The proposed USP apparatus (F in Fig. 1) consists of a stainless steel basket 3.6 cm. high and 2.5 cm. in diameter. The sides and bottom of the cylinder are 40 mesh stainless steel. The wire is welded to two stainless steel rings, top and bottom, and joined by welding at the seam. A stainless steel rod 30 cm. long with a 2.5-cm. plate and three spring clips are used to hold the basket (26). The results obtained with the proposed USP dissolution apparatus are shown in Fig. 6 for the diuretic (Curves 14–16, open symbols) and antidiabetic (Curves 14–16, closed symbols) compounds. For easy comparison, the dissolution profiles of both compounds obtained with the D.T. method are reproduced in Fig. 6.

For the diuretic compound, the initial dissolution rate and the extent of the drug released are enhanced by the increasing volume of dissolution medium (Curves 14 and 15) when the stirring mechanism is kept constant and by the use of additional stirrers (Curves 15 and 16) when the volume of dissolution medium is kept constant. This is in accord with the trend obtained with the basket method. The major difference between the basket method and USP dissolution apparatus is the stainless steel screen cloths used to fabricate the basket; USP apparatus uses 40-mesh screen, whereas 8-mesh screen is employed for the self-designed basket. When the basket method was replaced with the USP apparatus in determining the dissolution profile of the diuretic compound, no discernible difference was observed when the volume of dissolution medium was 300 ml. (Curve 14, Fig. 6, *versus* Curve 9, Fig. 5), whereas slight enhancement of the initial dissolution rate was observed when the volume was 600 ml. (Curve 15, Fig. 6, *versus* Curve 10, Fig. 5; and Curve 16, Fig. 6, *versus* Curve 12, Fig. 5).

The increase in the initial dissolution rate by substituting the basket method with the USP apparatus may be attributed to the higher agitation intensity of the smaller mesh screen used in the USP apparatus. With the larger screen used in the basket method, large drug particles and their agglomerates were observed to pass through the screen orifice and fall to the bottom of the dissolution flask after the dissolution of the capsule; the small screen employed in the USP method was observed to provide a mechanical sieve action which forced the drug particles and their aggregates through the small orifice of the screen as a fine dispersion, with lesser amounts of particulate matter swelling and remaining at the bottom of the dissolution vessel. However, due to the small orifice of the screen, the visual observation of the behavior of the capsule within the basket of the USP dissolution apparatus is impaired and not as convenient as when an 8-mesh screen was employed as in the basket method. It appears that a compromise lies in adopting a suitable screen cloth, between 8 and 40 mesh, to provide the convenience of visual observation of the capsule behavior in the basket as well as the prevention of the falling and accumulating of large drug particles and their aggregates at the bottom of the dissolution flask.

As shown in Figs. 5 and 6, the dissolution profiles obtained with the D.T. method provide the fastest rate and greatest extent of dissolution for both diuretic and antidiabetic compounds among the various devices employed in this investigation. It is sufficient to say that the turbulent flow created by D.T. apparatus operating vertically at 30 c.p.m. is stronger in agitation intensity than any other devices employing unidirectional convection and turbulence at 60 r.p.m. The disadvantage of the strong agitation intensity of the D.T. method is that the mild difference in the dissolution characteristics of several formulations to be screened may not be revealed explicitly.

SUMMARY AND CONCLUSION

The dissolution profiles of experimental antidiabetic and diuretic compounds in capsules were investigated by bead, plate, blade, holder, basket, disintegration time, and proposed USP dissolution methods.

These methods are capable of preventing the common problem of the floating of capsules on the surface of dissolution fluid. The evaluation of drug-release patterns by these seven methods was compared from the standpoint of apparent initial dissolution rate, extent of dissolution, and reproducibility within the period of 1 to 2 hr. at 60 r.p.m.

At the constant stirring rate of 60 r.p.m., the initial rate and the extent of dissolution are enhanced with increasing stirrer dimension. It was found that the larger the size of the stirrer, the smaller was the variation of dissolution profiles obtained among various dissolution devices. The observation of the degree of the dispersion of drug in the dissolution media can be used as a visual method to predict the dissolution patterns during dosage form development work. For hydrophobic compounds, the better the dispersion and the lesser the amount of drug remaining or swelling in the bottom of the flask, the faster was the rate and the greater was the extent of dissolution.

For the easy visualization and comparison of the dissolution profiles obtained with the seven methods employed in this investigation, the time needed for dissolving the 25, 50, 75, and 90% of the total drug from the capsule was obtained from Figs. 2–6 and summarized in Table II. It is clearly indicated that the D.T. method provides the fastest rate and the greatest extent of dissolution for both diuretic and antidiabetic compounds among various devices employed in this investigation. This finding is attributed to the stronger turbulent flow and the greater impacting force exerted on the capsule and the particulate aggregates by D.T. apparatus operating vertically at 30 c.p.m. than that obtained by other devices employing unidirectional convection and turbulence at 60 r.p.m.

Although the reproducibility of the dissolution profiles obtained with the seven dissolution methods for capsules is satisfactory and comparable, the authors prefer the simplicity, convenience, and versatility of the basket method and the proposed USP method. However, due to the small screen (40 mesh) used in the basket of the USP method, the visual observation of the behavior of the capsule in the USP method is impaired and the chance of clogging the screen by the granules is greater than with the self-designed (8-mesh screen) basket used in the basket method. For providing the convenient visual observation of the behavior of the capsule in the basket and for preventing the fall and accumulation of large drug particles and their aggregates at the bottom of the dissolution flask,

Effect of Nonionic Surfactants on the Transport of Testosterone across a Cellulose Acetate Membrane

P. M. SHORT*, E. T. ABBS†, and C. T. RHODES

Abstract □ Solubilization of testosterone by a series of three alkylpolyoxyethylene surfactants at 37° has been examined as a function of surfactant concentration. The effect of these surfactants has also been investigated upon the diffusion of testosterone through cellulose acetate membranes. Diffusion coefficients were calculated using a method that allows the measurements to be completed in a very short time. Possible mechanisms by which surfactants may affect drug transport are discussed. In all cases examined, the surfactants reduced the diffusion coefficient of testosterone.

Keyphrases □ Testosterone transport—cellulose membrane □ Surfactants effect—testosterone transport, cellulose membrane □ Solubilization, testosterone—surfactants □ Diffusion coefficient—testosterone

The effect of surfactants upon the biological availability and pharmacological activity of drugs has attracted the attention of a considerable number of researchers in recent years (1).

In the present work, the authors report an investigation of the solubilization of testosterone by three alkylpolyoxyethylene surfactants. The effect of these surfactants upon the diffusion of testosterone across a cellulose acetate membrane has been studied. The work was carried out in a simple closed system which may be more similar to physiological conditions than the use of a "sink." The authors utilized a method for the evaluation of membrane diffusion coefficients that is rapid and avoids the problems of back diffusion.

EXPERIMENTAL

Materials—Three *n*-alkylpolyoxyethylene surfactants of the general formula $C_{16}OE_nOH$ (A30, A45, and A60) were used.¹ The mean molecular weights of these compounds were estimated by NMR spectroscopy as previously described (2, 3). Testosterone,² m.p. 155.5–156.0° [lit. (4) 152–156°], glass-distilled water, spectral quality ethanol, and cellulose acetate membranes³ were also used.

Testosterone Assay—Testosterone was assayed in 50% ethanol by UV spectrometry at 245 $m\mu$. The molar absorptivity for testosterone at this wavelength was found to be 1.61×10^4 , obeying the Beer-Lambert law. Surfactant solutions were used as blanks when required.

Solubility Determinations—An aqueous suspension of testosterone, plus the appropriate amount of surfactant, was stirred for 1 week at $37 \pm 0.1^\circ$ until equilibrium had been reached. Samples were filtered twice through 0.22- μm membrane filters⁴ and assayed spectrophotometrically.

Determination of Diffusion Coefficients—The apparatus used was similar to that described by Humphreys and Rhodes (3). The Perspex donor and recipient cells were separated by the membrane and stirring was effected by bar magnets activated by immovable control units. The temperature was controlled at $37 \pm 0.1^\circ$. Preliminary

Figure 1—Testosterone concentration in donor (upper curve) and recipient (lower curve) cells as a function of time.

tests showed that the surfactant did not cross the membrane, although small traces of nonsurface-active impurities did. Blank solutions, not containing drug, were therefore used as reference in the spectrophotometric assay.

In all the diffusion results, from which diffusion coefficients, D values, were calculated, the total initial concentration of steroid, $[D_w] + [D_m]$, in the donor cell was $6.93 \times 10^{-5} M$.

The thickness of the membrane, L , used in the diffusion studies was obtained from replicate determinations made using two micrometer screw gauges; the L value for the wet membrane was $6.4 \times 10^{-5} m$.

Results were calculated using an Elliott 803 digital computer.

THEORY

A typical set of full-term diffusion study results showing the concentration of drug in both the donor and recipient cells as a function of time is shown in Fig. 1. It is possible, using equations based on first-order kinetic assumptions, to determine transport rates from such data. Although such determinations can be most useful, they are subject to several limitations. The transport process is often inconveniently lengthy. Also, back diffusion of drug can complicate the estimation of diffusion coefficients.

Rogers *et al.* (5) derived equations which overcome the difficulties outlined above. They investigated the diffusion of helium across glass and obtained the following equation:

$$\left(\frac{dp}{dt}\right) = (2A/V)SP_1 (D/\pi t)^{0.5} \sum_{m=0}^{\infty} \exp[-(L^2/4Dt) \times (2m+1)^2] \quad (\text{Eq. 1})$$

³ Visking, Scientific Instruments, Chichester, England.

⁴ Millipore Ltd., Middlesex, England.

Figure 2—Plot for the determination of diffusion coefficient.

where P represents the pressure, t the time, A the area of the membrane, L the membrane thickness, P_1 the pressure on the donor side of the membrane, S the solubility coefficient, and D the diffusion coefficient. This equation is derived from Fick's law and includes the assumptions that D is independent of time and pressure (*i.e.*, concentration for a solution). However, measurements are made over a very short time period and the D determined is that for when $t \rightarrow 0$. Thus, these assumptions are unlikely to be of great practical significance for small concentration changes.

By integrating the original equation of Rogers *et al.*, Eq. 2 is obtained, in which the diffusion coefficient is related to the amount of drug diffused:

$$\frac{S_0 Q}{S_i C_0 L} = \frac{8}{\sqrt{\pi}} \left(\frac{Dt}{L^2} \right)^{1.5} \exp - L^2/4Dt \left[1 - \frac{6Dt}{L^2} + 60 \left(\frac{Dt}{L^2} \right)^2 + \dots \right. \\ \left. - \frac{1}{9} \left\{ 1 - \left(\frac{6Dt}{9L^2} \right) + 60 \left(\frac{Dt}{9L^2} \right) - \dots \right\} \exp - 2L^2/Dt \right] \quad (\text{Eq. 2})$$

where S_0 is the solubility of drug in the solvent, S_i is the solubility of drug in the membrane, C_0 is the concentration of drug in the solvent, Q is the amount of drug diffused across the membrane, of length L , t is the time, and D is the diffusion coefficient.

Not all the terms of the integration are shown in Eq. 2 but, because of the inverted placement of t in the exponentials, this series converges most rapidly for very small values of t rather than for large values. After taking logarithms of both sides, Eq. 3 is obtained:

$$\log_e \left(\frac{Q}{t^{1.5}} \right) = \log_e \left(\frac{8C_0 S_i}{\sqrt{\pi} L^2 S_0} \right) + \frac{3}{2} \log_e D - \frac{L^2}{4D} \cdot \frac{1}{t} \quad (\text{Eq. 3})$$

By plotting $\log_e (Q/t^{1.5})$ as a function of reciprocal time, a straight line is obtained (Fig. 2). From the slope of the line the diffusion coefficient, D , may be obtained using Eq. 4:

$$\text{slope} = -L^2/4D \quad (\text{Eq. 4})$$

When accurate values of S_i are available, high precision values of D may be calculated by use of an iterative technique (Fig. 3). In

Figure 3—Plot for the determination of high precision diffusion coefficient.

the work reported in this paper, however, D has been calculated directly from Eq. 4.

There are limitations at either end of the straight line obtained by use of Eq. 3. At the beginning of the transport process, concentrations of drug in the recipient cell are very low and errors in their analytical estimation are thus relatively high. Later when the concentration of drug in the recipient cell exceeds a critical value, back diffusion occurs and the graph starts to curve. However, results on the linear portion of the graph always returned correlation coefficients approaching unity; for example, a typical set of results of five readings gave a correlation coefficient of 0.990.

RESULTS AND DISCUSSION

The results of the solubilization study are shown in Fig. 4. In all cases the relationship between steroid solubility and surfactant concentration was linear. This type of solubilization isotherm is indicative of micellar solubilization governed by a distribution equation (6). Distribution coefficients for testosterone in the solutions of the three surfactants have been calculated by the method of Humphreys and Rhodes (3) (Table I). When the extent of solubilization is calculated on a molar rather than a percent weight basis, the solubilization efficiency increases with chain length. This finding indicates that the solubilized steroid may be primarily located in the polyoxyethylene exterior of the micelle. Spectroscopic studies of the solubilization of several steroids have led to a similar conclusion (7).

In any aqueous isotopic surfactant solution containing a drug, the following equilibrium will exist:

where D_w represents the free and D_m the bound or micellar drug. In the transport of a drug from a surfactant solution across a membrane the bound or micellar drug is not normally involved. Passive transport of drug across a membrane is a function of the concentration (or more accurately, activity) gradient of free drug across the membrane, and reduction in the value of $[D_w]$ will tend to reduce drug transport. (In those cases in which pinocytosis of micellar drug can occur the situation will, of course, be more complex.)

Figure 4—Testosterone solubilization at 37° as a function of percentage *n*-alkyl polyoxyethylene concentration. Key: Top line, A30; middle line, A45; and bottom line, A60.

Table I—Diffusion and Micellar Partition Coefficients for Testosterone in *n*-Alkylpolyoxyethylene Surfactant Solutions at 37°

—	—	—	18.80
A30	34	476	7.41
A45	62	397	10.18
A60	88	333	11.58

There are several recent reports exemplifying the reduction in the antimicrobial action of drugs caused by surfactants. However, it is apparent that other effects besides reductions in $[D_w]$ are also operative (8, 9).

The second mechanism by which surfactants can alter the transport of drugs from solution across a membrane is by modifying the aqueous diffusion coefficient of the drug. Recent work by Bloor *et al.* has shown that surfactants can increase or decrease such values (10, 11). Thus, in systems where diffusion of drug to the membrane surface is a rate-limiting factor the presence of surfactant could increase or decrease the overall transport rate. It is also possible, though rather unlikely, that monomeric surfactant might reduce the aqueous activity coefficient of the drug, the diminished activity gradient resulting in slower diffusion.

In those cases where adsorption of drug upon the membrane surface is a necessary prerequisite to membrane passage, the presence of surfactant may have further influence. Reduction of surface tension at the interface is likely to have a generalized depressant effect upon the adsorption of all species. The possibility of competition between monomeric surfactant and drug for adsorption sites also exists. However, since it is feasible that a surfactant–drug complex, such as mixed micelle, might also be adsorbed, presence of surfactant could increase or decrease the amount of drug adsorbed. The overall effect will depend upon the relative concentrations of the various species present and the values of their free energies of sorption for the membrane involved. For those substances for which active transport systems exist in a biological membrane, there is a possibility of specific interference by the surfactant with this process. There are also a number of reports which may indicate that surfactants can have direct effects on membrane permeability (12–14). Such effects could be caused by partial defatting or interaction between the surfactant and protein or phospholipid (15).

Because surfactants may affect drug transport in so many ways, there are great advantages in using initially simple *in vitro* studies which can be designed so as to allow the different mechanisms to be distinguished. Such work, of course, can not be regarded as a substitute for *in vivo* evaluation.

Diffusion coefficients of testosterone in distilled water and in aqueous 1% w/v solutions of the three surfactants, increasing in HLB value, are shown in Table I, and the effect of surfactant concentration upon the testosterone diffusion coefficient is recorded in Table II. These results show that the higher the K_d value, *i.e.*, the more the equilibrium shown in Eq. 5 is in favor of the micellar pseudophase, the greater the reduction in diffusion coefficient. Plaxco *et al.* observed similar effects with ethylene oxide chain

Figure 5—Effect of surfactant (A30) concentration on testosterone diffusion coefficient.

length, and thus HLB, in investigations of drug release from suppositories (16).

Figure 5 shows the effect of the concentration of surfactant upon diffusion coefficient. The value of the diffusion coefficient determined in the presence of surfactant decreases linearly with increase in surfactant concentration.

Extrapolation, to zero surfactant concentration, of the relationship between finite surfactant concentration and diffusion coefficient yields a value substantially different to the diffusion coefficient of testosterone determined in distilled water. It is highly improbable that this finding is due to experimental error. Since the surfactant solutions used in this investigation were stirred during the membrane diffusion measurements, this effect cannot be attributed to modification of the aqueous diffusion of the steroid. This change must therefore be attributed to some effect of the surfactant upon the membrane. It seems likely that D changes rapidly at or about the CMC (critical micelle concentration). It has been established that there is no permanent interference with the integrity of the membrane. A membrane, which had been used for the study of the effect of surfactant upon the steroid membrane transport, when thoroughly washed, behaved normally with respect to the steroid diffusion. It is suggested that this depressant effect on steroid transport is probably due either to a generalized inhibition of adsorption at the membrane–solution interface or competition between the monomeric surfactant and steroid for adsorption sites upon the membrane. Further studies of the effect of surfactants upon the transport of drugs across membranes will be published shortly.

Hydrogenation of Substituted Isoquinolines over Nickel Catalyst II: Effects of Pressure and Temperature on the Hydrogenation of 5-Hydroxy-2-alkylisoquinolinium Salts

IAN W. MATHISON, WILEY L. FOWLER, Jr., and KATHLEEN C. FOWLER

Abstract □ A study of the effect of high pressure and high temperature on the nickel-catalyzed hydrogenation of 5-hydroxy-2-ethylisoquinolinium salt is described. The effects of these parameters on the yield and stereochemistry of the 5-hydroxy-2-ethyldecahydroisoquinolines produced are discussed. Comparisons of these data with those from analogous hydrogenations of the 5-nitro-2-methylisoquinolinium salt are included.

Keyphrases □ 5-Hydroxy-2-alkylisoquinolinium salts—hydrogenation □ Hydrogenation, isoquinolinium salts—temperature, pressure effect □ Vapor phase chromatography—analysis □ GLC—analysis □ IR spectrophotometry—structure

In a continuing study of the stereochemistry of variously substituted, fully reduced isoquinolines possessing pharmacological activity (1, 2), the authors have been recently interested in the hydrogenation of 5-substituted isoquinolines at high temperature and high pressure over Raney nickel catalyst (3). Their initial attention was directed toward the hydrogenation of a 5-nitroisoquinolinium salt in which they were able to demonstrate that increases in temperature were effective in inducing changes in the specificity of the hydrogenation while increases in pressure played little or no role in determining the stereochemistry of the desired 5-aminodecahydroisoquinolines produced. The results in regard to the effects of temperature were not totally unanticipated (4); however, an unexpected result was that increases in temperature initially resulted in increased specificity of hydrogenation up to a certain point which was then followed by a more randomized reduction. It was of significance that the *cis* ring junction decahydroisoquinoline was the heavily favored isomer produced (approximately 13:1 to 2:1, depending on conditions) (5, 6). The authors demonstrated that hydrogenolysis occurred to a significant extent at temperatures of 200° and above, while at 160° and 1500 p.s.i. an optimum yield of 71% of the desired 5-aminodecahydroisoquinolines was produced (*cis:trans*, 7.7:1). In view of the reported pharmacological activity of derivatives of 5-hydroxy-2-alkyldecahydroisoquinolines (2, 7) and the need for a rapid, efficient synthesis of these compounds, the authors wish to report the effects

Figure 1—Effect of temperature on reaction products at 2000 p.s.i.

of increased pressure and temperature on the one-stage hydrogenation of 5-hydroxy-2-ethylisoquinolinium *p*-toluenesulfonate over W7 Raney nickel catalyst. The effects of these parameters on the stereochemistry of the hydrogenation and yields of the 5-hydroxy-2-ethyldecahydroisoquinolines produced will be discussed and comparisons will be drawn with the previously reported study (3).

Hydrogenation of Substituted Isoquinolines over Nickel Catalyst II: Effects of Pressure and Temperature on the Hydrogenation of 5-Hydroxy-2-alkylisoquinolinium Salts

IAN W. MATHISON, WILEY L. FOWLER, Jr., and KATHLEEN C. FOWLER

Abstract □ A study of the effect of high pressure and high temperature on the nickel-catalyzed hydrogenation of 5-hydroxy-2-ethylisoquinolinium salt is described. The effects of these parameters on the yield and stereochemistry of the 5-hydroxy-2-ethyldecahydroisoquinolines produced are discussed. Comparisons of these data with those from analogous hydrogenations of the 5-nitro-2-methylisoquinolinium salt are included.

Keyphrases □ 5-Hydroxy-2-alkylisoquinolinium salts—hydrogenation □ Hydrogenation, isoquinolinium salts—temperature, pressure effect □ Vapor phase chromatography—analysis □ GLC—analysis □ IR spectrophotometry—structure

In a continuing study of the stereochemistry of variously substituted, fully reduced isoquinolines possessing pharmacological activity (1, 2), the authors have been recently interested in the hydrogenation of 5-substituted isoquinolines at high temperature and high pressure over Raney nickel catalyst (3). Their initial attention was directed toward the hydrogenation of a 5-nitroisoquinolinium salt in which they were able to demonstrate that increases in temperature were effective in inducing changes in the specificity of the hydrogenation while increases in pressure played little or no role in determining the stereochemistry of the desired 5-aminodecahydroisoquinolines produced. The results in regard to the effects of temperature were not totally unanticipated (4); however, an unexpected result was that increases in temperature initially resulted in increased specificity of hydrogenation up to a certain point which was then followed by a more randomized reduction. It was of significance that the *cis* ring junction decahydroisoquinoline was the heavily favored isomer produced (approximately 13:1 to 2:1, depending on conditions) (5, 6). The authors demonstrated that hydrogenolysis occurred to a significant extent at temperatures of 200° and above, while at 160° and 1500 p.s.i. an optimum yield of 71% of the desired 5-aminodecahydroisoquinolines was produced (*cis:trans*, 7.7:1). In view of the reported pharmacological activity of derivatives of 5-hydroxy-2-alkyldecahydroisoquinolines (2, 7) and the need for a rapid, efficient synthesis of these compounds, the authors wish to report the effects

Figure 1—Effect of temperature on reaction products at 2000 p.s.i.

of increased pressure and temperature on the one-stage hydrogenation of 5-hydroxy-2-ethylisoquinolinium *p*-toluenesulfonate over W7 Raney nickel catalyst. The effects of these parameters on the stereochemistry of the hydrogenation and yields of the 5-hydroxy-2-ethyldecahydroisoquinolines produced will be discussed and comparisons will be drawn with the previously reported study (3).

EXPERIMENTAL

The melting point is corrected. Analyses were run by Galbraith Laboratories, Knoxville, Tenn. Vapor phase chromatograms were recorded on a Varian Aerograph model 700 Autoprep chromatograph. Chromatographic peak areas were determined using a Dietzgen model D-1803-8 planimeter.

5-Hydroxy-2-ethylisoquinolinium *p*-Toluenesulfonate (I)—5-Hydroxyisoquinoline (25 g., 0.17 mole) and ethyl *p*-toluenesulfonate (35.5 g., 0.18 mole) were dissolved in dimethylformamide (100 ml.) and allowed to stand at room temperature for 72 hr. The precipitated crystals (50 g., 83%) of 5-hydroxy-2-ethylisoquinolinium *p*-toluenesulfonate were recrystallized from methanol to yield yellow needles, m.p. 212–213°.

Anal.—Calcd. for $C_{18}H_{19}NO_4S$: C, 62.59; H, 5.54; N, 4.06; S, 9.28. Found: C, 62.74; H, 5.67; N, 4.05; S, 9.57.

The IR spectrum (KBr) was consistent with the proposed structure (3200 cm^{-1} ; 1230 cm^{-1} , —OH).

HYDROGENATION PROCEDURE

The catalytic reduction of I (10 g.) was carried out in methanol (150 ml.) over W7 Raney nickel catalyst (8) (3.0 g.) in a Parr series 4000 hydrogenator under varying conditions of temperature and pressure. The temperature was carefully controlled using a Honeywell temperature controller No. 4811. Standardization of each hydrogenation experiment regarding time of heating and agitation has been previously described in detail (3). At the termination of the reduction, the hydrogenated solution was removed from the bomb and the exhausted catalyst was filtered using diatomaceous earth (Celite) as a filtering aid. The methanol filtrate was evaporated on the rotary evaporator to yield a pale-yellow viscous oil which was suspended in water, made strongly alkaline with sodium hydroxide, and extracted with ether. The dried ether extract was then distilled to yield a yellow oil. This oil was assayed gas chromatographically on a 6.09 m. \times 0.95 cm. (20 ft. \times 0.375 in.) SE 30 (30%) on Chromosorb W column at 215° using a thermal conductivity detector at a gas (helium) flow rate of 100 ml./min. Authentic samples, which were used for identification of the chromatographic peaks of the reaction product mixture, included:

1. *cis*-5,9,10-*H*-5-Hydroxy-2-ethyldecahydroisoquinoline (2). Retention time = 28.4 min.
2. *trans*-9,10-*trans*-5-*H*-5-Hydroxy-2-ethyldecahydroisoquinoline.¹ Retention time = 26.8 min.
3. *cis*-2-Ethyldecahydroisoquinoline.² Retention time = 14.3 min.
4. *trans*-2-Ethyldecahydroisoquinoline.² Retention time = 13.4 min.

RESULTS AND DISCUSSION

The average areas under each identified peak of duplicate gas chromatograms of at least two separate hydrogenations were plotted and Figs. 1–6 were obtained.

Effect of Temperature at Constant Pressure

The study was approached by an initial examination of the influence of temperature on the reduction of 5-hydroxy-2-ethylisoquinolinium *p*-toluenesulfonate. An initial bomb pressure of 2000 p.s.i. was utilized, since it allowed comparisons with the previous investigation (3). Examination of Figs. 1–3 shows clearly the overall effects of temperature on the hydrogenation. As anticipated, increases in temperature resulted initially in an increase in yield of the desired 5-hydroxy-2-ethyldecahydroisoquinolines (Fig. 3); this was followed by a decreased yield concurrently with increased hydrogenolysis (Figs. 1 and 3). It was apparent that the optimum temperature was in the region of 200°, a significantly higher temperature than that for the corresponding nitroisoquinolinium salt (3). The influence of temperature on the stereochemistry of the products yielded some interesting results (Figs. 1 and 2). It is evident (Fig. 1) that increased temperature resulted in increased yields of the *trans* ring junction product accompanied by a comparable decrease in the *cis* product. This holds up to 200–220°, at which point marked decreases in both isomers occur, primarily due to hydrogenolysis and decomposition. This trend, while evident

Figure 2—Effect of temperature on the stereochemistry at 2000 p.s.i.

during the reduction of the nitro analog (3), was not nearly so dramatic as in the present study on the hydrogenation of the hydroxy compound. Indeed, at 240° and above, the authors were able to produce predominantly the *trans* isomer, a situation never realized during the reduction of the nitro compound. More interesting were the data obtained regarding isomer ratios as temperature was increased (Fig. 2). At 100°, a favored *cis* ring junction hydrogenation occurred. As the temperature was increased to 200°, a more randomized hydrogenation resulted where the *cis:trans* ratio was 1:1. However, beyond 200° the randomization of hydrogenation was decreased which resulted in a *cis:trans* ratio of 0.8, i.e., a reduction favoring the *trans* isomer. While it is acknowledged that increased temperature favors a more randomized hydrogenation (4), the authors are unaware of temperature increases resulting in increased randomization followed by a decrease in the randomization. Additionally, it was unanticipated that such a marked reversal of the favored stereochemistry would result. No comparable data were obtained during the reduction of the nitroisoquinoline (3). It is also pertinent that in the reduction of the nitro compound the *cis*-5-amino-decahydroisoquinoline was the very heavily favored product (*cis:trans* ratio of 14:1 to 2:1 depending on the temperature), while in the present study with the hydroxy compound the *cis* isomer was the most favored at best at isomer ratios of only 2:1.

Figure 3—Effect of temperature on yield of 5-hydroxy-2-ethyldecahydroisoquinolines at 2000 p.s.i.

¹ Prepared from *trans*-9,10-*trans*-5-*H*-5-hydroxydecahydroisoquinoline using essentially the method of Blicke and Monroe (9) as outlined by Mathison *et al.* (2) for the corresponding *cis*-5,9,10-*H*-5-hydroxy-2-ethyldecahydroisoquinoline.

² Prepared by the catalytic hydrogenation of 2-ethylisoquinolinium *p*-toluenesulfonate using the general procedure outlined by Witkop (10).

Figure 4—Effect of pressure on reaction products at 220°.

Effect of Pressure at Constant Temperature

In view of the superior yield and nearly equal isomer ratio, it was decided to examine the effects of pressure at 220°. The results are summarized in Figs. 4–6. Figure 4 shows clearly that the production of the *trans* ring junction isomer is virtually unaffected by increases in pressure. On the other hand, the amount of the *cis* analog produced undergoes marked changes during a similar pressure increase. Increased pressure up to 2000 p.s.i. results in increased quantities of *cis*-5,9,10-*H*-5-hydroxy-2-ethyldecahydroisoquinoline, while pressure increases beyond this point result in decreased product. The correlation between the amount of *cis* isomer produced and the amounts of hydrogenolyzed products is of interest. As the amount of the *cis* analog increases, the hydrogenolysis products decrease and vice versa. The summation of the amounts of *cis* product and the hydrogenolysis products remains at a figure of approximately 39% of extracted material throughout the pressure range 1500–3000 p.s.i. These data strongly suggest that the *cis* isomer is more readily hydrogenolyzed than the *trans* analog, a finding compatible with the data obtained during the temperature

Figure 5—Effect of pressure on stereochemistry at 220°.

Figure 6—Effect of pressure on yield of 5-hydroxy-2-ethyldecahydroisoquinolines at 220°.

study on the hydrogenation of the nitro and hydroxy compounds. The authors were unable to demonstrate this trend in the analogous pressure experiments on the nitro compound (3). The results regarding the stereochemistry of the hydrogenation (Fig. 5) were comparable with the data obtained for the nitro compound. Increased pressure results in decreased specificity of hydrogenation up to a point (approximately 2000 p.s.i.); this is then followed by increased specificity. This finding is in contrast to the anticipated results (11). As pressure increases, hydrogen availability increases, and processes requiring hydrogen would be accelerated. One would expect, therefore, that greater *cis:trans* ratios would result since desorption from the catalyst surface would be less likely to occur prior to completion of the hydrogenation. The results concur with this rationale up to 2000 p.s.i.; however, beyond this point the data contradict this theory. The authors can only assume that pressures beyond 2000 p.s.i. in some way perturb the adsorption of the compound to the catalyst prior to completion of the reduction which results in desorption and, therefore, decreased specificity of hydrogenation. As anticipated, pressure was more effective than temperature in inducing higher yields of the desired 5-hydroxydecahydroisoquinolines. Superior yields, however, were obtained with the nitro compound at increased pressures (3).

The differences in stereochemistry observed between the hydrogenations carried out on the 5-nitro-2-alkylisoquinolinium salts (3) and the present study on the hydroxy compounds may be related to the basicity of the products, the aminodecahydroisoquinolines produced in the former investigations being stronger bases than the hydroxydecahydroisoquinolines produced in this study. It is well established (12) that pH is an important factor in determining the steric course of catalytic reductions.

Influence of Phase Equilibria on Properties of Emulsions

S. FRIBERG and L. MANDELL

Abstract □ An investigation was made concerning the phase equilibria in water-oil-emulsifier systems. The results have shown the presence of liquid crystalline phases and the pronounced influence of these on the properties of emulsions. The pronounced solubilizing power of emulsifier micelles in the oil phase, the changed stability due to these, and the drastic changes of volume ratios, water to oil, with increasing emulsifier concentration which this gives rise to, have been investigated.

Keyphrases □ Emulsions—phase equilibria effect □ Phase equilibria—w/o emulsions □ Stability, emulsions—emulsifier concentration □ Liquid crystalline phase—emulsions

The complicated behavior of emulsions has been treated in numerous articles and reviews, due to the importance of such systems in chemical technology and in a vast number of systems of biological origin. In his bibliography, Becher (1) dealt with the different factors that had been found responsible for the behavior of emulsions. Davies discussed the stability of emulsions based on a collision theory (2). Sherman has made important contributions concerning the general properties and rheological behavior of emulsions (3). Recently, Shinoda has introduced the PIT value (4), which denotes the phase inversion temperature. Shinoda assumes this temperature to be more useful than the well-known HLB value in the prediction of the behavior of emulsions from the properties of the emulsifiers.

The HLB value is useful to a very high degree; its success in practical emulsion preparation has shown this beyond doubt, but its shortcomings are obvious. As an example, Sherman (5) pointed out the inversion of emulsions when the amount of emulsifier is increased, and Davies (2) showed the difference in emulsion behavior when the oil phase was changed from benzene to petroleum ether. Neither of these examples can be explained by the HLB value of the emulsifier.

Preliminary results on the influence of phase equilibria on the properties of emulsions showed a sudden increase in stability in the presence of a mesomorphous phase (6). Further investigations (7) showed a pro-

nounced change in phase equilibria when the aromatic *p*-xylene in the oil phase was replaced by hexadecane. These results gave a tentative explanation to the problem stated by Davies (2). The rather complicated rheological behavior of emulsions when the emulsifier concentration was changed could also be satisfactorily explained by interpretation of phase equilibria (8). Since these results appeared to be promising, it was considered that further investigations of phase equilibria in the water-emulsifier-oil systems could be of general value.

Emulsions of w/o type are considerably more difficult to treat theoretically due to the low electric field strength in the continuous medium. Taking this into consideration, the authors chose a set of emulsifiers of the w/o type and determined the phase equilibria of the systems.

EXPERIMENTAL

Materials—The water was twice distilled. The nonylphenol diethyleneglycol ether was of commercial origin (Berol AB, Sweden), which was purified from polyglycols; other impurities are less than 0.01%. Other chemicals used were: octylamine (puriss. gas chromatographic >99%) and *p*-xylene (puriss. gas chromatographic >99.5%) (Fluka A.G., Switzerland); monocapryline (synthesized at the Institute of Medical Biochemistry, University of Gothenburg, Sweden); tricapryline (Eastman Distillation Products Industries); and lecithin, prepared from egg yolk according to a simplified method (9).

Phase Equilibria—The samples for investigation of the phase equilibria in the three-component systems given in Fig. 1 (A-D) were weighed directly into glass ampuls which were sealed. The samples were heated to homogeneity, slowly cooled to 20° under agitation, and allowed to stand at this temperature. The different phases were separated by ultracentrifugation and identified by visual observation under a polarizing microscope or by X-ray methods according to previous work on phase equilibria in ternary systems (10, 11).

Emulsion Preparation and Properties—The components were weighed into ampuls which were treated in an ultrasonic device at 20° for 1 min. followed by vacuum treatment to remove air. This was repeated five times.

The nature of the emulsion was determined by visual observation through a microscope of the spread of oil- or water-soluble dyes (Sudan III and Brilliant Blue F.C.F.). The emulsions with an

Emulsions of w/o type are considerably more difficult to treat theoretically due to the low electric field strength in the continuous medium. Taking this into consideration, the authors chose a set of emulsifiers of the w/o type and determined the phase equilibria of the systems.

EXPERIMENTAL

Materials—The water was twice distilled. The nonylphenol diethyleneglycol ether was of commercial origin (Berol AB, Sweden), which was purified from polyglycols; other impurities are less than 0.01%. Other chemicals used were: octylamine (puriss. gas chromatographic >99%) and *p*-xylene (puriss. gas chromatographic >99.5%) (Fluka A.G., Switzerland); monocapryline (synthesized at the Institute of Medical Biochemistry, University of Gothenburg, Sweden); tricapryline (Eastman Distillation Products Industries); and lecithin, prepared from egg yolk according to a simplified method (9).

Phase Equilibria—The samples for investigation of the phase equilibria in the three-component systems given in Fig. 1 (A-D) were weighed directly into glass ampuls which were sealed. The samples were heated to homogeneity, slowly cooled to 20° under agitation, and allowed to stand at this temperature. The different phases were separated by ultracentrifugation and identified by visual observation under a polarizing microscope or by X-ray methods according to previous work on phase equilibria in ternary systems (10, 11).

Emulsion Preparation and Properties—The components were weighed into ampuls which were treated in an ultrasonic device at 20° for 1 min. followed by vacuum treatment to remove air. This was repeated five times.

The nature of the emulsion was determined by visual observation through a microscope of the spread of oil- or water-soluble dyes (Sudan III and Brilliant Blue F.C.F.). The emulsions with an

Figure 1—Phase equilibria in water–oil–emulsifier systems at 20°. Key: A, water–p-xylene–octylamine; B, water–p-xylene–nonylphenol diethyleneglycol ether; C, water–tricapryline–monocapryline; and D, water–tricapryline–egg lecithin.

amine as emulsifier were too unstable for such a procedure. In that case the emulsion was allowed to settle, and the nature of the two developing layers was determined. This eased the determination of the emulsion type when one of the layers—the emulsion—was emulsified in the other, since a change from water to oil of the continuous phase gave indications of a double emulsion, which could later be confirmed by direct observation in the microscope.

The estimation of the emulsion stability was performed in a rough way by judging the sedimentation rate from photographs. With the pronounced differences of stability characteristic of these systems, the method was considered to be satisfactory. The

emulsions containing an amine as stabilizer were too unstable to be determined in this way. In that case the time for clarification of the phases was used as a measure of the stability.

The emulsions were prepared in several series. In each series the ratio of water to oil was kept constant while the amount of emulsifier was varied. The total compositions of the emulsions are found in Tables I and II.

RESULTS

Phase Equilibria—Figures 1A–D contain diagrams of the phase equilibria in the four systems of this investigation. The conditions in the tentative three-phase areas to the right in the diagram (Fig. 1D) have not been examined in detail, since they are of no value to the present investigation.

The diagrams (Figs. 1A–C) are all of the same general shape with a pronounced solution area where the oil and the emulsifier solubilize water. Xylene and octylamine solubilize water to such a high extent that a continuous solubility area connecting all three components is formed. The solubilizing power decreases in the order A to C in the diagrams; in the water–tricapryline–egg lecithin system, too little mutual solubility is found to be observable in the diagram. The solubilization only takes place in the form of a liquid crystalline phase with a layer structure (denoted D in the figure). This phase is also found in all other diagrams and is always formed by water and the emulsifier with the oil solubilized to a few percent.

Table I—Total Composition of Water–Tricapryline Emulsions with Monocapryline as Emulsifier

Series	Ratio, % Water		—Monocapryline Sample No.—			
	% Tri- capryline		1	2	3	4
I	95/5		9.5	19.2	32.1	
II	90/10		9.1	18.9	31.0	
III	80/20		8.2	16.7	28.7	
IV	60/40		6.3	13.1	23.1	36.6
V	40/60		4.2	16.8	27.9	40.5
VI	20/80		2.3	9.1	16.2	25.5

Emulsion Type—Figure 2 shows the emulsion type in the different parts of the region containing two liquid phases in the equilibrium. The system containing lecithin has not been included, since the corresponding two-phase area of that system is too small to be investigated conveniently.

The octylamine gives o/w emulsions in the water-rich part. In the remaining part of the two-phase area, it forms emulsions of the o/w/o type, which, however, are unstable and separate into two emulsions within a short time (Fig. 2A). Diglycol ether forms w/o emulsions when the emulsifier is associated in micelles in the *p*-xylene phase and when the ratio of *p*-xylene to water exceeds 0.70–0.75 (Fig. 2B). Monocapryline forms w/o emulsions in the whole area except where the water–tricapryline ratio is too high to permit the formation of a w/o emulsion (Fig. 2C).

Emulsion Stability—The stability of the system with diethylene-glycol ether as an emulsifier has previously been investigated and reported (12), and the system containing egg lecithin will not be treated here, since the solution areas of this are too small to be investigated conveniently.

The emulsions containing octylamine are considerably less stable than the other emulsions (Table II). The comparison between the stability of different emulsions in this system was consequently not done by means of photographing the emulsions, but it was made by measuring the time required for the upper phase to form a clear solution.

The upper layer is oil-continuous, and it is striking to compare (Table II) how the time for the clarification of this layer is reduced when the amount of emulsifier is increased. This tendency is most pronounced when the emulsion contains high amounts of *p*-xylene. On the other hand, the emulsions formed by the liquid crystalline phase and the solution were stable to a very high degree.

The emulsions containing water and tricapryline and with monocapryline as an emulsifier show two distinct regions of different behavior. At first, Series I and II contain the liquid crystalline phase in Sample 3 (Table I and Fig. 1C). This emulsion is by far the most stable that can be observed in Fig. 3. Only Series II is shown for spatial reasons. Sample 2, containing more emulsifier than Sample 1, is less stable.

This phenomenon of decreasing stability with increasing emulsifier concentration can be observed in all the emulsions belonging to the second region, the large two-phase area, in Fig. 1C. Only Series V is shown here as an example because of space limitations.

These results imply an optimum addition of monocapryline to obtain maximal stability. This has, however, not been investigated at present.

DISCUSSION

The results have shown two factors governing the stability of emulsions. The first one is the presence of a liquid crystalline phase

of the layer type which will increase the stability of the emulsion. This is well shown by Series II in Fig. 3 where Sample 3 contains the liquid crystalline phase. The same trend has been shown for other systems (6, 12). The two-phase area between water and the liquid crystalline phase containing only mono-glyceride and water was treated by Larsson (13), who also gave suggestions for the structure of such a dispersion in water.

The second factor is the presence of micelles. From the present investigations and from earlier studies (12), it appears that the emulsion will have a reduced stability when the concentration of the emulsifier is in excess of the critical micelle concentration. This is especially pronounced in the case of octylamine, *p*-xylene, and water where the increased emulsifier concentration gives a reduction of emulsion stability (Table II). The reason for this is not completely clear at present but the following explanation may serve as a hypothesis.

When two emulsified drops approach each other, a temporary oversaturation will be established in the region between the surfaces of the drops owing to the adsorbed emulsifier. This temporarily increased concentration may give rise to the formation of

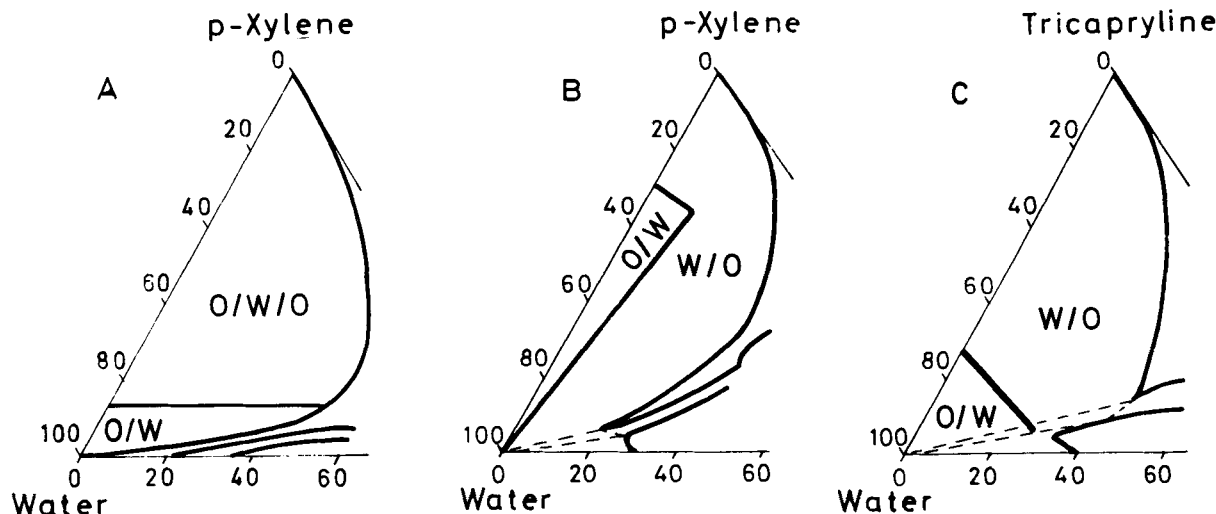

Figure 2—Emulsion type in different parts of the two-phase areas. Key: A, water-*p*-xylene-octylamine; B, water-*p*-xylene-nonylphenol diethylene glycol ether; and C, water-tricapryline-monocapryline.

Figure 3—The behavior of emulsions in series where the ratios of water to tricapryline are constant and the amount of monocapryline is increased. The composition of the samples is given in Table I.

micelles in the continuous phase, or micelle formation also can take place in the dispersed phase in some cases. It appears likely that the formation of micelles will mean a source of decreased order between the surfaces and, consequently, the resistance to coalescence will be reduced. If the increased concentration, on the other hand, gives rise to an ordered layer structure of the liquid crystalline type, the temporary overconcentration between the surfaces will not imply a disorder phenomenon. On the contrary, a several layer structure can be formed containing more ordered structures.

This hypothesis is not contradicted by any of the results—they all support it. The water-amine-*p*-xylene system, which can form micelles both in the aqueous and *p*-xylene phase, gives rise to a very unstable emulsion when the concentration of emulsifier is increased. At high amine to *p*-xylene ratios, where the solution changes from *p*-xylene to water continuous, the stability of the emulsion is very low. For the same ratio of *p*-xylene to amine but with the water content reduced to such a degree that the liquid crystalline phase is present, the stability is increased in the most pronounced way.

The marked increase of the water-solubilizing power of the oil phase at certain ratios (oil-emulsifier), which can be observed in Figs. 1A–C, is also an important factor. The solubilizing implies that the volume ratio, water to oil, can be most drastically changed when the concentration of emulsifier is increased. This means that the changed concentration of emulsifier—in some cases due to the evaporation of the solvents—can cause an inversion of the emulsion due to volume changes under certain conditions.

CONCLUSIONS

The investigations have shown how the properties of emulsions can be related to the phase equilibria in water-oil-emulsifier systems. They have confirmed the hypothesis about the pronounced influence of the liquid crystalline phases present on the properties of the emulsion but have also pointed to the influence of micelles in the systems. Both of these factors have been neglected in earlier studies of the behavior of emulsions except one preliminary study (14).

The results have also made evident the pronounced solubilization of water in the oil phase and shown how this fact can cause drastic changes in the volume ratios of the two liquid phases.

Rapid Determination of Aluminum in Pharmaceutical Dosage Forms by Neutron Activation

JOSEPH P. F. LAMBERT* and MICHEL MARGOSIS

Abstract □ A rapid, efficient, and highly accurate assay by neutron-activation analysis is presented for aluminum content as a function of the aluminum compounds contained in complex antibiotic formulations. The assay requires no chemical isolation or cleanup. The relatively short half-life of ^{28}Al allows rapid analysis, and the technique favors the detection of aluminum over possible interferences by longer lived radionuclides.

Keyphrases □ Aluminum in dosage forms—determination □ Oleaginous products—aluminum determination □ Neutron-activation analysis—aluminum

Aluminum monostearate (AMS) is incorporated as a thixotropic gelling agent in oleaginous pharmaceutical formulations. Many of these products are intended for use as intramammary infusions for the treatment of mastitis in dairy animals. These often comprise assorted mixtures of antibiotics (procaine penicillin G, neomycin sulfate, dihydrostreptomycin sulfate, polymyxin B sulfate, and sodium novobiocin), sulfonamides, corticosteroids, and various preservatives. Milk-out studies indicate that prolonged antibiotic residues in milk may be associated with certain formulations containing AMS, with greater prolongation being correlated with higher soap content.

The product known as sterile procaine penicillin G with aluminum stearate suspension is used in human medicine as a depot preparation to obtain prolonged duration of penicillin in the blood following a single intramuscular injection. Aluminum chlorohydroxide is a drug possessing astringent properties commonly used in antiperspirant formulations.

The analysis of aluminum salts in pharmaceutical dosage forms is usually performed titrimetrically with EDTA or gravimetrically as Al_2O_3 after combustion (USP, NF). These methods are often cumbersome, inefficient, tedious, occasionally erroneous, and generally lacking in specificity.

Well over 100 applications of neutron activation for the analysis of aluminum have been reported (1) but none in the field of pharmaceutical dosage forms. The technique reported here should be most valuable to drug chemists because of its specificity, accuracy, and practical application at the common dosage concentration. The reaction of thermal neutrons with aluminum, $^{27}\text{Al}(n,\gamma)^{28}\text{Al}$, is favorable, and the resulting radioactive nuclide has a half-life of 2.3 min. and a γ -ray energy of 1.78 Mev. A rapid recording of the γ -ray spectrum at the reactor site is dictated by the relatively short half-life of ^{28}Al . The short irradiation enhances the discrimination

against longer lived radionuclides and enables the rapid analysis for aluminum of a large volume of samples.

Interferences from fast neutrons reacting with silicon or phosphorus and from thermal neutrons reacting with magnesium (2) are minimized, since the analysis involves relatively large quantities of aluminum as compared with the amounts of the interfering elements, if at all present. Gamma-ray spectral interferences are also minimal, since the matrix is essentially organic, time of irradiation is short, and the γ -ray energy for aluminum is relatively high. Neutron-activation analysis is rendered even more efficient in this case, because there is no necessity to separate and isolate the aluminum in any fashion from these intractable formulations. This study covers mainly a variety of oleaginous commercial products containing antibiotics, but the method is readily applicable to any aluminum-containing drug.

EXPERIMENTAL

Irradiation Containers—The 0.40-dr. (1 ml.), capped polyethylene vials¹ were cleaned with 1:1 HNO_3 , rinsed with distilled water, and dried with acetone or methanol.

Standards—A stock solution of aluminum standard was prepared by dissolving 12.3534 g. of reagent grade $\text{Al}_2(\text{SO}_4)_3 \cdot 18\text{H}_2\text{O}$ in distilled water and diluting to 1 l. in a volumetric flask. A secondary standard was prepared by dissolving 0.0458 g. of aluminum wire (grade 1100) in dilute H_2SO_4 and diluting to 100 ml. in a volumetric flask. Aliquots of 1.00 ml. were transferred to the polyethylene vials.

Samples—About 1 g. of the oily product was accurately weighed into a polyethylene vial. Antiperspirants were prepared by diluting an accurately weighed sample of about 1 g. to 25 ml. with distilled water and transferring a 1.00-ml. aliquot to a polyethylene vial.

Apparatus—All samples were irradiated in either an exposure tube (thermal neutron flux of approximately $10^{13}\text{n/cm}^2\text{ sec.}$) or a pneumatic tube facility (thermal neutron flux of approximately $10^{12}\text{n/cm}^2\text{ sec.}$) at the 1-Mw. nuclear reactor of the Naval Research Laboratory, Washington, D. C. The γ -ray spectra were obtained with a 1024-channel pulse height analyzer,² using a $7.62 \times 7.62\text{-cm.}$ ($3 \times 3\text{-in.}$) NaI(Tl) detector.³ The readout equipment consisted of a teletype printer and an X-Y recorder.⁴ The samples were mounted approximately 10 cm. from the detector, which is housed in a large steel shield. This detector, which was covered with a 1-cm. thick plastic β -absorber, has a resolution of 8.0% at 662 kev. The pulse height analyzer was divided into four 256 channels, so four independent counts could be recorded. The gain control of the analyzer was set at 10 kev./channel over the 256 channels.

Procedure—Three samples and one standard were packaged into an irradiation bucket and lowered into the exposure tube for a 60-sec. irradiation, or one sample and one standard were packaged into

^a Based on technical grade containing 4.45% Al by neutron-activation analysis. ^b Based on USP grade containing 7.95% Al. ^c Actual or labeled amount on weight/volume basis. ^d Samples labeled A are duplicates. ^e Weight/weight basis. ^f Official drug.

a pneumatic tube shuttle and irradiated for 60 sec. in the pneumatic tube facility.

After a group irradiation, the standard was counted for 1 min. at a decay time of 10 min., whereas the three samples were counted individually for 1 min. at suitable decay times based on the indicated dead time of the pulse height analyzer.

The direct method of quantitation involves taking one count for each irradiated specimen at a given time, whereas the differential method requires a count of two different times for each specimen. The data were analyzed by the Covell method (3) for the photopeak area at 1.78 Mev., and the activity (net count summation) was adjusted to the time equivalent to the end of irradiation, using a calculated decay factor, according to equation

$$A_0 = A_1/e^{-\lambda t} \quad (\text{Eq. 1})$$

where A_0 is the activity of specimen at time equivalent to the end

Table II—Neutron-Activation Analysis of Aluminum in Products Containing Different Aluminum Salts

Salt	Al Found, %	Expected, %	% of Expected
Tristearate	0.0630	0.07078	89.0
Tristearate	0.0644	0.07078	91.0
Chlorohydroxide	4.50	4.79	93.9
Chlorohydroxide	4.95	5.03	98.4
Chlorohydroxide	4.86	5.03	96.6
Chlorohydroxide	5.00	5.03	99.4
Chlorohydroxide	5.00	5.03	99.4

of irradiation; A_1 is the activity of specimen at time count was made; λ is specific decay constant for nuclide; and t is equivalent time of count. When a sample and a standard are treated identically in every respect, the activity to aluminum content ratio is directly comparable.

The differential method subtracts the sample activity at two given times, t_1 , t_2 , and A_0 is determined as follows:

$$A_1 - A_2 = A_0(e^{-\lambda t_1} - e^{-\lambda t_2}) \quad (\text{Eq. 2})$$

$$\therefore A_0 = \Delta A / (e^{-\lambda t_1} - e^{-\lambda t_2}) \quad (\text{Eq. 3})$$

The relationship between activity and aluminum content of the sample is again compared to that of the standard.

The data obtained for all samples are based on total aluminum content, regardless of source, and physicochemical state of the specimen.

RESULTS

Table I lists results obtained for 39 different samples of oleaginous drug formulations from various manufacturers. Column 2 lists the actual amount of aluminum found; the values in Column 3 are calculated to the monostearate salt based on the technical grade (Table IV); and Column 4 lists the values calculated on the basis of the USP grade for comparison to the actual or labeled amounts as listed in Column 5. Table II likewise lists results for aluminum salts found in one otic and several antiperspirant formulations. The results obtained from various standard samples, using the pneumatic tube facility, are listed in Table III. Table IV shows results from several determinations of a sample of aluminum monostearate. Table V lists the results from four identical irradiations of the secondary standard, using the pneumatic tube facility.

Figure 1—Typical γ -ray spectra for an aluminum standard and a mastitis drug sample after a 1-min. irradiation in a flux of 10^{12} n/cm.² sec. Key: A, aluminum standard counted after 3-min. decay period; B, aluminum standard counted after 8-min. decay period; C, drug counted after 5-min. (upper) and 20-min. (lower) decay period; and D, drug counted after 10-min. decay period.

^a Ratio of Al determined by neutron activation to that calculated from sample weight. ^b SRM-87a Al-Si alloy is an NBS reference standard containing 91.0% Al. ^c Calculated on basis of USP value of 7.95% Al. ^d Sample assumed to be anhydrous, but was in fact the trihydrate; actually 99.2% recovery as Al₂O₃·3H₂O.

Figure 1 shows examples of typical γ -ray spectra for an aluminum standard and a drug.

DISCUSSION

Sterile procaine penicillin G with aluminum stearate suspension is an official USP drug containing 2% of aluminum monostearate. The soap, however, usually contains mixtures of stearates, palmittates, oleates, and free or loosely combined fatty acids, as well as hydrates and basic soaps (4). The aluminum content of AMS (USP) is equivalent to 14.5–16.0% of Al₂O₃ obtained by combustion, whereas the technical grade salt may yield around 10% Al₂O₃.

The results in Table I may then be used as a presumptive test, if necessary, to determine the grade of soap used in the formulation for control and regulatory purposes. In the first grouping, there was no ²⁶Al photopeak detected, and an upper limit value was computed from the counts. Considering an approximate 10% variation in density of the samples in comparing percent weight/weight against percent weight/volume, it is noted that most samples fall into one or the other grade. The standard deviation for samples listed in Table I approached 10%. When samples were handled individually, the standard deviation was lower than 3%; however, the rate of sample handling decreased about threefold.

The precision is also affected by the background, which may occasionally show other isotopes to be present in substantial amounts. For instance, peaks due to sodium, chlorine, and cobalt have been detected in many of these samples. The presence of chlorine (Fig. 1) and/or sodium contributes to the ²⁶Al γ -ray spectrum peak area. The Covell method or the differential technique of data analysis is used to correct for these spectral interferences. These corrections somewhat limit the overall precision of neutron-activation analysis for aluminum.

To verify the results in Table III, the AMS bulk and the aluminum oxide standard were subjected to combustion. The residue on ignition values of 9.4 and 67%, respectively, confirmed the results from neutron-activation analysis and verified the accuracy of the method. The sample of AMS was indeed of a technical grade; the aluminum oxide was indeed a trihydrate. The only outlying result in Table III is 111% recovery for the standard reference material.

Table IV—Determination of Aluminum in a Batch of AMS

Sample ^a	Weight, mg.	Al Found, mg.	Al, %
1A	23.90	1.07	4.48
1B	23.90	1.05	4.39
1C	23.90	1.077	4.51

3	20.25	0.885	4.37
4A	27.7	1.25	4.51
4B	27.7	1.24	4.48
4C	27.7	1.194	4.31
5	37.2	1.630	4.38

Av. = 4.45%

SD = 0.031 (0.7%)

^a Samples 1 and 4 were irradiated and counted three times each.

Table V—Precision in Relative Counts in Irradiations

Identification ^a	Relative Net Counts
Aliquot 1	9409 9295 9473
Aliquot 2	9597 9615
Av.	9478
SD	119 (1.26%)

^a The same sample was irradiated more than once over a period of 2 days. Both aliquots are from the same stock solution. A blank stock solution contained less than 0.002 mg. of Al.

However, this was not unexpected since the geometry of the sample was different from that of the primary standard, and the sample was small.

The secondary standard was handled individually; the results listed in Table V indicate that the relative counts from different irradiations are reproducible, showing a precision of better than 3%. Comparisons of values also indicate excellent accuracy.

Alternatives to the *National Formulary* Procedure for Detecting Nitrobenzene in Benzaldehyde

JOHN H. BLOCK*, MATHEWS A. NUNES†, and RICHARD O. MUHLHAUSER

Abstract □ A TLC technique has been developed which can be used to detect microgram quantities of nitrobenzene in benzaldehyde. This method, with its sensitivity and simplicity, provides a great advantage over the current detection procedure in the NF XII. A color complex reaction utilizing sodium pentacyanoamine ferroate and a spot test procedure on filter paper were also investigated, and each of these offers specific advantages over the current NF procedure. A mechanism for formation of the color complex is postulated.

Keyphrases □ Nitrobenzene detection—benzaldehyde □ TLC—analysis □ UV light—TLC spot visualization □ Colorimetric analysis □ Pentacyanoamine ferroate—color reagent □ Spot testing—nitrobenzene in benzaldehyde

Benzaldehyde has been in the official compendia since 1905 when it became a part of the *United States Pharmacopeia VIII*. In 1936 benzaldehyde was deleted from the USP and became official in the *National Formulary VI*. In 1916, a test for the detection of nitrobenzene became a part of the monograph, and this same test is still in the present revision. The test for nitrobenzene is included because it has an odor similar to benzaldehyde but is extremely toxic, having a lethal dose of 5–50 mg./kg. in man (1). Nitrobenzene is toxic by all routes and is capable of causing methemoglobinemia and destruction of red blood cells (2). The official test involves reduction of nitrobenzene to aniline and then oxidation with potassium dichromate to give a purple color if nitrobenzene is present in the sample (3). A problem which is often encountered is the formation of a precipitate that may make detection of the color difficult if not impossible. Furthermore, since the test is run by different technicians, results may be interpreted differently.

Aromatic nitro compounds have been detected by spot tests (4) and by formation of a colored complex (5). Interpretation of these results, however, is quite difficult for small amounts of nitrobenzene, and the procedures involve many steps. A spectrophotometric procedure was developed in 1949 by Glazko *et al.* (6); although quantitative results are obtained, the procedure is quite involved and lengthy.

To overcome problems associated with interpretation of results and complicated procedures, this paper reports and evaluates three different procedures for the detection of nitrobenzene in benzaldehyde.

EXPERIMENTAL

Reagents—The following chemicals and reagents were used without further purification: benzaldehyde NF and nitrobenzene (Matheson, Coleman & Bell), sodium fluorescein (Eastman Organic Chemicals), sodium pentacyanoamine ferroate (K & K Laboratories), and silica gel G and silica gel HF (Brinkmann Instruments, Inc.). Visualization was made by means of a General Electric purple-X 250 w. UV light.

Table I—Reagents and Results Obtained by Color Complexation Procedure

Benzaldehyde	Neg.	Butylamine	Neg.
Nitrobenzene	Pos.	Dimethylamine	Neg.
Aniline ^a	Pos.	Ethylbenzene	Neg.
N-Methylaniline	Neg.	Xylene	Neg.

N-Benzylisopropylamine	Neg.	Phenol	Neg.
N,N-Dibenzylaniline	Neg.	Anisole	Neg.
p-Aminobenzoic acid	Pos.	o-Anisidine	Pos.

^a A positive result was obtained also without the reduction step.

NF Procedure—Solutions analyzed by the NF XII procedure were nitrobenzene, benzaldehyde, and nitrobenzene in benzaldehyde 5:100 and 1:100. (All dilutions are by volume.)

Spot Tests (4)—Samples analyzed were nitrobenzene, benzaldehyde, and nitrobenzene in benzaldehyde 1:100 and 1:1000. Two drops of each solution was placed on a piece of filter paper, and 1–2 drops of 10% stannous chloride in ethanol saturated with hydrogen chloride gas was added. After absorption, 1 drop of 35% cuprous chloride in concentrated hydrochloric acid was added and allowed to be absorbed. Six drops of pyridine was added and a green color developed. Two drops of carbon tetrachloride was then added and the characteristic colors formed in 10–30 sec.

Color Complex (5)—Samples analyzed were nitrobenzene, benzaldehyde, and nitrobenzene in benzaldehyde 1:100, 1:1000, and 1:10,000. One-tenth milliliter of the solution to be analyzed was dissolved in 3 ml. of ethanol, previously heated on a hot water bath, in a 10-cm. (4-in.) test tube. Six drops of 10% calcium chloride solution and about 50 mg. of zinc dust were added, and the solution was heated to boiling in a hot water bath. The excess zinc was removed by filtration, and the cooled filtrate was treated with 1 drop of a 1% solution of sodium pentacyanoamine ferroate. A colored flocculent precipitate formed in about 1 min., the time required depending upon the amount of nitrobenzene present. Best results were obtained when the solution was not stirred. Dilute samples required 2–3 hr. if the solution was stirred after the addition of the sodium pentacyanoamine ferroate solution.

Additional samples were also tested to learn something about the nature of the complex formed. The samples used and results appear in Table I.

Thin-Layer Chromatography—TLC was carried out on 5 × 20-cm. chromatoplates prepared according to Stahl, utilizing silica gel G, with 0.04% sodium fluorescein, and silica gel HF. Eight solvent systems were investigated (7–9) (Table II); however, only the visualization technique of Berei and Vasaros (7) was employed.

The other adsorbent was investigated with the 2.5% acetone in benzene solvent system.

Samples analyzed were nitrobenzene, benzaldehyde, and nitrobenzene in benzaldehyde 1:100, 1:1000, and 1:10,000. In all of the initial chromatograms, normal spotting procedures using a capillary tube were employed. The sensitivity of this procedure was also evaluated; for this test, 10 μl. of the solution was spotted *via* a calibrated micropipet.

RESULTS AND DISCUSSION

NF Procedure—The 1:100 solution gave a negative result for nitrobenzene using this procedure. The 5:100 solution did give positive results; however, another analyst may well have judged the results to be negative when compared with a control sample.

Spot Tests—The pure sample of benzaldehyde gave a predominantly blue spot, and the nitrobenzene produced a definite red-orange color. However, problems were encountered in trying to

distinguish the characteristic orange color produced by the nitrobenzene from the yellowish discoloration of the filter paper due to the other chemicals. The 1:100 dilution was definitely positive; but with the 1:1000 dilution, it was not possible to determine whether the test was positive when compared with a control sample.

Color Complex—In this test, pure benzaldehyde produced a yellow precipitate whereas pure nitrobenzene produced a deep-purple precipitate. As the amount of nitrobenzene in the sample was reduced, the intensity of the color faded through blue to a blue-gray color for the 1:1000 dilution. No bluish hue was distinguishable for the 1:10,000 dilution.

The basis of these tests is the reduction of nitrobenzene and subsequent reaction with an appropriate reagent to produce a characteristic color. In the NF XII procedure the reduction is carried out with zinc and sulfuric acid, followed by the addition of potassium dichromate to yield a blue-green colored product if nitrobenzene was originally present. In the spot test procedure, stannous chloride and HCl reduce the nitro group to the primary aromatic amine. The color formed is most likely due to the formation of a complex between the amine and the cuprous ion (4).

In the colored-complex procedure, reduction is accomplished with zinc dust and the calcium chloride solution. The color formed is probably due to the formation of a complex between the reduced nitro group and the $\text{Fe}(\text{CN})_6^{3-}$ moiety of the sodium pentacyanoamine ferroate, $\text{Na}_3[\text{Fe}(\text{CN})_5\text{NH}_2]$. Two possibilities exist: (a) that there is a replacement of the NH_3 ligand by the $-\text{NH}_2$ portion of the aromatic amine or (b) that a charge transfer complex exists between iron and π electrons of the phenyl ring (10). On the basis of data in Table I, it seems reasonable to postulate that the complexation consists of a replacement of NH_3 ligand by the primary aromatic amine. If a charge transfer complex formed, all the aromatic compounds with strongly electron-donating groups would have been expected to form the complex. The data also indicate that a primary aromatic amine is necessary for complexation. The differences in inductive effects of aniline and *N*-methylaniline are so small that a charge transfer complex should have been formed with both. The methyl group of *N*-methylaniline, in addition to providing steric hindrance for ligand replacement, prevents overlap of the unshared *p*-orbital electrons of the nitrogen with the π electrons of the phenyl ring. It is this delocalization of electrons that is probably of primary importance in color change, as pointed out by the fact that the aliphatic amines tested did not delocalize and gave negative results. It would seem that phenol, which also has an unshared pair of electrons, should also form the complex. However, Basolo and Johnson have pointed out that the greater the base strength of a ligand, the greater the stability of the complex formed (11). Thus, aniline, which has a greater basicity than phenol, will form a more stable complex.

Thin-Layer Chromatography—Of the eight solvent systems examined, none gave better separation than that of 2.5% acetone in benzene. The solvent systems of benzene-methanol-acetic acid and of diethyl ether provided very poor separation, and the other systems used gave results similar to the 2.5% acetone in benzene system. This acetone-benzene system had the added advantage of being one of the faster systems, requiring only about 40 min. for the solvent front to travel 15 cm.

Using the silica gel G with 0.04% sodium fluorescein, the 1:100 dilution showed a red-violet band (R_f 0.93) which appeared purple under UV light. This band was not visible without irradiation at 1:1000 but was clearly seen with the aid of UV light. At a dilution of 1:10,000, this band was barely visible even with UV light, and the limit of the test was taken to be the 1:1000 dilution. Pure samples were also spotted for comparison, and the appearance of the chromatograms is shown in Fig. 1. Since aldehydes are easily

Figure 1—Thin-layer chromatograms. Solvent system: 2.5% acetone in benzene. Plates: A, B, and C, silica gel G with 0.04% sodium fluorescein; D, silica gel HF. Key: A, benzaldehyde; B, nitrobenzene; and C and D, nitrobenzene in benzaldehyde, 1:1000.

oxidized and possibly reduced, benzyl alcohol and benzoic acid were also chromatographed and found not to interfere.

The silica gel HF showed the same sensitivity as the silica gel G but had the advantage of not showing the spots at the lower end of the plate which are attributed to the benzaldehyde. Using silica gel G and spraying with 0.04% sodium fluorescein failed to differentiate between the nitrobenzene and the benzaldehyde.¹

Unlike the previous procedures, TLC does not require the reduction of nitrobenzene. Thus, it is possible to detect smaller amounts of nitrobenzene, since the other procedures are sensitive to only that portion of the nitrobenzene that has been reduced.

SUMMARY

A TLC technique has been developed which can be used to detect small amounts of nitrobenzene. The estimated limit of this test is 10^{-5} ml. or 12 micrograms of nitrobenzene. This test is 100 times as sensitive as the color complex procedure. In addition, there are fewer mechanical steps involved and, therefore, less chance of error when compared with the NF procedure.

The spot test procedure has approximately the same sensitivity as the NF procedure, but it takes much less time. It requires only about 5 min. as compared to about 1.5 hr. for the monograph procedure.

The color complex reaction is much more sensitive than either the NF or the spot test procedure. Nitrobenzene was detectable in 0.1 ml. of the 1:100 dilution which corresponded to 1.2 mg. of nitrobenzene. This procedure is also quite simple and requires less than 0.5 hr. total.

On the basis of this investigation, it can be stated that the color complex and the TLC procedures are superior to the present NF procedure, both from the standpoint of sensitivity and time required for routine use. The thin-layer procedure is the simpler and more sensitive of the two and could presumably be adapted to obtain quantitative results.

Spectrophotometric Determination of Chlorpromazine in Pharmaceutical Dosage Forms

B. S. R. MURTY and R. M. BAXTER

Abstract □ A rapid and convenient spectrophotometric method for the determination of chlorpromazine hydrochloride and its unit dosage forms is described. Extensive separation and extraction of the active ingredient are not required. The micro-sensitive color response (λ_{\max} , 520 $m\mu$) with Van Urk's reagent is the basis of the analytical technique. The results are reproducible.

Keyphrases □ Chlorpromazine dosage forms—analysis □ Colorimetric analysis—spectrophotometry □ Van Urk's reagent—color formation

Chlorpromazine hydrochloride (CPZH), a phenothiazine derivative, is a widely used psychopharmacological agent. Chlorpromazine hydrochloride and some of its unit dosage forms are official in BP 1968 (1), USP XVII (2), and Ph.I. (3). A number of gravimetric, titrimetric, opticometric, electrometric, and chromatographic methods for the quantitative determination of phenothiazines have been reported in the literature, each one claiming individual advantages. These have been reviewed by Blazek (4), Blazek *et al.* (5), and Gyenes (6). Blake and Agarwal (7) recently reported a photometric titration of phenothiazines with ceric sulfate. The current pharmacopeias recognized non-aqueous titrimetry for determining the drug, while the unit dosage forms containing the drug—*viz.*, tablets, injections, *etc.*, are determined by methods based on the UV absorption properties of the phenothiazine base. However, these methods involve a series of extractions of the active ingredient from the unit dosage forms.

The authors have observed that a color (λ_{\max} , 520 $m\mu$) results when CPZH is treated with Van Urk's reagent. The color-producing reaction with phenothiazines has not been previously reported in the literature. This investigation is primarily directed toward the evaluation of the observed novel reaction

Figure 1—Effect of time on the stability of color with Van Urk's reagent and CPZH.

as a quantitative measure of chlorpromazine in its various dosage forms.

EXPERIMENTAL

Instrumentation—Beckman DU spectrophotometer (1-cm. cell) was used.

Materials—Van Urk's reagent, BP 1968 (8), was used. Chlorpromazine hydrochloride and the various dosage forms were obtained from commercial sources. All reagents were analytical grade. Glass-distilled water was used throughout this work.

Standard Reference Solution—Chlorpromazine hydrochloride (50 mg.), previously dried, in distilled water (250 ml.) was used.

Sample Preparation—Tablets—Twenty tablets were weighed and reduced to a fine powder. An accurately weighed portion of the powder, equivalent to 50 mg. of the drug, was transferred to a 250-ml. volumetric flask. The flask was shaken thoroughly for 10–15 min. after adding 100 ml. of water and was made to volume. The contents of the flask were filtered.

Injections—An equivalent volume, representing 50 mg. of the drug, was measured and diluted with water to 250 ml.

Suppositories—Suppositories representing 100 mg. of the drug were placed in a 500-ml. volumetric flask and melted by heating on a

as a quantitative measure of chlorpromazine in its various dosage forms.

EXPERIMENTAL

Instrumentation—Beckman DU spectrophotometer (1-cm. cell) was used.

Materials—Van Urk's reagent, BP 1968 (8), was used. Chlorpromazine hydrochloride and the various dosage forms were obtained from commercial sources. All reagents were analytical grade. Glass-distilled water was used throughout this work.

Standard Reference Solution—Chlorpromazine hydrochloride (50 mg.), previously dried, in distilled water (250 ml.) was used.

Sample Preparation—Tablets—Twenty tablets were weighed and reduced to a fine powder. An accurately weighed portion of the powder, equivalent to 50 mg. of the drug, was transferred to a 250-ml. volumetric flask. The flask was shaken thoroughly for 10–15 min. after adding 100 ml. of water and was made to volume. The contents of the flask were filtered.

Injections—An equivalent volume, representing 50 mg. of the drug, was measured and diluted with water to 250 ml.

Suppositories—Suppositories representing 100 mg. of the drug were placed in a 500-ml. volumetric flask and melted by heating on a

Figure 2—Effect of water-soluble inert diluents on the absorption maxima. Key: . . . , CPZH and lactose and sucrose; ○, CPZH and acacia or tragacanth; and Δ, CPZH.

steam bath. Hot water (100 ml.) was added; the solution was shaken and finally made to volume with water. Following filtration, the filtrate was used for the assay.

Syrup—A volume of syrup representing 50 mg. of the drug was diluted with water to 250 ml.

Method—A 0.1–0.5-ml. aliquot of the sample solution, prepared as previously described, was treated with 4 ml. of Van Urk's reagent, shaken, and made to a known volume with water. The intensities of the colors developed by the sample solution and by the chlorpromazine standard, treated simultaneously with the reagent, were measured at 520 mμ against the reagent blank.

RESULTS AND DISCUSSION

The color produced in the reaction is stable for at least 60 min. (Fig. 1); the presence of 0.5 mg. of the commonly used inert diluents—acacia, tragacanth, lactose, and sucrose—did not interfere (Fig. 2). The most suitable slope of the calibration curve and the maximum color intensity were obtained with the use of 4 ml. of the reagent with 0.1–1.0 ml. of the standard solution in a total volume of

Figure 3—Effect of volume of Van Urk's reagent on absorbance. Key: volume of reagent: A = 1 ml.; B = 2 ml.; C = 3 ml.; and D = 4 ml.

10 ml. (Fig. 3). For a constant volume of Van Urk's reagent, an increase in the concentration of CPZH up to 20 mcg./ml. produced an increase in color intensity. Color generation under standard conditions obeyed Beer's law between 5–20 mcg./ml. (0.165–0.7 absorbance, respectively, at 520 mμ) (Fig. 3). The mean absorbance of 10 replicates from one solution to another was noted. The standard deviation was found to be ± 0.005 .

The data in Table I indicate that quantitative recoveries were obtained for the unit dosage forms and that the results were in good agreement with the official methods. The reported procedure has the advantage that it does not require the preliminary extraction of the active ingredient. The effect of decomposition products on the recovery of the parent compound has not been evaluated. The procedure allows for a simple, rapid, and accurate determination of small quantities of chlorpromazine.

Design and Evaluation of a Pressure Attachment for a Rotational Rheometer

KAKUBHAI R. M. VORA*, LARRY L. AUGSBURGER, and RALPH F. SHANGRAW

Abstract ☐ The problems associated with the measurement of the rheological properties of pressurized aerosol concentrates consisting of emulsions and/or micellar solutions are discussed. A pressure attachment for a commercially available rheometer is described, and data are presented for simple soap formulations. Pressurized concentrates exhibited pseudoplastic properties which could not always be correlated with the flow properties of resultant foams.

Keyphrases ☐ Rheometer, rotational—☐ aerosol rheological properties ☐ Pressure attachment, rheometer—☐ design, evaluation ☐ Diagram—☐ pressure attachment, rheometer ☐ Viscosity-increasing additives—☐ aerosol foam effect

A major problem, which has plagued the formulators of "aerosol" foams and other products utilizing high-consistency concentrates, has been the lack of a suitable and convenient means to evaluate their rheological properties. Most pharmaceutical and cosmetic foams utilize a pressurized concentrate in which the insoluble propellant is emulsified or micellized into the internal phase of an oil-in-water system by means of a suitable surfactant. Evaluation of the flow properties of the concentrate prior to the addition of propellant is of limited usefulness, because it does not reflect the influence of the internal phase. The fact that the concentrate systems are almost always non-Newtonian complicates the situation even further. The rheology of these pressurized concentrates plays an important role in the flow of material in the dip tube and valve assembly and influences drainage from the inside of the can during product use.

Although the importance of determining rheological characteristics of the non-Newtonian concentrates under pressure has been well recognized, very few reports are available in the literature. A preliminary report on the pressure-viscosity-time factors in dispensing of liquid aerosols was published by Mina in 1959 (1). The author measured the delivery rate of dimethyl silicone oils using a Precision Valve ($3 \times 0.040/0.080$) (Precision Valve Corp., Yonkers, N. Y.) at different pressures. By the use of suitable blending of different hydrocarbons and halocarbon propellants, the author was able to achieve a range of pressure from 10 to 100 psig. inside the sealed container. Viscosity determinations were made with an Ultra-Viscoson viscometer (Bendix Research Corp., Towson, Md.), utilizing a special twin-top adapter on the container to accommodate the ultrasonic probe as well as a normal valve. The author concluded that viscosity is significantly lowered under pressure as the pressure is increased, and

Figure 1—A schematic diagram of the pressure assembly for the Rotovisco viscometer.

this phenomenon is reversible upon removal of the added pressure.

Cohen *et al.* have described the use of the Brookefield viscometer (Brookefield Engineering Laboratory, Stoughton, Mass.) for measuring viscosity at low rates of shear, supplemented by use of the Severs extrusion rheometer model A-100 (Castor Laboratory Equipment Co., Pittsburgh, Pa.) for high shear measure-

Figure 2—Assembled pressure attachment.

ments (2, 3). A series of aerosol valves were calibrated in the Severs extrusion rheometer for pressures varying from 10 to 100 psig., and the rheological characterization method was demonstrated by the use of polymer "solutions" as well as a group of four commercial pressure-packaged toothpastes.

A qualitative method of evaluating pressurized emulsion systems was reported by Strickland (4). He compared different emulsions under pressure by measuring the time required for a 5-mm. diameter glass bead to fall through the emulsion when the transparent bottle was inverted. Sanders reported a method for evaluating the approximate viscosity of pressurized emulsions by inverting bottles slowly and noting the flow characteristics (5).

Augsburger made use of the Rotovisco viscometer with a modified pressure chamber assembly to accommodate the emulsion concentrate under pressure (6). Although Augsburger concluded that further modifications were necessary in the design of the pressure assembly, he was able to carry out rheological measurements of soap concentrates under pressure. He found that at a 5% (w/w) concentration of soap, propellant was solubilized in the soap solution, giving lower

viscosity values; at higher concentrations of soap the propellant was emulsified, giving higher viscosity values (6).

DESIGN AND CONSTRUCTION OF PRESSURIZED RHEOMETER

Rotational viscometers offer a means of transferring the standard model of Newtonian flow in a plane to a closed continuous system in which the liquid is trapped between the surfaces of a cup and a bob. By rotating either surface at a fixed rate and measuring the viscous drag transferred through the liquid (or on the rotating member itself), the two necessary parameters of viscosity—rate of shear, which is proportional to r.p.m., and shear stress, which is proportional to viscous drag—can be measured. Rotational viscometers are particularly useful in measuring non-Newtonian systems, because rates of shear can be varied and relationships between rate of shear and shear stress within a particular system can be established. These are most often described as flow curves.

The Haake Rotovisco rotational viscometer (Polyscience Corp., Evanston, Ill.), was employed in this study to determine the viscosity of the liquid concentrates as well as the rheological properties of the foams produced by the pressurized emulsion systems. The measuring head of the Rotovisco viscometer contains two readily interchangeable torsion springs, one of 50-g. cm. capacity for low-viscosity fluids and the other of 500-g. cm. capacity for medium-viscosity fluids. The use of the 50 head allows for expansion of lower stress readings over the entire dial range, giving greater accuracy to low-viscosity readings.

The pressure assembly previously utilized by Augsburger in his preliminary work on pressure rheometry was used in the current study, with some modifications. This assembly involves the use of a "driving" magnet, which is attached to the spindle of the viscometer in the same fashion that a bob is normally attached. On rotation of the spindle, this magnet drives a second magnet situated across a seal within a pressure chamber. A bob attached to the driven magnet inside the sealed chamber is held concentrically in the cup by means of a pair of ball bearings.

A schematic diagram of the pressure assembly is presented in Fig. 1. A magnet (A), attached to the spindle of the Rotovisco measuring head (B), drives a magnet (C) across the pressure seal plate (D). A spacer (E) assures that the driving magnet will not contact the pressure plate. Previous experience had shown that, under pressure, the pressure plate tends to become convex in the direction of the driving magnet, and that the clearance originally allowed for this magnet was insufficient. The driven magnet, tapped onto a standard Rotovisco spindle (F), rides on two Fafnir No. F4DD bearings (The Fafnir Bearing Co., New Britain, Conn.). The pressure chamber housing (G) is threaded to accommodate the sample cup (H). The dimensions of the cup and its relationship to the spindle are identical to that of the standard Rotovisco assembly. Consequently, all instrument constants remain the same for this attachment. An O-ring (I), at the base of the threads of the cup, seats itself against a ledge cut into the inner surface of the housing. By virtue of this O-ring, only minimal hand-tightening of the cup is required to make a pressure-tight seal. Hoke No. 450 toggle valves (Hoke, Inc., Cresskill, N. J.) are tapped into both the cup and the housing. The valve (K) in the cup was used to fill the chamber with the pressurized emulsions using a transfer actuator. The sample was removed from the same valve, because this minimizes internal foaming into the bearings when the pressure is released. The sleeve (L) is designed to fit over the lower portion of the Rotovisco measuring head where it is fastened with two thumb screws. While the housing was machined from brass, the cup was machined from plastic. A photograph of the pressure assembly is shown in Fig. 2.

Before proceeding further, it might be appropriate to summarize the difficulties encountered in the construction and operation of the pressure rheometer as follows:

(1) *Sealing of pressure chamber:* difficulty was solved by means of a Teflon spacer seal next to the brass plate and an O-ring at the base of the threads of the cup.

(2) *Concentricity of bob in the cup:* two bearings instead of one bearing were used to support the drive spindle more rigidly.

(3) *Introduction of samples into the cup:* as pressurized soap concentrates were transferred, they would foam into the cup. The foam

Figure 3—Relationship of shearing stress with and without pressure assembly, obtained with various standard viscosity liquids. Key: shear rate, sec^{-1} : \circ , 9.2; \bullet , 18.4; \square , 27.6; and \blacksquare , 55.2.

would occupy the gap between the cup and the bob, giving abnormally high readings. This difficulty was solved as follows: (a) prepressurizing the cup before loading the sample; and (b) machining the cup out of clear plastic so that the sample could be observed and determinations disregarded if foaming occurred.

(4) *Slippage on the surface of the bob*: the use of the MVII-P profiled bob (with serrated surface) minimized the slippage encountered with high-viscosity systems.

A major problem was associated with the small but ever present additional frictional drag on the measuring head produced by the

magnetic clutch and bearings. Standard viscosity liquids were measured and shear stress values at various rates of shear were determined, both with and without the pressure assembly. A relationship was found to exist between the stress values with and without the pressure assembly. As can be seen from Fig. 3, this relationship proved to be linear. The slope of the straight line is 0.95, which means that actual stress values were 95% of those observed with the pressure assembly.

EXPERIMENTAL

Pressurized Packaging—Soap concentrates were weighed into “6-ounce” standard coated cans¹ which had been previously purged with a few drops of propellant, and Precision 0.020/0.080 valves (Precision Valve Corp., Yonkers, N. Y.) were crimped into place. Dip tubes were omitted to facilitate the filling of test vessels. The propellant was filled into the test containers by weight. The finished products were shaken vigorously and placed in a 50° water bath for 20 min. to test for leakage and can distortion. After removal from the water bath, the cans were allowed to remain at room temperature for 3 days prior to testing; all tests were completed within 2 weeks of preparation to minimize any possible aging effects.

Foam Rheology—Foam rheology was carried out after the manner of Richman (7) using the Haake Rotovisco viscometer and the MVII-P profiled bob and cup system. After shaking the pressurized containers for 15 sec., the foam was introduced directly into the cup through a 12.7-cm. (5-in.) extension of 0.64-cm. (0.25-in.) polyethylene tubing attached to Precision foam actuator SP-115. The cup was filled slowly from the bottom up, and shearing was begun 1 min. after the cup was filled. Since dip tubes were not employed, pressurized containers were inverted during actuation. All measurements were made at $28 \pm 0.5^\circ$.

Basic Soap Formulation—Richman reported rheological measurements of soap solutions at atmospheric pressure and observed the dilatant nature of the flow curves at high-shear rates in the region of about 500 sec^{-1} (7). An experiment was designed to measure the

^a Normal scale value is one-fourth of fine scale reading. ^b Pressure factor = 0.95, from Fig. 3 (a factor to convert scale values with pressure assembly into equivalent values without pressure assembly). ^c Values for the foam extruded from the same basic formulation presented in this table for comparison and reference in the following sections.

shear stress values under pressure of the following basic soap formulation:

Soap concentrate	10%
Stearic acid	5 parts
Coconut oil fatty acids	3 parts
Triethanolamine	5 parts
.....90%	
Additive	(-%)
Distilled water <i>q.s. ad.</i>	100%
Propellant blend 12/114 (57:43)	10%

No additives were employed in the control formulation. Samples were prepared in duplicate, and the rheological measurements were carried out at $28 \pm 0.5^\circ$. Shear stress values obtained at varying rates of shear are presented in Table I. The flow curve appears in Fig. 4 as the control soap formulation.

Effect of Additives—Once the basic rheology of a simple pressurized concentrate was determined, the effects of viscosity-increasing additives were studied. Methylcellulose (4000 cps.) was selected for its known property of increasing the viscosity of aqueous soap solutions; three different concentrations (1.0, 1.5, and 2.0% w/w) were employed. The flow curves obtained from these systems are

Figure 6—Pressurized emulsion flow curves—the effect of additives on formulations containing 10% (w/w) soap. Key: Δ , 0.125% hydroxyethylcellulose; \circ , 0.125% commercial hydrocolloid; and \square , 40% glycerin.

presented in Fig. 4. To compare the effect of this additive on the rheology of foams produced from these same formulations, rheological measurements were carried out on the corresponding foams and the results are shown in Fig. 5. It becomes obvious upon examination of these data that the sequence of flow curves remains the same in both the concentrate and foam. In a subsequent experiment, soap solutions were prepared containing different additives known to increase the consistency of aerosol foams. While glycerin was selected for its Newtonian property, hydroxyethylcellulose and a commercial hydrocolloid² were selected for their non-Newtonian and pseudoplastic properties in aqueous solutions. Flow curves of the emulsion concentrates with various additives are presented in Fig. 6, and flow curves of the corresponding resultant foams are shown in Fig. 7. The sequence of flow curves is not the same in both figures. The pressurized emulsion containing the hydrocolloid gave higher shear stress values than the one containing hydroxyethylcellulose, whereas this order was reversed in the case of pressurized foams. Thus, it can be noted that the agents that affect bulk viscosity

² Polyhall-295R₁, a water-soluble nonionic polyacrylamide hydrocolloid of high molecular weight, Stein, Hall and Co., Inc., New York, N. Y.

of a concentrate may not affect the viscosity of the resulting foam in exactly the same manner. Surface viscosity and surface area are dominant factors in the viscosity of the pressurized foam.

The pressure rheometer can be a useful tool for studying aerosol concentrates containing propellants. Since foam-producing systems are generally emulsions or micellized solutions, determining the rheological properties of concentrates before pressurization is of limited value. Commercial pressure rheometers have become available since this research was begun. However, the magnetic clutch unit (introduced by the Polyscience Corp., Evanston, Ill.) for use with the Rotovisco viscometer requires a sample size of approximately 1 L, which makes it unattractive for product-development work. The Viscoclav MA attachment to the Contraves rheometer (Olkon Corp., Stanford, Conn.), which also utilizes a magnetically driven bob, employs a much smaller (10 ml.) sample.

It is important that cosmetic and pharmaceutical aerosol chemists investigate their pressurized systems using techniques such as those described in this paper if meaningful rheological data are to be generated.

SUMMARY AND CONCLUSIONS

The design of a device for modifying a commercially available rotational viscometer to measure the rheological properties of fluids under pressure is described.

Data presented for simple aerosol concentrate soap formulations revealed pseudoplastic properties which could not always be correlated with the flow properties of the resultant foams. This lack of

correlation may be attributable to the role that surface viscosity (rather than bulk viscosity) plays in determining foam consistency.

Titanium Dioxide Lakes I: Prepared from Certified Water-Soluble Dyes and Employed in Color-Coating Tablets

SAUL S. KORNBLUM and BENITO LOPEZ*

Abstract □ Titanium dioxide, ranging in particle size from 0.005 to 0.040 μ , has been investigated as an adsorbate in the manufacture of lake dyes from certified water-soluble dyes. The manufacturing technique for the titanium dioxide lakes and the pharmaceutical application in color-coating tablets have been demonstrated and discussed in conjunction with automatic spray coating.

Keyphrases □ Titanium dioxide lakes—preparation □ Lakes, water-soluble dyes—titanium dioxide adsorbate □ Spray drying—titanium dioxide lake preparation □ Color coating, tablets—titanium dioxide lakes

Color lakes, prepared in liquid suspension, have been extensively employed pharmaceutically for coloring sugar-coated tablets. There are advantages for using the color lakes rather than the water-soluble dyes, which are well known to the coating expert. These advantages consist of: significant time reduction for the color-coating operation, greater color stability, and greater color uniformity for consecutive batches (1). The majority of color lakes are manufactured by employing alumina as the adsorbate material interacted with various dyes. Commercial lakes are available

as micronized powders that render better color dispersion in liquid suspensions than if not so treated.

Color-concentrate suspensions prepared from color lakes are commercially available and are extensively used by the pharmaceutical industry for coloring sugar-coated tablets.

The purpose of this study was to determine the acceptability of titanium dioxide as an adsorbate material for color lake manufacture from water-soluble dyes. The titanium dioxide selected is referred to as "fumed" and possesses a submicron particle size. The ultimate goal of this project was to prepare extemporaneously color lakes for tablet coating.

EXPERIMENTAL

Materials—Fumed titanium dioxide¹ was selected for study as an adsorbate in the manufacture of color lakes because it possesses a suitable particle-size range from 0.005 to 0.040 μ . Titanium dioxide USP differs significantly from the fumed material with

Titanium Dioxide Lakes I: Prepared from Certified Water-Soluble Dyes and Employed in Color-Coating Tablets

SAUL S. KORNBLUM and BENITO LOPEZ*

Abstract □ Titanium dioxide, ranging in particle size from 0.005 to 0.040 μ , has been investigated as an adsorbate in the manufacture of lake dyes from certified water-soluble dyes. The manufacturing technique for the titanium dioxide lakes and the pharmaceutical application in color-coating tablets have been demonstrated and discussed in conjunction with automatic spray coating.

Keyphrases □ Titanium dioxide lakes—preparation □ Lakes, water-soluble dyes—titanium dioxide adsorbate □ Spray drying—titanium dioxide lake preparation □ Color coating, tablets—titanium dioxide lakes

Color lakes, prepared in liquid suspension, have been extensively employed pharmaceutically for coloring sugar-coated tablets. There are advantages for using the color lakes rather than the water-soluble dyes, which are well known to the coating expert. These advantages consist of: significant time reduction for the color-coating operation, greater color stability, and greater color uniformity for consecutive batches (1). The majority of color lakes are manufactured by employing alumina as the adsorbate material interacted with various dyes. Commercial lakes are available

as micronized powders that render better color dispersion in liquid suspensions than if not so treated.

Color-concentrate suspensions prepared from color lakes are commercially available and are extensively used by the pharmaceutical industry for coloring sugar-coated tablets.

The purpose of this study was to determine the acceptability of titanium dioxide as an adsorbate material for color lake manufacture from water-soluble dyes. The titanium dioxide selected is referred to as "fumed" and possesses a submicron particle size. The ultimate goal of this project was to prepare extemporaneously color lakes for tablet coating.

EXPERIMENTAL

Materials—Fumed titanium dioxide¹ was selected for study as an adsorbate in the manufacture of color lakes because it possesses a suitable particle-size range from 0.005 to 0.040 μ . Titanium dioxide USP differs significantly from the fumed material with

¹ Titanium Dioxide P-25, DeGussa, Inc., Kearny, N. J.; Cab-O-Ti, Cabot Corp., Boston, Mass.

regard to the particle-size range and the quantity of soluble titanium salts. Commercial titanium dioxide USP, which is used as an opaquing agent with soluble and insoluble dyes in tablet coating, is unsuitable for this purpose (2). The imbalance of electrostatic charges on the surface and particle-size dimensions of the titanium dioxide USP causes agglomerates to form which prevent significant physical or chemical surface interaction with the dyes. The water-soluble dyes employed in this project were: F.D. & C. Red No. 3, F.D. & C. Blue No. 1, F.D. & C. Yellow No. 5, F.D. & C. Violet No. 1, and F.D. & C. Green No. 3. In addition, surface-active agents, *i.e.*, polyoxypropylenepolyoxyethylene condensates;² binding agents, *i.e.*, partially hydrolyzed polyvinylacetate;³ and acidifying agents, *i.e.*, hydrochloric, acetic, tannic, and citric acids, were also employed in the manufacture of the color lakes.

Color Lakes Composition and Method of Manufacture—The following color lakes were prepared with modification of the composition as an indication of the versatility of this method for preparing color lakes. Numerous lakes have been prepared; however, only one example of each modification is described in the text. The component quantities indicated are representative of 1 kg. of finished color lake.

Type 1	Percent by Weight
Fumed titanium dioxide P-25	96
F.D. & C. Violet No. 1	4

The F.D. & C. Violet No. 1 was dissolved in 500 ml. of distilled water. The fumed titanium dioxide was dispersed in 2000 ml. of water and maintained in a state of agitation employing a Kady colloid mill⁴ with a rotor of 12,000 r.p.m. The dye solution was added to the titanium slurry and milled for 30 min. The resultant color slurry was filter pressed and washed with distilled water to remove soluble titanium salts. The slurry was then vacuum dried and stored in suitable glass containers.

Type 2	Percent by Weight
Fumed titanium dioxide P-25	75
F.D. & C. Red No. 3	20
Surface-active agent (Pluronic F-68)	5

The F.D. & C. Red No. 3 was dissolved in 2 l. of distilled water. The fumed titanium dioxide was dispersed in 700 ml. of distilled water and maintained in a state of agitation by employing a Kady colloid mill. The dye solution was added to the titanium slurry and milled for 30 min. The surface-active agent (Pluronic F-68) in 1 l. of distilled water was added to the color slurry. The color slurry and 1% acetic acid-ethanolic solution was then simultaneously pumped in equal portions into a Nerco-Niro portable laboratory spray dryer⁶ employing a Sigmamotor pump.⁶ The heated chamber of the spray dryer was maintained at 175° inlet and 75° outlet temperatures. The color lake obtained was then vacuum dried for 6–8 hr. at 45° and stored in a suitable glass container.

Type 3	Percent by Weight
Fumed titanium dioxide P-25	89.5
F.D. & C. Blue No. 1	5.0
Surface-active agent (Pluronic F-68)	0.5
Partially hydrolyzed polyvinylacetate	5.0

The F.D. & C. Blue No. 1 was dissolved in 2 l. of distilled water. The fumed titanium dioxide was dispersed in 900 ml. of distilled water and maintained in a state of agitation by employing a Kady colloid mill. The dye solution was added to the titanium slurry and milled for 30 min. Then the partially hydrolyzed polyvinylacetate in 1 l. of hot distilled water was added to the color slurry. The surface-active agent (Pluronic F-68) was dissolved in 300 ml.

Table I—Pertinent Operational Details of the Automatic Color-Coating Operation Employing the Titanium Color Lakes

Coating pan speed	26 r.p.m.
Air inlet temperature	55°, 150 c.f.m.
Air exhaust temperature	35°, 200 c.f.m.
Liquid nozzle (DeVilbiss)	AV 1115-D-S
Air nozzle (DeVilbiss)	491-D
Color-coating suspension temperature	55°
Liquid pressure	30 p.s.i.
Air pressure	20 p.s.i.
Spraying time	30 sec.
Dwell time	4 min.
Drying time	6.5 min.
Color coat weight	25–35 mg./tablet
Number of applications	8–12
Color coating time	100–120 min.

of distilled water and was added with thorough agitation. The color slurry was then spray dried in the same manner as described in Type 2; however, the acetic acid-ethanolic solution was eliminated from the procedure.

Fumed alumina⁷ was also employed in exactly the same manner as with Types 1, 2, and 3, which gave similar results as obtained with the fumed titanium dioxide.

Color-Coating Suspension—Fumed titanium dioxide lakes were employed to prepare coating suspensions that were applied to sized or smoothed tablets. As outlined in Method 2, extemporaneous preparation of the color lake with a sucrose syrup (71% w/w) was used to obtain a color suspension for pan-coating tablets. The composition of the color suspensions and two procedures for manufacture are outlined as Methods 1 and 2.

Method 1	Per 3 l.
Titanium dioxide color lake described as Type 2	60.0 g.
Polyvinylpyrrolidone	15.0 g.
Sucrose syrup 71% w/w to	3.0 l.

Sixty grams of color lake described as Type 2 was dispersed in 2.8 l. of sucrose syrup (71% w/w) in which 15 g. of polyvinylpyrrolidone was dissolved. The resulting suspension was milled, employing the Kady colloid mill for 30 min. The color suspension was brought to volume, and was then suitable for application to smooth-coated tablets.

Method 2	Per 10 kg.
Fumed titanium dioxide	0.100 kg.
F.D. & C. Violet No. 1	0.004 kg.
F.D. & C. Green No. 3	0.001 kg.
F.C. & C. Yellow No. 5	0.015 kg.
Titanium dioxide USP	0.100 kg.
Distilled water	2.000 kg.
Sucrose, granular	5.000 kg.
Sucrose syrup 71% w/w q.s. ad.	10.000 kg.

The F.D. & C. dyes were dissolved in 1 l. of distilled water. The fumed titanium dioxide was dispersed in 1 l. of sucrose syrup (71% w/w). The liquids were then placed in the Kady colloid mill and milled for 1 hr. Five kilograms of sucrose was added to the Kady mill vessel and milled until solution was obtained. The titanium dioxide USP was mechanically milled in 1 l. of distilled water and then was added to the color lake suspension. The resulting color suspension was brought to volume with sucrose syrup (71% w/w) and milled an additional 15 min.

The resulting color suspension was then applied to 25 kg. of smoothed tablets which were contained in a rotating coating pan. The tablets employed in this project had a 180-mg. core weight and 250-mg. smooth-coat weight. The tablet cores were 8 mm. in diameter and had a deep concave shape. The coating pan employed was the Manesty CP-2 which has a 91.44-cm. (36-in.) diameter. The coating pan was equipped with four baffles as described by Lachman (3). The color-coating suspension was sprayed, using an apparatus similar to that described by Steinberg (4). A DeVilbiss

automatic spray gun (AGB504) equipped with an internal mixing nozzle was employed in this study. Pertinent parameters of the automatic color-coating operation are outlined in Table I.

Color Fastness of the Color Lakes—The permanency of the color lakes prepared from fumed titanium dioxide and the soluble dyes was tested using a centrifuge technique. One gram of color lake was suspended in 30 ml. of water and submitted to centrifugal force at 5000 r.p.m. for 5 min. The supernatant liquid was poured off and observed for color-leaching tendencies. The same color lake was resuspended in 30 ml. of water and centrifuged. In most cases, negligible transfer of the dye to the aqueous media occurred during the first step but was absent after the second treatment.

Dispersibility of the Color Lakes—The dispersibility of the color lakes when in an aqueous suspension was determined by employing sedimentation-rate analysis. Commercially available lakes were used as a control for this study. Two grams of color lake was suspended in 100 ml. water and placed in a 100-ml. graduated cylinder. The commercial lakes settled out about five times as rapidly as those prepared and indicated poor dispersibility. The color lake particles containing fumed titanium had greater resistance to the force of gravity, which was evidenced by its flocculated state

RESULTS AND DISCUSSION

Fumed titanium dioxide was employed in this investigation as an adsorbate for color lakes. The application results from a physico-chemical reaction of the submicron material with water-soluble dyes. This results from the strong attractive forces existing between the positive-charged fumed inorganic dioxide and the negative-charged dye particles. The fumed material ranges in particle size from 0.005 to 0.040 μ , and thus it possesses a surface area (B.E.T. method) from 35 to 100 m.²/g. (5). The absence of permanent interaction between titanium dioxide USP and dyes without permanency of lake formation is well known to the dye chemist (6).

The traditional method for color lake formation involves the coprecipitation of a soluble dye with a selected, hydrated, inorganic oxide or freshly precipitated salt such as calcium sulfate or barium sulfate. This method is not applicable for titanium dioxide lake formation from the USP grade material since it does not have the necessary physical characteristics of the traditional lake adsorbates. Titanium dioxide USP used for pigmentary purposes results in particle aggregation and a deficient pigment having less than optimum dispersibility and decreased properties, *i.e.*, tinting strength. This causes the titanium pigments to possess the following undesirable qualities: poor dispersibility, aeration, and fast settling, which interfere with excellence in their pharmaceutical use. The titanium dioxide lakes which were prepared from the fumed material resulted in a lake particle having optimum pigmentary properties, notably tinting strength, and demonstrated improved dispersibility.

As a result of fumed titanium dioxide's smaller particle size as compared with the USP grade, when it was dispersed in an aqueous medium it appeared relatively transparent and exhibited a much lower tinting strength.

When the fumed titanium dioxide was dispersed in an aqueous medium, it showed an isoelectric point at pH 6.5. Fumed titanium dioxide differs from the regular opacifying grades, because it possesses a substantial positive surface charge which causes it to interact exceptionally well with negatively charged particles, *i.e.*, soluble dyes. Acidification of the titanium dioxide-dye slurry when preparing the color lake permitted greater dye inclusion, since the potential of the titanium dioxide is higher at a low pH. The isoelectric point should be avoided in lake formation because it would provide the lowest potential. The acidified dyes are poorly soluble in water, and the color lake formed was evaluated as more permanent. An important aspect of the titanium lakes is that strong acids such as hydrochloric and acetic may be employed to fix the

dye without causing the adsorbate to dissolve, as would occur with alumina. When a particular acid was varied in the treatment of the dye adsorbate, different shades of a specific color were obtained.

The spray-dried titanium lakes had a particle-size range similar to those obtained by a micronizing process and fall in a range from 1 to 10 μ as demonstrated by photomicroscopy. Excellent dispersibility of these color lakes in water was observed when compared with the commercially available color lakes prepared by jet-milled micronization.

An opaque gel structure formed during the extension of the dye on the fumed titanium dioxide. Addition of the dye caused a thickening of the fumed titanium slurry almost instantly, provided that the amount of dye was either in excess or sufficient to saturate the dye-adsorbing capacity of the fumed material. When the amount of titanium dioxide in the slurry was about 1% w/w and the dye about 1–2% w/w, a change occurred, a shifting from a colloidal suspension to a dense precipitate at the saturation point. If the dye saturation point was just reached, the lake obtained was easily separated by centrifugation; however, those slurries with a deficiency or excess of dye behaved like colloidal suspensions, and it was extremely difficult to separate the lakes from the dispersion medium by centrifugation. This phenomenon varied with the chemical structure of the dye considered.

The method of choice in the manufacture of the titanium lakes was the employment of the spray-drying technique which included preacidification before atomization into the spray-drying chamber. The inlet and outlet temperatures of the spray dryer were based on the composition of the dispersion media. The viscosity of the slurry prior to spray drying was decreased by using either inorganic or organic acids. If strong acids were employed, it was imperative that they were volatile at the inlet temperature of the spray dryer. The color fastness of these titanium dioxide lakes prepared by spray drying exhibited exceptional permanency of the dye-adsorbate interaction.

The color lakes prepared in this study were suspended in sucrose syrup (71% w/w), and the certified dye content, in certain cases, was utilized at 0.4% w/v. The color suspension was then applied to rounded, rotating tablets, and the tablets required about 8–12 applications to be considered acceptable from a color and physical appearance standpoint. The coating suspension permitted a reduction of the color-coating operation when compared with conventional dye solutions. The advantages of this process for coating tablets are: uniform color dispersion, consecutive batch reproducibility, extemporaneous preparation of color lakes, and the necessity of only 8–12 applications of the color suspension to obtain maximum color tone.

Synthesis of Radiolabeled 1,1-Bis(*p*-chlorophenyl)-2-nitropropane

RALPH H. JARBOE, Jr.*, JOHN B. DATA, and JOHN E. CHRISTIAN

Abstract □ Radiolabeled 1,1-bis(*p*-chlorophenyl)-2-nitropropane was synthesized, and its purity was established by TLC. Autoradiograms of labeled and unlabeled products were compared for authenticity. The specific activity was determined.

Keyphrases □ 1,1-Bis(*p*-chlorophenyl)-2-nitropropane—synthesis, specific activity □ ¹⁴C-Labeling—specific activity, 1,1-bis(*p*-chlorophenyl)-2-nitropropane □ Liquid scintillation spectrometry—specific activity □ TLC—analysis

The primary objectives of this work were to devise a practical synthesis and to establish the purity of radiolabeled 1,1-bis(*p*-chlorophenyl)-2-nitropropane (I) for the purpose of subjecting the compound to distribution and metabolic studies in its use as an insecticide. The preparation of I is basically an adaptation of the method described by Hass *et al.* (1):

The desired compound (I) was obtained in 32.5% yield. Purity of the product was established by TLC, using two solvent systems and a commercial adsorbent.¹ Autoradiograms of the labeled product were compared to an authentic, unlabeled sample. The pure product had a specific activity of $13.85 \pm 0.11 \mu\text{Ci}/\text{mmole}$.

EXPERIMENTAL

1-*p*-Chlorophenyl-2-nitro-1-propanol—Fifty-six grams (0.4 mole) of *p*-chlorobenzaldehyde was stirred mechanically for 3 hr. with 200 ml. of water containing 50.0 g. (0.475 mole) sodium bisulfite. Thirty-three grams (0.44 mole) nitroethane, previously dissolved in 80 ml. of 6.25 N NaOH at 8–13°, was added in small portions to the stirred, thick, white suspension of bisulfite addition product. As the reaction proceeded, the magma dissolved and a flocculent pre-

cipitate formed. Stirring was continued for 18 hr. after the last addition of the alkaline nitroethane solution.

The reaction mixture was transferred to a separator, the yellow organic layer which settled to the bottom was removed, and the milky aqueous layer was extracted three times with 25-ml. portions of ether to remove additional organic material. The combined organic substances were extracted with 50-ml. portions of 10% aqueous sodium bisulfite solution until all unreacted *p*-chlorobenzaldehyde had been removed. The ethereal solution was dried with anhydrous sodium sulfate for 2 hr. and filtered; the solvent was removed under reduced pressure to give 70.0 g. of light-yellow oil. Fractionation of the crude product gave 31.0 g. (36.1%) of highly viscous yellow oil which distilled at 145–147° at 0.2 mm.

1,1-Bis(*p*-chlorophenyl)-2-nitropropane-¹⁴C—To 25 ml. of 2% fuming sulfuric acid, maintained at 10° and mechanically stirred, was added 57 mg. (0.50 mmole) of chlorobenzene-¹⁴C (2.98 mc./mmole)² and 3.8 ml. of unlabeled chlorobenzene used to rinse the shipping vial. When the mixture had reached bath temperature, 8.78 g. (0.041 mole) of 1-*p*-chlorophenyl-2-nitro-1-propanol was added dropwise. The cooling bath was removed; the reaction mixture was stirred for an additional 1.5 hr., poured onto 100 g. cracked ice, and allowed to stand for 2 hr. The product was extracted exhaustively with ether, and the combined ether extracts were washed successively with 50-ml. portions of 5% sodium bicarbonate, 10% sodium bisulfite, and water. The ether was removed under reduced pressure, the oily residue was steam distilled, and the product remaining in the distillation flask was dissolved in ether.

The ethereal solution was dried with anhydrous sodium sulfate for 2 hr. and filtered. The ether was removed under reduced pressure, and the viscous oil was poured onto a watch glass to solidify overnight. About 2 ml. absolute ethanol was added to the original flask to dissolve residual material. The alcoholic solution and the solidified material were combined, crystallized from hot ethanol, and twice recrystallized from ethanol to obtain 4.1276 g. (32.5%) of a white, crystalline product.

TLC—Microscope slides coated with commercial adsorbent were placed vertically in individual, small, square, amber bottles containing 10 ml. of the desired developing solvent. The bottles were capped and slides were equilibrated overnight. Five microliters of the sample, in methanol, was pipetted onto each slide about 1 cm. above the solvent level. The slides were developed for about 10 min., air dried, exposed to UV radiation to locate I, and sprayed with a plastic preservative if subsequent autoradiography was intended. Repeated runs with authentic samples of I gave an R_f value of 0.48 in hexane-ethyl acetate (9:1) and 0.30 in hexane-acetic acid (9:1).

Autoradiography—For autoradiography, separate solutions of the authentic unlabeled product and of the labeled product containing 10 mg./ml. were prepared in methanol. Five-microliter samples of the authentic and labeled products were chromatographed in parallel on 20 × 20-cm. commercial adsorbent thin-layer plates, using both of the solvent systems described previously. In both solvent systems, UV irradiation of the plates disclosed identical R_f values for authentic and unlabeled samples. In neither solvent was there evidence of impurities. The plates were sprayed with plastic preservative to prevent sloughing, exposed for 6 days to film, developed, and fixed.³ For both solvent systems, a single radioactive

³ Eastman No Screen medical X-ray film. Developed and fixed in Eastman Kodak liquid developer and liquid fixer, respectively.

¹ Adsorbosil P-1, Allied Science Laboratories Inc., State College, Pa.

spot, corresponding to the position of the authentic unlabeled sample, was obtained. There was no tailing in the hexane-ethyl acetate system, but there was a small amount of tailing in the hexane-acetic acid system.

Determination of Specific Activity—A 10 mg./ml. solution of 1,1-bis(*p*-chlorophenyl)-2-nitropropane-¹⁴C in methanol was used to determine the specific activity of the compound.

Five samples were prepared by pipeting 100 μ l. of the solution into five scintillation vials containing a liquid scintillation cocktail composed of 0.14% PPO (2,5-diphenyloxazole) and 0.01% dimethyl POPOP [1,4-bis(4-methyl-5-phenyl-2-oxazolyl)benzene] in equal volumes each of toluene and 2-ethoxyethanol. These samples were cooled in a Packard TRI CARB liquid-scintillation spectrometer, model 3003, for 0.5 hr. The window width of 50–100° was chosen. Utilizing an internal standard of toluene-¹⁴C (toluene-¹⁴C, 5.01×10^6 dis./min./ml., R-21 Tracerlab), the observed counts per minute were converted to disintegrations per minute and corrected

for quenching and counter efficiency. A specific activity of $13.85 \pm 0.11 \mu\text{C./mmole}$ was obtained.

Development of Tolerance to Pentobarbital

JASBIR M. SINGH, BRUCE FIEGENSCHUE, and CARL SCHEXNAYDRE

Abstract □ Tolerance to pentobarbital developed 4 hr. after the first injection and reached a peak at 17–22 hr., after which it decreased to nonsignificant levels by 48 hr. The duration and frequency of administration of pentobarbital affected the degree of development of tolerance to pentobarbital. PTI (Percentage Tolerance Index) decreased progressively with the increase in the number of injections. When four injections were given within the span of 28 hr., the animals showed a greater degree of tolerance on the third injection which was administered 24 hr. after the initial injection. Tolerance was also present on the fourth injection but to a lesser degree when compared with the third injection. The experimental data from this study suggest that tolerance to pentobarbital does develop and is the result of the pentobarbital stimulating its own metabolizing enzyme.

Keyphrases □ Pentobarbital—tolerance development, rats □ Drug tolerance—pentobarbital, rats □ Tolerance, pentobarbital—rats

Animals can be shown to develop tolerance to barbiturates, pentobarbital and thiopental (1). Gruber and Keyser found that dogs tend to become tolerant to a variety of barbiturates (2). As a criterion of tolerance, they used the reduction of the sleeping time elicited by the same dose after it had been repeated several times. According to Goodman and Gilman, tolerance to barbiturates has developed when, after repeated administration, a given dose produces a decreasing effect or, conversely, when increasingly larger doses must be given to obtain true barbiturate effects obtained with the original dose (3). Tatum *et al.* provide the classic definition of tolerance as “a phenomenon characterized by the fact that more drug must be used to produce equivalent effects” (4). Jaffe and Sharpless have shown that some degree of physical dependence can be produced in as little as 20 hr. after pentobarbital administration (5). Singh has also shown that tolerance to pentobarbital and thiopental is developed within 24 hr. (1). The purpose of this paper is to report that: (a) a certain time

lapse occurs before the tolerance is developed, and (b) this developed tolerance reaches a peak and then declines.

EXPERIMENTAL

Female albino rats, random by breed (Caesarian Drive One) and weighing 125–175 g., were used. Pentobarbital sodium was dissolved in distilled water. The volume of each injection was kept constant, *i.e.*, 1 ml./kg. All injections of pentobarbital (25 mg./kg.) were given intraperitoneally. The sleeping time (difference between loss of righting reflex and regain in righting reflex in minutes) was determined.

Animals were divided into five major groups:

Group 1—Pentobarbital was administered to 34 animals at zero time and at an interval of 24 hr.

Group 2—Eighteen subgroups were composed of 10 to 15 animals each. In these subgroups, the first injection was given at zero time and then the second injection was given at intervals of 2, 3, 4, 7, 9, 13, 17, 18, 19, 20, 21, 21, 22.5, 22.5, 24, 48, 72, and 168 hr. Some experiments (21 and 22.5 hr.) were duplicated.

Group 3—Pentobarbital, 25 mg./kg., was administered daily to 10 animals at intervals of 24 hr. for 16 days.

Group 4—Three subgroups were comprised of 10 to 15 animals each. To each subgroup, pentobarbital, 25 mg./kg., was administered at intervals of 0, 2, 24, 26; 0, 3, 24, 27; and 0, 4, 24, 28 hr.

Group 5—Clinical signs, *i.e.*, water consumption, urine output, food consumption, and growth, were observed in animals that had developed tolerance to pentobarbital, 25 mg./kg. Each animal was housed separately in a metabolism cage, and initial observations on each animal were taken. Each animal was given two injections of pentobarbital after the initial observations. Then the animals were allowed to recover on the third and fourth day. Statistical methods used were those of Snedecor (6).

Because most work on the development of tolerance to barbiturates has been done on male rats, guinea pigs, mice, and dogs, in this project the authors decided to study tolerance to pentobarbital in female white rats. Percentage tolerance index (PTI) was computed as follows (1):

$$\frac{\text{hypnotic effect of first injection}}{\text{hypnotic effect of second injection}} \times 100$$

If PTI is unity, *i.e.*, 100%, it indicates no tolerance. PTI greater or less than unity indicates tolerance or cumulative effect. Before

spot, corresponding to the position of the authentic unlabeled sample, was obtained. There was no tailing in the hexane-ethyl acetate system, but there was a small amount of tailing in the hexane-acetic acid system.

Determination of Specific Activity—A 10 mg./ml. solution of 1,1-bis(*p*-chlorophenyl)-2-nitropropane-¹⁴C in methanol was used to determine the specific activity of the compound.

Five samples were prepared by pipeting 100 μ l. of the solution into five scintillation vials containing a liquid scintillation cocktail composed of 0.14% PPO (2,5-diphenyloxazole) and 0.01% dimethyl POPOP [1,4-bis(4-methyl-5-phenyl-2-oxazolyl)benzene] in equal volumes each of toluene and 2-ethoxyethanol. These samples were cooled in a Packard TRI CARB liquid-scintillation spectrometer, model 3003, for 0.5 hr. The window width of 50–100° was chosen. ^a Sample size is given in parentheses. ^b (+) or (-) indicates increase or decrease in S.T. ^c $p < 0.05$.

computing PTI, the data of the first and second injections were analyzed by means of differences (6).

RESULTS

Group 1—Significant tolerance ($p < 0.05$) was developed in female albino rats when the second injection of pentobarbital was administered at an interval of 24 hr. after the initial injection.

Group 2—Effect of pentobarbital (first and second injections) on the sleeping time is computed from Table I and given in Fig. 1. Significant cumulative hypnotic effect was present during the first 3 hr. The animals began to show tolerance after 4 hr., reaching a peak between 17 and 22 hr., then declining and was not evident at or after 48 hr.

Group 3—Table II shows the effect of continuous administration of pentobarbital on the development of tolerance. In this group, four injections of pentobarbital were given to the same animals at different time intervals. No tolerance was exhibited at 2 and 3 hr. However, tolerance was present if the third and fourth injections were given at 0, 2, 24, 26, 0, 3, 24, 27; and 0, 4, 24, 28 hr. Comparison is made between the first two injections (0, 2; 0, 3; 0, 4) and the last two injections (24, 26; 24, 27; 24, 28). Significant ($p < 0.05$) tolerance is developed at and after 24 hr. Significant ($p < 0.05$) tolerance was present when the fourth injection was given at 26, 27, and 28 hr. following the initial injection. However, the degree of developed tolerance was significantly ($p < 0.05$) less when compared with the third injection.

Group 4—The effect of continuous administration of pentobarbital daily for 16 days is shown in Table III. Significant ($p < 0.05$) tolerance was developed after 24 hr. PTI decreased progressively with the increase in the number of injections.

Group 5—Clinical signs, *i.e.*, urine output, water consumption, food consumption, and weight, were not affected during the development of tolerance to pentobarbital. However, on the 3rd day, 24 hr. after the second injection, a significant ($p < 0.05$) increase in water consumption and urine output was observed; food consumption was not altered over the period of 5 days. Weight remained constant in the treated rats. However, a significant ($p < 0.05$) increase in weight was observed in the control animals.

DISCUSSION

The hypothesis of the authors was that the development of tolerance to pentobarbital can be influenced by interval and frequency of administration of the drug, duration of administration of the drug, and metabolism in the liver.

Interval and Frequency of Administration of Drug—Singh has shown that tolerance to barbiturates, pentobarbital, and thiopental

Figure 1—Effect of pentobarbital, 25 mg./kg., on the percentage tolerance index of female albino rats.

is developed in 24 hr. (1). Results of the present experiment also indicate that a minimum of 4 hr. is necessary for the tolerance to be induced (Table I). Maximum tolerance is induced in an animal if the second injection is given between 17 and 22 hr.; then it declines. Nonsignificant tolerance is present after 48 hr. In less than 4 hr., animals showed cumulative effect instead of tolerance.

Duration of Administration of Drug—Duration of administration of pentobarbital will also affect the degree of development of tolerance to pentobarbital (Table III). PTI was greater on the second and subsequent administrations. In these experiments, all the injections were given daily for 16 days. On the other hand, when four injections were given within the span of 28 hr., animals showed a greater degree of tolerance on the third injection administered at 24 hr. after the initial injection (Table II). Tolerance was also present on the fourth injection but to a lesser degree when compared with the third injection.

Metabolism in the Liver—The liver plays an important role in the duration of action of barbiturates (3). Duration of action of barbiturates is decreased once tolerance is developed to barbiturates (Tables II and III). Anesthesia induced by barbiturates can be

prolonged by hepatic injury (7). Plaa *et al.* found a positive relationship between the doses of several hepatotoxins and the prolongation of pentobarbital sleeping time (7). Singh and Boyd found that tannic acid, which causes centrilobular liver necrosis, prolonged the sleeping time of thiopental (8). This effect became evident at 72 hr. after the administration of tannic acid. Balazs and Grice also reported that administration of carbon tetrachloride can prolong the sleeping time of pentobarbital (9).

Pentobarbital is metabolized in the liver (3). Conney *et al.* have shown that pentobarbital is an enzyme inducer (10). One explanation of the development of tolerance to pentobarbital is that pentobarbital possibly stimulates its own metabolizing enzyme and thus results in increased pentobarbital metabolism on repeated administration and decreased sleeping time (Tables I-III). This leads the

authors to suggest that in the development of tolerance to pentobarbital, the liver possibly is involved.

Clinical Signs—During the development of tolerance to pentobarbital, neither water consumption nor urine excretion was affected. However, on the day after the tolerance had been induced, a significant increase ($p < 0.05$) was noticeable in water consumption and urine excretion. Singh reported similar clinical findings with thiopental also (11).

Sterility Testing of Insulin by Membrane Filtration: A Collaborative Study

MIRIAM P. CALHOUN, MACK WHITE, and FRANCES W. BOWMAN

Abstract □ A membrane filtration procedure was devised for testing the sterility of insulin zinc suspensions solubilized in ascorbic acid diluting fluid. A collaborative study showed that the filtration procedure afforded significant improvements over the direct method of sterility testing.

Keyphrases □ Insulin, sterility—membrane filtration □ Membrane filtration—sterility testing, insulin zinc suspensions □ Sterility testing—insulin, membrane filtration □ Collaborative study—membrane filtration, insulin sterility

In 1941 the Federal Food, Drug, and Cosmetic Act was amended to establish a certification service to ensure the safety and efficacy of insulin-containing drugs by testing each lot prior to distribution. The official analytical methods and standards of quality and purity are described in the USP (1), the NF (2), and the *Code of Federal Regulations* (3). Since insulin must be admin-

istered by parenteral injection, these official compendia require all insulin preparations to be sterile.

The official USP XVII/NF XII method for the sterility testing of insulin requires that 20 containers from each "filling operation" be tested in thioglycollate broth for detecting bacteria and in Sabouraud fluid medium for molds and yeasts. The solution or suspension of insulin is transferred with a sterile syringe and needle directly to tubes of media. Tubes containing thioglycollate medium are incubated for not less than 7 days at 30-32° and those containing fluid Sabouraud for not less than 10 days at 22-25°. After incubation the media are examined for the presence or absence of microbial growth.

The principal objection to the USP XVII/NF XII method is that a precipitate is formed by the insulin suspensions in the culture media. Macroscopically the precipitate is indistinguishable from microbial growth;

Table III—Effect of Continuous Administration of Pentobarbital (25 mg./kg. i.p.) on Development of Tolerance

No. Injections	Injection Interval, Days ^a	Mean S.T., min. ^b	Tolerance Index, %

15	15	38.2 (8)	121 ^c
16	16	41.6 (8)	111

^a Injections were given daily to the same animals for 16 days. ^b The sleeping time was determined on 1, 2, 8, 9, 15, and 16 days. Sample size is given in parentheses. ^c $p < 0.05$.

prolonged by hepatic injury (7). Plaa *et al.* found a positive relationship between the doses of several hepatotoxins and the prolongation of pentobarbital sleeping time (7). Singh and Boyd found that tannic acid, which causes centrilobular liver necrosis, prolonged the sleeping time of thiopental (8). This effect became evident at 72 hr. after the administration of tannic acid. Balazs and Grice also reported that administration of carbon tetrachloride can prolong the sleeping time of pentobarbital (9).

Pentobarbital is metabolized in the liver (3). Conney *et al.* have shown that pentobarbital is an enzyme inducer (10). One explanation of the development of tolerance to pentobarbital is that pentobarbital possibly stimulates its own metabolizing enzyme and thus results in increased pentobarbital metabolism on repeated administration and decreased sleeping time (Tables I-III). This leads the

authors to suggest that in the development of tolerance to pentobarbital, the liver possibly is involved.

Clinical Signs—During the development of tolerance to pentobarbital, neither water consumption nor urine excretion was affected. However, on the day after the tolerance had been induced, a significant increase ($p < 0.05$) was noticeable in water consumption and urine excretion. Singh reported similar clinical findings with thiopental also (11).

Sterility Testing of Insulin by Membrane Filtration: A Collaborative Study

MIRIAM P. CALHOUN, MACK WHITE, and FRANCES W. BOWMAN

Abstract □ A membrane filtration procedure was devised for testing the sterility of insulin zinc suspensions solubilized in ascorbic acid diluting fluid. A collaborative study showed that the filtration procedure afforded significant improvements over the direct method of sterility testing.

Keyphrases □ Insulin, sterility—membrane filtration □ Membrane filtration—sterility testing, insulin zinc suspensions □ Sterility testing—insulin, membrane filtration □ Collaborative study—membrane filtration, insulin sterility

In 1941 the Federal Food, Drug, and Cosmetic Act was amended to establish a certification service to ensure the safety and efficacy of insulin-containing drugs by testing each lot prior to distribution. The official analytical methods and standards of quality and purity are described in the USP (1), the NF (2), and the *Code of Federal Regulations* (3). Since insulin must be admin-

istered by parenteral injection, these official compendia require all insulin preparations to be sterile.

The official USP XVII/NF XII method for the sterility testing of insulin requires that 20 containers from each "filling operation" be tested in thioglycollate broth for detecting bacteria and in Sabouraud fluid medium for molds and yeasts. The solution or suspension of insulin is transferred with a sterile syringe and needle directly to tubes of media. Tubes containing thioglycollate medium are incubated for not less than 7 days at 30-32° and those containing fluid Sabouraud for not less than 10 days at 22-25°. After incubation the media are examined for the presence or absence of microbial growth.

The principal objection to the USP XVII/NF XII method is that a precipitate is formed by the insulin suspensions in the culture media. Macroscopically the precipitate is indistinguishable from microbial growth;

^a MF = Membrane filtration method; USP = direct method; — = no growth; + = growth.

therefore, subcultures are necessary to determine whether viable microorganisms are present. Because the additional work required for these subcultures is time-consuming and expensive and could lead to false positive results due to adventitious contamination, a method was sought to improve the test.

EXPERIMENTAL

The membrane filtration sterility test method described for antibiotics by Bowman (4) is easily applied to insulin solutions, because they filter readily and leave no residue on the membrane. However, the suspensions (*e.g.*, protamine zinc insulin suspension, isophane insulin suspension, and insulin zinc suspension) are not amenable to the filtration sterility test, because the crystals are insoluble in the peptone diluting fluid used in the procedure.

Solubilization Studies—Because insulin suspensions presented problems in filtering, various procedures were tried for solubilizing them. When the pH was lowered from the normal of approximately 7.2 to 3.2 ± 0.2 , the suspended material immediately dissolved at

room temperature and the resultant solutions could then be filtered quickly, without leaving any visible residue on the membrane. However, when 1 *N* hydrochloric acid was used to lower the pH, it was toxic to some vegetative organisms.

Preliminary investigation indicated that ascorbic acid would be suitable for solubilizing insulin suspensions without adversely affecting the viability of microorganisms that might be present. A 1% ascorbic acid solution (AA diluting fluid) was prepared in 0.1% peptone (w/v) solution (pH 3.2 ± 0.2). Protamine zinc insulin suspensions were solubilized immediately and insulin zinc suspensions were solubilized in approximately 1 min. with the AA diluting fluid. The membranes were assayed by a radioimmuno assay for residual insulin (5). Less than 1 unit of insulin was retained by a membrane used to filter 1600 units of insulin (6).

Survival Studies—To assess the ability of organisms to survive in insulin suspensions, survival studies were performed. Vials of sterile insulin containing 0.1% methylparaben as a preservative were inoculated with vegetative bacteria or yeasts or with spores of bacteria or molds. Vials containing peptone water were used as controls. All were tested for sterility by the USP/NF method and by the proposed membrane filtration test at zero time and after 1 week at room temperature. Growth of the added microorganisms was ob-

^a Results are given as the maximum number of days incubation required for recovery of microorganisms. ^b Definitions and conditions as follows: CPU, colony-producing units; FTM, fluid thioglycollate medium incubated at 32-35°; SBCD, soybean-casein digest medium incubated at 22-25°. ^c Subcultures were necessary to determine whether viable microorganisms were present or absent when the direct method was used.

tained from all the suspensions at zero time. As shown in Table I, only the yeast and the sporing microorganisms survived in insulin for 7 days. In a similar study on globin insulin preserved with phenol, Sykes and Hooper (7) found that vegetative bacteria were killed by components other than preservatives (such as protamine) while spores of bacteria and molds survived.

The results obtained in these survival studies indicated that a filtration sterility test could be applied to insulin suspension and solutions. After some preliminary studies in collaboration with two manufacturers of insulin, it was decided that a definitive collaborative study should be conducted to establish the validity of the filtration method before proposing its inclusion in the USP and NF.

Collaborative Study on the Sterility Testing of Insulin—The procedure used was essentially that used for antibiotics (8) except that a separate membrane was used for each medium, soybean-casein digest broth was substituted for liquid Sabouraud medium, and the membrane was washed only once with 0.1% peptone (w/v) solution. These changes were based on the understanding that USP XVIII (9) and NF XIII (10) will include a similar membrane filtration sterility test as an alternative test for sterile preparations that are amenable to filtration.

Cultures of the eight microorganisms used in the study were supplied by the authors. Dilutions of inocula were selected to simulate low levels of contamination that might possibly be encountered in a contaminated insulin preparation.

The following directions (11) were followed by the two collaborating laboratories: aseptically add 39 ml. of insulin suspension preserved with 0.1% methylparaben to each of 80 sterile 60-ml. (2-oz.) prescription bottles. To each of another 80 bottles, add 39 ml. of 0.1% peptone solution. Prepare a dilution of one culture to yield five cells per ml., then aseptically add 1 ml. of this dilution to each of five bottles of insulin suspension and to five bottles of the control peptone solution. Prepare another dilution of the same culture to yield approximately 100 cells per ml., and add 1 ml. to each of another five bottles of insulin suspension and of peptone solution, respectively.

Perform a USP XVII/NF XII direct sterility test on the contents of two of the bottles of each dilution of microorganisms. From one bottle transfer 2-ml. portions to each of 20 tubes containing 40 ml. of thioglycollate medium and from the other bottle transfer 2 ml. to each of 20 tubes containing 40 ml. of soybean-casein digest medium.

Perform the proposed membrane filtration test, described here and in USP XVIII, using two more bottles of each dilution of microorganisms in the test fluids. These two bottles simulate the two pooled vessels (prior to filtration) to be described in the USP XVIII method.

As a control on the inoculum, filter the contents of the remaining bottle through a membrane filter; but instead of transferring the membrane to fluid media, place it on the surface of a soybean-casein digest agar plate.

Read all tests after incubation at the appropriate temperature for 7, 10, and 14 days.

Repeat this procedure for each of the other seven microorganisms.

Thus, for each microorganism, there is a total of 10 bottles for each testing fluid, five containing 5 cells per bottle and five containing 100 cells per bottle.

Proposed Membrane Filtration Method—Aseptically transfer the required volumes from each of 20 containers either directly to each of two sterile filter funnels or to each of two sterile flasks for pooling prior to transfer. [For required volume see the table in the chapter on Sterility Tests (9) in USP XVIII which describes the ratio of product to container content.] If the sample is a suspension, solubilize it by pouring the pooled insulin from a flask into 200–400 ml. of freshly prepared 1.0% ascorbic acid USP in 0.1% (w/v) peptone solution. (If the sample is a solution, omit this solubilization step.) After solubilization is complete, filter the solution through a bacteriological membrane filter. All air entering the system must be passed through air filters capable of removing microorganisms. Filter one 100-ml. portion of 0.1% peptone solution through the

membrane to remove residual insulin. Transfer the entire membrane to a sterile 38 × 200-mm. (outside dimensions) test tube containing approximately 90 ml. of sterile thioglycollate medium. Repeat this procedure for the pooled insulin in the second flask, and transfer the second membrane to a tube containing approximately 90 ml. of fluid soybean-casein digest medium. Incubate the tubes for 7 days at 32 and 25°, respectively, and then examine for macroscopic evidence of growth, i.e., the development of turbidity. The batch meets the requirements of the test if growth is absent in all tubes. If growth is observed in any tube, the lot fails to meet the requirements of the test for sterility, unless it can be demonstrated by re-tests or by other means that the test was invalid for causes unrelated to the product.

RESULTS AND CONCLUSIONS

As shown in Table II, both the high and low levels of microorganisms were recovered by the USP XVII/NF XII direct method and by the proposed membrane method. The inoculum control proved that the added test microorganisms were within the desired range of either 100 cells or 5 cells per 40 ml. of the sample. In each individual test by membrane filtration the microorganisms grew in one of the two media within 7 days. However, the USP/NF direct method required 10 days of incubation for the visual detection of *Aspergillus niger*, and the growth of *Saccharomyces cerevisiae* and *Candida albicans* could be determined only by subculture. Both collaborators agreed that the proposed membrane filtration method using AA diluting fluid to solubilize zinc insulin suspension is acceptable for sterility testing. Since USP XVIII (9) and NF XIII (10) are expected to recognize both the direct and the membrane filtration methods, either may be acceptable for the sterility testing of insulin after these compendia become official. However, several advantages accrue from the use of the filtration test. The incubation time is shortened from 14 to 7 days, the necessity for subculturing turbid broth tubes to determine the presence or absence of microbial growth is eliminated, and the volume of medium required for testing is drastically reduced.

Simultaneous TLC Separation of Khellin and Visnagin and Their Assay in *Ammi visnaga* Fruits, Extracts, and Formulations

M. S. KARAWYA*, M. A. EL-KIEY, A. SINA, and G. NOUR†

Abstract □ A rapid and sensitive two-dimensional TLC-colorimetric method for the simultaneous determination of khellin and visnagin in *Ammi visnaga* fruits, extracts, and formulations is presented. Horstmann's *m*-dinitrobenzene colorimetric method was studied; a modified method, ensuring stability of the produced color and strict adherence to Beer's law over a wide range of concentration (5–150 mcg.), is proposed.

Keyphrases □ Khellin—colorimetric determination, *m*-dinitrobenzene □ Visnagin—colorimetric determination, *m*-dinitrobenzene □ Column chromatography—separation □ TLC—separation, determination □ UV spectrometry—analysis

In 1956, Schönberg and Sidky (1) described a color test for 2-methylchromones with *m*-dinitrobenzene, in the presence of alkali, whereby a deep-violet color was produced. On the basis of this color test, Horstmann (2) later devised a quantitative method for estimating khellin and visnagin in *Ammi visnaga* fruits. He allowed the dry chromone derivative to react with *m*-dinitrobenzene ethanolic solution in the presence of ethanolic potassium hydroxide; he measured the developed dark-blue color at 570 m μ . However, Horstmann stated that the color was unstable and disappeared rather quickly. The authors of this article confirmed the instability of the produced color, and they found that the linear relationship between absorbance and concentration was poor in the range of concentration (10–70 mcg.) described by Horstmann, especially with visnagin. In addition, the ethanolic potassium hydroxide solution (12%) was unstable. It changed rapidly to a reddish-brown color, thus giving interference due to background absorption. Consequently, an attempt was made to improve the *m*-dinitrobenzene colorimetric method so as to obtain a stable, sensitive, and measurable color. It was hoped that this color could be used in a new TLC-colorimetric assay of khellin and visnagin in fruits, extracts, and pharmaceutical formulations of *Ammi visnaga*.

EXPERIMENTAL

Reagents and Apparatus—The following were used: authentic samples of khellin, visnagin, and other known constituents of *Ammi visnaga* fruits; *m*-dinitrobenzene solution, 2% w/v in ethanol; potassium hydroxide solution, 50% in water; sodium chloride solution, 10% in 25% ethanol; isobutanol-ether mixture (1:1); ethanol (aldehyde free); methanol; chloroform; aluminium oxide for adsorption chromatography (British Drug House); silica gel G (Rhône Poulenc); Beckman DU spectrophotometer; and Desaga TLC equipment.

Analytical grade reagents were used whenever possible.

Color Reaction—The factors affecting color development and stability due to the action of *m*-dinitrobenzene and potassium hydroxide on khellin or visnagin were investigated. These factors were: (a) temperature, (b) time, (c) medium of reaction, and (d)

concentration of reactants. The following experimental conditions for the colorimetric estimation of khellin or visnagin were found to be optimum.

For a concentration range of 5–150 mcg. of either khellin or visnagin in 1.5 ml. of an ethanolic solution, 0.5 ml. of 2% ethanolic *m*-dinitrobenzene and 0.5 ml. of 50% aqueous potassium hydroxide were adequate, giving a final ethanolic strength of about 75% in the medium. The color was obtained best at $20 \pm 2^\circ$, 30 min. after the addition of the reagents. The stability of the formed color was improved by its extraction with an isobutanol-ether mixture (1:1) in the presence of sodium chloride (10%) in ethanol (25%). The absorbance of the colored organic layer was measured at 570 m μ within 30 min. after the addition of the sodium chloride solution.

Standard Curve—These same conditions were employed, and absorbance-concentration curves for khellin and for visnagin were plotted using the following method. Introduce, from a 0.01% ethanolic solution of either khellin or visnagin, variable concentrations (5–150 mcg.) into dry, glass-stoppered 15-ml. test tubes and complete to 1.5 ml. with ethanol. To each tube add 0.5 ml. of *m*-dinitrobenzene solution and 0.5 ml. of potassium hydroxide solution. Mix gently and maintain the tube at $20 \pm 2^\circ$ for 30 min. Then add 5 ml. of sodium chloride solution and 5 ml. of isobutanol-ether (1:1). Stopper the tube, shake it for about 10 sec., and allow the phases to separate completely. Pipet a portion of the clear bluish-violet upper layer into a 1-cm. silica cell; measure the absorbance of the color at 570 m μ against a blank within 30 min. after the addition of the sodium chloride solution.

The amount of khellin or visnagin in a solution of unknown concentration can be deduced from the respective standard curve or simply by adaptation of a *K* factor:

$$K_{\text{khellin}} = \frac{\text{khellin (mcg.)}}{A_{570}} = 85.1 \quad (\text{Eq. 1})$$

$$K_{\text{visnagin}} = \frac{\text{visnagin (mcg.)}}{A_{570}} = 95.4 \quad (\text{Eq. 2})$$

where A_{570} is the absorbance value of the respective concentration at 570 m μ . These *K* values (average of six concentrations) of khellin and visnagin must be ascertained according to prevailing experimental conditions.

Quantitative TLC Recovery of Khellin and Visnagin from Their Mixtures—Silica gel G plates¹ (20 × 20 cm. and 0.25 mm. thick) were spotted with ethanolic solutions of both khellin and visnagin corresponding to a concentration range of 20–120 mcg. for each. Spotting was done, with an Agla micrometer, at the corner of each plate 2 cm. away from the lower edge and the side edge. The plates were developed with ethyl acetate until the solvent front ascended about 15 cm. The developed plates were allowed to dry and then were redeveloped with the same solvent to 15 cm. at a right angle to the former direction. The plates were then dried and examined under UV light. The well-separated yellowish-brown and greenish-blue fluorescent areas corresponding to khellin and visnagin, respectively, were removed quantitatively by means of a vacuum zone extractor and eluted with 5 ml. of chloroform. Simultaneously, similar blank areas of the silica gel G layer, free from any constituent, were treated in the same way. The chloroform was evaporated on a water bath; the residues, after cooling, were dissolved in 1.5 ml. of ethanol. The ethanolic solution was then treated with the color-developing rea-

¹ Before the layer was spread, the silica gel G was washed three times with three parts of boiling methanol and dried.

Table I—Recovery of Khellin and Visnagin from Their Mixtures by Silica Gel G Plates

Added, mcg.	Recovered, mcg.	Recovery, %

20	19.4	97.0

gents, and the color was measured following the method previously outlined. Results were deduced from previously constructed standard curves of reference khellin and of reference visnagin recovered from silica gel G plates (Table I).

Determination of Khellin and Visnagin in the Fruits and Extracts of *Ammi Visnaga* by the TLC-Colorimetric Method—In Fruits—Transfer 0.5 g. of powdered *Ammi visnaga* fruits to the top of 2 g. of acid alumina in the thimble of a small continuous extraction apparatus. Exhaust the powder with chloroform (Exhaustion is tested by evaporating a few milliliters of the extract to dryness and then adding a few drops each of ethanol, *m*-dinitrobenzene solution, and potassium hydroxide solution. No violet color should be obtained.) Evaporate the extract to dryness, dissolve the residue in chloroform, adjust the volume to 1.0 ml. with chloroform in a volumetric flask, and mix well. Apply aliquots of the chloroform solution containing 30–100 mcg. each of khellin and visnagin (usually about 10–30 μ l.) to the corner of a silica gel G plate and proceed as described under the preceding method. See Table II.

In Extracts—In the case of the liquid extract of *Ammi visnaga* fruits (Egyptian Pharmacopoeia 1963), an aliquot expected to contain 30–100 mcg. each of khellin and visnagin (corresponding to about 10–30 μ l.) was applied directly to the plate and treated as previously described. See Table II.

Determination of Khellin in Pharmaceutical Formulations—Simple Khellin Formulations—Lynamine and Lynamine Forte tablets,² containing 20 and 100 mg. of khellin, respectively, were used (Table III).

Weigh and powder 20 tablets. To an amount of the powder equivalent to 40 mg. of khellin, add 40 ml. of ethanol and stir with a magnetic stirrer, equipped with a heating device, for 30 min. Filter the supernatant alcoholic solution through dry filter paper (Whatman No. 2) into a dry 100-ml. volumetric flask. Repeat extraction of the residue with 3 \times 10 ml. of ethanol, filtering each time through the same filter into the same receiver. Wash, cool to room temperature, and adjust to volume with ethanol. Mix well. Dilute 10 ml. of this solution to 100 ml. with ethanol. From this dilution, pipet off 1.5 ml. (equivalent to 60 mcg. of khellin) into a dry, glass-stoppered test tube. Proceed with the *m*-dinitrobenzene colorimetric method described in the *Standard Curve* section, starting with the words, "add 0.5 ml. of *m*-dinitrobenzene solution. . . ."

Complex Khellin Formulations—Glucolynamine injections² were used. Each 10 ml. of the injection solution contained: khellin, 30 mg.; theophylline, 150 mg.; and glucose, 2000 mg.

Column Chromatographic Method—Measure accurately 10 ml. of the injection solution in a separator. Dilute with 30 ml. of water and extract with 4 \times 20 ml. of chloroform. Filter the combined chloroform extracts, through a small layer of anhydrous sodium sulfate previously washed with chloroform, into a 100-ml. volumetric flask. Wash the filter, and adjust to volume with chloroform. Mix well. Evaporate 10 ml. of the chloroform solution (equivalent to 3 mg. of khellin) to dryness. Dissolve the residue in 2 ml. of chloroform and transfer to the top of a previously prepared 17-g. aluminium oxide column (1.4-cm. diameter). Carry out the chromatographic process

^a Results represent the average of at least three assays.

in a dark cabinet equipped with UV light. Wash the column with chloroform containing 2% methanol. Reject the first nonfluorescent 8–10 ml. of effluent. Collect the yellowish-green fluorescent khellin zone into a 50-ml. volumetric flask until the eluate is free from any fluorescence. Bring to volume with chloroform and mix well. One milliliter of this solution is equivalent to 60 mcg. of khellin.

Pipet off 1 ml. of the chloroform extract, evaporate to dryness, dissolve the cooled residue in 1.5 ml. of ethanol, and complete the assay as previously described.

TLC Method—Spot directly a 20- μ l. aliquot of the injection solution (equivalent to 60 mcg. of khellin) on a silica gel G (methanol-washed) plate and develop the plate with the chloroform-ethanol (98.5:1.5) solvent system (3) for a distance of 15 cm.

Dry the plate in air, elute khellin from the respective spot area, and proceed as previously described.

RESULTS AND DISCUSSION

During this investigation of factors affecting the development and stability of the studied color reaction, the authors found that the test could be conducted in ethanolic solutions of khellin or visnagin instead of the dried residues of the chromone substances mentioned by Horstmann (2). Accordingly, the evaporation step of the ethanolic solutions of the chromones could be avoided. The direct conduction of the reaction was possible on ethanolic solutions of khellin prepared by extraction or simple dilution of pharmaceutical preparations, e.g., tablets and ampuls.

The appropriate concentration of *m*-dinitrobenzene was found to be 2% ethanolic solution as described by Horstmann (2). Lower concentrations, e.g., 1%, gave lower intensities of the developed color, while higher concentrations were unsuitable because crystals separated on standing. The 2% ethanolic solution was reasonably stable when kept at room temperature (25–30°) for about 2 weeks.

The color produced by reacting khellin or visnagin with *m*-dinitrobenzene in 95% ethanol was more intense than with the 50% ethanolic medium. However, the bluish-violet color obtained in 95% ethanol, as described by Horstmann, was highly unstable and thus difficult to measure. The reddish-brown color obtained in the 50% ethanolic medium had a different wavelength of maximum absorption (480 m μ) and did not obey Beer's law. On further trials, 75% ethanol was found to be a suitable medium for obtaining a sensitive and stable color. This was achieved by the addition of 0.5 ml. of 50% aqueous potassium hydroxide solution to a mixture of ethanolic solution of the sample (1.5 ml.) and 2% *m*-dinitrobenzene solution in 95% ethanol (0.5 ml.).

The optimum temperature for this color reaction was found to be 20 \pm 2°. Raising the temperature to 30 or 40° caused a diminution in the color intensity; the absorbances decreased by 20 and 15% at 30° for khellin and visnagin, respectively, although linearity between concentration and absorbance was still maintained.

The time necessary for maximum color intensity was found to be 30–40 min. Dilution of the reaction mixture after full development of the color with 50% ethanol, as described by Horstmann, led to a rapid fading of the color and diminution of the absorbance values. To increase the stability and sensitivity of the formed color after full development, the authors attempted its isolation by extraction of the reaction mixture with suitable organic solvents—viz.,

chloroform, ether, isopropyl ether, and isobutanol. The color could not be extracted with less polar solvents such as *n*-hexane, cyclohexane, and benzene. With chloroform and isopropyl ether, the clarity of the colored solution was impaired by the presence of interfering opalescence which could not be removed by either filtration or centrifugation. Ether gave a clear solution which was stable for about 110 min., but its volatility rendered it unsuitable for spectrophotometric measurements. Extraction of the colored product with isobutanol resulted in a clear solution, but the color was unstable. An isobutanol-ether mixture (1:1) proved to be the most suitable solvent, being less volatile and giving sharp and quick separation of the phases during extraction of the developed color, which was aided by the addition of 10% sodium chloride in 25% ethanol. The separated organic layer was clear and suitable for direct spectrophotometric measurement. The color thus obtained was found to be stable for at least 45 min. and obeyed Beer's law over a concentration range of 5–150 mcg. for either khellin or visnagin, which is a much wider range than that described by Horstmann (10–70 mcg.).

3,5-Dinitrobenzoic acid was also tried as a color-developing reagent, using similar conditions as described for the *m*-dinitrobenzene method. It gave a bluish-violet colored product with khellin and visnagin and was also soluble in an isobutanol-ether mixture (1:1).

Khellol and khellol-glucoside reacted also with *m*-dinitrobenzene and 3,5-dinitrobenzoic acid in the same manner as did khellin and visnagin, although their colored products with 3,5-dinitrobenzoic acid were not extractable with the organic solvent mixture, isobutanol-ether (1:1).

Extraction of the active principles from the powdered fruits was carried out by using chloroform according to a previously described method (4). Horstmann used boiling water, a nonselective solvent leading to the extraction of water-soluble impurities, which necessitated a preliminary purification of the aqueous extract before paper chromatography. The presence of acid aluminium oxide during the extraction step was beneficial; it retained most of the extractive matter other than the chromone constituents (4). In the proposed method, the chloroformic extract was chromatographed (TLC) directly without any need for preliminary purification.

Horstmann effected the separation of khellin and visnagin from *Ammi visnaga* fruit extracts by paper chromatography using filter paper impregnated with polyamide and water-saturated butanol as the developing solvent. In view of the well-known advantages, especially rapidity, of TLC over paper chromatography, the authors of this study resorted to the former technique. Successful separation of khellin and visnagin from the other constituents of *Ammi visnaga* fruits has been achieved on silica gel G plates (3). Contrary to previous findings (5, 6), the authors were not able to achieve complete separation of khellin from visnagin using the solvent systems described. Solvent systems other than those reported in the literature, e.g., chloroform-ethanol-methanol (97:1:2), chloroform-methanol-formamide (90:5:5), and chloroform-methanol-water (90:9:1), were tried and found unsatisfactory. However, two-dimensional TLC on silica gel G plates (Fig. 1), using ethyl acetate as the developing system, offered a better separation of khellin from visnagin than the unidimensional multiple-run technique. This method was used in the quantitative recovery of these two con-

Figure 1—Two-dimensional TLC using ethyl acetate as the developing system.

stituents and their subsequent colorimetric estimation. The results cited in Table I indicate the efficient recovery of khellin (95–98.5%) and visnagin (96.1–103.5%). The ratio of khellin content to visnagin content in the examined fruits and extracts of *Ammi visnaga* was found to range from 1.4:1 to 1.9:1 and from 1.3:1 to 1.6:1, respectively.

Quantitative extraction of khellin from tablets was achieved efficiently by hot ethanol. The *m*-dinitrobenzene colorimetric method could then be applied directly to the suitably diluted ethanolic extract. On the other hand, direct application of this color reaction to complex khellin formulations (e.g., glucolynamine injection) after suitable dilution with ethanol (1:100) was unsuccessful. The results obtained were about 70% of the labeled khellin concentration. Thus the separation of khellin from the other interfering ingredients (theophylline and glucose) was deemed necessary. This was achieved by either chromatographing the chloroform extract on aluminium oxide or recovery of khellin by TLC prior to its colorimetric determination.

Inhibitory Properties of Aminoalkylsuccinimides on Isolated Horse Serum Butyrylcholinesterase: *N*-Methyl-2-phenyl-2-(*tert*-aminoalkyl)succinimides

EDWARD O. MAGARIAN, SAMUEL TERRY CHRISTIAN*, and HARRY C. CLEMONS†

Abstract □ The butyrylcholinesterase inhibitory activities of several *N*-methyl-2-phenyl-2-(*tert*-aminoalkyl)succinimides were evaluated. The derivatives, all of which showed a mixed type of inhibition, were more potent as competitive than noncompetitive inhibitors. The results are discussed in terms of a possible mechanism for the formation of enzyme-inhibitor complexes.

Keyphrases □ *N*-Methyl-2-phenyl-2-(*tert*-aminoalkyl)succinimides—*inhibition*, butyrylcholinesterase □ Butyrylcholinesterase inhibition—aminoalkylsuccinimides □ TLC—analysis

The effectiveness of compounds containing the functional moiety $\text{N}-\text{C}-\text{C}-\text{CO}-\text{N}$ (amino-propionamide) as inhibitors of serum cholinesterase (acetylcholine acylhydrolase, E.C. 3.1.1.8) has been demonstrated (1–6). Several structural parameters have been investigated for possible correlations with potency of enzyme inhibition. For example, Lasslo *et al.* (3) found a direct relationship between the length of the alkyl chain in 3-(1-alkylpiperidyl)carboxamides and their ability to inhibit plasma cholinesterase (PChE), and Beasley and Williford (5) observed that the introduction of aralkyl groups between the two ring nitrogen atoms in bis(3-piperidinecarboxamides) increases the inhibitory potency of these compounds.

The influence of amino substituents on the rates of hydrolysis of certain pseudocholinesterase substrates has also been investigated. Holmstedt and Sjoqvist (7) reported that the introduction of an amino group in butyrylcholine, the optimum substrate for pseudocholinesterase, to give γ -aminobutyrylcholine strongly inhibits its hydrolysis by this enzyme. Beckett *et al.* (8) reported that benzoylcholine has a greater affinity than butyrylcholine for PChE, even though it is hydrolyzed at only 15% of the rate of butyrylcholine. Prompted by the reported effect of the amino group in γ -aminobutyrylcholine, they evaluated *p*-aminobenzoylcholine and found that it not only has a greater affinity for the enzyme than does benzoylcholine, but it is a more potent inhibitor of the hydrolysis of butyrylcholine and acetylcholine.

Recently, the preparation of several *tert*-aminoalkylsuccinimides (Structure I) was reported (9). These compounds embody structural features resembling not only those in the 3-piperidinecarboxamides but also those in γ -aminobutyrylcholine and *p*-aminobenzoylcholine.

Interest in the influence of amino substituents on cholinesterase-inhibitor interactions prompted the authors to investigate the cholinesterase-inhibitory properties of these succinimides. In the present report, some preliminary data are presented and discussed.

MATERIALS AND METHODS

All reagents and derivatives used in this study were of analytically pure grade or equivalent. These include acetylcholine chloride¹ and horse serum butyrylcholinesterase (acetylcholine acylhydrolase, E.C. 3.1.1.8) in the form of a lyophilized powder.² The succinimide derivatives were synthesized according to the procedures of Clemson *et al.* (9).

All the inhibitors were shown to be pure by TLC on silica gel, using various concentrations of absolute ethanol in benzene as the developing solvents (Table I).

Enzyme rate measurements were carried out potentiometrically with butyrylcholinesterase using a Radiometer automatic titrator (Type TTTlc) equipped with a recorder (SBR2c) and a syringe buret unit (SBU1a). Enzyme initial-velocity measurements were recorded at pH 7.40 ± 0.05 in a 25-ml. thermostated vessel at $27.0 \pm 0.10^\circ$. All reactions were run under a nitrogen atmosphere using a combination glass-calomel electrode (GK2026c), mechanical stirring, and 0.01 *N* sodium hydroxide as the titrant. The titration procedure is essentially the method developed by Stein and Laidler (10) in their studies on the kinetics of α -chymotrypsin. The reaction mixtures were 0.04 *M* in magnesium chloride and 0.01 *M* in sodium chloride and contained substrate, inhibitor, and 0.11 mg. of enzyme.³ The reaction mixtures, both control and with inhibitors, were preincubated for 5 min. at 27° prior to the initiation of the reaction by the addition of substrate. This preincubation time did not affect the initial rate measurement under the experimental conditions. Six substrate concentrations ranging from 7.7×10^{-3} *M* to 2.2×10^{-3} *M* (each differing by 1.1×10^{-3} *M*) were employed. The total reaction volume was 15 ml. At least two or more inhibitor concentrations were used, and the resulting data were plotted according to the method of Lineweaver and Burk (11). Data on the inhibitor dissociation constants were calculated from these plots (Fig. 1) according to a method described by Krupka (12). The final competitive (K_I) and noncompetitive (K_I') inhibitor dissociation constants are averages of at least two corresponding and independent determinations.

RESULTS AND DISCUSSION

The cholinesterase inhibitory potencies of the title compounds are shown in Table I. A typical plot used in determining the competitive (K_I) and noncompetitive (K_I') inhibitor dissociation constants for one of the inhibitors appears in Fig. 1. All of the com-

^a As an index of purity, all compounds were chromatographed on Eastman Silica Gel Chromagram Sheets (6061), using solutions of absolute ethanol in benzene as developing solvents.

pounds in this study displayed a mixed type of inhibition (13), thus indicating the presence of a competitive and a noncompetitive component. This suggests that the inhibitors are binding both at the active site (competitive) and at a peripheral site (noncompetitive).

The aminoalkyl derivatives of *N*-methyl-2-phenylsuccinimide are significantly more potent inhibitors of butyrylcholinesterase than is the parent compound (Table I). This is reflected by their lower competitive and noncompetitive inhibitor dissociation constants. However, it should be noted that these amino derivatives are more effective as competitive than as noncompetitive inhibitors. Discussion of the data will be limited to the competitive component, since it is this component that directly interferes with the binding of substrate.

It is apparent from Table I that there is no correlation between potency of inhibition and length of alkyl chain between the carbonyl carbon and the tertiary nitrogen. Indeed, the lengths of the chains in Compounds 4 and 7, the most potent inhibitors of the series, differ by one methylene group. This is in contrast to the observed effect in the piperidinecarboxamide series. The 4-piperidinecarboxamides, which contain three carbon atoms between the carbonyl carbon and the nitrogen atom, are less potent inhibitors than their 3-isomers, which contain only two (4). In the succinimide series, the aminoalkyl side chain is flexible and may, therefore, assume various conformations to accommodate the steric requirements of the active site on the enzyme. However, this is not possible in the piperidinecarboxamides since the aminoalkyl group, being part of the piperidine ring, is held in a rigid conformation.

From the results reported by Holmstedt and Sjoqvist (7), it would appear that the introduction of an amino group in butyrylcholine to give γ -aminobutyrylcholine induces a change in its mode of binding to butyrylcholinesterase. This modification of the substrate molecule may result in an improper orientation of the ester group at the esteratic site and, thereby, produce a reduction in the rate of hydrolysis. To illustrate this hypothesis, one may assume that the conformation of butyrylcholine in Fig. 2a is required for maximum hydrolysis. Then, as a consequence of an interaction between the amino group and a complementary group at Site A' (Fig. 2b), γ -aminobutyrylcholine may assume a slightly different conformation. The resulting conformational change of the ester moiety at the esteratic site (Site B) may be unfavorable for maximum hydrolysis. This effect is analogous to the apparent disturbance of an "ideal fit" between the enzyme and substrate by α - and β -methyl groups in butyrylcholine (8).

From all indications, binding of benzoylcholine and *p*-aminobenzoylcholine to the enzyme is similar to that for butyrylcholine and γ -aminobutyrylcholine (8). Benzoylcholine has a greater affinity but a lower hydrolytic rate than does butyrylcholine. The hydrophobic interactions of the phenyl ring of benzoylcholine with Area A (Fig. 2) would explain this increase in binding energy and would also tend to explain the decreased rate of hydrolysis due to an accompanying change of conformation of the ester group at Site B (esteratic site). The additional binding energy reported by Beckett *et al.* (8) in *p*-aminobenzoylcholine strongly suggests that the amino substituent further contributes to the affinity of the molecule for the enzyme by bonding with a complementary group at Site A.

It would seem probable that the interaction between the aromatic amino substituent in *p*-aminobenzoylcholine and a complementary

Figure 1—Mixed inhibition of horse serum cholinesterase (butyrylcholinesterase) by *N*-methyl-2-phenyl-2-(2-diethylaminoethyl)succinimide (Compound 7, Table I). Abscissa, reciprocal molar acetylcholine chloride concentration; ordinate, reciprocal enzyme initial velocity. Velocity is expressed in $\mu\text{moles of acetylcholine hydrolyzed/min./mg. of protein.}$

Figure 2—Concept of differences in conformations of butyrylcholine (2a) and γ -aminobutyrylcholine (2b) at the substrate binding site of butyrylcholinesterase. Key: A = nonpolar area; A' = complementary area in A which interacts with amino group; B = esteratic site; and C = "anionic" site.

group on the enzyme is not ionic in nature. Esters of *p*-aminobenzoic acid are weakly basic, *e.g.*, pK_s of ethyl *p*-aminobenzoate is 10.84 (14) and, consequently, the existence of the conjugate acid of *p*-aminobenzoylcholine at physiological pH would be negligible. Thus, it would appear that hydrogen bonding or dipolar interactions are more likely involved. However, in the case of γ -aminobutyrylcholine, its conjugate acid would be quite significant at physiological pH and could, therefore, enter into H-bond or ion dipole formation at Site A.

The mode of competitive binding of *N*-methyl-2-phenylsuccinimide (Compound 11, Table I) and its derivatives may be visualized as being analogous to those for butyrylcholine, benzoylcholine, and their amino derivatives. In this case, however, the imide function is pictured as complexing with the esteratic site. The interaction of amide moieties with esteratic sites of cholinesterases has already been proposed by several investigators (4, 6, 15). The aromatic ring, like that in benzoylcholine, may be involved in hydrophobic interactions with Site A and may, thereby, exert a directing influence in the formation of the enzyme-inhibitor complex. The increase in binding energies of the aminoalkylsuccinimide derivatives may be attributable to an additional interaction between the amino substituents and an appropriate group at Site A.

The data presented in this report on the inhibitory properties of some *tert*-aminoalkylsuccinimides are consistent with the hypothesis advanced to explain the interactions of γ -aminobutyrylcholine and *p*-aminobenzoylcholine with butyrylcholinesterase. From a study on the inhibitory properties of a series of 1-substituted 3-piperidinecarboxamides, Beasley *et al.* (6) offered an alternate explanation for the interaction of amino groups with the active site of butyrylcholinesterase. They suggested that the amide function binds at the esteratic site while the nitrogen atom of the piperidine ring binds at the "anionic" site (Site C, Fig. 2). There is no definitive evidence at the present time that discounts either of these hypotheses. Perhaps both modes of binding are operative. The real significance of these proposed mechanisms must await further experimentation.

Antimalarial Properties of a Variety of Substituted *p*-Sulfamoylphenylazo Compounds

R. E. HARMON, B. L. GELLER, S. K. GUPTA, M. H. HERBERT, and D. CHITHARANJAN

Abstract □ A wide variety of substituted *p*-sulfamoylphenylazo compounds were prepared, and their activity against *Plasmodium berghei* in mice was studied. A study of the effects of substitution in the sulfamoyl group revealed that substitution by pyrimidine, methylpyrimidine, and hexylresorcinol greatly increased the antimalarial activity, while substitution by thiazole, methylthiazole, and 2-methyl-3,4-thiadiazole did not lead to a comparable increase in activity. The least activity was seen in compounds with 2-pyridyl as the substituent. Coupling compounds derived from sulfa drugs, hexylresorcinol, and 1,3-dimethyl-6-aminouracil were either active or curative at lower doses than the remainder of the compounds evaluated. With pyrimidine as the substituent, an amino group in position 4 or 5 was necessary for antimalarial activity. It was also found that coplanarity is not an essential structural requirement for antimalarial activity.

Keyphrases □ *p*-Sulfamoylphenylazo compounds, substituted—antimalarial properties evaluated □ Antimalarials, evaluation—*p*-sulfamoylphenylazo compounds □ UV spectrophotometry—identification, structure □ IR spectrophotometry—identification, structure

Since Lythgoe *et al.* (1) found that azo coupling occurs in the 5-position of the pyrimidine ring, various substituted 5-arylazopyrimidines have been synthesized and their mode of action in various biological systems studied (2). It was found that at least one amino group adjacent to the arylazo link is necessary for optimum

activity and that the aryl group should be unsubstituted or contain electron-releasing substituents for maximum biological activity (3–5). The inhibitory actions of 5-phenylazo-2,4,6-triaminopyrimidine and 5-phenylazo-2,4-diamino-6-hydroxypyrimidine were unaffected by most bases and nucleotides involved in nucleic acid synthesis. This finding, in conjunction with the findings of Roy-Burman and Sen (5) that the inhibitory effects of arylazopyrimidines in the *Streptococcus faecalis* (ATCC 8043) system could be more efficiently reversed by 5-formyltetrahydrofolic acid than by folic acid itself, would seem to indicate that arylazopyrimidines may act as folic acid antagonists and interfere with the enzymatic conversion of folic acid to 5-formyltetrahydrofolic acid. Recent work by Hampshire *et al.* (6) on the inhibitory effects of 5-arylaazo-2,4,6-triaminopyrimidines on folic acid reductase from rat liver indicates that these compounds exhibit a wide range of activities, depending on the aryl substituent. There is a strong indication that some sulfonylphenylazo compounds have a high synergistic effect when used in combination therapy (7).

The reactions of various diazotized sulfa drugs with hexylresorcinol, 2,6-diaminopyridine, 3-phenylazo-2,6-diaminopyridine, 1-phenyl-3-methyl-5-pyrazolone, 1-phenyl-3-carbethoxy-5-pyrazolone, and several substituted pyrimidines were studied as an extension of the authors' earlier investigation (2) of the antimalarial

and anticancer properties of arylazopyrimidines. The structures and activities of the compounds are shown in Tables I–VIII.

EXPERIMENTAL

All melting points were determined using a Thomas-Hoover Unimelt apparatus. All the compounds melted with decomposition at or around the temperatures indicated in the tables. The UV spectra were determined by dissolving 10 mg. of the compound in 500 ml. of 1% sodium hydroxide solution. Spectrophotometers (Beckman model DB and Cary model 14) were used to determine the UV spectra. The IR spectra were obtained from mineral oil (Nujol) mulls on a Beckman IR-8 spectrophotometer.

The general procedure for the preparation of substituted *p*-sul-

famoylphenylazo compounds was as follows. All the compounds were synthesized using procedures analogous to those previously reported in the literature (2). In a typical preparatory method, 0.05 mole of the sulfonamide drug was dissolved in 100 ml. of 3 *N* HCl. On cooling to –5°, the amine hydrochloride was precipitated. It was diazotized by adding 0.05 mole of NaNO₂ in 25 ml. of H₂O. The temperature was maintained at 0°. The pyrimidine (0.05 mole) was dissolved in 3 *N* HCl and cooled to –5°; the solution of the diazonium salt was added to it slowly and with stirring. The addition took about 20 min. The temperature was maintained at 10° for 1 hr. and then at room temperature for 12 hr. A thick slurry containing the *p*-sulfamoylphenylazo compound as a bright-yellow or orange solid formed. The azo compound was filtered, washed with 95% EtOH, and recrystallized from boiling 2-ethoxyethanol. The compounds were analyzed for C, H, and N and were within the normal limits.

RESULTS AND DISCUSSION

IR Spectra—The IR spectra were not very useful in characterizing the azo linkage in arylazopyrimidines, since its absorption was ob-

^{a,b,c} See Table I.

scured by the strong absorption of the pyrimidine ring at 1600 cm.⁻¹. The absence of hydroxyl absorptions indicates that these compounds might exist in the tautomeric form (9, 10). In addition, the spectra showed medium to strong absorption bands characteristic of the pyrimidine and benzene rings at 1575 and 1625 cm.⁻¹, respectively; strong absorption bands at 1159 and 1320 cm.⁻¹ (—SO₂NH when present); medium to strong bands at 3100–3300 cm.⁻¹ (NH₂); and medium bands at 800–869 cm.⁻¹ (*p*-substituted benzene). These assignments are consistent with the assignments made by Bellamy (11) and Rao (12) for analogous compounds.

UV Spectra—Most of the substituted *p*-sulfamoylphenylazo compounds reported in Tables I–VIII were insoluble in common organic solvents such as ethanol, methanol, chloroform, and carbon tetrachloride. Therefore, they were dissolved in a 1% sodium hydroxide solution for determining the UV spectra. The UV spectral data for all the compounds are listed in Tables I–VIII. A majority of the compounds had two main UV absorption maxima around 400 and 250 mμ. In some cases the absorption maxima were shifted to about 500 and 300 mμ. But it was not possible to draw any definite conclusions about the structures and their UV absorptions.

Antimalarial Activity—All the compounds mentioned in this manuscript were tested for biological activity.¹ The effects of substitution on the antimalarial activity of a series of substituted *p*-sulfamoylphenylazo compounds are shown in Tables I–VIII. A study of the effects of substitution in the sulfamoyl group revealed an interesting pattern of activity. In general, substitution by pyrimidines and methylpyrimidines greatly increased the antimalarial activity, while substitution by thiazole, methylthiazole, and 2-methyl-3,4-thiadiazole did not lead to a comparable increase in activity. The lowest activity was observed in compounds with 2-pyridyl as the substituent.

The greatest activity was observed in the sulfamoyl compounds derived from 3-phenylazo-2,6-diaminopyrimidines (Table III). The next order of activity was seen in compounds derived from hexylresorcinol and 1-phenyl-3-methyl-5-pyrazolone. Coupling compounds derived from sulfa drugs, hexylresorcinol, and 1,3-dimethyl-6-aminouracil were either active or curative at lower doses than the other compounds evaluated. The substituent on the sulfamoyl group did not appear to exert a consistent effect on the antimalarial activity in changing from one group to the other. In the case of the pyrimidines, it has been observed that an amino group in position 4 or 5 is necessary for antimalarial activity.

It has been shown that substitution by an alkyl or aryl group in the 6-position of a 5-phenylazopyrimidine gives rise to a nonplanar

configuration of the pyrimidine and benzene rings (13). Since 2,4-diamino-5-(2-chlorophenyl)pyrimidine is an antimalarial of relatively low potency (13), lack of coplanarity is not the sole requirement for antimalarial activity. This is clearly substantiated by the observation that coupling compounds derived from 1-phenyl-3-methyl-5-pyrazolone and 1-phenyl-3-carbomethoxy-5-pyrazolone were found to have significant, if not curative, antimalarial activity. These compounds probably are noncoplanar since the carbon-to-nitrogen bond distance is shorter than the carbon-to-carbon bond distance. Osden *et al.* (8) essentially brought forth the same point of view in their work on the antimalarial activity of 2,4,7-triamino-6-*ortho*-substituted arylpteridines.

Dissolution Behavior of Commercial Tablets Extemporaneously Converted to Capsules

PRAFUL T. SHAH and WILLIS E. MOORE*

Abstract □ While conducting double-blind clinical trials, it is a common practice to convert a commercial tablet dosage form to a capsule so that it may serve as a control drug for the new drug under test. This report will show that when this was done, the *in vitro* dissolution times of drugs from the capsule dosage forms were strikingly prolonged. Various capsule adjuvants were examined, attempting to decrease dissolution times of drugs from capsules. Of the series tested, lyophilized glycine had the best positive effect in shortening the dissolution times of all drugs examined.

Keyphrases □ Dissolution behavior—commercial tablets converted to capsules □ Dissolution rates—effect of starch □ Starch—effect on dissolution

During both single- and double-blind clinical studies, a commercial tablet dosage form is frequently altered to a capsule dosage form (1). The alteration to a capsule from a tablet is usually accomplished by grinding the commercial tablet to a granular or fine powder and then adding a sufficient amount of a physiologically inert capsule adjuvant to prepare extemporaneously a capsule dosage form which is identical in appearance to the research drug.

It was of interest to study any effect on the dissolution process brought about by the conversion of commercial tablet dosage forms to extemporaneously prepared capsule dosage forms. Further, it was of interest to observe the overall effect of certain capsule adjuvants on the dissolution process with the objective of perhaps decreasing the dissolution times of drugs from a capsule formulation.

A drug's dissolution rate and *in vivo* physiological availability have been the subjects of extensive research in the pharmaceutical sciences (2–6). In a recent paper, Withey and Mainville (7) referred to various methods and apparatus for following dissolution rates. They also pointed out some important requirements for an adequate dissolution-rate test.

For this preliminary investigation, the dissolution characteristics were measured by a procedure that involved the use of a modified capsule holder designed by Paikoff and Drumm (8). For comparative purposes, T_{90} values (time required for 90% to dissolve) were obtained for three chemically different types of drugs: (a) acetylsalicylic acid,¹ (b) diphenhydramine,² and (c) meprobamate.³

EXPERIMENTAL

Equipment—The capsule holder-stirrer had two glass blades with a platinum wire loop attached at the bottom to hold various size

capsules. The stirrer was attached to a Heller stirrer (model No. GT 21).

Procedure—A 500-ml. quantity of dissolution medium (deionized water) in an 800-ml. beaker was maintained at $37 \pm 0.5^\circ$ in a temperature-controlled bath. The dosage form was introduced into the medium by attaching it to the stirrer loop and then inserting the assembled unit into the beaker at a controlled height from the bottom. Constant preselected rotational speeds of 60–200 r.p.m. were used for each of the three different drugs. Aliquots for assay were withdrawn with a sampling pipet at appropriate time intervals. After each sample removal, fresh medium was added back to the dissolution test beaker to maintain a constant volume.

The methodology described was suitable for capsules and tablets of acetylsalicylic acid and for diphenhydramine, but it had to be modified for the testing of meprobamate tablets and capsules to prevent flotation of capsule fragments and larger aggregates. A stainless steel wire net (20 mesh) resting on the bottom of the dissolution test beaker was used to hold the tablets and capsules of meprobamate. The glass stirrer without the loop was used.

There was no intention of comparing the dissolution characteristics between drugs. What was examined was the dissolution characteristics of commercial tablets and those tablets after conversion to a capsule dosage form, using the equivalent methodology for both forms.

The acetylsalicylic acid samples were hydrolyzed, and the absorbance of salicylic acid was measured at $294 \text{ m}\mu$ with the Beckman DK-2A (9). Diphenhydramine was assayed by two methods, one a conductometric method in the absence of glycine and the other a spectrophotometric method using a wavelength of $277 \text{ m}\mu$. The meprobamate was assayed according to the method of Maggiorelli (10) with a modification that included using an acetic anhydride and glacial acetic acid mixture to dissolve the evaporated residue from the chloroform-carbon tetrachloride (1:1 v/v) extract (11).

Preparation of Capsules—The capsules were prepared from uncoated commercial tablets (standard compressed tablets) by grinding the tablets to a powder (through 40 mesh) with a mortar and pestle. Sufficient amounts of various capsule adjuvants were added to the powder and mixed well, and the diluted powder was packed into an appropriately sized hard gelatin capsule (Table I).

RESULTS AND DISCUSSION

The conversion of a tablet to a capsule dosage form did bring about a marked change in the *in vitro* dissolution times of all three drugs studied (Tables II–V). Without exception, the capsule dosage form containing starch took a much longer time to release 90% of its contents than did the tablet dosage form. This phenomenon, since it was observed with three different chemical types of drugs, should be more extensively studied and the results called to the attention of designers of clinical trials because of its frequency of occurrence in blind studies. Slowing down the dissolution rate of a commercial drug used as a control in a clinical trial could severely bias the results of such trials.

The materials used as diluents to prepare the capsules (starch, urea, and various forms of glycine, Table I) had varying effects upon the dissolution times. The lyophilized form of glycine had outstandingly beneficial effects upon the dissolution times of all three chemical types of drugs (Tables II–V).

The data reported in Tables II–V are abstracted from the total experimental data developed in this study. To conserve space, data falling into sampling intervals not covered by the table have been omitted. For example, Product D, Table II, had the following experimental sampling intervals in minutes: 3, 6, 10, 12, 15, 18, and 23. Since this inclusive table has only Columns 10 and 15, the data at only these matching times are included. The minimum number of

^a Product A consists of commercial tablets. ^b Number in parenthesis indicates size of capsules.

sampling intervals for any product was 4, the maximum was 13, and the average was 6 data points. The data reported are the averages of three experimental dissolution studies on each product.

After each dissolution test, orders were estimated as either an apparent first- or zero-order process after the various plots had linearized following a short, but variable, lag time. Least-squares regression lines were calculated; from the appropriate values for the equation, the T_{90} values were calculated. No special significance is claimed for any of the apparent first or zero orders reported.

Wagner (12) has suggested that apparent dissolution-rate orders are artifacts at best. This technique was used only to obtain a value to serve as a basis for the comparison of the dissolution behavior of a tablet and its extemporaneously prepared capsule.

Starch is frequently used as a disintegrating or a wet binding agent in tablet formulations. By identity test, each of the three commercial tablet formulations contained starch in varying amounts. When additional starch was added to the ground-up tablet, it did not visibly show any disintegrant or dispersing effect upon the

Mechanism of Action of Salicylates VIII: Effect of Topical Application of Retinoic Acid on Wound-Healing Retardation Action of a Few Anti-Inflammatory Agents

K. H. LEE and THEODORE G. TONG

Abstract □ Oral administration of phenylbutazone, oxyphenbutazone, mefenamic acid, flufenamic acid, or indomethacin, like salicylates or corticosteroids, retards skin wound healing in rats. The healing inhibitory action of any one of these anti-inflammatory agents can be reversed by local application of retinoic acid.

Keyphrases □ Retinoic acid, topical application—inhibition of wound-healing retardation of anti-inflammatory agents □ Anti-inflammatory agents, wound-healing retardation—retinoic acid inhibition □ Salicylates, wound-healing mechanism—analogy to other anti-inflammatory agents

Recently, it has been shown that oral administration of acetylsalicylic acid, sodium salicylate, or prednisone and topical application of salicylic acid or hydrocortisone in nonionic bases (NIB) retard skin wound healing in rats (1-3). The inhibitory action of

these agents is, at least, partially attributed to their anti-inflammatory action since inflammation is an essential feature in healing. Salicylates also inhibit mucopolysaccharide synthesis, which is also an essential feature in wound healing (2). Intraperitoneal injection of retinol or topical application of retinoic acid can reverse the inhibitory action of these anti-inflammatory agents (2, 3).

Phenylbutazone, oxyphenbutazone, mefenamic acid, flufenamic acid, and indomethacin are a few well-known anti-inflammatory agents. These agents, like salicylates, inhibit mucopolysaccharide synthesis (4). In the present study, it was found that all of these anti-inflammatory agents also retard wound healing, and topical application of retinoic acid can reverse the inhibitory action of these agents.

Mechanism of Action of Salicylates VIII: Effect of Topical Application of Retinoic Acid on Wound-Healing Retardation Action of a Few Anti-Inflammatory Agents

K. H. LEE and THEODORE G. TONG

Abstract □ Oral administration of phenylbutazone, oxyphenbutazone, mefenamic acid, flufenamic acid, or indomethacin, like salicylates or corticosteroids, retards skin wound healing in rats. The healing inhibitory action of any one of these anti-inflammatory agents can be reversed by local application of retinoic acid.

Keyphrases □ Retinoic acid, topical application—inhibition of wound-healing retardation of anti-inflammatory agents □ Anti-inflammatory agents, wound-healing retardation—retinoic acid inhibition □ Salicylates, wound-healing mechanism—analogy to other anti-inflammatory agents

Recently, it has been shown that oral administration of acetylsalicylic acid, sodium salicylate, or prednisone and topical application of salicylic acid or hydrocortisone in nonionic bases (NIB) retard skin wound healing in rats (1–3). The inhibitory action of

these agents is, at least, partially attributed to their anti-inflammatory action since inflammation is an essential feature in healing. Salicylates also inhibit mucopolysaccharide synthesis, which is also an essential feature in wound healing (2). Intraperitoneal injection of retinol or topical application of retinoic acid can reverse the inhibitory action of these anti-inflammatory agents (2, 3).

Phenylbutazone, oxyphenbutazone, mefenamic acid, flufenamic acid, and indomethacin are a few well-known anti-inflammatory agents. These agents, like salicylates, inhibit mucopolysaccharide synthesis (4). In the present study, it was found that all of these anti-inflammatory agents also retard wound healing, and topical application of retinoic acid can reverse the inhibitory action of these agents.

Table I—Retinoic Acid and Healing Retardation Action of a Few Anti-Inflammatory Agents^a

Group	No. of Animals	Drugs Given		Mean Tensile Strength, g.	Percent Control
		Orally	Topically		
I	14	—	NIB	451 ± 9	100
II	9	Indomethacin, 4 mg./kg.	NIB	374 ± 9	83
III	14	Indomethacin, 4 mg./kg.	1% retinoic acid in NIB	433 ± 8	96
IV	7	Mefenamic acid, 20 mg./kg.	NIB	424 ± 9	94
V	16	Mefenamic acid, 40 mg./kg.	NIB	407 ± 7	90
VI	6	Mefenamic acid, 40 mg./kg.	1% retinoic acid in NIB	456 ± 10	101
VII	8	Flufenamic acid, 40 mg./kg.	NIB	398 ± 10	88
VIII	6	Flufenamic acid, 40 mg./kg.	1% retinoic acid in NIB	427 ± 7	95
IX	7	Phenylbutazone, 100 mg./kg.	NIB	403 ± 4	89
X	7	Phenylbutazone, 100 mg./kg.	1% retinoic acid in NIB	427 ± 9	95
XI	7	Oxyphenbutazone, 100 mg./kg.	NIB	385 ± 8	85
XII	6	Oxyphenbutazone, 100 mg./kg.	1% retinoic acid in NIB	439 ± 10	97

^a The difference between the experiments and the controls is highly significant ($p < 0.01$, Student's *t* test) except Group IV animals receiving only 20 mg. of mefenamic acid/kg. ($p < 0.10$).

EXPERIMENTAL

Material and Drugs—The following materials and drugs were used in this study: retinoic acid,¹ phenylbutazone,² oxyphenbutazone,² mefenamic acid,³ flufenamic acid,³ indomethacin,⁴ and NIB.⁵ The strength of retinoic acid used was 1% in NIB. Methylcellulose USP⁶ (400 cps.) was also used.

Administration of Drugs—All drugs were fed to rats daily for 4 days through a short stomach tube (PE 160) connected to a blunt hypodermic needle (No. 17) attached to a 50-ml. syringe, starting 1 day before operation. Each drug was suspended in a 0.5% methylcellulose solution. One milliliter of the suspension was fed to each rat.

Application of Retinoic Acid in NIB—Retinoic acid in NIB was applied with gentle rubbing directly on the sutured wound right after wounding. The application was repeated, once a day, on the 1st and 2nd days of wounding. For the control, only NIB was applied.

Wound Procedure—Sprague-Dawley male rats, weighing 230–240 g., were anesthetized with ethyl ether in an open mask. The hair on the back was depilated with an electric clipper. One incision, 6 cm. in length, was made through the skin and cutaneous muscles at a distance about 1.5 cm. from the midline on each side. No ligatures were used. Bleeding usually ceased after a few minutes. The incisions were closed with continuous through-and-through sutures with stitches 0.5 cm. apart. Black silk surgical thread (No. 3–0) and a curved needle (No. 19) were used. The continuous suture was pulled tight enough to secure good adaptation of the wound edges. The wounds were left undressed.

Measurement of Healing—Tensile strength, the force required to open a healing skin wound, was used to measure healing. On the 7th day after wounding, the tensile strength of the wound was measured with a simple laboratory-made tensiometer as described previously (1).

RESULTS AND DISCUSSION

The results of the effect of phenylbutazone, oxyphenbutazone, mefenamic acid, flufenamic acid, and indomethacin on skin wound healing in rats are summarized in Table I. The mean tensile strength of the healing wound of the control animals from Group I was 451 ± 9 g. These animals received only topical application of NIB. Group II animals received 4 mg. of indomethacin/kg. of body weight orally, and the mean tensile strength of the healing wound was reduced to 374 ± 9 g., which is 83% of the control. Group III animals were treated the same way as Group II except that 1% retinoic acid in NIB was applied to the wound once a day during the first 3 days of wounding. The mean tensile strength of Group III animals was increased to 433 ± 8 g. Group IV animals received 20 mg. mefenamic acid/kg. of body weight orally; the mean tensile strength of these animals was 424 ± 9 g., which is not appreciably less than the control. An increased dosage of 40 mg. of mefenamic acid/kg. of body weight was used to feed Group V animals. The mean tensile strength of Group V animals was significantly reduced to 407 ± 7 g. Group VI animals received the same treatment as Group V animals except that retinoic acid was topically applied to the wound as described for Group III animals. The mean tensile strength of Group VI animals was increased to 456 ± 10 g. Group VII animals received 40 mg. of flufenamic acid/kg. of body weight, and the mean tensile strength was reduced to 398 ± 10 g. The reversal of wound-healing retardation action of flufenamic acid by local application of retinoic acid was demonstrated by the increase of mean tensile strength in Group VIII animals. Group IX animals received 100 mg. of phenylbutazone, and Group XI animals received a dosage of 100 mg. of oxyphenbutazone. The mean tensile strengths of Groups IX and XI were reduced to 403 ± 4 and 385 ± 8 g., respectively. Groups X and XII demonstrated that the local application of retinoic acid reverses the wound-healing inhibitory action of phenylbutazone and oxyphenbutazone.

Inflammation and mucopolysaccharide synthesis are the two known essential features in wound healing. Phenylbutazone, oxyphenbutazone, mefenamic acid, flufenamic acid, and indomethacin, like salicylates, prednisone, and hydrocortisone, are anti-inflammatory agents. They are also potent inhibitors to mucopolysaccharide synthesis at the site where uridine-5'-diphosphoglucose is oxidized to UDPGA, as reported recently (5). These anti-inflammatory agents, therefore, retard wound healing also by their anti-inflammation activity and their inhibitory action on mucopolysaccharide synthesis.

SUMMARY

The healing retardation action of anti-inflammatory agents, phenylbutazone, oxyphenbutazone, mefenamic acid, flufenamic acid, and indomethacin, has been demonstrated in rats.

Topical application of retinoic acid can reverse the healing inhibitory action of these anti-inflammatory agents.

The mechanism of action of these agents has been discussed.

New Compounds: Some Potential Chemotherapeutic Agents Derived from Aralkyl Ketones

PYARE PARIMOO* and W. LEWIS NOBLES†

Abstract □ The Mannich reaction has been successfully applied to some aralkyl ketones, valerophenone and caprophenone, and their substituted derivatives in efforts to find efficient agents to be screened for possible CNS stimulant, analgesic, or antispasmodic activity. The aminoketones (Mannich bases) were converted to the γ -amino secondary alcohols by treatment with sodium borohydride. The synthesis of a series of γ -amino tertiary alcohols was achieved by the application of the Grignard reaction to the corresponding Mannich bases. The last section of the study involved the preparation of γ -amino alkyl esters from the corresponding secondary and tertiary alcohols.

Keyphrases □ Chemotherapeutic agents—aralkyl ketone derivatives, synthesis □ Aralkyl ketone derivatives—synthesis, structure-activity relationships □ Mannich reaction—synthesis □ Grignard reaction—synthesis

The significant action of pyrovalerone hydrochloride (I) as a CNS stimulant has been reported (1):

In view of this activity, the authors undertook the synthesis and study of aminoketones having the following structure (II):

Am = substituted amino group
R = aryl group or substituted aryl group
n = 2, 3

To investigate a possible structure-activity relationship, a number of analogs and derivatives were prepared. Recorded in the literature (2-5) are numerous ketonic Mannich bases prepared for pharmacological

testing, such as antispasmodic, analgesic, local anesthetic, or chemotherapeutic agents. From the correlation of the chemical structure of these ketones with their antispasmodic activities, the following conclusions were drawn: (a) Activity is enhanced by the introduction of a phenyl group into the α -position of the propiophenones. (b) The piperidyl group was the most active amino group, while the morpholino group was the least active amino moiety. (c) Simple substituents in the p -position of the aromatic rings of the propiophenones decreased activity (5). Since some of the structural modifications in these various ketones had an effect on the physiological activity, the transformation of the ketones to the corresponding alcohols might possibly have a greater effect; also the amino alcohols are generally much more stable than the corresponding ketones (6). Lutz *et al.* (7) have reported the preparation and screening of 184 amino alcohols against avian malaria. The general structure (III) of the secondary alcohols is represented as follows:

These compounds included examples of 50 variations in the benzene nucleus and over 60 variations in the N,N -dialkyl groups on the nitrogen. The change in activity with variation in chemical structure led Denton *et al.* (8) to prepare more than 100 γ -amino tertiary alcohols; a majority of them have exhibited pharmacological activity. The general structure (IV) of the amino tertiary alcohols prepared by these workers is reported as follows:

where R is usually aryl; R' is alkyl, cycloalkyl, or aryl; and the amino group is, most commonly, dimethyl amino, pyrrolidino, piperidino, and morpholino.

Compounds in which $n = 1$ or 3 usually showed reduced antispasmodic activity. The compound trihexyphenidyl hydrochloride (Artane, Lederle Laboratories), prepared by Cunningham (9), was found to be a potent antispasmodic. The pyrrolidine homolog (Kemadrin, Burroughs Wellcome & Co.) was prepared by an analogous procedure. In large doses, these compounds stimulated the CNS in a manner similar to that of atropine.

A number of esters of 4-dialkyl amino-1,2-diphenylbutanol have been reported to possess a high order of analgesic activity in animals (10). One of these isomers, dextropropoxyphene (Darvon, Eli Lilly and Co.), has been found to be an effective analgesic in human beings (11). In view of these studies, the authors decided to prepare some related open-chain esters. The general

structure (V) of the aminoalkyl esters is represented as follows:

DISCUSSION

The first group of compounds described in this research is related to the CNS stimulant pyrovalerone hydrochloride, Compound I; the structures described in Tables I–III represent, in a general way, the variations applied to the antispasmodic and analgesic agents. In any event, the analogy of pyrovalerone hydrochloride to Type II compounds does not seem remote. Upon inspection of molecular models, certain points of resemblance stand out and the spatial similarity of pyrovalerone hydrochloride becomes

apparent. 2-(1-Pyrrolidino methyl)-4'-methyl valerophenone hydrochloride (Compound 6, Table IV) bears a strong resemblance to pyrovalerone hydrochloride. A practical variation of this compound in which the methyl group on the aromatic nucleus was replaced by a methoxy group and also the introduction of an acetoxy methyl in place of the carbonyl group in the alkyl chain has been devised. The acetoxy group may help in favorably altering the distribution of the compound in the animal body and also in increasing the concentrations in the brain. Moreover, such a change as the replacement of the pyrrolidino group by the morpholino group may be effective for the increased activity, possibly because of a certain attraction between the cation head and the unshared pair of electrons on oxygen. The reduction of the keto group to the carbinols may show parallel results, the latter being more stable to the biological reactions.

Aralkyl ketones (valerophenone and caprophenone) and their substituted derivatives were prepared as indicated in the *Experimental* section. The Mannich bases and the corresponding secondary and tertiary alcohols were obtained by modifying the methods in the literature (12-14). The preparation of aminoalkyl esters was patterned after the work of Burckhalter and Johnson (15) and that of Pohland and Sullivan (10). A number of procedures (15-17) and their modifications were attempted to bring about the successful esterification of the tertiary amino alcohols. Each attempt met with failure. An examination of the IR spectrum of each reaction product did not reveal the presence of the characteristic alkyl ester absorption in the region of 1735-1750 cm^{-1} , indicating no reaction had taken place. Similar difficulties in obtaining the acyl derivatives of tertiary amino alcohols have been recorded (13, 18), one of the possible explanations for the failure to bring about this esterification being steric inhibition.

EXPERIMENTAL

Aralkyl ketones were prepared according to the methods described in the literature (19-21).

p-Methyl Caprophenone—Eighty grams (0.06 mole) of *n*-hexanoyl chloride was gradually added to a mixture of 184.0 g. (2.0 moles) of dry toluene and the 131.0 g. (1.0 mole) of powdered anhydrous aluminum chloride. The reaction mixture was stirred for 12 hr. at room temperature and thereafter refluxed for 3 hr. The dark-colored reaction mixture was cooled and then decomposed in a solution of ice and concentrated HCl. The organic layer was separated and washed with 10% NaOH and water, respectively. The product was dried over anhydrous MgSO_4 and distilled at 280° . Redistillation yielded 70.0 g. (40%) of a clear liquid, b.p. 280° . *Anal.*—Calcd. for $\text{C}_{13}\text{H}_{18}\text{O}$: C, 82.01; H, 9.58. Found: C, 82.13; H, 9.41.

Mannich Bases—Three methods were investigated; Procedure A, as will be noted, was the general method for the preparation of the compounds in Table IV.

2-(1-Pyrrolidinomethyl)-valerophenone Hydrochloride—Method A—A solution of 3.35 g. (0.05 mole) of pyrrolidine in 50 ml. of absolute alcohol was cooled and treated with concentrated HCl until the final solution was acidic. Valerophenone (8.10 g., 0.05 mole) and paraformaldehyde (1.80 g., 0.05 mole) were then added and the reaction mixture was refluxed for 8 hr. Two further additions (0.90 g., 0.03 mole) of paraformaldehyde were also made. The solvent was distilled *in vacuo*, and the residue was treated with 30 ml. of water and extracted with ether. The ether portion was discarded. The aqueous layer was made alkaline with 30% NH_4OH and ether extracted. The ether portion was washed with water, dried over anhydrous MgSO_4 , and treated with gaseous HCl, producing an oil. The oil solidified after refrigeration for 48 hr. Recrystallization from benzene yielded 3.0 g. (21%) of white crystals, m.p. $139-140^\circ$.

γ -Amino Secondary Alcohols—2-(1-Morpholinomethyl)-1-(4-methylphenyl)-1-pentan-1-ol Hydrochloride—A solution of 1.10 g. (0.03 mole) of sodium borohydride in 100 ml. of 50% MeOH was cooled to 20° . To this was added gradually a solution of 8.25 g. (0.03 mole) of 2-(1-morpholinomethyl)-4-methylvalerophenone in 50% MeOH with stirring for several hours. The temperature was then raised to $55-60^\circ$ to decompose excess sodium boro-

hydride. The solvent was distilled *in vacuo*. The residue was dissolved in ether and washed with 50-ml. portions of water. The ether portion was dried (MgSO_4) and treated with gaseous HCl, producing a solid product. Recrystallization of HCl salt from ethanol-ethyl acetate mixture yielded 7.0 g. (77%) of product, m.p. 175° .

γ -Amino Tertiary Alcohols—2-(1-Piperidinomethyl)-1,1-Diphenylhexan-1-ol Hydrochloride—This preparation was chosen as a representative of all the Grignard reactions reported in this research. To a solution of 0.06 mole of phenyl magnesium bromide in 100 ml. dry ether was gradually added 5.36 g. (0.02 mole) of 2-(1-piperidinomethyl)caprophenone. The reaction mixture was stirred overnight. The mixture was then decomposed by the dropwise addition of a saturated ammonium chloride solution; the temperature was regulated with an ice bath. The ether solution was decanted from the granular material, and the solid material was washed with 50 ml. of ether. The combined ether solutions were dried (MgSO_4) and treated with gaseous HCl, producing a sticky mass which solidified after refrigeration for 24 hr. Recrystallization from methanol-ethyl acetate mixture yielded 3.5 g. (42%) of product, m.p. $210-211^\circ$.

New Compounds: Structural Analogs Related to Asarone and Mescaline

B. S. R. MURTY and R. M. BAXTER

Abstract □ The synthesis and spectral data of a series of trimethoxyphenyl derivatives related to asarone and mescaline are reported.

Keyphrases □ Asarone, mescaline trimethoxyphenyl derivatives—synthesis □ Mescaline, asarone trimethoxyphenyl derivatives—synthesis □ TLC—identification □ UV spectrophotometry—structure, analysis □ IR spectrophotometry—structure, analysis □ NMR spectrophotometry—structure, analysis

Various types of biological activity have been reported for trimethoxyphenyl derivatives. Initially, knowledge regarding the pharmacological activity in trimethoxybenzene derivatives came with the isolation and determination of the chemical structure of mescaline, a potent hallucinogenic agent. Dandiya and Menon (1-3) demonstrated the promising tranquillizing properties of asarone, an active principle isolated from *Acorus calamus* by Baxter *et al.* (4, 5). Although asarone (2,4,5-

trimethoxy-1-propenyl benzene) and mescaline (3,4,5-trimethoxy-β-phenethylamine) exhibit a structural resemblance, they manifest more or less opposite pharmacological actions. This led the authors to synthesize a series of compounds in an attempt to establish the structural characteristics that influence the pharmacological activity toward one type or the other. The synthesis and spectral data for one series of compounds are reported. The results of pharmacological evaluation and the associated structure-activity relationships will be communicated subsequently.

EXPERIMENTAL

Synthesis—The carbonyl compound (1 mole) was added to ethylmagnesium bromide (1.6 moles) in tetrahydrofuran (THF) in a flask fitted with a reflux condenser and stirring arrangement. The addition products formed were isolated and purified by standard procedures. The physical and spectral data for six compounds are presented in Tables I and II.

New Compounds: Demethylated Methocarbamol

C. M. DARLING* and E. K. ROSE

Abstract □ Two isomeric monocarbamates of 3-(*o*-benzyloxyphenoxy)-1,2-dihydroxypropane and 3-(*o*-hydroxyphenoxy)-1,2-dihydroxypropane were synthesized. The structural assignments are supported by spectral data.

Keyphrases □ Demethylated methocarbamol derivatives—synthesis, structure determination □ Methocarbamol metabolites—synthesis, structure determination □ NMR spectroscopy—structure, identification

Baizer *et al.* (1) have presented rigorous proof of the structure of some isomeric monocarbamates of 1,2-dihydroxy-3-aryloxypropanes by independent unequivocal synthesis. In a later paper, Swidinsky *et al.* (2) reported the preparation of two isomeric monocarbamates of 3-(*o*-hydroxyphenoxy)-1,2-dihydroxypropane, Compounds III and IV, by catalytic debenzyla-tion of Compounds I and II. However, their tenta-tive structural assignments differ from those reported here.

This work was prompted by a need for one of the metabolites (Compound III) of methocarbamol.¹ It is shown that the isomeric monocarbamates can be identified by spectral data. The results of a single run indicate that the major product of the reaction of ammonia with the cyclic carbonate, 4-(*o*-benzyloxy-phenoxy)methyl)-1,3-dioxolone-2, is a primary car-bamate (Compound I) and the minor product is a secondary carbamate (Compound II). The isomeric compounds and their melting-point values are shown in Table I.

The NMR spectra of the isomeric pairs (I, II and III, IV) taken in dimethyl sulfoxide-*d*₆ exhibit signifi-cant and distinguishing differences. Compound II clearly must have the secondary carbamate structure

as shown by the splitting of the primary hydroxyl proton into a triplet (δ 4.90; J = 5.5 cps.)² by the ad-jacent methylene group, rather than a doublet as ex-pected for a secondary hydroxyl proton. In addition, the methylene protons, CH₂OH, adjacent to the hy-droxyl group are coupled by approximately the same coupling constant (5.5 cps.) to the OH proton and the adjacent methine hydrogen, giving rise to a triplet (δ 3.67) which collapses to a doublet on deuteration.

The isomeric Compound I in dimethyl sulfoxide-*d*₆ shows only a single unsplit hydroxyl peak³ with all five aliphatic hydrogens appearing under a broad dis-torted doublet centered at δ 4.1. Acetylation of the hydroxyl group, however, shifts the secondary methine absorption approximately 1.3 p.p.m. down-field,⁴ supporting the primary carbamate structure for Com-pound I.

The NMR structural assignments are supported by the fact that the comparable features of the spectra of I and II are nearly identical to those of the related analogs of known structure (1), 3-(*o*-methoxyphenoxy)-2-hydroxy-1-propyl carbamate and 3-(*o*-methoxy-phenoxy)-1-hydroxy-2-propyl carbamate, respectively.

EXPERIMENTAL⁵

The method of Swidinsky *et al.* (2) was used for the preparation of 4-(*o*-benzyloxyphenoxy)methyl)-1,3-dioxolone-2.

3-(*o*-Benzyloxyphenoxy)-2-hydroxy-1-propyl Carbamate (I)—While maintaining a reaction temperature below 40°, a suspension of 4-(*o*-benzyloxyphenoxy)methyl)-1,3-dioxolone-2 (74 g., 0.25 mole) in isopropyl alcohol (800 ml.) was saturated with ammonia. The mixture was allowed to stand at ambient temperatures for 24 hr.

² The OH absorption is superimposed on the methine multiplet but is clearly distinguishable and easily removed by deuteration.

³ Evidently the exchange rate is too great in this case for splitting to be seen.

⁴ This comparison was made using CDCl₃ as the solvent for both the acetylated and nonacetylated samples.

⁵ Melting points are corrected. Elemental analyses were performed by the Analytical Department, Research Laboratories, A. H. Robins Co., Inc., Richmond, Va.

¹ Methocarbamol is marketed as Robaxin by A. H. Robins Co., Inc., Richmond, Va.

Thin-Layer Chromatography—Thin-layer plates (5 × 20 cm.) made of silica gel G were used. Van Urk's reagent (6) was used as a spray reagent to differentiate the starting material and product by a varied color response.

Spectra—UV spectra were obtained on a Beckman DK 2 spectrophotometer (1-cm. cell) in methylene chloride as solvent. IR spectra were determined on a Beckman IR 8 spectrophotometer in potassium bromide pellets and methylene chloride liquid films. NMR spectra were determined on a Varian 60 MC spectrophotometer using deuteriochloroform as the solvent and tetramethylsilane as the internal standard.

New Compounds: Demethylated Methocarbamol

C. M. DARLING* and E. K. ROSE

Abstract □ Two isomeric monocarbamates of 3-(*o*-benzyloxyphenoxy)-1,2-dihydroxypropane and 3-(*o*-hydroxyphenoxy)-1,2-dihydroxypropane were synthesized. The structural assignments are supported by spectral data.

Keyphrases □ Demethylated methocarbamol derivatives—synthesis, structure determination □ Methocarbamol metabolites—synthesis, structure determination □ NMR spectroscopy—structure, identification

Baizer *et al.* (1) have presented rigorous proof of the structure of some isomeric monocarbamates of 1,2-dihydroxy-3-aryloxypropanes by independent unequivocal synthesis. In a later paper, Swidinsky *et al.* (2) reported the preparation of two isomeric monocarbamates of 3-(*o*-hydroxyphenoxy)-1,2-dihydroxypropane, Compounds III and IV, by catalytic debenzyla-tion of Compounds I and II. However, their tenta-tive structural assignments differ from those reported here.

This work was prompted by a need for one of the metabolites (Compound III) of methocarbamol.¹ It is shown that the isomeric monocarbamates can be identified by spectral data. The results of a single run indicate that the major product of the reaction of ammonia with the cyclic carbonate, 4-(*o*-benzyloxy-phenoxy)methyl)-1,3-dioxolone-2, is a primary car-bamate (Compound I) and the minor product is a secondary carbamate (Compound II). The isomeric compounds and their melting-point values are shown in Table I.

The NMR spectra of the isomeric pairs (I, II and III, IV) taken in dimethyl sulfoxide-*d*₆ exhibit signifi-cant and distinguishing differences. Compound II clearly must have the secondary carbamate structure

as shown by the splitting of the primary hydroxyl proton into a triplet (δ 4.90; J = 5.5 cps.)² by the ad-jacent methylene group, rather than a doublet as ex-pected for a secondary hydroxyl proton. In addition, the methylene protons, CH₂OH, adjacent to the hy-droxyl group are coupled by approximately the same coupling constant (5.5 cps.) to the OH proton and the adjacent methine hydrogen, giving rise to a triplet (δ 3.67) which collapses to a doublet on deuteration.

The isomeric Compound I in dimethyl sulfoxide-*d*₆ shows only a single unsplit hydroxyl peak³ with all five aliphatic hydrogens appearing under a broad dis-torted doublet centered at δ 4.1. Acetylation of the hydroxyl group, however, shifts the secondary methine absorption approximately 1.3 p.p.m. down-field,⁴ supporting the primary carbamate structure for Com-pound I.

The NMR structural assignments are supported by the fact that the comparable features of the spectra of I and II are nearly identical to those of the related analogs of known structure (1), 3-(*o*-methoxyphenoxy)-2-hydroxy-1-propyl carbamate and 3-(*o*-methoxy-phenoxy)-1-hydroxy-2-propyl carbamate, respectively.

EXPERIMENTAL⁵

The method of Swidinsky *et al.* (2) was used for the preparation of 4-(*o*-benzyloxyphenoxy)methyl)-1,3-dioxolone-2.

3-(*o*-Benzyloxyphenoxy)-2-hydroxy-1-propyl Carbamate (I)—While maintaining a reaction temperature below 40°, a suspension of 4-(*o*-benzyloxyphenoxy)methyl)-1,3-dioxolone-2 (74 g., 0.25 mole) in isopropyl alcohol (800 ml.) was saturated with ammonia. The mixture was allowed to stand at ambient temperatures for 24 hr.

² The OH absorption is superimposed on the methine multiplet but is clearly distinguishable and easily removed by deuteration.

³ Evidently the exchange rate is too great in this case for splitting to be seen.

⁴ This comparison was made using CDCl₃ as the solvent for both the acetylated and nonacetylated samples.

⁵ Melting points are corrected. Elemental analyses were performed by the Analytical Department, Research Laboratories, A. H. Robins Co., Inc., Richmond, Va.

¹ Methocarbamol is marketed as Robaxin by A. H. Robins Co., Inc., Richmond, Va.

and concentrated *in vacuo*. The residue was recrystallized from ethyl acetate with the aid of activated charcoal, yield 49 g. (61.5%).

A sample of the acetate derivative, Compound V, was prepared for NMR analysis by refluxing a mixture of 0.5 g. of I, 20 ml. of acetic anhydride, and 0.5 g. of sodium acetate for 1 hr. After workup, the product was recrystallized from isopropyl ether, yield 0.3 g.

3-(*o*-Benzyloxyphenoxy)-1-hydroxy-2-propyl Carbamate (II)—The filtrate from the preparation of Compound I was concentrated to about two-thirds volume and refrigerated. The crystals were filtered and recrystallized twice from ethyl acetate, 3.5 g. (4.5%). TLC (eluted with 10% methanol in chloroform) indicated a single component different from Compound I.

3-(*o*-Hydroxyphenoxy)-2-hydroxypropyl Carbamate (III)—A solution of Compound I (12.6 g., 0.04 mole) in absolute ethanol (200 ml.) containing about 1 g. of palladium-on-charcoal (10%) was subjected to Parr hydrogenation at ambient temperature. The theoretical amount of hydrogen was absorbed during 10 min. The mixture was filtered and the filtrate was concentrated *in vacuo*. The residue was recrystallized twice from ethyl acetate, yield 2.8 g. (31%).

1-Hydroxymethyl-2-(*o*-hydroxyphenoxy)ethyl Carbamate (IV)—The procedure followed was the same as that with Compound III.

The product from 2.7 g. of Compound II was recrystallized twice from ethyl acetate, yield 0.2 g. (11%).

Unequivocal Distinction between Betamethasone and Dexamethasone by Mass Spectrometry

Keyphrases ☐ Dexamethasone, betamethasone—distinction, determination ☐ Mass spectrometry—identity

Sir:

In a review on stereoisomeric effects on mass spectra, Meyerson and Weitkamp (1) state that mass spectra of stereoisomers are, in general, qualitatively and quantitatively similar. Reference is made therein to work that demonstrates differences between the mass spectra of epimeric pairs of secondary and tertiary steroid alcohols. More recently, Grostic and Rinehart (2) have distinguished between epimeric 11-hydroxyprogesterones by mass spectrometry.

We wish to report that mass spectrometry provides an unequivocal method of distinguishing between the epimeric pair of synthetic corticosteroids betamethasone

3,20-dione). The difference is large enough to be of considerable value in forensic analysis. The spectra, which will be discussed fully at a later date in combination with spectra of related compounds, are shown (Fig. 1 = betamethasone, Fig. 2 = dexamethasone). The principal distinguishing feature is the peak at m/e 343, which corresponds to a loss of 49 mass units. In the dexamethasone spectrum, this peak is the next most prominent after the base peak (m/e 122); whereas in the spectrum of betamethasone, it is relatively insignificant.¹

The peak at m/e 343 ($M - 49$) almost certainly arises from loss of water from the D-ring followed by cleavage of the 20,21-bond. Dexamethasone has a *trans*-diaxial arrangement of the 16 β -hydrogen and 17 α -hydroxyl, which favors dehydration. In betamethasone, there is no hydrogen *trans*-diaxially oriented to the 17 α -hydroxyl. An analogous situation has been reported by Zaretskii *et al.* (3).

The high sensitivity of mass spectrometers means that this distinction may be carried out with a very limited amount of material, particularly in view of the relative abundance of the $M - 49$ peak in the spectrum of dexamethasone. There is, in addition, the advantage

Figure 1—Mass spectrum of betamethasone.

Figure 2—Mass spectrum of dexamethasone.

(9 α -fluoro-11 β ,17 α ,21-trihydroxy-16 β -methylpregna-1,4-dien-3,20-dione) and dexamethasone (9 α -fluoro-11 β ,17 α ,21-trihydroxy-16 α -methylpregna-1,4-dien-

Audiosensitization: Potential Screening Method for Drugs Affecting the CNS

Keyphrases ☐ CNS active drugs—screening method ☐ Stress, sound induced—seizures

Sir:

With the advent of new types of CNS active drugs, new screening tests with predictive association for subtle drug effects are needed. The phenomenon of audio-conditioned convulsions (1, 2) affords unique potential as such a screen.

The exaggerated and abnormal responses of psychiatric patients to auditory stimuli (3) prompted the use of audiogenic seizures in genetically susceptible strains of mice as an analogous reaction pattern for CNS drug research (4, 5). The present report suggests the use of audioconditioning and the subsequent susceptibility to sound-induced seizures as a simple and more informative analogy. Both analogies are based on the hypothesis that stress-induced neurosis can be measured by quantal observations of CNS hyperexcitability in response to a specific triggering mechanism. The use of audioconditioning has the advantage of offering the induction of stress susceptibility, as well as the stress-induced crisis for drug modification and study.

Susceptibility to sound-induced seizures can be conditioned in "sound-resistant" strains of mice by a short period (30 sec.) of auditory stimulation at a critical early age (1, 2). In mice, early experiments with the classical conditioning method of physiology showed that pretest exposure to sound elevates or reduces seizure threshold, depending upon the temporal parameters of treatment (6). In such reports, however, the durations of both the conditioning stimulus and the condition-test interval have been short, generally only a few seconds. The audioconditioned convulsions described here are inherently similar, but the condition-test interval is much longer and is measured in days.

Sound-resistant mice [*e.g.*, CAW:CF-1 (SW)]¹ display an auricular startle upon initial sound exposure (audioconditioning), but less than 5% convulse (2). The sound source is a 6.3-cm. doorbell which produces approximately 95 db. (relative to 0.0002 dyne/cm.²) within a glass testing chamber, 25 cm. in diameter by 15 cm. deep. If conditioned at the optimally sensitive age (18–20 days for CF-1), virtually all mice will convulse upon the second (test) sound exposure 2–3 days later. The initial conditioning stimulation is absolutely essential for the genesis of convulsions.

The typical seizure in such sensitized animals consists of a sudden burst of wild running, followed by clonic and then tonic convulsions. Less severe seizures terminate after running or clonus. Estimates of seizure severity can be derived from latency and duration times as well as from seizure pattern (2, 7). The following experimental factors affect these parameters (2, 7, 8):

1. The interval between conditioning and testing is critical. Maximal clonic-tonic convulsions characterize seizures after a 2- or 3-day condition-test interval; with a 1- or 5-day interval, only clonus is seen.

2. Repeated auditory stimulation prior to the development of convulsibility makes mice temporarily refractory to seizure, and prolongation of the initial conditioning sound (over 6 hr.) imparts permanent seizure resistance without causing deafness. Once an animal experiences a convulsion, however, seizure susceptibility persists for several weeks. This indicates that audiosensitization and seizure susceptibility are mediated by separate mechanisms.

3. The tonal characteristics of the sound stimulus are equally or more important than the intensity. Although reproducibility is excellent, it is necessary to bioassay each bell periodically. After extensive use, a bell may no longer induce maximal seizures, despite no alteration in intensity.

4. Genetic and environmental factors must be controlled. Noises in the animal quarters, such as the clatter of metal garbage cans, have profound influence. The critical age for sensitization and the optimum condition-test interval vary from strain to strain. CF-1 mice have a high incidence of maximal seizures, a short duration of audiosensitivity, and a low death risk.

When these experimental factors are controlled, seizures of predictable incidence, severity, and latencies are produced (2).

Theoretically, pharmacologic alteration of audio-conditioned seizures should be afforded by: (a) drugs that impair hearing or otherwise interfere with input of the sound stimulus; (b) drugs that block central perception of the stimulus; (c) drugs that inhibit or enhance the slow process of sensitivity development; (d) drugs that block the effect of intertrial stress; and (e) drugs that modify the mechanism of seizure production. The novel interest in audioconditioning as a screen will be for drugs that alter the development of sensitization (b and c as previously mentioned). For these drugs, this screen is unique because the potential drug need not be present at the time the animals are challenged for a test response. Thus, the prosensitizing

2. Repeated auditory stimulation prior to the development of convulsibility makes mice temporarily refractory to seizure, and prolongation of the initial conditioning sound (over 6 hr.) imparts permanent seizure resistance without causing deafness. Once an animal experiences a convulsion, however, seizure susceptibility persists for several weeks. This indicates that audiosensitization and seizure susceptibility are mediated by separate mechanisms.

3. The tonal characteristics of the sound stimulus are equally or more important than the intensity. Although reproducibility is excellent, it is necessary to bioassay each bell periodically. After extensive use, a bell may no longer induce maximal seizures, despite no alteration in intensity.

4. Genetic and environmental factors must be controlled. Noises in the animal quarters, such as the clatter of metal garbage cans, have profound influence. The critical age for sensitization and the optimum condition-test interval vary from strain to strain. CF-1 mice have a high incidence of maximal seizures, a short duration of audiosensitivity, and a low death risk.

When these experimental factors are controlled, seizures of predictable incidence, severity, and latencies are produced (2).

Theoretically, pharmacologic alteration of audioconditioned seizures should be afforded by: (a) drugs that impair hearing or otherwise interfere with input of the sound stimulus; (b) drugs that block central perception of the stimulus; (c) drugs that inhibit or enhance the slow process of sensitivity development; (d) drugs that block the effect of intertrial stress; and (e) drugs that modify the mechanism of seizure production. The novel interest in audioconditioning as a screen will be for drugs that alter the development of sensitization (b and c as previously mentioned). For these drugs, this screen is unique because the potential drug need not be present at the time the animals are challenged for a test response. Thus, the prosensitizing

¹ Carworth Farms, New City, N. Y.

or antisensitizing effects of the drug can be isolated from any sedative-anticonvulsant action it may have.

Physical impairment of hearing (*e.g.*, glycerin in the ear) during conditioning reduces the incidence of sensitization (and subsequent seizures); impairment at the time of testing reduces seizure severity. When hearing is impaired on both occasions, the two effects are combined (7). The latter should be the case when ototoxic drugs are tested with this screen. Transient and permanent effects can be partitioned by subjecting the mice to a third sound exposure 3 days after the test exposure.

A drug that blocks central perception of the sound stimulus should be detected by its ability to prevent sensitization when present during conditioning, but not when administered immediately afterward. Prototypes of many pharmacologic classes have been tested, but no drug has been found that effectively blocks audioconditioning at nontoxic doses. Latency changes and a decreased incidence of maximal seizures can be observed. However, because of the reduced metabolic and excretory potential of young mice, it is difficult to determine whether these are due to impairment of audioconditioning or to residual drug effects on seizure response. The latter remains a possibility even after the 2- or 3-day condition-test interval. Phenobarbital and diphenylhydantoin have been shown to be proconvulsant (rather than anticonvulsant) 2 days after their administration (8).

It is interesting to note that ether and pentobarbital anesthetics do not block central perception of the stimulus. Their presence during conditioning does not prevent sensitization but rather appears to enhance its development and to counteract the antisensitization effects of unilateral ear blockade (7).

In contrast to drugs that only inhibit or enhance sensitization, we recently have discovered that high doses of atropine sulfate (25 mg./kg., *i.p.*) completely block the development of sensitization. While this admittedly is an extremely high dosage, it is the first indication that audioconditioning can be prevented by drugs. Furthermore, since it is an ED_{100} dose, it is likely that a lower dose range can be found.

A drug that alters postconditioning development of sensitization would be detected by its ability to inhibit or enhance sensitization when administered after the conditioning stimulus. Several drugs of this type have been observed in our laboratory (8). Low doses of edrophonium (1–2 mg./kg., *i.p.*) inhibit sensitization when administered 30 min. after conditioning. When tested 2 days later, seizure incidence and severity are reduced and latencies are prolonged. The effect is similar but less striking when edrophonium is given before conditioning. This perhaps is explained by the fact that the postconditioning duration of drug action is shorter in this case. When edrophonium-treated mice are challenged at a 3-day condition-test interval, the usual seizures are elicited, indicating that this drug slows rather than blocks the development of sensitization.

A multitude of drugs promote or inhibit the seizure response when present at the test exposure to sound. In general, convulsants promote seizures, whereas anti-

convulsants, sedatives, and tranquilizers inhibit their onset and severity (8). These drugs produce similar effects on audiogenic seizures in genetically susceptible strains of mice.

The advantages of audioconditioned seizures as a screening method lie in several areas. As a biomodel of stress-induced neurosis, it does not require the use of genetically susceptible strains, special diets, chemicals, or surgical manipulation. The test response is a quick quantal observation which can be easily assessed by a technician. Also, since it involves the use of immature animals, this screen may have special predictive value for drugs to treat neurologic diseases of children.

It is our conclusion that audioconditioning should serve as an important experimental approach to the study of neural hyperexcitability and as a useful screening method for drugs affecting the CNS.

Binding of Salicylate to Crystalline Bovine Serum Albumin and to Fraction V Bovine Serum Albumin

Keyphrases ☐ Salicylate binding—bovine serum albumin ☐ Bovine serum albumin, crystalline, Fraction V—salicylate binding comparison ☐ Equilibrium dialysis—bovine serum albumin salicylate binding

Sir:

In the course of developing analytical methods for protein-binding studies, we have routinely used Fraction V bovine serum albumin (BSA) rather than the more costly crystalline BSA in preliminary work. For a drug such as sulfaethidole (SETD), there appears to be little difference in binding of the drug to Fraction V BSA and to crystalline BSA; a survey of references cited in a recent review (1) indicates that many workers have

or antisensitizing effects of the drug can be isolated from any sedative-anticonvulsant action it may have.

Physical impairment of hearing (e.g., glycerin in the ear) during conditioning reduces the incidence of sensitization (and subsequent seizures); impairment at the time of testing reduces seizure severity. When hearing is impaired on both occasions, the two effects are combined (7). The latter should be the case when ototoxic drugs are tested with this screen. Transient and permanent effects can be partitioned by subjecting the mice to a third sound exposure 3 days after the test exposure.

A drug that blocks central perception of the sound stimulus should be detected by its ability to prevent sensitization when present during conditioning, but not when administered immediately afterward. Prototypes of many pharmacologic classes have been tested, but no drug has been found that effectively blocks audioconditioning at nontoxic doses. Latency changes and a decreased incidence of maximal seizures can be observed. However, because of the reduced metabolic and excretory potential of young mice, it is difficult to determine whether these are due to impairment of audioconditioning or to residual drug effects on seizure response. The latter remains a possibility even after the 2- or 3-day condition-test interval. Phenobarbital and diphenylhydantoin have been shown to be proconvulsant (rather than anticonvulsant) 2 days after their administration (8).

It is interesting to note that ether and pentobarbital anesthetics do not block central perception of the stimulus. Their presence during conditioning does not prevent sensitization but rather appears to enhance its development and to counteract the antisensitization effects of unilateral ear blockade (7).

In contrast to drugs that only inhibit or enhance sensitization, we recently have discovered that high doses of atropine sulfate (25 mg./kg., i.p.) completely block the development of sensitization. While this admittedly is an extremely high dosage, it is the first indication that audioconditioning can be prevented by drugs. Furthermore, since it is an ED_{100} dose, it is likely that a lower dose range can be found.

A drug that alters postconditioning development of sensitization would be detected by its ability to inhibit or enhance sensitization when administered after the conditioning stimulus. Several drugs of this type have been observed in our laboratory (8). Low doses of edrophonium (1-2 mg./kg., i.p.) inhibit sensitization when administered 30 min. after conditioning. When tested 2 days later, seizure incidence and severity are reduced and latencies are prolonged. The effect is similar but less striking when edrophonium is given before conditioning. This perhaps is explained by the fact that the postconditioning duration of drug action is shorter in this case. When edrophonium-treated mice are challenged at a 3-day condition-test interval, the usual seizures are elicited, indicating that this drug slows rather than blocks the development of sensitization.

A multitude of drugs promote or inhibit the seizure response when present at the test exposure to sound. In general, convulsants promote seizures, whereas anti-

convulsants, sedatives, and tranquilizers inhibit their onset and severity (8). These drugs produce similar effects on audiogenic seizures in genetically susceptible strains of mice.

The advantages of audioconditioned seizures as a screening method lie in several areas. As a biomodel of stress-induced neurosis, it does not require the use of genetically susceptible strains, special diets, chemicals, or surgical manipulation. A preliminary report was presented at the AAAS meeting, Pharmaceutical Sciences section, Boston, Mass., 1969.

Binding of Salicylate to Crystalline Bovine Serum Albumin and to Fraction V Bovine Serum Albumin

Keyphrases ☐ Salicylate binding—bovine serum albumin ☐ Bovine serum albumin, crystalline, Fraction V—salicylate binding comparison ☐ Equilibrium dialysis—bovine serum albumin salicylate binding

Sir:

In the course of developing analytical methods for protein-binding studies, we have routinely used Fraction V bovine serum albumin (BSA) rather than the more costly crystalline BSA in preliminary work. For a drug such as sulfaethidole (SETD), there appears to be little difference in binding of the drug to Fraction V BSA and to crystalline BSA; a survey of references cited in a recent review (1) indicates that many workers have

Figure 1—Binding of SETD to 4.55% crystalline (●) and Fraction V (○) BSA, pH 7.4, 37°.

Figure 2—Binding of salicylate to 4.55% crystalline (●) and Fraction V (○) BSA, pH 7.4, 37°.

Figure 3—Binding of salicylate to 4.55% Fraction V BSA (○) and the effect of 10 mg.% SETD on binding of salicylate (●), pH 7.4, 37°.

utilized Fraction V BSA to study drug binding. In studies with salicylate, however, we observed a marked difference in binding to these two BSA fractions. There have been reports of striking species differences in serum albumin binding of drugs (2-5), but the potential erroneous predictions which might arise from the assumption that if one drug exhibits similar binding to both crystalline and Fraction V BSA other drugs will also exhibit similar binding to both fractions have not been emphasized.

As shown in Fig. 1, SETD exhibits little difference in binding to Fraction V and crystalline BSA. Figure 2, however, illustrates considerably greater binding of salicylate to crystalline BSA than to Fraction V BSA. For example, at a total salicylate concentration of $47 \times 10^{-4} M$, 91% is bound in the presence of 4.55% crystalline BSA, while only 63% is bound by 4.55% Fraction V BSA.

A further and striking difference between the crystalline and Fraction V BSA is that 10 mg.% SETD, an agent that competes for binding sites with salicylate, and an agent that is effectively displaced from serum albumin by salicylate (6), greatly enhances the binding of salicylate to Fraction V BSA, while it exhibits the expected displacement of salicylate from binding to crystalline BSA and pooled human plasma (7). As illustrated in Fig. 3, at total salicylate concentrations less than about $6 \times 10^{-4} M$ (9.6 mg.% sodium salicylate), there is displacement of salicylate upon addition of 10 mg.% SETD. But at higher salicylate concentrations, there is markedly enhanced binding of salicylate to the protein in the presence of 10 mg.% SETD.

It is apparent that Fraction V and crystalline BSA differ in such a manner that the binding of SETD is not

greatly affected, but the binding of salicylate to Fraction V is greatly diminished. In Fraction V BSA, all of the salicylate binding sites may not be available or readily accessible to the drug. Upon addition of 10 mg.% SETD, however, there may be a subtle conformational change induced by the binding of SETD such that the Fraction V resembles the crystalline BSA in affinity for salicylate. Further studies in progress are directed toward exploration of the nature of the conformational change and its influence on the number of salicylate binding sites and the respective affinity constants.

Binding data were obtained by equilibrium dialysis for 12 hr. at 37°, in pH 7.4, 0.054 M phosphate buffer made isotonic with sodium chloride. Both inside and outside solutions were assayed for drug content, utilizing the Bratton-Marshall procedure for SETD (8), and both UV spectrophotometric analysis and ¹⁴C were used for determination of salicylate.

"Absorption Rate Constants" Calculated According to the One-Compartment Open Model with First-Order Absorption: Implications in *In Vivo-In Vitro* Correlations

Keyphrases □ "Absorption rate constants"—one-compartment open model □ *In vivo-in vitro* correlations, "absorption rate constants"—calculation method effect

Sir:

Plasma or serum concentrations of unchanged drug observed following oral administration of single doses of a drug frequently are readily fit by the one-compartment

ment open model with first-order absorption (Model I). Wagner and Metzler (1) cited much of the literature on this fitting; such fitting leads to Eq. 1:

$$C = C^{\circ} \left(\frac{k_I}{k_I - K_I} \right) (e^{-K_I t} - e^{-k_I t}) \quad (\text{Eq. 1})$$

Even when simulated data are generated by application of Eqs. 2 and 2a,

$$C_1 = \frac{k_{II} D}{V_1} \left[\left\{ \frac{K_{-1} - \alpha}{(k_{II} - \alpha)(\beta - \alpha)} \right\} e^{-\alpha t} + \left\{ \frac{K_{-1} - \beta}{(k_{II} - \beta)(\alpha - \beta)} \right\} e^{-\beta t} + \left\{ \frac{K_{-1} - k_{II}}{(\alpha - k_{II})(\beta - k_{II})} \right\} e^{-k_{II} t} \right] \quad (\text{Eq. 2})$$

$$\alpha, \beta = \frac{1}{2} [(K_1 + K_{-1} + K_2) \pm \sqrt{(K_1 + K_{-1} + K_2)^2 - 4K_{-1}K_2}] \quad (\text{Eq. 2a})$$

which are appropriate to the two-compartment open model with first-order absorption (Model II), most sets of C_1, t data can be fitted with two exponential terms (Eq. 1) rather than three exponential terms (Eq. 2). With real plasma or serum concentration data ob-

served following oral administration, the same situation exists; however, in some cases, intravenous administration of the same drug tends to dictate the two-compartment open model.

When correlating "absorption rate constants" derived from plasma concentrations measured in man with *in vitro* rates of drug dissolution from dosage forms, one is most interested in relative values or ratios and not with absolute individual values.

The data in Table I are taken from Wagner and Metzler (1). When apparent "rate constants for absorptions," k_I , were estimated by nonlinear least-squares estimation, by applying Eq. 1 to data generated with Eqs. 2 and 2a, the absolute values of k_I deviated from the k_{II} values (either 0.5 or 2.0 hr.⁻¹), but the ratios of the k_I values were very close to the ratio of the true k_{II} values (namely, 4.0) when $8 \geq V_1/V_2 = K_{-1}/K_1 \geq 1$. It was previously shown (1) that where Model II was elaborated from actual plasma or serum level data, the ratio of parameters was within the limits shown in Table I.

This observation may help the dilemma of the biopharmaceutical and pharmacokinetic scientist who frequently can fit plasma or serum concentration data, obtained following oral administration, with Eq.

greatly affected, but the binding of salicylate to Fraction V is greatly diminished. In Fraction V BSA, all of the salicylate binding sites may not be available or readily accessible to the drug. This observation may help the dilemma of the biopharmaceutical and pharmacokinetic scientist who frequently can fit plasma or serum concentration data, obtained following oral administration, with Eq.

Table I—Parameter Ratios Used to Calculate C_1 Values of Model II and k_I Values and their Ratios Obtained by Fitting the $C_{1,t}$ Values to Model I^a

Set No.	V_1/V_2 $= K_{-1}/K_1$	K_1/K_2	k_I when $k_{II} = 0.5$	k_I when $k_{II} = 2.0$	Ratio of k_I 's
1	8	0.1	0.529	2.07	3.91
2	8	1.0	0.569	2.31	4.06
3	8	2.0	0.543	2.24	4.13
4	8	10.	0.510	2.06	4.04
5	8	100.	0.501	2.005	4.00
6	2	0.1	0.513	2.03	3.96
7	2	1.0	0.763	2.78	3.64
8	2	2.0	0.806	3.19	3.96
9	2	10.	0.609	2.80	4.60
10	2	100.	0.510	2.06	4.04
11	1	0.1	0.507	2.02	3.98
12	1	1.0	0.790	2.71	3.43
13	1	2.0	1.005	3.56	3.54
14	1	10.	0.840	4.43	5.27
15	1	100.	0.530	2.21	4.17
					Av. 4.05

For Model II, $K_2 = 0.15$, $D = 1,000,000$, and $V_1 = 5000$ for each set. Note that the ratio of k_{II} values is 4.0. A typographical error in Table II of Reference 1 gave $K_2 = 0.015$ instead of the actual $K_2 = 0.15$.

1 but not with Eq. 2, even though other data, obtained following intravenous administration, provide strong evidence for Model II or a more complicated model. If he wishes to correlate the apparent "absorption rate constants" derived from application of Model I and Eq. 1, he may be reasonably safe if he utilizes the ratios of the "absorption rate constants" and correlates these with ratios of rates of dissolution or times to dissolve a given percentage of drug derived from an *in vitro* test.

I have been quite successful in doing this and will report the details in a future publication.

BOOKS

REVIEWS

Human Ecology and Public Health. 4th Edition. Edited by EDWIN D. KILBOURNE and WILSON G. SMILLIE. Macmillan, New York, N. Y., 1969. xii + 462 pp. 18 × 26 cm. Price \$11.95.

Fairly priced, handsomely printed, sympathetically edited, well illustrated (49 tables; 75 figures), and eminently readable, *Human Ecology and Public Health* is a useful reference for pharmaceutical scientists.

This fourth edition of a work previously entitled *Preventive Medicine and Public Health* relates public health principles to the broader concepts of human ecology. The book is divided into three main divisions—Human Ecology and Human Disease, Public Health Problems and Practice, and the Administration of Health Services; the divisions are subdivided into fifteen chapters. The contributing authors' credentials are excellent; their efforts match their credentials. The references at the conclusion of the chapters are quite comprehensive.

The senior editor describes ecology as an "in" word, and admits to using it with some trepidation. Some examples out of context bear out this concern—on page 85, we learn that "nuclear energy has been harnessed to provide electrical power without polluting

the air or depleting natural resources," while on page 90 we are told that the introduction of nuclear reaction power plants has expanded the need for water cooling, "further aggravating the problem" of thermal pollution that alters the life support process of our lakes and streams. We learn of the problems caused by the introduction of synthetic hydrocarbon detergents and are told that the problem was remedied by newly developed biodegradables. No discussion follows about the potential of overloading of surface waters with phosphates, thus upsetting another ecological balance.

Despite these brief lapses from a balanced presentation of bioecology, the book has great merit. Major problem areas—the population explosion, pollution, automobile accidents, and inner-city tensions—are treated with great objectivity. One almost wishes for a touch of the urgent tones of a Commoner (see his *Science and Survival*, for example) when the specific problem of pesticides is considered in Chapter 4, although the purpose of this work does not call on urgency as a teaching device.

Of special note for pharmaceutical scientists are Chapters 2, 3, and 10 which deal, respectively, with Genetic Determinants of Health and Disease; Genetic Interactions of Man and Microbes; and Approaches to the Control of Human Infection. The first two chapters in the division—The Administration of Health Services—are an excellent introduction for the first-time reader and are a

New Dimensions in Legal and Ethical Concepts for Human Research
Vol. 169, art. 2. Consulting Editor, IRVING LADIMER, New York Academy of Sciences, 2 East 63rd St., New York, NY 10021, 1970. pp. 297-593. 15 × 23 cm. Price \$23.00.

The papers in this volume are drawn from a conference of the same name held by the New York Academy of Sciences from May 19 to 21, 1969.

The conference was divided into six sections each of which included the presentation of papers and panel discussions. The sections included were Ethical and Legal Base Lines for Professions and Community; Special Problems of Medical Disciplines; Special Problems of Related Professions; Experience in Design, Conduct, and Evaluation of Research; Professional Controls—Internal and External; and Social Responsibility through Communication.

This conference on "New Dimensions in Legal and Ethical Concepts for Human Research" was convened to enable representatives of major disciplines, mainly medical and legal fields, to present their experience and recommendations for meeting current and anticipated problems of experimentation on and with human beings.

These topics have relevancy to the recent activity in the areas of organ and tissue transplants. Work in these areas suggests that technology can surmount virtually all impediments, but this capacity may have to be curbed by social, ethical, legal, and religious strictures in order to achieve professional and community support.

Of particular interest to the pharmaceutical scientist are the papers on "Control and Surveillance of Investigational Drugs" by Herbert S. Carlin and Ronald T. Turnbull, "Conducting Investigational Drug Studies for Industry" by Kenneth G. Kohlstaedt, and "Drug Evaluation Problems in Academic and Other Contexts" by Louis Lasagna.

Parenteral Dosage Forms. By CAROLYN G. HALL and KENNETH E. AVIS. Parenteral Drug Association, Inc., Philadelphia, PA 19107, 1969. vi + 262 pp. 22 × 28 cm. Price \$7.50.

This comprehensive annotated bibliography of the literature pertaining to parenteral dosage forms has been prepared by Mrs. Carolyn G. Hall and Dr. Kenneth E. Avis, Department of Pharmaceutics, University of Tennessee, College of Pharmacy.

It covers the period 1959 to 1963 and contains approximately 950 entries. The book is arranged topically with a complete author index. The period just prior to the inception of *International Pharmaceutical Abstracts* was chosen for the first of what is anticipated will be a series of bibliographies because the authors felt that no coverage of this important period was available.

Staff Review ■

Clinical Pharmacy Handbook. By HUGH F. KABAT. Lea and Febiger, Washington Square, Philadelphia, PA 19106, 1969. v + 108 pp. + 70 workbook style tear-out pp. 21.5 × 27.5 cm. Price \$6.50 paperbound.

Portions of this volume were originally presented as course material to the senior students at the University of Minnesota College of Pharmacy. The first three chapters deal with course objectives, a course introduction, and notes on the pharmacist-patient relationship as viewed by the author. Some later chapters involve a collection of common hospital abbreviations and meanings, drug interaction tables, a list of sources of drug information, and a workbook section that affords the pharmacy student the opportunity to investigate the physical, chemical, and pharmacologic properties of any drug by means of charts that must be completed and questions that must be answered and referenced. Approximately one-half of the book is devoted to forms concerning general patient information, the clinical status of the patient, patient progress, and laboratory results. These forms are to be filled in by the pharmacy student as soon as the appropriate information becomes available.

The author indicates in the preface that this text is intended for use by students and for "any pharmacist venturing into the clinical setting." Those others not initiated into a clinically oriented pharmacy practice may find this book to be of some value because some important aspects of clinical pharmacy are presented. For example, the drug interaction tables and the chart on drug-induced modifications of laboratory tests are valuable pieces of literature and the collection of common hospital abbreviations and meanings is a step in dispelling the "language barrier" that, at first, exists between the medical staff and the new pharmacist practitioner.

Those educators thinking of initiating a clinical pharmacy course may also find this book of value because it does offer some basic "patient following" forms that were adapted from forms now in use at other hospitals with a clinical pharmacy service. The book also presents some basic philosophy on the pharmacist-patient relationship and some basic operating rules for the student and clinical instructor while in a patient-care area.

Any pharmacist or pharmacy student who has had any exposure to a clinically oriented pharmacy practice will find this book extremely fundamental and perhaps too course-oriented to be of any great value. The material in the book, for the most part, has already been published in one journal or another. The author has simply compiled such pieces of literature as Dr. Edward Hartshorn's drug interaction tables as they appeared in *Drug Intelligence* and the tables on the drug-induced modifications of laboratory values as they were published in the *American Journal of Hospital Pharmacy*. Any pharmacist entertaining thoughts of a clinical practice should already have well in hand the material that is presented in this book.

Biologically Active Amines Found in Man. By FRANZ FRANZEN and KURT EYSELL. Pergamon Press, Maxwell House, Fairview Parks, Elmsford, NY 10523, 1969. vii + 244 pp. 23 × 16 cm. Price \$13.50.

As stated by the authors, there has not been an extensive survey of the field of "biogenic amines" since 1951, although during this time there has been a considerable expansion of our knowledge of these compounds.

In 128 pages of text, the authors, who are apparently clinicians, discuss numerous aspects of these amines derived from decarboxylation of alpha amino acids. In separate chapters the biochemistry, pharmacology, and pathophysiological significance of biologically active amines are discussed. This *Handbuch* is unique as a comprehensive survey of this subject as related to clinical medicine. The

fine reference source for the more experienced student of public health management.

Considering the individual and society generally, the state of our ecologic environment, and our artificial environment and the interrelationships of each and all of these to disease, the book is eminently successful and well worth study by the pharmaceutical scientist concerned with human ecology and public health.

New Dimensions in Legal and Ethical Concepts for Human Research
Vol. 169, art. 2. Consulting Editor, IRVING LADIMER, New York Academy of Sciences, 2 East 63rd St., New York, NY 10021, 1970. pp. 297-593. 15 × 23 cm. Price \$23.00.

The papers in this volume are drawn from a conference of the same name held by the New York Academy of Sciences from May 19 to 21, 1969.

The conference was divided into six sections each of which included the presentation of papers and panel discussions. The sections included were Ethical and Legal Base Lines for Professions and Community; Special Problems of Medical Disciplines; Special Problems of Related Professions; Experience in Design, Conduct, and Evaluation of Research; Professional Controls—Internal and External; and Social Responsibility through Communication.

This conference on "New Dimensions in Legal and Ethical Concepts for Human Research" was convened to enable representatives of major disciplines, mainly medical and legal fields, to present their experience and recommendations for meeting current and anticipated problems of experimentation on and with human beings.

These topics have relevancy to the recent activity in the areas of organ and tissue transplants. Work in these areas suggests that technology can surmount virtually all impediments, but this capacity may have to be curbed by social, ethical, legal, and religious strictures in order to achieve professional and community support.

Of particular interest to the pharmaceutical scientist are the papers on "Control and Surveillance of Investigational Drugs" by Herbert S. Carlin and Ronald T. Turnbull, "Conducting Investigational Drug Studies for Industry" by Kenneth G. Kohlstaedt, and "Drug Evaluation Problems in Academic and Other Contexts" by Louis Lasagna.

Staff Review ■

Parenteral Dosage Forms. By CAROLYN G. HALL and KENNETH E. AVIS. Parenteral Drug Association, Inc., Philadelphia, PA 19107, 1969. vi + 262 pp. 22 × 28 cm. Price \$7.50.

This comprehensive annotated bibliography of the literature pertaining to parenteral dosage forms has been prepared by Mrs. Carolyn G. Hall and Dr. Kenneth E. Avis, Department of Pharmaceutics, University of Tennessee, College of Pharmacy.

It covers the period 1959 to 1963 and contains approximately 950 entries. The book is arranged topically with a complete author index. The period just prior to the inception of *International Pharmaceutical Abstracts* was chosen for the first of what is anticipated will be a series of bibliographies because the authors felt that no coverage of this important period was available.

Staff Review ■

Clinical Pharmacy Handbook. By HUGH F. KABAT. Lea and Febiger, Washington Square, Philadelphia, PA 19106, 1969. v + 108 pp. + 70 workbook style tear-out pp. 21.5 × 27.5 cm. Price \$6.50 paperbound.

Portions of this volume were originally presented as course material to the senior students at the University of Minnesota College of Pharmacy. The first three chapters deal with course objectives, a course introduction, and notes on the pharmacist-patient relationship as viewed by the author. Some later chapters involve a collection of common hospital abbreviations and meanings, drug interaction tables, a list of sources of drug information, and a workbook section that affords the pharmacy student the opportunity to investigate the physical, chemical, and pharmacologic properties of any drug by means of charts that must be completed and questions that must be answered and referenced. Approximately one-half of the book is devoted to forms concerning general patient information, the clinical status of the patient, patient progress, and laboratory results. These forms are to be filled in by the pharmacy student as soon as the appropriate information becomes available.

The author indicates in the preface that this text is intended for use by students and for "any pharmacist venturing into the clinical setting." Those others not initiated into a clinically oriented pharmacy practice may find this book to be of some value because some important aspects of clinical pharmacy are presented. For example, the drug interaction tables and the chart on drug-induced modifications of laboratory tests are valuable pieces of literature and the collection of common hospital abbreviations and meanings is a step in dispelling the "language barrier" that, at first, exists between the medical staff and the new pharmacist practitioner.

Those educators thinking of initiating a clinical pharmacy course may also find this book of value because it does offer some basic "patient following" forms that were adapted from forms now in use at other hospitals with a clinical pharmacy service. The book also presents some basic philosophy on the pharmacist-patient relationship and some basic operating rules for the student and clinical instructor while in a patient-care area.

Any pharmacist or pharmacy student who has had any exposure to a clinically oriented pharmacy practice will find this book extremely fundamental and perhaps too course-oriented to be of any great value. The material in the book, for the most part, has already been published in one journal or another. The author has simply compiled such pieces of literature as Dr. Edward Hartshorn's drug interaction tables as they appeared in *Drug Intelligence* and the tables on the drug-induced modifications of laboratory values as they were published in the *American Journal of Hospital Pharmacy*. Any pharmacist entertaining thoughts of a clinical practice should already have well in hand the material that is presented in this book.

Biologically Active Amines Found in Man. By FRANZ FRANZEN and KURT EYSELL. Pergamon Press, Maxwell House, Fairview Parks, Elmsford, NY 10523, 1969. vii + 244 pp. 23 × 16 cm. Price \$13.50.

As stated by the authors, there has not been an extensive survey of the field of "biogenic amines" since 1951, although during this time there has been a considerable expansion of our knowledge of these compounds.

In 128 pages of text, the authors, who are apparently clinicians, discuss numerous aspects of these amines derived from decarboxylation of alpha amino acids. In separate chapters the biochemistry, pharmacology, and pathophysiological significance of biologically active amines are discussed. This *Handbuch* is unique as a comprehensive survey of this subject as related to clinical medicine. The

sections on renal implications and tumor-secreted active amines are especially lucid. The authors cite 1890 references without being overly verbose. The book contains several useful tables of important data such as amine concentrations in blood, urine, and tissues in both normal and pathologic conditions; concentrations of dopamine, norepinephrine, serotonin, and other amines in 41 areas of post-mortem brain; and the influence of a variety of amines on the formation and excretion of urine in various animals and man.

This book should prove a useful addition to the library of researchers and clinicians in the fields of autonomic pharmacology and endocrine pathophysiology involving altered secretion or levels of these amines. The discussion is not particularly instructive although it is comprehensive and thorough in reviewing the available literature.

The National Formulary, Thirteenth Edition. Prepared by the National Formulary Board with the approval of the Board of Trustees, by the authority of the American Pharmaceutical Association. The American Pharmaceutical Association, 1970. Distributed by Mack Publishing Co., Easton, PA 18042. lxxiv + 1012 pp. 14.5 × 23 cm. Price \$15.00 (Domestic and Foreign).

The publication of the National Formulary, or any other comparable source for methods or standards, is often viewed as an event in itself, rather than the climax of a long series of procedures. In reality, any book of this nature is the end product of much research, fact finding, study, and evaluation. National Formulary, Thirteenth Edition, represents the results of a five-year revision program carried on by the American Pharmaceutical Association, involving more than 500 persons from the fields of medicine, pharmacy, and chemistry.

Certainly, one of the most important considerations—and the most apparent in the preparation of a new NF edition, is the selection of drugs and dosage forms to be recognized and the preparation of monographs for those chosen. Of the 992 officially recognized articles in NF XIII, 411 are newly admitted. Two hundred twenty-one drugs, recognized in NF XII, have been dropped in going to the new edition.

But a second aspect of the NF, which in certain respects has even more far-reaching consequences, is the application of new techniques and methods and the establishment of new criteria by which to ensure the quality and purity of pharmaceuticals. It is this aspect of the NF revision program which probably reflects to a greater extent the rapid changes and advances in technological capabilities and quality control methodology.

In pursuit of its fundamental purpose—to provide standards and specifications which can be used to evaluate the quality of pharmaceuticals—the NF has fostered the study of factors bearing on drug availability. As a result, NF XIII draws upon and utilizes the many recent developments in drug analysis and methodology in providing new tests, new specifications, and new standards.

Of the 80 General Tests chapters in NF XIII, 16 are new; those carried over from NF XII have been revised and updated to reflect more adequately current needs and capacities.

Among the new General Tests chapters, those on X-ray diffraction and dissolution test are important examples. The first provides a technique enabling the NF Board to specify in these drug substance monographs where polymorphism of the crystal may be a problem affecting bioavailability that the article must conform to a specified X-ray diffraction pattern, while dissolution test specifications provide an objective means of determining dissolution characteristics of a solid dosage form. The inclusion of these chapters and specifications in pertinent individual monographs represents an initial effort by the NF to establish specifications where appropriate both for the active ingredient and the final dosage form, to serve as an index of drug quality from the standpoint of expected biological availability.

The aerosol dosage form is recognized officially for the first time in NF XIII through inclusion of monographs for several therapeutically important aerosol preparations. Among the procedures used to establish standards for aerosol products are leak testing, delivery rate, and pressure testing. NF XIII provides standards and specifications for four aerosol propellants in addition to monographs for six individual aerosol dosage forms.

The rise of consumerism on all levels and the increasing consumer awareness and sophistication concerning drugs—in part due to the drug efficacy study, the hearings on oral contraceptives, the cyclamate controversy, concern over misuse of drugs, and rising medical costs in general—have resulted in increased pressure on the official compendia to keep abreast of trends and developments in the scientific areas. In response to this challenge, the NF revision program is to be put on an even more continuous basis with the first supplement having a scheduled official date of September 1, 1970, coinciding with NF XIII.

In accordance with the objectives of a more continuous revision program, additional NF XIII supplements are planned at regular intervals throughout the revision period.

Among the new General Tests chapters, those on X-ray diffraction and dissolution test are important examples. The first provides a technique enabling the NF Board to specify in these drug substance monographs where polymorphism of the crystal may be a problem affecting bioavailability that the article must conform to a specified X-ray diffraction pattern, while dissolution test specifications provide an objective means of determining dissolution characteristics of a solid dosage form. The inclusion of these chapters and specifications in pertinent individual monographs represents an initial effort by the NF to establish specifications where appropriate both for the active ingredient and the final dosage form, to serve as an index of drug quality from the standpoint of expected biological availability.

The aerosol dosage form is recognized officially for the first time in NF XIII through inclusion of monographs for several therapeutically important aerosol preparations. Among the procedures used to establish standards for aerosol products are leak testing, delivery rate, and pressure testing. NF XIII provides standards and specifications for four aerosol propellants in addition to monographs for six individual aerosol dosage forms.

The rise of consumerism on all levels and the increasing consumer awareness and sophistication concerning drugs—in part due to the drug efficacy study, the hearings on oral contraceptives, the cyclamate controversy, concern over misuse of drugs, and rising medical costs in general—have resulted in increased pressure on the official compendia to keep abreast of trends and developments in the scientific areas. In response to this challenge, the NF revision program is to be put on an even more continuous basis with the first supplement having a scheduled official date of September 1, 1970, coinciding with NF XIII.

In accordance with the objectives of a more continuous revision program, additional NF XIII supplements are planned at regular intervals throughout the revision period.

February 27, 1917, the day U. S. Patent No. 644,077 expired, a whole new vista opened to the drug industry. What was, and is, the best seller of all times could easily be classed as the wonder drug of all ages. From the latest available figures of the U. S. Tariff Commission,¹ there would be over 200 tablets available for every man, woman, and child in the United States if all the U. S. yearly production was made into tablets containing 325 mg. (5 gr.) of acetylsalicylic acid, more popularly known as aspirin.

Aspirin has the unique standing in the medical world of still being the most widely used drug, even with the

advent of modern, highly potent therapeutic agents. Aspirin has superior qualities as an antipyretic and as a general analgesic, but more specifically in the relief of headaches, muscular pain, postoperative and traumatic pain, postpartum pain, dysmenorrhea, malignancy, colds and respiratory diseases, rheumatoid arthritis, acute rheumatic fever, and in the field of dental analgesia.

With such a versatile drug, it was obvious that aspirin would be combined with other drugs with the result that a more potent and effective preparation would result. It is the purpose of this review to emphasize the plight that continually plagues the analytical chemist in his constant search for a truly reliable method of measuring the decomposition of aspirin in the presence of other drugs or compounds. What makes this problem even more acute is that aspirin is highly selective of the type of compounds it intimately associates with. In fact, if aspirin acquires even a trace of moisture, it begins to fall to pieces. It thus becomes a problem of product development to finalize a stable formulation that will withstand a "normal" shelflife under all types of adverse conditions such as humidity, temperature, and interreactions with other components, even in the solid state.

DETERMINATION OF DECOMPOSITION OF ASPIRIN

When aspirin was first introduced as a drug, controversies ensued almost instantaneously as to how one could characterize truly good aspirin. Some became experts on detecting trace amounts of acetic acid and so classed the elegance of the aspirin accordingly. Even in those early days, the advertising agencies made the most

¹ From 1968 preliminary report: 31,248,000 pounds of aspirin by U. S. production.

of this purely subjective classification. Very few papers have been presented on the quantitative determination of acetic acid as a decomposition product of aspirin, chiefly because of the known volatility of acetic acid. Unless the original container was completely airtight, one would be measuring only the residual acetic acid, which would not be representative of the total acetic acid formed by the decomposition of the aspirin. General methods evolved in which dry air was passed over and through a thin layer of the finely powdered sample. The acetic acid vapor was trapped in the water and then titrated with very dilute sodium hydroxide. A simpler approach utilized a Conway micro diffusion cell. The more refined approach involved GLC.

It is interesting to note that visually the presence of any whiskers (very thin elongated crystals of salicylic acid) observed on the surface of a solid product containing aspirin is definitely an indication that some of the aspirin has decomposed and that the resulting salicylic acid has sublimed through the solid material. Here, again, if the container is not airtight, the possibility exists whereby the released salicylic acid, through sublimation, would leave the sample area and so not be measured. This crucial point, on the sublimation of salicylic acid, will be discussed more thoroughly in this review. As with most subjective tests, the evaluation of solid aspirin products by the appearance of salicylic acid whiskers is limited. Time is required for this sublimation to take place, so one would not normally apply it to fresh products. Therefore, one could actually have a poorly made aspirin tablet which, on the surface, showed no whiskers but internally had a high content of salicylic acid.

It is the intent of this review, therefore, to pursue a quantitative approach in the determination of the amount of decomposition of aspirin through the presence of salicylic acid rather than acetic acid.

No biological samples, such as blood, containing aspirin will be discussed in this review. Nor will this review include salts of aspirin, such as aluminum aspirin, solutions, or aspirin suspensions. The stability of aspirin in all these cases is definitely limited. The presence of any moisture (with the salts of aspirin, the water of hydration) results in the hydrolysis of aspirin at such a rate that the given formulation does not have a practical or useful shelflife. There is, however, a definite need in the field of pediatrics and geriatrics for a stable liquid formulation of aspirin, because there is no easier or simpler way to give a medicinal than by mouth to infants or to the feeble.

Even limiting this review just to solid preparations leaves a great deal confronting the analyst. A step-by-step evaluation of the approaches published in the scientific literature will be presented. One will readily see the tremendous need for a simple, reliable, universal test for the decomposition of aspirin which can be applied easily and rapidly to a completely unknown preparation containing aspirin.

HYDROLYSIS STUDIES

Decomposition of aspirin results from hydrolysis of the ester group, with the end products being acetic acid

and salicylic acid. The oversimplified reaction for the hydrolysis of aspirin is presented only at this time, so one may visualize the overall picture of the decomposition of aspirin (Scheme I).

Scheme I

Those who have made a thorough study of the hydrolysis of aspirin under various well-controlled and stated conditions report that the reaction is very complex. Judged by the number of papers on this subject alone, the reaction is also highly controversial.

The first publication on the hydrolysis of aspirin in water was reported by Rath (1) who conducted his work at an extremely high temperature (100°). As was later found, the hydrolysis of aspirin is very sensitive to temperature changes, even near room temperature. The rate of hydrolysis was determined by titrating the total acidity at stated time intervals. The calculated values indicated a monomolecular reaction. Tsakalotos and Horsch (2, 3) also followed the hydrolysis of aspirin but at more reasonable temperatures (20, 50, and 60°). It took about 100 days to effect complete hydrolysis of aspirin in water at room temperature. Hydrogen ion was found to accelerate the hydrolysis rate, hydrochloric acid being more effective than sulfuric acid. Acetic acid and citric acid caused an initial increase in the rate of hydrolysis; but as the days passed, a decrease in the rate of hydrolysis was noted. The unfounded explanation given by these authors for this slowdown was that the salicylic acid produced was being acylated.

Wolf (4) substantiated the hydrogen-ion effect on the hydrolysis of aspirin by showing that the velocity constant in an acid medium (diluted hydrochloric acid) doubled over that of just water.

Aspirin was solubilized in water at room temperature by Morton (5) with the aid of potassium and sodium citrates and acetates. The degree of hydrolysis was followed by titrating the samples with standard alkali at stated time intervals. The rate of hydrolysis was reported to be independent of not only the concentration of the aspirin but also of the solubilizing salt concentration.

Saponification (alkaline hydrolysis) of aspirin was reported by La Mer and Greenspan (6) at $25.000 \pm 0.005^\circ$. The reaction was stopped by making the given sample (not an aliquot of the bulk solution as is the usual approach in hydrolysis studies) acidic with standard sulfuric acid. The excess acid was then titrated with 0.02 *M* sodium hydroxide. It is assumed that this back titration was conducted immediately; otherwise, hydrolysis of aspirin in the strongly acidic medium would become an unwanted factor in the calculation of the saponification rate. This study showed that aspirin underwent a simple ionic bimolecular reaction with sodium hydroxide in aqueous solution. Thus, a second-order rate constant was calculated.

Figure 1—pH-rate profile for hydrolysis of aspirin. [Reprinted, with permission, from L. J. Edwards, *Trans. Faraday Soc.*, **46**, 723(1950).]

Continuing this same approach, Sturtevant (7) analyzed the rate of saponification of aspirin at 35° calorimetrically with the aid of a thermocouple. His conclusion is not often seen in print other than by authors commenting about the previous contributions in relationship to their own work: "The results of these experiments have shown, however, that it would be very difficult to get accurate heat data on these reactions, and it has, therefore, not been considered worthwhile to carry the measurements any further."

A complete and thorough kinetic study of the factors involved in the hydrolysis of aspirin in dilute solution ($3 \times 10^{-3} M$) was conducted by Edwards (8, 9). Using a UV spectrophotometric method for simultaneous determination of aspirin and salicylic acid, he observed the rate of decomposition to be first order at a fixed pH value (between pH 0.53 and 12.77) and constant ionic strength at 17°. Figure 1 depicts the relationship between velocity (rate) constant and pH. This curve was subject to only slight alteration with change in ionic strength. Temperature dependence of this aspirin reaction was studied between 10 and 50°. The pH-rate profile was of the same shape for every temperature, with displacement upward with increasing temperature. This plot of $\log k$ against pH helps to show visually that the hydrolysis was catalyzed appreciably by hydrogen

Table I—Comparison of Hydrolysis Rates of Aspirin in Various Media

Investigator	k , Day ⁻¹	Medium
Rath (1)	4.35×10^{-2}	Water
Edwards (8)	4.1×10^{-2}	Water
La Mer and Green-span (6)	7.05×10^3	Sodium hydroxide
Sturtevant (7)	7.2×10^3	Sodium hydroxide
Edwards (8)	7.50×10^3	Sodium hydroxide
Morton (5)	0.103	Potassium citrate buffer about pH 7
Edwards (8)	0.117	pH 7

ion (section AB of figure) and very strongly by hydroxyl ion (section FG of figure). Over the pH range 5–8 (section DE of figure), the rate was constant; in the pH range 2–3 (section C of figure), there was a pronounced minimum rate where the reaction velocity dropped to less than a quarter of the stationary value (DE) which is usually taken to represent the "spontaneous reaction." Edwards explained the relationship between the rate constant and pH on the assumption that the hydrolysis of aspirin may take place *via* the six simultaneous reactions shown in Scheme II.

Through many relationships involving these six equations, the observed unimolecular (first-order) velocity constant could be expressed as a function of the six second-order constants (Eq. 1):

$$k = \frac{k_1 C_H + k_2 C_{H_2O} + k_3 C_{OH^-}}{1 + K/C_H} + \frac{k_4 C_H + k_5 C_{H_2O} + k_6 C_{OH^-}}{1 + C_H/K} \quad (\text{Eq. 1})$$

When each of the six components of k was plotted on a pH- $\log k$ diagram, four types of curves were obtained. The combination of these four individual curves into one overall curve resulted in a single final curve similar to that depicted in Fig. 1, including the previously inexplicable minimum (C in figure), which Edwards calculated as being at pH 2.44. (The observed minimum was at pH 2.5.)

A comparison of the results of this work (Table I) with those obtained by previous investigators showed good agreement in the rate constant when expressed in the same terminology and conditions.

The hydrolysis of aspirin was accounted for over the whole pH range by considering all the possible bimolecular reactions between the five species present in the equilibrium as: $2H_2O \rightleftharpoons H_3O^+ + OH^-$ on the one hand and the equilibrium: $CH_3COOC_6H_4COOH \rightleftharpoons CH_3COOC_6H_4COO^- + H^+$ on the other hand.

The mechanism of intramolecular catalysis of the hy-

Scheme II

hydrolysis of aspirin in the pH region of 5–8 led Davidson and Auerbach (10) to investigate the behavior of aspirin in nonaqueous media. In the presence of dissolved base, aspirin possessed acid anhydride properties and functioned as an effective acetylating agent. They postulated the existence of a cyclic intermediate which results from the intramolecular nucleophilic attack by the ionized carboxyl group on the ester carbonyl. They also postulated that this base-catalyzed isomerization was the rate-controlling step for the hydrolysis of aspirin in the pH 5–8 range. This work was done with organic solvents, and there was no evidence for reactions of this type in aqueous solution.

Ferroni and Baistrocchi (11) measured the rate of hydrolysis of aspirin by determining the liberated salicylic acid fluorometrically. They reported that the reaction followed first-order kinetics and the rate constant was evaluated as 0.0122 hr^{-1} at 18.5° and pH 9.42.

Hydrolysis rate constants for aspirin, reported by Miyamoto *et al.* (12), agreed with the k_s rate constant of Edwards (8): 2.625×10^{-3} at 24° and 6.909×10^{-3} at 37° . A general comment was made that aspirin hydrolyzed more quickly in simulated intestinal fluid than in simulated gastric fluid.

Garrett (13), extending the work of Edwards (8) to include a number of acyl salicylates in a very complete investigation, looked more thoroughly into the pH-rate profile of aspirin hydrolysis, particularly in the pH 4–8 range. Edwards' own demonstration that the hydrolysis was not catalyzed by acetate ion (varied from 0.005 to 0.3 *M*) was not consistent with the mechanism involving an attack by a water molecule on the aspirin anion, because the acetate ion is a considerably more powerful nucleophile than water. Garrett's work pointed rather to intramolecular nucleophilic catalysis by the ionized carboxyl group. Even though the carboxylate ion is an unfavorable case from the point of view of nucleophilicity, it apparently participates catalytically in a number of intramolecular catalyses of esters. The hydrolysis of aspirin may be regarded as a classical example. On increasing the alcohol concentration greatly in the pH-independent region of the pH-rate profile, a very unexpected increase was found.

In this light, alcohol would have to be considered a more active nucleophile than water. To clarify this anomalous enhancement of "spontaneous" hydrolysis with increasing alcohol content (0–60%), Garrett made a thorough study. The addition of alcohol to the solvent increased the rate of solvolysis; ethyl acetate was a resulting product. He ruled out the possibility that the rate increase was a generalized solvent effect by showing that the addition of dioxane had very little effect on the rate of hydrolysis of aspirin. He tried to explain his results by proposing a mechanism involving nucleophilic attack by alcohol on the tetrahedral carbon atom of an intermediate compound. This explanation has not been generally accepted. Nevertheless, the demonstration that the addition of alcohol increased the rate of solvolysis did suggest strongly that the question of the involvement of a molecule of solvent in the transition stage ought to be studied.

Using the same four acyl esters of salicylic acid as in the mentioned studies, Garrett (14) studied the stability

of their saturated solutions. Prediction of stability in such solutions was made from separate studies of solubility rates and homogeneous rates on dilute solutions of these esters, since solvolytic degradation was a function of these two rates. This study did show that aspirin was the least stable of the esters studied.

Okano and Kojima (15) investigated the effect of salicylic acid upon the rate of aspirin decomposition in solution. They observed deceleration of the aspirin hydrolysis between pH 2.2 and 7 with increasing amounts of salicylic acid being added to the medium. Below pH 2.2 the opposite effect was noted. These studies were conducted for 10 days at 35° , or 8 hr. at 50° , and the rate constants were calculated. The reversal effect of the salicylic acid on the hydrolysis of the aspirin is in the vicinity of the minimum shown by Edwards' (8) pH-rate profile of aspirin hydrolysis.

The hydrolysis of aspirin at pH 6 in water containing 4.3 atom % of ^{18}O produced, after 22 hr. refluxing, salicylic acid containing 6% of the excess ^{18}O in the water. This result was in agreement with the theoretical prediction made by Bender *et al.* (16) and gave backing to the hydrolysis mechanism of aspirin postulated by Garrett (14) and others. This involved an intramolecular attack of the carboxylate ion on the carbonyl carbon atom of the ester to produce acetylsalicyl anhydride, which subsequently hydrolyzes rapidly to produce acetate and salicylate ion, or alternatively that the addition of the carboxylate ion to the carbonyl group of the ester is followed by some reaction with water leading to the same products. It can be calculated from the relative rates of hydrolysis of ethyl acetate and ethyl salicylate that the reaction producing salicylic acid- ^{18}O should occur to the extent of 2.5%. The 6% observed was considered to be reasonable and consistent with the postulated reaction in which water was involved.

Using a BPC mixture of aspirin, James (17) investigated the kinetics of the hydrolysis of aspirin from aqueous suspension by comparative, rather than quantitative, means. As long as there was a good excess of aspirin suspension present at the different temperatures, the hydrolysis rate was zero order. Thus, the more concentrated the suspension, the more stable was the aspirin. After 62 days at room temperature, suspensions of 3.3, 6.5, and 13.0% aspirin showed the following percent of intact aspirin remaining: 90, 94, and 97%, respectively. This follows, as the hydrolysis rate depends on the amount of aspirin in solution. Hence, suspensions show a low degree of hydrolysis relative to the total amount of aspirin in suspension.

While James used a titration procedure to follow the rate of hydrolysis in his study, Blaug and Wesolowski (18) used a more refined UV procedure in a pH 3 buffer. This pH was selected because it is the pH of a saturated solution of aspirin (approximately 4 g./l.). The effect of the following additives (calcium gluconate, glycerin, *N*-methyl-2-pyrrolidone, polyethylene glycol 6000,² polyvinylpyrrolidone, salicylic acid, sorbitol, pH 3.0 buffer, and water) on the stability of aspirin suspensions (6.5% of 100-mesh and 13% of 60-mesh aspirin) was followed

² Carbowax 6000, Union Carbide Corp.

by measuring the salicylic acid content at 298 m μ . The thermodynamic values reported in the paper were calculated from the data obtained with these various suspensions. The suspensions (in duplicate) were stored in a $50 \pm 0.5^\circ$ mechanical shaker for 24 hr. Samples were removed from the suspensions at hourly intervals for assay. Calcium gluconate accelerated the hydrolysis by increasing the pH of the medium, while the *N*-methyl-2-pyrrolidone or glycerin enhanced the solubility of the aspirin, thus increasing the hydrolysis. The presence of saturated salicylic acid did not affect the hydrolysis rate. The most promising additives were polyethylene glycol 6000 and polyvinylpyrrolidone, but physically they were unsatisfactory at this temperature as they formed gummy, insoluble masses of the suspension. Only sorbitol showed any potential stabilizing effect on the aspirin suspension.

In continuing his studies on the effect of alcohol on the hydrolysis rate of aspirin, Garrett (19) synthesized the mixed anhydride of aspirin and acetic acid to help establish his mechanism for the hydrolysis reaction. This compound did not form ethyl acetate as expected in the alcohol medium, so a logical explanation regarding the experimental evidence was still lacking.

Further studies with deuterium oxide solvent isotope effects in the nucleophilic reactions of phenylesters were reported by Bender *et al.* (20). One of the continuing problems associated with the hydrolytic reactions of carboxylic acid derivatives is to distinguish between nucleophilic and general basic catalysis of hydrolysis. The former involves the attack of a nucleophile upon a substrate, leading to the formation of an unstable intermediate which spontaneously breaks down to give the product and regenerates the catalytic entity. The latter catalysis involves the attack of a general base on the substrate removing a proton in a rate-determining stage. Either of these two processes may be carried out by a given substance which, by definition, is at one and the same time both a nucleophile and a general base. The deuterium oxide solvent isotope effect has been used to distinguish between these two possibilities.

The aspirin hydrolysis has been shown, on the basis of kinetic and isotopic experiments, to involve an intramolecular nucleophilic-catalyzed hydrolysis involving an anhydride intermediate. For the purpose of calculation, it has been assumed that the transition state of the reaction was one in which the carboxylate ion has been added to the carbonyl group of the ester, forming a tetrahedral addition intermediate. The formation of this intermediate is, in general, the slow step in the nucleophilic reactions of carboxylic acid derivatives. The authors concluded that the use of deuterium oxide solvent isotope effects as a criterion to distinguish between general base- and nucleophilic-catalyzed reactions was ambiguous; but when applied in a restricted sense, it may be empirically rewarding.

Nogami *et al.* (21) examined the effect of cationic (cetyltrimethylammonium bromide and benzalkonium chloride), anionic (sodium lauryl sulfate), and nonionic (polyoxyethylene lauryl ether) surfactants on the suppression of the hydrolysis of aspirin which exists in anionic and undissociated forms in aqueous solution. The decomposition-rate constants in the buffer

solutions (pH 1–7.5) were obtained, with or without the surfactant, and compared. Samples were kept at $37 \pm 0.1^\circ$, with aliquots being removed at given intervals and assayed for salicylic acid with a ferric nitrate reagent. The color was determined spectrophotometrically at 530 m μ .

The hydrolysis of aspirin was found to follow a pseudo-first-order reaction in the media studied. In the pH 5–7.5 range, aspirin was chiefly in the anionic form. Due to electrostatic attraction, it formed a complex with the cationic surfactant which moved into micelles composed of excess surfactant. Thus, the hydrolysis of aspirin in this pH region was suppressed only by a cationic surfactant. In the pH 1–5 range, all the surfactants suppressed the hydrolysis of aspirin. Because the undissociated aspirin existed in this region, it moved into micelles and was less hydrolyzable. Near pH 1, only the anionic surfactant lost its effect on suppressing the hydrolysis of aspirin. This was explained by the promoting effect of sodium lauryl sulfate on the hydrolysis of aspirin, due to the attracted hydrogen ion on the micelle environment competing with the suppressing effect of the solubilization. Even though this report shows suppression of the hydrolysis of unionized aspirin by all the surfactants and the suppression of the anionic form by cationic surfactants, it by no means implies that these solutions could be used as a stable pharmaceutical formulation.

Nelander (22) reported the heat of hydrolysis of aspirin at 25° by a calorimetric procedure. The $-\Delta H$ (kcal./mole) for aspirin was 25.39 ± 0.03 in 0.8 *N* sodium hydroxide in water–alcohol, 2:3. The heat of solution in aqueous tromethamine solution, ionic strength 0.1, initial pH 8.05, for aspirin was 5.72 ± 0.08 kcal./mole.

The first application of ultrasonic energy in accelerated drug stability studies was published by Mario and Gerraughty (23). Duplicate samples of aspirin in the given buffer (pH 2.00, 4.00, or 5.95) were put in two constant-temperature baths at 21, 25, 35, and 45° , one with ultrasonic energy and the other (control) without. Aliquots from both baths were taken at stated time intervals and assayed for salicylic acid at 302 m μ ; the content was calculated from standard curves of salicylic acid in the same buffer. Aspirin runs were done at two different concentration levels. The agreement of duplicate runs was good and indicated that the experimental technique was reproducible.

Pseudo-first-order rates were found at all pH values and with varying temperatures, both with and without ultrasonic energy. The hydrolysis rate constant, *k*, was calculated. The Arrhenius relationship was followed in all cases, and the heat of activation of the hydrolytic degradation of aspirin was not changed by the introduction of the ultrasonic energy. The increase in the rate found with the ultrasonic samples was equivalent to increasing the reaction mixture temperature within the range of 1.8–2.9°. This range was consistent, regardless of the pH or temperature used. Although the effects of ultrasonic energy were not startling on increasing hydrolysis, these studies did show the potential of this new technique, particularly with heat labile ingredients.

Table II—Apparent Zero-Order Rate Constants of Salicylic Acid at Constant pH

Aspirin plus Lubricant	k , mg. FSA/hr.	pH
None	0.123	2.60
Stearic acid	0.133	2.62
Hydrogenated vegetable oil	0.123	2.68
Talc	0.133	2.71
Aluminum stearate	0.281	3.16
Calcium stearate	0.986	3.75
Magnesium stearate	1.314	4.14

Needham and Gerraughty (24) pursued further the hydrolysis of aspirin in mixed solvent systems by ultrasonic energy. The solvent systems were: alcohol–water, 10, 30, 50, and 70%; ether–water, 3 and 5%; and ethylene glycol–water, 5, 10, 30, and 50%. The pH for all of the media was kept at 3.67. Since the thermal energy (use of dual constant-temperature baths) was kept constant for both ultrasonified and control systems, it was apparent that the ultrasonic energy was responsible for the increase in the kinetic rates. With the ethylene glycol–water system, as the concentration ratio was increased, the subsequent increase in viscosity apparently reduced the movement of molecules caused by the ultrasonic vibration, as shown by the smaller rate constants for the hydrolysis of aspirin.

In studying the interaction of aspirin with urea, Santopadre and Bolton (25) shook saturated solutions of aspirin in water at 30° with known varying amounts of urea (0 through 10 *M*) for 5 hr. Kinetic studies were made at pH 2.0, 2.5, 2.75, 3.0, and 3.5 at 30 ± 0.2°. First-order rate constants were calculated. Urea increased the rate of hydrolysis below pH 2.75 and decreased the rate of hydrolysis at pH values greater than 2.75. It is interesting to note that this “crossover” occurs at a pH corresponding to the pH of maximum stability, as reported by Edwards (8). This pH may thus represent a point where the hydrolysis mechanism changes, and this could provide an explanation for the change in the effect of urea.

Murthy and Rippie (26) studied the hydrolysis of aspirin in the presence of polysorbate 80. Saturated solutions of aspirin at 30 ± 0.1° were prepared in 0, 1, 2.5, and 4% solutions of polysorbate 80 at the following pH's: 2.63, 3.63, 4.10, 4.21, and 4.43. Kinetic studies were carried out on suspensions, saturated solutions, and half-saturated solutions for 48 hr. at 30 ± 0.1°. Samples were removed at stated times and assayed by the UV method described by Edwards (8).

With the suspensions, the observed increase in degradation-rate constants (pseudo-zero-order) with added polysorbate 80 was due to the instability of undissociated aspirin in the micellar phase. With the homogeneous solutions, the rate of hydrolysis of aspirin in the polysorbate micelles, while lower than in the aqueous phase, was not negligible. The solubility determinations in the various media showed the absence of dissociated aspirin in the micellar pseudophase of the polysorbate 80 solutions.

Hydrolysis of solubilized aspirin in the presence of the nonionic surfactant, cetomacrogol, was studied by Mitchell and Broadhead (27). All the studies were con-

ducted at 37 ± 0.1° in the pH range of 1–7 on solutions of aspirin with cetomacrogol concentrations of 0.1 through 0.07 *M*.

The hydrolysis of aspirin proceeds as a first-order reaction, both in aqueous buffer and in buffered cetomacrogol solutions. Reaction rate constants were determined. At the pH of maximum stability, pH 2.27, where aspirin exists largely in the unionized form, the half-life increased with cetomacrogol concentration. In 0.07 *M* cetomacrogol, the half-life was approximately twice that in the control buffer. In the plateau region where aspirin is largely ionized, the rate of hydrolysis was independent of cetomacrogol concentration.

Kornblum and Zoglio (28) evaluated the commonly used tablet lubricants as to their effect on the stability of aspirin. Suspensions of aspirin with the various lubricants (talc, hydrogenated vegetable oil,³ stearic acid, aluminum stearate, calcium stearate, and magnesium stearate) were prepared. The lubricants were also in excess to ensure saturation through the experiments.

The suspensions were maintained at 30°, with appropriate aliquots withdrawn at various time intervals for pH and salicylic acid determination by adding ferric chloride and reading at 540 m μ in a spectrophotometer. From the kinetic studies of these suspensions, the reaction rate appeared to be of zero order. The pH remained relatively constant through the 30-hr. study for the given suspension.

The results are summarized in Table II.

With both calcium and magnesium stearates, the rate of decomposition of aspirin was due to more than just the increase in pH. The authors showed that this increase was due to the high solubility of calcium and magnesium aspirin which were formed in these suspensions. The mechanism primarily involves a reaction of the alkali cation with aspirin in a solution to form a salt of aspirin which, in the presence of solvated aspirin, comprises a buffer system at a pH detrimental to the stability of aspirin.

Reduction of the water content in the aspirin–calcium stearate suspension was done to approach that found in a solid dosage form, the ultimate aim being the achievement of reproducible data which would permit subsequent extrapolation to the tablet or capsule dosage form. A major conclusion from this interesting study is that stearate salts should be avoided as tablet lubricants in preparing aspirin formulations.

In their study on salicylic acid sublimation, Gore *et al.* (29) determined the hydrolysis rates for aspirin at temperatures ranging from 17.2 to 30.2 ± 0.1° at pH 7.4 and reading the resulting salicylic acid at 296.5 m μ . Their data are summarized in Table III. These values are in close agreement with those reported by Morton (5) and Edwards (8).

It is only by pure coincidence, but certainly quite appropriate, that the last papers dealing with hydrolysis of aspirin in this review clarified the situation immensely. In an attempt to circumvent the problems raised by the kinetic equivalence of the several possible mechanisms, Fersht and Kirby (30, 31) looked first at

³ Sterotex, Capitol City Products, Columbus, Ohio.

Table III—Rate Constants for the Hydrolysis of Aspirin in pH 7.40 Buffer Solution at Various Temperatures

Temperature	k , Day ⁻¹

the reactivity toward hydrolysis of a series of substituted aspirins. The results suggested, unambiguously, that the most likely mechanism for the hydrolysis of aspirin was one in which the carboxylate group acts not as a nucleophile but as a general base.

The rate of hydrolysis of aspirin was measured in these studies by following the initial rate of release of salicylate at the isosbestic point, 298.5 m μ , and at $39.0 \pm 0.03^\circ$. The ionic strength was maintained at 1.0 with added potassium chloride. It was this fact that showed why Edwards (8) failed to detect catalysis by acetate ion, because the ionic strength was not kept constant in his experiments. Fersht and Kirby (30, 31) found that the small acceleration due to the addition of a given concentration of acetate was almost exactly equal to the opposite effect of the increase in ionic strength. If Edwards had only known this fact, there no doubt would have been fewer controversial papers dealing with the mechanism of the hydrolysis of aspirin.

The pH-rate profile for aspirin hydrolysis, measured by Edwards (8), shows that the transition state for hydrolysis in the pH-independent region involves the aspirin anion, either alone in a unimolecular reaction or together with one or more molecules of solvent. Three mechanisms were consistent with this kinetic result for intramolecular catalysis of the hydrolysis of aspirin by the carboxyl group:

1. A unimolecular process in which the carboxylate group acts as a nucleophile. There was no longer any evidence that specifically supported the nucleophilic mechanism. It was not consistent with the effect of substituents on the reaction, and there were several indications that the rate-determining step was not a unimolecular process.

2. A general acid catalysis of the attack of hydroxide ion by the undissociated carboxylic acid group. This mechanism was rejected because intermolecular general acid catalysis by the carboxy group of aspirin should be observed for attack by acetate as well as by the hydroxide ion.

Scheme III—Mechanism of hydrolysis of aspirin as a classical general base catalysis

3. A general base catalysis of the attack of a water molecule by the carboxylate anion. There seems little doubt that the intermolecular reaction of acetate with the aspirin anion represents general base catalysis. There is even less doubt that intramolecular catalysis of hydrolysis by the carboxylate group of aspirin involves the same mechanism as the intermolecular reaction with acetate ion.

In actuality, it seems probable that the aspirin reaction lies close to the borderline between nucleophilic and general base catalysis (Scheme III).

DETERMINATION OF SALICYLIC ACID IN ASPIRIN AND ASPIRIN PRODUCTS WITH FERRIC IRON

Until 1965, the most prominent method of determining salicylic acid in aspirin, or products containing aspirin, was the reaction with ferric iron under a variety of conditions. The complex produced on mixing ferric ion and salicylic acid (a bidentate ligand) results in the formation of a series of intensely colored metal chelates having ligand-ferric-ion ratios of 1:1, 2:1, and 3:1. The formation of the cyclic chelate structure (I) involves the displacement of the weakly acidic, phenolic hydrogen by the metal, resulting in the formation of a six-membered ring by coordination of the metal through the phenolate and carboxylate groups of salicylic acid:

In the first of these publications, in 1911 (32), the sample containing aspirin was shaken with water or alcohol and filtered; then one drop of ferric chloride solution was added. On standing, the color changed from red-dish to dark violet. This, in essence, was the beginning of the official compendia tests for salicylic acid in aspirin. It was noted very early by Melzer (33) that the presence of either sodium phosphate, tartaric acid, or borax masked the iron-salicylic acid color reaction. The useful suggestion was made that the tablets first be extracted with ether, since only the aspirin and salicylic acid would be extracted; thus a simple separation from the interfering compounds was easily accomplished. This immediately brings to mind that it would be easy to obtain false negative tests for salicylic acid if such a compound was incorporated in the aspirin tablet and no prior separation were made. Before the year was over, Linke (32) had refined the method for determining free salicylic acid in aspirin tablets by comparing the resulting iron-salicylate color to a series of salicylic acid standards. As little as 1 mcg. salicylic acid/ml. could be detected.

A limit test of 0.1% salicylic acid in aspirin was described by Leech (34), using a small volume of alcohol to dissolve the aspirin completely and then diluting with water before the addition of the ferric chloride reagent. This test became the basis for USP procedure when aspirin became official in 1926. It was emphasized that the standard salicylic acid tube should contain the same

amount of alcohol as the sample, because the final color was affected (decreased) by the presence of alcohol. Jones (35) stated that for tablets the limit test should be 0.15% salicylic acid and that there should be no turbidity in the final solutions.

Rather than compare the salicylic acid extract from aspirin, as described, Dahm (36) prepared a permanent color series containing various amounts of cobalt chloride dihydrate. After standardization with known quantities of salicylic acid, one could compare directly, under the stated conditions, aspirin extracts and "read" the percent free salicylic acid (FSA) directly. As these cobalt colors were of a permanent nature, it would save the analyst preparing a fresh salicylic acid reference standard.

Comments about the BP salicylic acid test made by Nutter-Smith (37, 38) brought forth that the official test was not effective below 0.04% salicylic acid, because the ferric chloride reagent was the limiting factor due to its own color. Using ferric ammonium sulfate corrected this situation. The presence of tartaric or citric acid in tablets (1%) has been shown to mask the presence of 0.2% salicylic acid. Thus, if one obtains a negative test for the FSA in unknown aspirin tablets, proper steps should be taken to separate the salicylic acid from the interfering material. Ruddiman (39, 40) added oxalic and tannic acids as masking agents of the iron-salicylate test and commented that sodium phosphate and borax did not interfere with the iron-salicylate test as had been believed. Incompatibility of aspirin with many drugs was proven by Snidow and Langenhan (41) using ferric alum reagent qualitatively.

Valentin and Lieber (42) showed that if ether was used to extract aspirin and salicylic acid from other materials, the evaporation step must be done with care, because too much heat results in high FSA values. They suggested chilling the ether and passing a stream of air over the solution to expedite the evaporation.

The use of a spectrophotometer in the determination of FSA was introduced by Hoffman (43) in 1929. Since the tablets being analyzed contained magnesium oxide, 4 *N* sulfuric acid was added during the grinding of the tablets. This was added to prevent hydrolysis (although not stated, it would also free any salicylic acid which might have been combined with magnesium ion) of the aspirin before the salicylic acid was extracted with a 1:1 mixture of ether and pentane. After evaporation of the clear extract, alcohol was added to dissolve the salicylic acid, and the iron reagent (ferric chloride) was added. This color was then compared with a standard series in the spectrophotometer.

Chloroform was introduced as a direct extractant of aspirin by Hitchens (44). This chloroform extract was shaken with 2% sodium bicarbonate aqueous solution to remove the aspirin (and salicylic acid). This, in turn, was made acidic with hydrochloric acid and extracted quantitatively with ethyl acetate. The ethyl acetate extract was evaporated under reduced pressure in a water bath maintained between 40–45°. The residue was dissolved in alcohol and diluted with water; ferric ammonium sulfate solution was then added. The resulting color was compared with standards of salicylic acid in the same medium. Because hydrolysis does take place in

alkaline medium, Hitchens showed that, at 20° for 1 hr. in the sodium bicarbonate solution, about 0.25% of the aspirin was hydrolyzed. At 30°, about 0.35% of the aspirin was hydrolyzed. Since the procedure described took less than 20 min. in the alkaline medium, the error caused by this alkaline hydrolysis was called negligible. With standard runs of aspirin USP, the FSA content was less than 0.15% by this extraction procedure. With various mixes and commercial tablets, the FSA found was never over 0.2%. The purpose of this extraction procedure was to isolate quantitatively the aspirin from compounds such as acetphenetidin, caffeine, acetanilid, antipyrine, amidopyrine, and phenylsalicylate.

In 1937, Banchetti (45) made a critical evaluation of many of the pharmacopeias in regard to their FSA tests which used various ferric iron reagents after extraction of the aspirin and salicylic acid. It was pointed out that the tests should be done at the lowest practical temperature and as rapidly as possible to minimize hydrolysis of the aspirin while conducting the procedure. If evaporation of a solvent extract is required, it should be done with as little heat as possible to avoid excessive FSA values.

The first reported humidity- and temperature-controlled experiments with aspirin tablets in different packagings was conducted by Canback (46). Tablets were stored in wood boxes, tins, impregnated paper, and glass bottles at $20 \pm 0.2^\circ$ for 1 year at various humidity stations (0, 19, 44, 59, 75, and 100% relative humidity). Using 2.5 *M* acid to acidify the pulverized powder, the aspirin and salicylic acid were extracted with a 1:1 mixture of ether and petroleum ether. An aliquot was evaporated, and the salicylic content was determined by dissolving the residue with diluted alcohol. Ferric chloride solution was added, and the resulting color was read in a colorimeter after standing 15 min. After a year at the various humidity stations, the aspirin tablets stored in glass showed very little change in FSA content. The other packagings were greatly inferior with the wooden one being the poorest in regard to aspirin stability. The higher the humidity, the larger and quicker the FSA values increased (other than in the glass bottles where little change was found at any of the humidity stations).

Using a Duboscq colorimeter, Tsuzuki and Sawada (47) measured the amount of FSA produced after aspirin had been heated at 110 and 128°. The heated sample (after 5–35 min. at the stated temperature) was dissolved in methanol, the ferric chloride reagent was added, and the solution was compared to standards. The relationship of increased FSA with a corresponding lowering of the melting point of the aspirin was shown.

Pankratz and Bandelin (48) made a systematic and comprehensive study of the optimum conditions for the reaction of ferric iron and salicylic acid and its reproducibility. Maximum absorption of the ferric-salicylate complex in a nearly aqueous medium was at 525 $m\mu$. This complex was very sensitive to pH changes. On studying pH effect at one pH unit increments from 1.0 through 9.0, the maximum color was found between 3.5 and 8.0. Above pH 6.5 the color faded rapidly, so the useful pH range was between pH 4.0 and 6.0. This emphasizes the point that unless the pH of the sample and of the standard series are close, the equivalent

Table IV—Percent Decomposition of Aspirin of Varying Particle Size after 6 Months^a at 37°

amount of color will not result. One variable, the alcohol concentration, was not controlled. But at the levels used, it apparently did not affect the linearity of the color to concentration. With such a study, one would have expected a comparison of the different ferric salts, particularly those which have been used in the past such as ferric chloride and ferric ammonium sulfate. Instead, this is the first paper in which ferric nitrate was used.

A study involving just pure aspirin, by Yamamoto and Takahashi (49), answered many questions which arise when one seriously wonders under what conditions aspirin is stable or the most stable. The effect of the particle size of the aspirin on its decomposition rate was studied at 37° over a storage period of 6 months at three controlled humidities. The data in Table IV indicate that the finer the crystals and the higher the relative humidity, the more aspirin hydrolyzed. One may also conclude that under 60% relative humidity at 37°, the percent decomposition of aspirin did not change with particle size. With today's use of micronized aspirin, this is a valuable fact.

In studies at 60° for a total of 25 hr. at 30, 60, 80, and 100% humidities, decomposition was linear with time, and the linearity seemed proportional to the vapor pressure because the slope of each line increased with an increase in vapor pressure. Although the FSA content never exceeded 0.04%, this study showed that an increase in humidity did result in an increase in the decomposition rate.

At 90° and at low humidity, the authors found that, after a total of 12 hr., aspirin decomposition was linear with time but had not surpassed 0.1%. At 120° (low humidity), over 15% of the aspirin was decomposed within 5 hr., and the rate of decomposition was no longer linear with time. This study emphasized the fact that temperature increases alone accelerated the decomposition of aspirin.

Grinding of aspirin for 15-120 sec. did not increase appreciably the percent decomposition. On repeated compression (three times) of aspirin, the percent decomposition was found not to have increased appreciably.

In another paper dealing with the stability of aspirin when mixed with other compounds, Yamamoto and

Takahashi (50) found that such mixtures should be stored at the lowest practical humidity to prevent excessive decomposition of the aspirin (Table V).

In a comparison of aspirin mixtures with various salts of ethylenediamine, the importance of acid strength on the decomposition of aspirin was shown (Table VI). This study was conducted at 37° and 84% relative humidity for 15 days with a 100:3 ratio of aspirin to ethylenediamine salt.

Further investigation of a 10:1 molar ratio of aspirin-antipyrine mixture stored at 37° and 84% relative humidity for 2 months produced salicylic acid and antipyrine salicylate. The mechanism proposed for this interaction is given in Scheme IV.

Scheme IV was explained in the following manner. First there was an acid-base reaction between aspirin and antipyrine; but because this salt was highly unstable, it decomposed rapidly to antipyrine salicylate. Since aspirin and salicylic acid have approximately the same acidity, the excess aspirin present was capable of reacting with the antipyrine salicylate, releasing salicylic acid and regenerating the unstable aspirin-antipyrine salt which, in turn, started the cycle again.

A similar reaction cycle was proposed for the decomposition of aspirin with pheniramine maleate (amine salt of a weak acid), while no reaction took place with pheniramine hydrochloride (amine salt of a strong acid)

because aspirin was not capable of displacing the hydrochloric acid.

Without the aid of the computer age, Ribeiro *et al.* (51) undertook a massive, well-executed study of variables in the manufacturing of a stable APC tablet (aspirin, phenacetin, and caffeine). To study the probable causes of the decomposition of aspirin, a factorial experiment was set up testing all combinations of lubricants at two levels, pressure at two levels, moisture at two levels, and two types of aspirin; the entire series was repeated for each of the seven different lubricants (a $2^4 \times 7$ factorial experiment). These variables were selected because they seemed to be the most probable causes of aspirin breakdown in APC tablets. An Association of Official Agriculture Chemists (AOAC) (6th edition) procedure for salicylic acid was modified by using absolute alcohol to extract the salicylic acid from the pulverized tablets and to develop the final iron-salicylate color in a 35% alcohol medium. A spectrophotometer was used to read the resulting color at 537 m μ . Concentrations of salicylic acid were obtained from a standard curve of salicylic acid prepared exactly as the samples. These salicylic acid values were converted to aspirin values and reported in this paper as percent of aspirin content that had decomposed.

Before presenting the data in tabular form, a brief explanation of all the symbols used in the table is essential for proper interpretation of the percent decomposition of aspirin in the tablets after being stored in loosely capped bottles at 45° for 27 days. Tables VII and VIII summarize the results.

Interpretation of these results indicated that more stable combinations were possible if the lubricants used were talc, talc plus mineral oil, mineral oil, or glycerin monostearate rather than stearic acid, magnesium stearate, or calcium stearate. Compression pressure levels showed no effect. Moisture levels were not different enough to be consequential. The crystalline aspirin was superior to the starch-aspirin granulation.

Since difficulties arose in applying the BP colorimetric test for the FSA, Edwards *et al.* (52) initiated an investigation of the kinetics of aspirin hydrolysis and of conditions affecting the formation and stability of the ferric-salicylate complex. Time, as already well known, was an important factor, because aspirin hydrolyzes continually once it is in a given solvent (here alcohol and later water). The need for fast filtration was obvious. Higher temperature expedited the hydrolysis of aspirin, so the lowest practical temperature should be used throughout the test. Constant pH for the test was a

^a The freshly compressed tablets showed negligible decomposed aspirin.

must because the rates of hydrolysis of aspirin vary appreciably with pH. The intensity of the ferric-salicylate complex depends greatly on the pH of the medium. The maximum intensity was obtained between pH 2.5 and 3.5 and was best maintained using an acetic acid-ammonium monochloroacetate buffer. Below or above this pH range the intensity of the color decreased rapidly (intensity at pH 3 was over five times as strong as that at pH 1.5).

As the BP method for FSA is a limit test, a quantitative procedure was developed utilizing the maximum conditions described. If no known interfering materials were present, the aspirin and salicylic acid were dissolved in absolute ethanol diluted with water, all at 25°, and maintained by a thermostated water bath. The time (T_0) was noted when the buffer and ferric ammonium sulfate solution were added and mixed. The volume of the solution was made up to the mark with water, mixed, and kept at 25° for about 10 min. An aliquot was filtered, transferred into an absorption cell, and read at 530 m μ against a reagent blank; the time (T_1) was noted. At least three aliquots were withdrawn at intervals of not less than 10 min. apart. From these values (T_1 , T_2 , and T_3), a value for the extinction coefficient at zero time (T_0) was obtained by extrapolation. From a standard salicylic acid curve, the amount of salicylic acid at T_0 was thus obtained.

If interfering matter such as phosphate or citrate was present, the aspirin and salicylic acid were extracted from the powdered sample in a separator with benzene. The filtered and pooled benzene was then extracted with small volumes of a solution of the buffer and ferric ammonium sulfate reagent, until an aliquot showed no further coloration in the aqueous extract. The pooled aqueous solution was made to volume with the remaining buffered ferric ammonium sulfate solution and filtered, if necessary, before reading at 530 m μ . The FSA was calculated from a standard salicylic acid curve as before, but without having to calculate a T_0 value; the intact aspirin remains in the benzene layer, so no hydrolysis should be taking place in the aqueous layer.

It is of interest to note that the pH of the aqueous solution (2.95 ± 0.05) read at 530 m μ for both procedures was near the minimum of the hydrolysis rate of aspirin in regard to its pH-rate profile. On comparing the FSA values obtained by using these proposed procedures with those of the BP on several commercial products, the proposed procedure consistently found more FSA, which again raises doubt about the sensitivity of the official BP test for FSA.

Quite independently, Strode *et al.* (53) conducted a systematic study similar to Edwards, only this study involved modifying the USP XV free salicylic test from a limit test to a sensitive, reproducible procedure which was applicable in FSA testing not greater than 0.25%. Hydrolysis curves were constructed from transmittance measurements made at timed intervals on thermostated solutions of aspirin and ferric alum. Under the conditions of the spectrophotometric method, these curves indicated that salicylic acid increased at the rate of 0.0028%/min. at 20°, 0.0036%/min. at 25°, and 0.0054%/min. at 30°. This definitely emphasizes the need for reasonably close temperature control. To obtain re-

liable readings, 100-mm. cells instead of the usual 10-mm. cells were used. The ferric alum solution in 0.01 *N* hydrochloric acid was kept refrigerated and prepared fresh each week. The calibration standards were prepared so that they would be at the same pH and essentially of the same composition as the sample solutions being measured. This was accomplished by adding an aliquot of freshly prepared aspirin solution in alcohol (SD 30) and water at 25° to individual standard increments of salicylic acid, and noting the time between addition of the ferric alum solution and the reading of final solution (this should be within 5 min.). Through a simplified calculation, a correction for the hydrolysis of the aspirin during this short time interval may be applied. Thus, this is the first time where the salicylic standards contained essentially the same amount of aspirin as the samples being assayed. With colorless aspirin solutions or those from green-tinted formulations, the final iron-salicylate color was read at 515 m μ while the pink-tinted formulations were read at 575 m μ . Appropriate standard curves were run at these given wavelengths. Within the range of concentration measured, the precision and accuracy of this method were within 0.005% salicylic acid at the 95% confidence level.

They also developed a rapid visual method using matched Nessler tubes and a series of salicylic acid standards, which were prepared exactly as the sample in regard to pH, alcohol (SD 30) content, and ferric alum solution. These standard solutions were stable for 2 weeks. The aspirin sample (colorless for this test) was dissolved in alcohol (SD 30), the appropriate aliquot diluted with water cooled to 10°, then treated with the ferric alum solution, and compared within 30 sec. to the standard series of salicylic acid. The salicylic acid content was estimated visually to the nearest 10 mcg. of salicylic acid. By conducting this comparison test so rapidly and at 10°, the hydrolysis error appeared to be within experimental error.

In a thesis and later a publication, Leeson (54) and Leeson and Mattocks (55) made a very thorough study of the decomposition of aspirin in the solid state, utilizing a modification of the AOAC 6th edition procedure which improved the accuracy and sensitivity of the measurements. The aspirin and salicylic acid were dissolved in absolute alcohol. The final color of a given aliquot, which was developed in a 50% alcohol medium, was read in a spectrophotometer at 532 m μ (a slit width of 0.02 mm.) along with a series of salicylic standards treated exactly as the samples.

The step in which the sample or standard salicylic acid aliquot is diluted to exactly 50 ml. with absolute alcohol is an extremely important one. The original procedure consisted of adding the given aliquot to 50 ml. of absolute alcohol, but since the size of the aliquot varied, the concentration of alcohol in the final dilution was not constant. To determine the effect of alcohol concentration on the iron-salicylate color, three different concentrations of salicylic acid were made. They were read over a varying range of alcohol from 5 through 85% alcohol at increasing increments of 10% alcohol. It was readily concluded that the final concentration of alcohol had a significant effect on color intensity. With

the lowest salicylic acid concentration, alcohol content of 30 ml. instead of 25 ml. could introduce an error of 6.7% in FSA value. This error increases greatly with higher concentration of alcohol. For this reason, although a worker may select any alcohol volume desired, he must keep it constant throughout the study for both the samples and standards.

Under anhydrous conditions in sealed ampuls, aspirin (100–140-mesh) with and without calcium stearate (a lubricant in aspirin tablets which has been shown to expedite the decomposition of aspirin) were stored at 35, 45, 60, 80, 100, and 110°. Samples were removed at various time intervals over a period of 50 days and assayed for FSA content. Samples of aspirin alone showed little or no decomposition at 80° or below, while those with calcium stearate decomposed within 2 days to the extent of about 1% FSA and then remained near this level during the remainder of the study. At both 100 and 110°, with or without calcium stearate, the aspirin showed about 2% FSA in 5 days and then decreased gradually with time. As these samples both melted and changed color, it was not known whether the formation of a polymolecular salicylide accounted for the decrease in salicylic acid.

From these studies, it was believed that the small amount of decomposition found could have been caused by traces of moisture, which contaminated the dry aspirin during the filling and sealing of the ampuls. The amount of water necessary to account for the decomposition observed was approximately 10^{-6} moles. The conclusion was thus reached that below 80°, the decomposition of aspirin in the absence of moisture was of minor importance.

Consequently, the role of humidity, or more specifically vapor pressure, on the decomposition of aspirin was studied at various temperatures (50, 60, 70, and 80°) with vapor pressures varying from 46 through 232.5 mm. At various time intervals over a period of nearly 1 year, samples were taken from the given humidistats and assayed for FSA content. Decomposition was noted at all stations. The amount depended on the length of time in the given humidistat, temperature, and vapor pressure. The higher the temperature and vapor pressure, the more rapid was the decomposition.

Tablets containing aspirin, starch, and talc (washed and unwashed) were prepared and studied under similar conditions as the aspirin crystals. The effect of

washed talc on the stability of the aspirin was not appreciably different from the talc. The complications arose at various humidistats in that the tablets would liquefy, particularly at the 80° stations (but not below 60°), once the salicylic acid content reached a critical level. Once liquefaction occurred, the salicylic acid content decreased sharply and the study with that humidistat was discontinued. Along with previous workers' conclusions, Leeson showed that the compression into tablets did not change the mechanism of decomposition.

The widespread use of aspirin in combination with various antacid compounds as buffering agents led Bandelin and Malesh (56) to study the stability of aspirin with 11 commonly used antacid compounds. Using a modification of the method of Pankratz and Bandelin (48), previously discussed, the FSA content of powder mixtures of two parts aspirin to one part antacid powder, after being stored at room temperature or at 37.5° for periods of time up to 1 year, were assayed at stated time intervals. The antacid powders were used directly from the commercial container so they were not pretreated or dried in any way before using. Table IX summarizes their results.

Both dihydroxy aluminum aminoacetate and calcium gluconate were definitely superior to the other antacids studied in regard to "available" FSA. The word available is used with the FSA reported in that the mixture assayed was extracted directly with acetone. It was not shown, or stated, if aluminum, calcium, or magnesium salicylate was formed during the decomposition of the aspirin, or if the acetone would dissolve these salts. Further, if they did dissolve, would the ferric iron replace the cation in the 50% acetone medium in which the iron–salicylate color was developed?

The unusual was done by Wirth (57) in that he followed the USP XV procedure for FSA *without* any modifications when assaying APC tablets. The FSA values reported were acceptable.

Using the procedure of Ribeiro *et al.* (51), Kral *et al.* (58) studied various mixtures of drugs commonly given with aspirin. Samples of the various mixes were kept at four different stations: room temperature, anhydrous state at room temperature, 97% relative humidity at room temperature, and 37° for periods up to 6 months. The individual mixtures of aspirin with phenacetin, caffeine, phenobarbital, dextrose, sucrose, or lactose were classed as being stable, while those with

Table X—Effect of Amphetamine Salts on the Stability of Aspirin

Acid tartrate	3.02	

^a Second dissociation constant.

antipyrine, amidopyrine, and quinine hydrochloride decomposed slightly. Mixtures of sodium bicarbonate, hexamethylenetetramine, and caffeine sodium benzoate decomposed rapidly.

In his thesis, Lippmann (59) used the colorimetric procedure developed by Leeson (54), but substituted 95% alcohol for absolute alcohol in his studies of aspirin decomposition with various amphetamine salts. Mixtures of 100 parts of aspirin (50–70-mesh) and 2.935 parts of amphetamine salt as base (60-mesh) were stored in humidity cabinets at 73° and 67% relative humidity. Amphetamine salts used were sulfate, diphenylacetate, *p*-aminobenzoate, 2-naphthoate, phthalate, and picrate. The phthalate salt increased the rate of decomposition of the aspirin the greatest; the order was as follows: phthalate > diphenylacetate = *p*-aminobenzoate = 2-naphthoate > picrate > sulfate.

A relationship between pK of the parent acid in the amphetamine salt and rate of decomposition of aspirin (Table X) correlated well with the acid strength discussed by Yamamoto and Takahashi (50).

Four different tablets of aspirin were manufactured by Nazareth and Huyck (60) to study the effect of calcium salts on the stability of aspirin. The tablets were stored at 9–12, 25–30, and 45° for a period of 8 weeks. Samples were removed weekly and assayed for salicylic acid by essentially the method of Pankratz and Bandelin (48), reading the final color in a 20% alcohol medium. Table XI summarizes their work.

It was noticed that when the percent FSA was over 6, needle-shaped crystals (whiskers) of salicylic acid appeared on the sides and neck of the container. This study showed that aspirin was unstable in the presence of either calcium carbonate or calcium succinate. This was in agreement with Yamamoto and Takahashi (50), who found that the presence of a salt of a weak acid accelerates the decomposition of aspirin.

Continuing the same type of study, Nazareth and Huyck (61) studied the stability of aspirin in four differently manufactured APC tablets. The tablets were stored for 5 weeks and samples removed weekly for the FSA assay.

Only Tablet A in Table XII showed a rapid decomposition of aspirin. It was the only tablet containing magnesium stearate as a lubricant.

As DeMarco and Marcus (62) did not require the sensitiveness described by Leeson (54), they modified the iron reagent to account for larger amounts of salicylic acid and still adhere to Beer's law (Table XIII).

Reagent No. 1 was used by Leeson and was shown to be very sensitive to the alcohol concentration. Reagent No. 4 was recommended, as it was not only insensitive

to alcohol concentration changes, but the intensity of the iron-salicylate complex was greatly increased. Reagent No. 7 emphasized the need for acid in the color development medium.

Okano *et al.* (63) conducted a factorial experiment (2⁸ × 4) like Ribeiro *et al.* (51) and obtained essentially the same conclusions. Of the lubricants, talc, edible oil, and stearic acid were better than magnesium stearate or calcium stearate at 56°. Room relative humidity caused less decomposition than 84% relative humidity. Storage temperature at 45° caused more aspirin decomposition than room temperature (10–20°). Presence of lactose or diphenylpyraline hydrochloride resulted in an increase in aspirin decomposition. Little effect was noticed on the stability of aspirin, with or without starch, whether it was prism or needle form. The number of times the tablets were compressed at different pressures did not affect the aspirin.

In continuing their studies on the stability of aspirin with other drugs or compounds, Patel and Huyck (64) manufactured aspirin tablets with and without aluminum hydroxide dried gel USP. The tablets were stored for nine weeks and samples removed weekly for FSA assay as previously described.

The results in Table XIV are in agreement with the work reported by Bandelin and Malesh (56).

In two papers, Grabowska (65, 66) reported on the stability of aspirin with other drugs as powders or tablets after a year's storage. No decomposition of aspirin was reported when mixed with caffeine, quinine sulfate, codeine phosphate, phenobarbital, phenacetin, carbromal, urea, or *p*-aminobenzoic acid.

Slight decomposition was reported with quinine hydrochloride or sodium benzoate. The presence of sodium phenobarbital, codeine base, or caffeine sodium benzoate greatly accelerated the decomposition of the aspirin. Four stabilizers, magnesium oxide, aluminum hydroxide, calcium carbonate, and calcium gluconate, were mixed individually with aspirin, sodium phenobarbital, and caffeine mix, and aspirin, caffeine, and so-

dium benzoate mix. Magnesium oxide was best with the former mix, while aluminum hydroxide, calcium carbonate, or calcium gluconate was effective in stabilizing the aspirin in the latter formulation.

Control methods used in the Australian pharmaceutical industry for FSA in aspirin formulations were described by Green (67). The method of Strode *et al.* (53) was used in determining the FSA content in aspirin and aspirin–starch formulations. The results were in line with the BP FSA limits. If the formulation contained magnesium hydroxide, it was necessary to release the salicylic acid from its magnesium salt by first adding an aqueous acid and extracting the salicylic acid immediately with 1:1 pentane–ether solution. After evaporation of the mixed solvent the residue was dissolved in alcohol and assayed.

The effect of selected USP talcs on the stability of aspirin in tablets was reported by Gold and Campbell (68), utilizing a direct benzene extraction of the pulverized tablets. After vigorous shaking and centrifuging until clear, an aliquot was shaken with a ferric ammonium sulfate reagent. The clear aqueous layer, after centrifuging, was read in a colorimeter at 515 m μ . FSA content was calculated from a standard series of salicylic acid treated as the sample. Three series of tablets were prepared. The first used the talc, as is; the second used acid-washed talc. The third series used the best of the four talcs, Talc A, plus known amounts of various impurities (aluminum silicate, red iron oxide, calcium silicate, and calcium carbonate which were mixed individually with the talc to prepare the aspirin tablets).

The data indicated that the four USP talcs were different in regard to FSA formation after being stored at 40° and 90% relative humidity for 12 weeks (FSA varied from 0.8 to 25.8%). The decomposition, however, did not appear to be directly related to the pH of

the talc. The acid washing of the talc before use did improve the aspirin stability greatly, particularly with Talc C. Of the added impurities to Talc A, the presence of aluminum silicate or red iron oxide did not significantly affect the stability of the aspirin, while both the calcium salts (carbonate being the worst offender) influenced appreciably the rate of decomposition of the aspirin.

Though the main interest of Troup and Mitchner (69) was on degradation of phenylephrine hydrochloride in tablet formulations containing aspirin, they did assay for FSA according to the Gold and Campbell (68) procedure. For the degradation of phenylephrine in aspirin-containing tablets to occur, the breakdown of the aspirin was prerequisite. This was accelerated greatly by the presence of magnesium stearate as a lubricant in the manufacturing of the tablets. For any one formulation held at elevated temperature (usually 70°), the increase in salicylic acid content plotted against the decrease in phenylephrine content gave a linear relationship.

The effect of four granulating solvents in the manufacturing of aspirin tablets was reported by Trose and Danz (70). Granulations prepared with 95 and 70% alcohol or spiritus gelatine did not increase the decomposition of the aspirin, while the use of 5% gelatin mucilage did. The FSA content was found by extracting the pulverized sample with alcohol, filtering, diluting with water, adding ferric chloride reagent, and reading the resulting color at 530 m μ in a colorimeter. If phosphates are present in the formulation, a preliminary extraction and evaporation must be made with 1:1 ether–petroleum ether mixture.

Jaminet and Evrard (71) evaluated the effectiveness of precirol (a glyceryl palmitostearate), a binder lubricant, in the manufacturing of aspirin tablets. After 3 months at 50° and 80% relative humidity, no FSA was reported from the tablets using this substance. The FSA was determined in the pulverized tablets by first extracting with 1:1 ether–petroleum ether solution, filtering, evaporating, dissolving the residue in alcohol, diluting with water, and adding a ferric ammonium sulfate reagent. The solutions were read at 520 m μ .

The effects of humidity on aspirin, on its mixtures and tablets, with five different fillers were reported by Wisniewski and Piasecka (72). The FSA was determined by dissolving the aspirin in alcohol, filtering if

required, and adding an aliquot to a Nessler cylinder containing water and the ferric ammonium sulfate reagent. These were compared with the prepared salicylic acid standard solutions. The samples were stored over a period of 4 months at 93, 58, and 20% relative humidity along with changing humidity conditions in the laboratory. The decomposition at 93% relative humidity took place in the following decreasing order of filler used: magnesium oxide > magnesium carbonate > calcium carbonate > magnesium stearate > no filler. This same decomposition order existed at 58 and 20% relative humidity, along with ambient conditions. It is one of the few times that magnesium stearate has not led the list in degree of decomposition of aspirin. During these studies, it was shown that alcohol concentration affected the final color, as did varying amounts of acetic acid. None of the fillers used altered the final color.

In a paper similar to that of degradation of phenylephrine (69), Koshy *et al.* (73) reported on the acetylation of acetaminophen (APAP) in tablet formulations containing aspirin. With tablets stored at 50° for a period of 6 weeks, the formation of diacetyl-*p*-aminophenol (DAPAP) indicated a linear relationship between the rate of formation of salicylic acid through a 4-week period (Fig. 2). The same trend existed in various samples stored at ambient conditions, although at lower salicylic acid and DAPAP levels. Commercial tablets of unknown age, purchased from retail outlets and containing both APAP and aspirin, showed this same relationship of aspirin decomposition and formation of DAPAP. As one of these lots showed high DAPAP, a study was conducted at 50° for 4 weeks on the effect of stearic acid in one and magnesium stearate in the other. The magnesium stearate mix produced nearly 1000 times as much DAPAP as the stearic acid or regular mix.

Continuing their study on the stability of aspirin, Jaminet and Louis (74) made tablets with various lubricants. On assaying these tablets after being stored 6 months at 50° and 80% relative humidity, the lubricants may be listed in order of increased amounts of salicylic acid being found. Magnesium stearate was the poorest lubricant in that nearly 90% of the aspirin was decomposed, the next being polyethylene glycol 6000 (about 15% being decomposed) > glycerol monostearate II > stearic acid > stearyl alcohol > glycerol monostearate I > precirol = geleol. The last two lubri-

cants were the best in protecting the aspirin from decomposing under these conditions.

It is befitting that the last paper using an iron reagent would be titled "An Automated Colorimetric Method for Determination of Free Salicylic Acid in Aspirin-Containing Products," by Cullen *et al.* (75). The number of salicylic acid determinations required in the development of a stable aspirin product, or in production quality control, can be overburdening. The need to automate the salicylic acid analysis was, and is, great, as the saving in analytical time, effort, manpower, and expense can be tremendous.

The method selected for automation was that of Pankratz and Bandelin (48), as they had reported on the optimum conditions needed in order to obtain the greatest accuracy and reproducibility in the quantitative determination of salicylic acid in pharmaceutical preparations. A flow diagram (Fig. 3) is presented at this time only to show the equipment arrangement utilizing a standard Technicon automated system which was programed at 15 samples/hr. Specificity studies are summarized in Table XV.

Turbidity accounted for the high values given by the presence of calcium and magnesium stearate and stearic acid. The quenching effect (negative interference) was brought about by citric acid which forms a nonionized salt with iron. Phenothiazine derivatives react directly with the ferric iron and so must be removed if present in the aspirin formulation. Linearity of the salicylic acid in the microaperture flow-through cells was excellent. The precision of standard salicylic acid showed a repeatability deviation of 1.5%, while replicate samples of a commercial tablet were within 2%. Good accuracy was demonstrated by recovery of known amounts of standard salicylic acid added to powdered commercial tablets and by comparing this to the manual procedure.

DETERMINATION OF SALICYLIC ACID IN ASPIRIN AND ASPIRIN PRODUCTS BY UV SPECTROPHOTOMETRY

Until Tinker and McBay (76) introduced their simple and rapid spectrophotometric method of analysis for aspirin and salicylic acid, two separate determinations had to be made for the intact aspirin and hydrolyzed aspirin. In selecting the solvent for the UV studies, they found that in using chloroform A.R. grade, both aspirin and salicylic acid had higher absorbances and stabilities than in either aqueous or alcohol solutions. Also, the greatest difference between maximum and minimum absorbance values for any given concentration was observed in chloroform. The maximum absorbance for aspirin and salicylic acid was found to be 278 and 308 $\text{m}\mu$, respectively, as shown in Fig. 4. Beer's law was conformed to in the concentration ranges used. Equations were developed for this two-component mixture, and the application to aspirin, aspirin tablets, or capsules was valid and had an error of less than 0.2%. Samples of aspirin were dissolved in chloroform (filtered if necessary) and read at 308 $\text{m}\mu$ for salicylic acid content. A portion of the bulk solution was diluted 100 times and then read at 278 $\text{m}\mu$ for aspirin content. Both readings were against a chloroform blank.

Ebert (77) found that the existing methods for determining amphetamine sulfate, phenacetin, and aspirin in the corresponding tablets involved many laborious

Figure 4—UV spectrocurves of aspirin (---) and of salicylic acid (—) in chloroform.

time-consuming extractions. After the separations were completed, lengthy titrations or a gravimetric procedure were required. With all this work, very little, if any, reliable information was available in regard to subtle changes such as the presence of salicylic acid which could be formed from the decomposition of the aspirin. Ebert, with meticulous care, designed a three-component spectrophotometric method for the simultaneous determination of aspirin, phenacetin, and salicylic acid. It was not only a more rapid method of analysis, but was found to give increased accuracy and precision. Alcohol was selected as the solvent of choice. In this medium, aspirin was found to have an absorption maximum at 226 $\text{m}\mu$, salicylic acid at 235 $\text{m}\mu$, and phenacetin at 250 $\text{m}\mu$. As there was a great deal of overlapping of the three absorption curves, it was important to prove that the absorbance of this mixture, particularly where the aspirin showed 0, 50, and 100% hydrolysis, represented the sum of the absorbances of the individual compounds comprising the mixture at that wavelength. The validity of this was well proven by Ebert's work. From all these basic data, the appropriate validated equations were derived. The equations were then tried on tablets which had been extracted with ether. The three compounds in alcohol were then determined spectrophotometrically. The estimate of the accuracy and precision compared favorably with those methods used in the past. Though the major emphasis of this work was on the stability of sympathomimetic amine salts when combined with aspirin and phenacetin, interesting facts evolved about the stability of aspirin in these combinations. It might be added that in all the stability studies conducted here, phenacetin did not show any appreciable change.

Stability studies on tablets containing amphetamine sulfate, aspirin, and phenacetin were conducted in regard to the effects of temperature, moisture, and lubricants on these compounds. All the tablets were packaged in loosely capped amber bottles. These bottles were stored under the following conditions: room temperature, 0% relative humidity; room temperature, 95% relative humidity; 43°, 0% relative humidity, and 43°, 95% relative humidity. After a year's storage and many assays, the important finding was that aspirin decom-

position appeared to be associated with the disappearance of the amphetamine sulfate. The aspirin decomposition appeared to be dependent upon the lubricant present in the following decreasing order: magnesium stearate > talc and magnesium stearate > stearic acid > talc. The increase of temperature accelerated the decomposition of aspirin, but the increase of humidity at the same temperature had a much greater effect. Methamphetamine hydrochloride was substituted for the amphetamine sulfate in a similar stability study, and the conclusions were the same as mentioned for amphetamine sulfate. It is of interest to note that no aspirin decomposition occurred in any of the formulas stored at room temperature, 0% relative humidity, regardless of the ingredients present. In another study, salicylic acid replaced aspirin in the tablet with the result that it had little or no effect on the amphetamine sulfate.

Ebert checked on the possibility that aspirin might be capable of acetylating amphetamine. Working with the pure compounds, he isolated acetylamphetamine which proved this belief. The addition of an equivalent amount of salicylic acid and acetic acid in place of the aspirin in that study did not result in the isolation of any acetylamphetamine. Isolation of any acetylamphetamine from the tablets studied was not successful. Today, with the aid of TLC and GLC, such a decomposition product could readily be detected quantitatively.

Though Leeson's work with aspirin (54) involved chiefly a colorimetric procedure, he used the UV procedure developed by Ebert. This was done to check that no loss of salicylic acid (through volatilization) from the vials on stability had occurred. As the tablets used here did not contain amphetamine sulfate or phenacetin, the interpretation required was simpler. Absolute alcohol was used in place of the 95% alcohol. This would assure better stability of the aspirin during the assay. Readings were taken at 226 m μ (slit width of 0.8 mm.) and at 235 m μ (slit width at 0.6 mm.) against absolute alcohol. On assaying many tablets randomly, the summation (in moles) of the aspirin and salicylic acid found accounted for all the aspirin originally employed. In short, no salicylic acid was being lost through volatilization under the storage conditions.

In the first of a series of many interesting and valuable publications dealing with the determination of the stability of aspirin in many products, Levine (78) introduced a rapid chromatographic assay for APC tablets which included the determination of salicylic acid. Previous papers using this column technique did not discuss the determination of salicylic acid.

The pulverized APC sample was extracted with chloroform containing a small amount of acetic acid (to convert any aspirin salt to the free acid and so be extracted by the chloroform). Without filtering off the insoluble excipient material, an aliquot was diluted with freshly water-washed ether and passed directly to the single duplex column which had just been washed using water-washed ether. The upper segment of the column contained 1 *N* sodium bicarbonate on diatomaceous earth⁴ which acted as the supporting phase. The sodium bicarbonate trapped both the aspirin and salicylic acid.

The lower segment of the column contained 4 *N* sulfuric acid on diatomaceous earth. The sulfuric acid retained the caffeine while the phenacetin passed through into an evaporating dish. Water-washed ether was passed through the column in small portions to elute quantitatively all the phenacetin. A volumetric flask was placed under the column and sufficient water-washed chloroform was passed through the column to elute quantitatively the caffeine. Immediately, the column was eluted with acetic acid in chloroform (previously water-washed before adding the acetic acid) into another volumetric flask. This last eluate was read immediately in a suitable spectrophotometer at 280 m μ for aspirin and 310 m μ for salicylic acid, as aspirin was not stable in this medium. The caffeine was read at 276 m μ while the phenacetin was evaporating. The residue in the evaporating dish was dissolved in a little chloroform and then diluted with isooctane in a volumetric flask and read at 285 m μ .

This entire procedure, from grinding of the tablets to the final UV readings, took less than 1 hr. Though it was not emphasized, the aspirin should not be left on the column any longer than necessary, as it has been found to hydrolyze readily. From experience it has been found that the phenacetin may be dissolved and diluted with chloroform; thus another solvent (isooctane) is unnecessary.

In calculating, standards of the three drugs and salicylic acid are read in the UV at the stated wavelength in the same medium as the sample. For practical purposes, it was assumed that aspirin's absorbance at 310 m μ was negligible (100 mcg. aspirin/ml. read 0.010). Thus, any reading at 310 m μ was calculated as salicylic acid. From this absorbance value at 310 m μ , the absorbance due to the salicylic acid at 280 m μ can be calculated from the values of the standard salicylic acid read at these two wavelengths and deducted from the total absorbance at 280 m μ ; the remainder can be considered to be the absorbance of the intact aspirin.

This partition chromatographic procedure compared excellently with the old and very laborious NF X procedure. The fact of the matter is that Levine's work was so convincing (and deservedly so) that in the next revision of the NF (NF XI) his procedure replaced the old official method except for the FSA limit test. There were also other firsts in this paper; Levine broke tradition with conventional partition chromatography techniques by altering the nature of the immobile phase (neutralizing the sodium bicarbonate phase of the column with acetic acid) as a step in the process. In so doing, the versatility of partition chromatography was thus broadened to permit separations not previously possible. In earlier techniques, the constitution of the immobile phase remains unchanged.

In 1959 and 1960, Smith (79, 80) reported on an AOAC collaborative study of the Levine method for APC. As a result of these studies, the Levine method became official in the Tenth Edition of the Methods of Analysis of the AOAC. These collaborative tests did show a weakness in the procedure, in that the values reported for the salicylic acid content varied appreciably (from 0.15 to 3.17% as hydrolyzed aspirin). As stated before, with care the hydrolysis of the aspirin on the

⁴ Celite 545, Johns-Manville Corp., New York, N. Y.

sodium bicarbonate column can be avoided, chiefly by eluting the column as quickly as possible. Smith suggested that the aspirin and salicylic acid content could be calculated by simultaneous equations rather than make the assumptions already discussed in the Levine paper.

Heuermann and Levine (81) and later Heuermann (82) expanded the usefulness of Levine's original work to the analysis of combinations of aspirin, phenacetin, and caffeine with other drugs. The other drugs were pyrilamine maleate, chlorprophenpyridamine maleate, phenindamine tartrate, methapyrilene hydrochloride, doxylamine succinate, thonzylamine hydrochloride, codeine sulfate or phosphate, phenobarbital, or cyclopentylallylbarbituric acid. In neither paper were there any salicylic acid values reported, although discussion was made of its determination. An absorbance figure greater than 0.020 at 310 $m\mu$ indicated that partial hydrolysis of the aspirin had taken place and must be accounted for in the calculations of the aspirin content of the sample. Simultaneous equations were used in determining the intact aspirin and the FSA content of the sample.

In the application of his partition chromatographic procedure to just aspirin and aspirin tablets, Levine (83) required only the sodium bicarbonate segment of the column. With this paper, he clarified the salicylic acid status in that if 5% or more FSA was found, the aspirin and salicylic acid contents of the given sample were found simultaneously by the described UV procedure. If the FSA was under 5%, another technique was used. (This technique will be described later in this Review Article.)

With the UV procedure, it was noted earlier that aspirin was not stable in chloroform so a little acetic acid was added to acidify the medium. However, in the case of buffered tablets, a stronger acid was needed, not only to stabilize the aspirin but to protect it from the hydrolytic effect of the buffering agents present. This was accomplished by preparing a 0.24 *N* hydrochloric acid solution in methanol and adding a small amount of this solution to the original extraction medium of chloroform. The amount of acid present did not affect the efficiency of the chromatographic column, even if the tablets being assayed were not buffered. An aliquot of the aspirin solution was passed through the column with the aid of more chloroform (no ether was required as with APC tablets). The aspirin was eluted with acetic acid in chloroform and determined at 280 $m\mu$, while the reading at 310 $m\mu$ showed the salicylic acid content. If the absorbance at 310 $m\mu$ was 0.075 or higher, it represented a concentration of 5% or more FSA. The aspirin reading at 280 $m\mu$ was corrected for this FSA absorbance so that the intact aspirin could be reported. If the FSA was below 5%, another method was used in reporting FSA since this spectrophotometric procedure resulted in too low an absorbance reading to be accurate. This procedure was successfully applied to regular aspirin tablets (white), pink aspirin tablets, orange-colored and flavored children's aspirin tablets, enteric-coated tablets, buffered aspirin tablets, and aluminum aspirin tablets.

The stability of aspirin compounded with 10 different

kinds of antacids was reported by Kubo *et al.* (84). The samples were stored for a total of 90 days at: 5°, 52% relative humidity; 20°, 75% relative humidity; and 30°, 92% relative humidity. Samples were removed intermittently for assay by a UV spectrophotometric assay. The FSA content was calculated directly from the value at 308 $m\mu$, while the intact aspirin value at 275 $m\mu$ had to be corrected for the salicylic acid absorbance value. The antacids studied were aluminum silicate, magnesium carbonate, magnesium trisilicate, calcium gluconate, calcium lactate, sodium phosphate, dried aluminum hydroxide gel, calcium carbonate, magnesium oxide, and sodium bicarbonate. Only the 5° station showed good stability with these antacids. At the 30° station, the last four mentioned antacids were completely incompatible with aspirin, as shown by the high FSA values.

Even though pyrilamine was known to interfere with the salicylic acid reading at 308 $m\mu$, Siegel *et al.* (85) used the Tinker and McBay (76) UV procedure to expedite the analysis of tablets of pyrilamine resin adsorbate with aspirin and ascorbic acid. Tablets were stored at 60° for 1 week and for a total of 12 weeks at 45°. Samples removed at various time intervals showed an unexpected trend because the type of container closure and degree of fill were of prime importance for evaluating these products by accelerated temperature studies. Tablets stored in open bottles, or those with polyethylene snap caps, had greater stability than those with Bakelite screw caps. Filled containers appeared to have greater instability than partially filled ones; bottles that had been opened frequently, compared to those opened only once, appeared more stable. The following explanation was offered by the authors: the passage of air would remove moisture as well as gaseous acidic degradation products which promote instability in these tablets; thus, in tightly closed and well-filled bottles, this would not take place to as large a degree.

Chapman and Harrison (86) determined FSA in soluble aspirin tablets by dissolving the aspirin in glacial acetic acid, filtering, and reading the absorbance at 320 $m\mu$ against glacial acetic acid. The salicylic acid content was found from a standard calibration curve of salicylic acid run exactly as the sample. This solvent was selected because aspirin was not stable in chloroform for UV studies, and the results obtained were more reproducible than the BP procedure.

A more thorough study of the Tinker and McBay (76) procedure was reported by Lodomery (87). Chloroform was replaced with absolute spectral alcohol as the solvent for aspirin and salicylic acid. At the wavelength of maximum absorbance for salicylic acid, 300 $m\mu$, Beer's law held through 80 mcg./ml. of absolute spectral alcohol. Similar equations were calculated, only using the absorption data acquired from the alcohol medium. Application of this method was acceptable and accurate.

For APC preparations which contain both barbituric acid derivatives and certain organic bases, it was the objective of Turi (88) to develop a single method rather than using two procedures as described by Heuermann and Levine (81). He was successful with capsules

or tablets containing aspirin, phenacetin, caffeine, ito-barbital, and one of four phenothiazine derivatives (chlorpromazine hydrochloride, promethazine hydrochloride, thiethylperazine dimaleate, or thioridazine hydrochloride). No mention, however, was made of determining salicylic acid by this column procedure other than that a prolonged stay (on Column III) would result in a partial *in situ* degradation of the aspirin.

For the determination of aspirin, caffeine, and acetaminophen (APAP), Koshy (89) found that the reversal of the column arrangement described by Heuermann and Levine (81) was all that was required. The three active ingredients could be assayed beside the potential decomposition products, salicylic acid and *p*-aminophenol. After the two columns were prepared in the usual manner and placed in tandem, such that the top column contained the sulfuric acid as the immobile phase and the bottom column contained the sodium bicarbonate as the immobile phase, they were both washed with ether. The powdered sample was dissolved in ethyl acetate, an aliquot of which was then passed through the two columns and collected in a volumetric flask. The columns were further eluted with ether. This fraction contained intact APAP. The columns were then eluted with chloroform. This fraction contained the caffeine. The two columns were then separated, and the bottom column (sodium bicarbonate phase) eluted immediately with acetic acid in chloroform. This fraction contained the aspirin and salicylic acid and was assayed in the usual manner. The top column (sulfuric acid phase), containing *p*-aminophenol, was washed with ether to remove the chloroform. The diatomaceous earth support was then extruded from the column with air under pressure and collected in a beaker. The ether was evaporated from this material, and 0.1 *N* hydrochloric acid was added to dissolve the *p*-aminophenol. This extract was filtered and an aliquot was assayed colorimetrically using 1-naphthol as described by Greenberg and Lester (90).

The effect of water vapor pressure on moisture sorption and the stability of aspirin and ascorbic acid in tablet matrixes reported by Lee *et al.* (91) utilized the Tinker and McBay (76) procedure in evaluating the stability of the aspirin in these studies. Conclusions reached from these studies showed that the moisture adsorptive capacity of each compressed tablet formulation affected the stability of the two drugs to a great extent and were directly related to the moisture sorption and tablet hardness. (The harder the tablet, the less moisture it sorbed and the more stable the drug.) Of the six diluent systems studied, calcium sulfate and cellulose produced the most stable tablets of aspirin and ascorbic acid, while amylose produced the least stable. Under stress-storage conditions, screw-cap glass bottles proved to be a better moistureproof container than snap-top plastic vials. Cellophane and aluminum foil strip packaging materials were about equally effective. Both were more effective than the glass or plastic containers.

Reed and David (92) described a simple direct spectrophotometric determination of salicylic acid in either one complete capsule or one intact tablet of an aspirin containing medicinal, provided no interference by the

other components with the salicylic acid absorption at 300 $m\mu$ was encountered. The entire dose unit is shaken with alcohol for 1 hr. along with a similar freshly prepared unit dose as a "blank" (as this was generally not available, an equivalent amount of fresh aspirin was weighed and used as the blank). This exposure to an alcoholic medium for 1 hr. could lead to generated hydrolysis in the case of aspirin tablets containing buffers as there is no mention of pH control here or in the aqueous dilution being read at 300 $m\mu$. The sample was read against the blank so that the effect of the intact aspirin would be cancelled out, provided the difference between the two concentrations was not great.

Application of the Tinker and McBay (76) procedure was applied by Day *et al.* (93) in following the stability of two mixtures official in the BPC. They reported the accuracy of the method to be $\pm 2.5\%$.

In a general paper on the use of UV for analysis of drugs in pharmaceuticals, Sattler (94) applied the method described by Ladomery (87) which was a modification of the Tinker and McBay procedure.

A direct spectrophotometric determination of five compounds, aspirin, salicylamide, caffeine, phenacetin, and salicylic acid, in tablets or powders without any preliminary separation was reported by Clayton and Thiers (95). The powdered sample was extracted with chloroform. From this extract, three aliquots (same volume size) were added to separate volumetric flasks, one to be an acidic medium, another to be a basic medium, and the third a hydrolyzed medium. A mixed solvent consisting of isopropanol, water, and a small amount of hydrochloric acid was added to each flask followed by a solution of 50% sodium hydroxide to the basic and hydrolyzed labeled flasks. After hydrolysis of the aspirin was complete at room temperature (about 15 min.), concentrated hydrochloric acid was added to the hydrolyzed labeled flask, rendering it acid again. On diluting all flasks to volume with the mixed solvent, the solutions were then read at the following wavelengths along with the appropriate reference blank solution. The acidic labeled solution was read at 250, 273, and 310 $m\mu$, the basic labeled solution at 333 $m\mu$, and the hydrolyzed labeled solution at 301 $m\mu$. Using a variety of equations, the content of the individual components was calculated. The comment was made that if salicylic acid were absent, it was possible to omit one step, but the omission is not recommended, since this step provides a measure of any hydrolysis of aspirin which might have occurred during storage or manufacture of the product analyzed.

Use of the isosbestic point as a base line in differential spectrophotometry was applied to aspirin and salicylic acid by Shane and Routh (96). When a series of concentrations of salicylic acid were used to prepare differential absorption spectra, monosodium salicylate (at pH 9) in the reference cell *versus* disodium salicylate (at pH 13.5) in the sample cell, two maxima at 246 and 319 $m\mu$, two minima at 233 and 203 $m\mu$, and two isosbestic points at 268 and 300 $m\mu$ were observed. If differential absorption spectra of aspirin solutions were prepared by the same procedure (monosodium acetylsalicylate in the reference cell *versus* disodium salicylate equivalent to the monosodium acetylsalicylate in the sample cell), a

Figure 5—Differential spectra of salicylic acid (A, B, C) and aspirin (A', B', C'). [Reprinted, with permission, from N. A. Shane and J. I. Routh, *Anal. Chem.*, 39, 414, (1967).]

maximum at 300 $m\mu$, a minimum at 268 $m\mu$, and an isosbestic point at 272 $m\mu$ were observed. Figure 5 illustrates the differential absorption spectra of three concentrations of salicylic acid (A, B, and C) compared to the spectra of three concentrations of aspirin (A', B', and C') in the region from 260 to 340 $m\mu$. Each curve is constructed from the two spectra of the same concentration of either salicylic acid or aspirin obtained at pH 9 and 13.5 by subtracting one spectrum from the other spectrum, resulting in the differential absorption spectrum of the given compound. The isosbestic point in differential spectrophotometry would be the wavelength at which each difference curve crosses the zero line. The correlation of the isosbestic point at 300 $m\mu$ for salicylic acid, and the maximum at the same wavelength for aspirin, permits the use of the isosbestic point as the zero or base line for the quantitative determination of intact aspirin in the presence of salicylic acid. Thus, one would not need to do a FSA determination as the value reported for aspirin is for the intact aspirin.

A very much needed publication on the significance of salicylic acid sublimation in stability testing of aspirin-containing solids was presented by Gore *et al.* (29). A more than negligible loss of salicylic acid formed from the decomposition of aspirin would preclude the common practice of analytically determining changes in salicylic acid content in solid dosage forms of aspirin as a measure of degrading aspirin. The salicylic acid method could obviously underestimate the extent of decomposition of aspirin and, therefore, provide false confidence in the stability of the tested products. It thus became necessary to develop a method of gauging aspirin stability in solids which would be unaffected by any loss of salicylic acid.

A simultaneous spectrophotometric assay, based chiefly on the work of Edwards (8), was developed for aspirin and salicylic acid in a Clark and Lubs buffer, pH

Table XVI—Constants for Aspirin and Salicylic Acid UV Assay

Compound	Concentration Range, mcg./ml. of pH 7.4 Buffer	Absorptivity Value at	
		262 $m\mu$	296.5 $m\mu$
Aspirin	0–160	3.2	0
Salicylic acid	0–10	3.3	—
Salicylic acid	0–30	—	26.0

Table XVII—Sublimation Rates of Salicylic Acid at Various Temperatures

Temperature	Rate of Sublimation, mg./hr.
40 \pm 0.05°	0.026
50 \pm 0.20°	0.062
70 \pm 0.20°	0.372

7.4. It was found that this aqueous medium resulted in improved precision over the chloroform medium used by earlier workers. This slightly alkaline medium afforded a relatively rapid solution of solid aspirin and salicylic acid, and a medium in which slight variation in the pH would not introduce an error into the determination as a consequence of the differential absorption of ionized and unionized aspirin or salicylic acid. The rate of hydrolysis of aspirin has been reported (8) to be independent of pH in the range of 4 through 8. Hydrolysis rate constants were determined at pH 7.4 and 25.5°, and showed a delay of 13 min. between the sample preparation and reading on the spectrophotometer would cause an error of approximately 1%. The actual error was reduced to below 0.1% by maintaining the solutions below 15°, usually at 0°, and reading them within 5–10 min. of their preparation.

Table XVI presents the pertinent data required in the construction of the calibration curves used here.

Before applying this UV procedure, several sublimation studies were conducted in which the need for such an assay was demonstrated quite convincingly. Using an electrobalance, the weights of salicylic acid were monitored continually at the stated temperatures for 12 hr. From this study the following rates of sublimation were calculated (Table XVII).

An Arrhenius-type plot of the apparent zero-order sublimation rates was shown. The slope of the curve was predominately determined by the enthalpy of sublimation of salicylic acid. The observed rates of sublimation may be expected to depend directly upon the area through which the mass transfer occurred. These results, therefore, were not intended to be quantitatively indicative of sublimation loss of salicylic acid during the stability testing, but merely substantiate that such a loss can occur even at moderately elevated temperatures.

A similar sublimation study of purified aspirin revealed no significant loss of weight up to 70°. It was concluded that aspirin does not appreciably sublime under the conditions of the experiment.

With a 9:1 mixture of aspirin–salicylic acid, the results from 12 hr. at 70° indicated that only salicylic acid was lost. This was verified by using the UV procedure discussed.

Aspirin tablets were stored at 50° and 81.2% relative humidity for a period of 98 days. At various time intervals tablets were removed and assayed by first grinding to a fine powder and dissolving in pH 7.4 buffer maintained at 0°. After filtration, an aliquot of the filtrate was further diluted with the cold pH 7.4 buffer and the absorbance measured at 262 and 296.5 $m\mu$. In this application, an error of 0.003 absorbance unit at 262 $m\mu$ could contribute an error of approximately 1% in the

Table XVIII—Comparison of Aspirin Tablet Stability Testing Results at 50° and 81.2% Relative Humidity, Based on Determination of Aspirin and Salicylic Acid Content of the Tablets^a

Time, Days	Aspirin Content Based on Analysis of Aspirin, %	Aspirin Content Based on Analysis of Salicylic Acid, %	Error Due to Sublimation of Salicylic Acid, %
0	100	100	0
15	99.1 ± 0.038	99.1 ± 0.028	0
30	98.4 ± 0.042	98.8 ± 0.215	0.4
45	97.2 ± 0.123	98.7 ± 0.075	1.5
60	97.1 ± 0.178	98.6 ± 0.023	1.5
98	95.0 ± 0.288	97.9 ± 0.311	2.9

^a Each value is the average of four determinations recorded with ±1 standard deviation.

determination of the aspirin content of a solid consisting of 80% aspirin using a 50-mg. aliquot for analysis. The results of this study are presented in Table XVIII.

The last column does show that salicylic acid is lost from these tablets by sublimation under the stated conditions of the experiment.

By employing the UV procedure presented in this publication, the determination of the residual aspirin, rather than the apparent salicylic acid, in a solid can be used as a valid means of gauging the stability of the formulation. This method of analysis showed an accuracy within at least 1.5%.

DETERMINATION OF SALICYLIC ACID IN ASPIRIN AND ASPIRIN PRODUCTS WITH THE AID OF A FERRIC-ION CHROMATOGRAPHIC COLUMN

Analytically, the need has always been great to separate and isolate the salicylic acid from aspirin as well as other components in the pharmaceutical preparation. The potential susceptibility of aspirin to hydrolysis is constantly prevalent, so the more rapidly the intact aspirin is removed from the medium, once a given procedure is begun, the truer the reported FSA values will be.

Again Levine (83) appeared to be first in breaking away from the traditional methods of determining salicylic acid in aspirin formulations. On using the chromatographic columns he had introduced in 1957 with a diatomaceous earth–2% ferric chloride mix, the passage of a chloroform solution of aspirin and salicylic acid resulted in the trapping of the salicylic acid (shown by a purple zone on the column). The aspirin passed through, and by using several washes with chloroform, the aspirin was completely removed from the column. The bound salicylic acid was then eluted quantitatively with chloroform containing acetic acid. This eluate was read at 310 mμ for FSA. For the procedure to be valid, the purple zone should not reach the bottom of the tube during the washing out of the aspirin. If it does, the procedure must be repeated with another prepared column. As the original procedure was written, this was a major downfall in using this technique, because too many times the purple zone moved partially off the column during the aspirin removal step.

This procedure was applied to pink aspirin tablets, children's flavored and colored aspirin tablets, buffered aspirin tablets, and aluminum aspirin tablets. With the colored tablets, the dyes remained at the top of the

column throughout the entire assay. With the buffered tablets, the chloroform-insoluble salts of aspirin or salicylic acid must be transformed to soluble acids in order that the FSA could be eluted in the proper fraction. Acetic acid could not be used since it would dissociate the ferric ion–salicylic acid complex on the column. Boric acid, however, was used for this transformation without affecting the column performance. A solution of boric acid in methanol was added to the sample, followed by chloroform to dissolve the freed aspirin and salicylic acid.

For enteric-coated tablets it was found best to mount in tandem a column containing just diatomaceous earth above the regular ferric ion–diatomaceous earth column. The plain diatomaceous earth column removed the surface-active agents present in these tablets, so the aqueous phase would not be stripped off the regular ferric ion–diatomaceous earth column during both the prewashing step and elution of the salicylic acid. This double column setup could be used also where dyes are present in the original chloroform extract, as well as for large amounts of excipient material in the sample being added to the column.

As will be seen with later papers dealing with this novel approach of Levine's, a delicate balance was being maintained with the ferric chloride content on the diatomaceous earth. A sufficiently low concentration of ferric chloride must be maintained to trap the salicylic acid, but at the same time a sufficiently large quantity of ferric chloride must be present to provide an excess over the amount removed during the washing step. It is thus recommended that the modifications of this procedure, to be discussed in this review, be used rather than the method described in this publication. Just the introduction of this approach to the literature served a very worthwhile purpose as the official compendia now use a procedure based on this original study.

Green (67) applied this described procedure by Levine and as he did not present any comments in his paper, it could be assumed that he did not experience any major difficulty with the columns.

In 1961 Weber and Levine (97) made note that "several investigators have encountered difficulty with the published method" (83). During the elution of the aspirin, the salicylic acid migrated slowly down the column (as evidenced by the position of the purple complex) and spread out into a diffuse band, which sometimes becomes difficult to discern.

In this publication, this was rectified by modifying the ferric chloride reagent. This radical improve-

ment in the chromatographic separation was achieved by having a high concentration of urea in the ferric chloride solution. The resultant effects were tremendous: the band of the ferric-salicylate complex obtained with this new reagent was more deeply colored than that obtained with just the simple ferric chloride reagent. The dense, sharply delineated band migrated only slightly during the elution of the aspirin.

It, therefore, became feasible to use a shorter column which did not require extraordinary care in packing. This column even accommodated larger samples of aspirin.

Optimum conditions were obtained with an immobile phase containing 5% ferric chloride solution which was 10 *M* with respect to urea. The pH must be maintained between 3.1 and 3.3. At lower pH levels the salicylic acid band became diffuse and more loosely retained, while at higher pH levels, recovery of salicylic acid from the column may be incomplete using the specified volume of eluant.

For aspirin or aspirin tablets, the pulverized sample was dissolved with chloroform and passed through the column with the aid of several more portions of chloroform to wash the intact aspirin through the column. A volumetric flask containing some hydrochloric acid in methanol was placed under the column, and the column first eluted with acetic acid in ether followed by chloroform. Concomitantly the absorbance of this solution and of the standard salicylic acid in the same medium was determined at 306 $m\mu$.

For APC tablets and flavored tablets, a column containing a small pad of cotton was placed in tandem over the regular ferric chloride-urea column. The sample in the chloroform was passed first through the cotton column to remove the dyes and any insoluble excipients. Another portion of chloroform was passed through the two columns, and then the top column was discarded. The regular column was then washed with chloroform and the salicylic acid eluted.

As moderate amount of urea was eluted together with the salicylic acid from the column, the hydrochloric acid in the receiving flask was added to maintain acidity of the eluate. The methanol was present to achieve miscibility of the acid with the eluting solvent.

With buffered aspirin tablets, the boric acid was replaced with oxalic acid in methanol, as the oxalic acid was more effective in releasing the bound salicylic acid from the antacid. The oxalic acid solution recovered quantitatively salicylic acid from its calcium salt. However, neither this nor any other reagent thus far tested quantitatively released salicylic acid from aluminum hydroxide gel without causing extensive hydrolysis of aspirin.

Excellent reproducibility on replicate analyses of a wide variety of commercial samples was shown.

Though Weber's publication (98) on the analysis of salicylic acid and benzoic acid does not deal with aspirin, *per se*, it had a valuable innovation regarding the ferric chloride-urea-diatomaceous earth column. When eluting salicylic acid of larger quantities than usual, the occasional leakage of ferric chloride was noted which invalidated the assay. This was seen visually by the presence of a yellow color rather than the usual colorless

clear eluate. If any yellow is present in the solution read, the reading at 306 $m\mu$ would have to be voided. Weber found that a small layer of diatomaceous earth with 30% phosphoric acid as the immobile phase placed at the bottom of the column on top of the glass wool support, and then followed by the regular ferric chloride-urea-diatomaceous earth mix, resulted in no ferric chloride leakage. The phosphoric acid retained any ferric chloride which might be removed during the elution step of the salicylic acid.

In their study on the formation of acetylcodeine from aspirin and codeine, Jacobs *et al.* (99) used the original Levine procedure (83) in isolating the salicylic acid which resulted from the previously mentioned reaction.

On discussing pharmaceutical heterogeneous systems, Zoglio *et al.* (28) have presented four papers regarding the hydrolysis of aspirin. The salicylic acid resulting from the degradation of aspirin in the various formulations was determined by a modification of Levine's iron-diatomaceous earth procedure (83). The first paper [Kornblum and Zoglio (28)] is discussed in the *Hydrolysis Studies* portion of this review. They demonstrated that calcium or magnesium stearate accelerated the production of salicylic acid from aspirin through the solubilization of aspirin as a calcium or magnesium salt. More aspirin would thus be in solution which in turn would hydrolyze in the existing pH which was conducive to hydrolysis. This effect was not as pronounced when aluminum stearate was used as a lubricant, as the aluminum salt of aspirin has a low solubility in water.

On pursuing this alkali stearate effect, Zoglio *et al.* (28) prepared capsules containing aspirin (20 parts), magnesium stearate (1 part), and 0, 1, 2, 5, 10, and 20 parts of hexamic, maleic, malic, or tartaric acids, or maleic anhydride. These capsules were stored at 22, 40, and 50° for 30 days. A minimum of 20% by weight of hexamic, maleic, or malic acid was required to retard the hydrolysis of aspirin in these capsules. Tartaric acid or maleic anhydride was not effective at the higher temperatures. Besides the lower desired pH contributed by the added acid, the mechanism of inhibiting the degradation of aspirin involved the additive acid and aspirin competing for the magnesium ion.

Maulding *et al.* (28) showed that stearic acid USP, which is nearly a 1:1 mixture of stearic and palmitic acids, promoted the decomposition of aspirin more than either reagent grade stearic or palmitic acid. On preparing various synthetic mixtures of reagent stearic and palmitic acids, the one simulating the amounts of the two acids in stearic acid USP behaved similarly as the stearic acid USP in accelerating the decomposition of aspirin. This ratio of stearic and palmitic acids was also the melting point minimum of the various mixes of these two acids. The possibility exists, therefore, of a liquid or semiliquid being present in formulations containing stearic acid USP which might serve as the medium for aspirin hydrolysis.

The fourth paper dealt with the acceleration of aspirin hydrolysis by various common additives (hexamic acid, aluminum hydroxide calcium stearate, magnesium stearate, or magnesium trisilicate), at a 5 or 10% level of the powder mix or tablet. The formulations con-

taining magnesium trisilicate resulted in the largest amount of FSA (about 13%) after 45 days at 40°. Hexamic acid, under these storage conditions, retarded aspirin hydrolysis. The salicylic acid values resulting from these various formulations were in good agreement with values obtained from extrapolating apparent zero-order rates of aspirin suspensions of the same powder mix as used in the tablet. These studies show that stability prediction for solid dosage forms from apparent zero-order rates of suspensions is feasible and informative.

The determination of the FSA in buffered aspirin tablets by Levine and Weber (100) explored further the usefulness of their ferric chloride-urea-diatomaceous earth column. It was essential that the entire amount of aspirin and salicylic acid be dissolved in the mobile phase before the chromatographic treatment, and that the aspirin was not hydrolyzed during the preparation of that solution. These two requirements are not readily achieved in the case of buffered aspirin tablets. Chloroform solutions of aspirin, in the presence of basic materials such as those which comprise the buffering components of the tablets, undergo hydrolysis together with aspirin anhydride formation. Boric acid stabilizes the solution, at least with respect to the hydrolysis of aspirin, but does not achieve the necessary release of the aspirin and salicylic acid from the buffer components to permit their complete solution in chloroform.

In designing a valid assay procedure, the acid which is used must: (a) produce only minimal hydrolysis of aspirin under the conditions of the assay; (b) rapidly and completely release aspirin and salicylic acid from the buffer components of the tablet; (c) be soluble in chloroform; and (d) be readily removed from the chloroform, so that the ferric-salicylic acid complex will not be dissociated during the following step of the analysis.

These requirements were fulfilled by 98–100% formic acid. The distribution of formic acid between chloroform and inorganic acids was greatly in favor of the aqueous phase; therefore, the formic acid was removed from the chloroform solution by passage over dilute hydrochloric acid.

In the analysis of buffered aspirin tablets, two columns are prepared and placed in tandem. The top column consists of diatomaceous earth with 0.05 *N* hydrochloric acid as the immobile phase. It is here that the formic acid in the chloroform is removed. The packing of this column should be such that a flow rate of chloroform of 12 ml./min. is obtained.

The bottom column consists of a layer of diatomaceous earth with 30% phosphoric acid as the immobile phase. The phosphoric acid retains any ferric iron which may be eluted during the procedure. The upper stage of this column consists of the 5% ferric chloride and 10 *M* urea as the immobile phase on diatomaceous earth.

In the procedure, water-saturated solvents were used throughout. To a ground sample of tablets in a volumetric flask, the 98% formic acid was added with swirling to wet the sample completely (not more than 30–45 sec.) followed by chloroform. This mixture was shaken for 10 min. The extent of hydrolysis of aspirin

during the period of contact of the sample with the formic acid before dilution lies in the range of 0.01–0.02%/min., so here the extent of hydrolysis will be in the order of 0.01%. After dilution with the chloroform, the hydrolysis of aspirin sharply decreased to an average of only 0.03%/hr. Thus a negligible amount of hydrolysis occurs during the 10-min. shaking period for dissolving the aspirin and salicylic acid. On diluting to volume with chloroform and mixing, the solution was filtered through a loose plug of glass wool. An aliquot of this filtrate was then passed through the double columns which were washed with more chloroform to remove the aspirin. The eluate and the top column were discarded. A receiver containing hydrochloric acid in methanol was placed under the remaining (bottom) column, and ether containing acetic acid was passed through the column followed by chloroform containing acetic acid. This eluate was read at 306 $m\mu$ along with a salicylic acid standard in the same medium.

By this method, great strides have been made in regard to freeing salicylic acid from various antacids. It was shown that the formic acid treatment readily recovers salicylic acid from its calcium or magnesium salts but that aluminum salicylate was quite refractory to this treatment. As dried aluminum hydroxide gel is present in several of the commercial buffered aspirin tablets, the need is still acute for a method which will recover salicylic acid from its aluminum salt.

On studying the USP XVII limit test for salicylic acid in aspirin tablets containing buffers, Guttman (101) obtained spurious and nonreproducible results. Low recoveries were explained by an adsorption phenomenon. Significant adsorption of salicylic acid occurred when solutions of chloroform were in contact with chloroform-insoluble agents which are commonly employed as buffers in aspirin tablets. The affinity of salicylic acid for magnesium carbonate and aluminum glycinate was high, but the capacity of these solids for the acid was rather low. These two compounds held tenaciously to the salicylic acid, as it was impossible to elute completely adsorbed material by repeated contacts with fresh solvent.

High recoveries of salicylic acid resulted from a surprisingly rapid transformation of aspirin to a product having the chromatographic characteristics of salicylic acid. This was observed only when solid basic material (here magnesium carbonate) was suspended in the chloroform solution of aspirin. This transformation of aspirin was thus surface catalyzed.

On repeating this experiment with different commercially available buffered aspirin products, the same phenomenon occurred except with one—and it contained citric acid monohydrate besides two antacid compounds. With this sample, the salicylic acid content did not increase appreciably with time of contact with the solid suspension. With all these suspension studies, it was of interest to note that, upon filtration, immediate cessation of salicylic acid production resulted. This was shown by the readings in the UV at 278 and 306 $m\mu$ on the chloroform filtrate or when the ferric chloride-urea-diatomaceous earth column procedure (USP XVII) was used.

Table XIX—Results Obtained when Various Methods Were Employed to Estimate Salicylic Acid (SA) Contents of a Number of Commercial Buffered Aspirin Products

Product	Buffers Present	USP Procedure	% SA Found Using

7	Calcium carbonate Magnesium carbonate	—	1.96	—	3.37

On further studies with aspirin in chloroform and magnesium carbonate in suspension with and without an equal weight of citric acid monohydrate, it was found that no salicylic acid was produced in 200 min. at 25° with citric acid present. After 60 min. of magnesium carbonate being in contact with the aspirin solution, the addition of citric acid monohydrate resulted in no further salicylic acid production. It was visually observed that the addition of citric acid had a pronounced effect on the nature of the suspension. Marked flocculation of particles was apparent immediately after the addition of citric acid monohydrate. Citric acid which had been previously oven-dried showed a much less marked effect in inhibiting salicylic acid production. This showed that presence of water from the hydrate was essential in this reaction with suspended material. Applying this citric acid monohydrate to the previously studied commercial buffered tablets on an equal weight basis showed that in all systems studied here, the citric acid was effective in markedly reducing the catalytic ability of suspended solids in the production of salicylic acid from the aspirin in chloroform.

Repeating the magnesium carbonate-aspirin adsorption experiment discussed earlier, only this time with and without an equal amount of citric acid monohydrate, it was found that in the presence of citric acid there was no appreciable adsorption of the aspirin from the chloroform. It is also of interest that treatment of antacid compounds in suspension in chloroform with citric acid monohydrate significantly reduced their capacities for adsorbing salicylic acid.

Guttman's study demonstrated very convincingly that finely divided solids of antacids do catalyze a conversion of aspirin to a product which, by the analytical method employed, was determined as salicylic acid. The reaction occurred under essentially anhydrous conditions, and adsorption of the aspirin was apparently a prerequisite for the transformation. The presence of citric

acid monohydrate was shown to be effective in inhibiting the formation and adsorption of salicylic acid in the systems reported here. A feasible explanation was given: citric acid monohydrate, which is essentially chloroform insoluble, inhibits the reaction by releasing water of hydration to the surface of the adsorbent. A neutralization reaction takes place in the hydrate layer which modifies the surface characteristics of the adsorbent so as to destroy the adsorption sites. Thus, the catalytic production of salicylic acid from aspirin is never initiated.

Results from studies presented in this paper showed that addition of citric acid monohydrate to the official chromatographic procedure in the original extraction of the sample resulted in almost quantitative recovery of salicylic acid. It was also noted that this citric acid treatment was not effective in displacing salicylic acid from metallic salts which are known to form in buffered aspirin products.

In applying the procedure suggested in the preceding paper, Guttman and Salomon (102) compared its usefulness (and superiority) over the existing USP XVII FSA test for buffered tablets of aspirin. The method consisted of treating, by trituration, a powdered sample with an equal weight of citric acid monohydrate, and dissolving the aspirin and the FSA from the powder mass with chloroform. The remaining residue was treated with an aqueous solution of a strong acid (hydrochloric acid), and this solution was extracted with chloroform. The two chloroform extracts (one containing the FSA and the other containing the non-aspirin salicylates) were combined, and the salicylic acid content determined by the chromatographic method of Weber and Levine (97). With the assumption that the citric acid treatment results only in desorption of salicylic acid and aspirin and does not cause conversion of salicylate salts to free acid, one would have a method available for the estimation of the FSA content

Figure 6—Gas chromatogram of aspirin in alcohol. [Reprinted, with permission, from J. G. Nikelly, *Anal. Chem.*, **36**, 2248 (1964).]

as well as total nonaspirin salicylate contents of buffered tablets of aspirin. Table XIX summarizes the results on applying four different procedures to commercially available buffered aspirin tablets: USP XVII (using boric acid in the initial extraction), Guttman's citric acid procedure, Guttman and Salomon's citric acid procedure for total nonaspirin salicylates, and the Levine and Weber procedure (100) which used formic acid in the initial extraction medium.

Inspection of this table makes obvious that the FSA values, as determined by the USP procedure, were consistently and significantly lower than those determined by the other methods. It is logical to assume that these low values resulted from adsorption of significant amounts of salicylic acid during sample extraction, and to the insensitivity of the procedure to salicylic acid which is present in the sample in the form of salts. The latter two methods appear to be equally precise. It is interesting to note the difference between the citric acid procedure for FSA and the citric acid procedure for total nonaspirin salicylates. The differences reflect the fact that significant amounts of salicylic acid can be present in buffered tablets as chloroform-insoluble salts. It is also apparent that no relationship exists between the FSA content and total nonaspirin salicylate content of these tablets.

DETERMINATION OF SALICYLIC ACID IN ASPIRIN AND ASPIRIN PRODUCTS BY MISCELLANEOUS METHODS

Schulek and Burger (103) stated that on using BrCl as a brominating agent, salicylic acid could be brominated quantitatively in 2 min., even in the presence of aspirin. With the usual amounts of FSA present in aspirin products, it is debatable whether such a titration would be sensitive enough to be of value.

The application of differential thermal analysis (DTA) and thermogravimetric analysis (TGA) to aspirin was published by Wendlandt and Hoiberg (104). No mention was made of the effects of the presence of salicylic acid, but application of this approach would definitely be of interest in evaluating the purity of aspirin.

Gas chromatography has a great potential in the analysis of aspirin products, but only two papers have mentioned the possibilities. Crippen and Freimuth (105)

stated that their proposed procedure would differentiate aspirin from salicylic acid only if the temperature of 100–125° and a 1.23–1.83-m. (4–6-ft.) column were used. Nikelly (106) showed (Fig. 6) that under the stated conditions used in the determination of aspirin, the amount of acetic and salicylic acids could be estimated.

In applying an IR spectrophotometric assay of aspirin anhydride, Garrett and Johnson (107) concluded that the insignificance of salicylic acid in these lots of varied purity showed that little definition was lost on ignoring it. Though samples of aspirin were not used here, the usefulness of IR studies on the purity of aspirin in regard to salicylic acid would be of value.

The need for actual physical separation of salicylic acid from aspirin is great. The work by Vietti-Michelina (108) and Wagner (109) on paper chromatographic or paper electrophoretic separation of aspirin and salicylic acid might be applied successfully by using the latest techniques available in this field.

A too often neglected technique in drug studies in the United States is the application of polarography. In 1949 Korshunov *et al.* (110) reported on the reduction of weak acids at a dropping-mercury cathode. The half-wave potentials were given as 1.52 to 1.65 (for 1–7 mmoles/l.) for aspirin and 1.66 to 1.83 (for 1–9 mmoles/l.) for salicylic acid in 0.05 *N* tetramethylammonium iodide. With the more sensitive polarographs of today, such an approach in the analysis of aspirin products could prove to be useful.

Quantitative separation of aspirin and salicylic acid by sephadex G gel filtration was reported by Lee *et al.* (111). No detectable (fluorometrically) hydrolysis of aspirin on the column was noted.

TLC should be an invaluable tool in aspirin stability studies. By using a mixture of hexane, glacial acetic acid, and chloroform (20:5:5), Reimers (112) separated aspirin and salicylic acid. After resolving the mixtures of aspirin–salicylic acid on thin-layer plates [using ascending technique and a hexane, glacial acetic acid, and chloroform mixture (85:15:10), *R_f* values of 0.2 and 0.35 were obtained for aspirin and salicylic acid, respectively], the spots were removed from the dried plates, packed in an appropriate cell, and determined by UV reflectance spectroscopy. A linear relationship at 302 mμ between absorbance and the square root of the concentration was observed by Frodyma *et al.* (113) with spots containing up to 3.0 μmoles of either compound.

An exhaustive paper on differentiating nonaqueous titration of salicylic acid and aspirin by Lin (114) showed that such a procedure was feasible. Dimethylformamide was the solvent of choice along with the titrant of 0.1 *N* tetrabutylammonium hydroxide in benzene–methanol (10:1) using either a glass–calomel or platinum–calomel electrode pair.

Mechanisms of Reactions of Ring-Substituted Bis(1-aziridinyl)phosphinyl Urethan Antineoplastic Agents

C. K. NAVADA, Z. F. CHMIELEWICZ, and T. J. BARDOS*

Abstract □ Bis(*trans*-2,3-dimethylaziridinyl)phosphinyl urethan (IV) was synthesized and compared with the corresponding *cis*-2,3-dimethyl derivative (III). The comparative alkylating activities and rates of hydrolysis of these two stereoisomeric aziridine derivatives, III and IV, were determined and compared with corresponding data for the monomethyl derivative (V) and two other clinically tested members of this series of antineoplastic agents (dual antagonists), AB-100 (I) and AB-132 (II). The structures of the final hydrolysis products of III, IV, and V were determined and confirmed by direct synthesis. The results indicate that the mechanisms of hydrolysis of III, IV, and V (as that of the unsubstituted aziridine derivative, AB-100) are essentially S_N2, in contrast to the much faster hydrolysis of the 2,2-dimethylaziridine analog, AB-132, which involves a carbonium-ion mechanism. These studies give further support to the hypothesis that the unique pharmacologic properties of AB-132, as compared to other members of this series, may be related to the unique chemical properties of the 2,2-dimethylaziridine moieties.

Keyphrases □ Antineoplastic agents—reaction mechanisms □ Bis-(*trans*-2,3-dimethylaziridinyl)phosphinyl urethan—synthesis □ Alkylating activity—*cis*-, *trans*-2,3-dimethylaziridine analogs □ Hydrolysis mechanism—ring-substituted aziridine derivatives □ IR spectrophotometry—identity □ NMR spectroscopy—identity

The synthesis of a series of bis(1-aziridinyl)phosphinyl carbamates, termed "dual antagonists" (I and its analogs containing different carbamate moieties) (1, 2), and their antineoplastic activities in experimental animals (3, 4) and in man (5-9) were previously reported. In an effort to decrease the hematologic toxicity due to the "alkylating" aziridine groups, derivatives were syn-

thesized in which the C-atoms of the aziridine rings were substituted with methyl or ethyl groups (10). One member of this new series, ethyl bis(2,2-dimethyl-1-aziridinyl)phosphinyl carbamate (AB-132, II), has been studied to a considerable extent experimentally (11) as well as clinically (12-17). Its interesting pharmacologic properties [*e.g.*, cholinesterase inhibition (18-20)] and its radiation potentiating effect (21-23) suggested that this compound may act by a different mechanism than the C-unsubstituted aziridine derivatives (24). This conclusion was supported by chemical studies of its hydrolytic and alkylation reactions (11, 25), which indicated that the unique properties of II may be related to the ability of the 2,2-dimethylaziridine group to participate in S_N1 reactions with its substituted carbon (by forming a tertiary carbonium ion) and, alternatively,

Mechanisms of Reactions of Ring-Substituted Bis(1-aziridinyl)phosphinyl Urethan Antineoplastic Agents

C. K. NAVADA, Z. F. CHMIELEWICZ, and T. J. BARDOS*

Abstract □ Bis(*trans*-2,3-dimethylaziridinyl)phosphinyl urethan (IV) was synthesized and compared with the corresponding *cis*-2,3-dimethyl derivative (III). The comparative alkylating activities and rates of hydrolysis of these two stereoisomeric aziridine derivatives, III and IV, were determined and compared with corresponding data for the monomethyl derivative (V) and two other clinically tested members of this series of antineoplastic agents (dual antagonists), AB-100 (I) and AB-132 (II). The structures of the final hydrolysis products of III, IV, and V were determined and confirmed by direct synthesis. The results indicate that the mechanisms of hydrolysis of III, IV, and V (as that of the unsubstituted aziridine derivative, AB-100) are essentially S_N2 , in contrast to the much faster hydrolysis of the 2,2-dimethylaziridine analog, AB-132, which involves a carbonium-ion mechanism. These studies give further support to the hypothesis that the unique pharmacologic properties of AB-132, as compared to other members of this series, may be related to the unique chemical properties of the 2,2-dimethylaziridine moieties.

Keyphrases □ Antineoplastic agents—reaction mechanisms □ Bis-(*trans*-2,3-dimethylaziridinyl)phosphinyl urethan—synthesis □ Alkylating activity—*cis*-, *trans*-2,3-dimethylaziridine analogs □ Hydrolysis mechanism—ring-substituted aziridine derivatives □ IR spectrophotometry—identity □ NMR spectroscopy—identity

The synthesis of a series of bis(1-aziridinyl)phosphinyl carbamates, termed "dual antagonists" (I and its analogs containing different carbamate moieties) (1, 2), and their antineoplastic activities in experimental animals (3, 4) and in man (5-9) were previously reported. In an effort to decrease the hematologic toxicity due to the "alkylating" aziridine groups, derivatives were syn-

thesized in which the C-atoms of the aziridine rings were substituted with methyl or ethyl groups (10). One member of this new series, ethyl bis(2,2-dimethyl-1-aziridinyl)phosphinyl carbamate (AB-132, II), has been studied to a considerable extent experimentally (11) as well as clinically (12-17). Its interesting pharmacologic properties [*e.g.*, cholinesterase inhibition (18-20)] and its radiation potentiating effect (21-23) suggested that this compound may act by a different mechanism than the C-unsubstituted aziridine derivatives (24). This conclusion was supported by chemical studies of its hydrolytic and alkylation reactions (11, 25), which indicated that the unique properties of II may be related to the ability of the 2,2-dimethylaziridine group to participate in S_N1 reactions with its substituted carbon (by forming a tertiary carbonium ion) and, alternatively,

- I. $R_1 = R_2 = R_3 = R_4 = H$ (AB-100)
 II. $R_1 = R_2 = CH_3$; $R_3 = R_4 = H$ (AB-132)
 III. $R_1 = R_3 = CH_3$; $R_2 = R_4 = H$ (*cis*) (AB-144)
 IV. $R_1 = R_4 = CH_3$; $R_2 = R_3 = H$ (*trans*) (AB-145)
 V. $R_1 = CH_3$; $R_2 = R_3 = R_4 = H$ (AB-143)

in S_N2 reactions with its unsubstituted methylene carbon (25).

In view of the observed profound effect of the 2,2-dimethyl substitution in the aziridine ring on the chemical and pharmacologic properties of II, it was of interest to investigate the chemical reaction mechanisms of the stereoisomeric 2,3-dimethylaziridine derivatives, III and IV (which are position isomers of II), and of the monomethylaziridine derivative, V.

RESULTS AND DISCUSSION

There are three stereoisomeric forms of 2,3-dimethylaziridine: *meso* (*cis*) and L and D (*trans*). The first two of these were synthesized from D- (as well as DL) *threo*-3-amino-2-butanol and L-*erythro*-3-amino-2-butanol, respectively, by Dickey *et al.* (26). By stereo-specific syntheses, Dickey *et al.* (26) also established their absolute configurations. In the present work, commercial 3-amino-2-butanol,¹ a mixture of the DL-*threo* and DL-*erythro* isomers (VI), was used as the starting material. Cyclization of the acid sulfates VII gave a mixture of the two optically inactive diastereoisomeric aziridines, VIII and IX. These were separated by fractional distillation, as described in the *Experimental* section, and their NMR spectra were consistent with the configurational assignments of Dickey *et al.* (26) (Scheme I).

The synthesis and physicochemical properties of the ring-substituted bis-aziridinylphosphinyl carbamates III and V were previously reported (10). The *trans*-2,3-dimethyl analog, IV, was synthesized according to the same general procedure, by the reaction of dichlorophosphinyl urethan with DL-*trans*-2,3-dimethylaziridine (IX). Although two diastereoisomers of IV might be expected to arise from this reaction (since two molecules of the racemic aziridine reacted with each molecule of dichlorophosphinyl urethan), only one, sharp melting, crystalline product could be isolated from the reaction mixture by repeated crystallization from *n*-hexane.

The IR spectra of the *cis*- and *trans*-aziridine derivatives, III and IV, are almost superimposable, except in the 700–950 cm^{-1} region where the differences in the ring-deformation frequencies of the two compounds result in characteristically different absorption patterns. The NMR spectra show the expected differences between the two compounds in the chemical shifts of their ring-CH and -CH₃ protons, corresponding to the differences between the NMR spectra of the aziridines from which they were derived. In the spectra of both III and IV, the multiplets of the ring-CH protons are split by the phosphorus into two symmetrical groups of resonance lines.

The comparative chemical alkylating activities (S_N2 -reactivities) of Compounds III, IV, and V were determined according to the previously described method (25, 27) by measuring the rates of alkylation (colored product formation) with γ -(4-nitrobenzyl)-pyridine (NBP) at 80° temperature and standard initial concentrations of the reactants. The initial reaction rates [k'_{80} values (27)] are given in Table I. It is apparent that the *trans*-isomer (IV) is much more reactive than the *cis* (III). This result seems reasonable, considering that in the case of IV the nucleophilic reactant can

Table I—Comparative Alkylating Activities and Relative Stabilities to Hydrolysis of Ethyl Bis(1-aziridinyl)phosphinyl Carbamates

Compound	Aziridine Ring Substituents	Alkylating Activities, ^a $k'_{80} \times 10^3$ min^{-1}	Half-Lives, $t_{1/2}$ in H_2O at 37°
I	None	3.3 ^c	60
II	2,2-CH ₃	2.4 ^c	2.5
III	<i>cis</i> -2,3-CH ₃	0.8	125
IV	<i>trans</i> -2,3-CH ₃	1.9	35
V	2-CH ₃	2.0 ^c	80

^a For definition, see Reference 27. ^b Based on residual titratable aziridine rings. ^c Data taken from Reference 25.

approach one of the carbon atoms from either side of each aziridine ring; while in the case of III, only one side of each ring is open to nucleophilic attack. Both compounds are considerably less reactive than the “unsubstituted” analog (I), but IV is only slightly less reactive than the monomethyl and gem-dimethyl aziridine derivatives (V and II, respectively) in which one of the aziridine carbons is unsubstituted.

The relative rates of hydrolytic cleavage of the aziridine-rings of Compounds I–V, in distilled water at 37°, can be compared on the basis of the half-life data given in Table I. If the hydrolysis of all compounds was to proceed entirely by an S_N1 mechanism, as was found in the case of the 2,2-dimethyl aziridine analog, AB-132 (II) (11), then the relative rates would depend on the comparative ease with which they are capable of forming a carbonium-ion intermediate. Therefore, the following order of hydrolysis rates would be expected: $\text{II} > \text{IV} \geq \text{III} > \text{V} > \text{I}$. Instead, the rates of hydrolysis show the following sequence: $\text{II} \gg \text{IV} > \text{I} > \text{V} > \text{III}$. Thus, it is evident that the hydrolytic cleavage of the aziridine rings in some of these compounds appears to involve other than S_N1 mechanisms. For example, the 3–4 times faster hydrolysis rate of the *trans*-2,3-dimethylaziridine derivatives IV as compared to the *cis*-isomer III almost parallels their relative S_N2 reactivities in the alkylation of NBP.

Preliminary studies relating to the mechanisms of hydrolysis of I and II were previously reported, indicating that in water solution, I undergoes bimolecular polymerization with its P–N linkages remaining largely intact (25), while the very fast hydrolysis of II proceeds *via* a tertiary carbonium ion and with the cleavage of all three of its P–N bonds (11, 25). To elucidate the mechanisms of hydrolysis of III–V, their final hydrolysis products, obtained after 3 weeks of incubation of each compound in deionized distilled water solution at 37°, were isolated and identified. In all cases, urethan and a phosphate ester were isolated from the hydrolysates as the two major, final hydrolysis products (Scheme II).

¹ Commercial Solvents Corp., New York, N. Y.

The structures of the phosphate esters were identified by elemental analysis, IR and NMR spectra, and alkaline hydrolysis, yielding the known amino alcohols.² In addition, most of the phosphate mono- and diesters, salts, and ester-salts that could have resulted from the hydrolysis of Compounds III–V were directly synthesized for comparison with the isolated products (see *Experimental*). The phosphate mono- and diesters were generally prepared by reacting the appropriate aziridine with phosphoric acid. Since the ring-opening reactions of the stereoisomeric 2,3-dimethylaziridines are known to proceed with a single Walden inversion (28), and 2-monosubstituted aziridines are cleaved by strong acids at the unsubstituted 3-position (29), the structures of the phosphate esters were unambiguously defined by their synthesis. However, additional proof of structure was obtained by alkaline hydrolysis to yield the known amino alcohols. The ester-salts were synthesized by reacting the monoesters with one equivalent of the amino alcohol, while the phosphate salts were prepared by combining one equivalent of phosphoric acid with two equivalents of the amino alcohol. If the elemental analysis and melting points did not permit unambiguous identification of the hydrolysis products with the synthetic salts or esters (because of variations in water of crystallization), comparison of the spectra served well for this purpose. In general, the phosphate salts showed much sharper absorption bands in their IR and NMR spectra than the phosphate esters which are zwitterions. Although the positions of the absorption peaks for the phosphate ester and the corresponding salt were similar, it was possible to differentiate between them on the basis of their resolution and splitting patterns. In particular, the splitting by the phosphorus of the CH or CH₂ protons adjacent to the P—O bond in the phosphate esters increased the complexity of the resonance pattern in the 3.5–4.5 p.p.m. region and in the case of XIV gave rise to a well-resolved quartet.

The results show that the *cis*-2,3-dimethylaziridine derivative III yields the phosphate ester-salt of *threo*-3-amino-2-butanol (XII), while the *trans*-2,3-dimethylaziridine analog IV yields the phosphate monoester of *erythro*-3-amino-2-butanol (XIII). If the hydrolysis of the aziridine rings would have proceeded by an S_N1 mechanism, the same carbonium-ion intermediate derived from either III or IV should have given identical mixtures of the phosphates of the two isomeric amino alcohols. Actually, the ring-opening hydrolysis reactions of both III or IV appear to involve in each case a single Walden inversion (*trans*-opening) and, therefore, must be mechanistically S_N2, although they are pseudo-first-order from a kinetic point of view. Furthermore, the structure of the hydrolytic product XIV of the 2-methylaziridine derivative V shows that the ring-opening reaction of this compound occurred at the unsubstituted (less hindered) carbon, thus indicating that the mechanisms of this reaction similarly followed an S_N2 course. The fact that the hydrolysis of all three compounds, III–V, resulted in the formation of a phosphate ester bond, indicates that the ring-opening reaction involves an inter- or intramolecular S_N2 attack of a P—O[−] anion on the protonated aziridine ring. This reaction requires either prior or concerted hydrolytic cleavage of a P—N bond, possibly initiated by tautomerization of the O=P—NH— grouping; eventually, all three P—N bonds are cleaved to give the final hydrolysis products.

CONCLUSIONS

On the basis of these results, it is now possible to explain satisfactorily the order of hydrolysis rates for Compounds I–V. Thus, II is the only compound of this series which hydrolyzes by an S_N1 mechanism, and this is consistent with its exceptionally fast rate of hydrolysis. In contrast, the relative rates of hydrolysis of Compounds I, V, and III appear to depend on the comparative steric hindrances of their aziridine moieties to nucleophilic attack. The relative hydrolysis rate of Compound IV is somewhat anomalous and may suggest some smaller contribution of an S_N1 mechanism (which possibility in the case of this compound is not entirely excluded by the structure of the isolated hydrolysis product XIII, since the latter contains only half of the total amount of amino alcohol resulting from the hydrolysis of

IV). In any case, the mechanisms of hydrolysis of III–V are largely S_N2 and, therefore, just as the hydrolytic polymerization of the ring-unsubstituted-aziridine derivative I (25), they do not involve carbonium-ion intermediate formation to any substantial degree. The importance of the tertiary carbonium-ion intermediate formed in the hydrolysis of the geminally substituted aziridine derivative II has been previously discussed (11). Other studies on the comparative chemical and biological activities of conventional and "branched-chain" aromatic nitrogen mustards (27) have indicated that the biological activities in a given series of alkylating agents may be related to their different chemical reaction mechanisms (27, 30). On the whole, the results of the present study underline the uniqueness of the 2,2-dimethylaziridine derivative II (AB-132) with respect to its chemical behavior, as compared to other members of this series of alkylating agents.

It should be mentioned that the *in vivo* toxicities and antitumor activities (in several rodent tumor systems)³ of Compounds I, III–V are qualitatively similar, and that their relative magnitudes closely parallel the relative "S_N2 reactivities" of these compounds with respect to NBP. This is in contrast to the qualitatively and quantitatively different pharmacological activities of AB-132 (II).

EXPERIMENTAL

Comparative alkylating activities and rates of hydrolysis were determined by previously-described procedures (25, 27). The IR spectra were recorded on a Perkin-Elmer model 237 (Infracord), and the NMR spectra were obtained in a Varian Associates model A-60 using deuterium oxide as solvent, except where noted. The melting points were determined on a Mel-Temp melting point apparatus and are uncorrected.

The syntheses of Compounds I–III and V were previously reported (1, 2, 10).

Ethyl [Bis(2,3-*trans*-dimethyl-1-aziridinyl)phosphinyl]carbamate (IV)—Commercially available 3-amino-2-butanol, a mixture of *DL*-*threo* and *DL*-*erythro* isomers (VI), was cyclized through its amine sulfate (26) to yield a stereoisomeric mixture of 2,3-dimethylaziridine. The separation of the *DL*(*trans*)-isomer from the *meso* (*cis*)-isomer, VIII, b.p. 81–83° (771 mm.) [previously employed for the synthesis of III (10)], was accomplished by fractional distillation through a spinning band column, and the fraction, b.p. 75–75.5° (765 mm.) (IX), was collected. NMR spectra (in CCl₄ with tetramethylsilane as internal standard) are as follows: VIII (*cis*): 1.05 (6H, d, *J* = 6 c.p.s., CH₃), and 2.06 p.p.m. (2H, multiplet, CH); IX (*trans*): 1.12 (6H, d, *J* = 4 c.p.s., CH₃), and 1.50 p.p.m. (2H, multiplet, CH). The reaction of *DL*(*trans*)-2,3-dimethylaziridine with dichlorophosphinyl urethan was carried out under nitrogen in the usual manner (10). After filtration, the filtrate was concentrated *in vacuo* at 30° to give an oily residue. Several crystallizations from *n*-hexane gave a pure product, m.p. 103–104°, yield 20%. Ethylenimine assay (31): 102% of the theoretical value (based on two ethylenimine groups and a mol. wt. of 275).

Anal.—Calcd. for C₁₁H₂₂N₃O₃P: C, 47.99; H, 8.00; N, 15.26. Found: C, 47.89; H, 7.84; N, 15.42.

IR absorption bands (KBr) (cm^{−1}): 3050, 2960, 1730 (s) (C=O); 1460 (s) sh. 1420, 1440 (m) (C—CH₃, CH₂); 1380 (m) (C—CH₃); 1330 (w) (P=O); 905 (m); 835 (s) (doublet).⁴

NMR (in CDCl₃, with tetramethylsilane as internal standard), 1.35 (15H, multiplet, CH₃), 2.42 (4H, multiplet, —CH—N), and 4.15 p.p.m. (2H, quartet, CH₂—O).

Hydrolysis Products—The final hydrolysis products of III–V were obtained by incubating 0.015 mole of each compound with 2.2 moles of deionized distilled water at 37° for 3 weeks. The aqueous suspension was then extracted with ether, and the aqueous layer was lyophilized, washed with ether, and dried. The combined ether extracts, on evaporation of the solvent, yielded in each case a crystalline material which had a melting point and an IR spectrum identical with those of an authentic sample of ethyl

² Alkaline hydrolysis of phosphate esters proceeds *via* attack of the hydroxyl ion on the phosphorus (which carries a residual positive charge) and does not involve the asymmetric carbon of the alcohol which is liberated without change in its configuration.

³ A detailed study on the comparative biological activities of all members of this series of "dual antagonists" in various experimental systems, including a large spectrum of animal tumors, is in preparation and will be published by the cooperating biological investigators.

⁴ In the previously reported spectrum of the *cis*-analog III (10), the last three band assignments were erroneously transcribed; this region of the spectrum of III should read: 9.75 μ (1025 cm^{−1}) (s); 9.90 μ (1010 cm^{−1}) (s); 11.00 μ (905 cm^{−1}) (m); and 11.9 μ (835 cm^{−1}) (m).

Table II—Final Hydrolysis Products

	M.p.	Empirical Formula	Analysis, %		NMR Spectra δ , p.p.m.
			Calcd.	Found	
Hydrolysis product of III (XII)	194–195°	C ₈ H ₂₈ N ₂ O ₅ P	C, 37.21 H, 8.92 N, 10.85 P, 12.01	C, 37.08 H, 8.80 N, 11.03 P, 12.17	1.28 (12H, doublet, CH ₃) 3.25 (2H, multiplet, CH—N) 3.82 (2H, multiplet, CH—O)
Hydrolysis product of IV (XIII)	275–276°	C ₄ H ₁₂ NO ₄ P	C, 28.40 H, 7.10 N, 8.28 P, 18.34	C, 28.53 H, 7.23 N, 8.26 P, 18.12	1.25 (6H, doublet, CH ₃) 3.42 (1H, multiplet, CH—N) 4.43 (1H, multiplet, CH—O)

carbamate. The ether-insoluble products obtained from the aqueous layer were crystallized from methanol-ether. The melting points, elemental analyses, and NMR spectra of these "final hydrolysis products" (XII–XIV) are given in Table II.

Preparation of Phosphate Esters

Phosphate Monoesters—*A. Reaction of Substituted Aziridine with Phosphoric Acid*—To an ice-cooled, stirred solution of the substituted aziridine (0.10 mole) in 10 ml. of water was slowly added an equimolar quantity of 86% phosphoric acid. The resulting solution was stirred at room temperature for 48 hr. and then concentrated to dryness by lyophilization. The products were recrystallized several times from methanol or methanol-ether.

B. Pyrolysis Method—Equimolar quantities of the amino alcohol and phosphoric acid were stirred for 3 hr. at room temperature. The solution was concentrated *in vacuo* at 70°, and the resulting oily residue was heated *in vacuo* (0.8 mm. Hg) for 3 hr. at 160°.

The solid residue was recrystallized from methanol or methanol-ether. The product was identical with that obtained by Procedure A, using the corresponding substituted aziridine, by mixed melting point, IR, and NMR.

Phosphate Diesters—The procedure used for the synthesis of the phosphate diesters was essentially similar to that described for the synthesis of the phosphate monoester, Procedure A, except that two equivalents of substituted aziridine (0.2 mole) were reacted with one equivalent (0.1 mole) of phosphoric acid. The products were recrystallized from methanol-ether.

The melting points, elemental analysis, and NMR spectra of the phosphate mono- and diesters are presented in Table III.

Hydrolysis of Phosphate Esters

The phosphate esters were hydrolyzed, to yield the corresponding amino alcohol and sodium phosphate, by refluxing 0.02 mole of the ester for 48 hr. in 100 ml. of 15% sodium hydroxide solution.

After cooling to room temperature, the solution was saturated with solid sodium hydroxide and extracted with several portions of ether. The combined ether extracts were dried over anhydrous sodium sulfate and, after filtration, the ether was removed *in vacuo*. The oily product was identified by comparison of its IR and NMR spectra with those of an authentic sample of the amino alcohol.

Preparation of Phosphate Salts

To a stirred solution of two equivalents of amino alcohol (0.03 mole) in 20 ml. water was added dropwise one equivalent of phosphoric acid. The reaction mixture was stirred for 1 hr. and then lyophilized. The crude material was recrystallized from methanol. The products were characterized by their melting points, elemental analyses, IR, and NMR spectra (Table III).

Preparation of Phosphate Ester-Salts

To an aqueous solution of the phosphate monoester, prepared as described in Procedure A (0.05 mole in 15 ml. of water), was added 0.05 mole of the corresponding amino alcohol in 10 ml. of water. The mixture was stirred for 24 hr. at room temperature and then lyophilized. The product (95–100% yield) was crystallized from methanol or methanol-ether to yield the phosphate half ester-half salt. Analytical results and spectra are presented in Table III.

Metabolic Fate of Mineral Oil Adjuvants Using ^{14}C -Labeled Tracers I: Mineral Oil

JAMES N. BOLLINGER

Abstract □ This investigation was undertaken to determine the metabolic fate of injected mineral oil using *n*-hexadecane as the tracer. Female white rats and female squirrel monkeys were injected either subcutaneously or intramuscularly with an emulsion containing $1\text{-}^{14}\text{C}$ -*n*-hexadecane made with mineral oil and mannide monooleate. The amount of radioactivity remaining at the site of injection and the distribution of radioactivity in the major organs were determined at varying time periods up to 10 months after injection. One week after injection, 85–98% of the $1\text{-}^{14}\text{C}$ -*n*-hexadecane-labeled mineral oil remained at the site of injection. After 3 months, 50–60% of the mineral oil remained; and after 10 months, approximately 25–30% of the labeled mineral oil was still at the site of injection. The mineral oil tracer, which migrated from the site of injection, was readily incorporated into lipids. Aside from the site of injection, there did not appear to be any accumulation of the $1\text{-}^{14}\text{C}$ -*n*-hexadecane-labeled mineral oil in the major organs.

Keyphrases □ Mineral oil—metabolic fate □ $1\text{-}^{14}\text{C}$ -*n*-Hexadecane—mineral oil—mannide monooleate emulsion—distribution □ Radioactivity accumulation—labeled mineral oil injection, monkeys, rats □ Scintillometry—analysis □ TLC—analysis

Mineral oil emulsions are used in many bacterial and viral preparations in present experimental immunization programs. However, little is known concerning the metabolic fate of the mineral oil. Many observations, both present and in the past, show that mineral oil emulsions are not always well tolerated (1). The safety of mineral oil adjuvants has been questioned on the basis of data that indicate mineral oil alone or Freund's (2) complete or incomplete mineral oil adjuvant, given with or without added antigens, may cause or be associated with induction of plasma cell tumors, autoimmune reactions, or excessive formation of focal granulomata (3–6). Some of the questions that have arisen from these observations are whether these adverse effects are a function of an incapability of animals to mobilize and metabolize mineral oil, adverse cellular

Figure 2—Plexiglas metabolism cages designed for monkeys.

effects due to emulsifying agents, or the result of bacterial and viral biochemical action on the adjuvant preparation itself or at the site of injection.

Several investigators have attempted to answer some of these questions. Peck *et al.* (7) and Woodhour *et al.* (8) have substituted a vegetable oil for mineral oil in their adjuvant preparation. These investigators reported that the clinical, gross, and histomorphologic reactions were much less than were those obtained in comparable test with Freund's (2) incomplete mineral oil adjuvant. These data, however, could be interpreted to reflect that the ability to metabolize the vegetable adjuvant oils was a factor in lowering toxicity. However, since the extent of metabolism was not measured, no definite conclusion could be drawn. On the other hand, several investigators have shown that straight-chain hydrocarbons (C-16–C-18) are metabolized to fatty acids (9–11).

Investigations by Berlin (12) involving a nonionic emulsifier¹ indicated that the toxic reactions of mineral oil emulsions may be, in part or in whole, related to the level of ester hydrolysis and oxidative changes of the emulsifier. More recently, Hardegree and Pittman (13) have shown that the emulsified tetanus vaccines, which caused sterile abscesses in humans, contained free fatty acids and that a variety of antigens were capable of releasing free fatty acids from a water emulsion of mannide monooleate. At any rate, it would appear that emulsions containing vegetable oil instead of mineral oil would yield as high or higher free fatty acid levels with added antigens. Peck *et al.* (7), however, found less toxicity (guinea pig dermal irritation and mouse peritoneal irritation) with peanut oil than with mineral oil in influenza virus vaccine preparations.

Figure 3—Plexiglas metabolism cages designed for rats.

It is the purpose of this study to determine the metabolic fate of the mineral oil in an injected adjuvant emulsion using a major mineral oil component, *n*-hexadecane, as the tracer.

EXPERIMENTAL

Adjuvant Components—A gas-liquid chromatographic analysis of mineral oil² is shown in Fig. 1.

TLC analysis of the surfactant, mannide monooleate,³ shows this material to contain at least 15 components. Identification of the various components has recently been accomplished by O'Neill and Yamauchi (14).

The emulsion used in this study was prepared by using 1 volume surfactant, 9 volumes mineral oil, and 9 volumes water. The resulting emulsions, prepared either by sonic vibration or the double-hubbed needle, double-syringe method, passed the suggested tests for stability (1). However, to eliminate any difficulties with emulsion stability in this investigation, all emulsions were administered within 30 min. after preparation.

¹⁴C-Labeled Tracers—A representative ¹⁴C-labeled paraffin (*n*-hexadecane) was selected to serve as the ¹⁴C-tracer on the basis of its similarity to one of the major components of the mineral oil (Fig. 1), as well as its ability to serve as an effective adjuvant (15). Tritium-labeled materials were considered but are less desirable, since there always exists the possibility of tritium-exchange reactions which invariably complicate interpretation of experimental data (9).

The 1-¹⁴C-*n*-hexadecane⁴ used in this study had a specific activity of 2.35 mc./mmole. The radiochemical purity was determined with the aid of TLC and a liquid-scintillation spectrometer.⁵ Hexane was used to develop and resolve the 1-¹⁴C-*n*-hexadecane on thin-layer plates coated with 125 μ of silica gel.⁶ Removal of a 3% impurity was accomplished by using a 5 \times 0.5-cm. silicic acid column. The impurity remained on the column after elution of the 1-¹⁴C-*n*-hexadecane with glass-distilled hexane. Subsequent analysis indicated that there was less than 0.001% radioactive impurity remaining in the 1-¹⁴C-*n*-hexadecane tracer.

Emulsions containing the radioactive tracer were prepared by prior mixing of the 1-¹⁴C-*n*-hexadecane tracer into the unlabeled mineral oil.

Metabolism Studies—Two types of experimental animals were used in this investigation: albino female rats⁷ weighing approximately 250 g. and female squirrel monkeys⁸ weighing 500–700 g. A total of 36 rats and 36 monkeys was used.

The dose was administered into the right rear thigh, either subcutaneously or intramuscularly. Prior to injection, several 1- μ l.

samples were removed from the ¹⁴C-labeled emulsion, and a check was made on the distribution uniformity of the tracer within the emulsion. The size of dose administered was 0.1 ml. (approximately 5 μ c.) of the emulsion for rats and 0.3 ml. (approximately 15 μ c.) for monkeys. The dose was administered with a 1-ml. disposable syringe equipped with a 23-gauge needle. A similar but unlabeled dose of the emulsion was injected into the left thigh. The control legs were examined by a veterinary pathologist during the study and immediately upon death.

After injection of the radioactive emulsions, the animals on 1-, 2-, and 7-day experimental periods were immediately housed in Plexiglas metabolism cages (Figs. 2 and 3). These cages were constructed in such a manner as to allow reasonable freedom of movement and easy access to water and food. The cages were opened for 15–20 min. every 24 hr. for cleaning and to replenish food and water.

In the long-term studies, 1, 2, 3, and 10 months, animals were housed in metal metabolism cages which allowed monitoring of urine and feces but not CO₂.

After the 1-, 2-, or 7-day experimental periods or the 1-, 2-, 3-, or 10-month experimental periods, the animals were killed by exsanguination following anesthetization with sodium pentobarbital. All animals were immediately examined by gross necropsy with particular emphasis placed on the site of injection of an unlabeled emulsion in the left, or control, leg.

To ensure complete removal of the site of injection for radioactivity determinations, entire thighs were excised. The thighs were then placed in a 600-ml. stainless steel beaker, frozen with liquid nitrogen, and shattered with a steel 5.08-cm. (2-in.) engine valve and a hammer. This technique produced a very fine powder out of the muscle, bone, and skin. The crushed legs were then placed into pint jars; 100 ml. of a 2:1 chloroform-methanol solution was added, and the mixture was homogenized with a high-speed blender.⁹ After separation into two phases (methanol-water and chloroform), the two phases and the residue were analyzed for radioactivity.

A portion of the major organs of both monkeys and rats was removed for the determination of the radioactivity. Major organs examined were liver, depot fat, spleen, kidney, small intestine, ovary, lung, and, in some cases, the heart, blood, and brain. The inguinal lymph nodes of monkeys were also removed and assayed for radioactivity.

Leg extracts as well as some organ extractions were fractionated by TLC, and attempts were made to ascertain the nature of radioactivity present by the migration on thin-layer plates relative to known standard materials.

Radioactivity Determinations—Respired ¹⁴CO₂ was trapped in NaOH as Na₂CO₃ and then precipitated as BaCO₃. The BaCO₃ was

removed from the aqueous phase by filtration and dried in an oven at 120° for a minimum of 6 hr. After BaCO₃ dried, it was pulverized to a fine powder. Approximately 50-mg. samples were removed and suspended in a scintillation-gel (16) for radioactivity determination. The liquid-scintillation counting efficiency under the study conditions was 86%. Total radioactivity removed *via* respiratory ¹⁴CO₂ was then calculated from the total CO₂ collected over 24-hr. experimental periods.

Urine and feces collected over 24-hr. experimental periods for the 1st week after administration were also assayed for radioactivity. The amount of radioactivity in the feces was determined by a perchloric acid–hydrogen peroxide digestion of 100-mg. samples (17). Radioactive urine was determined by using Bray's method (18). One milliliter of urine was counted, and the total activity eliminated *via* the urine was calculated from total urine volumes.

Radioactivity in the major organs, including blood and feces, was determined by the method of Mahin and Lofberg (17). This method involves perchloric acid digestion of 100-mg. wet tissue samples (0.2 ml. blood). The color is removed from the digested samples with hydrogen peroxide. These samples were then taken up in 20 ml. toluene and ethylene glycol–monoethyl ether (Cellosolve), 2:1, containing the scintillator PPO (6 g./l. counting solution) and counted. Counting efficiency in this system was about 53%.

The fractions obtained from serial scraping of thin-layer chromatographic plates were assayed for radioactivity in the gel-scintillation system as described for Ba¹⁴CO₃ determinations. Serial scrapings were obtained by the aid of mineral oil and lipid standards¹⁰ and I₂ vapor visualization.

RESULTS

The amount of 1-¹⁴C-*n*-hexadecane remaining at the site of injection from 1 to 10 months after administration is summarized in Table I. In general, the mineral oil was slowly removed from the site of injection. In monkeys, 96–98% was still present after 1 week, while in rats the amount remaining at the site of injection ranged from 85 to 90% after 1 week. After 1 month, approximately 65–75% remained, and by 3 months both groups of animals had retained 50–60% of the total radioactivity at the site of injection. Ten months after injection, approximately 25–30% was still at the site of injection.

Several mathematical equations (linear and semilogarithmic derived equations) were prepared to predict the length of time required to remove all of the oil from the site of injection. However, since there were too few animals at each time point as well as a considerable amount of scatter of the data, it was found that a confident mathematical prediction could not be made.

Virtually all (95–99%) of the activity remaining at the site of injection in monkeys after 3 and 10 months was present in the hydrocarbon fraction (Table II). On the other hand, 3–4% of the radioactivity found in the legs of rats had been incorporated into triglycerides with 91–93% still associated with the hydrocarbon fraction. A reason for this difference was that the rats had a larger amount of depot fat (triglycerides) in the thigh area than did the monkeys. In both animal groups, a certain amount of radioactivity (1–3%) also was associated with the phospholipids of the leg muscles. McCarthy (11) demonstrated that C-16 and C-18 hydrocarbons were converted *in vivo* into fatty acids of the same chain lengths, suggesting that the incorporation of radioactivity into the various leg lipid fractions was the result of 1-¹⁴C-*n*-hexadecane

mobilization to the liver, where it was converted to fatty acids and returned in the form of various lipid classes to leg muscle tissue.

Tables III and IV show the average level of radioactivity found in the major organs of monkeys and rats, respectively, after the administration of a mineral oil mannide monooleate emulsion containing 1-¹⁴C-*n*-hexadecane tracer. After the first 24 hr., all organs tested contained radioactivity. The liver had the highest activity of any organ 24 hr. after injection. Two days after injection of the emulsion containing 1-¹⁴C-*n*-hexadecane, the level of radioactivity in the liver increased four- to fivefold, as did the level in the depot fat. The radioactivity in all other organs increased to varying degrees. Radioactivity in the depot fat of both animals continued to increase until it became about fourfold over that amount present after 2 days. After 1 month, the amount of radioactivity in the liver of both monkeys and rats decreased; after 2 months, it had returned to those levels recorded for the first 24-hr. period after injection. The specific activity of the depot fat remained high throughout the 3-month period. After 10 months, the radioactivity in the depot fat had decreased to about one-fourth the level measured at 3 months. However, the level of radioactivity in the depot fat was still 50- to 100-fold greater than any other organ. Other than the liver and depot fat, no organ appeared to accumulate large amounts of radio-

activity. Most of the detectable radioactivity in the various organs resided in the fat-soluble fraction, with little or none appearing in the water-soluble and residue fractions.

Table V shows the distribution of radioactivity in chloroform-methanol extracts of various organs taken from monkeys 2 days after the administration of an emulsion containing 1-¹⁴C-*n*-hexadecane. These data indicate that a substantial portion of the radioactivity in the liver (30%), fat (42%), kidney (74%), spleen (81%), and ovary (90%) was unmetabolized 1-¹⁴C-*n*-hexadecane tracer. The remaining radioactivity was located in the various lipid classes such as phospholipids, free fatty acids, and triglycerides, indicating that hexadecane was undergoing metabolism.

By 1 month, however, the amount of radioactivity in the various organs associated with 1-¹⁴C-*n*-hexadecane was greatly reduced, and most of the radioactivity (80-95%) was associated with the major lipid classes. After 3 months the major lipid classes contained as much as 95-98% of the radioactivity (Table VI).

Only a small amount of radioactivity from 1-¹⁴C-*n*-hexadecane was eliminated the 1st week in the respiratory CO₂ by either monkeys or rats (Table VII). The amount eliminated per day varied considerably among animals, but it was usually less than 0.2% and, in many cases, was as little as 0.01%. As a result, the average total amount

eliminated by respiratory $^{14}\text{CO}_2$ the 1st week ranged from 0.5 to 2.0%. The major reason for these low levels was that this material was only slowly mobilized from the site of injection, and its conversion to fatty acids and subsequent CO_2 was limited by the rate of mobilization. There was little or no difference in the rate of mobilization from subcutaneous and intramuscular injections.

Some radioactivity from 1- ^{14}C -*n*-hexadecane was eliminated in the urine and feces during the 1st week after administration; however, in both groups of animals, the total amount for the entire week was less than 0.01%.

All animals received an unlabeled dose of the emulsion in the opposite leg. Upon death, each of the control legs was immediately examined by gross necropsy by a veterinary pathologist. At no time was there any indication of any type of infection or a sterile abscess due to the injection.

SUMMARY

This investigation has shown that the *n*-hexadecane component and most likely other straight-chain hydrocarbon components of a mineral oil adjuvant emulsion are very slowly mobilized from the site of injection in monkeys and rats. Results have been presented which show that as much as 25–30% of the ^{14}C -*n*-hexadecane tracer remains at the site of injection after 10 months. The *n*-hexadecane tracer, which is mobilized from the site of injection, was readily metabolized to naturally occurring lipids.

Gross necropsy did not reveal any evidence of any pathological states at the sites of injection.

Metabolic Fate of Mineral Oil Adjuvants Using ^{14}C -Labeled Tracers II: Mannide Monooleate

JAMES N. BOLLINGER

Abstract □ This investigation was undertaken to determine the metabolic fate of mannide monooleate when employed in a mineral oil emulsion. Female white rats and female squirrel monkeys were injected subcutaneously or intramuscularly with an emulsion made with mineral oil and surfactant and including either 1- ^{14}C -oleate or UL- ^{14}C -mannide-labeled mannide monooleate tracer preparations. It was shown that 30–40% of the surfactant mixture is removed from the site of injection after 24 hr. After 1 week, 40–60% of the surfactant is removed from the site of injection; while after 3 months, 10–30% of the surfactant still remains. The 1- ^{14}C -oleate-

labeled mannide monooleate was largely incorporated into the various lipid classes, while the UL- ^{14}C -mannide-labeled mannide monooleate preparation was largely eliminated in the urine. There was some indication that the inguinal lymph nodes of monkeys may have contained unusually large amounts of radioactivity.

Keyphrases □ 1- ^{14}C -Oleate-labeled mannide monooleate—metabolic fate □ UL- ^{14}C -Mannide-labeled mannide monooleate—metabolic fate □ Mineral oil—mannide monooleate emulsion—subcutaneous, intramuscular injection □ Metabolic fate—mannide monooleate in mineral oil emulsion □ TLC—identity

Freund (1) found that “mannide monooleate”¹ was an effective agent in combining antigens and mineral oils in the form of a water and oil emulsion. However, subsequent use has indicated an infrequent occurrence of cysts following injection of vaccines and allergens (2) made with certain lots of this surfactant. Berlin (3) performed studies which showed that the toxic reactions of a mineral oil–“mannide monooleate” emulsion may

be, in part or in whole, related to the level of ester hydrolysis and oxidative changes of this material. Recently, Hardegree and Pittman (4) have shown that the tetanus vaccines which caused sterile abscesses in humans contained free fatty acids and that a variety of these antigens were capable of releasing free fatty acids from a water emulsion of “mannide monooleate.”

This study was undertaken to obtain information on the mobilization and metabolism of a mannide monooleate surfactant preparation when it is received as an injected mineral oil emulsion.

EXPERIMENTAL

Adjuvant Components—The adjuvant emulsion used consisted of mineral oil,² “mannide monooleate,” and water in proportions of 9 parts mineral oil, 1 part surfactant, and 9 parts water.

The surfactant preparation used was obtained from Hilltop Laboratories, Inc., Cincinnati, Ohio. TLC analysis showed the material to contain at least 12 components (Fig. 1). Identification of the various components is tentative in this investigation; however, O'Neill and Yamauchi (5), who recently identified many of the components present in this particular surfactant, indicated that a neutral fraction from the “mannide monooleate” consisted of at least 12 components characteristic of peracylated carbohydrate structures. The intermediate or moderately polar material contained 14 components of the mannide monooleate class. The polar fraction contained predominantly carbohydrate polymers, conjugated dienes, and cyclic fatty acids.

The emulsion used in this study was prepared as described previously (6), using either sonic vibration or a double-hubbed needle, double-syringe method.

¹⁴C-Labeled Emulsion—Since the mannide monooleate preparation is not pure but a mixture of monooleate, dioleate, trioleate, etc., and various positional isomers of these esters plus various isomeric forms of dehydrated mannitol and oleic acid, it was decided that the most representative tracer would be ¹⁴C-labeled surfactant prepared in the same manner as that used for the preparation of the normally unlabeled material.

Two preparations³ were used in this study. One was made from 1-¹⁴C-oleic acid and unlabeled mannitol, while the other was made from UL-¹⁴C-mannitol and unlabeled oleic acid. The specific activity of the 1-¹⁴C-oleate mannide was 2.2 μc./mg., and that of the UL-¹⁴C-mannide oleate was 2.1 μc./mg. Results of TLC analysis of the separated components of the two tracers are shown in Fig. 1 and Table I, respectively. The relative amounts of each of the components present in the ¹⁴C-labeled material were roughly (visual analysis) the same as those present in the unlabeled material. The data indicate that about 50% of the labeled surfactant is esterified, while the remainder is nonesterified material (chemically altered mannitol and oleic acid).

Dose and Administration—The radioactive tracers were thoroughly mixed with unlabeled surfactant and the mineral oil emul-

sion prepared as described (6) and used immediately (within 30 min. after preparation).

The size of the dose was 0.1 ml. (approximately 5 μc.) of the emulsion for rats and 0.3 ml. (approximately 15 μc.) for monkeys. The dose was administered with a 1-ml. disposable syringe equipped with a 23-gauge needle. The dose was administered in the right thigh either subcutaneously or intramuscularly, depending upon the phase of the experiment. A total of 60 female white rats and 60 female squirrel monkeys were used in this investigation. Prior to injection, several 1-μl. samples were removed from the ¹⁴C-labeled emulsions, and a check was made on the uniformity of distribution of radioactivity within the emulsion. An unlabeled emulsion preparation of the same volume was injected into the left thigh for pathological evaluation by a veterinary pathologist.

After injection of the radioactive emulsions, the animals on the short-term studies (1–7 days) were immediately housed in Plexiglas metabolism cages. In long-term studies (1–3 months), the animals

Figure 1—Plate I shows the distribution of the components of “mannide monooleate” (Lane A) and the relative location of free fatty acids and esterified naturally occurring lipids (Lane B). The letters a–m indicate the components isolated for radioactivity determinations (Table I). The TLC system consisted of 100-μc. silica gel-coated plates developed in a chloroform-diethyl ether-acetic acid (95:5:1) system. Plate II depicts the same materials as Plate I but was developed in a more polar chloroform-diethyl ether-acetic acid (80:20:1) system. The letters depict the areas isolated for radioactivity determinations.

were housed in metal metabolism cages which allowed monitoring of urine and feces but not CO_2 . Collection of $^{14}\text{CO}_2$ was carried out as described in a previous study (6). The determination of mobilization and degree of metabolism were monitored as previously described (6).

RESULTS AND DISCUSSION

Table II shows the average percentage of 1- ^{14}C -oleate mannide tracer preparation remaining at the site of injection 1 day to 3 months after administration. Approximately 20–25% of this tracer

was removed from the site of injection of rats and monkeys the 1st day after both intramuscular (IM) and subcutaneous injection (Sub Q). Seven days after injection, however, 40% (rats) to 60% (monkeys) had been removed from both sites of injection. After 3 months, 22% (Sub Q) to 35% (IM) still remained at the site of injection in monkeys; in rats the average amount that remained ranged from 9% (Sub Q) to 20% (IM).

The amount of UL- ^{14}C -mannide oleate preparation remaining at the site of injection of monkeys and rats for 1 day to 3 months after injection is summarized in Table III. During the first 24 hr. after administration, as much as 35–45% of the radioactivity injected into rats and monkeys had been removed from both IM and Sub Q sites of injection. Two to seven days after injection, the amount remaining in both monkeys and rats changed very slowly, an average of 50% being removed from the site of injection the 1st week. After 1 month, intramuscularly injected animals lost approximately 60%, and subcutaneously injected animals lost 70–80% from the site of injection. Essentially, no change was noted after 2 months. By the 3rd month after injection, both the intramuscularly and subcutaneously injected animals had lost, from both sites of injection, approximately 88% of the radioactivity associated with the UL- ^{14}C -mannide oleate preparation.

In general, one-half of the ^{14}C -labeled "mannide monooleate" was removed from the site of injection the 1st week. It took 3 months, however, to remove roughly one-half to three-quarters of the material remaining after 1 week.

In an effort to define the nature of the radioactive material left at the site of injection, the chloroform-methanol leg extracts (6) were applied to TLC plates. The extracts were developed in a chloroform-diethyl ether-acetic acid system (95:5:1), an example of which is shown in Fig. 1. The distribution of radioactivity on the TLC plate (Table IV) indicated that the material remaining at the site of injection of both monkeys and rats was the esterified components of mannide monooleate preparation. The free fatty acids, free sugar, and their altered forms apparently were removed from the site of injection. The nature of the material removed and of that left at the site of injection was not verified chemically.

Distribution of Radioactivity among the Major Organs—The average levels of radioactivity (counts/min./100-mg. wet tissue) of the major organs of monkeys and rats after the administration of 1- ^{14}C -oleate and UL- ^{14}C -mannide surfactant preparations are presented in Tables V and VI, respectively. All organs of both monkeys and rats incorporated radioactivity within the first 24 hr. However, the level (c.p.m./100-mg. wet tissue) was less with UL- ^{14}C -mannide oleate than with the 1- ^{14}C -oleate mannide preparation. The depot of fat of those animals receiving 1- ^{14}C -oleate-labeled surfactant consistently contained the highest specific activity of any organ except the inguinal lymph nodes. In those animals receiving UL- ^{14}C -mannide oleate tracer, the depot fat contained comparatively little radioactivity.

Approximately 75% of the inguinal lymph nodes analyzed had a fairly large amount (200–2000 c.p.m./20-mg. wet tissue) of radioactivity, regardless of the tracers administered. These data seem to indicate that the lymph was a major route in the transport of the surfactant and not necessarily a site of accumulation.

Nature of the Radioactivity in the Major Organs—Attempts were made to evaluate the distribution of radioactivity within the major organs of monkeys 3 months after administration of a mineral

^a Pooled tissue extracts. ^b Probable contents of fractions: (a-b) phospholipids and chemically altered oleic acid; (c-i) chemically altered oleic acid, oleic acid, and monoglycerides; (j-solvent front) esterified surfactant and esterified naturally occurring lipids (triglycerides, sterol esters, and free sterols).

oil—"mannide monooleate" emulsion containing either UL-¹⁴C-mannide or ¹⁴C-oleate-labeled surfactant. The results (Tables VII and VIII) of the serial TLC scrapings and liquid-scintillation counting of the fractions obtained from organ extracts varied considerably. This variation was interpreted as an indication of metabolism once these tracers had reached the various tissues. For example, the depot fat contained some radioactivity associated with free fatty acids and a large amount (64%) associated with newly synthesized triglycerides when the ¹⁴C-oleate mannide preparation was used. The spleens of the same animals, on the other hand, contained large amounts of radioactivity (60%) at the origin of the TLC plates, indicating that this was probably newly synthesized phospholipids.

The distribution of radioactivity in those monkeys receiving the UL-¹⁴C-mannide oleate was completely different from those receiving the ¹⁴C-oleate mannide preparation. Since no definite chemical studies were performed, these results can best be explained on the basis that the metabolism of the labeled oleate and the labeled mannitol tracers would be expected to be different. The nature of the radioactivity found in the lymph nodes also, unfortunately, remained undetermined. However, it was suspected to be esterified material of the surfactant.

Respiratory ¹⁴CO₂—A substantial amount of radioactivity is eliminated in the respiratory CO₂ of animals given the ¹⁴C-oleate mannide preparation as the tracer (Table IX). In monkeys, the average daily rate of ¹⁴CO₂ eliminated was approximately 0.9%, yielding a total average of 6% of the administered radioactivity eliminated the 1st week. Similar results were obtained with rats; however, the daily rate was slightly higher, and the total amount eliminated during the 1st week averaged close to 7% of the amount given.

On the other hand, a very small amount (0.1–0.2%) of the UL-¹⁴C-mannide oleate tracer preparation was eliminated in the respiratory CO₂ the 1st week after injection. No determinations were made after the 1st week.

Urine and Feces—Table X data show that only a very small amount of radioactivity was eliminated in the urine of monkeys and rats when the ¹⁴C-oleate-labeled surfactant was administered. The total amount eliminated for 1 week after injection ranged from 0.5 to 1%.

When the UL-¹⁴C-mannide surfactant was administered, a large amount of radioactivity, roughly 25% of the dose administered, was eliminated in the urine the first 24 hr. During the 2nd day, the

^a Probable contents of fractions: (a-g) nonesterified, unaltered, and chemically altered mannitol; (h-m) esterified surfactant.

amount decreased to about 3 and 5% in rats and monkeys, respectively. Three to seven days after injection, the level eliminated in the urine stabilized to about 1% daily. The total amount eliminated the 1st week was about 35–40%. In general, there was no significant difference between monkeys and rats in the total amount eliminated in the urine. The results on the total amount eliminated in the urine of rats agree with those of Porter and Titus (7). However, these investigators studied only the mannide-labeled surfactant. As shown, the 1- ^{14}C oleate-labeled material is not eliminated in the urine.

Table XI presents TLC separation and a liquid-scintillation counting analysis of the radioactive components in the urine of those animals receiving the UL- ^{14}C -mannide oleate preparation. These data indicate that the material eliminated so rapidly in the urine was the nonesterified sugar components of the surfactant.

No appreciable amount of radioactivity was detected in the feces when either tracer was given.

Pathological Observations—Gross necropsy of all animals indicated that no sterile abscesses, infections, nor other observable pathological conditions were produced at the site of injection. No extensive histological examinations were performed; therefore, it is not possible to state definitely whether any subtle histopathological conditions existed.

SUMMARY

This study has shown that, when using a “mannide monooleate”-mineral oil emulsion, the surfactant was removed from the site of injection faster (40–60% the 1st week) than the mineral oil (1–5% the 1st week) (6). The obvious danger in this phenomenon is that the

loss of the emulsifier may allow the mineral oil to coalesce into larger droplet sizes and thereby retard mineral oil mobilization from the site of injection. Those components of the “mannide monooleate” preparation that were retained at the site of injection for longer periods of time (3 months or more) appeared to be the esterified components as opposed to the nonesterified components (free oleic acid, mannitol, and their chemically altered forms), which appeared to be removed within 24 hr. after injection. These data suggest that, had this surfactant been pure mannide monooleate or even its other esterified forms, its longer retention at the site of injection may have also assisted in a more uniform mobilization of mineral oil.

This investigation has yielded additional information on the mobilization and metabolism of the mannide monooleate surfactant preparation when it is received as an injected emulsion. No information was obtained directly which would implicate the surfactant used in this study as a particularly noxious material. Although not tested in this study, this would seem to indicate that the reported toxic effects associated with this material are in some way related to the various antigen preparations.

In Vivo Electrometric Study of Carcinogenic Hydrocarbon Interaction with Mouse Epidermis

V. F. SMOLEN, D. E. SNYDER, and R. J. ERB

Abstract □ A bioelectrometric technique was implemented in the study of 3-methylcholanthrene and benzene interaction with the epidermis of hairless mice. In contrast to previous studies of this nature, the experimental results were obtained entirely *in vivo* without causing injury to the mice. The results obtained are analogous to titration curves of amphoteric macromolecules. Inspection of the curves and their temporal variations following the topical application of the hydrocarbons revealed the induction of significant changes in the density of ionogenic groups affixed to the epidermal colloids. The carcinogenic 3-methylcholanthrene was observed to induce consistently a reduction of net cationic fixed-charge density attributable to the loss or discharge of basic nitrogenous groups titratable above, at least, pH 7.4. A discussion of some of the possible mechanisms of this observation is presented. The results of the present study indicate the bioelectrometric method to be complementary to the more direct experimental techniques commonly employed.

Keyphrases □ Carcinogenic hydrocarbon interaction—mouse epidermis □ Epidermis, mouse—3-methylcholanthrene, benzene □ 3-Methylcholanthrene, benzene effects—epidermal net charge density □ Bioelectrometric determination—epidermis—hydrocarbon interaction

The ability of hydrocarbons such as 3-methylcholanthrene (3-MC) to induce malignanzation following topical application to skin has been well documented (1). It has been found generally that the greater the extent to which a hydrocarbon possessing a reactive, electron-rich, *K*-region binds to the skin, the greater is its carcinogenic potency (2–4). It has also been demonstrated that binding occurs to protein components of mouse skin (5). The extent of interaction of the hydrocarbons varies with time (2, 4–7), reaching a maximum for 3-MC at approximately 10 hr. (7). The binding of carcinogenic relative to inactive hydrocarbons has been found to be especially high for water-soluble proteins extracted from mouse skin found in a fraction termed “proteins I” (8, 9); the *in vivo* binding of hydrocarbons to nucleic acids appears to remain in some doubt (10). It has been concluded (11) that oxidative biotransformation of the *K*-region of the hydrocarbons yields dicarboxylic acids which bind protein through amide, imide, or ester linkages but most probably through the formation of amides.

The experimental methods employed in these previous investigations concerning the extent and nature of hydrocarbon interaction with mouse skin have been destructive; they necessitated the sacrifice of the animals, disintegration of the skin, and fractionation of its constituents. Such procedures are disadvantaged by the difficulty and necessity of correcting for any *in vitro* binding of the carcinogen which may occur during the extraction process. The observation of significant amounts of *in vitro* binding has led some authors (12) to conclude that carcinogens that were not bound in the

intact tissue became bound in the process of disintegrating the tissue. The difficulty of distinguishing between binding sites active *in vivo* and those activated by the *in vitro* treatment of the tissue is readily apparent. Results obtained from the use of destructive methods have, therefore, been open to question with respect to their verity in representing actual *in vivo* conditions.

In the present study, a nondestructive bioelectrometric method, previously described (13, 14), was utilized. It permitted the investigation of hydrocarbon interaction with mouse epidermal colloids to be accomplished entirely *in vivo* under physiological conditions. The completely innocuous nature of the experimental procedure allows each animal to serve as its own control; repeated measurements can be made on the same animal to discern the temporal dependency of the induced effects. The present study was primarily undertaken to examine the ability of the bioelectrometric method to discern the effects of 3-MC on mouse skin and, secondarily, to determine if any responses to the carcinogen previously undetected when employing destructive techniques could be made apparent in an all *in vivo* study.

MATERIALS AND METHODS

Methods—The electrometric method employed in the present study is essentially based upon the Gibbs-Donnan equilibrium. It involves the measurement of electrical potentials developed at the boundary of the tissue and a buffer solution, which may or may not contain the substance whose interaction is to be studied. The results obtained from treated surfaces are compared to untreated controls.

The net density of fixed charge on the tissue surface, arising from the dissociation of ionogenic groups bonded or adsorbed to the surface, can be computed from the measured null point potentials. If these results are obtained under conditions of varying pH and plotted as a function of pH, the curves resemble, and are analogous to, titration curves of amphoteric macromolecules. The shape of these curves is dependent upon the nature of the dissociating groups, the presence of interacting solutes, and the state of aggregation of the colloids composing the tissue surface. The fixed-charge density on tissue surfaces and, therefore, the shape of the titration curves are quite sensitive to interacting substances. Variations in the curves can be interpreted to yield information about the extent and nature of the interaction.

The verity of the measured potentials in representing the fixed-charge density has been established in the principal author's laboratory (unpublished) as well as by others (15). The details of the calculation of the net fixed-charge densities and the elementary interpretation of titration curves have been described (13–15). It has recently been found, in the principal author's laboratory, that for human epidermis the thickness of the colloid phase, whose properties are reflected in the electrometric measurements, is approximately 4 μ . This represents about 40% of the depth of the stratum corneum. Although this same determination has not been performed for mouse skin, which is thinner by several cellular layers, the results of the present study could pertain, at least, to a similar relative depth.

Figure 1—Experimental arrangement for the determination of fixed-charge density of the epidermal surface of hairless mice.

Figure 1 contains a diagram of the experimental arrangement used in the present investigation with hairless mice. The mice were ether-anesthetized and rendered immobile for the treatments and subsequent measurements by restraining them securely to a specially constructed mouse board prior to their recovery from the anesthetic. The differences of the measured potentials, used for the calculations of the fixed-charge density, are independent of the location of the reference surface on the animal. The tail of each mouse was selected for use in the present case because of its convenience. It was rinsed well with distilled water and 0.15 *N* NaCl and placed into the vessel containing the 0.15 *N* NaCl reference solution. The tail was not disturbed further during the course of the series of measurements corresponding to any given time. The dorsal side of the mouse was cleansed by swabbing with 70% ethanol, followed by a thorough, yet gentle, scrubbing with a solution of soap, and rinsing with distilled water. This cleansing procedure had previously been found to reduce both intrasubject and intersubject variations of the potential differences measured under any given set of conditions (13).

After cleansing, the back of the mouse between the neck and the tail was divided equally into three separate areas by drawing thin lines with an ink marker. The anterior third of the back was treated three times with a liberal application of benzene on a cotton swab and allowed to dry. The posterior third of the back was similarly treated with a 1% w/v solution of 3-MC in benzene. The middle area was left untreated and served as the control. Immediately prior to the measurement of potentials from any of the areas on the mouse, the area was rinsed with distilled water and allowed to hydrate by covering with a pledget of cotton wetted with 0.15 *N* NaCl for approximately 15 min. The electrical potentials were consistently read from the three areas in the order of benzene-treated, control, and 3-MC-treated skin. No significant differences in measurements performed on the three skin areas prior to their treatment were observed.

Titration curves for each treatment area on four separate mice corresponding to approximately 1, 4, 9, 20, 34, and 50 hr. after treatment were constructed over a range of pH from 1.0 to 7.4, using values of fixed-charge density calculated from the observed potential differences.

The data for a titration curve were obtained by swabbing the area with pH 1.0 buffer following the 15-min. soaking with 0.15 *N* NaCl. A 0.5 × 0.5-cm. piece of filter paper saturated with pH 1.0 buffer

Figure 2—The average relationship of the fixed-charge density of the epidermal surface colloids of mouse skin to pH. Each point represents the average of 24 determinations on four separate mice studied at each of six different time intervals varying from 1.1 to 50.3 hr. following treatment with benzene (—■—) and 1% 3-MC solution in benzene (—▲—). The remaining curve (—●—) represents results obtained from the untreated control skin areas on each of the mice.

was placed in the center of the area of interest. Despite any movement by the mouse, the paper was held firmly in place, in part by the weight of the calomel electrode mounted in a movable arm assembly. A potential, E_1 , was continuously recorded until observed variations in the potentials were less than approximately 0.2 mv./min.; this stability was usually achieved within 1–2 min. The electrode was then removed, the tip rinsed with saturated KCl solution, and wiped clean. Any remaining excess solution was swabbed from the back of the mouse. A smaller piece of filter paper, wetted with 0.15 *N* NaCl (except at pH 1.0 where a 1:10 dilution of the buffer itself was used), was placed within the area previously covered and was followed immediately by the replacement of the electrode and the recording of a potential, E_2 . The electrode and skin surface were treated again as described, and the potential E_1 was redetermined to ensure that conditions had remained constant between the time of E_1 and E_2 measurements. The potential difference, $E_2 - E_1$, termed the dilution potential, E_d , was computed with the average of E_1 values which agreed within 1.0 mv. The E_d values allow the calculation of the fixed-charge density in the manner previously described (13, 14). Following pH 1.0, the fixed-charge densities of the epidermal surface corresponding to pH 2.2, 3.7, 4.6, 6.0, and 7.4 were obtained from dilution potentials measured in the same manner using the isoosmotic buffer solutions of higher pH.

Materials—The compositions of the isoosmotic buffer solutions have been reported earlier except for the pH 1.0 solution which consisted of 0.10 *M* HCl and 0.05 *M* NaCl. Spectrograde benzene was used. The 3-MC was supplied by Eastman Chemicals.

Hairless, strain HRS/J mice (Jackson Labs, Bar Harbor, Maine) were used in the experiment. The mice were 7-week-old males.

Corning miniature fiber-junction saturated calomel reference electrodes were used in conjunction with a Sargent model SR potentiometric recorder. The potentials were read directly from the recorder chart.

Statistical calculations were conducted with the aid of an IBM 7094 computer.

RESULTS

Gross Graphical and Statistical Results—The experiment can be described as being of three-factor, unsymmetrical design. Four responses, corresponding to the replicate determinations of the dilution potential on four individual mice, were recorded for each factor level. The determinations were made at 1.1, 4.8, 9.4, 20.4, 34.0, and 50.3 hr. and at pH 1.0, 2.2, 2.9, 3.9, 4.6, 6.0, and 7.4 on each of the treated and control areas on the mice. Significance

Figure 3—The relationship of the net fixed-charge density of hairless mouse epidermis, averaged over pH, to the time following treatment of the skin with benzene (—■—), 1% 3-MC in benzene solution (—▲—), as well as for untreated control skin (—●—). Each point is the average of 28 determinations on four different mice.

levels, resulting from an analysis of variance, for the main effects and primary interactions are shown in Table I; $p > 0.05$ was taken as not significant (N.S.). Some of the effects listed in Table I are graphically illustrated in Figs. 2–4. In Fig. 2, the fixed-charge densities plotted at each pH are averages of the values calculated from observed E_d values at each time and for each mouse. The relatively parallel nature of the titration curves corresponding to each treatment over considerable ranges of pH illustrates the insensitivity of the treatment effects to pH. The relatively small vertical distances between the curves and their crossing can account for the comparatively low order of significance of the treatments. Figure 3 is similar to Fig. 2, except the values of the fixed-charge densities are averaged over pH and plotted as a function of time. The pronounced effect of 3-MC, relative to the benzene control, is clearly evident for the majority of the time course of the study.

It is evident from Fig. 3 that a general trend toward an increased net density of positive fixed charge on the affected colloids underlies the treatment-induced responses. The three curves appear to possess this trend in common, differing only by the superimposition of the treatment-induced effects. Consistent with this trend toward a net increase in cationic fixed-charge density, examination of the titration curves for the untreated control skin areas revealed later curves

Figure 4—Comparison of titration curves obtained for untreated mouse epidermis at 1.1 (—●—) and 50.3 (—■—) hr. Each point is the average of four determinations on separate mice plotted \pm its standard error. By a paired t test, the curves are significantly different at $p < 0.01$.

always to lie below earlier curves. The extreme differences in the curves are depicted in Fig. 4 where the 1.1- and 50.3-hr. curves are presented. Each point is plotted with its standard deviation. A paired t test revealed the curves to be significantly different at $p < 0.01$. This agrees with the highly significant pH–time interaction and supports the reality of the underlying general trend toward positivity.

It can be surmised from further inspection of Fig. 3 that, relative to the benzene control, the treatment with 3-MC can be calculated from the vertical differences between the two curves to have induced an overall average reduction of 23% in net cationic fixed-charge density. Exempting the anomaly at 4.8 hr., the reduction appears to decline exponentially with time from 49% at 1.1 hr. to 10% at 50.3 hr. and has an approximate half-life of 20 hr.

To resolve more precisely the influence of pH and time on the effects of the benzene and 3-MC treatments, paired t tests were performed. The significance levels calculated from the tests are presented in Tables II–IV, from which it is evident that the effects are mostly significant at 1.1 and 9.4 hr. and nearly independent of pH. The highly significant differences between the 3-MC (plus benzene as the solvent) and benzene control can partly be attributed to the antagonistic effects of benzene and 3-MC on the net density of fixed charge at these times. This is evident from inspection of the titration curves observed at 1.1 and 9.4 hr. (Figs. 5 and 6) where it can be seen that the benzene and 3-MC displaced curves lie on opposite sides of the untreated control; moreover, in Fig. 3 the benzene curve is observed to lie above the untreated control at 1.1 and 9.4 hr. In each case a reduction of net cationic charge has been elicited by the 3-MC while the benzene has induced an increase at these times; the effect of benzene has subsided, while that of 3-MC has been elevated, at 9.4 hr. relative to 1.1 hr. The opposite effects of benzene and 3-MC are only apparent at 1.1 and 9.4 hr. At all other times the effects of the two hydrocarbons appear additive in reducing the average net density of fixed cationic charge on the involved colloids.

Superficially at least the relatively high significance of the effects of 3-MC at 9.4 and 1.1 hr. may be compared to the maximum in protein binding observed at approximately 10 hr. following treatment of mouse skin (7). That carcinogenic hydrocarbons interact with tissue constituents to alter cellular functions within an hour of their application to mouse skin has also been demonstrated (17, 18).

The appearance and disappearance of statistically significant treatment effects are likely the consequences of the various simul-

taneously operative rate processes affecting the observed net density of fixed charge in a complex manner. In some instances, it is possible to resolve the influence of some of these processes.

DISCUSSION

Analysis of the Trend toward Positivity and the Time-Dependent Effects of Benzene—Close inspection of the untreated control titration curves in Fig. 4 reveals that the curves begin to diverge appreciably beyond pH 2.2, i.e., in the range of pH where anionogenic groups generally become titratable. On this basis, the observed trend toward positivity can be attributed to a progressively increasing, time-dependent, net loss of anionogenic groups from the epidermal colloids. In contrast, a significant difference between titration curves

at pH 1.0, coupled with significant vertical differences at higher pH, characteristically accompany a diminution of cationogenic groups titratable in the pH range presently studied. In this case the curves would also be required to approach one another and eventually become coincident once the pH range in which these groups are titratable has been exceeded. Clearly this behavior is not characteristic of the curves in Fig. 4. The loss of anionogenic groups from the epidermal colloids remains the only acceptable explanation of their behavior.

Comparison of the benzene control with the untreated control curves (Figs. 5 and 6) observed at 1.1 and 9.4 hr. reveals a similar loss of anionogenic groups to be responsible for the benzene-induced effects on the fixed-charge densities of the epidermal colloids. An initial acceleration in the loss of anionogenic titratable groups in response to benzene treatment, followed by a slowing in the rate of subsequent loss, could account for the relatively high significant differences between the benzene and control curves at 1.1 hr. and the subsequent loss of significance at later times as the extent of anionogenic group loss from the untreated control skin approaches that for benzene-treated skin. Since carboxyl groups are primarily titratable over the pH range for which the benzene-control differences are significant, it may be speculated that the titratable anionogenic groups were initially diminished by the extraction of fatty acids in the benzene treatment and later lost through further elutriation into the applied 0.15 *N* NaCl and buffered titrating solutions. Joseph *et al.* (19) have made similar observations on toluene-treated skin and derived similar conclusions regarding the effect of the organic solvent.

It can be further hypothesized that the approach of the benzene curve in Fig. 3 to the control curve, in addition to being a consequence of the slowing of the benzene-induced initially accelerated loss of anionogenic materials, is also a result of a slower loss of cationogenic materials from the epidermis which becomes increasingly appreciable with time. Support for this hypothesis is gained from observing that beyond 1.1 hr., the benzene titration curve at pH 1.0 consistently lies above the control, even though the only individual difference that is significant occurs at 50.3 hr. It has been demonstrated (20) that the treatment of skin with organic solvents removes lipoidal substances but does not directly remove hydrophilic materials from skin. However, such treatment predisposes their loss from the skin by leaching when the skin is subsequently exposed to water or aqueous solutions. The loss of these hydrophilic materials is accompanied by a lowering in the water-sorption capacity of the skin. It has been shown that amino groups are predominantly responsible in affecting the water-binding capacity of skin (21). The water-soluble extractives from skin have been identified as nitrogenous and consisting of amino acids and polypeptides (20, 22). The pretreatment of the skin with 70% ethanol and soap may also be expected to have contributed to the elutriative loss of materials from the skin into the applied aqueous solutions. The untreated control skin, however, appears to have been left substantially unaffected with regard to changes in cationic fixed-charge density, as evidenced by the observation of the relatively constant values of positive fixed-charge density at pH 1.1 having a range of 350–380 meq./l. and an overall average of 361 meq./l. The higher values consistently correspond to later times.

In addition to this explication of the observed behavior of the control and benzene-displaced titration curves, the possibility of the changes resulting from the systemic absorption or lateral diffusion of 3-MC into the control areas also exists. To reduce the possibility of

systemic absorption in this study, the mice were isolated between measurements to prevent their licking one another. Iversen and Evensen (16) minimize the importance of systemic absorption of the hydrocarbons in affecting their results. Since each treatment area would be equally affected by systemically absorbed materials, the differences observed between the skin areas could still be attributed to the treatments, even if systemic absorption of the hydrocarbons occurred to an appreciable extent.

Reduction of Net Cationic Charge Density by 3-MC—The approximately constant vertical distance between the 3-MC and other curves in Figs. 2, 5, and 6 demonstrates that the 3-MC-induced diminution in net fixed-cationic charge density does not appreciably rely on pH in the range studied. Such pH independence may be expected to result only if the affected cationic groups are titratable in an alkaline range of pH above the limit of pH 7.4 adopted in the present study. Such basic groups could include the guanidyl group of arginine, the ϵ -amino group of lysine, α -amino groups (23), and some of the nitrogenous groups of purine and pyrimidine bases (24). It is, of course, not possible to discern the individual involvement of each of these groups in the presently observed phenomena. Provided the pK's of the different groups are sufficiently separated, further information might be gained in a future study by extending the alkaline limit of pH and noting the region of pH at which the anticipated coincidence of the 3-MC- and benzene-displaced titration curves is observed. Such observations might conceivably distinguish between the involvement of α -amino, ϵ -amino, and guanidyl groups.

It could be a temptation to conclude that the observed neutralization of charge on the involved base-binding groups, induced by the action of 3-MC, results from the acylation of these groups by carboxylated derivatives of the hydrocarbon. However, the observed up to nearly 50% involvement of the total fixed cationic groups on the colloids is quantitatively grossly inconsistent with the estimated 0.001% of amino acid residues which become conjugated with hydrocarbons (25). The discrepancy would not be appreciably mitigated even if the latter percentage is corrected on the basis of assuming that only strongly basic side-chain amino groups interact with the hydrocarbons. Assuming arginine and lysine to constitute 16.65% of the total amino acids in epidermis (26), a maximum of only 0.006% of their number would be directly bound to the hydrocarbons. Including the possibility of other binding sites as well, e.g., as might occur on nucleic acids, would again diminish this value and add further to the disagreement. A greatly potentiated elutriative loss of water-soluble cationic constituents from the skin, induced by the 3-MC, is not considered a likely mechanism for the unaccounted changes since the observed reduction in net cationic charge, relative to benzene, is maximal at 1.1 hr. As previously discussed, the extent of such losses by leaching increases with time.

Although the results of the present study do not justify the establishment of any firm conclusions regarding the mechanisms by which the 3-MC-induced reduction of fixed cationic charge density is manifested, it is certainly interesting to speculate the possibilities. The simplest possibility to consider is for the interaction of carboxylated derivatives of 3-MC with the tissue colloids to occur through the action of secondary valence forces in addition to the formation of covalent linkages. The severity of the extractive procedures used in direct studies of hydrocarbon-protein interaction only allows the detection of the latter type of combinations. The use of the electrometric method permits changes in cationic fixed-charge density resulting from either type of binding to become demonstrative. The reversible nature of electrostatic and Van der Waals' binding could conceivably allow the resolution of the contribution of each type of interaction to the reduction of net cationic charge density to be elucidated. The removal of the labile interacted hydrocarbon from the skin might be accomplished through extensive washing of the surface. The decline of the 3-MC effect, relative to the benzene control, could have arisen through such a loss of weakly bound anionic derivatives of 3-MC into the applied solutions.

However, if the oxidative carboxylation of the hydrocarbon only occurs concomitantly with its covalent binding to protein (10), it then follows that free anionic forms of the hydrocarbon would not be available for secondary valence force interactions with the proteins. If this is the case, an alternative explanation of the observed diminution in cationic charge density has to be sought.

Because of its very extensive implications, an exceptionally intriguing possibility is the reduction of cationic charge density result-

ing from the operation of an allosteric mechanism (27). By this means, a cooperative release of protons from the affected macromolecular structures could conceivably result from the interaction of the hydrocarbon at a paucity of cardinal sites; these sites would, however, control the acid-base properties of comparatively large numbers of proton-binding sites. Consideration of Mason's bioelectronic theory (28) of carcinogenesis and Ling's association-induction theory (29, 30) lends some degree of credence to this conjecture. In the framework of Mason's theory, the release of protons from the macromolecular structures could result from the formation of mobile positive holes in the protein molecules following the fusion of conduction bands between the macromolecules and the interacted hydrocarbons. Inductive and electrostatic field effects responsible for the release of protons could be conveyed to the basic side chains in a manner analogous to the mechanisms postulated by Ling (29). A net reduction of cationic charge on macromolecules may be expected to diminish their affinity for forming polysalt complexes with polyanions, such as polynucleotides, or cause the dissociation of such complexes already in existence (31). Such hydrocarbon-induced reductions of cationic charge density on nuclear proteins could conceivably accomplish the derepression of genes central to Pitot and Heidelberger's theory of carcinogenesis (32).

This last hypothesis, in addition to being able to explicate the results observed in the present study, appears to be capable of integrating the various prominent theories of carcinogenesis. Although direct experimental evidence for the hypothesis is at present obviously lacking, its verity could readily be tested on the basis of gaining predictive evidence from both *in vivo* and *in vitro* experimentation. This and the determination of whether the effects of hydrocarbon-tissue interactions involving K and L regions of the molecules can be distinguished by the bioelectrometric method could provide worthwhile objectives for future experimentation.

CONCLUSIONS

Despite the apparent need for conjecture in some instances to interpret the results, the utility of the bioelectrometric method as a tool complementary to more direct, although destructive, techniques by which tissue-carcinogen interactions can be studied has been demonstrated in the present investigation. It would be of interest in future studies to prolong the experiment to determine whether the method is capable of predicting imminent neoplasia prior to the appearance of morphologic evidence.

Table I—Histopathological Observations at Death from Oral Administration of Dimethoate to Albino Rats

Organ	Histopathology
Adrenal glands	Lipoid globules prominent, especially in zona fasciculata
Brain	Meninges and brain hyperemic and congested
Gastrointestinal tract:	
Cardiac stomach	Occasionally submucosa hyperemic
Pyloric stomach	Areas of ulceration of the inner half of the gastric glands
Small bowel	Mild capillary congestion of the lamina propria of the villi
Cecum	Occasionally small infiltrative ulcers of the mucosa and submucosa
Colon	Normal appearance
Heart	Occasionally mild capillary congestion of the myocardium
Kidneys	Congestion of the glomerulus and loop of Henle; venous stasis and thrombosis; occasionally debris beneath Bowman's capsule; cloudy swelling, fine fatty degeneration, and early necrosis of the convoluted tubules
Liver	Sinusoidal congestion and cloudy swelling; fatty degeneration in animals of Group I
Lungs	Usually capillary congestion and venous stasis and thrombosis
Muscle (ventral abdominal wall)	Normal appearance
Pancreas	Deficiency of zymogenic granules in the acinar glands
Salivary (submaxillary) glands	Mucous glands shrunken; serous glands shrunken, granulated, and sometimes vacuolated
Skin	Occasionally ischemic
Spleen	Red pulp contracted
Testes	Deficiency of normal sperm in delayed deaths; inhibition of spermatogenesis in animals of Group I
Thymus gland	Loss of thymocytes, particularly in animals of Group I

animal sources. After 2 weeks of feeding the animals weighed 171 ± 5 g.

At the end of the dieting period, each rat was placed singly in a metabolism cage with water. They received no food for 16 hr. (overnight) to empty the stomach prior to oral administration of dimethoate. Technical dimethoate⁴ was freshly dissolved in cottonseed oil USP and given intragastrically in a volume of 20 ml./kg. body weight. Following pilot dose studies in each dietary group, a series of definitive doses, estimated to yield mortality rates from just above 0% to just below 100%, were administered to 10 rats per dose with 15–20 controls given cottonseed oil.

The animal was then returned to its metabolism cage with an excess of diet and drinking water. Clinical signs were measured in units of 1+ to 4+ at hourly intervals during the balance of the 1st day and then at intervals of 24 hr. or as indicated. Body weight gain, food intake, water intake, colonic temperature, urinary volume, urinary blood, urinary glucose and protein output, and urinary pH were measured daily for 5 days.

An autopsy was performed upon all dead animals, the gross pathology was recorded, and a microscopic examination was made upon any organ that appeared abnormal to gross examination. Histopathology was recorded at death upon all organs listed in Table I in representative dead animals of each dietary group.

The wet weight of organs listed in Table II was measured upon animals which could be autopsied within 1 hr. of death to avoid postmortem shifts in organ weights and water levels described by Boyd and Knight (11). Water content was measured upon aliquots of the organs listed in Table III dried to constant weight in a Fisher forced draft isotherm oven at 95° and was calculated as grams water per 100 grams dry weight of tissue.

⁴ Cygon, 93.3% dimethoate, Agricultural Division, American Cyanamid Co., Princeton, N. J.

The results were analyzed statistically by the application of *t* tests to the significance of differences between means and by the regression of differences on dose or time. The $LD_{50} \pm SE$ was calculated by linear regression analysis of dose on response. Details of the method, including statistical analysis, have been reviewed by Boyd (12).

RESULTS

Data on calculated lethal doses of dimethoate are assembled in Table IV. The LD_{50} in Group I is identical to that in Group II, and both values are about half that in Group III. The interval to death varies inversely with the dose; *i.e.*, the higher the dose of dimethoate, the more rapid is the occurrence of death. The mean interval to death is identical in all three dietary groups. Pathological lesions seen on gross examination at autopsy are similar in all three dietary groups.

The clinicopathological syndrome of toxicity is essentially the same in animals of all three dietary groups. It will be exemplified by describing changes in animals previously fed laboratory chow (Group III) and by noting significant differences in animals of the other two dietary groups.

The dominant clinical signs of toxicity during the first few hours are tremors, prostration, dacryorrhea, and exophthalmos (Fig. 1). They reach a peak of intensity during the afternoon of the 1st day and begin to disappear at 24 hr. A delayed clinical syndrome, which reaches a peak at 24 hr. (Fig. 2), consists of piloerection, listlessness, sialorrhea, and soiling of the fur. These clinical signs are accompanied by a marked inhibition of food and water intake, hypothermia, and marked loss of body weight (Fig. 3). At 24 and 48 hr., all mean changes shown in Fig. 3 are significant at $p < 0.01$.

Figure 1—Mean clinical units of intensity of clinical signs which were dominant during the 1st day of the toxicity syndrome to oral administration of lethal doses of dimethoate in albino rats previously fed laboratory chow.

^a Water levels were measured as grams water per 100 g. dry weight of tissue. The results are expressed as mean percent change from controls fed the same diet and given cottonseed oil without dimethoate, specifically as $[(\bar{X}_d - \bar{X}_c)/\bar{X}_c] \times 100$, where \bar{X}_d is the mean in dimethoate-treated rats and \bar{X}_c in controls. ^b ** indicates that $\bar{X}_d - \bar{X}_c$ was significant at $p = 0.01$ or less. ^c * indicates that $\bar{X}_d - \bar{X}_c$ was significant at $p = 0.05$ to 0.02 .

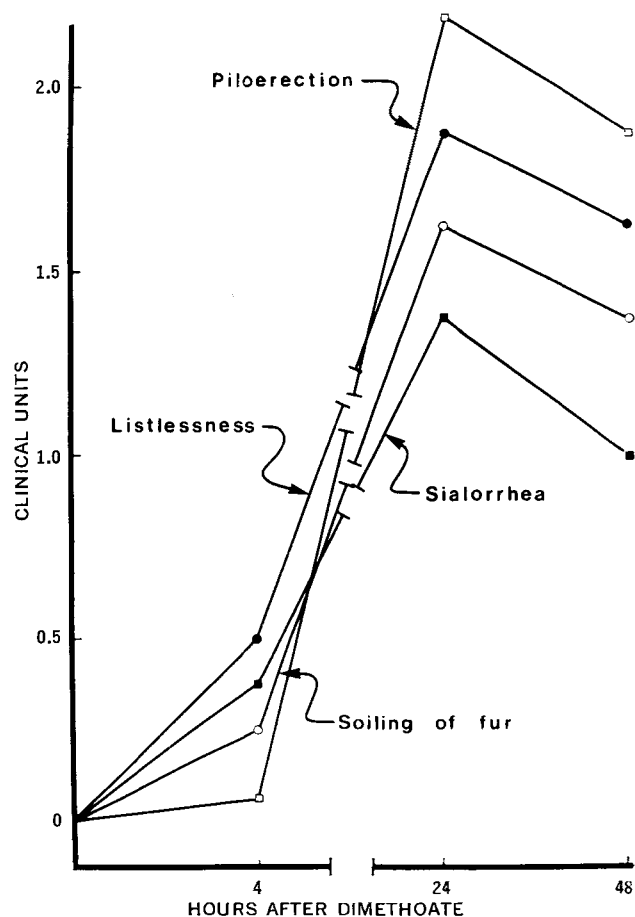

Figure 2—Mean clinical units of intensity of clinical signs which were dominant at 24–48 hr. after oral administration of lethal doses of dimethoate to albino rats previously fed laboratory chow.

and hematuria begin to appear during the first 24 hr. and are present in survivors at 48 and 72 hr.

The protein-deficient animals of Group I do not exhibit exophthalmos and have less hypothermia during the first few hours after receiving dimethoate, and piloerection is marked at this time. There is no delayed reaction at 24 hr., and recovery of survivors is rapid in Group I; growth rate, for example, returns to normal during the 2nd day.

In Group II, fed a diet of 26% casein, the initial reaction is similar to that of Group III except that listlessness, piloerection, and sialorrhea are present immediately after dimethoate. Soiling appears at 24 hr., but there is no glycosuria or hematuria. Recovery is delayed to the 3rd day as in Group III.

Microscopically (Table I), there is a moderate, local, irritant gastroenteritis with ulceration in the pyloric or glandular part of the stomach and in the cecum. Cecal ulcers are not particularly common in studies of this nature. After absorption, the most common lesion is vascular congestion. This is accompanied by degenerative changes in the kidneys, liver, pancreas, salivary glands, and testes. There is a stress reaction in the adrenal glands, spleen, and thymus gland and the skin is ischemic. There are signs of kwashiorkor due to protein deficiency in animals of Group I, as indicated by impaired development of several organs.

There is a marked loss of weight in most organs (Table II). Loss of weight is particularly marked in the tissues of the gastrointestinal tract, liver, lungs, muscle, spleen, and thymus gland. Loss of weight is due in part to dehydration as shown by data summarized in Table III. The changes are, in general, similar in animals of all three dietary groups, and the few differences which are found may be seen from values quoted in Tables II and III.

DISCUSSION

The results of this investigation indicated that dimethoate was no more toxic to rats fed a protein-deficient diet than to controls

Table IV—Lethal Doses, Interval to Death, and Gross Pathology following Oral Administration of Lethal Doses of Dimethoate

Figure 3—Significant mean differences in daily body weight gain ($Y \times 4$), colonic temperature ($Y \times 0.1$), food intake ($Y \times 1$), and water intake ($Y \times 1$) following oral administration of lethal doses of dimethoate to albino rats previously fed laboratory chow. Differences were calculated as mean percent change from controls given cottonseed oil, specifically as $[(\bar{X}_d - \bar{X}_c)/\bar{X}_c] \times 100$, where \bar{X}_d is the mean in dimethoate-treated animals and \bar{X}_c the corresponding mean in controls. Note that the ordinate units must be multiplied by the factors indicated in parenthesis to obtain the mean percentage change for daily gain in body weight and for colonic temperature.

Figure 4—Significant mean changes in the urine of albino rats previously fed laboratory chow following oral administration of lethal doses of dimethoate. The ordinate units for volume, protein output, and pH represent mean percent change from controls calculated as in Fig. 3. The ordinate units for glucose output indicate milligrams per kilogram body weight per day since there was no glucose in the urine of controls given cottonseed oil. The ordinate for urinary blood indicates units of blood. The ordinate units must be multiplied by the factors indicated in parenthesis to obtain the mean change in each parameter.

fed adequate amounts of protein as casein. Protein deficiency causes degenerative changes and inhibition of growth in the liver (10) and could be expected to limit production of hepatic detoxifying enzymes. This, in turn, could lessen production of the highly toxic oxygen analog of dimethoate. A decreased production of the oxygen analog could account for no increase in the toxicity of dimethoate in the protein-deficient rat, which is generally more susceptible to pesticide toxicity.

Available data on pesticide toxicity in protein-deficient rats have been summarized in Table V. Dimethoate is the only pesticide studied which is not more toxic to the protein-deficient rat. Five pesticides were twice as toxic to the protein-deficient rat; the five were diazinon and malathion, which are organic phosphorothioates like dimethoate, and chlordane, endrin, and lindane, which are chlorinated organic insecticides. Dicophane or DDT and monuron, an herbicidal chloro compound, were three times as toxic. Four compounds were four times as toxic: chlorpropham, which is an herbicide related to monuron, demeton (an organic phosphorothioate), and two chlorinated insecticides (endosulfan and toxaphene). Carbaryl is a physostigminelike cholinesterase inhibitor of the naphthyl carbamate series and was six times as toxic. Parathion is a *p*-nitrophenyl organic phosphorothioate and was eight times as toxic. Casterline and Williams (29) have reported parathion to be more toxic in young adult rats fed for 30 days on a diet containing no protein than in animals fed a diet containing 15% of protein as casein. Captan is a mercapto-phthalidimide related structurally to thalidomide and was 26 times as toxic.

Table V—Acute Oral LD₅₀ of Pesticides in Male Albino Rats Fed for 28 Days from Weaning on a Protein-Deficient Diet Containing 3.5% Casein Compared with Values in Controls Fed a Normal Protein Diet Containing 26% Casein^a

Pesticide	Protein-Deficient Diet, Group I	Normal Protein Diet, Group II	Quotient: II/I	Reference
Dimethoate	147 ± 29	152 ± 22	1	This paper
Chlordane	137 ± 30	267 ± 44	2	13
Diazinon	215 ± 26	415 ± 39	2	14
Endrin	6.69 ± 0.80	16.6 ± 3.0	2	15

^a The LD₅₀ is expressed as mg./kg. ± SE.

The results of these investigations indicate that further studies, including clinical toxicology trials, should be done upon pesticides listed toward the bottom of Table V to determine if they present a particular hazard when used in countries where the diet is low in protein. No evidence is present in these investigations to indicate that such a hazard exists for pesticides listed toward the top of Table V.

The type of dietary protein does not appear to be as important a factor contributing to augmented susceptibility to pesticides as is deficiency of protein. Of the pesticides listed in Table V, chlorpropham and monuron were twice as toxic in rats fed laboratory chow as in rats fed normal amounts of protein as casein, while dimethoate was half as toxic. Dietary soy protein in normal amounts has been found, in current studies, to augment the susceptibility of rats to certain drugs such as phenacetin. There may be significant differences depending upon the type of protein in a protein-deficient diet, a problem which has not been studied in this laboratory.

Variation in the concentration of dietary protein involves alteration in the concentration of other dietary ingredients and is usually accomplished by changes in the amount of carbohydrate. The type of carbohydrate selected is of considerable importance. Soluble sugars such as glucose and sucrose should not be used in large amounts, because they can produce dehydration and death (30), and, in sublethal doses, they can add to the toxicity of drugs (31). Starch, on the other hand, produces death only by bowel obstruction from huge doses (32) and is nontoxic in large amounts in the diet. In the present study, therefore, cornstarch was used, rather than a sugar, to replace a lowered concentration of dietary protein.

Effect of Solvent Composition on Association between Small Organic Species

HARALD KRISTIENSEN, MASAHIRO NAKANO*, NAOMI I. NAKANO, and TAKERU HIGUCHI†

Abstract □ Effects of different organic solvents on the extent of complex formation in binary aqueous organic solvent mixtures were studied by means of spectrophotometry, spectropolarimetry, and solubility technique. In every instance, the stability constants of the complexes decreased as the ratio of organic solvent to water increased. The complexes were much less stable in aqueous dioxane mixtures than in similar mixtures of water and polyhydroxy compounds such as glycerin and sucrose. These studies strongly indicate the significant contribution made by hydrophobic bonding to these interactions and the major role of the water structure.

Keyphrases □ Organic species, small—interaction □ Complex formation—solvent composition effect □ Stability constants, complexes—solvent composition effect □ Solvent effect—small organic species interaction

The uniqueness of water as an environment for biological interactions has been realized in recent years (1). To account for the fact that many solute molecules, notably polymers, associate more strongly in water than in organic solvents, the concept of hydrophobic bonding has been developed (2). The exact role played by water, however, is not yet fully understood. Recent studies of the effect of various solvents on the stability constants of the tetramethylpyrimidopteridinetetrone-*N,N*-dimethylcinnamide complex indicated that the complex was less than one-tenth as stable in organic solvents as in water (3). Weber has reported the effect of solvents on quenching of the fluorescence of flavins in the presence of complexing agents (4). The quenching was observed only in water and not in organic solvents, including formamide which is more polar than water.

Sinanoglu and Abdunur have undertaken theoretical studies on the effect of solvents on the denaturation of deoxyribonucleic acid (5, 6). They indicated that the main source of stability of the helical structure of the

nucleic acid in water over organic solvents comes from the large surface enthalpy of water, *i.e.*, large surface tension of water. Subsequently, Moser and Cassidy have examined the extent of quinuhydrone formation in various mixtures of water and organic solvents and found a reasonable correlation between surface tension and the extent of complex formation (7).

As a part of the present investigation into the nature of molecular association of small organic species in aqueous solution (3, 8–11), the authors have undertaken a quantitative study of the influence of various organic solvents in mixed solvent systems on the extent of complexation. The main purpose of the present study was to obtain additional information about the factors determining the stability of these complexes in aqueous solution.

EXPERIMENTAL

Materials—*trans*-Cinnamic acid, 3,4-dimethoxycinnamic acid, and 1,3,7,9-tetramethylpyrimido(5,4,g)pteridine-2,4,6,8(1H,3H,7H,9H)-tetrone (abbreviated as TMPPT) were from the same commercial source¹ and were purified and used as previously described (12). Riboflavin, menadione, sodium salicylate, caffeine, sucrose, and glycerin were USP grade chemicals. Caffeine was dried at 105° overnight to obtain an anhydrous compound. Tryptophan² was recrystallized from ethanol-water. *N,N*-Dimethylcinnamide was synthesized in this laboratory (10). Methanol,³ acetonitrile,⁴ acetone,³ and dioxane⁵ were reagent grade solvents. Water was purified by distillation in an all glass still.

Determination of Stability Constants—The stability constants of 1:1 and 1:2 complexes were defined in the following way:

$$A + B = AB \quad K_{1:1} = \frac{[AB]}{[A][B]} \quad (\text{Eq. 1})$$

$$AB + B = AB_2 \quad K_{1:2} = \frac{[AB_2]}{[AB][B]} \quad (\text{Eq. 2})$$

where brackets refer to equilibrium concentrations. Experimental procedures and calculations of stability constants employed in this study are reported elsewhere; the procedures include spectrophotometric (13), spectropolarimetric (11), and solubility (12, 14) techniques.

RESULTS

Effect of Solvent Composition on Stability Constants of Complexes—Riboflavin-Salicylate Ion—Apparent 1:1 stability constants of the riboflavin-salicylate-ion complex in water-methanol mixtures were determined spectrophotometrically; the results are shown in Fig. 1. Displacement of a fraction of water with methanol resulted in a steady decrease in the stability constant of the complex.

Menadione-Caffeine—Effect of solvent composition on the stability constant of the menadione-caffeine complex was also

Figure 1—Stability constant of riboflavin-salicylate-ion complex plotted against solvent composition as measured spectrophotometrically at 25°.

investigated spectrophotometrically; the results are shown in Fig. 2. A drastic decrease in stability constants with increasing methanol fraction is also apparent with this complex.

Tryptophan-Caffeine—Effects of environment on the stability constant of this amino acid-alkylxanthine complex were examined spectropolarimetrically. The results presented in Fig. 3 for this complex exhibit the same trend as observed in other systems investigated here.

TMPPT-3,4-Dimethoxycinnamate Ion—The stability constants of 1:1 and 1:2 complexes ($K_{1:1}$ and $K_{1:2}$) formed by the interaction of TMPPT with 3,4-dimethoxycinnamate ion in various compositions of methanol-water mixtures were computed from the phase-solubility diagrams. The stability constants are presented in Fig. 4 as a function of the solvent composition. It is apparent from the figure that both constants decrease with increasing fraction of methanol and the equilibria are highly dependent upon the solvent composition.

Figure 3—Stability constant of tryptophan-caffeine complex plotted against solvent composition as measured spectropolarimetrically at 25°.

Figure 4—Stability constant of 1:1 complex (○) and 1:2 complex (□) of TMPPT with 3,4-dimethoxycinnamate ion plotted against solvent composition as measured by solubility technique at 25°.

TMPPT-Cinnamate Ion—Figure 5 presents the stability constants of the TMPPT-cinnamate-ion complex ($K_{1:1}$) in both water-methanol mixtures and water-dioxane mixtures. These stability constants were determined by the solubility technique and are shown in Fig. 5 as a function of solvent composition. These results again indicate that environment plays a major role in the stability of the complex. Dioxane was more effective in dissociating a complex than methanol. This point was further examined as presented in the next section.

Comparison of Effects of Various Solvents at 10% Level on Stability Constants—Since the stability constants of the complexes tend to be quite low in most organic solvents, the effects of such solvents on stability constants can be more easily evaluated at lower solvent concentrations in water. For this reason, the effects of various organic solvents on the stability constants of complexes were investigated in 10% v/v organic solvent in water. The TMPPT-*N,N*-dimethylcinnamide and menadione-caffeine complexes were chosen as model complexes for this purpose and studied by the solubility method and spectrophotometry, respectively.

The results are shown in Table I together with the values of surface tension of the media. Compounds such as sucrose and glycerin exhibited a much less destabilizing effect on the complexes than the other solvents investigated. Acetonitrile, acetone, and dioxane displayed a larger dissociating effect than the hydroxy compounds, dioxane exhibiting the greatest effect among the solvents investigated.

DISCUSSION

As amply demonstrated in this study, organic solvents have an unfavorable effect on the stacking interactions of organic planar molecules in water. Thus, irrespective of the solutes investigated here and of the methods employed to study these interactions, a steady decrease in the stability of a complex was observed with increasing fractions of organic solvent in aqueous media. Further, the comparison of various organic solvents at the 10% organic solvent-water mixture level indicates that the destabilizing effect of these organic solvents depends upon the nature of solvents and also upon the nature of interacting molecules.

Although interactions in pure organic solvents are greatly reduced in comparison with those in water, there nevertheless exists some associative tendency in pure organic solvents. For instance, the TMPPT-*N,N*-dimethylcinnamide complex has a stability constant of 60.0 M^{-1} at 25° in water, whereas in pure organic solvents such as methanol, acetone, and dioxane, the values range between 2.5 and 4.6 M^{-1} at 25° (3). Yet it is evident that an aqueous environment is necessary for significant interaction to take place between these species. The considerable stability of these complexes

Figure 5—One-to-one stability constant of TMPPT-cinnamate-ion complex plotted against solvent composition as measured by solubility technique at 25°. Key: O, methanol-water mixture; and Δ , dioxane-water mixture.

in water may then be regarded as medium-facilitated interactions. Although the exact mechanism by which water uniquely facilitates this type of association is not known, it may be speculated that the structural feature of water plays a major role.

With the exception of the existence of a hydrogen-bonded network, the structure of water still remains controversial. A popular view in recent years is to consider water as a mixture of bulky four-coordinated cluster and dense monomeric water (15, 16). Regarding the influence of solutes upon water structure, Frank outlined the most widely held view (15, 16). Hydrogen-bonding molecules are, in general, expected to alter water structure comparatively little. Those that cannot participate in the four-coordinated clusters, however, tend to break water structure. Sucrose and glycerin are considered to be capable of hydrogen bonding with water because of their polyhydroxyl groups, whereas others such as acetonitrile, acetone, and dioxane can be looked upon as the breakers of the regular structure of water. This may explain the reason why sucrose and glycerin are less effective in dissociating complexes than the nonhydroxyl solvents.

It is interesting to compare the effect of organic solvents on the extent of complexation with that on the micellar properties of surfactants in aqueous solution. It has been observed that critical micelle concentration increases in a monotonic manner with increasing fraction of organic solvent in aqueous media (17, 18). The effect was found to be more pronounced in dioxane-water mixtures than in ethanol-water mixtures. Thus, the relative effects of dioxane and the alcohol on the micellar properties of surfactants are similar to those observed in the present study of complex formation. Since hydrophobic interaction is supposed to be responsible for micelle formation, a similar effect of organic solvents on both micelle and complex formations may be reasonable, and hydrophobic interactions may be considered to be of importance for the association of solute molecules in water.

There are two theories as to the cause of hydrophobic interaction. Hydrophobic bonding is attributed by some workers to the structural restriction of water around nonpolar groups of a solute molecule; i.e., nonpolar groups are surrounded by an "iceberg" zone of water in which the orientation disorder is smaller than bulk water (19, 20). According to this theory, the total number of structurally restricted water molecules will be smaller when two molecules are brought together than when they are separated. This leads to an increase in entropy upon complexation. This positive entropy term

Table I—Stability Constants of Complexes in 10% v/v Organic Solvent in Water at 25°

is considered to be the major contribution to the free energy of hydrophobic interaction.

The second school of thought ascribes hydrophobic interaction to the energy gained when two cavities accommodating two single molecules coalesce to one when a complex is formed (5, 6). In this theory the enthalpy term (i.e., negative ΔH) is largely responsible for the favorable interaction in water. This theory thus places a particular emphasis upon the large surface tension of water as being responsible for the unique behavior of water in stabilizing complexes of this nature.

Experimentally, however, negative ΔS for the interactions of simple organic species are more common than positive ΔS as the first theory suggests (11). Fitness of the second theory (enthalpy contribution), on the other hand, gave some suggestive trend. Although the extent of interaction cannot be quantitatively correlated with the surface tension of the media (Table I), surface tension probably is nevertheless related to a common physical property which also influences the intensity of hydrophobic bonding.

Hydrophobic bonding is generally recognized as important for the stability of protein conformations in aqueous solution (2, 20) and is referred to as the intramolecular force operating between the nonpolar side chains of these macromolecules. It is important to emphasize that the systems studied in the present work are interactions between small organic species, and it may be far from secure at this stage to correlate the observed binding in this case with the behavior of large molecules in solution. While the proteins are denatured to varying extent in aqueous organic solvents and in pure organic solvents, the same cannot, of course, take place for the aromatic and heterocyclic species studied here.

As was pointed out in the studies of complex formation between small organic molecules in aqueous solution (8, 9, 12), variation in the ability to bind cannot be certainly explained by hydrophobic forces alone. For example, it has been shown that hydroxy groups on benzoates and cinnamates had a strong enhancing effect on the observed binding in water (8, 9, 12). It is difficult to attribute this effect to a higher hydrophobic character of the interacting species. It has also been demonstrated that the contribution from flexible alkyl side chains was very small (12).

The observation that the binding between organic species dissolved in water apparently takes place most effectively between members of two large, distinct classes of structures (12) has strongly suggested that some selectivity must be operating among the interactants. This again tends to indicate that hydrophobic forces alone cannot be largely responsible, in most instances, for the observed binding, but rather a mechanism of some nonclassical "donor-acceptor" type may be operating. Also the fact that a slight change in molecular structure, notably by introducing substituents having mesomeric effects, results in substantial changes in the observed stability constants (8, 9, 12) appears to support this hypothesis.

Since water may be considered to participate in these interactions, a possible mechanism of the donor-acceptor type apparently should be classified as being not of the classical type but peculiar to water. The authors would expect that the effect of different solvents on the overall stability of a classical charge-transfer complex should reflect competitive solvation effects. Thus, in polar solvents that can act as both donor and acceptor, the medium would be expected to solvate both free solute species and the com-

plex itself. The overall net effect would probably render complex formation less favorable in the presence of such solvents than in an inert solvent.

Such available data concerning the influence of solvents on the stability of charge-transfer complexes suggest that these classical complexes in general are formed in appreciable amount only in nonpolar solvents. For example, the stability constants for the trinitrobenzene-*N,N*-dimethylaniline complex decrease with the solvents in the following order (21): cyclohexane > *n*-hexane, *n*-heptane > carbon tetrachloride > chloroform > *s*-tetrachloroethane > 1,4-dioxane. The stability constants in cyclohexane and *n*-hexane were 9.5 and 8.2 M^{-1} , respectively. In chloroform, *s*-tetrachloroethane, and dioxane, they were of much less magnitude, being 1.3, 0.2, and 0.15 M^{-1} , respectively.

The iodine-naphthalene complex decreases in stability with the solvents in the following order (22): *n*-heptane > cyclohexane > carbon tetrachloride > *n*-hexane > chloroform. Similarly, it has been shown that the stability constants for the complex between tetrachlorophthalic anhydride and hexamethylbenzene decrease when the solvents are varied in the following order (23): *n*-hexane > carbon tetrachloride > dibutyl ether > benzotrifluoride > fluorobenzene \approx benzene \approx cyclohexanone. The magnitude of the stability constants were reported to be 260 M^{-1} in *n*-hexane and 145 M^{-1} in carbon tetrachloride. For comparison, the constants in dibutyl ether, benzotrifluoride, fluorobenzene, and cyclohexanone were 77, 52, 29, and 23 M^{-1} , respectively.

In all the cited examples it is seen that in going from nonpolar solvents to typical polar solvents such as chloroform, *s*-tetrachloroethane, dibutyl ether, fluorobenzene, benzotrifluoride, cyclohexanone, and dioxane, there is a substantial decrease in the stability of the charge-transfer complexes. If donors and acceptors interact to form complexes that are appreciably ionic in character, these generalizations may no longer apply; in such cases, complex formation may be facilitated in media that promote ionization (24, 25). However, this has by no means been found to be a general rule (25), and the type of complexes which are more stable in polar solvents presumably involve ion radicals and are not simple donor-acceptor complexes. With the exception of some complexes of tetramethylphenylenediamine with various tetrahaloquinones, tetracyanoethylene, and related acceptors, it appears that the known classical charge-transfer complexes are in general formed in appreciable amounts only in nonpolar solvents (25).

Although this discussion suggests that contribution from classical charge-transfer complexes may not be a major factor in aqueous solution because of the competitive participation of water, the authors cannot exclude the possibility that a donor-acceptor mechanism, peculiar to water, may contribute to the stability of the complexes studied. Such a speculation may be justified, since hydrophobic forces alone appear to fail to account for all the observed effects.

CONCLUSIONS

From the preceding discussion, it is apparent that the favorable interaction between small organic species in water may be due to a summation of several factors. The net enhancement in binding by increasing the content of water in the environmental solvent cannot be rationalized on the basis of any single binding mechanism alone. Although hydrophobic bonding and a nonclassical donor-acceptor mechanism may have been the major forces involved, with the contributions from the former possibly of lesser magnitude, further investigations along these lines may shed light on additional factors which have not been evident in this limited study. Since

the balance of forces operating between the complex components in pure aqueous solution is not known, it is difficult to separate and interpret the gross effect seen in mixtures of organic solvents with water.

Acetylcholinesterase Substrates: β -Methylcholine Esters

G. M. STEINBERG, M. L. MEDNICK, R. E. RICE, and J. P. MADDOX

Abstract β -Methylcholine propionate (Compound II) and isobutyrate (Compound III) are "good" substrates for eel acetylcholinesterase. Enzymatic hydrolysis of the corresponding pivalyl ester is barely detectable. For study of acetylcholinesterase under conditions where the "blank" hydrolysis rate of substrate must be reduced to a minimum, Compounds II and III can be used advantageously. Like acetylcholine and β -methylcholine acetate, Compound II shows substrate inhibition. The isobutyryl ester (Compound III) gives no significant substrate inhibition. Kinetic constants for both enzymatic and nonenzymatic hydrolysis are reported for the group of esters. Evidence is presented which suggests that the rate of acylation of the enzyme parallels reactivity with hydroxide ion for acetylcholine and the acetyl and propionyl esters of β -methylcholine. With the isobutyryl ester of β -methylcholine, there is a relative decrease in enzymatic acylation rate.

Keyphrases \square Acetylcholinesterase substrates— β -methylcholine esters \square β -Methylcholine esters—synthesis \square Hydrolysis rates, enzymatic, nonenzymatic— β -methylcholine esters \square Michaelis constants— β -methylcholine esters

For studies (to be published) on oxime reactivation of phosphorylated acetylcholinesterase (AChE) (acetylcholine acetylhydrolase, EC 3.1.1.7), which the authors wished to perform by the continuous monitoring procedure of Kitz *et al.* (1) using an autotitrator, it was important to reduce the "blank" hydrolysis rate of the substrate to a minimum. In the region of pH 9, acetylcholine (ACh), its normal substrate, gives undesirably high "blank" values.

Like most enzymes, AChE has a moderately wide range in its specificity and is capable of hydrolyzing a considerable variety of esters other than ACh (2). It is well known that the rates of aqueous (alkaline) hydrolysis within a family of esters can be decreased by insertion of bulking groups near the ester linkage (3). Recently, Gunter (4) observed that *ortho*-substitution in phenyl acetate, which decreases the alkaline hydrolysis rate, does not interfere with enzymatic hydrolysis by AChE. Hence, it seemed appropriate to examine several homologs of acetyl β -methylcholine with increasing bulk on the acetyl methyl group. The compounds are listed in general structure I. Two of the compounds, Compounds II and III, satisfied the requirements.

Since these compounds may have general utility for studies with AChE, particularly where the "blank" hydrolysis of substrate becomes a problem, the authors

explored their properties. In this paper, they report the nonenzymatic and enzymatic hydrolysis rates and Michaelis constants (at pH 7.4).

EXPERIMENTAL

Acetylcholine bromide (ACh) and acetyl β -methylcholine bromide (Compound I) were obtained commercially. The AChE (Worthington Biochemicals) was purified, stable, dry powder from electric eel, Code ECHP, 1000 units/mg. Twenty milligrams of enzyme was dissolved in 1.6 ml. of a previously boiled aqueous solution, pH approximately 7.4, containing KCl (0.225 M) and 0.25% gelatin (KCl/gel) to give enzyme concentrate E_w . The concentration of active sites in E_w is estimated to be $2.5 \times 10^{-5} M$.¹

Both enzymatic and solvolytic rates were determined from the rate of addition of standard alkali needed to maintain constant pH using a Radiometer TTTI autotitrator, fitted with an ABUI buret, a SBR2 recorder, and a PHA 630 scale expander. The titrator was fitted with the 0.25-ml. buret (0.25 ml. = 100 scale divisions of chart displacement), and the 6-ml. jacketed titration vessel was covered and maintained at 25°. Nitrogen was slowly passed over the reaction solution to minimize CO₂ absorption. The titrant was 0.00353 M carbonate-free sodium hydroxide.

Enzymatic Hydrolysis—All measurements were made at pH 7.4, 25°. To 3.0 ml. of 0.225 M KCl, there were added 2.0 ml. of aqueous substrate and 15–500 μ l. of appropriately diluted (in KCl/gel) enzyme concentrate, E_w . Dilutions ranged from 1/1000 to 1/10,000 (except for Compound IV, in which case undiluted E_w was used). Records were made of initial hydrolysis rates. The enzymatic hydrolysis data are presented in Lineweaver-Burk reciprocal plots (Figs. 1 and 2). For convenience of comparison, the results have been normalized by conversion of the observed rates to those calculated for concentrated enzyme solution, E_w , assuming a direct linear relationship between enzyme concentration and v , the velocity in moles per liter of ester hydrolyzed per minute. The values of k_{cat} and $K_m(\text{app.})$ were computed from the slope and y-intercept using Eqs. 2 and 2a.

Nonenzymatic Hydrolysis—Reactions were run at 25° at the appropriate pH values, which were maintained constant during each run. The 5.0 ml. reaction mixture contained 0.135 M KCl and 0.1 M ester. Measurements were made of initial hydrolysis rates under conditions where less than 0.1% of the ester was hydrolyzed. The continuous records of alkali delivered (to maintain constant pH) as a function of time were linear over the period of measurement. The values reported have been corrected for the CO₂ blank. At the pH values employed the water component of the observed hydrolytic reaction rate constant, k_{obs} , is negligible (5). Hence the reaction, $\text{RCO}_2\text{R}' + \text{OH}^- \rightarrow \text{RCO}_2^- + \text{R}'\text{OH}$, is first order in ester and in hydroxide ion. Because the autotitrator adds alkali automatically to maintain a constant pH, the rate of addition of alkali is equivalent to the rate of formation of acid.

Synthesis—Compounds II, III, and IV were prepared as follows.

2-Hydroxypropyldimethylamine—To a cooled (8°) stirred solution of dimethylamine (54 g., 1.2 moles) in absolute methanol (300 ml.), 1,2-propylene oxide (58 g., 1.0 mole) was added in small portions over 25 min. while maintaining the temperature below 8°. After this addition, the temperature was permitted to rise to 30° and was held there for 20 min. After removal of the cooling bath, the solution was left to stand 1.5 hr. (maximum temperature 40°). Distillation through a simple head followed by redistillation through a 15 \times 1-cm. vacuum-jacketed Vigreux column gave 46 g. (45%) of 2-hydroxypropyldimethylamine, b.p. 126° (uncorrected).

Compounds II, III, and IV—The propionyl and isobutyryl esters were prepared by treating 2-hydroxypropyldimethylamine with a

¹ Calculated from turnover number = $6.7 \times 10^5 \text{ min.}^{-1}$, pH 7.4, 0.33 M KCl, 0.0073 M AChE, 0.25% gelatin, 25°, $K_m(\text{app.}) = 2.8 \times 10^{-4} M$ (H. Michel, private communication).

small excess of the corresponding acyl anhydride. For the pivalate, the reaction was run in benzene using equivalent quantities of aminoalcohol, pivalyl chloride, and pyridine. The tertiary aminoesters were quaternized by treatment with a small excess of methyl iodide in acetone and recrystallized from acetone or acetone-methanol. The physical properties of the tertiary aminoesters and the quaternary products, together with elemental analyses of the latter, are given in Table I.

RESULTS AND DISCUSSION

Nonenzymatic Hydrolysis—Table II contains the observed rates of reaction with the aqueous solvent. Measurements on each compound were made at two pH values. The essential identity in the pairs of computed k_{OH} values (within the range of experimental error) indicates that for each ester the “water” reaction is negligible. Thus, one can compute the rate of the “blank” hydrolysis reaction, $k_{obs.}$, at any pH above those reported² from the relationship $k_{obs.} = k_{OH} [OH^-]$. For convenience in comparison, the actual observed “blank” hydrolysis rates are also given for each of the esters (Table II). It is noteworthy that the effect of increased bulking on going from ACh to Compound III reduces the hydrolysis rate approximately 20×, so that the “blank” for Compound III at pH 9.5 is hardly greater than that of ACh at pH 8.0.

Enzymatic Hydrolysis—In Fig. 1, Lineweaver-Burk reciprocal plots are given for ACh and Compounds I and II. Like ACh, Compounds I and II are good substrates for AChE and each shows marked substrate inhibition at high concentration.³ Compound III (Fig. 2) does not show substrate inhibition even at the highest concentration of substrate that was used, 0.1 M.

Table III contains data on enzymatic hydrolysis at pH 7.4 and substrate concentrations of 5×10^{-3} and 5×10^{-2} M, together with the computed ratios of the rates of the enzymatic to nonenzymatic hydrolyses. It also lists the values of $K_m(app.)$, computed from the Lineweaver-Burk plots in Figs. 1 and 2. Enzymatic studies were performed at pH 7.4 rather than at another higher pH because it provides data which can be more readily collated with those of other AChE substrate studies, the bulk of which have been performed in the pH 7–7.5 range. It may be assumed that changes in the Michaelis constants due to variation in pH will be substantially the same for the entire group of compounds, so the relative value of v/k_{OH} for the group can be applied at higher pH values.

For the selection of the best substrate for a particular study using an automatic titrating device such as the Radiometer TT1, one must bear in mind that the conveniently useful range in delivery rate of the buret is perhaps only 20×, i.e., from approximately 1–2 div./min. of chart paper to 20–30 div./min. At pH values above 9, where the “CO₂” blank becomes significant, the range becomes even

Table II—Nonenzymatic Hydrolysis of Substrates

	10.5	7.7	0.43

^a Div. (on radiometer) = 2.5×10^{-3} ml.; 5.0 ml. of 0.1 M ester was present in titration vessel. Titrant, 0.00353 M NaOH. ^b $k_{obs.} = k_{OH} [OH^-]$. ^c Reported: 72 and 80.4 (Reference 5).

smaller. By increasing the concentration of titrant, the “blank” delivery rate for a given substrate concentration can be reduced. However, by doing so, sensitivity is reduced and, therefore, more of the substrate must be hydrolyzed to obtain measurable hydrolysis records.

Under conditions where the enzyme concentration is the limiting factor, Compound II is best. Its values of v/k_{OH} , the ratio of the enzymatic to the “blank” hydrolysis rates, are equal to or greater than the others. Its lower “blank” value makes it more useful than Compound I. Where the enzyme is nonlimiting, i.e., its concentration can be made high enough to give maximum delivery of titrant, Compound III is preferred because of its lower “blank.” The enzymatic hydrolysis of Compound IV is so slow that one may question whether it is hydrolyzed by AChE at all. It is certainly possible that the slight activity is produced by some impurity in the enzyme preparation. However, if it is truly a substrate for AChE, it might be used for monitoring the concentrated enzyme, if and when it becomes available in reasonably large quantities.

β-Methylcholine exists as a DL-pair. It is known that with the acetate ester, only the L(+) isomer acts as an AChE substrate, while the D(–) isomer is an inhibitor⁴ (10, 11). In these studies, the authors have observed that enzymatic hydrolysis of Compounds II and III give only approximately one-half of the theoretical

Figure 1—Lineweaver-Burk reciprocal plots of velocity of substrate hydrolysis as a function of substrate concentration, pH 7.4, 25°. Substrates: ACh and Compounds I and II. S represents concentration of racemic mixture.

² Extrapolation probably can be carried to lower pH also. An estimated lower limit for extrapolation is approximately pH 5 (6).

³ Mounter and Ellin (7) report no substrate inhibition by Compound I. Their studies appear to have been made without addition of supporting electrolyte. If this is so, the ionic strength of the medium changed with each change in concentration of substrate. Since the properties of eel AChE vary significantly with changes in ionic strength (see, for example, References 8 and 9), this may be the cause of the difference.

⁴ A very rough estimate of the value of K_I for the D(–) isomer is 10^{-3} M, calculated from data in Reference 11.

Figure 2—Lineweaver-Burk plot for Compound III. *S* represents concentration of racemic mixture.

quantity of acid. Here, too, only one member of each DL-pair acts as substrate. Hence, by using the pure enzymatically active isomers, one should be able to increase the *v*/OH ratios by at least two times and probably even more, since the inactive isomers may inhibit the enzymatic reaction.

For both the Lineweaver-Burk plots (Figs. 1 and 2) and the computation of $K_{m(\text{app.})}$ (Table III), use was made of total ester concentration and not actual concentration of active isomer.

Observations on Enzyme Kinetics—Since the purposes of this study were pragmatic, the choice of substrates was made entirely on that basis and without regard to theoretical implications of the kinetic results. However, analysis of the data that were obtained points to probable relationships between substrate structure and enzyme kinetic constants which may warrant further investigation.

AChE functions kinetically in a three-step reaction (Eq. 1) (12). Enzymatic hydrolysis follows Michaelis-Menten kinetics (at concentrations below those which cause substrate inhibition) (Eq. 2); however, the kinetic constants are complex functions (Eqs. 3–5) (13).

$$v = \frac{V_{\text{max.}} S}{S + K_{m(\text{app.})}}; \quad \text{where } V_{\text{max.}} = k_{\text{cat.}} E_0 \quad (\text{Eq. 2})$$

$$\frac{1}{v} = \frac{1}{V_{\text{max.}}} + \left(\frac{K_{m(\text{app.})}}{V_{\text{max.}}} \right) \frac{1}{S} \quad (\text{Eq. 2a})$$

$$k_{\text{cat.}} = \frac{k_2 k_3}{k_2 + k_3} \quad (\text{Eq. 3})$$

$$K_{m(\text{app.})} = \frac{K_s k_2}{k_2 + k_3}; \quad K_s = \frac{k_2 + k_{-1}}{k_1} \quad (\text{Eq. 4})$$

$$\frac{k_{\text{cat.}}}{K_{m(\text{app.})}} = \frac{k_2}{K_s} \quad (\text{Eq. 5})$$

where k_1 , k_{-1} , k_2 , and k_3 are rate constants; *v* is the observed rate of product formation; and E_0 and *S* are, respectively, the concentrations of enzyme and substrate.

Inhibitors can bind to *E* or *E*-acyl or to both (Eq. 6).

Binding to *E* results in competitive inhibition while binding to *E*-acyl results in noncompetitive inhibition. Inhibition by excess substrate is believed to result from its binding to *E*-acyl and consequent interference with the deacylation step (14). Binding and interference in this fashion will be observed kinetically only if the relevant kinetic step is rate limiting [with ACh, deacylation is rate

limiting; $k_2 = 6-10 \times k_3$ (15)]. Thus, the failure of Compound III to give substrate inhibition may be due to its failure to bind to the acyl enzyme, i.e., a marked increase in K_a , or alternatively may be the result of a change in the rate-limiting step, i.e., $k_3 > k_2$.

Table IV contains the values of $k_{\text{cat.}}$ computed (Eq. 2a) from the linear portions of the Lineweaver-Burk plots in Figs. 1 and 2 together with the computed values of k_2/K_s (Eq. 5)^b for each substrate. For the latter calculation, the actual concentration of active isomer was used in computing $K_{m(\text{app.})}$.

It can be seen that for ACh and Compounds I and II, the values of k_2/K_s , the rate constant for acylation of the enzyme divided by the dissociation constant of the enzyme substrate complex, closely parallel the corresponding values of k_{OH} , the rate constant for acylation of the hydroxide ion; i.e., the value of $k_2/K_s k_{\text{OH}}$ (Table IV) is constant. If one makes the not unreasonable assumption that the value of K_s does not vary greatly among this group of substrates,⁶ then the results suggest that over the range in structural variation represented by ACh and Compounds I and II, the enzyme displays little kinetic selectivity, the differences in reaction rate paralleling the reactivity of the ester toward hydroxide ion.

In the case of Compound III, there is a marked fall in $k_{\text{cat.}}$ and in the value of k_2/K_s . Also, as noted earlier, Compound III does not show substrate inhibition. These results suggest that the principal cause of the reduction in the rate of hydrolysis of Compound III by AChE is due to reduction in the rate constant of the acylation step, k_2 . Further, the $k_{\text{cat.}}$ values for the hydrolysis by eel AChE of the acetyl and isobutyryl esters of phenol are substantially the same.⁷ For phenyl acetate, $k_2 \gg k_3$ (17). Therefore, the values of k_3 for the acetate and isobutyrate (and probably the propionate) are closely similar.⁸ Hence, the fall in $k_{\text{cat.}}$ for Compound III represents a fall in the value of k_2 .

The rate of reaction of Compound III with hydroxide is less than that of the esters I and II (Table II). The reduction in its "normalized" reaction rate with enzyme, $k_2/K_s k_{\text{OH}}$ (Table IV), is appreciably greater. Thus, with the increase in molecular size or com-

⁵ The values of both $k_{\text{cat.}}$ and $K_{m(\text{app.})}$ are reduced by the presence of the inhibitory nonsubstrate isomer. However, it can be shown that both are affected to approximately an equal extent, so that the value of k_2/K_s is not appreciably affected.

⁶ With alkyl trimethylammonium salts, K_I values vary by no more than $2-3 \times$ over a several carbon atom range in the chain length of the alkyl group. See Reference 16.

⁷ The $k_{\text{cat.}}$ value for phenyl acetate is approximately $3 \times$ greater than that for phenyl isobutyrate (G. M. Steinberg and J. Maddox, to be published).

⁸ An inversion in the rate-determining step for the phenyl isobutyrate hydrolysis by AChE is highly unlikely in view of the extremely high rate of the reaction. However, if this was the case, it would mean that k_3 would be greater than $k_{\text{cat.}}$ and, hence, would not invalidate the conclusions.

plexity on passing from Compound II to III, one observes the beginning of kinetic selectivity by the enzyme.

It is noteworthy that if one sets $k_2 = k_{OH} [OH^-]$ for ACh, to achieve the enzymatic acylation rate one would have to use a hydroxide-ion concentration of $6 \times 10^4 M$.

Carotid Sinus Pressure Reflex Bioassay for *Veratrum viride*

B. KOROL, A. V. ZUBER*, and L. D. MILLER†

Abstract □ From a total of 238 anesthetized dogs, a series of regression analyses was performed examining the relationship between the variables (sex of the animal, date on which the experiment was performed, effect of the three veratrum alkaloidal drug preparations studied, and the number of days the dogs were stored in the animal house) on the arterial pressure pressor amplitudes of the predrug and postdrug carotid occlusion response and on the blood pressure-lowering effects of the drug treatments. The seasonal date of the experiment and the drug treatments significantly influenced the arterial pressure responses, while sex of the animal or days stored prior to use did not consistently alter the slope constants or arterial pressure responses for the drug subgroups.

Keyphrases □ *Veratrum viride* alkaloids—bioassay □ Carotid sinus pressure reflex—*V. viride* bioassay □ Sex, time of year effects—blood pressure lowering, drugs □ Regression analysis—factors affecting blood pressure lowering

The method presently used for the quantitative assessment of extracts of *Veratrum viride* is based on the progressive loss of the pressor response induced by bilateral occlusion of the common carotid arteries in the anesthetized dogs as reported by O'Dell (1). The potency of the test material is expressed in terms of carotid sinus reflex (CSR) units defined as follows: "One CSR unit represents the amount of intravenously administered hypotensive agent per kilogram of body weight which just abolishes the pressor response to the carotid sinus reflex in dogs" (1).

In a study on anesthetized dogs, Prochnik *et al.* (2) concluded that minimal pressor response to bilateral carotid occlusion is to be expected when the mean arterial pressure is below 88 mm. Hg. Since the regression line approaches zero response at the basal mean

arterial pressure level of 60 mm. Hg, it was suggested that minimum variability would be obtained if the carotid occlusion pressor responses were expressed as: (mm. Hg rise due to occlusion $\times 100$)/(mean arterial pressure [mm. Hg] - 60).

Rubin and Burke (3) reported that since the changes in carotid pressor reflex response and in the existent mean arterial pressure are highly correlated, the steeper dose-response curve exhibited by the carotid pressor reflex response would be a more sensitive measure. They also concluded that the *V. viride* hypotensive principles examined did not act *via* adrenergic, sympathetic, or ganglionic blocking actions. However, more recently, Jandhyala and Buckley (4) reported that the effects of cryptenamine, an alkaloidal preparation from *V. viride*, were inhibited by reserpine, α -methyldopa, and adrenalectomy and therefore did act through a mechanism of action involving catecholamines and the adrenal medulla.

The authors have used the method as described by O'Dell (1) for the bioassay of several alkaloidal preparations from *V. viride*. The studies referred to previously alluded to the high correlation between the basal arterial pressure and the pressor response amplitude to bilateral carotid occlusion. The authors have also made unpublished observations on other possible influencing variables, such as time of the year the study was performed and length of time the dog was maintained in the animal quarter. To understand more fully the relationships between these variables, a series of regression analyses was performed on the data obtained over the last few years. This report is concerned with the findings obtained in this study.

plexity on passing from Compound II to III, one observes the beginning of kinetic selectivity by the enzyme.

It is noteworthy that if one sets $k_2 = k_{OH} [OH^-]$ for ACh, to achieve the enzymatic acylation rate one would have to use a hydroxide-ion concentration of $6 \times 10^4 M$.

Carotid Sinus Pressure Reflex Bioassay for *Veratrum viride*

B. KOROL, A. V. ZUBER*, and L. D. MILLER†

Abstract □ From a total of 238 anesthetized dogs, a series of regression analyses was performed examining the relationship between the variables (sex of the animal, date on which the experiment was performed, effect of the three veratrum alkaloidal drug preparations studied, and the number of days the dogs were stored in the animal house) on the arterial pressure pressor amplitudes of the predrug and postdrug carotid occlusion response and on the blood pressure-lowering effects of the drug treatments. The seasonal date of the experiment and the drug treatments significantly influenced the arterial pressure responses, while sex of the animal or days stored prior to use did not consistently alter the slope constants or arterial pressure responses for the drug subgroups.

Keyphrases □ *Veratrum viride* alkaloids—bioassay □ Carotid sinus pressure reflex—*V. viride* bioassay □ Sex, time of year effects—blood pressure lowering, drugs □ Regression analysis—factors affecting blood pressure lowering

The method presently used for the quantitative assessment of extracts of *Veratrum viride* is based on the progressive loss of the pressor response induced by bilateral occlusion of the common carotid arteries in the anesthetized dogs as reported by O'Dell (1). The potency of the test material is expressed in terms of carotid sinus reflex (CSR) units defined as follows: "One CSR unit represents the amount of intravenously administered hypotensive agent per kilogram of body weight which just abolishes the pressor response to the carotid sinus reflex in dogs" (1).

In a study on anesthetized dogs, Prochnik *et al.* (2) concluded that minimal pressor response to bilateral carotid occlusion is to be expected when the mean arterial pressure is below 88 mm. Hg. Since the regression line approaches zero response at the basal mean

arterial pressure level of 60 mm. Hg, it was suggested that minimum variability would be obtained if the carotid occlusion pressor responses were expressed as: (mm. Hg rise due to occlusion $\times 100$)/(mean arterial pressure [mm. Hg] - 60).

Rubin and Burke (3) reported that since the changes in carotid pressor reflex response and in the existent mean arterial pressure are highly correlated, the steeper dose-response curve exhibited by the carotid pressor reflex response would be a more sensitive measure. They also concluded that the *V. viride* hypotensive principles examined did not act *via* adrenergic, sympathetic, or ganglionic blocking actions. However, more recently, Jandhyala and Buckley (4) reported that the effects of cryptenamine, an alkaloidal preparation from *V. viride*, were inhibited by reserpine, α -methyldopa, and adrenalectomy and therefore did act through a mechanism of action involving catecholamines and the adrenal medulla.

The authors have used the method as described by O'Dell (1) for the bioassay of several alkaloidal preparations from *V. viride*. The studies referred to previously alluded to the high correlation between the basal arterial pressure and the pressor response amplitude to bilateral carotid occlusion. The authors have also made unpublished observations on other possible influencing variables, such as time of the year the study was performed and length of time the dog was maintained in the animal quarter. To understand more fully the relationships between these variables, a series of regression analyses was performed on the data obtained over the last few years. This report is concerned with the findings obtained in this study.

METHODS

A total of 238 male and female mongrel dogs, weighing between 7.0 and 14.0 kg. each and anesthetized with pentobarbital sodium, 35 mg./kg. i.v., was used throughout.

Following the induction of anesthesia, both common carotid arteries were exposed and isolated by conventional surgical procedures. End arterial pressure was measured from either common carotid artery through a polyethylene tube inserted and fixed in the artery and connected to an E&M Physiograph pressure transducer which was coupled to an E&M Physiograph recorder. The cannula and pressure transducer were filled with a physiological saline solution containing 0.05% heparin sodium. A femoral vein was surgically exposed and used for the administration of all test drug solutions.

The experimental procedure was as follows: after a 5-min. equilibration period, a control pressor response was obtained by the unilateral occlusion of the remaining (either left or right) unused common carotid artery for a period of 45 sec. The test solution was then administered i.v.; 4 min. later, carotid occlusion again was performed. The test drug solution administration and challenging carotid occlusions were made at the time intervals mentioned previously until there was completely diminished carotid occlusion pressor response or until subsequent injections failed to alter the carotid occlusion induced pressor response.

The relationship between the variables, expressed by the regression equation $Y = a + bX$ (5) where the slope constant $b = xy/x^2$ and the intercept a is calculated from this formula by using the mean values of $x(X)$ and $y(Y)$, was examined with the use of a oneway analysis of variance. Using an IBM 360/50 computer, the following regression relationships were made:

A. Influence of sex (male or female) on the relationship between the basal arterial pressure and:

1. The amplitude of the predrug carotid occlusion response.
2. The amplitude of the postdrug carotid occlusion response.
3. The blood pressure-lowering effects by total drug treatment.

B. Influence of date (months October–March—Group 1, and April–September—Group 2) of experiment on the relationships between basal arterial pressure and 1, 2, and 3 of A.

C. Influence of drug: (a) cryptenamine alkaloids, (b) cryptenamine tannate, and (c) crude alkaloids on the relationship between basal arterial pressure and 1, 2, and 3 of A.

D. Influence of date of experiment on the relationship between basal arterial pressure and amplitude of predrug and postdrug carotid occlusion response clustered by drug treatments.

E. Relationship between days stored of dogs in animal house on basal arterial pressure and on amplitude of predrug carotid occlusion response clustered by drugs (a), (b), and (c).

RESULTS

The regression analysis of the relationships between the variables are summarized and presented in Tables I–V.

A. Influence of sex (male or female) on the relationship between the basal arterial pressure and predrug and postdrug carotid occlusion pressor response and on the blood pressure-lowering effects by total drug treatment (Table I).

It can be seen from Table I that the male dog population before drug treatment had a mean basal arterial pressure (BAP), Column Y,

Table I—Influence of Sex (Male or Female) on the Relationship between Basal Arterial Pressure and Response

Factors ^a	b	Y	X	a
BAP:BCO (B) M	0.7319	130.3	190.09	-8.83
BAP:BCO (B) F	0.6560	132.55	195.05	4.60
BAP:BCO (A) M	0.7424	75.07	101.12	0
BAP:BCO (A) F	0.6961	75.60	104.81	2.64
DD:BP M	-0.0531	10.339	55.091	13.264
DD:BP F	0.0014	9.949	56.780	9.149

^a BAP = mean basal arterial pressure in mm. Hg; BCO = peak blood pressure (mm. Hg) during carotid occlusion episode; (B) = before drug; (A) = after drug; M = male; F = female; DD = drug dose in mcg./kg.; and BP = blood pressure-lowering response.

Table II—Influence of Date (Fall, Winter–Spring, Summer) of Experiment on the Relationship between Basal Arterial Pressure and Response

Factors ^a	b	Y	X	a
BAP:BCO (B) 1	0.6447	129.97 ^b	185.54 ^c	10.35
BAP:BCO (B) 2	0.7313	131.90 ^b	195.11 ^c	-10.78
BAP:BCO (A) 1	0.7437	73.49 ^d	95.15 ^e	2.73
BAP:BCO (A) 2	0.7162	75.51 ^d	105.22 ^e	0.15
DD:BP 1	0.158	10.91	56.11	11.80
DD:BP 2	0.0379	9.87	56.32	12.0

^a BAP = mean basal arterial pressure in mm. Hg; BCO = peak blood pressure (mm. Hg) during carotid occlusion episode; (B) = before drug; (A) = after drug; 1 = experiments performed October through March; 2 = experiments performed April through September; DD = drug dose in mcg./kg.; and BP = blood pressure-lowering response. ^b $p < 0.036$. ^c $p < 0.024$. ^d $p < 0.048$. ^e $p < 0.016$.

of 130.3 mm. Hg; a mean peaked blood pressure response to bilateral carotid artery occlusion (BCO), Column X, of 190.09 mm. Hg; with a regression slope constant, Column b, of 0.7319. The female dogs before drugs did not significantly differ from the male group and had calculated mean values of 132.55 and 195.05 mm. Hg for BAP and BCO response, respectively, and a regression slope of 0.6560.

After treatment with total drugs, the male and female populations were not significantly different and demonstrated, in the case of the males, BAP, BCO, and slope values of 75.07 mm. Hg, 101.12 mm. Hg, and 0.7424, respectively, while the female population had values of 75.60 mm. Hg, 104.81 mm. Hg, and 0.6961, respectively.

Total drug treatment (DD) in the two sexes was not associated with a difference in: mean blood pressure-lowering activity (BP), Column X; mean dose in mcg./kg., i.v., Column Y; or slope constant, Column b.

B. Influence of time of the year experiment performed on the relationship between the basal arterial pressure and response.

As shown in Table II, the date when the experiment was performed significantly influenced the mean basal arterial pressure levels (Column Y) before as well as after total drug treatment. The experiments performed in the fall–winter (Group 1) showed a lower mean basal arterial pressure value of 129.97 mm. Hg compared to the mean value of 131.90 mm. Hg obtained from the experiments performed in the spring–summer (Group 2). Similarly, after total drugs the mean basal arterial pressure was significantly lower in Group 1 (73.49 mm. Hg) than in Group 2 (75.51 mm. Hg).

The mean peaked blood pressure responses (Column X) also demonstrated significantly different amplitude of response when comparison was made between Group 1 (185.54 mm. Hg) and Group 2 (195.11 mm. Hg) before drug treatment, and Group 1 (95.15 mm. Hg) and Group 2 (105.22 mm. Hg) after total drug treatment.

The date of the experiment did not influence the mean blood pressure-lowering response of total drugs nor the mean total drug dose.

C. Influence of date of experiment performed on the relationship between dose of drug and amplitude of blood pressure-lowering response.

Summarized in Table III are the regression analyses of the relationship between the dose of the drug treatment and the blood pressure-lowering response. The drugs used were: (a) cryptenamine alkaloids, (b) cryptenamine tannate, and (c) an alkaloidal fraction of *V. viride*. It can be seen that the slope constants (Column b) of the relationship between the drug-dose treatment and the blood pressure-lowering response were significantly different, exhibiting negative slopes of -0.0035 and -0.109 for cryptenamine alkaloids and alkaloidal fraction, respectively, while a positive slope constant of 0.214 was obtained for the cryptenamine tannate. In the total population there was no difference in the three drug groups in their mean drug dose or in the mean blood pressure-lowering response.

When the data were analyzed according to the date when the experiment was performed, a similar finding of significantly different slope constants was observed in the October–March (Group 1) experiments.

Here again, cryptenamine alkaloids and alkaloidal fraction demonstrated negative slopes of -0.0404 and -0.622, respectively, and cryptenamine tannate showed a positive slope constant of 0.1638.

Table III—Influence of Date on the Relationship between Blood Pressure-Lowering Response and Dose of Drug Clustered by Drug Groups

Factors ^a	b	Y	X	a
DD:BP a	-0.0035 ^b	9.27	51.71	9.29
DD:BP b	0.214 ^b	11.06	52.73	0.22
DD:BP c	-0.109 ^b	10.40	56.67	16.58
DD:BP a 1	-0.0464 ^c	9.63 ^d	53.25 ^e	2.48
DD:BP b 1	0.1638 ^c	14.0 ^{d,f}	48.95 ^{e,g}	-8.00
DD:BP c 1	-0.0622 ^c	9.1 ^d	63.05 ^{e,g}	3.93
DD:BP a 2	0.0091	9.14	59.24	-0.53
DD:BP b 2	0.0246	9.80 ^f	54.35 ^g	1.35
DD:BP c 2	-0.1183	10.90	54.35 ^g	6.44

^a DD = drug dose in mcg./kg.; BP = blood pressure-lowering response; a = cryptenamine alkaloids; b = cryptenamine tannate; c = alkaloidal; 1 = experiments performed October through March; and 2 = experiments performed April through September. ^b $p < 0.0567$, ^c $p < 0.06$, ^d $p < 0.03$, ^e $p < 0.045$, ^f $p < 0.031$, ^g $p < 0.024$.

In these experiments there were also significant differences in the mean drug dose employed (Column Y) of 9.63, 14.0, and 9.1 mcg./kg. and between the amplitude of the mean blood pressure-lowering response (Column X) of 53.25, 48.95, and 63.05 mm. Hg for cryptenamine alkaloids, cryptenamine tannate, and alkaloidal fraction, respectively.

When the experiments were performed during April–September, Group 2, there were no significant differences between the slope constants obtained for the three experimental drugs. Also, the mean drug dose as well as the mean arterial pressure-lowering response did not significantly differ between the three subgroups.

When comparison was made of the Date 1 to Date 2 results, it was observed that a cryptenamine tannate dose of 14.0 mcg./kg. (Date 1) was significantly greater than the mean dose of 9.8 mcg./kg. used in the Date 2 experiments. Also, the mean blood pressure-lowering responses of cryptenamine and of alkaloidal fraction of 48.95 and 63.05 mm. Hg, respectively, for Date 1 were significantly different from the Date 2 values of 54.35 mm. Hg for these drug groups.

D. Influence of date experiment performed on the relationship between arterial pressure, drug doses, and the amplitude of the arterial pressure response to bilateral carotid occlusion.

As shown in Table IV, within the Date 1 group there was no significant difference between the three drug subgroups before treatment (B), in slope constant (b), basal mean arterial pressure (Y), or in peaked mean arterial pressure response (X) to carotid occlusion. Similarly, within the Date 2 group there were insignificant differences between the three drug subgroups before treatment (B), as far as slope constant (b) and peaked mean pressor response (X) to carotid occlusion are concerned, although the initial mean

Table IV—Influence of Date on the Relationship between Basal Arterial Pressure, Drug Treatment, and BCO Response Clustered by Drug Groups

Factors ^a	b	Y	X	a
BAP:BCO (B) a 1	0.6244 ^b	128.63	185.21 ^c	12.98
BAP:BCO (B) b 1	0.6475 ^b	124.71	180.81 ^c	7.64
BAP:BCO (B) c 1	0.6423 ^b	137.5	191.3	14.6
BAP:BCO (B) a 2	0.7256 ^b	126.53 ^d	193.57 ^c	-13.92
BAP:BCO (B) b 2	0.7222 ^b	139.88 ^d	199.35 ^c	-4.09
BAP:BCO (B) c 2	0.7182 ^b	131.62 ^d	193.29	-7.20
DD:BCO (A) a 1	0.187 ^{e,f}	9.6 ^g	17.125 ^h	3.193
DD:BCO (A) b 1	0.1598 ^{e,f}	14.0 ^{e,i}	23.667 ^h	-3.781
DD:BCO (A) c 1	0.0361 ^{e,f}	9.368 ^g	26.316	-0.941
DD:BCO (A) a 2	0.0176 ^{i,j}	9.143	29.6 ^h	-0.512
DD:BCO (A) b 2	0.0303 ^{i,j}	9.796 ⁱ	31.796 ^h	-0.954
DD:BCO (A) c 2	0.4620 ^{i,j}	10.873	27.945	-12.90

^a BAP = mean basal arterial pressure in mm. Hg; BCO = peak blood pressure (mm. Hg) during carotid occlusion episode; (A) = after drug; (B) = before drug; a = cryptenamine alkaloids; b = cryptenamine tannate; c = alkaloidal; 1 = experiments performed October through March; 2 = experiments performed April through September; and DD = drug dose in mcg./kg. ^b $p < 0.03$, ^c $p < 0.05$, ^d $p < 0.005$, ^e $p < 0.05$, ^f $p < 0.01$, ^g $p < 0.03$, ^h $p < 0.03$, ⁱ $p < 0.05$, ^j $p < 0.001$.

arterial pressure (Y) levels between the three subgroups were statistically different. When comparison was made of the regression analysis of each drug subgroup [(a), (b), or (c)] between Dates 1 and 2, before treatment (B), it is observed that there was a statistically significant difference in slope constants of 0.6244 to 0.7256 for cryptenamine alkaloids, 0.6475 to 0.7222 for cryptenamine tannate, and 0.6423 to 0.7182 for alkaloidal fraction. No significant difference in the drug subgroup values was observed between Dates 1 and 2 for the mean basal arterial pressure (Y). There was significant difference in pressor response to bilateral carotid occlusion between Dates 1 and 2 for cryptenamine alkaloids, 185.21 to 193.57 mm. Hg; and for cryptenamine tannate, 180.81 to 199.35 mm. Hg; whereas the difference on the mean response of the alkaloidal fraction was not significantly influenced by the date the experiment was performed.

Summarized on the bottom half of Table IV are regression analyses made on the influence of the date of experiment (1 or 2) on relationship between drug dose (DD) separated by drugs [(a), (b), or (c)] on the peaked mean arterial pressure response to carotid occlusion (BCO) after (A) the drug treatment. Examination of these Date 1 regression analyses reveals that the slope constants of 0.187 and 0.1598 obtained for drug subgroups (a) and (b), respectively, significantly differed from the slope constant of 0.0361 for subgroup (c). The mean doses of drug (a) 9.6 and (c) 9.368 mcg./kg. were observed to differ significantly from the mean dose of 14.0 mcg./kg. of drug (c). The peak pressor response to BCO was not significantly different between the three drug subgroups.

During Date 2, only the slope constants for drug (a), 0.0176; drug (b), 0.0303; and drug (c), 0.4620 were significantly different for the three drug subgroups. The mean drug doses (Y) and the peak mean pressor response to the bilateral carotid occlusion (X) did not vary significantly between the three drug subgroups.

The slope constants for the Date 1 cryptenamine alkaloids, 0.187; cryptenamine tannate, 0.1598; and alkaloidal fraction, 0.0361; significantly differed from their Date 2 values of 0.0176, 0.0303, and 0.4020, respectively. The mean drug dose of cryptenamine tannate of 14.0 mcg./kg. for Date 1 and 9.796 mcg./kg. for the Date 2 experiments were significantly different. The BCO responses (X) also differed significantly for cryptenamine alkaloids and cryptenamine tannate between Date 1 (17.125 and 23.667 mm. Hg) and Date 2 (29.6 and 31.796 mm. Hg), respectively.

E. Relationship of days stored in the animal house of the dogs on the mean basal arterial pressure and on the pressor response to BCO, before drug treatment, separated into drug subgroups.

The data, summarized in Table V, reveal that the duration of days the dogs were stored (dH) in the animal house was not significantly different for the three drug subgroups; however, there was a significant difference for the BAP (Column X) and for the slope constants for the three drug subgroups. The animals which subsequently received cryptenamine alkaloids had a mean BAP of 127.07 mm. Hg and slope constant of 0.0032; for the cryptenamine tannate group, a mean BAP of 135.33 mm. Hg and slope constant of -0.1669; and, in the case of the alkaloid fraction group, a mean BAP of 133.19 mm. Hg with a slope constant of 0.1176.

The influence of the duration of days held on the peaked blood pressure response to BCO did not significantly vary between the three drug subgroups.

DISCUSSION

Examination of the regression analysis presented in the *Results* section leads to the following conclusions:

The sex of the animal does not influence the mean BAP and the magnitude of the pressor response to BCO both before as well as after total drug treatment, nor influence the relationship between total drug-dose treatment and the intensity of the arterial pressure depression.

The date of the experiment, that is, whether the experiment was performed in October through March or in April through September, did have a profound influence on the mean BAP and on the magnitude of the pressor response to BCO both before and after total drug treatment, but did not significantly influence the relationship between total drug-dose treatment and blood pressure-lowering response.

The calculated mean doses of cryptenamine alkaloids, cryptenamine tannate, and the alkaloidal fraction were significantly different.

Table V—Influence of Days Stored in Animal House in the Basal Arterial Pressure and BCO Responses Clustered by Drug Groups

^a dH = days held in storage; BAP = mean basal arterial pressure in mm. Hg; BCO = peak blood pressure (mm. Hg) during carotid occlusion episode; (B) = before drug; *a* = cryptenamine alkaloids, *b* = cryptenamine tannate; and *c* = alkaloidal. ^b $p < 0.0148$. ^c $p < 0.03$.

There was a statistical difference in slope constant, mean drug dose, and in the amplitude of the blood pressure-lowering response for the experiments performed in October through March. When examination was made of the data from experiments performed April through September, there were no calculated significant differences in these relationships. There were no significant differences between the slope constants, mean drug dose, and blood pressure-lowering responses for the three drug subgroups when the data collected from October through March were compared to those obtained in April through September.

There were no differences in the slope constants, mean BAP, and in the amplitude of the pressor response to BCO before drug treatment between the three drug groups for the experiments performed during the October through March period. There was only a significant difference in mean BAP between the three drug groups when the experiments were performed during April through September. However, there were significant differences for the three drug subgroups in slope constant and amplitude of the pressor response to BCO when the two 6-month experimental periods were compared.

After drug treatment, there were significant differences between the three drug groups in slope constant and in mean drug dose for the experiments performed during October–March. Only the slope constants between the three drugs differed significantly when the experiments were performed during April–September. When comparison was made between the two 6-month periods, there was significant difference in slope constants, in mean drug dose (cryptenamine tannate), and in mean peak arterial pressure response to BCO for the cryptenamine alkaloids and cryptenamine groups.

It was observed that although there was no difference between the three drug subgroups in the mean number of days the dogs were stored in the animal house prior to use, there was a significant difference in slope constants and in mean BAP for the three drug subgroups.

Examination of the results reveals that although the mean BAP is markedly lowered by total drug treatment, the slope constants for the relationships between the mean BAP and the pressor response to BCO did not significantly differ. These findings thus support the conclusions of Prochnik *et al.* (2) who suggested that when employing the bilateral carotid occlusion pressor bioassay, correction be made for drug-induced changes in mean BAP and also for the findings that the pressor response was physiologically absent when the arterial pressure reached 60 mm. Hg.

Although there was no difference in mean total drug dose and blood pressure-lowering response, when these factors were separated by drug groups there was significant difference in slope constants. Here, cryptenamine tannate produced the most desirable slope constant indicative of an increase in blood pressure-lowering response with increasing dose. Cryptenamine alkaloids and the alkaloid fraction exhibited negative slopes, thus indicating that increasing drug dose decreases the degree the blood pressure falls. Further separation of these results into time of the year the experiment was performed showed that during October through March, cryptenamine tannate, although administered at a significantly higher dose, again demonstrated a positive slope while the other drugs exhibited negative slope constants in the relationship between drug dose and blood pressure-lowering effects. When the experiments were performed during April through September, cryptenamine

alkaloids and cryptenamine tannate showed very low but positive slope constants, while the alkaloid fraction still demonstrated a negative slope constant for the relationship between the drug dose and the intensity of the blood pressure depression. It was of interest to note that for all three drug subgroups there was a significant increase in slope constants, while the peak BCO response (before drugs) only significantly increased for cryptenamine alkaloids and cryptenamine tannate, and no differences were observed in the mean BAP when comparison was made between the October–March and April–September groups. Similar findings were observed when examination of the relationship between drug dose and BCO (after drug) was made.

The days the animals were stored in the animal house prior to use did not consistently affect the slope constants nor the BAP on the BCO response amplitude for the three drug subgroups.

Examination of these results thus indicates that the date at which the experiment was performed did significantly influence most of the examined relationships and if this bioassay procedure continued to be employed, necessary corrections must be applied to adjust for these influences.

These seasonal influences are possibly the result of rhythmic changes in disposition and deposition of adipose tissue and other changes during different seasons as reported by Fisher *et al.* (6) and Hilditch (7). Since in all these experiments pentobarbital was used as the anesthetic, it is quite conceivable that the observed seasonal difference in mean BAP, in pressor response amplitude to BCO, and the blood pressure-lowering effects of the three drugs were the result of either a different level of anesthesia occurring during the different seasons or, more generally, a seasonally induced changed physiological state resulting in differential responding.

It is well known that the physiological state of the preparation can profoundly influence both the nature as well as the intensity of a fixed treatment response. This is particularly in evidence with the alkaloids ibogaine and yohimbine. It was reported (8) that in the anesthetized dog, ibogaine produced a marked lowering of arterial pressure while in the conscious preparation an equal dose of ibogaine appeared to be devoid of hypotensive activity. Likewise, yohimbine is reported (9) to produce a hypertensive response in the conscious animal while evoking an arterial pressure depressor response when the animal is anesthetized with pentobarbital sodium.

In order to examine the possibility that use of the anesthetic is a factor in influencing the responses as described, a series of experiments will be performed in chronically prepared dogs while conscious and in the anesthetized state. With each dog serving as its own control, it will be possible to assess the influence of the anesthetic on many of the relationships examined in this study.

Comparative Distribution, Excretion, and Metabolism of ^{14}C -Labeled Quaternary Ammonium Compounds of Promazine, Chlorpromazine, and Triflupromazine

C. L. HUANG, J. Z. YEH, and I. A. MUNI

Abstract ☐ The tissue distribution and biotransformation patterns of the quaternary methiodides of promazine, chlorpromazine, and triflupromazine in rats were investigated. After parenteral administration, high concentrations of these compounds were found in the liver, kidneys, and intestines. The majority of these compounds was metabolized by the liver and excreted in the intestines *via* the bile duct. In contrast to the corresponding tertiary amine, the majority of these compounds was excreted unchanged; however, a trace of chlorpromazine sulfoxide methiodide was detected in the urine.

Keyphrases ☐ Promazine, chlorpromazine, triflupromazine ^{14}C -methiodides—synthesis ☐ Triflupromazine, chlorpromazine, promazine ^{14}C -methiodides—synthesis ☐ Biotransformation, distribution—quaternary phenothiazine compounds ☐ IR spectrophotometry—identity ☐ UV spectrophotometry—identity ☐ Scintillometry—analysis ☐ Radiochromatography—analysis

Molecular modification of phenothiazines with an aim to isolate sedative effect from antihistaminic activity has been contemplated by quaternization of the tertiary amino nitrogen. Albanus *et al.* (1) prepared promethazine hydroxyethyl ammonium chloride¹ and demonstrated that this compound had an antihistaminic activity similar to that of the parent compound but lacked sedative effect. Hanngren (2) reported that this compound caused a decrease in the volume and acidity of the gastric juice in human subjects by inhibiting the gastric basal secretion.

Levine *et al.* (3–5) studied the rate of absorption of monoquaternary ammonium compound of benzomethamine by using *in vivo* intestinal loops in rats. The data indicated that the quaternary ammonium salt was poorly absorbed by the gastrointestinal tract due to its high degree of ionization and the positive charge which promotes the formation of a nonabsorbable complex with the intestinal mucin. Levine stated that more than a passive diffusion was involved in the kinetics of intestinal absorption of benzomethamine and other onium compounds.

The rate of excretion of onium compounds is dependent upon the route of administration and the degree of ionization of the compound. By subcutaneous administration, some 7–37% of radioactivity was recovered in the urine during the same period of time. In a comparative study made by Hansson and Schmitterlöw (6) and Allgen *et al.* (7) on *in vivo* behavior of tertiary and quaternary promethazine, markedly different excretion patterns were found between these compounds. Both compounds were excreted mainly *via* the kidneys, and only 25% was found in the feces

after subcutaneous administration. However, with oral administration, tertiary promethazine was excreted mainly in the urine, whereas the majority of the quaternary compound appeared in the feces.

Recently, distribution and excretion patterns of quaternary ammonium salts of mepazine, promethazine, trifluoperazine (8), and perphenazine (9) with one or two moieties of ^{14}C -methyl groups attached to the terminal nitrogen have been studied. The rate of absorption of the *i.p.* administered ^{14}C -methiodide of these compounds was rapid, as evidenced by the quick disappearance of radioactivity from the injected site and further reflected in fairly high blood levels with peaks, in most cases, at 0.5 hr. after the administration of the compounds. Contrary to the previous speculations of a high blood-brain barrier for these compounds, brain levels of the compounds were low but above the significant level. This finding may provide direct evidence as to why these compounds are active on the CNS.

It appears that the distribution and biotransformation pattern of quaternary phenothiazine compounds are quite different from those of the corresponding tertiary amino derivatives. The majority of the administered quaternary ammonium compounds is found in organs such as liver, intestines, kidneys, gastric mucosa, and pancreas; the majority of the tertiary amine derivatives is found in the lungs and brain. Tertiary phenothiazine derivatives are known to be metabolized *in vivo* largely through four pathways: sulfoxidation, hydroxylation, glucuronidation, and *N*-demethylation; however, quaternary derivatives undergo these metabolic processes to a much lesser extent.

Apparently, two types of major excretion patterns exist, the urinary and fecal types, for these methiodide derivatives. Perphenazine methiodide exhibited the former type of excretion, while methiodides of mepazine, promethazine, and trifluoperazine belonged to the latter category. The difference in the metabolic behavior between these compounds was apparently due to the difference in the affinity of these compounds for the liver cells; perphenazine methiodide could not enter into the active metabolic process of the liver, whereas other compounds actively participated in the excretory mechanism of the liver and thus were excreted in the intestines *via* the bile duct.

The toxicity of these phenothiazine derivatives did not diminish by quaternization, as evidenced by the fact that the LD_{50} of these compounds administered by the *i.p.* route was higher than that of the corresponding tertiary amino derivatives. Antimicrobial activities were also retained by these quaternary ammonium salts in that growth of *Staphylococcus aureus* and *Escherichia*

¹ Aprobil, Recit Co., Stockholm, Sweden.

coli was inhibited at the concentrations of 1 and 10 mcg./ml., respectively.

Review of the literature indicated that only a few quaternary ammonium compounds of phenothiazine derivatives were studied extensively in regard to their distribution, excretion, and metabolism in animals. It is the purpose of this study to compare the *in vivo* behavior of three quaternary compounds of promazine, chlorpromazine, and triflupromazine which are similar in structure except for the functional group attached to the Position 2.

In this report, comparative studies on the tissue distribution and elimination of the methiodide of three structurally related phenothiazine derivatives—promazine, chlorpromazine, and triflupromazine—are presented. These three compounds differ only by the presence of substituent groups at the Position 2 on the aromatic ring system (Structures I, II, and III).

METHODS²

Synthesis of Promazine Methiodide (PRZ-MEI) and Promazine Methiodide-¹⁴C (PRZ-MEI-¹⁴C)—Promazine hydrochloride (0.5 g.) was dissolved in 5 ml. of water, and the solution was adjusted to pH 10 (pHydrion paper) and extracted several times with benzene. The benzene extracts were combined and the solvent removed under reduced pressure to leave an oil (0.42 g.). The oil was dissolved in 5 ml. of acetone, and 0.2 g. of methyl iodide was added. Crystallization commenced within 15 min. at room temperature. The crystals were collected and recrystallized from acetone to yield 0.57 g. (90%) of PRZ-MEI with m.p. 255–257° and R_f 0.71; $\lambda_{\max.}$, 210 and 354 m μ .

Anal.—Calcd. for $C_{18}H_{23}IN_2S$: C, 50.70; H, 5.40; N, 6.57. Found: C, 50.80; H, 5.50; N, 6.70.

The free base of promazine (265 mg., 0.93 mmole) obtained was dissolved in 1.5 ml. of acetone and pipetted into the capillary guard of a breakseal tube which contained 85.5 mg. (0.60 mmole) of ¹⁴C-methyl iodide (11.7 μ C./mg.). The capillary seal was broken to allow 1 ml. (163 mg., 0.60 mmole) of the solution to enter the tube under negative pressure. The tube was stoppered immediately and allowed to stand overnight at room temperature. About 100 mg. of unlabeled methyl iodide was added to ensure a complete quaternization of the promazine base. Then ether was added to the mixture until turbidity occurred. Crystallization commenced within 15 min. The crystals were collected and washed with ether to yield 345 mg. (87%) of PMZ-

MEI-¹⁴C with m.p. 255–257° and specific activity 3.19 μ C./mg. Radiochromatograms showed only one spot with an identical R_f (0.71) with PMZ-MEI, and mixed melting point with PMZ-MEI did not show depression (255–257°).

Synthesis of Chlorpromazine Methiodide (CPZ-MEI) and Chlorpromazine Methiodide-¹⁴C (CPZ-MEI-¹⁴C)—Chlorpromazine hydrochloride (0.5 g.) in 5 ml. of water was adjusted to pH 10 and extracted several times with benzene. The combined benzene extracts were dehydrated with anhydrous sodium sulfate and evaporated *in vacuo* to leave 0.43 g. of an oil. To the acetone solution (5 ml.) of the oil, 0.2 g. of methyl iodide was added. The mixture was shaken occasionally and left at room temperature overnight. Then ether was added to the mixture to precipitate the product. The precipitate was collected and recrystallized from acetone-ether to yield 0.49 g. (81%) of CPZ-MEI with m.p. 145–147°; $\lambda_{\max.}$, 216 and 256 m μ .

Anal.—Calcd. for $C_{18}H_{22}ClIN_2S$: C, 46.91; H, 4.78; N, 6.08. Found: C, 47.23; H, 5.11; N, 5.96.

The oily free base of chlorpromazine (190 mg., 0.6 mmole) in 2 ml. of acetone was reacted with 85.5 mg. (0.6 mmole) of ¹⁴C-methyl iodide (11.7 μ C./mg.) as described for promazine. The reaction was allowed to proceed for 12 hr. at room temperature; then a suitable amount of ether was added to initiate crystallization. The crystals were collected and recrystallized from acetone-ether to yield 218 mg. (80%) of CPZ-MEI-¹⁴C with m.p. 145–147° and specific activity 2.89 μ C./mg.

The radiochemical purity and authenticity of this compound were checked by paper chromatography (R_f , 0.79) coupled with a radiochromatogram scanner. The mixed melting point of this compound with CPZ-MEI did not show depression (145–147°).

Synthesis of Triflupromazine Methiodide (TFP-MEI) and Triflupromazine Methiodide-¹⁴C (TFP-MEI-¹⁴C)—Triflupromazine hydrochloride (0.5 g.) was dissolved in water, and the solution was adjusted to pH 10 by adding sodium hydroxide solution. The oily precipitate appearing in the mixture was extracted several times with ether. The combined ether extracts were dehydrated with anhydrous sodium sulfate and the solvent removed *in vacuo*. The free base of triflupromazine (0.45 g.) was dissolved in 5 ml. of acetone, and methyl iodide (0.2 g.) was added. The mixture was allowed to stand at room temperature overnight; then a suitable amount of ether was added to initiate crystallization. The crystals were collected and recrystallized from acetone-ether to give 0.38 g. (60%) of TFP-MEI with m.p. 169–170° and R_f 0.81; $\lambda_{\max.}$, 216 and 258 m μ .

Anal.—Calcd. for $C_{19}H_{20}F_3IN_2S$: C, 46.16; H, 4.49; N, 5.67. Found: C, 46.33; H, 4.48; N, 5.71.

To the free base of triflupromazine (224 mg., 0.6 mmole) in 2 ml. of acetone was added ¹⁴C-methyl iodide (11.7 μ C./mg., 85.5 mg., 0.6 mmole). The reaction was allowed to proceed for 12 hr. at room temperature; then ether was added until crystallization commenced. The crystals were filtered off and recrystallized from acetone-ether to yield 188 mg. (60%) of TFP-MEI-¹⁴C with m.p. 169–170° and specific activity 3.11 μ C./mg. Radiochemical purity and authenticity of the product were checked by chromatography coupled with radiochromatogram scanner, mixed melting point (169–170°), and cochromatography (R_f 0.81) with an authentic sample of TFP-MEI.

Excretion Studies—In the excretion studies, 1 mg. each of the quaternary ammonium compounds of promazine (3.19 μ C./mg.), chlorpromazine (2.89 μ C./mg.), and triflupromazine (3.11 μ C./mg.) was injected i.p. to six albino rats weighing 250–280 g. The animals were maintained in metabolic cages with free access to food and water. The urine and feces specimens were collected separately every 8 hr. for a period of 5 days. Urine specimens were diluted five times with water; an aliquot of 0.5 ml. was measured in a planchet, dried, and the activity recorded. It was a thin-layer preparation and no correction for the self-absorption was required. Feces specimens were dried and powdered. An aliquot of 0.1 g. was placed in a planchet and the activity measured. Corrections were made for the self-absorption.

Tissue Distribution Studies—Three groups of albino rats (five rats in each group) weighing 250–280 g. were administered through the intraperitoneal route with 1 mg. each of PRZ-MEI-¹⁴C, CPZ-MEI-¹⁴C, and TFP-MEI-¹⁴C, respectively. The animals were housed in individual cages and were sacrificed at the following intervals: 0.5, 1, 2, 4, and 8 hr. The following organs and tissues were isolated: liver, lungs, kidneys, spleen, heart, stomach, intestines, blood, brain, muscle (femoral), and bone (femur). The surface of the intestines

² Melting points were taken on a Fisher-Johns apparatus and were corrected. UV and IR absorption spectra were recorded on a Perkin-Elmer model 202 and model 137 infrared spectrophotometer, respectively. Paper chromatograms were developed in a solvent system; *n*-butanol-ethanol-water (5:2:2). Albino rats were purchased from Southern Animal Farms, Prattville, Ala. Radioactivity in the tissues was recorded in a G-M counter (Tracerlab, model TGC-2), and radiochromatograms were scanned in a radiochromatogram scanner, Actigraph III (Nuclear-Chicago).

^a Expressed in terms of percent of the administered activity.

was rinsed with saline to remove mechanical contamination of the administered material, and the peritoneal cavity was washed several times with detergent to recover the unabsorbed portion of the activity. The whole organs, except for the blood and bone, were homogenized in a homogenizer and diluted with water to an extent that 16 ml. represented 1 g. of the organ. An aliquot of 150 mcg. of the dilution was measured in a planchet, dried, and the activity recorded.

Metabolic Studies—Since the ¹⁴C-methyl group is attached to the nitrogen of the 10-substituted side chain of the phenothiazine ring system, it was essential to study its fate *in vivo*. In this study, three rats were injected i.p. with ¹⁴C-methiodide (1 mg.) of these compounds. The animals were maintained in a large metabolic jar, and the expired air was passed through a washing bottle containing 40% sodium hydroxide solution for 24 hr. to collect carbon dioxide. The carbon dioxide trapped as sodium carbonate was treated with a calcium chloride solution; the precipitate of the calcium carbonate thus formed was collected and the activity determined.

A portion (usually 0.5 ml.) of the urine collected 24 hr. after the intraperitoneal administration of these compounds was placed linearly on Whatman No. 3 chromatographic paper along with radioactive standards. The chromatogram was developed by an ascending technique in the usual solvent system (10). The chromatogram was dried and scanned in a radiochromatogram scanner to record the activity, and the *R_f* value of the spot was calculated. Feces collected over a 3-day period were placed in a continuous extraction apparatus and extracted successively with ether for 2 days and then with methanol for 3 days. The methanol extracts were reduced to about 1 ml. *in vacuo*, and an aliquot of 0.1 ml. was placed linearly on Whatman No. 3 chromatographic paper along with the radioactive standard. The chromatogram was developed by an ascending technique in the solvent system described for the urine specimens. After the chromatogram was dried, the activity was recorded in a radiochromatogram scanner and the *R_f* value was calculated.

Synthesis of Methiodide of Chlorpromazine Sulfoxide—About 0.5 g. of chlorpromazine sulfoxide was dissolved in 5 ml. of acetone

and reacted with 0.5 ml. of methyl iodide. The crystal appeared spontaneously. The compound was recrystallized from the acetone-ether mixture to a crystalline powder with m.p. 242–243°. The *R_f* value was 0.65. This material was used as a reference compound for the identification of metabolites of chlorpromazine methiodide.

Biliary Excretion Studies—Male Holtzman rats weighing about 300 g. were anesthetized by subcutaneous administration of 70 mg./kg. of pentobarbital sodium. Through an abdominal incision, the bile duct was cannulated with a polyethylene tube (PE50, Clay-Adams Inc.). About 1 ml. of the drug solution (1 mg./ml.) was dropped directly into the abdominal cavity before the incision was closed. Bile was collected at the intervals of 0.5, 1, and 2 hr. All animals were sacrificed at the end of 2 hr., and the entire intestines were removed and the radioactivity was recorded as described previously (*Tissue Distribution Studies*). The radioactivity in the urine and bile was determined according to the procedure described under the urinary excretion study.

RESULTS

Excretion of PRZ-MEI, CPZ-MEI, and TFP-MEI—Table I summarizes the urinary and fecal excretion of radioactivity by rats after a single intraperitoneal administration of PRZ-MEI-¹⁴C, CPZ-MEI-¹⁴C, and TFP-MEI-¹⁴C. Total radioactivity recovered in the urine in 5 days was: PRZ-MEI, 29.83%; CPZ-MEI, 11.36%; and TFP-MEI, 8.43% of the administered radioactivity. The majority of the ¹⁴C in the urine was recovered within the first 8 hr., and the first 24-hr. excretion accounted for 70–90% of the total urinary radioactivity recovered during the 5-day period. However, fecal excretion was the major route of excretion, which is approximately 2–6 times the urinary excretion for these compounds. The radioactivity in the feces was low in the first 8 hr., but the activity reached its peak in 16 hr. and declined slowly thereafter. Occasional fluctuation of radioactivity was observed which was due to the uneven fecal excretion by these animals. Total radioactivity recovered during the 5-day period was: PRZ-MEI, 53.62%; CPZ-MEI, 54.55%; and TFP-MEI, 51.37% of the administered activity. The ratio between the urinary and fecal excretion for PRZ-MEI, CPZ-MEI, and TFP-MEI was 1:1.8, 1:5, and 1:7.3, respectively. The combined radioactivity of PRZ-MEI recovered in the urine and feces was the highest (83.45% of the administered activity), followed by CPZ-MEI (65.91%) and TFP-MEI (59.80%). The difference in the rate of excretion in these compounds is apparently due to the different substituent groups attached to the Position 2.

Tissue Distribution of PRZ-MEI, CPZ-MEI, and TFP-MEI (Tables II and III)—The blood levels of these ¹⁴C-compounds were generally low with peaks at 0.5 hr. The concentrations declined slowly after 1 hr. but remained significant until after 8 hr. Among the three compounds tested, PRZ-MEI showed the highest blood level. The brain level of PRZ-MEI showed an interesting trend of increasing radioactivity in contrast to the decreasing trend of the blood level during the 8-hr. period. However, the brain levels of CPZ-MEI and TFP-MEI were almost parallel to the blood levels. The brain levels declined after 0.5 hr. and were insignificant after 2 hr. In all cases, the intestines showed the highest radioactivity followed by the muscle, liver, and kidneys. Apparently, the liver was

^a A value of 100 represents nonspecific tissue distribution. Relative activity = $\mu\text{c./g. tissue}/(\text{total activity/body weight}) \times 100$.

the major organ that metabolized these compounds; it showed a peak level between 0.5 and 1 hr. and maintained a fairly high level throughout the 8-hr. period. The radioactivity accumulated in the intestines reflected the fact that hepatobiliary excretion was the major route of elimination for these compounds. The overall radioactivity in the kidneys was lower than that in the liver; however, the specific activity of the kidneys was higher than that of the liver when the radioactivity was expressed in terms of percent specific activity (Table III). The kidney level had its peak at 0.5 to 1 hr. and then steadily declined. The increase of radioactivity in the urine recovered from the urinary bladder by autopsy coincided with the decrease in the kidney level. Abdominal washings were obtained to estimate the rate of absorption of these compounds after the intraperitoneal administration. The recovered radioactivity indicated that the rate of absorption of these compounds by rats was quite rapid; 4.67–9.32% of the administered activity remained in the abdominal cavity at 0.5 hr. but only 0.05–1.38% was recovered after 8 hr.

When the tissue distribution data were expressed in terms of relative activity in respect to the specific activity of the whole body, the distribution pattern of the activity in each organ remained the same. However, the relative specific activity of these organs changed (Table III). The specific activity of PRZ-MEI-¹⁴C in the kidneys became the highest, followed by that in the liver at 0.5 hr. The specific activity of TFP-MEI-¹⁴C in the spleen was higher than that in the liver and kidneys. A considerably high specific activity was found in the stomach, which had a higher level than that of the heart and lungs. The specific activity of these compounds in the intestines was 1–3 times higher than that of the whole body at 0.5 hr. and eventually it became 4–7 times at 8 hr.

Metabolic Studies—N-Demethylation in vivo—No radioactivity was detected in the carbon dioxide collected from animals administered with the ¹⁴C-methiodide of promazine, chlorpromazine, and triflupromazine. This finding indicated that N-demethylation of the quaternary ammonium compounds did not occur *in vivo*.

Urinary Metabolites—A paper chromatogram of the urine specimens collected from animals given PRZ-MEI-¹⁴C and TFP-MEI-¹⁴C showed only one spot as indicated on the recording of a radiochromatogram scanner. The *R_f* values matched those of the corresponding original compounds, indicating that both compounds were excreted in the urine unchanged. The chromatogram of the urine specimens from the CPZ-MEI group of animals showed a trace of the second metabolite with an *R_f* value of 0.66. It was identified to be its sulfoxide by comparing the *R_f* value (0.66) and UV absorption spectrum (240 and 310 *mμ*) with those of the authentic specimen of chlorpromazine sulfoxide methiodide.

Fecal Metabolites—The ether extracts of the feces specimens from animals given the compounds appeared greasy and showed no radioactivity. Most of the radioactivity in the feces was found in methanol extracts; however, about 10–15% of the radioactivity was left in the residue after the methanol extraction. A paper chromatogram of the methanol extract showed only one spot, as indicated on the recording of a radiochromatogram scanner. The *R_f* values of the spot matched each of the original starting materials (PRZ-MEI, 0.73; CPZ-MEI, 0.78; and TFP-MEI, 0.81).

A study was conducted to establish the rate of fecal excretion of CPZ-MEI-¹⁴C after various routes of administration. During the 5-day period, 55% of the administered activity was recovered in the

feces after an intraperitoneal administration and about 57% by a subcutaneous route; after an oral route of administration, nearly 98% of the material was recovered within 48 hr. Thus, it was established that fecal excretion was the main route of elimination of CPZ-MEI irrespective of the route of administration. The ratio between the urinary and fecal excretion was as follows: intraperitoneal route, 1:5; subcutaneous route, 1:2.2; and oral route, 1:320. By parenteral routes of administration, usually a slight inflammation was observed at the site of injection.

DISCUSSION

Fecal excretion was the major route of elimination of the N-methiodide of promazine, chlorpromazine, and triflupromazine. A substituent group of either Cl or CF₃ at Position 2 on the promazine molecule caused a remarkable change in the rate of elimination of these compounds. The rate of absorption of these compounds after the intraperitoneal route of administration was rapid, as indicated by a rapid disappearance of the compounds from the site of injection. Urinary excretion represented about 8–30% of the administered activity, and 51–55% of the activity was found in the feces. The total excretion in the urine and feces combined was 60–83% of the administered dose in a 5-day period, and a slow excretion continued after 5 days. Apparently, a substituent group of Cl and CF₃ at Position 2 on the promazine molecule remarkably changed the rate of elimination of these compounds, as evidenced by the fact that the extent of excretion for PRZ-MEI (83%) was the highest, followed by CPZ-MEI (66%), with TFP-MEI (60%) the lowest.

By parenteral routes of intraperitoneal and subcutaneous administration of CPZ-MEI, the radioactivity recovered in the feces was 55% and 57%, respectively. However, because of the ionic nature of this compound, it was poorly absorbed by the stomach. Therefore, with oral administration, 98% of the compound was recovered in the feces, and urinary excretion represented only a trace of the compound (9).

Blood level of PRZ-MEI was the highest among the three compounds with a proportionally high brain level. It appeared that the blood-brain barrier is low for PRZ-MEI, which is contrary to the general concept that quaternary ammonium compounds have a high blood-brain barrier. However, the brain level of CPZ-MEI and TFP-MEI was very low and was insignificant against the background after 2 hr.

The majority of the i.p. administered compounds was metabolized by the liver and excreted in the feces. This metabolic route was confirmed by cannulating the common bile duct of animals previously treated with CPZ-MEI. The bile specimen collected in this manner was subjected to paper chromatographic analysis as described previously for urine specimens. A single spot with *R_f* 0.78 was identified to be the unchanged CPZ-MEI.

Apparently the bile excretion is the major source of radioactivity in the intestines. This is evidenced by the fact that when the common bile duct was ligatured, only a trace of radioactivity was detected in the intestines.

Except for the intestines, the liver and the kidneys are the major organs representing most of the activity. However, the specific activity in the spleen was considerably higher than in other organs.

The methyl groups attached to the terminal nitrogen are quite stable, as evidenced by the negative finding of the radioactivity in the expired air of the animals pretreated with the quaternary compounds. Chromatographic analyses indicated that the majority of the urinary and fecal metabolites was the unchanged drug, except for a metabolite of CPZ-MEI which was identified to be the sulfoxide of CPZ-MEI.

SUMMARY

1. The i.p. administered ^{14}C -methiodides of the three structurally related phenothiazine derivatives—promazine, chlorpromazine, and trifluorpromazine—were well absorbed by the rats.
2. Promazine methiodide showed higher blood and brain levels than the 2-chloro (chlorpromazine) and 2-trifluoromethyl (trifluorpromazine) substituted analogs.
3. Liver was the major organ which metabolized the drug and eliminated it to the intestines through biliary excretion.
4. The majority (51–55%) of the administered radioactivity was recovered in the feces, and urinary excretion represented 8–30% of the administered activity.
5. The methyl groups attached to the terminal nitrogen were stable and not demethylated in the metabolic process. No radioactivity was detected in the carbon dioxide collected from the expired air of the animals.
6. Paper chromatography revealed that chlorpromazine methiodide was metabolized to its sulfoxide, while promazine methiodide and trifluorpromazine methiodide were excreted unchanged.

Conformations of *erythro*- and *threo*-Dimethylacetylcholine Iodides in the Solid State

ELI SHEFTER*, PHYLLIS SACKMAN*, WILLIAM F. STEPHEN, Jr.†, and EDWARD E. SMISSMAN†

Abstract □ The structures of *erythro*- and *threo*- α,β -dimethylacetylcholine iodides were determined by X-ray crystallographic procedures. The two molecules have substantially different conformations. The conformation of the *threo*-compound appeared to be dominated by coulombic attraction between the carbonyl oxygen and the quaternary nitrogen group, while in the *erythro*-analog the acyloxy oxygen atom was involved in a similar intramolecular interaction.

Keyphrases □ *erythro*- α,β -Dimethylacetylcholine iodides—structure determinations □ *threo*- α,β -Dimethylacetylcholine iodides—structure determination □ Conformation, structural—*erythro*- and *threo*- α,β -dimethylacetylcholine □ X-ray crystallography—structure determination

Substitution of methyl groups on the α - and/or β -carbons of the acetylcholine molecule (ACh) has dramatic effects on both the muscarinic activity of the analog and the hydrolysis rate of the molecule in the presence of acetylcholinesterase (AChE) (1, 2). Pharmacological studies (2) on the *erythro*(\pm)- and *threo*(\pm)- α,β -dimethylacetylcholine compounds indicated that the racemic *erythro*-material is over 300 times more potent as a muscarinic agent than the racemic *threo*-compound. However, *erythro*(\pm)-dimethylacetylcholine has approximately one-tenth the activity of ACh. When relative rates of hydrolysis by AChE of the two molecules are

compared, a reverse situation is found, i.e., the *threo*(\pm)-material is hydrolyzed at approximately one-tenth the rate of ACh and the *erythro*(\pm)-analog is negligibly hydrolyzed and possibly acts as an antagonist. In consideration of these results, it was deemed worthwhile to carry out structural studies on these molecules to learn to what extent their electronic and steric features might account for their observed properties. The crystal structures of the *erythro*- and *threo*-compounds are reported in this article.

EXPERIMENTAL

The iodide salts of the racemic mixtures of the two compounds crystallized as prisms from ethanol-ether (for *erythro*-material) and ethanol-benzene (for *threo*-compound) solutions. The individual *threo*-crystals were found to be optically active, and the crystal chosen for the X-ray study was found to contain the $\alpha(R)\beta(R)$ enantiomer. Figure 1—General views of the threo- $\alpha(R)\beta(R)$ -dimethylacetylcholine molecule showing intramolecular bond distances and angles.

Intensity data¹ were collected by the stationary counterstationary crystal technique (3) using balanced filters for Cu K α radiation (Ni versus Co). The intensities of 795 out of 826 unique data for the *threo*-compound and 1140 out of the 1267 independent data for the *erythro*-crystals in the 2θ -range of 0–100° had intensities significantly greater than their respective background counts. Corrections were applied to the data for α_1 - α_2 splitting, Lorentz-polarization factors, and absorption. The absorption correction was an approximate one, based on the anisotropy of transmission of the X-ray beam for a reflection at $\chi = 90^\circ$ for each crystal. The absorption (μ -linear absorption coefficients $\sim 200 \text{ cm}^{-1}$) by these crystals was the greatest source of error in the data.

The structures were obtained by the "heavy atom" technique (4) and refined by least squares, using a block diagonal approximation to the normal equations. During the refinement of the *threo*-structure, the absolute configuration of the enantiomorph in the crystal was derived by considering the agreement between the observed and calculated structure factors (calculations included the anomalous scattering term for iodine) for the $\alpha(S)\beta(S)$ and $\alpha(R)\beta(R)$ structures.

The R values for the refined structures are 0.096 and 0.132 for the observed data of the *erythro*- and *threo*-structures, respectively.² Weighting schemes were chosen in both structures such that the average weighted difference squared was approximately constant over the whole range of observed structure factors, and the "unobserved" data were given zero weight. The positional and thermal

parameters with their respective standard deviations are presented in Table I. No attempt was made to locate the hydrogen positions in these structures.

RESULTS AND DISCUSSION

The estimated deviations in the bond distances and angles are on the average 0.04 Å and 2° for the bonding parameters in the two structures. The intramolecular bond lengths and angles are shown in Figs. 1 and 2 for the two compounds. In general, these

Figure 2—View of the *erythro*- $\alpha(S)\beta(R)$ -dimethylacetylcholine structure with intramolecular bonding parameters noted.

² A list of the observed and calculated structure factors is in the Health Sciences Library of the State University of New York at Buffalo, and a copy may be obtained from the librarian.

Figure 3—Conformations of the threo- $\alpha(R)\beta(R)$ (a) and erythro- $\alpha(S)\beta(R)$ (b) molecules about the C4-C5 bond.

parameters are similar to one another (*i.e.*, the differences are not highly significant) and are in substantially good agreement with comparable bonds in other structures (5-7). There is, however, a substantial distortion of the angles about C4 and C5 of the *threo*-compound away from tetrahedral symmetry. This angular distortion is an inexpensive way of relieving the overcrowding of the C8 and C9 methyl groups in this structure. The distance between the α - and β -methyl groups is quite similar in the two structures (3.18 Å in the *threo*-structure and 3.11 Å in the *erythro*-molecule), even though the C8-C4-C5-C9 torsion angles are markedly different. In both structures, there is also a slight distortion (not highly significant) of the angles about C4, possibly resulting from nonbonded repulsions between the quaternary methyl groups and the α -methyl group. This effect can also be seen in Fig. 3.

The spatial disposition of the nonhydrogen atoms of an ACh analog can be described in terms of three torsion angles, herein called ϕ_1 , ϕ_2 , and ϕ_3 for the N-C4-C5-O1, C4-C5-O1-C6, and C5-O1-C6-C7 groupings of atoms, respectively.³ These angles are defined in accordance with the Klyne and Prelog (8) rules; for example, the torsion angle for the N-C4-C5-O1 system is the angle between the N-C4 and C5-O1 bonds as viewed down the C4-C5 bond, with a positive value when measured clockwise and a negative value when measured counterclockwise. The values of ϕ_1 , ϕ_2 , and ϕ_3 of these two molecules are compared with those found for some related molecules in Table II.

From molecular models⁴ of the *threo*- and *erythro*-compounds, it is observed that the size of the substituents on the choline residue limits the number of conformations that the two molecules may take up without substantial molecular distortions taking place. Models indicate that the restrictions on ϕ_2 and ϕ_3 are not nearly as great as that on ϕ_1 , but the presence of the β -methyl group will sterically prevent free rotation of ϕ_2 . The ϕ_3 angles of various analogs of ACh (see Table II) are all relatively close to 180°, this value being the preferred conformation for the concerned atoms in primary esters (10).

A model of the $\alpha(S)\beta(R)$ enantiomer of the *erythro*-compound indicates that ϕ_1 values at approximately $-gauche$ and $-trans$ ⁵ would be sterically favored over other possible rotamers. Repulsions between the β -methyl and the acyloxy oxygen atom and with the cationic methyls would make the *trans*-conformation less favorable. The $\alpha(R)\beta(S)$ minima would be at $+gauche$ and $+trans$. For the *threo*- $\alpha(R)\beta(R)$ stereoisomer, models suggest that minima can be placed at approximately $-gauche$ and $-trans$. The *threo*- $\alpha(S)\beta(S)$ molecule would have similar angular minima but with their signs reversed. A very small amount of angular distortion would result in both compounds when ϕ_1 is 180° due to nonbonded repulsion between the β -methyl and quaternary nitrogen methyls; energy needed to overcome this should be small.

³ The quaternary nitrogen methyls are in a staggered pattern relative to C4 and C5. This sterically favored arrangement is typical of quaternary nitrogen compounds (6, 7, and 9) and is not felt to be pertinent to the present discussion.

⁴ C.P.K. atomic models, Ealing Corp., Cambridge, Mass.

⁵ For purposes of simplicity in describing the conformations of ϕ_1 , *gauche* and *trans* are used to refer to angles within the range of 60-90° and 140-180°, respectively. The prefixed sign indicates the preference for a particular configuration.

An estimate of the relative rotational barrier for the interconversion of the *gauche*-*trans*-conformations for the two diastereoisomers is possible from molecular models. This barrier for the *threo*-enantiomers apparently is not very much greater than that for ACh. However, it was only possible to transform the $-gauche$ -form of the erythro- $\alpha(S)\beta(R)$ enantiomorph to the *trans*-conformation with extensive strains in the bonding parameters, suggesting a large energy barrier due to steric factors. Thus, unless some of the *trans*-rotamer was formed in the synthetic process, a very limited concentration of this conformation would be expected in solution.

In the solid-state structures of these materials, only one conformer is found for each molecule. The value of ϕ_1 found for each molecule suggests that the energy difference between the possible rotamers (based on steric considerations) is influenced greatly by intramolecular attractive forces. These may be described as coulombic attraction between the acidic quaternary nitrogen grouping and the basic ester linkage (11). The *threo*-compound's preference for the -143° conformation over the *gauche* one in this structure may result from crystal forces, such as intermolecular Van der Waals' contacts. A 180° rotamer assumes that no intramolecular attraction exists between the quaternary nitrogen group and the basic oxygens.

Although the hydrogens were not located in these structures, molecular models point to the possibility of further stabilization of the two conformations by N-C-H...O interactions. The latter type of "hydrogen bonds" have been implied as stabilizing factors for ACh molecules in both the solid state and solution (6, 12).

Figure 4—Packing arrangement about the iodine in the erythro(\pm)-dimethylacetylcholine structure with shortest contacts noted.

Table II—Conformation Angles and Relative Hydrolytic Rates in the Presence of Acetylcholinesterase of Some ACh Analogs

Compound	ϕ_1	ϕ_2	ϕ_3	Relative Rate ^a	Ref.
ACh Br	77°	79°	167°	100	6
Acetylthiol choline Br	171°	129°	150°	100	11, 14
Acetylselenolcholine I	175°	123°	155°	100 ^b	13, 14
erythro- α (R) β (S)-Di-methyl ACh I	76°	-155°	173°	0 ^c	2

L(+)- β (S)-Methyl ACh I	85°	-147°	175°	54 (46 ^c)	1, 15
D(+)- α (R)-Methyl ACh I	90°	170°	175°	78 (92 ^c)	1, 16
	-148°	176°	177°		

^a Relative to ACh. ^b Rate-determining step different from that in ACh mechanism (14). ^c For racemic mixture.

Further studies are presently being carried out in these laboratories to learn about the conformations of these molecules in solution and the solid state to assess the relative strengths of the intramolecular forces.

No intermolecular contacts in either structure are significantly shorter than the sum of the Van der Waals radii of the atoms or groups involved. The arrangements of molecules about the iodine atoms in these structures are typical of that found in analogous quaternary nitrogen structures (9, 13). The packing arrangement of erythro- α , β -dimethyl ACh molecules about iodine is shown in Fig. 4.

Even though definitive evidence is lacking as to the conformation of ACh analogs in biological systems and at the active site of AChE, it is tempting to speculate on the nature of the substrate-enzyme complex from presently available crystallographic, chemical, and biological data. Pauling has made two such attempts, first suggesting (17) that ϕ_1 may be +60° for the ACh molecule bound to the enzyme and more recently that +150° appears to give "optimum" hydrolytic conditions (18). To make these speculations, it was assumed that only one conformation of the substrate is relevant to the esterase for hydrolysis. However, the data in Table II together with experimental data on conformationally constrained ACh analogs (2, 19, 20) suggest that substrates having ϕ_1 values other than +150° are capable of being hydrolyzed by AChE. Along these lines, recent studies on the muscarinic "receptor" (21) and AChE (22) imply a dual mode of substrate binding, a common anionic site which is flanked by two bonding loci for polar and nonpolar side chains of the quaternary trimethylammonium ligands.

The differences in relative rates of the various compounds in Table II suggest that factors such as the electronic feature of the ester linkage and steric repulsion between the methyl groups of the choline moiety and the enzyme surface are probably as important as the ϕ_1 angle in influencing the kinetic processes involved in AChE hydrolysis and cholinergic activity. The importance of the electronic nature of the ester linkage on this rate process has recently been discussed (11). Although it is tempting to speculate on specifics relating to the enzyme-substrate complex and to structural details of each kinetic step for ACh analogs in general, more structural and kinetic data are needed before a highly probable postulate can be put forth which would account for all the factors.

The authors thank the Computing Center of the State University of New York at Buffalo for use of their facilities (which are supported in part by Grants NSF-GP-7318 and PHS-P07FR0012605).

Note: A neutron diffraction study was very recently completed by T. F. Brennan, F. Ross, W. C. Hamilton, and E. Shefter (unpublished) on the erythro- α , β -dimethylacetylcholine iodide crystals. The results conclusively show that there is no intramolecular C—H...O hydrogen interactions.

Interaction of Ascorbic Acid with Silicic Acid

WEN-HUNG WU, TING-FONG CHIN, and JOHN L. LACH

Abstract □ Interaction of ascorbic acid with silicic acid in the solid state was studied using diffuse reflectance spectroscopic techniques. Surface degradation products from ascorbic acid breakdown were effectively observed using diffuse reflectance spectroscopy, whereas the corresponding transmittance spectral method did not give significant information concerning degradation products. Adsorption of ascorbic acid from methanol solution by silicic acid did not occur. However, after evaporation of the methanol, ascorbic acid did undergo strong interaction with silicic acid, probably through hydrogen bonding. Thermal degradation of ascorbic acid in the adsorbed state was found to be different from that in solution. In acid solution, furfural was a major degradation product; whereas in the adsorbed state, furfural could not be detected.

Keyphrases □ Ascorbic acid-silicic acid—solid-state interaction □ Silicic acid-adsorbed ascorbic acid—stability □ Thermal stability—ascorbic acid □ TLC—analysis □ Diffuse reflectance spectroscopy—analysis

Silicic acid, an almost completely inert adsorbent, has found considerable use as a support in chromatography and as a carrier material for some oil-soluble vitamins and other medicinal agents. The surface of silicic acid consists of a plane of exposed silicon atoms to which are attached covalent surface hydroxyl groups, or silanols, the only important adsorption sites. The adsorbed molecules interact with silanols by hydrogen bonding, in which the adsorbed molecule normally acts as an electron donor (1). Gueyne and Duffaut (2) reported complex formation between an alkaline silicate and organic acids, including ascorbic acid. Strohecker and Henning (3) stated that it is not suitable to employ silica gel plates for quantitative assay of ascorbic acid, since too much is lost on the silica gel. Since a loss of ascorbic acid has also been reported to occur when ascorbic acid is present in a vitamin preparation containing oil-soluble vitamins which have been adsorbed onto silicic acid, this study was undertaken to obtain information concerning the nature of this loss. This study also represents a continuing program in the investigation of drug-excipient interactions.

EXPERIMENTAL

Materials—Ascorbic acid (USP reference standard);¹ L-ascorbic acid, reagent grade, m.p. 190–193°;² silicic acid, average particle diameter, 3 μ ;³ dehydroascorbic acid;⁴ levulinic acid;⁵ furfural;⁶ 2,6-dichlorophenolindophenol sodium;⁷ and 2-diphenylacetyl-1,3-indandione-1-hydrazone, m.p. 241°,⁸ were used.

Apparatus and Methods—All diffuse reflectance spectra (DRS) were taken according to the method of Lach and Bornstein (4)

Table I—Thermal Degradation of Pure Ascorbic Acid at 100°

Time, hr.	Ascorbic Acid Found, mg.	% Degradation	Color Change
0	100	0	White

by using a spectrophotometer equipped with reflectance attachment.⁹

Determination of Ascorbic Acid—This was performed by the dye method described in USP XVII (5).

TLC for Identification of Degradation Products of Ascorbic Acid—Silica gel G plates (0.25 mm.) and a solvent system of chloroform-*n*-heptane (1:8) were used. Ten grams of darkened sample containing silicic acid, ascorbic acid, and its degradation products was continuously extracted in a continuous extraction apparatus with anhydrous ether for 24 hr. The ethereal extract was concentrated to 1 ml. and then reacted with 2-diphenylacetyl-1,3-indandione-1-hydrazone (DIH) in a mixture of methanol and chloroform using 1 drop hydrochloric acid as a catalyst. The solution was spotted on a plate together with chloroform solutions of a reaction product of furfural and DIH (F-DIH), levulinic acid and DIH (L-DIH), and DIH itself. After development, the plates were examined under UV light. Since DIH shows a bright-yellow fluorescence under UV light,

RESULTS AND DISCUSSION

Stability of ascorbic acid in the solid state was first studied by heating 100 mg. each of finely powdered ascorbic acid in a number of 50-ml. beakers in a dry oven at $100 \pm 0.5^\circ$. Quantitative determination of these solid samples was followed at varying time intervals, and the results are shown in Table I. The data in this table indicate that there is no apparent relationship between degradation of ascorbic acid and color change. It is probable that only the surface layer of each ascorbic acid particle was decomposed and that this degradation product(s) could act as a protecting film so that no further decomposition was observed within the time interval studied. Thermal stability of ascorbic acid has been previously studied by several workers (6-8), and their results indicated that pure ascorbic acid is thermally stable at elevated temperatures.

Since silicic acid is known to adsorb various compounds, adsorption of ascorbic acid by silicic acid in methanol solution was undertaken. Ten milligrams of ascorbic acid in 10 ml. methanol was equilibrated with varying quantities of silicic acid for 18 hr. under nitrogen; after centrifugation, the concentration of ascorbic acid in the clear supernatant liquid was determined, and the results are shown in Table II. Since the amount of ascorbic acid that remained in solution phase was approximately constant, it may be concluded that the adsorption of ascorbic acid by silicic acid from the methanol solution was negligible.

However, after complete evaporation of methanol in such equilibrated systems, ascorbic acid was strongly adsorbed to silicic acid since this acid was only very slowly removed from the adsorbent surface by metaphosphoric-acetic acids T.S. This is shown in Fig. 1, Curve A, in which 20 mg. of ascorbic acid/g. of

silicic acid was equilibrated in methanol under nitrogen and the solvent evaporated at room temperature under vacuum. Accurately weighed portions of this dried sample were then titrated under nitrogen or after stirring at constant speed for a specified time. As is seen in Fig. 1, approximately 80 min. was required for desorption to occur. These results indicate that ascorbic acid is adsorbed to silicic acid on removal of the methanol and that this adsorption probably occurs through hydrogen bonding between the silanols on the silicic acid and the carbonyl oxygen of ascorbic acid. The lack of quantitative desorption of ascorbic acid as seen in Fig. 1, Curve A, may be attributed to its oxidation in the adsorbed state and will be discussed later.

Stability aspects of ascorbic acid adsorbed on silicic acid were also carried out. Portions of the methanol-equilibrated and vacuum-dried samples were heated at $100 \pm 0.5^\circ$ in a dry oven, and at various time intervals the intact ascorbic acid was determined. The results are shown in Fig. 1, Curves B-D. From this figure and Table

I, it is evident that degradation of ascorbic acid is significantly greater in the adsorbed state than in pure powder form. This accelerated degradation rate may be due simply to a difference in the total surface area, since in this adsorbed state a larger number of ascorbic acid molecules are available for degradation than in the surface of the pure powder. Or it may be due to the fact that in this adsorbed state, as shown in Scheme I, hydrogen bond formation between the carbonyl oxygen of ascorbic acid and the silanol

Scheme I

hydrogen requires a strong bonding of the lone pair electrons on the carbonyl oxygen to the silanol hydrogen. This can induce a general electron shift through the α,β -enone π -orbitals toward this new bond, so that the dissociation of the two hydroxy hydrogens on the

Figure 3—Correlation of reflectance and degradation of ascorbic acid in adsorbed state.

2- and 3-positions in ascorbic acid is enhanced. This increased dissociation may facilitate the oxidation of ascorbic acid to various carbonyl compounds, presumably through dehydroascorbic acid.

The degradation of pure ascorbic acid in the solid state was also studied using DRS. When a portion of the faintly yellow sample shown in Table I was appropriately diluted with acidified water and the transmittance spectrum taken, the solution showed an absorption maximum at 245 m μ . However, when another portion of the same sample was mixed with silicic acid and the reflectance spectrum taken, two absorption maxima appeared. The one at 245 m μ corresponded to the transmittance spectrum of the acidified ascorbic acid solution. The other, which appeared at 275 m μ , might be a composite maximum due to the various carbonyl compounds produced from the surface degradation of ascorbic acid. Although the quantity of degradation products formed from pure ascorbic acid was small, as shown in Table I, they are mainly concentrated on the surface and are effectively shown in the reflectance spectrum. However, in solution state, they are homogeneously mixed with the intact ascorbic acid molecules, so that the overwhelming amount of ascorbic acid present can sufficiently mask any spectral effects of this small quantity of degradation products. This clearly illustrates the advantage of the DRS method in studying degradation occurring at the surfaces.

When 60 mg. of ascorbic acid was equilibrated with 1 g. of silicic acid in methylene chloride and the dried sample was heated at $100 \pm 0.5^\circ$, the reflectance spectra taken at varying time intervals showed different intensities; these are given in Fig. 2. As is illustrated in this figure, the intensity of the maximum at 245 m μ gradually decreased with time, whereas a new maximum at about 300 m μ appeared with increasing intensity. This second maximum at 300 m μ is different from that observed in the degradation of pure ascorbic acid, in which case the second maximum appeared at 275 m μ . This suggests that the degradative mechanisms might be different. Along with the spectra, quantitative determinations of ascorbic acid in these equilibrated and heated samples were carried out, and the results are shown in Table III and Fig. 3. For purposes of comparison, reflectance readings, r_{∞} , at 245 m μ were converted to remission functions, $f(r_{\infty})$ since the remission function is directly related to concentration (9). Examination of Fig. 3 does show this remission function concentration dependency which is maintained in the degraded sample, suggesting that quantitized degradation in the solid state can be studied by this technique.

With respect to ascorbic acid it is interesting to note that its degradation products from aqueous solution have been determined by Otani (10) using TLC, and reported to be dehydroascorbic acid, 2,3-diketo-1-gulonic acid, 2-keto-1-gulonic acid, and furfural. Formation of furfural from aqueous solution of ascorbic acid was also discussed by various workers (11-13), the rate of furfural formation being studied in detail by Finholt *et al.* (14).

However, in the present study furfural was not found as part of the degradation products resulting from the breakdown of ascorbic acid in the adsorbed state. Instead, levulinic acid was detected

on thin-layer plates as described in the *Experimental* section. The DIH reagent was used because of its high reactivity toward carbonyl compounds (15, 16). Thermal degradation products of this ascorbic acid-silicic acid system are shown in Fig. 4. Examination of the chromatogram does indicate the absence of furfural, the possible presence of levulinic acid, and, in addition, other unidentified degradation products, and strongly suggests that ascorbic acid in this adsorbed state undergoes a different type of degradation from that in aqueous solution. Although furfural was not detected in this system, it is still possible that any furfural formed could have volatilized from the solid surface or undergone polymerization. It is highly unlikely, however, that levulinic acid results from furfural degradation, since Lamden and Harris (11) pointed out that the formation of furfural in solution degradation does not result from dehydroascorbic acid which, as mentioned before, is probably the first step in the oxidation of ascorbic acid in the adsorbed state. It is, therefore, highly likely that the degradation pathway in the adsorbed state may be quite different from that in solution.

Electrostatic Interaction of Oil Droplets with Adsorbed Surface-Active Ions in Dilute Electrolyte Solutions

N. F. H. HO, A. SUZUKI*, and W. I. HIGUCHI

Abstract □ Using the Haydon-Taylor model in which the surfactant head groups are situated at some distance from the oil surface, the interaction energy of electrostatic repulsion (V_R) between oil droplets in dilute electrolyte solutions is derived for the two cases: constant-surface potential and constant-surface charge. For comparison, the repulsive energy is also derived for the constant-surface charge case without the effect of this adsorbed layer model. The Haydon-Taylor model accounts for the penetrability of the electrolyte and dielectric constant in the adsorbed surfactant layer of varying thickness, the degree of surface coverage, particle-size effect, ionic strength, and the dielectric constant in the bulk solution. In the constant-potential case, the resulting V_R equation is identical to the classical Derjaguin, Landau, Verwey, and Overbeek (DLVO) one. Computations show that as flat plates and spheres approach each other, V_R (constant-surface charge with impenetrable adsorbed layer) $> V_R$ (constant-surface charge with penetrable adsorbed layer) $> V_R$ (constant-surface potential). Because of the possible 50- to 100-fold difference in magnitude between them, proper choice of the model is important when considering application of the theory to the rigorous kinetic treatment of the coalescence of o/w emulsions and flocculation of suspensions.

Keyphrases □ Oil droplets, electrostatic interaction—adsorbed surface-active ions □ Electrolyte solutions—oil droplets, adsorbed surface-active ion interaction □ Repulsive interaction—flat plates, spheres □ Emulsions—particle collision probability

In those dispersed systems in which the primary barrier to flocculation (or coalescence) is electrical, the classical theory of the repulsive interaction of overlap-

ping electrical double layers between two particles combined with the attractive interaction due to dispersion forces is used. Moreover, the usual model employed for the repulsive energy requires that the surface potential remains constant during the collision of particles, although the model on constant-surface charge, in which case the surface potential increases during the encounter, is applicable in most dispersed systems (1).

Frens *et al.* (2, 3) showed that the collision of silver iodide colloidal particles in aqueous electrolyte solutions was more appropriately explained by the constant-surface charge condition. They employed the exact solution of the Poisson-Boltzmann equation in the form of elliptical integrals. Recently, while examining the question of the surface potential or charge remaining constant during the mutual approach of particles, Jones and Levine (4) derived approximate expressions in series form, and Muller (5) derived exact equations expressed as elliptical integrals.

Haydon and Taylor (6-8) proposed a model for the adsorption of ionic surface-active agents at the oil/water interface, allowing for the penetration of mobile ions into the adsorbed layer of surfactant molecules situated at some equilibrium distance from the interface. They calculated the potential in the aqueous surface phase and related it to surface-pressure area measurements. The Poisson-Boltzmann equation was

on thin-layer plates as described in the *Experimental* section. The DIH reagent was used because of its high reactivity toward carbonyl compounds (15, 16). Thermal degradation products of this ascorbic acid-silicic acid system are shown in Fig. 4. Examination of the chromatogram does indicate the absence of furfural, the possible presence of levulinic acid, and, in addition, other unidentified degradation products, and strongly suggests that ascorbic acid in this adsorbed state undergoes a different type of degradation from that in aqueous solution. Although furfural was not detected in this system, it is still possible that any furfural formed could have volatilized from the solid surface or undergone polymerization. It is highly unlikely, however, that levulinic acid results from furfural degradation, since Lamden and Harris (11) pointed out that the formation of furfural in solution degradation does not result from dehydroascorbic acid which, as mentioned before, is probably the first step in the oxidation of ascorbic acid in the adsorbed state. It is, therefore, highly likely that the degradation pathway in the adsorbed state may be quite different from that in solution.

Electrostatic Interaction of Oil Droplets with Adsorbed Surface-Active Ions in Dilute Electrolyte Solutions

N. F. H. HO, A. SUZUKI*, and W. I. HIGUCHI

Abstract □ Using the Haydon-Taylor model in which the surfactant head groups are situated at some distance from the oil surface, the interaction energy of electrostatic repulsion (V_R) between oil droplets in dilute electrolyte solutions is derived for the two cases: constant-surface potential and constant-surface charge. For comparison, the repulsive energy is also derived for the constant-surface charge case without the effect of this adsorbed layer model. The Haydon-Taylor model accounts for the penetrability of the electrolyte and dielectric constant in the adsorbed surfactant layer of varying thickness, the degree of surface coverage, particle-size effect, ionic strength, and the dielectric constant in the bulk solution. In the constant-potential case, the resulting V_R equation is identical to the classical Derjaguin, Landau, Verwey, and Overbeek (DLVO) one. Computations show that as flat plates and spheres approach each other, V_R (constant-surface charge with impenetrable adsorbed layer) $> V_R$ (constant-surface charge with penetrable adsorbed layer) $> V_R$ (constant-surface potential). Because of the possible 50- to 100-fold difference in magnitude between them, proper choice of the model is important when considering application of the theory to the rigorous kinetic treatment of the coalescence of o/w emulsions and flocculation of suspensions.

Keyphrases □ Oil droplets, electrostatic interaction—adsorbed surface-active ions □ Electrolyte solutions—oil droplets, adsorbed surface-active ion interaction □ Repulsive interaction—flat plates, spheres □ Emulsions—particle collision probability

In those dispersed systems in which the primary barrier to flocculation (or coalescence) is electrical, the classical theory of the repulsive interaction of overlap-

ping electrical double layers between two particles combined with the attractive interaction due to dispersion forces is used. Moreover, the usual model employed for the repulsive energy requires that the surface potential remains constant during the collision of particles, although the model on constant-surface charge, in which case the surface potential increases during the encounter, is applicable in most dispersed systems (1).

Frens *et al.* (2, 3) showed that the collision of silver iodide colloidal particles in aqueous electrolyte solutions was more appropriately explained by the constant-surface charge condition. They employed the exact solution of the Poisson-Boltzmann equation in the form of elliptical integrals. Recently, while examining the question of the surface potential or charge remaining constant during the mutual approach of particles, Jones and Levine (4) derived approximate expressions in series form, and Muller (5) derived exact equations expressed as elliptical integrals.

Haydon and Taylor (6-8) proposed a model for the adsorption of ionic surface-active agents at the oil/water interface, allowing for the penetration of mobile ions into the adsorbed layer of surfactant molecules situated at some equilibrium distance from the interface. They calculated the potential in the aqueous surface phase and related it to surface-pressure area measurements. The Poisson-Boltzmann equation was

Figure 1—Distribution of potential between weakly interacting electrical double layers of oil droplets in a dilute electrolyte solution with an ionic surfactant layer extending from the o/w interface. Region I is the surfactant layer penetrable to small ions and Region II is the bulk solution.

assumed and applied to both sides of the plane of the head groups. Levine *et al.* (9) criticized Haydon and Taylor's mathematical estimation of the extended equilibrium distance of the ionized monolayer and pointed out that the assumption of a Boltzmann distribution of penetrating counterions behind the plane of the ionized monolayer becomes physically somewhat unrealistic in the limit that the available space for ion penetration becomes small as compared to the size of the penetrating ion. Recently, Gingell (10, 11) used the model to calculate the changes in the potential in the surface and aqueous phases between two approaching particles as a possible physical mechanism for intercellular interactions. The purposes of this paper are to utilize the model for interacting particles to derive simple expressions for the repulsive energy of interaction at constant-surface charge and to compare them with the usual energy expressions for constant-surface potential. As will be seen, this becomes necessary for the rigorous study of the kinetics of flocculation (or coalescence) of emulsions whereby one accounts for the probability of random collision of the entire particle-size distribution through Smoluchowski's fundamental equation and Fuchs' stability factor (12, 13). The results of this paper can also apply to suspensions.

THEORY

The Haydon-Taylor model for o/w emulsions containing ionic surfactants in dilute electrolyte solutions is assumed. The adsorbed surfactant molecules at the o/w interface are arranged in such a manner that the ionized head groups extend to some distance from the interface (Fig. 1). To treat the interaction energy of electrostatic repulsion between two oil droplets by way of the energy of interaction between two flat plates, the following system is used.

1. Region I, in which ($-\delta \leq x \leq 0$) and ($2d \leq x \leq 2d + \delta$), is the

Figure 2—Comparison of repulsive energy profiles for constant-surface charge, constant-surface charge with a penetrable surfactant layer, and constant charge with an impenetrable surfactant layer models for two equal spheres; $\psi_0 = \psi_{0,\infty} = 10$ and 25 mv., $\kappa = 10^7$ cm.⁻¹, $\epsilon = 80$, $\epsilon_I = 4$, $a = 1.0 \mu$, $\delta = 1/\kappa$ cm., and $\alpha^2 = 0.75$.

region of the adsorbed surfactant layer and with the dielectric constant ϵ_I . The surface-active ions are mobile, and the ionic head assumes an equilibrium distance δ from the o/w interface. Since solvent and electrolyte are allowed to penetrate this layer, there is an α^2 , the volume fraction of this region accessible to small ions, and the characteristic κ_I , the reciprocal Debye-Hückel length. The o/w interface is uncharged, and there is no penetration of ions into the oil phase, thus requiring that $(d\psi/dx)_{-\delta} = 0$ (9).

2. Region II, in which ($0 \leq x \leq 2d$), is the region of the bulk aqueous phase of dielectric constant ϵ and reciprocal length parameter κ . The size of the surface-active head group is neglected.

Repulsive Interaction between Similar Flat Plates—Assuming the modified Gouy-Chapman model of the electrical double layer for a flat plate and the linearized Debye-Hückel approximation for small potentials (<25 mv.), the resulting Poisson equations are:

$$\text{Region I: } \frac{d^2\psi}{dx^2} = \alpha^2 \kappa_I^2 \psi \quad (\text{Eq. 1})$$

$$\text{Region II: } \frac{d^2\psi}{dx^2} = \kappa^2 \psi \quad (\text{Eq. 2})$$

where ψ is the potential and the other terms are previously defined. When the boundary conditions for the left plate are applied, *i.e.*,

$$\text{Region I: } \psi = \psi_0 \text{ at } x = 0$$

$$\frac{d\psi}{dx} = 0 \text{ at } x = -\delta$$

$$\text{Region II: } \psi = \psi_0 \text{ at } x = 0$$

$$\frac{d\psi}{dx} = 0 \text{ and } \psi = \psi_d \text{ at } x = d$$

Figure 3—Comparison of total potential energy profiles between three interacting double-layer models; $\psi_0 = \psi_{0,\infty} = 25$ mv., $\kappa = 10^7$ cm.⁻¹, $\epsilon = 80$, $\epsilon_I = 10$, $a = 0.5$ μ , $\delta = 1/\kappa$ cm., and $\alpha^2 = 0.75$.

the solutions to Eqs. 1 and 2, respectively, are

$$\psi_{I,L} = \frac{\psi_0 \cosh \alpha \kappa_I (\delta + x)}{\cosh \alpha \kappa_I \delta} \quad (\text{Eq. 3})$$

$(-\delta \leq x \leq 0)$

$$\psi_{II,L} = \frac{\psi_0 \cosh \kappa (d - x)}{\cosh \kappa d} \quad (\text{Eq. 4})$$

$(0 \leq x \leq d)$

For the corresponding right plate,

$$\psi_{I,R} = \frac{\psi_0 \cosh \alpha \kappa_I (2d + \delta - x)}{\cosh \alpha \kappa_I \delta} \quad (\text{Eq. 5})$$

$(2d \leq x \leq 2d + \delta)$

$$\psi_{II,R} = \frac{\psi_0 \cosh \kappa (x - d)}{\cosh \kappa d} \quad (\text{Eq. 6})$$

$(d \leq x \leq 2d)$

The surface charge density for the left plate is defined by

$$\sigma_L = \frac{\epsilon_I}{4\pi} \int_{-\delta}^0 \left(\frac{d^2 \psi}{dx^2} \right)_I dx + \frac{\epsilon}{4\pi} \int_0^d \left(\frac{d^2 \psi}{dx^2} \right)_{II} dx \quad (\text{Eq. 7})$$

$$\sigma_L = \frac{\psi_0 \epsilon \kappa}{4\pi} \left[\frac{\alpha}{b} \tanh \alpha b \kappa \delta + \tanh \kappa d \right] \quad (\text{Eq. 8})$$

where $b^2 = \epsilon/\epsilon_I \geq 1$ and, consequently, $\kappa_I = b\kappa$. It can be shown from the symmetry of the system that

$$\sigma_L = \sigma_R \quad (\text{Eq. 9})$$

Depending upon the case when the surface potential or charge is constant, Eq. 8 expresses each parameter as a function of plate distances.

When the plates are brought together from infinity, the general expression for the potential energy of repulsion is

$$V_{R(P/P)} = F_{2d} - F_\infty \quad (\text{Eq. 10})$$

Figure 4—Effect of the dielectric constant in the penetrable ionic surfactant layer on the repulsive energy of interaction between two equal spheres under the condition of constant charge; $\psi_{0,\infty} = 25$ mv., $\kappa = 10^7$ cm.⁻¹, $\epsilon_I = 80$, $a = 1.0$ μ , $\delta = 1/\kappa$ cm., and $\alpha^2 = 0.75$.

If the surface potential, ψ_0 , is constant and small and the potential between the interacting plates is equal to the sum of the potentials of the individual double layers, the free energy of the two similar plates (14) can be approximated by

$$F_{2d} = -\frac{1}{2}(\sigma_L \psi_{0L} + \sigma_R \psi_{0R}) \quad (\text{Eq. 11})$$

$= -\sigma \psi_0$

and

$$F_\infty = \lim_{2d \rightarrow \infty} F_{2d} \quad (\text{Eq. 12})$$

After substituting for σ from Eq. 8 into Eqs. 11 and 12, the potential energy is

$$V_{R(P/P)} = \frac{\epsilon \kappa \psi_0^2}{4\pi} (1 - \tanh \kappa d) \quad (\text{Eq. 13})$$

$$\psi_0 = \text{const.}$$

On the other hand, if the surface charge density, σ , is considered to be constant and small,

$$F_{2d} = \frac{1}{2}(\sigma_L \psi_{0L} + \sigma_R \psi_{0R}) \quad (\text{Eq. 14})$$

$= \sigma \psi_0$

Substituting for ψ_0 from Eq. 8 into Eqs. 14 and 12,

$$V_{R(P/P)} = \frac{4\pi \sigma^2}{\epsilon \kappa} \left[\frac{1 - \tanh \kappa d}{(A + 1)(A + \tanh \kappa d)} \right] \quad (\text{Eq. 15})$$

$$\sigma = \text{const.}$$

Table I—Influence of the Constant Potential and Charge Repulsive Energy Models on the Collision Probability of Equal Spherical Particles^a

ψ_0 , mv.	$\ln W\sigma/W\psi_0$	$W\sigma/W\psi_0$
5	3.91	5.00×10^1
10	15.65	6.26×10^6
15	35.21	1.95×10^{14}
20	62.60	1.52×10^{25}
25	97.81	$\gg 10^{25}$

^a $a = 1.0 \mu$, $\epsilon = 80$, $\kappa H_m \sim 1$.

where $A = \alpha/b \tanh \alpha b \kappa \delta$ ($0 \leq A < 1$). However, it is recognized from Eq. 8 that because the plates are infinitely apart, the constant-surface charge is

$$\sigma = \frac{\epsilon \kappa}{4\pi} \psi_{0,\infty} (A + 1) \quad (\text{Eq. 16})$$

where $\psi_{0,\infty}$ is the surface potential of a single double layer and is comparable in magnitude to the ζ -potential. Thus, Eq. 15 may be expressed again by

$$V_{R(P/P)} = \frac{\epsilon \kappa \psi_{0,\infty}^2 (A + 1)}{4\pi} \left(\frac{1 - \tanh \kappa d}{A + \tanh \kappa d} \right) \quad (\text{Eq. 17})$$

$$\sigma = \text{const.}$$

If Region I of the adsorbed layer is impenetrable to small ions, *i.e.*, $A = 0$, then Eq. 17 reduces to the interaction energy of repulsion for a classical flat-plate model at constant-surface charge:

$$V_{R(P/P)} = \frac{\epsilon \kappa \psi_{0,\infty}^2}{4\pi} \left(\frac{1 - \tanh \kappa d}{\tanh \kappa d} \right) \quad (\text{Eq. 18})$$

$$\sigma = \text{const.}$$

Repulsive Interaction between Spheres—It has already been shown that the approximate interaction energy of repulsion between two spheres can be derived *via* the flat, double-layer approach (15). In general,

$$V_{R(S/S)} = \frac{2\pi a_1 a_2}{a_1 + a_2} \int_H^\infty V_{R(P/P)} dH \quad (\text{Eq. 19})$$

$$(a_1, a_2 \gg H)$$

$$(\kappa a_1, \kappa a_2 \gg 1)$$

where a_1 and a_2 are the radii of the corresponding spheres, and H is identical to $2d$ for the plate distances. Analogous to the various cases of $V_{R(P/P)}$ in the previous section, it follows that:

(a) If ψ_0 is constant,

$$V_{R(S/S)} = \frac{\epsilon a_1 a_2}{a_1 + a_2} \psi_0^2 \ln(1 + e^{-\kappa H}) \quad (\text{Eq. 20})$$

(b) If σ is constant and the adsorbed ionic surfactant layer model is assumed,

$$V_{R(S/S)} = \frac{\epsilon a_1 a_2 (A + 1)}{(a_1 + a_2)(A - 1)} \psi_{0,\infty}^2 \ln \left[1 + \frac{(A - 1)}{(A + 1)} e^{-\kappa H} \right] \quad (\text{Eq. 21})$$

(c) If σ is constant and the adsorbed layer is impenetrable to small ions,

$$V_{R(S/S)} = \frac{\epsilon a_1 a_2}{(a_1 + a_2)} \psi_{0,\infty}^2 \ln \left(\frac{1}{1 - e^{-\kappa H}} \right) \quad (\text{Eq. 22})$$

It is noteworthy that, in the constant-surface potential case, the resulting $V_{R(S/S)}$ of Eq. 20 is identical to the classical DLVO one (16). It is implicit in Eqs. 17, 18, 21, and 22 that the potential at the surface (ψ_0) increases as the two particles approach each other. In the limit of $a_1 \gg a_2$, the interaction energy of repulsion for a sphere and a plane can be approximated. Here, the energy is dependent upon the particle with the smallest radius of curvature.

Table II—Correction to the ζ -Potential for the Usual Constant-Surface Potential Model of Repulsion Energy Used when the Constant-Surface Charge Case Is the Physically Applicable Model^a

ζ , mv.	ψ_0 , mv.	
	$\kappa H_m = 0.5$	$\kappa H_m = 1$
10	14.0	12.1
15	21.1	18.2

30	42.1	36.3
50	70.2	60.5

^a Calculations based on Eq. 26 assuming $\zeta \simeq \psi_{0,\infty}$.

It is possible to estimate the volume fraction α^2 in Region I accessible to small ions in terms of the surface charge density:

$$\alpha^2 = 1 - \frac{3r^2 \delta \sigma}{a} \quad (\text{Eq. 23})$$

where r is the radius of the surfactant chain taken as a cylinder.

RESULTS AND DISCUSSION

Significance of the Repulsive Energy Models on Emulsion Stability—Computation employing Eqs. 20–22 were carried out for a range of conditions. Figure 2 shows that as two particles approach each other, V_R (constant σ without the effect of the adsorbed layer

Figure 5—Effect of the thickness of the adsorbed surfactant layer on the repulsive energy between two equal spheres under the condition of constant charge; $\psi_{0,\infty} = 25$ mv., $\kappa = 10^7$ cm.⁻¹, $\epsilon = 80$, $\epsilon_f = 4$, $a = 1.0 \mu$, and $\alpha^2 = 0.75$.

Figure 6—Effect of the volume in the adsorbed layer available for ion penetration on the repulsive energy curve; $\psi_{0,\infty} = 25$ mv., $\kappa = 10^7$ cm.⁻¹, $\epsilon = 80$, $\epsilon_1 = 4$, $a = 1.0$ μ , and $\delta = 1/\kappa$ cm.

model) $> V_R$ (constant σ with effect of the model) $> V_R$ (constant ψ_0). Because a 50- to 100-fold difference in magnitude may exist between the three cases at close interparticle distances under certain environmental conditions, i.e., in the order of $0.5/\kappa$ to $1/\kappa$ cm., the proper choice becomes important when one desires to apply it to the rigorous treatment of the coalescence of o/w emulsions and also the flocculation of suspensions. At far distances, the V_R 's of the three models approach the same asymptotic values.

To illustrate the importance of the proper choice of the repulsive energy model to predict emulsion stability, consider the two extreme models: V_R (ψ_0 constant) and V_R (σ constant for an ion-impenetrable adsorbed surfactant layer). In general, the probability of collision between two equal spheres is given by the reciprocal of

$$W \sim \frac{1}{2\kappa a} e^{V_{T\max.}/kT} \quad (W \geq 1) \quad (\text{Eq. 24})$$

where W is the Fuchs probability factor, and $V_{T\max.}$ is the maximum in a potential energy curve consisting of the sum of the repulsive and attractive energy of interaction ($V_T = V_R + V_A$). Using Eqs. 20, 22, and 24, it can be shown that

$$\ln \frac{W_{\sigma\text{const.}}}{W_{\psi_0\text{const.}}} = \left(\frac{V_{R\max.}}{\sigma_{\text{const.}}} - \frac{V_{R\max.}}{\psi_{0\text{const.}}} \right) / kT \quad (\text{Eq. 25})$$

The results of Eq. 25 for $1.0\text{-}\mu$ radius particles in a dilute electrolyte solution, in which the minimum interparticle distance H_m is approximately $1/\kappa$ cm., are found in Table I. Usually, the V_R (ψ_0 constant) model is used to describe the electrostatic barrier, in which case there must be rapid equilibrium of desorption and ad-

sorption of surface charges during collision. However, in most physical systems it is more reasonable that the surface charge remains constant during the encounter, in which case the double-layer overlap leads to an increase in ψ_0 (1). Therefore, depending upon the model chosen, it becomes evident from Table I that one can overestimate or underestimate the probability of collision (or emulsion and suspension stability) by many orders of magnitude. In Fig. 3 the total potential energy curve illustrates another example. There are experimental evidences that may be explained in part by the constant-surface charge model. In the study of the flocculation of latex particles, Higuchi *et al.* (17) required higher concentrations of electrolyte to reproduce the same initial rate, despite repeated efforts to purify the particles. Also, Johnson *et al.* (18) obtained stable arachidic acid sols at zero ζ -potential. However, later they showed some evidence that the structuring of water about the particles might provide an additional repulsive factor (19).

This discussion leads to the questionable use of ζ -potential measurements to predict the stability of dilute aqueous dispersions in which the primary barrier is electrical. Again consider the two extreme cases and equate Eqs. 20 and 22. It follows that

$$\frac{\psi_0^2}{\psi_{0,\infty}^2} = - \frac{\ln(1 - e^{-\kappa H_m})}{\ln(1 + e^{-\kappa H_m})} \quad (\text{Eq. 26})$$

and some results are shown in Table II. If Eq. 20 is used to estimate the repulsive interaction energy and collision probability and if the constant-surface charge model is more correct, then one should use a surface potential higher in magnitude than the observed ζ -potential ($\zeta \simeq \psi_{0,\infty}$). From a practical viewpoint, the low absolute value of the ζ -potential may underestimate the degree of repulsive interaction and stability of a system unless the potential is sufficiently high so that it does not make a difference.

Repulsive Energy According to the Penetrable Adsorbed-Layer Model—To study the behavior of the properties of the adsorbed

Figure 7—Effect of the particle size of two spheres on the repulsive energy curve; $\psi_{0,\infty} = 25$ mv., $\kappa = 10^7$ cm.⁻¹, $\epsilon = 80$, $\epsilon_1 = 4$, $\delta = 1/\kappa$ cm., and $\alpha^2 = 0.75$.

Figure 8—Effect of the electrolyte concentration on the repulsive energy curve; $\psi_{0,\infty} = 25$ mv., $\epsilon = 80$, $\epsilon_I = 4$, $a = 1.0 \mu$, $\delta = 1/\kappa$ cm., and $\alpha^2 = 0.75$.

layer of ionic surfactant on the interaction energy of repulsion, Eq. 21 was used. Figures 4–6 show that a decrease in dielectric constant, the thickness of the adsorbed layer, or the volume fraction of the adsorbed layer accessible to small ion penetration leads to a V_R larger in magnitude than that for the opposite situation and, in effect, makes the layer less penetrable to small ions. The thickness of the layer is about 3–10 Å. The low dielectric constant of the solvent in the layer affects the solubility and ionic distribution. Usually, the dielectric constant of the bulk aqueous solution is taken to be 80, while that in the layer is considerably lower, perhaps 4–10.

It is observed that the V_R (constant-surface charge) of the adsorbed-layer model approaches V_R (constant-surface potential) at close particle separations as the values of ϵ_I , δ , and α^2 are increased. The greater penetrability of ions leads to a more effective screening of the surface charges and a decrease in the interaction energy.

In Fig. 7, it is seen how the particle size has a marked effect on the magnitude of the repulsive energy and a consequential increase in the preference for coalescence (or flocculation) of small particles over larger ones. The usual influence of the electrolyte concentration on the V_R versus H profiles is shown in Fig. 8.

CONCLUSION

In an o/w emulsion, in which the change in the particle-size distribution with time appears to occur primarily through droplet-droplet coalescence after overcoming an electrostatic barrier to the encounter, the repulsive energy of the constant-surface potential model may prevail in the initial kinetic history of the emulsion. The surface coverage of ionic surfactants is low in a freshly prepared emulsion, say about 5–10% of maximum coverage. Here it is believed that rapid equilibrium of desorption and adsorption of surfactant molecules occurs during the close approach of the droplets. However, at later periods when the total surface area of the system is smaller and the surface coverage higher, the repulsive energy according to the Haydon-Taylor model under the condition of constant-surface charge may then prevail. Intermediate situations between these two periods are also conceivable. Kinetic studies of this nature are being conducted on o/w emulsions with ionic surfactants utilizing Smoluchowski's fundamental flocculation equation treatment reported in an earlier paper (13).

Molecular-Scale Drug Entrapment as a Precise Method of Controlled Drug Release I: Entrapment of Cationic Drugs by Polymeric Flocculation

HARRIS GOODMAN* and GILBERT S. BANKER

Abstract □ A system of molecular-scale drug entrapment has been developed which provides a physicochemical and highly reproducible method of effecting drug entrapment and subsequent controlled drug release from polymeric matrices. The flocculation of highly concentrated colloidal polymeric dispersions (latices), in the presence of the drug in solution which is to be occluded, provides the entrapment mechanism. A solid-state, highly reproducible molecular entrapment combination of methapyrilene hydrochloride and an acrylic copolymer was prepared and evaluated for sustained-action characteristics. A significant increased duration of action and a reduction of the acute toxicity of methapyrilene in the entrapped form were established by *in vivo* effectiveness studies. The broad application of the entrapment process to acid salts of 11 widely used cationic nitrogen-containing drugs was demonstrated.

Keyphrases □ Polymeric flocculation—cationic drug entrapment □ Flocculation, polymeric—drug-concentration effect □ Drug release, controlled—polymeric matrices □ Release rates—drugs in polymeric matrices □ Dialysis—methapyrilene-polymer, binding determination

Potential and alteration of drug action have been of interest to the medical and pharmaceutical professions for many years. In the last 15 years, prolongation of the therapeutic effects of orally administered medicinals has become of prime interest and concern to the industrial pharmacist.

The methods employed for the production of sustained-action dosage forms can be broadly classified into two categories: physicochemical and mechanical. These can be further subdivided into various groups such as gastroresistant coatings, chemical complexes, drug embedments, and ion-exchange techniques.

The majority of the methods employed are based on some type of gross embedment or coating of the medication to yield the desired effects. The procedures are usually time consuming and laborious, involve mechanical techniques which are difficult to control, and in many cases result in products with excessive variability. Much of this variability can probably be traced to the product design and methods of production.

If optimization of drug action through controlled drug delivery rates from solid oral dosage forms is to become a reality, precise physicochemical methods of controlling drug release must replace earlier empirical and mechanical controlled-release methods.

This investigation was motivated by the need for a simple and highly reproducible procedure for drug entrapment and the development of controlled-release dosage forms employing this principle. The purpose of this study was to investigate the applicability of a molecular entrapment phenomenon as a unique approach to sustained-action dosage forms. The major objectives were:

1. The investigation of the properties of various polymeric materials as they would apply to a sustained-

release mechanism based on molecular scale, solid-state entrapment of drugs.

2. The utilization and investigation of a process exhibiting broad application to the molecular entrapment of drugs.

3. The *in vitro* and *in vivo* evaluations of the sustained-action characteristics and activity of a polymer-drug entrapment system.

EXPERIMENTAL

Materials and Equipment—A linear, anionically charged, acrylic copolymer¹ composed of acrylic and methacrylic acids and esters and having a molecular weight exceeding 300,000 was supplied in an emulsion (latex) form, containing $40 \pm 0.5\%$ solids. Also used were other polymeric materials evaluated as possible entrapment media.^{2,3,4}

The drugs studied were NF or USP grade; where appropriate, the purity was checked by melting point and chloride determinations.

Particle-size reduction and classification of all polymer and polymer-drug systems were accomplished using a comminuting machine (Fitzpatrick model M) and a series of standard sieves. All pH determinations were made on a pH meter (Beckman model N) equipped with a glass electrode (Beckman type E-2). A constant-temperature bath equipped with a mechanism for the rotation of sample bottles, similar to that reported by Souder and Ellenbogen (1), was employed for *in vitro* release-rate studies.

Initial Polymer Screening—Based on a polymer literature screening of toxicity and physical properties, the following polymers were chosen for initial study and aqueous solubility characterization: (a) acrylic copolymer emulsion,¹ (b) carbohydrate polymers,² (c) polyethylene glycol,³ and (d) a sodium polyacrylate solution.⁴

Samples evaluated for solubility characteristics were comminuted, and the fraction passing a 60-mesh screen was employed. The two acrylic acid derivatives (the acrylic copolymer emulsion and the sodium polyacrylate solution) were first extracted from their aqueous media to provide the solid polymeric materials for solubility study.

Approximate rates of solubility of the polymeric materials in artificial gastrointestinal fluids were determined employing the rotating-bottle method (1, 2). Seven 1.0-g. samples of each polymer were sprinkled onto the surface of separate 60-ml. portions of artificial gastric fluid USP (without pepsin) in 3-oz. amber glass powder jars. The jars were sealed with a water-resistant electrical tape⁵ and were rotated at 41 r.p.m. in a constant-temperature bath at $37 \pm 2^\circ$. At specified time intervals, a sample bottle was removed and its contents vacuum filtered through a fine sintered-glass filter. The sample was then carefully transferred to a watch glass and dried at 50° . The remaining sample bottles were adjusted in pH as outlined in Table I. The data in Table I illustrate the approximate pH levels for the designated sample time intervals employed and the changes in the test fluids that were made to establish these levels.

Table I—pH Gradient for Approximate Rate of Solubility Test

Time, hr.	Amount of Fluid Removed, ml. ^a	pH of Test Fluid
1	0.0	1.4
2	20.0	2.1
3	15.0	2.6
4	20.0	5.5
5	30.0	6.9
6	50.0	7.4
8	—	7.4

^a The clear supernatant fluid removed was replaced by an equal quantity of artificial intestinal fluid USP (prewarmed to 37°).

The dried polymeric material was weighed, and the percentage of polymer dissolved at each time interval was calculated. The acrylic copolymer emulsion showed the most promising rate of solution, and this material was studied by further evaluative methods.

Drug Assay Procedures—Methapyrilene hydrochloride⁶ was used because it represents a widely employed compound having characteristics suitable for development as a sustained-action dosage form. The drug is quick acting, having a fairly short duration of action, with single doses exhibiting a therapeutic effect for about 3.5 hr. (3, 4).

A pH-induced differential spectrophotometric method was developed which permitted the analysis of methapyrilene hydrochloride without interference from the polymer (5).

A base-line UV spectrophotometric analysis method, outlined by Reilly and Sawyer (6), was successfully adopted for the quantitative determination of phenylephrine hydrochloride in the presence of the polymeric material. The spectra were all analyzed at pH 12.9 to eliminate any shifts of the absorption maxima of this compound (5). This pH value was found to concur with that reported by Riegelman *et al.* (7).

Entrapment Procedure—Various methods of producing the polymer-drug entrapment systems were attempted. The addition of the acrylic copolymer emulsion to concentrated aqueous solutions of methapyrilene hydrochloride resulted in the flocculation and precipitation of the polymer affording the greatest possibility of drug entrapment since the drug molecules themselves were causing the flocculation. Other methods attempted included the addition of the drug solution to the polymeric system and the acidification of an alkaline aqueous solution of the drug and the polymer.

The following formula and procedure were the basic entrapment method used:

Formula I

Methapyrilene hydrochloride	20.0 g.
Distilled water	100.0 ml.
Acrylic copolymer emulsion	125.0 ml.

The acrylic copolymer emulsion was slowly added to a constantly mixing solution of the methapyrilene in distilled water, resulting in an immediate flocculation and precipitation of the added polymeric material. When the addition of the emulsion was complete, the slurry was allowed to mix for another 5 min. The mixture was then vacuum filtered through a coarse sintered-glass filter, applying vacuum from a water aspirator for about 10 min. The collected material was dried for 4 hr. at 50°. The dried material (a granular white solid) was then comminuted in a comminuting machine, employing a 40-mesh screen and the hammer edge of the blades in the forward position. The comminuted material was then screened through a 60-mesh sieve.

Reproducibility of the entrapment procedure was evaluated by preparing replicate batches and determining the percentage of drug entrapped in each batch.

The effect of drug (solution) concentration on the entrapment product was investigated by utilizing various drug concentrations in aqueous solution and holding constant the amount of polymer emulsion employed.

Table II—pH Gradient for the *In Vitro* Release-Rate Test

Cumulative Time, hr.	pH of Test Fluid
0.5	1.3
1.5	1.3
2.5	2.3
4.5	6.7
6.5	7.3
8	7.3

Dialysis Studies—A dialysis study was conducted to determine whether methapyrilene hydrochloride was chemically bound to the polymeric material (in solution) in such a manner as to reduce the availability and the therapeutic activity of the drug. A dialysis method similar to that described in the literature (8, 9) was used. Dialysis sacs prepared from a semipermeable cellulosic membrane⁷ were used for investigation of free methapyrilene hydrochloride, free acrylic copolymer, and acrylic copolymer-methapyrilene hydrochloride entrapment products. The dialysis samples were rotated for preselected time periods of 48, 72, or 107 hr. at 37°. The dialysis fluid employed was artificial intestinal fluid USP (without pancreatin) adjusted to pH 7.4. This medium caused dissolution of the polymer as well as the drug. The fluids inside the sacs, as well as the surrounding media, were assayed for drug content.

***In Vitro* Release-Rate Procedure**—A rotating-bottle method (1, 2) was used for the evaluation of the powdered and compressed sustained-action dosage forms. The comminuted polymer-drug samples were weighed into six individual dosage units, each to contain 100 mg. of methapyrilene hydrochloride. The samples were carefully transferred to 3-oz. amber glass powder jars and filled with 60 ml. of artificial gastric fluid. Table II illustrates the pH levels for the designated sample time intervals employed. These pH values agree well with those found by Borgstrom (10) in numerous *in vivo* tests. The test fluids were treated with artificial intestinal fluid and 1.0 N sodium hydroxide solution in such a manner as to yield the noted pH levels for the designated time intervals.

Suitable aliquots of the filtered test medium were taken (at the specified time periods) and differentially analyzed for methapyrilene hydrochloride.

***In Vivo* Evaluation**—Various methods have been proposed to evaluate the activity and the duration of action of antihistaminic compounds (3, 4, 11, 12). A guinea pig histamine aerosol procedure (4, 12, 13) was employed in this study. Duration of action of an orally administered dose of an acrylic copolymer-methapyrilene hydrochloride entrapment product was compared with that of the free drug.

It has been reported (4, 12) that 1–3 mg./kg. of methapyrilene hydrochloride administered to guinea pigs has shown protective action against histamine vapor for about 3.5 hr. In this study, a dosage level of 2.5 mg./kg. of body weight was employed. The powdered forms of the product were washed through a catheter tube directly into the stomach of the animal. The product and control drug were code labeled so that the investigator performing the actual experiments did not know which system was being given to the individual guinea pigs, thereby reducing prejudiced judgments. A total of 20 experimental runs was made, with 10 test animals receiving the free drug and 10 a polymer-drug entrapment product.

Toxicity Reduction—A reduction in the acute toxicity of a drug should occur with its formulation into a sustained-action dosage product. A preliminary investigation established a dose of 200 mg./kg. as the approximate LD₅₀ in rats for orally administered methapyrilene hydrochloride. Six rats were orally dosed with 200 mg./kg. of the free methapyrilene hydrochloride, and another six were given 200 mg./kg. of the drug in a polymer-drug entrapment product. The time of death after oral administration was noted, and a 24-hr. survival time was considered the "cutoff" point for the test procedure.

Flocculation Phenomenon—It was felt that the precipitation of the polymer emulsion in the presence of methapyrilene hydrochloride was due to a flocculation phenomenon. Riddle (14) has stated: "The presence of salts in polymer dispersions usually has

⁶ Methapyrilene hydrochloride (Histadyl HCl), Eli Lilly and Co., Indianapolis, Ind.

⁷ NoJax Casing, Size 30, Visking Co., Chicago, Ill.

the same effect as in other colloidal systems, *i.e.*, the particle size is increased and some of the polymer may coagulate."

It was also hypothesized that as the pH of the acrylic copolymer emulsion (an anionically charged copolymer) was increased, the polymeric compound would become more hydrophilic, resulting in increased solvation and increased stability to electrolytes. Conversely, as the pH decreases, the colloidal system becomes more hydrophobic and more prone to flocculation due to the presence of electrolytic agents.

To test this hypothesis, the acrylic copolymer emulsion was adjusted to pH values of 3.3 and 6.0, maintaining a 20% polymer solids content in both systems. Five-milliliter samples of the system being evaluated were placed in 15.24-cm. (6-in.) (20-ml. capacity) test tubes, and 5 ml. of varying concentrations of sodium chloride or methapyrilene hydrochloride solutions was added. The contents were mixed by inverting the test tubes three or four times. The flocculation value was taken as the minimum concentration of an electrolyte that caused complete flocculation within 2 hr. Complete flocculation was observed as a separation of a voluminous solid phase and a clear aqueous layer.

Flocculation Phenomenon in the Presence of Drugs—Flocculation values for acid salts of 11 widely used cationic nitrogen-containing drug compounds were determined in the copolymer emulsion system. The compounds studied varied in salt form, molecular weight, solubility characteristics, and therapeutic use. Included in this group of drugs were primary, secondary, and tertiary amines and a quaternary ammonium compound.

Preparation of Tablet Samples—Tablets were prepared from acrylic copolymer-methapyrilene hydrochloride entrapment products containing 13.3 and 33.4% active ingredient. In all cases, the tablets contained 100 mg. of drug, and they were compressed (on a Carver laboratory press) directly from the finer than 60-mesh material (hydraulic pressure setting of 8000 lb./in.²). Two sets of tablets were prepared from each of the two employed polymer-drug systems, one set containing 10% starch as a disintegrant while the other contained no disintegrating agent. The tablets containing 13.3% active ingredient were prepared with a 1.27-cm. (0.5-in.) s.c. punch and die set, and those containing 33.4% drug were prepared with a 0.95-cm. (0.375-in.) s.c. punch and die set. Tablet hardness was determined using a hardness tester (Monsanto), and their *in vitro* release rates were determined using the rotating-bottle method.

RESULTS AND DISCUSSION

Polymer Solubility—The powdered polyethylene glycols and the carbohydrate polymers were eliminated from the study since all samples dissolved (all commercial types and molecular weights evaluated) within 1 hr. in artificial gastric fluid.

The polymeric material of the acrylic copolymer emulsion was found to exhibit solubility characteristics desirable for use as a sustained-action matrix. The polymer showed limited solubility in the pH region of 1.4–5.5 (7–11% of the polymer dissolved over a period of 5 hr.). The solubility rate greatly increased as the pH was raised from 5.5 to 6.9 and finally to 7.4. The sodium polyacrylate exhibited similar solubility characteristics in the low pH range but dissolved almost immediately when the pH of the test fluid was raised to 5.5.

The results indicate that the sodium polyacrylate might be suitable as an enterosoluble agent and that the acrylic copolymer has solubility properties more appropriate for a sustained-action preparation. The high molecular weight (over 300,000), available toxicity data (15), and linear nature of this acrylic copolymer (16), coupled with its solubility characteristics, justified further investigation as to its applicability to drug entrapment and sustained-release preparation.

Reproducibility of the Entrapment Procedure—The data in Table III show the assayed amounts of drug found in each of six identically prepared entrapment products. Two analyses were performed on each batch, with the averages being used to calculate the standard deviation of the batches prepared.

Based on the statistical analysis of the experimental data, one can expect that approximately 90% (employing 5 degrees of freedom) of the sample values will fall within ± 5.12 of the sample mean (*i.e.*, 132.87 ± 5.12). The coefficient of variability falls within the 5% limits that are established for most pharmaceutical preparations.

Table III—Reproducibility of the Entrapment Process

Batch No.	mg. of Methapyrilene HCl/g. of Collected Solid	Average of Two Assays
1	135.28 134.59	134.94
2	133.05 139.11	136.08
3	133.94 133.87	133.91
4	130.99 129.77	130.38
5	132.95 131.69	132.32
6	127.22 131.98	129.60

Effect of Drug Concentration on Entrapment Results—Figure 1 depicts the results obtained when various concentrations of methapyrilene hydrochloride solutions were employed with a constant amount of acrylic copolymer emulsion. The same formula (except for the drug concentration) and technique were employed as outlined for the drug entrapment procedure. It appears that a linear relationship exists between the initial drug concentration (in the range of 0.13–2.01 molal) and the amount of drug entrapped in the solid product. The equation for the line covering this portion of the graph was estimated employing the method of least squares.

The equation established was:

$$X_m = 14.22 (M) + 4.19 \quad (\text{Eq. 1})$$

where M represents the molality of the methapyrilene hydrochloride solution and X_m is the amount (g.) of methapyrilene hydrochloride found in 100 g. of the resultant mixture. The sample correlation coefficient (r) found for the points used to calculate the equation was 0.995, indicating that the observed points are all very close to the calculated regression line. It is, therefore, possible to predict accurately the amount of methapyrilene hydrochloride to be found in an entrapment product. This relationship also allows for the reproducible production of products that might exhibit different and desirable effects, which are controllable by the drug-polymer ratio of the system.

No definite explanation can be presented for the break in the curve (Fig. 1) as the molality of the methapyrilene hydrochloride solution exceeds 2.01. The aqueous solubility limit of methapyrilene hydrochloride is being approached at the 3.0 molal concentration level. However, the range of 0.13–2.01 molal solutions presents a very broad and useful area for the production of acrylic copolymer-methapyrilene hydrochloride entrapment compositions.

Figure 1—Effect of drug concentration on the acrylic copolymer-methapyrilene hydrochloride entrapment ratio.

Table IV—Dialysis of Acrylic Copolymer–Methapyrilene Hydrochloride Entrapment Compositions

Sample No.	Hours Dialyzed	Molarity ^a of System	Molarity Outside the Sac	Molarity Outside Molarity of System
1 ^b	48	7.36	7.24	0.98
2	48	7.68	7.12	0.93
3	48	7.77	7.08	0.91
4 ^b	72	7.05	6.97	0.98
5	72	7.39	6.97	0.94
6 ^b	107	6.92	6.50	0.94
7	107	7.43	6.50	0.87
8	107	7.42	7.12	0.96
9	107	7.00	6.30	0.90

^a Molarity of the system was based on the total drug concentration found inside and outside of the dialysis sacs. All molarity concentrations presented are times 10³. ^b Represents free drug samples, while all others are polymer–drug entrapment compositions.

Drug Availability from Polymer–Drug Solutions—Preliminary dialysis studies showed that the dialysis membrane employed acted as an impermeable barrier towards the polymer molecules (acrylic copolymer) while allowing free passage of the methapyrilene hydrochloride. The pH of the test fluid (range 1.4–7.4) had no apparent effect on the dialysis of the drug across the membrane or upon the impermeability of the membrane towards the polymer molecules. Table IV presents the dialysis data for the drug and polymer–drug entrapment systems.

If complete equilibration occurred, the value obtained by dividing the molarity outside the dialysis sac by the total calculated molarity of the system would be equal to 1; but as can be noted in Table IV, even in the cases of the free drug samples the values attained were not exactly 1. These slight differences of the drug systems from unity may be attributed to errors involved in the dialytic and analytical procedures or to a low order of drug binding to the membrane.

No major differences were noted at the three time intervals employed. It appears that approximately 5–10% of the drug in the polymer–drug product is not passing freely through the membrane and, in some manner, is being bound or retarded by the polymeric system. It was concluded that the major portion (90% or more) of the methapyrilene hydrochloride present in the polymer–drug entrapment products is readily available for passage through a semipermeable membrane. It was felt that this would also be true in a biological system where the membrane of the gastrointestinal tract would act as the semipermeable barrier, excluding the high molecular weight polymer and permitting passage (absorption) of the unbound drug molecules.

In Vitro Release-Rate Studies—Data given in Table V show the release-rate patterns of six individually prepared batches of the acrylic copolymer–methapyrilene hydrochloride entrapment product. In all cases, the samples had been screened through a 60-mesh screen and were weighed to contain 100 mg. of drug (all mixtures contained approximately 13.3% active ingredient) (Table III).

Standard deviations of the release rates for the individual sample periods are shown at the bottom of Table V. Figure 2 represents a graphical presentation of the mean cumulative percent release values plotted against time.

Table V—Release Rates of Acrylic Copolymer–Methapyrilene Hydrochloride Entrapment Compositions

Batch No.	Cumulative Percent Release					
	0.5 hr.	1.5 hr.	2.5 hr.	4.5 hr.	6.5 hr.	8 hr.

SD	6.2	5.2	5.4	6.7	3.7	2.8

Figure 2—In vitro release-rate pattern of the acrylic copolymer–methapyrilene hydrochloride entrapment product.

Several investigators (1, 17–19) have attempted to correlate *in vitro* release-rate patterns with *in vivo* results. Urinary excretion rate data of various sustained-action dosage forms of dextroamphetamine sulfate, phenylpropanolamine hydrochloride, and trimetopazine maleate have been compared with *in vitro* release-rate results obtained with the rotating-bottle method.

The reported *in vitro* release values shown in Table VI were for those products exhibiting suitable sustained-action properties (usually 10–12 hr.) when evaluated *in vivo* by urinary excretion studies. The experimental data (entrapment composition) depicted in Table VI were found to lie within or very close to the values reported for the satisfactory sustained-action products. The entrapment product exhibited *in vitro* sustained-action characteristics in the fine subdivided state without further formulation into granules, pellets, and compression-coated, sugar- or film-coated, or layer tablets.

The results shown in Table VII illustrate the effect of the polymer–drug ratio (percent drug present in the entrapment product) on the release-rate pattern. The polymer–drug ratio may be another means of controlling and changing release-rate patterns.

The 13.3% level of entrapment was used for *in vivo* evaluation because it presented what was believed to be the best *in vitro* characteristics for methapyrilene hydrochloride. The more rapid release patterns may be useful for drugs with a more limited solubility characteristic or when this fine material is formulated into some compacted dosage form.

In Vitro Release Rates from Tablet Preparations—The results in Table VIII show the effect of tableting on the release-rate patterns. The tablets containing 13.3% drug with 10% starch as a disintegrant completely broke apart in about 10 min. The resultant material exhibited almost the identical release-rate pattern as the original 60-mesh screened powder employed for the production of these tablets. This formulation and tableting approach could be used advantageously when the original powdered material exhibits suitable release characteristics.

The tablets (13.3% drug) compressed without any disintegrating agent failed to break apart in the 8-hr. period investigated. In the first 0.5–1.5 hr. of immersion in artificial gastric fluid, the tablets were swollen to about twice their original size. During the initial test period (0–1.5 hr.), 45.6% of the entrapped drug was being released, presumably by a leaching action of the test fluids. This

Table VI—Comparison of Reported Release Values with Experimental Results

Time, hr.	Cumulative Percent Release	
	Reported Values	Experimental Values
0.5	32–43	45.7
1.5	—	62.6

leaching effect was felt to be the predominant mechanism of release until about the 3rd or 4th hr. when the tablets began to diminish in size due to the slow dissolution of the polymeric material (as the pH of the test fluid increased). The portion of the drug content more tightly entrapped in the polymeric network was then being slowly released as the polymer dissolved.

The tablets containing 33.4% drug prepared with and without the addition of starch had the same general appearance during release-rate evaluation as those containing 13.3% drug without any added disintegrating agent (*i.e.*, initial swelling and then slow dissolution with increasing pH of the test fluids). The total release (in 8 hr.) from these tablets was less than that found for the tablets containing 13.3% drug. This reduction in total release of the two-tablet systems containing 33% drug is undoubtedly due to the increased hardness of these tablets (Table VIII).

The tablets containing 13.3% active ingredient (no starch) and the ones containing 33.4% drug with 10% starch demonstrated very uniform hourly rates of drug release for the test period from 2.5 to 8 hr. (Table IX).

In Vivo Studies—Results shown in Table X were obtained after oral administration of free methapyrilene hydrochloride samples and a polymer-drug entrapment product to guinea pigs, with the animals then being subjected to the histamine aerosol chamber. The 95% confidence interval for the difference between the means (pure drug and entrapped drug) was found to be 4.9 ± 1.2 hr., indicating an increased duration of activity of the drug when it is administered in the polymer-drug entrapment system. It was concluded that the drug was slowly being released from the entrapment product in concentrations adequate to maintain a pharmacologic effect over this extended period of time.

Toxicity Reduction—An oral dose of 200 mg./kg. of free methapyrilene hydrochloride was found to kill five out of six rats within 30 min. after administration of the drug. The rats died in an acute convulsive state. One of the six rats survived the preselected 24-hr. cutoff point.

The same dose of methapyrilene hydrochloride administered in a polymer-drug entrapment product had no lethal effect on six rats when observed over a 24-hr. period. The results of this acute toxicity study present further supportive data for the *in vitro* and guinea pig investigations, showing that the polymer-drug entrapment product is preventing the immediate release of all the drug and is protracting its availability over an extended period of time.

Mechanism of Entrapment—Table XI summarizes the results obtained when testing the hypothesis that the acrylic copolymer emulsion system would be more stable to electrolytes as the pH of the system was increased. The results indicate that the original

hypothesis was correct and that the presence of methapyrilene hydrochloride was causing flocculation of the polymeric system as exemplified in the drug entrapment procedure.

During the entrapment procedure as the added polymeric system was being flocculated, the drug molecules were entrapped (enclosed) in the formed aggregates, thus retarding their release in subsequent test procedures.

The cause of flocculation can be traced to the added electrolyte (drug molecules), which decreased the thickness of the diffuse ionic layer (of the polymeric material) and thus facilitated the flocculation of the polymeric material. Whether the approaching particles agglomerate or not is determined by the balance of the attractive van der Waals-London forces and the repulsive coulombic forces (20).

Further evidence that the drug was not chemically interacting with the polymer in some salt or direct ionic bond formation was the fact that a chloride analysis showed that approximately 50% of the entrapped drug was still in the chloride salt form. Jirgensons (20) reports that instances in which discharging and resultant flocculation can be explained as an ionic interaction between the ions of the particles and those of the added electrolyte are very rare.

Baron (21) has defined a type of entrapment product, known as inclusion compounds, which does not arise from the linkage of two reactants by means of covalent or coordinate bonds but from the ability of one compound to enclose another spatially. "The enclosed compound (guest) is in a situation whereby it cannot readily

Table VIII—Effect of Tableting on the *In Vitro* Release-Rate Pattern

Table XI—Flocculation Values of Sodium Chloride and Methapyrilene Hydrochloride for an Acrylic Copolymer Emulsion System

	Flocculation Value ^a	
	pH 3.3	pH 6.0
Sodium chloride	250	1000-1250
Methapyrilene hydrochloride	10	35

^a Flocculation value is the concentration of the drug in mmoles/l. in the final system required to cause complete flocculation within 2 hr.

leave its position, although it is not actually bonded to the including compound" (21).

The polymer-drug entrapment products formed in this study do not directly fall into this class but may be considered as a type of inclusion system where the host molecules are being held together in a flocculated (aggregated) state entrapping the guest (drug) molecules.

Application of the Process to Entrapment of Other Drugs—Table XII depicts the results obtained employing the flocculation procedure for 11 other cationic drugs. The drugs studied readily caused flocculation of the polymeric material, and the majority of these had flocculation values of about 10–20. The method of drug entrapment described in this study appears applicable to many cationic drugs, without changing the procedure. Possible modifications that could be made in the entrapment process are: (a) the use of anionic medicinal agents for the flocculation of cationic polymeric systems; (b) the application of nonaqueous solvent systems to cause flocculation; and (c) the use of physiologically inert electrolytes to aid in the flocculation and entrapment technique.

Figure 3 illustrates the effect of the phenylephrine concentration employed in the entrapment procedure on the amount of drug found entrapped in the collected solid mixture. The percent of drug concentration of the entrapment product was found to increase sharply as the molality of the solution employed increased from 0.98 to 1.72. Further increases in molality produced only comparatively slight changes in the polymer-drug ratio until the sudden upswing occurring at the molalities of 3.50 and 3.68, similar to the upswing noted with methapyrilene hydrochloride (Fig. 1). The study of acrylic copolymer-phenylephrine hydrochloride entrapment products further exemplifies the applicability of the developed entrapment procedure to other drugs.

SUMMARY AND CONCLUSIONS

The phenomenon of the flocculation of polymeric systems has been evaluated for the molecular entrapment of drugs as a physico-

Figure 3—Effect of drug concentration on the acrylic copolymer-phenylephrine hydrochloride entrapment ratio.

chemical approach to the development of oral controlled- or sustained-action dosage forms.

A solid reproducible molecular entrapment composition of methapyrilene hydrochloride and an acrylic copolymer was prepared and evaluated for sustained-action properties.

In vitro results obtained using the rotating-bottle method indicated satisfactory sustained-release properties of the drug from the entrapment product. The results of *in vivo* studies in guinea pigs were found to correlate with the *in vitro* data. An increase in the continuous duration of action of 4.9 ± 1.2 hr. was shown for the polymer-drug product when compared with a mean duration for the free drug.

A reduction of the acute toxicity of methapyrilene hydrochloride in the entrapped form was established by an *in vivo* investigation in rats.

The polymer-drug entrapment product was found to exhibit characteristic protracted-release patterns in the tableted as well as the fine-powder state.

The broad application of the entrapment process to the acid salts of numerous cationic nitrogen-containing medicinal agents was demonstrated.

Table XII—Flocculation of an Acrylic Copolymer Emulsion System by Acid Salts of Various Cationic Nitrogen-Containing Medicinals

Compound	Molecular Weight	Type of Amine	Category	Flocculation ^a Value
<i>d</i> -Amphetamine sulfate	368.5	Primary	Central stimulant	10
Chlorpromazine hydrochloride	355.3	Tertiary	Tranquilizer	10
Atropine sulfate	694.9	Tertiary	Parasympatholytic	10
Homatropine methylbromide	370.3	Quaternary ammonium	Parasympatholytic	20
Ephedrine hydrochloride	201.7	Secondary	Sympathomimetic	20–25
Phenylephrine hydrochloride	203.7	Secondary	Sympathomimetic	40–50
Morphine sulfate	758.9	Tertiary	Narcotic analgesic	10–15
Dihydrocodeinone bitartrate	494.5	Tertiary	Antitussive	20
Methapyrilene hydrochloride	297.9	Tertiary	Anti-histaminic	10
Pyrilamine maleate	401.5	Tertiary	Anti-histaminic	10
Chlorpheniramine maleate	390.9	Tertiary	Anti-histaminic	10

^a The flocculation value is the concentration of the drug in mmoles/l. in the final system required to cause complete flocculation within 2 hr.

Synthesis and Anticonvulsant Properties of Some Derivatives of *N*-Methyl-2-phenylsuccinimide II

H. C. CLEMSON*, E. O. MAGARIAN†, and J. F. REINHARD*

Abstract □ Several substituted *N*-methyl-2-phenylsuccinimides have been prepared and evaluated for protective activity against convulsions induced by electroshock and pentylenetetrazole.

Keyphrases □ *N*-Methyl-2-phenylsuccinimide derivatives—synthesis □ Anticonvulsant activity—*N*-methyl-2-phenylsuccinimide derivatives □ IR spectrophotometry—structure □ NMR spectroscopy—structure

Phensuximide,¹ *N*-methyl-2-phenylsuccinimide (I), is a well-known anticonvulsant agent which has been employed in the treatment of petit mal epilepsy. The first paper of this series described the synthesis and biological evaluation of several *tert*-aminoalkyl derivatives of Structure I as potential anticonvulsants (1). As part of a continuing study, several additional derivatives of I have been prepared and screened for anticonvulsant properties.

DISCUSSION

Until recently, the methods used in the preparation of succinimide anticonvulsants have involved the cyclization of appropriate succinonitrile and succinic acid derivatives (2-6). However, the feasibility of direct substitution on the succinimide ring has been demonstrated as a useful synthetic tool (1, 7, 8).

Table I—NMR Spectral Data

No.	Chemical Shift (δ) ^{a, b}
I	3.00 (2H,M), 3.02 (3H,S), 4.00 (1H,Q), 7.23 (5H,M)
IIa	2.85 (3H,S), 3.06 (2H,S), 3.10 (1H,D), ^c 3.58 (1H,D), ^c 7.38 (10H,M)
IIb	2.20 (3H,S), 2.69 (1H,D), ^d 3.03 (3H,S), 4.01 (1H,D), ^d 7.31 (5H,S)
IIc	2.98 (1H,D), ^d 3.12 (3H,S), 4.07 (1H,D), ^d 7.42 (8H,M), 7.96 (2H,M)
III	3.07 (3H,S), 3.23 (1H,D), ^d 3.88 (1H,D), ^d 5.78 (1H,S), 7.18 (10H,M)
IV	2.60 (3H,S), 3.24 (1H,D), ^d 3.58 (1H,D), ^d 5.49 (1H,S), 7.43 (10H,M)
V	3.15 (3H,S), 3.71 (2H,S), 7.67 (5H,M)

^a S = singlet, D = doublet, M = multiplet, Q = quartet. ^b All compounds were run as 10% solutions in deuteriochloroform, excepting Compound IV whose concentration was 4% in deuteriochloroform. ^c $J = 13.5$ c.p.s. ^d $J = 18.0$ c.p.s.

The proton in the 2-position of I is relatively acidic, because it is flanked by a benzene ring and a carbonyl group. Consequently, it was readily removed using either sodium amide or sodium ethoxide in anhydrous toluene. The resulting carbanion intermediate was subsequently utilized in alkylating and acylating reactions, as outlined in Scheme I.

The bromination of IIa in carbon tetrachloride yielded two compounds which are isomeric (Scheme II). The NMR spectra of the products indicate that they are geometric isomers having Formulas III and IV (Table I). The resonance peak for the methyl protons (2.60 δ) in IV appears upfield to the corresponding peak in III (3.07 δ).

It would appear from Dreiding stereomodels that Structure IV should possess a strong conformational bias, since the benzyl group is flanked on the one side by the large bromine atom and on the other side by the rather bulky phenyl group. As a result of this strong restriction to free rotation, the benzyl group is so oriented that the methyl group appears in the shielding portion of the induced currents of the aromatic ring. With less restriction to rotation, the benzyl group in III has a decreased influence on the methyl protons; consequently, their resonance peak occurs at a lower field position. The absorption peak for the methyl protons (2.84 δ) in IIa, the parent molecule, is intermediate in position to those in III and IV. Location of the methyl peak in III downfield to that in IIa may be attributed to the influence of the bromine atom. Compound V, which was prepared by treating I with bromine in carbon tetrachloride (Scheme III), also displayed a similar deshielding effect by its bromine atom (Table I).²

The substitution of the bromine atoms on the benzylic carbons to give diastereomers was also considered. However, the large difference in chemical shifts of the methyl protons cannot be rationalized in terms of these structures. Dreiding stereomodels indicate that the benzyl group should influence the methyl protons to about the same degree in either diastereomer, and that there should be little difference in their chemical shifts.

EXPERIMENTAL

All melting points have been determined on either a Fisher-Johns block or a Kofler micro hot stage and have been corrected.

Scheme II

² The preparation of V by a different method was previously reported by Izzo (13).

Scheme III

Pertinent physical data for each of the products are listed in Table II.³

The IR spectra were determined on a Beckman IR-8 spectrophotometer using KBr pellets. All succinimide derivatives exhibited the two characteristic frequencies between 1690 and 1775 cm^{-1} (9–11).

NMR spectra were acquired using a Varian A-60 spectrometer and deuteriochloroform solutions with tetramethylsilane as an internal standard. Appropriate data are given in Table I.

N-Methyl-2-phenylsuccinimide (I)—This compound was prepared according to the procedure of Miller and Long (12).

2-Benzyl-N-methyl-2-phenylsuccinimide (IIa)—To 0.10 mole of sodium amide in liquid ammonia (2.3 g. of sodium metal in 150 ml. of liquid ammonia), 18.9 g. (0.10 mole) of *N*-methyl-2-phenylsuccinimide (I) in 150 ml. of anhydrous toluene was added with stirring. After heating at reflux for 3 hr., the mixture was cooled to room temperature and a solution of freshly distilled benzyl chloride (12.7 g., 0.10 mole in 50 ml. of anhydrous toluene) was added with stirring over a period of 15 min. The reaction mixture was heated at reflux for 30 min. and then allowed to stir at room temperature for 12 hr. Finally, it was treated with 20 ml. of water, and the organic layer was separated and dried (MgSO_4). The toluene was removed *in vacuo*, yielding an oil which solidified upon standing. The product was recrystallized from 95% ethanol to give 20.2 g. of IIa.

2-Acetyl-N-methyl-2-phenylsuccinimide (IIb)—A solution of 18.9 g. (0.10 mole) of *N*-methyl-2-phenylsuccinimide (I) and 150 ml. of anhydrous toluene was added to 0.15 mole of sodium ethoxide in 200 ml. of absolute ethanol. The ethanol-toluene azeotropic mixture was distilled, and the volume of the reaction mixture was kept constant by the addition of anhydrous toluene. After the suspension had been cooled to 35°, 15.3 g. (0.15 mole) of acetic anhydride dissolved in 60 ml. of anhydrous toluene was added and the mixture was stirred for 8 hr. at 35°. The mixture was then treated with 100 ml. of a 10% sodium bicarbonate solution. The toluene layer was dried over anhydrous MgSO_4 and evaporated *in vacuo* to give a viscous, yellow liquid which solidified when triturated with 95% ethanol. Recrystallization from the same solvent gave 13.6 g. of IIb.

2-Benzoyl-N-methyl-2-phenylsuccinimide (IIc)—This derivative was prepared in a manner similar to the procedure for IIb except that 15.5 g. (0.11 mole) of benzoyl chloride was used in place of the anhydride. The product was recrystallized from 95% ethanol, yielding 14.9 g. of IIc.

Bromination of 2-Benzyl-N-methyl-2-phenylsuccinimide (III and IV)—To a mixture of 4.9 g. (0.018 mole) of 2-benzyl-N-methyl-2-phenylsuccinimide (IIa) and 50 ml. of carbon tetrachloride at reflux was added dropwise 2.8 g. (0.018 mole) of bromine over a period of several hours. When the addition was complete, the mixture was heated at reflux for an additional 14 hr., followed by the addition of 50 ml. of water. The organic layer was separated and dried (MgSO_4). Evaporation of the carbon tetrachloride solution *in vacuo* gave an oil which solidified upon cooling. Recrystallization from *sec*-butyl alcohol resulted in two fractions. The less soluble fraction gave 1.7 g. of III, and the second fraction yielded 3.8 g. of IV.

2-Bromo-N-methyl-2-phenylsuccinimide (V)—A stirred solution of 2.5 g. (0.013 mole) of *N*-methyl-2-phenylsuccinimide (I) in 20 ml. of carbon tetrachloride was treated dropwise with 2.1 g. (0.013 mole) of bromine in 20 ml. of carbon tetrachloride. After the reaction mixture had been heated at reflux for 48 hr., the solvent was removed *in vacuo*. The residue was triturated with 95% ethanol; the solid, thus obtained, was recrystallized from this solvent, affording 2.1 g. of V.

³ Elemental analyses were performed by Galbraith Laboratories, Inc., Knoxville, Tenn., and by Micro-Analysis, Inc., Wilmington, Del.

PHARMACOLOGY

Methods and Materials—The succinimides were tested for anticonvulsant activity by modifications of two methods described by Swinyard *et al.* (14). In the first procedure (maximal electroshock seizures), the compounds were suspended in 10% (aqueous) acacia and administered orally to adult, male, albino mice in groups of 10 at a dosage of 200 mg./kg. At intervals of 0.5, 1, and 2 hr. thereafter, the animals of each group were challenged by delivering 60 ma. (a.c.) through the corneal electrodes for 0.2 sec. The end-point indicating anticonvulsant activity is the abolition of the hindlimb tonic extensor component of the maximal seizure pattern. The time of peak effect was determined by observing which time interval gave optimum protection. Whenever substantial effectiveness was demonstrated in this manner, a second investigation was undertaken to determine potency more precisely. The compound was administered at three or more dosage levels, generally 10 animals per dosage, and the animals were challenged at the predetermined time of peak effect. The dosage of compound required to produce the anticonvulsant end-point in 50% of the animals (ED₅₀ with 95% fiducial limits) was computed by the method of Litchfield and Wilcoxon (15).

The second procedure (chemoshock) involved protection against a chemical convulsant, pentylenetetrazol.⁴ Again, the compound was administered orally at a dosage of 200 mg./kg. to 10 adult, male, albino mice. At the time of peak effect, a 97% convulsant dosage of pentylenetetrazol (106 mg./kg.) was injected subcutaneously. Anticonvulsant activity was indicated by the failure of clonic convulsive seizures to appear within 1 hr. following pentylenetetrazol. Whenever indicated, ED₅₀'s were determined in the manner previously described.

The mice⁵ employed in these investigations were housed 20 per cage and fed Charles River Rat and Mouse Food and tap water *ad libitum*.

⁴ Marketed as Metrazol by Knoll Pharmaceutical Co., Orange, NJ 07051

⁵ Obtained from the Charles River Breeding Laboratories, N. Wilmington, Mass.

Table III—Anticonvulsant Activity of Succinimide Derivatives in the Mouse

Compound	Fraction of Animals Protected following 200 mg./kg. of		Time of Peak Activity, hr.
	Electroshock	Chemoshock	
I	9/10 ^a	9/10 ^b	0.5
IIa	0/5	0/10	—
IIb	9/10 ^c	9/10 ^d	0.5
IIc	0/10	2/10 ^e	—
III	0/10	0/10 ^f	—
IV	0/10	0/10	—
V	1/10	2/10 ^g	1

^a ED₅₀ = 115 (92–144) mg./kg. ^b ED₅₀ = 134 (87–208) mg./kg. ^c ED₅₀ = 96 (64–144) mg./kg. ^d ED₅₀ = 86 (60–124) mg./kg. ^e ED₅₀ = 610 mg./kg. (approx.). ^f 4/10 protected at 400, only 2/10 at 800 mg./kg. ^g 6/10 protected at 400, but only 2/10 at 600 mg./kg.

Results and Discussion—The data summarized in Table III reveal that, in general, anticonvulsant potency was inversely proportional to the size of the side chain in the 2-position. Where this chain contained a benzyl or benzoyl group, anticonvulsant activity was either absent or weak in the sense that total protection could not be achieved at any dosage, owing to the superimposition of the toxicity of the test compound. However, the 2-acetyl derivative (IIb) was the most active member of the series, equalling the potency of the parent compound, phensuximide (I). A similar relationship between the size of alkyl substituents in some aryldialkylsuccinimides and anticonvulsant potency was reported by Hauck *et al.* (6).

In all of the studies conducted on these succinimides, anticonvulsant activity was in all cases associated with depression of the CNS; yet the hypnotic activity did not appear in response to high dosage, even in the toxic range. Therapeutically, this combination of effectiveness against seizures without risk of undue CNS depression is a distinctly desirable feature of any anticonvulsant, since it must be given daily for prolonged periods.

Kinetic Salt Effect in Pharmaceutical Investigations

J. THURØ CARSTENSEN

Abstract □ The use of the kinetic salt effect in kinetic investigations has been widespread since its original derivation by Brønsted and Bjerrum in 1925. Its derivation is tied in with the Debye-Hückel theory, and it would be expected that the concentration range of applicability of the kinetic salt effect would be confined to that of the corresponding Debye-Hückel expression, *i.e.*, less than 0.01 *M*. A review of the pharmaceutical literature shows that applications may be extended to higher concentration ranges. Deviations from the Debye-Hückel expressions by the charged reactants and by the transition complex may be of the same magnitude and sign, and this may be the cause for the concentration range extension.

Keyphrases □ Kinetic salt effect—pharmaceutical solutions □ Ionic strength effect—high ionic concentrations □ Hydrolysis—kinetic salt effect □ Degradation, drug—kinetic salt effect

Properly conducted kinetic studies always, directly or indirectly, take into account the so-called kinetic salt effect. By varying the ionic strength by addition of an inert electrolyte (*e.g.*, NaCl) while keeping other concentrations constant, the rate constants for reacting species will either increase, remain constant, or decrease. Accordingly, the effect is denoted positive, absent, or negative. As shall be seen in the following discussion, the sign or the absence of the kinetic salt effect is a valuable aid in interpretation of mechanisms. Strictly quantitative relations between rate constants and ionic strength are only theoretically valid at exceedingly low concentrations. Since pharmaceutical investigations are most often conducted at ionic strength ranges higher than the theoretical limits, a review of findings from kinetics of pharmaceutical model systems might throw light on the actual range to which the kinetic salt effect can be extended.

THEORY

It can be shown (1) by means of transition-state theory that for a reaction in solution:

the rate constant, *k*, is related to the activity coefficients, γ , of the reactants (*A* and *B*) and the transition complex ($[AB^\ddagger]$) by:

$$\log k = \alpha + \log [\gamma_A \gamma_B / \gamma_{[AB^\ddagger]}] \quad (\text{Eq. 2})$$

The charges, *z*, of the three species are related to one another by $z_A + z_B = z_{[AB^\ddagger]}$. Applying this and the Debye-Hückel limiting law:

$$\log \gamma = -Q \cdot z^2 \sqrt{\mu} \quad (\text{Eq. 3})$$

Table I—Values of $2Q = 3.65 \cdot 10^6 \cdot [\rho / \epsilon^3 T^3]^{0.5}$ at Various Temperatures

to Eq. 2 for a solution of overall ionic strength, μ , leads to the well-known Brønsted-Bjerrum equation (2-5):

$$\log k = \alpha + 2 \cdot Q \cdot z_A \cdot z_B \cdot \sqrt{\mu} \quad (\text{Eq. 4})$$

where $2Q = 1.018$ for aqueous solutions at 25°. Since $Q = 1.825 \cdot 10^6 \cdot [\rho / \epsilon^3 T^3]^{0.5}$, where ϵ is the dielectric constant, ρ is density, and *T* is the absolute temperature, the coefficient to $\sqrt{\mu}$ changes with temperature. A list of values of $2Q$ is given in Table I.

The Debye-Hückel equation is usually only obeyed in ionic strength ranges up to 0.01 (6). Figure 1 is an example of this showing the mean activity coefficients of hydrochloric acid in potassium chloride solutions of varying ionic strength (7). Equation 4 is, therefore, only strictly applicable up to this concentration.

The modified Debye-Hückel equation for higher concentrations is

$$\log \gamma_{\pm} = \frac{z^2 \cdot Q \cdot \sqrt{\mu}}{1 + \beta \sqrt{\mu}} \quad (\text{Eq. 5})$$

and holds up to an ionic strength of about $\mu = 0.1$ (8). Using this in the development outlined for Eq. 4 yields

$$\log k = \alpha + 2 \cdot Q \cdot z_A \cdot z_B \cdot \frac{\sqrt{\mu}}{1 + \beta \sqrt{\mu}} \quad (\text{Eq. 6})$$

It is recalled that μ is the overall ionic strength, but β depends on the ionic diameter of the reacting species, and this usually is unknown. Linearity and slopes, however, are not very sensitive to the magnitude of β , which is always close to unity; it is the practice of some authors (9) to test kinetic salt effects with this assumption, *i.e.*,

$$\log k = \alpha + 2 \cdot Q \cdot z_A \cdot z_B \cdot \frac{\sqrt{\mu}}{1 + \sqrt{\mu}} \quad (\text{Eq. 7})$$

The slope of such a plot should be close to the value of $2 \cdot Q \cdot z_A \cdot z_B$ (which is not necessarily an integer, all depending on tem-

Kinetic Salt Effect in Pharmaceutical Investigations

J. THURØ CARSTENSEN

Abstract □ The use of the kinetic salt effect in kinetic investigations has been widespread since its original derivation by Brønsted and Bjerrum in 1925. Its derivation is tied in with the Debye-Hückel theory, and it would be expected that the concentration range of applicability of the kinetic salt effect would be confined to that of the corresponding Debye-Hückel expression, *i.e.*, less than 0.01 *M*. A review of the pharmaceutical literature shows that applications may be extended to higher concentration ranges. Deviations from the Debye-Hückel expressions by the charged reactants and by the transition complex may be of the same magnitude and sign, and this may be the cause for the concentration range extension.

Keyphrases □ Kinetic salt effect—pharmaceutical solutions □ Ionic strength effect—high ionic concentrations □ Hydrolysis—kinetic salt effect □ Degradation, drug—kinetic salt effect

Properly conducted kinetic studies always, directly or indirectly, take into account the so-called kinetic salt effect. By varying the ionic strength by addition of an inert electrolyte (*e.g.*, NaCl) while keeping other concentrations constant, the rate constants for reacting species will either increase, remain constant, or decrease. Accordingly, the effect is denoted positive, absent, or negative. As shall be seen in the following discussion, the sign or the absence of the kinetic salt effect is a valuable aid in interpretation of mechanisms. Strictly quantitative relations between rate constants and ionic strength are only theoretically valid at exceedingly low concentrations. Since pharmaceutical investigations are most often conducted at ionic strength ranges higher than the theoretical limits, a review of findings from kinetics of pharmaceutical model systems might throw light on the actual range to which the kinetic salt effect can be extended.

THEORY

It can be shown (1) by means of transition-state theory that for a reaction in solution:

the rate constant, *k*, is related to the activity coefficients, γ , of the reactants (*A* and *B*) and the transition complex ($[AB^\ddagger]$) by:

$$\log k = \alpha + \log [\gamma_A \gamma_B / \gamma_{[AB^\ddagger]}] \quad (\text{Eq. 2})$$

The charges, *z*, of the three species are related to one another by $z_A + z_B = z_{[AB^\ddagger]}$. Applying this and the Debye-Hückel limiting law:

$$\log \gamma = -Q \cdot z^2 \sqrt{\mu} \quad (\text{Eq. 3})$$

Table I—Values of $2Q = 3.65 \cdot 10^6 \cdot [\rho / \epsilon^3 T^3]^{0.5}$ at Various Temperatures

^a ϵ -values used in the computation are from Reference 43, and ρ -values are from Reference 44.

to Eq. 2 for a solution of overall ionic strength, μ , leads to the well-known Brønsted-Bjerrum equation (2-5):

$$\log k = \alpha + 2 \cdot Q \cdot z_A \cdot z_B \cdot \sqrt{\mu} \quad (\text{Eq. 4})$$

where $2Q = 1.018$ for aqueous solutions at 25°. Since $Q = 1.825 \cdot 10^6 \cdot [\rho / \epsilon^3 T^3]^{0.5}$, where ϵ is the dielectric constant, ρ is density, and *T* is the absolute temperature, the coefficient to $\sqrt{\mu}$ changes with temperature. A list of values of $2Q$ is given in Table I.

The Debye-Hückel equation is usually only obeyed in ionic strength ranges up to 0.01 (6). Figure 1 is an example of this showing the mean activity coefficients of hydrochloric acid in potassium chloride solutions of varying ionic strength (7). Equation 4 is, therefore, only strictly applicable up to this concentration.

The modified Debye-Hückel equation for higher concentrations is

$$\log \gamma_{\pm} = \frac{z^2 \cdot Q \cdot \sqrt{\mu}}{1 + \beta \sqrt{\mu}} \quad (\text{Eq. 5})$$

and holds up to an ionic strength of about $\mu = 0.1$ (8). Using this in the development outlined for Eq. 4 yields

$$\log k = \alpha + 2 \cdot Q \cdot z_A \cdot z_B \cdot \frac{\sqrt{\mu}}{1 + \beta \sqrt{\mu}} \quad (\text{Eq. 6})$$

It is recalled that μ is the overall ionic strength, but β depends on the ionic diameter of the reacting species, and this usually is unknown. Linearity and slopes, however, are not very sensitive to the magnitude of β , which is always close to unity; it is the practice of some authors (9) to test kinetic salt effects with this assumption, *i.e.*,

$$\log k = \alpha + 2 \cdot Q \cdot z_A \cdot z_B \cdot \frac{\sqrt{\mu}}{1 + \sqrt{\mu}} \quad (\text{Eq. 7})$$

The slope of such a plot should be close to the value of $2 \cdot Q \cdot z_A \cdot z_B$ (which is not necessarily an integer, all depending on tem-

Figure 1—Logarithm of the activity coefficient of hydrochloric acid as a function of the square root of ionic strength (2).

perature) and should allow evaluation of the integer value of the product of z_A and z_B .

In the case of higher ionic strengths, an ionic strength effect is possible even if one or both reacting molecules are uncharged. At high ionic strength, if A was charged and B not, then reaction $A + B \rightarrow [AB^+]$ would dictate that $z^\ddagger = z_A$. At high ionic strength, the following relation (10) often holds:

$$-\log \gamma_A = -\log \gamma^\ddagger = \frac{z^2 \cdot \alpha \cdot \sqrt{\mu}}{1 + \beta \sqrt{\mu}} - b \cdot \mu \quad (\text{Eq. 8})$$

At high ionic strength (11), the activity coefficient of the uncharged species adheres to

$$\log \gamma_B = b_B \mu \quad (\text{Eq. 9})$$

which, by a treatment similar to the one leading to Eq. 7, yields

$$\log k = \log k_0 + [b_A + b_B - b^\ddagger] \cdot \mu \quad (\text{Eq. 10})$$

i.e., the logarithm of the rate constant should be proportional to the ionic strength. In the case of two uncharged molecules, application of Eq. 9 by itself would lead to an equation of the type of Eq. 10.

Aside from these so-called primary salt effects, a secondary salt effect at times is important. In buffer-catalyzed degradations, an ionized species B^- may be catalytic, whereas the corresponding acid, HB , may not be. The ionization constants of the acid are affected in a manner similar to that described by Eqs. 4 and 10. Increasing ionic strength can affect the concentration of B^- and, in this indirect manner, influence the value of the rate constant.

EXAMPLES

Zero Effect—One of the values of the kinetic salt effect as an experimental tool is that if a decomposition does not exhibit a kinetic salt effect, then reactions of two charged species can be eliminated from consideration, since either z_A or z_B would have to be zero. Examples of this are hydrolysis of the following compounds in aqueous solution: streptozotocin (12), streptovaricin (13), diethylaminoethylsalicylate hydrochloride (14), acetylsalicylic acid anhydride (15), procaine hydrochloride (16, 17), chloramphenicol (18), *N*-acetyl-*p*-aminophenol (19), chlorobutanol (20), ascorbic acid (21, 22), phenobarbital (23), idoxuridine (24), penicillin at low pH (25), morphine (26), cycloserine (27), and hydroxocobalamin (28).

Integer Effects—Where kinetic salt effects do exist, they imply that charged species are of identical or opposite charge. Since even model pharmaceutical systems by necessity are in concentration ranges above 0.01 ionic strength, Eq. 4 cannot be expected to hold. In all of the cases to be cited (29–38), however, linearity prevails, but the slopes differ from $2 \cdot Q \cdot z_A \cdot z_B$, and other evidence has been employed by the respective authors to support proposed mechanisms.

Brooke and Guttman (29) used kinetic salt effect data in investigating the complex formation between 3-carbomethoxy-1-methylpyridinium cation (NME) and 8-chlorotheophyllinate anion (CT). Figure 2 shows their data plotted both according to Eqs. 4 and 7 and (in spite of the scatter) implies the applicability of Eq. 7

Figure 2—Kinetic salt effect on degradation of 3-carbomethoxy-1-methylpyridinium cation (29) at 30°, plotted according to Eq. 4 (Δ , upper scale) and according to Eq. 7 (\circ , lower scale).

up to an ionic strength of 1.2. When plotted according to Eq. 7, the slope is close to the theoretical.

Hussain *et al.* (30), in studying the degradation of echthiophate in aqueous solution, supported their proposed mechanism by a negative kinetic salt effect and found linearity up to an ionic strength of 0.02 when plotting was performed according to Eq. 4; the slope (0.9) is close to the theoretical as shown in Fig. 3. It is seen from Fig. 3, however, that use of Eq. 7 extends the useful range to an ionic strength of 0.2 (but not 0.5), still yielding a slope (0.91) close to the theoretical.

Felmeister *et al.* (31) employed the kinetic salt effect to support their contention that dismutation of the semiquinone free radical of chlorpromazine (C^\cdot) took place via a reaction of the type $C^{\cdot+} + H^+ \rightarrow [HC^{\cdot++}]$. However, they point out that at pH 1.96, the species $H_2C^{\cdot++}$ might also react with H^+ to form a transition complex. The former type, at 25°, should yield a positive slope of 2.036, as opposed to the value of 1.6 found when plotting was performed according to Eq. 4. As shown in Fig. 4, plotting according to Eq. 7 yields a slope of 2.3, i.e., somewhat closer to the theoretical value, and may be implying that $H_2C^{\cdot++} + H^+$ plays a part in the overall scheme. The useful range would appear to be up to $\mu = 0.2$, but tabulated data (31) would imply linearity according to Eq. 7 (but not Eq. 4) up to $\mu = 0.5$.

Finholt *et al.* (25) demonstrated a positive kinetic salt effect in penicillin degradation at alkaline pH. Their data are shown in Fig. 5, plotted according to both Eqs. 4 and 7. At pH 6.8, the positive effect is used to postulate penicillin (P) degradation according to the scheme $P^- + HPO_4^{2-} \rightarrow$ products, and the slope of 2 resulting from Eq. 7 would support such a view. The probable mechanism at pH

Figure 3—Kinetic salt effect on degradation of echthiophate at 22° (30), plotted according to Eq. 4 (\bullet , upper scale) and according to Eq. 7 (\circ , lower scale).

Figure 4—Kinetic salt effect on degradation of chlorpromazine at 25° (31), plotted according to Eq. 4 (○) and according to Eq. 7 (●).

8.75 would be a reaction of the type $P^- + H_2BO_3^- \rightarrow$ products. This is not in conflict with the reported pH profile since, well below the pK_2 of boric acid, the logarithm of the concentration of $H_2BO_3^-$ is proportional to pH. In this case, use of Eq. 7 appears valid to an ionic strength of 0.5.

Koshy and Mitchner (32) studied the hydrolysis of 2-(4-phenyl-1-piperazinylmethyl)cyclohexanone (X) at 60°. At pH 5 the kinetic salt effect yields a slope of -0.61 when plotted according to Eq. 4 and a slope of -1.29 , i.e., close to the theoretical, when plotted according to Eq. 7. This strongly supports the authors' contention (32) that $X^+ + B^- \rightarrow$ products is the predominant reaction. In this case, both Eqs. 4 and 7 yield linearity up to $\mu = 0.4$.

Fractional Effects—The theoretical slope values, of course, can only be expected when the possibility of parallel reactions can be eliminated (unless both of the same ionic makeup). Szulcowski *et al.* (33) studied the isomerization and hydrolysis of 4,6-diamino-1-(3,5)-dichlorophenyl-1,2-dihydro-2,2-dimethyl-1,3,5-triazine (I) at 65° and a pH of 1.85 and found it to involve both IH^+ and I. When plotted according to Eq. 4, their data yield a slope of 0.5, whereas use of Eq. 7 results in the value 0.86, i.e., still somewhat removed from the theoretical value. Equations 4 and 7 here hold up to $\mu = 0.16$.

A similar situation exists in the degradation of thiamine (34). Here, again, plotting (Fig. 6) according to Eq. 7 extends the useful range of ionic strength to $\mu = 0.22$, but the slope (0.87) is not close to the theoretical. As pointed out by the authors (34), secondary salt effects may be of significance in their system.

The positive kinetic salt effect reported for acid hydrolysis of niacinamide (N) at 89.4° by Finholt and Higuchi (35) yields a slope value of 0.1 if plotted according to Eq. 4 and a slope of 0.6 if plotted according to Eq. 7. Therefore, as pointed out by the authors (35), both $N^+ + H^+$ and $N + H^+$ must be involved, with rate constants of the same order of magnitude.

Other examples of fractional effects are the study on barbital degradation by Goyan *et al.* (36) and the degradations of diethylaminoacetylsalicylate hydrochloride (37) and methylpyrrolidylacetylsalicylate hydrochloride (38) reported by Garrett.

Behavior at High Ionic Strength—At ionic strengths above 1, Eq. 10 may be expected to hold, but the b -values are mostly of such low magnitude that absence of ionic strength effect would result in the cases to which it applies. There are three cases in recent pharmaceutical literature where Eq. 10 applies: (a) Schroeter's

Figure 5—Kinetic salt effect on degradation of penicillin in phosphate buffer at pH 6.8 and 60° (25), plotted according to Eq. 4 (○) and according to Eq. 7 (●). Plots in borate buffer at pH 8.75 parallel the lines shown in the figure.

Figure 6—Kinetic salt effect on degradation of thiamine at pH 6.40 and 96.4° (34), plotted according to Eq. 4 (○) and according to Eq. 7 (●).

investigation of salicyl alcohol interaction with sulfites (39); (b) the investigation of Siegel *et al.* (40) of the hydrolysis of methyl DL- α -phenyl-2-piperidylacetate; and (c) Hou and Poole's investigation of degradation of ampicillin at low pH (41).

DISCUSSION

The only case in recent pharmaceutical literature where the extended Debye-Hückel equation has been used is the (nonkinetic) study by Zografi *et al.* (42). The intents of this communication have been to advocate the advantages of using Eq. 7 as a plotting procedure when kinetic salt effects are under study, and to point to the fact that the concentration range in which it may be used may be as high as unity ionic strength, i.e., well beyond the range of both Eqs. 3 and 5.

Table II lists, in tabulated form, the slope values and ionic strength ranges extracted from this survey. It is quite obvious that the range of applicability is considerably higher than what would be expected from the limiting μ -ranges for Eqs. 3 and 5. Only in the case of echthiophate is the maximum allowable ionic strength definitely less than 0.5. Since Eq. 8 holds for ionic strength ranges above $\mu = 0.1$, an equation of type 7 can be derived to yield:

$$\log k = \log k_0 + \frac{2 \cdot z^2 \cdot Q \sqrt{\mu}}{1 + \beta \sqrt{\mu}} - [b_A + b_B - b_T] \cdot \mu \quad (\text{Eq. 11})$$

Table II—Slope Values and Ionic Strength Ranges for the Kinetic Salt Effect in Degradations Reported in Pharmaceutical Literature

Substance	Reference	Slope			Maximum Ionic Strength, μ	Temperature
		Eq. 4	Eq. 7	2Q		
3-Carbomethoxy-1-methylpyridinium cation	29	0.42	1.2	1.03	$0.2 < \mu_{\max.} > 1.2$ $\mu_{\max.} < 0.5$ $\mu_{\max.} > 0.5$ $\mu_{\max.} > 0.5$	30
Echthiophate	30	0.9	0.9	1.01		22
Chlorpromazine	31	1.6	2.3	2.04		25
Penicillin	25	0.8	2.0	2.18		60
2-(4-Phenyl-1-piperazinylmethyl)cyclohexanone	32	-0.61	-1.29	-1.09	$\mu_{\max.} > 0.4$	60
4,6-Diamino-1-(3,5)-dichlorophenyl-1,2,2,2-dimethyl-1,3,5-triazine	33	0.5	0.86	1.10	$\mu_{\max.} > 0.16$	65
Thiamine	34	-0.37	-0.87	-1.19	$\mu_{\max.} > 0.22$	96.4
Niacinamide	35	0.1	0.6	1.17	$\mu_{\max.} > 0.8$	89.4

An explanation for the extended range could be that, in most cases, the factor $[b_A + b_B - b_{\dagger}]$ is close to zero. Both b_A and b_B can be determined experimentally by measuring activity coefficients as a function of ionic strength for the reactants A and B . Of course, b_{\dagger} is not subject to direct experimental determination.

In Vitro and In Vivo Chlorpromazine Availability from Flocculated Polysalt Complex Systems

P. A. JABLON*, G. S. BANKER, and V. F. SMOLEN

Abstract □ An insoluble drug-polysalt complex of chlorpromazine hydrochloride, sodium carboxymethylcellulose, and protamine sulfate was selected as a model to evaluate the effects of these macromolecular constituents on the *in vitro* and *in vivo* availability of the interacted drug. The *in vitro* liberation of drug from the polysalt complex was studied in simulated gastrointestinal fluids as a function of particle size, pH of formation of the complex flocculate, and presence and absence of enzymes in the medium. The *in vitro* drug-release studies conducted under these varying conditions suggested that the product possessed prolonged-release properties. In contrast, the *in vivo* studies with rats revealed a promoted bioavailability of the drug in the presence of the polysalt complex. Protamine sulfate, a known pinocytotic inducer, was observed to be specifically implicated in this phenomenon.

Keyphrases □ Flocculated complex systems, polysalt—chlorpromazine-³⁵S availability □ Chlorpromazine-³⁵S-polysalt complex systems—*in vivo*—*in vitro* availability □ Release rates—chlorpromazine-³⁵S-polysalt complex □ pH effect—chlorpromazine-³⁵S-polysalt complex stability □ Scintillometry—analysis

The physical form of a polyelectrolyte salt complex (polysalt) is a function of the charge densities of the

interacting species. Macromolecules with high charge densities tend to form precipitates (floculates), while those with lower charge densities tend to form a gel (coacervate) or quasiliquid product (1). The use of complex coacervates as a means of microencapsulating drugs has been claimed in a number of patents (2-7). Luzzi and Gerraughty (8, 9) have noted that complex coacervates of gelatin and acacia with pentobarbital may be employed to control the liberation of the encapsulated material into gastrointestinal fluids. They studied the release rate of the drug as a function of pH, temperature, ratio of solid to encapsulating material, quantity of hardening agent (formaldehyde), and addition of surfactants. In contrast, polysalt floculates have received relatively little attention in the pharmaceutical literature.

The present drug-polysalt system was chosen on the basis of preliminary studies. It was found that a polysalt of sodium carboxymethylcellulose (NaCMC) and protamine sulfate interacted with appreciable quantities of

An explanation for the extended range could be that, in most cases, the factor $[b_A + b_B - b_{\dagger}]$ is close to zero. Both b_A and b_B can be determined experimentally by measuring activity coefficients as a function of ionic strength for the reactants A and B . Of course, b_{\dagger} is not subject to direct experimental determination.

In Vitro and In Vivo Chlorpromazine Availability from Flocculated Polysalt Complex Systems

P. A. JABLON*, G. S. BANKER, and V. F. SMOLEN

Abstract □ An insoluble drug-polysalt complex of chlorpromazine hydrochloride, sodium carboxymethylcellulose, and protamine sulfate was selected as a model to evaluate the effects of these macromolecular constituents on the *in vitro* and *in vivo* availability of the interacted drug. The *in vitro* liberation of drug from the polysalt complex was studied in simulated gastrointestinal fluids as a function of particle size, pH of formation of the complex flocculate, and presence and absence of enzymes in the medium. The *in vitro* drug-release studies conducted under these varying conditions suggested that the product possessed prolonged-release properties. In contrast, the *in vivo* studies with rats revealed a promoted bioavailability of the drug in the presence of the polysalt complex. Protamine sulfate, a known pinocytotic inducer, was observed to be specifically implicated in this phenomenon.

Keyphrases □ Flocculated complex systems, polysalt—chlorpromazine-³⁵S availability □ Chlorpromazine-³⁵S-polysalt complex systems—*in vivo*—*in vitro* availability □ Release rates—chlorpromazine-³⁵S-polysalt complex □ pH effect—chlorpromazine-³⁵S-polysalt complex stability □ Scintillometry—analysis

The physical form of a polyelectrolyte salt complex (polysalt) is a function of the charge densities of the

interacting species. Macromolecules with high charge densities tend to form precipitates (floculates), while those with lower charge densities tend to form a gel (coacervate) or quasiliquid product (1). The use of complex coacervates as a means of microencapsulating drugs has been claimed in a number of patents (2-7). Luzzi and Gerraughty (8, 9) have noted that complex coacervates of gelatin and acacia with pentobarbital may be employed to control the liberation of the encapsulated material into gastrointestinal fluids. They studied the release rate of the drug as a function of pH, temperature, ratio of solid to encapsulating material, quantity of hardening agent (formaldehyde), and addition of surfactants. In contrast, polysalt floculates have received relatively little attention in the pharmaceutical literature.

The present drug-polysalt system was chosen on the basis of preliminary studies. It was found that a polysalt of sodium carboxymethylcellulose (NaCMC) and protamine sulfate interacted with appreciable quantities of

chlorpromazine hydrochloride (CPZ HCl) to form a drug-polysalt complex. This material was insoluble at pH 7.40 and very slowly soluble in 0.1 *N* hydrochloric acid. Another important characteristic was the presence of a proteolyzable polymer. Therefore, it was proposed that a system of this type may be of value in controlling the liberation of the interacted drug in gastrointestinal fluids by utilizing not only its slow dissolution but also the possible destruction of the flocculated drug-polysalt matrix through enzymatic degradation. The present work was directed to elucidate *in vitro* release properties of the drug-polysalt complex in simulated gastrointestinal fluids and to compare these results with the *in vivo* behavior of the system as reflected in its pharmacological response characteristics.

MATERIALS AND METHODS

Materials—All reagents were analytical grade, except barbital NF. The protamine sulfate utilized as the polycation in this work represented a highly purified protein which met all USP requirements.¹ A low-viscosity grade (25–50 cps. in 2% solution) of NaCMC² was employed as the polyanion. The specific activity of the ³⁵S-CPZ HCl,³ initially 3.57 μ Ci/mg., was adjusted to 20,000 d.p.m./mg. with unlabeled drug,⁴ and this powder dilution was used in all subsequent experiments. Animals utilized in the *in vivo* portion of this study were 75-day-old albino male rats, Holtzman⁵ strain.

Solutions—A pH 7.70 buffer was prepared from 0.05 *M* barbital and sufficient sodium hydroxide. Sodium acetate (0.05 *M*) and hydrochloric acid were employed to prepare a pH 4.75 buffer. Gastrointestinal fluids were prepared according to USP XVII unless otherwise noted. The scintillation cocktail XDC (10) was utilized as a counting solution. When required, approximately 15.0 ml. of the scintillation fluid was added to a low potassium glass counting vial⁶ containing 5.0–5.5% colloidal silica pigment.⁷ A thick gel promptly formed which was suitable for suspending any materials precipitated from solution by the XDC.

Preparation of Labeled CPZ-Polysalt Complex—Buffered stock solutions of the polymers were prepared. An aliquot of the NaCMC solution was transferred to a beaker containing an accurately weighed quantity of the ³⁵S-CPZ HCl. The mixture was stirred until a precipitate had completely formed. Protamine sulfate solution was then added with constant stirring to flocculate the system. The contents of the beaker were filtered through a medium sintered-glass funnel with the aid of suction. The gummy mass was vacuum dried to constant weight, crushed in a mortar, and assayed for drug content. Drug-polysalts were prepared in this manner from ³⁵S-CPZ HCl, 2 parts protamine sulfate, and 3 parts NaCMC. Drug-polysalt complexes flocculated in buffers at pH values of 4.75 and 7.70 were designated drug-polysalt A and drug-polysalt B, respectively. Tablets of these drug-polysalt materials, weighing approximately 250 mg. and containing approximately 100 mg. of drug, were prepared by direct compression on a Carver laboratory press with a 0.78-cm. (0.31-in.) standard cup punch and die set using an applied load of 500 lb./in.²

Preliminary work had revealed that this procedure and the order of combination of polymers in the ratio of 2 parts protamine sulfate to 3 parts NaCMC (in the presence of drug) yielded a flocculated product which was optimal with respect to the quantity of drug and colloids cleared from solution. Flocculated drug-polysalts prepared in three separate replications at each pH were found to contain $41.05 \pm 1.5\%$ and $40.08 \pm 0.59\%$ w/w of drug for drug-polysalt A and drug-polysalt B, respectively. In the absence of drug, maximum quantities of the polymers were found to be flocculated and cleared from solution when the polymers were

combined in electrically equivalent quantities. For example, the apparent equivalent weights of protamine sulfate and NaCMC in the pH 7.70, 0.05 *M* barbital buffer were determined, from the measurement of Donnan membrane potentials, to be 1260 and 615 g. per equivalent of charge, respectively. As anticipated, the most stable flocculates were obtained when the polymers, in the absence of drug, were combined in approximately the ratio of 2 parts protamine to 1 part NaCMC.

Radioassay for ³⁵S-CPZ HCl—Solutions of the labeled drug were counted for 10 min. (or 10,000 counts) in a Packard⁸ Tricarb model 574 liquid scintillation spectrometer. The counting efficiency was determined by the internal standard method. Before assay for drug content, samples of the flocculated drug-polysalt were pre-treated with hot concentrated sulfuric acid to effect solution.

In Vitro CPZ Release Methodology—A dissolution dialysis technique was selected for the *in vitro* drug-release studies in an attempt to simulate *in vivo* conditions. The polymer impermeable membrane utilized was intended to approximate the behavior of the gastrointestinal mucosal membrane by retaining soluble drug-polymer complexes released from the drug-polysalt system. Only the availability of the free drug, and perhaps drug associated to very small fragments of proteolyzed protamine, would be measured. Therefore, the dissolution dialysis release profile may be expected to be more closely representative of the *in vivo* absorption of CPZ from the polysalt complex than a release profile based upon dissolution alone.

Dissolution dialysis experiments utilized a cell composed of a sac of Nojax² cellulose tubing which contained 10 ml. of dialysis fluid and the materials to be dialyzed. Before use, the casing was boiled in 5% acetic acid and flushed well with distilled water. The sac was prepared by cutting the tubing to the required length and tying one end closed. The materials were introduced through the open end of the casing, which was then tied tightly with nylon cord at the upper level of the liquid. Free casing above the closure was knotted around the cord and the excess trimmed off. Sacs prepared in this manner had approximately the same surface area. The sacs were immersed in round, amber, 90-ml. (3-fl. oz.) bottles filled with 50 ml. of the dialysis fluid. The cap of the cell was sealed with tape. The *in vitro* release characteristics of the labeled drug-polysalts were evaluated in simulated gastric fluid, simulated intestinal fluid, and simulated intestinal fluid without enzymes. The drug-release cells were assembled and placed on the reciprocating platform of a shaker-type water bath maintained at 37°. At appropriate intervals during an 8-hr. period, samples of the (outside) fluid were removed from the cells and transferred to counting vials. An equal quantity of the test fluid was then added to the cell to maintain a constant volume. All fluids were freshly prepared and prewarmed to 37° before use. The cells were agitated at a constant rate of approximately 60, 3.8-cm. excursions/min.

In Vivo Studies of the Drug-Polysalt System—The criterion selected for evaluating the *in vivo* characteristics of the flocculated drug-polysalt complex was the depression of spontaneous motor activity in rats. Williamson⁸ activity cages (11), which showed negligible differences in sensitivity, were employed to measure this pharmacologic response. The ED₅₀ to produce the desired effect in the rat has been reported as 4.4 mg./kg. of CPZ HCl (12). Dragstedt (13) emphasized the importance of administering identical doses of drug in the same fashion when testing products for sustained-release properties. In accordance with this principle, all animals that received a dosage form of the drug as a treatment were given 4.4 mg./kg. of CPZ HCl.

In the first set of *in vivo* experiments, rats were selected at random in groups of three at a time from a colony of 32 previously untreated animals. Each rat in the colony was fasted for 24 hr., orally dosed with polysalt blank (*i.e.*, polymers interacted in the absence of drug), and placed in the Williamson cages for 11.5 hr. The spontaneous activity of these rats was then redetermined in the same manner, except that one of the four treatments was substituted for the polysalt blank. The animals received either a second dose of polysalt blank, a 40% mixture of CPZ HCl in mannitol (drug control), drug-polysalt A, or drug-polysalt B. To optimize sensitivity, the experiments were run from 8:00 p.m. until 7:30 a.m. Rats are nocturnal animals and therefore most active at night. Influences arising from environmental disturbances were minimal

during this time period. Each of the four treatments was replicated on eight different rats.

A dosing device was developed to administer the treatments orally. The apparatus, illustrated in Fig. 1, consisted of an oral dosing needle through which a copper wire bearing a dried epoxy resin plunger was inserted at the far end. A section of catheter tubing was attached to the beveled end of the needle over the plunger. The material that the animal received was weighed into the bottom half of a tared No. 5 gelatin capsule which was subsequently moistened until flexible, folded in half, and placed in the section of tubing. The dosing needle was then inserted into the esophagus of the animal; the copper wire plunger rod was pushed forward to eject the capsule. Since rodents do not have the ability to regurgitate, the capsule and its contents were carried to the stomach by peristalsis. Immediately following dosing with the capsule, the animal received about 0.5 ml. water through the dosing needle.

A second set of *in vivo* experiments was conducted on a new colony of 18 rats according to the general procedure already outlined. The three treatment groups were a drug control of 40% CPZ HCl in mannitol, a physical mixture of 40% CPZ HCl and protamine sulfate, and particles of drug-polysalt which would not pass a 30-mesh screen. Each of the three treatments was replicated on six different rats.

RESULTS AND DISCUSSION

***In Vitro* Release Studies in Simulated Gastric Fluid**—Figure 2 illustrates the dissolution dialysis of various physical forms of the drug in simulated gastric fluid. The uppermost curve in Fig. 2 was obtained with 100 mg. of ^{35}S -CPZ dissolved in 10 ml. of simulated gastric fluid contained within the dialysis sac. This is the same quantity of CPZ as was contained in the drug-polysalts studied in the same manner. However, the dialysis sac served in this case to restrain the ready transfer of CPZ into the outside compartment. It is apparent from the other curves that the presence of a polysalt complex provided a significant additional retardation.

Comparison of the curves for the tablets prepared from drug-polysalt B and small particles of the same material (>30 mesh) reveals the delaying effect of compression on the release of CPZ. This result obviously implicates the surface area of the drug-polysalt as a factor affecting the release of drug from the system.

Figure 2—*In vitro* release of ^{35}S -labeled chlorpromazine through cellulose sacs into simulated gastric fluid. Key: \square , dialysis solution control of drug alone; \bullet , tablets drug-polysalt A; \blacksquare , tablets drug-polysalt B; \blacktriangle , particles drug-polysalt B (>30 mesh); and \circ , tablet control (physical mixture of polymer and drug).

Upon immersion of the drug-polysalt tablets in gastric fluid, the cream-white biconcave disk appeared to swell slightly; a uniform three-dimensional gray band began to form around the outer edge, widen, and move gradually toward the core. After 8–10 hr., the cream-white solid matrix was replaced by a gray, swollen, gel-like structure. From these visual observations, it can be hypothesized that as the simulated gastric fluid penetrated the matrix, it began to solubilize the protamine, forming a network of channels in the

Figure 3—Release of ^{35}S -labeled chlorpromazine from drug-polysalt tablets into simulated intestinal fluid without enzymes. Key: \blacktriangle , tablet control (physical mixture of polymers and drugs); \blacksquare , tablets drug-polysalt A; and \bullet , tablets drug-polysalt B.

remaining structure of insoluble free acid CMC. The entrapped drug was also solubilized by the gastric fluid; as channels were created, it dissolved and slowly leached out into the surrounding medium.

CPZ Release in Simulated Intestinal Fluids—At pH 7.4 the tablets swelled rapidly and the matrix soon broke apart into large cream-white particles. The particles, although swollen, appeared to retain their structural integrity in contrast to the behavior of the polysalt complex in gastric fluid. Figure 3 illustrates the slow release of drug from the polysalt system in simulated intestinal fluid without

enzymes. Figure 4 presents the dissolution dialysis profile of drug-polysalt A and B tablets in simulated intestinal fluid with enzymes following pretreatment by immersion, for 2 hr., in gastric fluid. This system was intended to simulate *in vivo* conditions where the enzymes can serve as additional means of degrading the complex and liberating the drug. However, in all cases with intestinal fluid, only relatively small amounts of CPZ were released. This can be attributed to the insolubility of the drug and the stability of its polysalt matrix in this medium. It was found that a control study of CPZ dialysis could not be performed for intestinal fluid in the same manner as that done for gastric fluid because of the limited solubility of the drug in this medium.

Influence of pH of Formation on the Stability of the Drug-Polysalt Complex—Since both the drug and polymers are weak electrolytes, the extent of drug-polymer and polymer-polymer electrostatic interactions would be expected to vary with pH. A given drug-polysalt complex should be maximally stable at its pH of formation when combined in electrically equivalent quantities. It is, therefore, also expected that the complex formed at pH 4.75 would be more stable in solutions of lower pH than a corresponding product flocculated at pH 7.70. Conversely, the drug-polysalt complex formed at pH 7.70 should be more stable in solutions at higher pH values relative to the product flocculated at pH 4.75. The release profiles of drug-polysalt complex tablets A and B (shown in Fig. 2) are clearly inconsistent with such expectations. Figure 2 reveals a faster and more complete liberation of CPZ in acid media from the drug-polysalt A tablet than from its B counterpart. Furthermore, visual observations during the study indicated that the tablet matrix of drug-polysalt A was less cohesive than that of the corresponding B product. The observed phenomenon is partly explicable in terms of the greater solubility of CPZ salt relative to free base. In the pH 7.70 formed drug-polysalt complex, the CPZ occurs to a greater extent in the less soluble form of the free base relative to the drug in the pH 4.75 formed complex. Although the relatively slow dissolution of the unionized form of the drug is a factor contributing to the limited release rate of the drug from the tablet matrix, it is not wholly responsible for the slow release. This is indicated in Fig. 3 by the observed faster drug release from a physical mixture of the drug with the polymers relative to the flocculate where, neglecting the occurrence of localized drug-polymer interaction, the rate-limiting factor in the availability of the drug from the tablet may be presumed to be its dissolution in the medium. The similarity in the

curves shown in Fig. 2 for drug release from tablets composed of a physical mixture and drug-polysalt B indicates, however, that under acidic conditions in the medium the slow dissolution of the unionized drug may be an important factor in limiting the drug's release.

Another factor may be one similar to the electrolyte plasticization effect observed by Michaels (14); the ions constituting the salt form of the drug can act as a shield to decrease the electrostatic attraction between polycation and polyanion, resulting in a less consolidated system with a greater elasticity and tendency to swell. The looser polymer network formed at pH 4.75 by this mechanism could allow the physically entrapped drug to be more readily released from the matrix.

Proposed Mechanism of Drug-Polysalt Interaction—Based on the preliminary observations and *in vitro* release studies, it can be hypothesized that the mechanism of uptake of the drug by the polysalt involves two consecutive processes. The drug first becomes bound to the NaCMC; upon addition of the protamine polycation, which possesses a greater affinity for the anionic binding sites on the CMC, some bound CPZ is competitively displaced. The released drug may then precipitate from solution due to local saturation and become physically entrapped within the solid polysalt matrix. The drug, therefore, likely exists in both a mechanically entrapped and physically adsorbed form within the polysalt matrix. Its mechanisms of release accordingly include desorption and dissolution.

In Vivo Studies of CPZ Availability—CPZ is cleared very rapidly from the bloodstream (15); the time course of pharmacological response intensity, *i.e.*, magnitude of depression of spontaneous motor activity, was studied in rats in lieu of direct determinations of the drug in body fluids. Male rats were selected because their general level of activity, although lower than the female's, is not subject to the cyclization accompanying the female's estrus cycle. The results of the first study are illustrated in Fig. 5. The "deviation" statistic utilized to describe the treatment-induced effects was obtained as the difference in pretreatment and posttreatment activity readings. The mean of this value for each treatment group was plotted as a function of time. A single factor analysis of variance was employed to indicate the presence of an overall significant difference among the four treatment groups at each hourly interval. At those time periods where the variance ratio, $F_{obs.}$, exceeded the critical value for the 0.05 probability level, comparison tests were employed to determine the exact group(s) responsible. These tests are summarized in Tables I and II. Table I is related to Fig. 5 in that it indicates the times and probability levels at which treatment-induced effects are significant. Table II specifies which treatments are responsible. It is obvious from the results that, contrary to expectation, no prolonged action effect was demonstrated by the drug-polysalt complexes.

However, a closer inspection of the results over a 6-hr. period following the treatments revealed that the depression of activity in one or both of the groups receiving a drug-polysalt was consistently greater than that in the group receiving the drug control. A comparison test, utilizing the average deviation of the two drug-polysalt treatment groups *versus* the drug control group, revealed a

statistical difference in activity for the 6-hr. period at approximately the 0.15 probability level.

Since only a heterogeneous mixture of drug-polysalt particles was utilized in the first experiment, it was felt that the use of larger particles (>30 mesh) might provide the desired sustained action. (The small quantity of drug-polysalt complex administered precluded its direct compression into tablets.) Of equal interest was an investigation into the possible cause of the apparently enhanced activity of the drug. The ability of such proteinaceous materials as protamine sulfate to act as inducers of pinocytosis has been well documented in the literature (16–21). Indeed, the striking observations of Whitmore (23), that gelatin microcapsules of streptomycin exhibited enhanced transport into polymorphonuclear leukocytes and macrophages, take on new meaning when he attributes the phenomenon to "phagocytosis" (*sic*) and cites as evidence the high degree of cytoplasmic vacuolation. These facts could conceivably provide a basis on which to explain the enhanced drug activity. Hence, another treatment variable was introduced to determine the effect of protamine sulfate alone on the biological availability of CPZ. Based on these considerations, a second set of *in vivo* experiments was performed. The results are shown in Fig. 6. A single factor analysis of variance (22) for significant differences among the various treatment combinations over an 11.5-hr. period is summarized in Table III. These data clearly demonstrate that the depression of spontaneous activity produced by both treatments was greater than that of the drug control group. Despite the larger particles used, however, no significant sustained action of the drug-polysalt complex was observed. There are several possible explanations for these findings. It is apparent that the presence of protamine alone and with CMC enhances the activity of CPZ. The mechanism by which this occurs is probably not merely Donnan exclusion (24), since drug release *in vitro*, where this nonspecific effect would also be manifested for the interacted system, is delayed rather than facilitated. Although the results of the present study do not provide direct evidence for its occurrence, stimulation of pinocytosis or some other effect of the polymers on the mucosal-absorbing surface in the gastrointestinal tract appears to be a reasonable possibility. If protamine does have the ability to induce cells of the gastrointestinal mucosal-absorbing surface to invaginate the surrounding medium, it could enhance the absorption of any drug present in that medium. If this was shown to be the case unequivocally, an entirely new concept of drug dosage design could be initiated. However, with the drug-polysalt system, there may be additional components to the mechanism involved in the augmented activity of the drug. Because CPZ is unstable in acidic solution, the polysalt complex possibly also acts to protect the drug from destruction in the stomach and thereby allows a larger fraction of the released medicament to be absorbed intact. Still another

Figure 6—Chlorpromazine-induced depression of spontaneous motor activity of rats as a function of time following administration of chlorpromazine in different dosage forms. Each point represents the average of six replications on different animals. Key: ▲, drug control (chlorpromazine HCl and mannitol); ●, chlorpromazine hydrochloride-protamine sulfate physical mixture; and ■, chlorpromazine-polysalt particles (>30 mesh).

alternative possibility in explaining the phenomena is that the drug is released from the system as a protamine complex which is absorbed more rapidly. The CMC may also be implicated in this process, since it can be taken up by mammalian tissue (25); indeed, CPZ itself has been reported to affect absorption through cell membranes (26). Thus, it may even be speculated that the particular combination of materials in the interacted system possesses a maximal ability to affect cellular uptake and enhance the pharmacologic response to CPZ.

The conditions employed in the *in vitro* release studies are obviously only a crude approximation of those actually obtained *in vivo*. Consequently, a diversity of factors may have been operative to produce the clearly evidenced lack of correlation between the *in vitro* and *in vivo* drug availability. Notable among these factors are the small volumes of gastrointestinal fluid available for the dissolution of the drug *in vivo* relative to that used in the *in vitro* study, as well as differences in mechanical agitation of the drug-releasing materials. These differences could contribute significantly to the discrepancy between the *in vitro* and *in vivo* results. Conceivably, *in vivo* the drug-release medium could have become rapidly saturated with drug. This would result in the passage of the drug across the gastrointestinal barrier to become the rate-limiting step in its absorption rather than its release from the dosage form. In this case, the differences in *in vivo* drug availability noted for the different formulations could be attributed to the specific effects of the macromolecular constituents of the dosage form on the barrier properties of the absorbing surfaces and/or their effects on the stability of the drug in the fluids. Because of the demonstrated

ability of such materials in altering the permeability properties of cells, the former effect may be considered more likely.

Also, in considering the relatively small volumes of fluid available for action upon the administered materials *in vivo*, it cannot be neglected that gelatin-encapsulated particles were used *in vivo* while compressed tablets were used *in vitro*. The use of gelatin-encapsulated particles was necessitated by the difficulties in compressing the small amounts of drug-polysalt complex comprising the dose of CPZ for the rats. A slow dissolution of the gelatin capsules in the limited fluids available *in vivo* could have slowed the release of the drug in all cases and also masked the differences among the formulations such as were observed *in vitro*.

CONCLUSIONS

In vitro dissolution dialysis studies clearly indicated a prolongation of drug release from polysalt flocculates. The *in vivo* results with rats did not, however, support this conclusion. Nevertheless, these results do elicit the speculation that, should the observed *in vivo* effects of the polymeric constituents on CPZ availability be a consequence of an active alteration of the permeability properties of the mucosal barrier, *e.g.*, endocytotic induction, it may also be possible, in general, to promote similarly the absorption of irregularly and poorly absorbed orally administered drugs.

Cytochrome P-450 and Alkaloid Synthesis in *Claviceps purpurea*

S. H. AMBIKE and R. M. BAXTER

Abstract □ Tryptophan, 4-dimethylallyltryptophan, and various analogs of tryptophan were investigated for their effect on binding to cytochrome P-450 and on cytochrome P-450 and total alkaloid levels in *Claviceps purpurea*. These compounds were shown not to affect cytochrome P-450 levels, in contrast to phenobarbital which increased the levels, but rather exhibited stereospecific binding to cytochrome P-450. Those compounds (L-tryptophan and L-4-dimethylallyltryptophan), which showed the highest binding affinity and are known precursors, caused the greatest increase in total alkaloid levels. The significance of these findings is discussed.

Keyphrases □ Cytochrome P-450, alkaloid synthesis—*Claviceps purpurea* □ ¹⁴C-L-Tryptophan, tryptophan analogs—cytochrome P-450 □ *Claviceps purpurea* growth—tryptophan analogs □ Colorimetric analysis—spectrophotometer

The occurrence of cytochrome P-450 in a clavine-producing strain of *Claviceps purpurea* has been previously reported (1). Phenobarbital-treated *C. purpurea* exhibited a parallel increase in the cytochrome P-450 and in total alkaloid. Cyanide produced a gradual but marked decrease in both cytochrome P-450 and alkaloid levels. The interconversion of cytochrome P-450 and P-420 has been utilized to provide additional evidence for its presence in *C. purpurea* (2).

Cytochrome P-450 is now recognized as an "oxygen-activating enzyme," participating in the hydroxylation of a wide variety of compounds (3, 4). Substrate interaction with cytochrome P-450 gives rise to two types of difference spectra which have been utilized to measure the nature and degree of interaction of cytochrome P-450 with various compounds. Type I spectral

changes are characterized by a difference spectrum, with a trough at 420 mμ and a peak at 385 mμ, and are characteristic of that produced by the interaction of cytochrome P-450 with hexobarbital, aminopyrine, phenobarbital, and chlorpromazine. Type II spectral changes exhibit a difference spectrum, having a peak at 430 mμ and a trough at 390 mμ; the spectrum is produced by the interaction of aniline, nicotine, nicotinamide, etc., with cytochrome P-450. The magnitude of the spectral changes is substrate concentration-dependent (5). It has been suggested (6) that the substrate forms complexes with the oxidized form of cytochrome P-450 and that the rate-limiting step of the reaction is the reduction of the substrate-cytochrome P-450 complex. However, it has also been suggested that the complex is more readily reduced by NADPH cytochrome P-450 reductase than is cytochrome P-450 in the absence of the substrate (7).

The present study is concerned with the possible role of cytochrome P-450 in alkaloid synthesis and extends the previously reported data. The binding of tryptophan, tryptophan analogs, isopentenyl pyrophosphate, and 4-dimethylallyltryptophan to cytochrome P-450 was studied using the difference absorbance. The effect of these compounds on the levels of cytochrome P-450 and total alkaloid and the correlation of these values with effects on binding are also reported.

^a Concentration = 2 mM.

the binding of ^{14}C -aniline to cytochrome P-450. The cytochrome P-450-containing mycelial pellet preparation (1) was incubated at 37° for 60 min. in 2.5 ml. of a reaction mixture containing 1 ml. of 0.05 M tromethamine (pH 7.5). One milliliter of 0.12 M KCl, 0.5 ml. of 1.67 M $\text{Na}_2\text{S}_2\text{O}_4$, and 1 ml. of 1 mM solution ^{14}C -L-tryptophan (sp. act. 9.0 mc./mM) were added. After incubation, the sample was diluted to 10 ml. with ice-cold 0.15 M KCl and centrifuged at 105,000 $\times g$ for 60 min. The pellet was resuspended in 10 ml. of 0.15 M ice-cold KCl and recentrifuged. The washing was repeated three times or until the last washing was devoid of radioactivity. The washed pellet was suspended in 2 ml. of 0.15 M KCl and lyophilized. The residue was dissolved in 1 ml. of hyamine hydroxide and 10 ml. of scintillating solution (PPO, 4 g.; POPOP, 100 mg. dissolved in 1 l. of toluene). The radioactivity in counts per minute was determined according to the usual procedure, using a Packard liquid scintillation spectrometer. The results in counts per minute were utilized to determine the percentage of ^{14}C -L-tryptophan bound. The radioactivity in counts per minute was also determined for a 1 mM solution of ^{14}C -L-tryptophan and for the combined washings (three).

Effect of Carbon Monoxide on Binding of ^{14}C -L-Tryptophan to Cytochrome P-450—The washed pellet was suspended in 2.5 ml. of the reaction mixture. Carbon monoxide was bubbled into the mycelial pellet suspension for 30 sec. After centrifugation at 105,000 $\times g$ for 60 min. and after three washings, the radioactivity was determined as described.

Determination of the Magnitude of Spectral Changes—The mycelial pellet, containing cytochrome P-450, prepared as described (2), was suspended in 2.5 ml. of the reaction mixture. One milliliter of a solution of L-tryptophan (range 0.5–6.0 mM/ml.) was added, followed by incubation at 37° for 60 min. The difference in absorbance was measured between the two wavelengths, 385 and 420 μ . The difference absorbance for the binding of other compounds was determined in a similar manner. The results in Table I

Figure 1—Binding of L-tryptophan to cytochrome P-450 in the mycelial pellet of *C. purpurea*.

were obtained using a 1-ml. solution of a concentration sufficient to give a final concentration of 2 mM.

Growth of *C. purpurea* in the Presence of Analogs—*C. purpurea* was grown as previously described (2). The analog of tryptophan and other additives were added to a final concentration of 2 mM on the 10th day. On the 16th day (6 days after additions), the medium was removed from the mycelial mat and used for estimating total alkaloids by the method of Taber and Vining (9). The preparation of the mycelial pellet was as previously described (2), and the estimation of cytochrome P-450 was by the method of Sato and Omura (10).

RESULTS

A comparison of the binding capacity of cytochrome P-450 in the mycelial pellet preparation from control and phenobarbital-treated *C. purpurea* revealed an increased binding capacity for L- ^{14}C -tryptophan for the cytochrome P-450 in the mycelial pellet from phenobarbital-treated *C. purpurea*. Treatment of the mycelial pellet with carbon monoxide in the presence of dithionite resulted in a release of most of the bound L- ^{14}C -tryptophan (Table II). Figure 1 illustrates the increase in binding with increasing tryptophan concentration expressed as an absorbance difference ($A_{385-420}$). Maximum binding was observed at a concentration of 5 mM of L-tryptophan, with one-half maximum being observed at 1.4 mM concentration of L-tryptophan.

Over a pH range from 4.0 to 9.5, binding was maximal at pH 5–5.5 and decreased by approximately 30% at pH 4.0 and 9.5. Table I summarizes the relative binding affinity of cytochrome P-450 as measured by absorbance difference for tryptophan, isopentenyl pyrophosphate, 4-dimethylallyltryptophan, and certain analogs of tryptophan. The effects of these compounds on cytochrome P-450 and total alkaloid levels in *C. purpurea* when added during the alkaloid-producing period are also indicated. It will be observed that the binding affinity is greatest for L-tryptophan and relatively low for D-tryptophan. The analogs of tryptophan used were the DL-isomers; therefore, the values recorded for these should be compared with those recorded for DL-tryptophan. None of the compounds in Table I produced any significant changes in the cytochrome P-450 levels from those of the control. However, L-tryptophan and 4-dimethylallyl-L-tryptophan, which are known precursors of ergot alkaloids, exhibit the highest binding affinities for cytochrome P-450 as well as causing the greatest increases in total alkaloid. The 5-methyl analog of DL-tryptophan exhibited a binding affinity similar to that of DL-tryptophan, but its addition during the alkaloid-producing period of growth of *C. purpurea* resulted in a greater increase in total alkaloid than that produced by DL-tryptophan.

The effects of various analogs of tryptophan when added during the alkaloid-producing period of growth of *C. purpurea* on cytochrome P-450 on total alkaloid levels and the affinity of the cyto-

Table III—Effect of Tryptophan Analogs^a on Binding Affinity of Cytochrome P-450 for Tryptophan and Alkaloid Levels

Compound ^b	Absorbance Difference, $A_{385-420}$	Amount of Cytochrome P-450 in μ moles, $A_{450-490}$	Total Alkaloid in mg./Flask
4-Methyl-DL-tryptophan	0.020	6.14	3.12
5-Methyl-DL-tryptophan	0.044	6.10	5.90
6-Methyl-DL-tryptophan	0.030	5.95	3.14
4-Fluoro-DL-tryptophan	0.024	6.10	3.10
5-Fluoro-DL-tryptophan	0.039	5.87	3.87
4-Dimethylallyl-L-tryptophan	0.048	6.14	6.10

^a Analogs (2 mM) and L-tryptophan (2 mM) added on the 10th day to the culture of *C. purpurea*. Binding affinity of cytochrome P-450 of mycelial pellet, cytochrome P-450, and alkaloid levels determined on the 16th day (6 days after additions). ^b Concentration = 2 mM.

chrome P-450 for L-tryptophan are summarized in Table III. No significant differences were observed in the cytochrome P-450 levels. The cytochrome P-450 of *C. purpurea* grown in the presence of 4-methyl-DL-tryptophan and 4-fluoro-DL-tryptophan exhibited a significantly reduced affinity for L-tryptophan and also a lower total alkaloid. The known precursor 4-dimethylallyl-L-tryptophan, under the same conditions, increased the affinity of the cytochrome P-450 and a significant increase in total alkaloid resulted. The non-precursor analog, 5-methyl-DL-tryptophan, produced an increase [tryptophan 0.038 (Table I) versus 0.044 (Table III)] in binding affinity over that exhibited by the cytochrome P-450 from *C. purpurea* which had not been exposed to any additive and produced an increase in total alkaloid nearly equivalent to that produced by 4-dimethylallyl-L-tryptophan.

The binding affinity of cytochrome P-450 of *C. purpurea* grown in the presence of L-tryptophan exhibited a markedly enhanced affinity for isopentenyl pyrophosphate over that exhibited by cytochrome P-450 from *C. purpurea* which had not been exposed to any additive [0.051 (Table IV) versus 0.015 (Table I)]. D-Tryptophan, 5-methyl-DL-tryptophan, and 5-fluoro-DL-tryptophan appeared not to exert a significant effect.

DISCUSSION

The binding of tryptophan to the cytochrome P-450 of the mycelial pellet of *C. purpurea* was both pH and temperature dependent. Maximum binding was observed at a pH of approximately 5.5. Orrenius and Ernster (8) reported that binding to cytochrome P-450 is pH dependent. At 37°, maximum binding was observed after 60 min. The extent of binding observed was 30% of maximum after 15 min., 50% after 30 min., and 80% after 45 min.

Carbon monoxide, which is known to form an enzymically inactive complex with reduced cytochrome P-450 (12), prevents binding of the compound which, once bound, is released in the presence of dithionite and carbon monoxide. Thus, an enzymically functional cytochrome P-450 is necessary for the binding to cytochrome P-450 and for active hydroxylation (8). From Table II, it will be observed that the extent of binding of ¹⁴C-L-tryptophan was greatly diminished by carbon monoxide. The addition of dithionite had no effect on the extent of binding, but treatment with carbon monoxide resulted in the release of a large proportion of the already bound ¹⁴C-tryptophan.

The binding of tryptophan to the cytochrome P-450 of the mycelial pellet of *C. purpurea* exhibits a high degree of stereospecificity. The data of Table I indicate that the cytochrome P-450 exhibits a relatively high binding affinity for L-tryptophan in contrast to D-tryptophan. The binding affinity exhibited for 4-dimethylallyl-L-tryptophan is at least of the same order as that exhibited for L-tryptophan or greater. These results are particularly significant with respect to the biosynthesis of the ergolene nucleus, since it has been established that ¹⁴C-L-tryptophan is more efficiently incorporated into the ergolene nucleus than is ¹⁴C-D-tryptophan. In addition, Agurell (13) has reported that 4-dimethylallyl-L-tryptophan is more efficiently utilized than 4-dimethylallyl-D-tryptophan or L-tryptophan. From Table I, it is also apparent that those compounds which exhibited the greatest degree of stereospecific binding also produced the greatest increase in total alkaloid.

Table IV—Effect of Tryptophan Analogs^a on the Binding Affinity of Cytochrome P-450 for Isopentenyl Pyrophosphate and Alkaloid Levels

Compound ^b	Absorbance Difference, $A_{385-420}$	Amount of Cytochrome P-450 in μ moles, $A_{450-490}$	Total Alkaloid, mg.
L-Tryptophan	0.051	6.10	6.30
D-Tryptophan	0.020	5.85	3.20
DL-Tryptophan	0.030	5.90	4.10
5-Methyl-DL-tryptophan	0.020	5.80	3.38
5-Fluoro-DL-tryptophan	0.025	6.04	4.04

^a Analogs (2 mM) and isopentenyl pyrophosphate (2 mM) added on the 10th day to culture of *C. purpurea*. Binding affinity of cytochrome P-450 of mycelial pellet, cytochrome P-450, and alkaloid levels determined on the 16th day (6 days after additions). ^b Concentration = 2 mM.

Although various routes have been proposed for the formation of ergot alkaloids, the route proposed by Arigoni (14) would appear of particular interest relative to the results reported here. The pathway proposed by Arigoni is one in which 4-dimethylallyltryptophan is hydroxylated to form an intermediate which is then converted to agroclavine. Thus the results presented in this and earlier reports suggest a role for cytochrome P-450 in the formation of the ergolene nucleus. The most obvious involvement of cytochrome P-450 on the basis of present evidence would be in a reaction in which 4-dimethylallyltryptophan is hydroxylated. However, the high binding affinity exhibited by cytochrome P-450 of the mycelial pellet for L-tryptophan (Table I) and the greatly enhanced affinity for isopentenyl pyrophosphate of the cytochrome P-450 of the mycelial pellet from *C. purpurea* grown in the presence of L-tryptophan (Table IV) suggest the possible involvement of cytochrome P-450 at an earlier stage.

The effect of growing *C. purpurea* in the presence of analogs of tryptophan on the binding affinity of the cytochrome P-450 of the mycelial pellet for L-tryptophan and their effect on cytochrome P-450 and total alkaloid levels are indicated in Table III. No significant changes in cytochrome P-450 levels were produced by any of the compounds. However, those compounds that increased the binding affinity for L-tryptophan (5-methyl-DL-tryptophan and 4-dimethylallyl-L-tryptophan) caused a significant increase in total alkaloids. Those analogs (4-methyl-DL-tryptophan and 4-fluoro-DL-tryptophan) that reduced the binding affinity tended to cause a reduction in total alkaloids. These results offer a possible explanation for earlier observations (15) that the 4-methyl and 4-fluoro analogs inhibited alkaloid synthesis relatively selectively and that such inhibition was only partially reversible by tryptophan. Protein synthesis was not significantly affected by these analogs; thus the effect of 5-methyl-DL-tryptophan in increasing total alkaloid (Table IV) and in increasing the incorporation of ¹⁴C-L-tryptophan into agroclavine (15) may be explained in part by its effect on the binding affinity of cytochrome P-450 for L-tryptophan or perhaps 4-dimethylallyl-L-tryptophan.

The binding affinity of cytochrome P-450 of the mycelial pellet of *C. purpurea* for isopentenyl pyrophosphate was altered when *C. purpurea* was grown in the presence of tryptophan and tryptophan analogs. The increase in affinity for isopentenyl pyrophosphate when L-tryptophan was added to the growth medium was the most significant finding observable from the data in Table IV. A stereospecific effect was observable in the alterations in binding affinities (compare L-tryptophan and D-tryptophan).

The results reported here and elsewhere (1) indicate that an increase or decrease in total alkaloid may be paralleled (or the result of): (a) an increase or decrease in cytochrome P-450 levels or (b) an increase or decrease in binding affinity of cytochrome P-450 for the alkaloid precursors (L-tryptophan and isopentenyl pyrophosphate or 4-dimethylallyl-L-tryptophan). Either or both of these may play a role in the initiation of alkaloid synthesis in *C. purpurea*, which is known to follow the active synthesis of primary metabolites such as protein. Thus, an increase in cytochrome P-450 levels in the presence of the precursors might result in the initiation of alkaloid synthesis. Equally as possible would be the initiation of alkaloid formation as a result of an increase in the binding affinity of existing cytochrome P-450 for alkaloid pre-

cursors. The results in Table IV might allow for the speculation that the increased availability of tryptophan resulting from reduced protein synthesis could sufficiently alter the binding of cytochrome P-450 for isopentenyl pyrophosphate that alkaloid synthesis might proceed, whereas at lower levels of available tryptophan such would not occur because of the low affinity of the cytochrome P-450 for isopentenyl pyrophosphate. Based on the observation that benzyl thiocyanate, which has been shown to enhance tetracycline formation (16), increased total alkaloid in *C. purpurea* to almost the same degree as phenobarbital (15), it is suggestive that cytochrome P-450 may be involved in the formation of certain other secondary cell metabolites in addition to that which has been discussed in this report.

Detection of Decomposition and Analytical Interferences in Pharmaceutical Preparations Containing Corticosteroids

ROBERT E. GRAHAM*, PATRICIA A. WILLIAMS*, and CHARLES T. KENNER†

Abstract □ Since the blue tetrazolium and phenylhydrazine reagents for corticosteroids react with the intact side chain at C₁₇, and the isonicotinic acid hydrazide method and UV spectrophotometry depend upon conjugation in Ring A at the other end of the molecule, the analytical results by the four methods give information concerning decomposition caused by oxidation of the C₁₇ side chain and by deconjugation in Ring A. Methods are proposed which allow the detection and determination of both acidic and neutral decomposition products. Measurement of the variation of absorbance with time can be used to detect unidentified interferences in the blue tetrazolium, phenylhydrazine, and isonicotinic acid procedures. The extent of interference of several substances which interfere in at least one of the color reactions is reported. Several examples of the use of the proposed methods to detect and determine decomposition and/or interference are given.

Keyphrases □ Corticosteroids, decomposition determination—methods compared □ Decomposition, corticosteroids—C₁₇ side-chain oxidation determination □ Interference—corticosteroid analysis □ Blue tetrazolium, phenylhydrazine, isonicotinic acid hydrazide, UV spectrophotometry methods—analysis

the reactions in these four methods occur with different portions of the molecule, they can be used to detect and distinguish between decomposition which occurs at the C₁₇ side chain and decomposition caused by deconjugation in Ring A. Quantitative agreement between all four methods indicates that the corticosteroid is not decomposed and that there is no interference in the determinative steps of any of the methods due to components of the preparation. Differences between the values by the four methods indicate decomposition or interference.

The most common type of corticosteroid decomposition encountered in pharmaceutical preparations is caused by the oxidation of the C₁₇ side chain by readily reducible organic and inorganic compounds, by metal ions, and by air in alkaline solutions (9–16). Much less common is the destruction or movement of the double bonds in Ring A caused by absorption of UV light (17–20). The degradation products caused by oxidation of the C₁₇ side chain are neutral or acidic in character (9, 11, 21–23) and are a complex mixture of organic acids together with neutral compounds such as aldehydes and ketones. These decomposition products can be separated by extraction into chloroform, since the neutral compounds will be extracted along with the undecomposed steroid while the acidic components will remain in the aqueous phase.

The BT reaction is the official method in USP XVII (24) and NF XII (25) for preparations listed in these compendia. It is more specific than the INH or UV method for corticosteroids since the BT reagent reacts with that portion of the molecule usually involved in decomposition. The BT method is subject to many interferences, as shown in Tables I and II. Table I lists reported interferences with each of the three types of reactions used to determine corticosteroids. Inter-

ferences in the UV determination are not included, since a large number of ingredients in corticosteroid preparations absorb in the same region and the interference is relatively easy to detect due to changes in the UV spectra. The PH reaction is specific for the 17,21-dihydroxy-20-keto side chain at C₁₇ and is less subject to interference than the BT procedure.

Many substances which interfere in the BT, PH, INH, and UV procedures are usually removed during sample cleanup by extraction, by magnesium silicate¹ column chromatography (26), by TLC (17, 27), by paper chromatography (28–30), and by column-partition chromatography (31, 32). Water-soluble acidic decomposition products and interferences are removed by the use of acidic and basic traps in column procedures and by acidic or basic extractions in separator procedures. Neutral decomposition products extract with the undecomposed corticosteroid.

This paper reports several unreported interferences to the determinative methods (Table II) and suggests methods of evaluation of results by the four methods to detect and determine decomposition in corticosteroid preparations and to detect interferences.

EXPERIMENTAL

Reagents and Equipment—The reagents called for in the references for the individual methods were prepared as directed. All reagents were USP or ACS grade. All corticosteroid standard solutions were prepared from USP, NF, or commercial reference standards.

All measurements were made on a Cary spectrophotometer, model 15.

Methods—In all methods used, the samples were carried through any necessary cleanup and preparative steps. The final solution obtained was evaporated to dryness carefully under air on a steam bath. The residue was dissolved and made to volume with alcohol USP, so that the concentration was approximately 0.010 mg./ml. of the corticosteroid. This solution was used for the determinative steps for all four methods. A standard solution of the corticosteroid of the same concentration was also used in the determinative steps of each method. In all cases, the absorbance spectra of the first standard and the first sample were rescanned after all measurements in the series had been completed.

BT Method—The procedure given in USP XVII (24) and NF XII (25) was followed except that 10.0-ml. aliquots and 1.0 ml. each of the BT reagent and the tetramethylammonium hydroxide reagent were used.

PH Method—The procedure of Silber and Porter (7) was followed without modification.

INH Method—The procedure of Umberger (8) was used, except that the INH reagent was modified by using twice the recommended concentration of hydrochloric acid to increase the sensitivity of the reaction (33).

UV Spectrophotometry—The alcohol USP solution was scanned directly in a 1-cm. cell.

Interference Studies—The interference of several ingredients in corticosteroid preparations, which has not been reported previously, was investigated. The interfering substance was added to a standard solution of hydrocortisone, which was then evaporated to dryness and the residue dissolved in alcohol USP prior to color development. In each case, the absorbance was compared to the absorbance of a standard hydrocortisone solution under the same conditions.

Time Study of Absorbance Variation to Detect Interference—The absorbance of the sample solution and of the standard solution was measured periodically during and after the standard color development period.

Detection of Decomposition or Interference—The absorbance of the sample and standard solution was determined by all four

^a T = solution becomes turbid so that absorbance cannot be determined.

methods. Significant differences between the values obtained indicate either decomposition or interference in one or more methods.

Procedure for Determination of Decomposition at C₁₇ Side Chain—

Prepare an alcohol USP extract of the sample and determine the amount of corticosteroid by either the INH or UV method. This is the total amount of the undecomposed plus any decomposed corticosteroid present.

Dissolve or suspend the sample in an aqueous solution and extract with chloroform. Retain both solutions.

Determine the acidic decomposition products in the aqueous fraction by evaporation of a known aliquot to dryness, followed by determination by the INH or UV method.

Determine the undecomposed corticosteroid in the chloroform fraction by evaporation of a known aliquot to dryness, followed by determination by the BT or PH method.

Determine the neutral decomposition products plus the undecomposed corticosteroid in the chloroform fraction by evaporation of a known aliquot to dryness, followed by determination by the INH or UV method.

RESULTS AND DISCUSSION

The major portion of the determinations in this investigation has been made on hydrocortisone samples and standards, but the results are equally applicable to other corticosteroids since the decomposition pathways and determinative reactions are similar for all corticosteroids.

Several components of corticosteroid preparations were found to cause interference in the determinative steps of at least one of the four corticosteroid methods. The results are summarized in Table II.

Table III—Analysis of Corticosteroid Preparations

Product	Corticosteroid	Concn.	% of Declared Value by		
			BT	PH	INH
Lotion

Lotion	Hydrocortisone (0.25%)	76	12	12

Typical results of determinations by the three methods on samples from different lot or batch numbers of the same preparation are shown in Table III. The difference between the results obtained from samples that have undergone decomposition and the results obtained from undecomposed samples is immediately apparent. The samples of ophthalmic drops are typical of samples in which there is no decomposition but in which the amount of corticosteroid is less than the declared amount. In all cases in which there is a significant discrepancy between the results by the BT and PH methods, a study of the variation of absorbance with time indicated that there was interference in the BT determination. In these cases, the value by the PH method is assumed to be correct.

Decomposition at the C₁₇ side chain is indicated whenever the results by BT and PH methods are comparable but are lower than those by the INH or UV method. If no decomposed corticosteroid is found, the difference in values is due to a negative interference in the BT or PH method and/or a positive interference in the INH or UV method. The extent of the decomposition and the amounts of acidic and neutral decomposition products determined for several different corticosteroid preparations are given in Table IV. The amount of neutral decomposition products was determined by subtraction of the values obtained by the BT or PH method from those obtained by the INH or UV method on the chloroform extract of the sample. The value of the total decomposed fraction was calculated by subtraction of the value obtained by the BT or PH method on the chloroform extract from the values obtained by the INH or UV procedure on the alcohol USP extract of the sample.

Decomposition in Ring A is indicated whenever the results by INH and UV methods are comparable and are lower than the values obtained by the BT and PH methods. Decomposition of Ring A is due primarily to absorption of UV light and is not found often in corticosteroid preparations. It is more probable that such a difference in values is due to a positive interference in the BT or PH reaction. Positive interferences in the BT are more probable than negative interferences in the INH or UV procedure, as shown in Tables I and II.

All four methods are subject to interference by components of corticosteroid preparations; detection and elimination of such interferences are important to the correct interpretation of analytical results. Methods of detecting interferences include comparison of the PH and BT results. Differences between these values indicate interference, since the color-development reactions are different even though the reagents react with the same portion of the corticosteroid molecule. The BT reaction is subject to more interferences than the PH reaction, since the BT reagent is less specific for corticosteroids than the PH reagent.

Interference in the BT reaction can be either positive or negative. Positive interferences, such as lanolin, are those that react with the BT reagent to produce the diformazan. Negative interferences are

often due to the acidic nature of the interfering substance. The BT reaction is highly pH dependent; substances which lower the pH below the optimum value can cause decrease of color formation or even completely inhibit the color formation. The negative interference of stearic acid and of salicylamide is probably due to pH effect, since increasing amounts of each cause a decrease in the pH of the BT reagent sample solution. As an example, the absorbance of a standard hydrocortisone solution containing 50 mg. of stearic acid was 0.331 compared to an absorbance of 0.608 for the standard alone. The pH of the BT solution containing the stearic acid and standard was 13.15 and that of the BT solution of the standard alone was 13.80.

The PH reaction is also subject to both positive and negative interferences by components of corticosteroid preparations. Interference is caused by some surface-active agents such as polysorbate 60, sorbitan monooleate, and sorbitan monostearate. Interference is also caused by organic acids which are soluble in chloroform but insoluble in the strongly acidic phenylhydrazine-sulfuric acid-alcohol solution used. The insoluble compound raises the base line by light dispersion and causes an increase in the absorbance of the sample which is not always compensated by the blank. Lack of compensation by the blank is probably due to the fact that the particle size of the solid separating from the sample is not always identical to the particle size of the solid separating from the blank. Such differences in size cause differences in the amount of light dispersion and the rate of settling during the actual measurement. The negative interference of phenothiazine (34) in the PH reaction is probably due to a reaction with phenylhydrazine which is not corrected for by the blank used.

Differences between the results by the INH and UV methods also indicate interference in one or both procedures. Positive interference in the INH procedure is caused by substances such as vanillin, which form derivatives with the reagent, or by substances such as oil-soluble vitamins and salicylamide, which absorb in the same region of the spectrum.

Many of the components of corticosteroid preparations interfere with the determination by simple UV spectrophotometry, since they absorb in the same region of the spectrum. Stabilizers such as methylparaben and propylparaben fall into this category. Such interference is usually detected readily by comparison of the absorbance curve of the sample to that of the standard. Interfering substances cause distortions of the spectra which are readily discernible.

Many of the interferences discussed can be detected by time studies of absorbance variation during the color-development period of the samples and standards. This is especially true with the BT procedure, since the absorbance developed by the BT reagent with corticosteroids becomes constant after a certain period of time or continues to increase at a rate dependent upon the individual steroid (35). Remeasurement of the absorbance of

Table V—Detection of Interference in the BT Method by Variation of Absorbance with Time

Absorbance					Difference	
	Sample 1. Hydrocortisone Lotion 0.125%					
Minutes	90			126		
Standard hydrocortisone	0.591			0.592		0.001
Sample	0.491			0.528		0.037
	Sample 2. Hydrocortisone Lotion 0.125%					
Minutes	30	60	90	150	210	Difference (90-150)
Standard	0.551	0.561	0.568	0.565	0.570	0.003
Sample A (2.1 g.)	0.462	0.490	0.515	0.528	0.540	0.013
Sample B (3.0 g.)	0.668	0.720	0.756	0.784	0.798	0.028

both the standards and samples 20 or 30 min. after the specified time for color development will show any major interference present. Minor interferences usually require an extended time study of absorbance variation during and after the color-development period for both standards and samples. Examples of the detection of interference by the measurement of the variation of absorbance with time are shown in Table V. The increase of 0.037 unit in the absorbance of Sample 1 during the 36 min. after the standard had become constant is an obvious indication that some component in addition to hydrocortisone is reacting with the BT reagent. This particular case of interference was detected by a routine rescan of the absorbance of the first standard and sample of a series of determinations after all samples and standards had been measured. The time lapse of 36 min. was required to measure all samples and standards. Sample 2 is an example of interference that is not immediately apparent by a rescan of the first standard and sample after completion of the series of measurements. In this particular case, a small increase in absorbance was noted for the sample when it was rescanned so that the extended time study was made. This study definitely proves that some interfering substance was present.

Many of these interfering substances may be separated from the corticosteroid in samples by use of a new acetonitrile-diatomaceous earth² column procedure (40).

GLC of Mycophenolic Acid and Related Compounds

FRANK E. GAINER and HAROLD J. WESSELMAN

Abstract □ A GLC method is described for the quantitative determination of mycophenolic acid and monosodium mycophenolate. Data are presented to show that both the methyl ester and ethyl ester derivatives of mycophenolic acid can be chromatographed along with a cyclic acid hydrolysis product of mycophenolic acid. In addition, quantitative results are presented for the assay of mycophenolic acid and the monosodium salt in various formulations. Spectral and TLC results are also included.

Keyphrases □ Mycophenolic acid, related compounds—determination □ TLC—separation □ GLC—analysis □ Tetraphenylethylene, chloroform dissolved—internal standard □ IR spectrophotometry—structure □ NMR spectroscopy—structure

Mycophenolic acid (Structure I) is an antibiotic fermentation product which is isolated from penicillium cultures (1, 2). The antibiotic is known to have

- I, R = H
II, R = Na
III, R = CH₃
IV, R = C₂H₅

antibacterial and antifungal properties which have been studied previously (3, 4). Recently, two groups of researchers (5, 6) reported on the antitumor activity of mycophenolic acid, while Williams *et al.* (7) reported that the substance exhibited both antiviral and antitumor properties. Work has been done, both chemical and physical in nature, to elucidate the structure of mycophenolic acid (8, 9) and some related compounds, which were isolated from the culture filtrates of a strain that produces mycophenolic acid (10). Birch and Wright (11) have devised a scheme for the total synthesis of mycophenolic acid. This paper reports the quantitative determination of mycophenolic acid and related compounds by GLC.

Ethyl mycophenolate (IV) may be formed during the isolation of mycophenolic acid from penicillium cultures (12) and recrystallization of the acid by interaction of the acid and ethanol. However, Campbell *et al.* (10) have reported the isolation of ethyl mycophenolate from the culture filtrates of a strain that produces mycophenolic acid. The cyclic compound, 3,4-dihydro-5-methoxy-2,6-dimethyl-9(7H)-oxo-2H-furo-(3,4-*h*)benzopyran-2-propionic acid (V) was isolated from the reaction vessel after heating the acid at 100° in 10% hydrochloric acid for 18 hr. Methanol leads to partial esterification of mycophenolic

acid during extraction processes (12), probably resulting in methyl mycophenolate (III). Monosodium mycophenolate (II) may be formed by adjusting a slurry of mycophenolic acid to pH 7–8 with sodium hydroxide.

No record was found in the literature, either directly or indirectly, reporting the quantitative determination of mycophenolic acid.

EXPERIMENTAL

Equipment—A gas chromatograph (Hewlett-Packard model 402) equipped with a flame-ionization detector was used for the experimental work. The detector signal was fed to a 1-mv. recorder (Honeywell Electronik 16) with a chart speed of 15 in./hr. and a 1-sec. full-scale response. Samples were injected with a 10- μ l. syringe (Hamilton No. 701).

Materials—Helium was used as a carrier gas, while electrolytic hydrogen and oxygen were used in the detector. The stationary phase was 3.8% Linde W-98 silicone gum applied by the solution technique to silanized diatomaceous earth (Diatoport S) (80/100 mesh) and packed in a borosilicate glass column, 0.91 m. \times 0.64 cm. o.d. Chloroform (Reagent ACS) was used to dissolve the tetraphenylethylene (Reagent ACS) internal standard. The silylating reagent was bis(trimethylsilyl)trifluoroacetamide.¹ Concentrated hydrochloric acid (Reagent ACS) and absolute methanol were employed.

Operating Conditions—The column was operated isothermally at 235°, with the detector block at 280° and the sample injection port at 280°. The helium flow rate was 55 ml./min., with an inlet pressure of 40 psig. Oxygen and hydrogen flow rates were 200 and 50 ml./min., respectively. The electrometer range was 10, with an attenuation of 128. Sample injections of 1.5 μ l. were used throughout the study.

Quantitative Analysis—Tetraphenylethylene, 25 mg. in 100 ml. of chloroform, is used as an internal standard.

Mycophenolic Acid—Accurately weigh 50 mg. of mycophenolic acid into a 50-ml. volumetric flask, and dilute to volume with chloroform. Pipet 1.0 ml. of the solution into a 3-ml. butyl-rubber-stoppered ampul, and add 1.0 ml. of the internal standard solution. Carefully evaporate the solution in the ampul to dryness, using a gentle stream of nitrogen and a warm water bath. Add 0.5 ml. of bis(trimethylsilyl)trifluoroacetamide to the ampul, and seal before heating for 1 hr. in a heating block at 80°. Cool to room temperature before chromatographing. Prepare a standard reference solution by accurately weighing 50 mg. of mycophenolic acid reference standard into a 50-ml. volumetric flask and diluting to volume with chloroform. Treat this solution exactly as the sample solution.

^a Mycophenolic acid equivalency per unit sample.

Mycophenolic Acid Capsules, 200 mg.—Weigh five filled capsules and empty the contents into a small beaker. Wash the empty capsules with chloroform, discarding the washings. Allow the capsules to dry before weighing. Subtract the weight of the empty capsules from that of the filled capsules to determine the average fill weight. Thoroughly mix the dry powder in the beaker, and accurately weigh a portion of the sample equivalent to 100 mg. of mycophenolic acid. Quantitatively transfer the sample to a 125-ml. separator containing 20 ml. of purified water. Extract the compound with three 20-ml. portions of chloroform, allowing 2 min. for each extraction. Filter the chloroform layer through anhydrous sodium sulfate into a 100-ml. volumetric flask. Wash the sodium sulfate with chloroform, and collect the washings in the flask. Dilute to volume with chloroform and shake well. Pipet 1.0 ml. of this solution into a 3-ml. butyl-rubber-stoppered ampul, and proceed as directed for mycophenolic acid, using the same internal standard and standard reference solution.

Monosodium Mycophenolate—Accurately weigh 100 mg. of sodium mycophenolate into a 100-ml. volumetric flask containing 50 ml. of methanol. Add 0.5 ml. of concentrated hydrochloric acid to the flask and shake well. Dilute to volume with methanol and shake well before transferring 10 ml. of the solution to a butyl-rubber-stoppered ampul. Seal the ampul and place it in a heating block at 80° for 0.5 hr. Cool the contents of the ampul to room temperature. Pipet 1.0 ml. of the solution into a 3-ml. butyl-rubber-stoppered ampul and proceed as with mycophenolic acid. Prepare a standard reference solution by accurately weighing 100 mg. of monosodium mycophenolate standard into a 100-ml. volumetric flask containing 50 ml. of methanol. Treat this solution exactly as the sample solution.

Monosodium Mycophenolate Ampuls, 10%—Pipet 1.0 ml. of the ampul solution into a 100-ml. volumetric flask containing 50 ml. of methanol. Proceed as directed for monosodium mycophenolate, using the same internal standard solution and standard reference solution.

Experimental procedures and details for the GLC of ethyl mycophenolate, methyl mycophenolate, and the cyclic compound are the same as for mycophenolic acid.

Chromatograph the standard and sample solutions, and measure the peak heights of the respective internal standard, standard, and sample peaks.

Calculations—

$$\frac{\text{peak height sample}}{\text{peak height sample internal standard}} = R_1 \quad (\text{Eq. 1})$$

$$\frac{\text{peak height standard}}{\text{peak height standard internal standard}} = R_2 \quad (\text{Eq. 2})$$

$$\frac{R_1 \times \text{milligram standard}}{R_2 \times \text{milligram sample}} \times \text{standard purity milligram/gram} = \text{milligram active ingredient/gram sample} \quad (\text{Eq. 3})$$

Substitute milliliter sample for milligram sample when solutions are assayed.

$$\text{Eq. 3} \times \text{average fill weight of capsule} = \text{milligram active ingredient/capsule} \quad (\text{Eq. 4})$$

If the active ingredient is monosodium mycophenolate, the acid equivalency can be obtained by multiplying Eqs. 3 and 4 by the factor 0.935.

RESULTS AND DISCUSSION

Each of the compounds studied, except monosodium mycophenolate, is chloroform soluble; thus, it was convenient to do simple extractions and dilutions with this solvent. Monosodium mycophenolate is very soluble in water and relatively insoluble in most organic solvents except methanol, which was used for this compound.

Since it is more difficult to silylate the sodium salt of a carboxylic acid than the acid itself, initial efforts were made to convert monosodium mycophenolate in methanolic solution to mycophenolic

**Figure 1—Typical chromatogram of internal standard and sample.**

Table III—Retention Times of Trimethylsilyl Ethers of Mycophenolic Acid and Related Compounds

Compound	Retention Time, ^a min.

^a Using chromatographic parameters described under operating conditions. ^b Internal standard.

acid by the addition of concentrated hydrochloric acid with shaking. This resulted in a solution containing two compounds, as shown by GLC and TLC. The chromatograms suggested that the compounds were methyl mycophenolate and mycophenolic acid. Both IR and NMR confirmed that one component was methyl mycophenolate. Additional checks were not made to determine whether the second component was mycophenolic acid; but the chemistry of the system, along with stability observations, indicated that it was the acid. Since methanol and hydrochloric acid are conducive to ester formation, it was convenient to form methyl mycophenolate from monosodium mycophenolate instead of forming the acid. TLC and GLC of aliquots taken from the reaction mixture at various time intervals indicated that esterification was taking place at a measurable rate even at room temperature. It was possible to obtain complete esterification by heating the reaction mixture at 80° for 0.5 hr. Again, TLC and GLC confirmed that the solution contained only one component, methyl mycophenolate. Chromatography also indicated that no formation and subsequent esterification of the cyclic acid hydrolysis compound (V) were occurring. The methylated cyclic compound has a lower R_f value and a longer retention time than methyl mycophenolate.

To confirm that the sodium salt was being converted to the ester, an alternate method of preparation was employed in which a methanolic solution of mycophenolic acid was treated with gaseous hydrogen chloride. IR and NMR confirmed that the product was methyl mycophenolate. The product, from both methods of preparation, had the same R_f value by TLC.

It was found necessary to heat all compounds studied during the silylating reaction to obtain consistent results. Assay results for mycophenolic acid and monosodium mycophenolate were reproducible, and recoveries were good. Table I shows the results of assays of several lots of mycophenolic acid raw material and formulations. Assay results for monosodium mycophenolate are shown in Table II.

The response of the detector is linear over a range of concentrations from 0.5 to 1.5 mg./ml. for the silylated derivatives of myco-

phenolic acid and methyl mycophenolate. The continual use of the silylating agent causes a deposit to form on the detector anode, which eventually causes a loss in precision and accuracy. This problem can be eliminated by periodically cleaning the anode in an ultrasonic bath.

Both mycophenolic acid and monosodium mycophenolate are very stable compounds which lend themselves to quantitative assays as silylated derivatives. A typical chromatogram, showing peaks for the internal standard and silylated mycophenolic acid, is shown in Fig. 1. Although no quantitative work was done on ethyl mycophenolate and the cyclic compound, it should be possible to quantitate these compounds by using the same experimental parameters used for mycophenolic acid. Metabolites, other than ethyl mycophenolate, that are related to mycophenolic acid (10) also should be amenable to GLC. It is significant that mycophenolic acid, related metabolites, and other related compounds can be chromatographed by using very similar experimental conditions. Table III presents the retention times for the compounds studied.

Anhydrotetracycline and 4-Epianhydrotetracycline in Market Tetracyclines and Aged Tetracycline Products

VERNON C. WALTON, MARGARET R. HOWLETT, and GEORGE B. SELZER

Abstract □ A large number of tetracycline samples were tested for the presence of anhydrotetracycline and 4-epianhydrotetracycline when they were fresh and after being stored under normal and adverse conditions. It was found that: (a) Newly manufactured tetracycline preparations contain only small amounts of anhydrotetracycline and 4-epianhydrotetracycline. (b) Storage under adverse conditions markedly increases the percentage of degradation products, but storage under normal conditions results in only a slow increase in anhydrotetracycline and 4-epianhydrotetracycline. In syrups, this can be correlated with loss in tetracycline potency. (c) Citric acid greatly increases the tendency of tetracycline to degrade. (d) Tetracycline hydrochloride is more stable than tetracycline phosphate. (e) Demethylchlortetracycline is the most stable of the tetracycline derivatives studied. (f) Rolitetracycline is extremely unstable.

Keyphrases □ Anhydrotetracycline determination—tetracycline products □ 4-Epianhydrotetracycline determination—tetracycline products □ Column chromatography—separation □ UV spectrophotometry—analysis □ Colorimetric analysis—spectrophotometer □ Turbidimetric analysis—biological potency

Degradation products of tetracycline (TC) and 4-epianhydrotetracycline (EATC), in particular, have been implicated in renal dysfunction (1-9). It was, therefore, of interest to determine the amount of degradation in TC products on the market. A large number of market TC products were examined for EATC content. Several lots were tested for stability under normal and adverse storage conditions to determine the amount of EATC that may reasonably be expected in newly manufactured TC products and to reveal what increase in EATC could be expected with time.

Several analytical methods for the determination of 4-epitetracycline (ETC), anhydrotetracycline (ATC), and EATC have been described (10-17). The most convenient are those of Dijkhuis (15), Kelly (16), and Selzer and Wright (17); these have been adopted for use in this study.

EXPERIMENTAL

Methods—Column Chromatography—The method of Kelly (16) is a column chromatographic separation of ATC and EATC from each other and from TC and other interfering substances. The column consists of acid-washed diatomaceous earth¹ moistened with 0.1 *M* ethylenediaminetetraacetic acid (EDTA) buffer, pH 7.8; the compounds are eluted with chloroform and determined spectrophotometrically. For this study, the method was modified to ensure that the sample was at pH 7.8 when it was applied to the column. A 5-ml. sample of TC syrup containing 25 mg. of TC/ml. or a 2-ml. sample of pediatric drops containing 100 mg. of TC/ml. was diluted to 10 ml. with 0.1 *M* EDTA buffer, pH 7.8 (prepared by dissolving 0.1 mole of EDTA disodium salt in 800 ml. of water, adjusting the pH to 7.8 with ammonium hydroxide, and diluting to 1 l.). The sample was then brought to pH 7.8 with ammonium

hydroxide-water (1:9) and diluted to 25 ml. with the EDTA buffer. One tablet containing 125 mg. of TC or capsule material containing 125 mg. of TC was ground in a mortar and pestle with 10 ml. of 0.1 *M* EDTA buffer, pH 7.8, brought to pH 7.8 with ammonium hydroxide-water (1:9), and diluted to 25 ml. with the EDTA buffer. Each 250-mg. capsule was blended with 25 ml. of 0.1 *M* EDTA buffer, pH 7.8, brought to pH 7.8 with ammonium hydroxide-water (1:9), and diluted to 50 ml. with the EDTA buffer. Difficultly soluble samples were dissolved first in 10 ml. of 0.1 *N* HCl, brought to pH 7.8 with ammonium hydroxide-water (1:9), and then diluted to 50 ml. with 0.1 *M* EDTA buffer, pH 7.8.

A 1-ml. aliquot of the diluted sample was then mixed with 1 g. of dry diatomaceous earth, applied to the column, and covered with a 1-cm. layer of diatomaceous earth moistened with 0.1 *M* EDTA buffer, pH 7.8. The method was further modified in that no supporting circle of filter paper was used under the column, no layer of sand was used, and the 0.1 *M* EDTA buffer was not equilibrated with CHCl₃ before use.

Spectrophotometric Screening Method—The method of Dijkhuis (15) was used to screen powder, tablet, and capsule samples for total anhydrotetracycline content (ATC + EATC). The sample preparation was modified to ensure the dissolution of samples containing TC base or TC phosphate. A 50-mg. sample of TC powder was weighed into a 50-ml. volumetric flask, and 10 ml. of 0.1 *N* HCl was added. The flask was shaken until the sample dissolved; the contents were then diluted to the mark with water and assayed. Capsule powder or finely ground tablet powder equivalent to 250 mg. of TC hydrochloride was placed in a 250-ml. volumetric flask; 50 ml. of 0.1 *N* HCl was added, and the flask was shaken on a mechanical shaker for 5 min. The sample was then diluted to volume with water and filtered through a fluted-filter paper. The first 20 ml. of filtrate was discarded and the remainder was collected for assay. The calculations were modified in that the formula recommended by Dijkhuis (15) for the calculation of the percent ATC in dosage forms was also used for TC powder.

Paper Chromatography—The method of Selzer and Wright (17) was used. It is an ascending paper chromatographic method for the separation of TC compounds by a resolving solvent of chloroform-nitromethane-pyridine (10:20:3) on 20.3 × 20.3-cm. (8 × 8-in.) Whatman No. 1 paper moistened with McIlvaine's buffer, pH 3.5; the spots are observed by their fluorescence under UV light. To vary the relative positions of the different TC and degradation products on the chromatogram and to facilitate their identification, the chromatographic paper was moistened with any of three buffers: McIlvaine's buffer, pH 3.5; 0.1 *M* EDTA buffer, pH 4.5; or 0.1 *M* EDTA buffer, pH 7.7.

Potency Determination—The biological potencies of the samples of TC used in these studies were determined by the turbidimetric assay method (18) with *Staphylococcus aureus* (ATCC 6538P) as the test organism.

Standards—**ATC-EATC Mixture**—A standard mixture of 50:50 ATC-EATC was prepared as follows: a mixture of 2 g. of TC HCl, 1 ml. of glacial acetic acid, and 20 ml. of water was incubated overnight at 37°. One milliliter of concentrated HCl was added, the mixture was heated on a steam bath for 30 min., and the liquids were removed by lyophilization. The dry powder was dissolved in methanol, and an aliquot was chromatographed on paper as described previously, using each of the three buffers mentioned to moisten the paper. In each case, two spots of equal intensity, corresponding to ATC and EATC, were detected. Analysis of the powder by the column chromatographic method indicated that it contained 48.9% ATC and 50.9% EATC. Comparison of the 100-Mc.p.s. NMR spectrum of a CF₃COOH solution with data in the literature (19) confirmed the identity of the mixture. The bands in a 100-Mc.p.s. spectrum were better resolved, and those bands due to H_a and H_a¹ (Structures I and II) could be integrated. Comparison

of the peak areas indicated that the powder contained 45% ATC and 55% EATC.

Additional quantities of mixed ATC and EATC were prepared by heating TC HCl for 5 min. in 2 N HCl (15). The compositions of these materials were determined by the method of Kelly (16) and by comparison of their absorptivities at 356 and 430 mμ.

Anhydrotetracycline HCl Hydrate—Anhydrotetracycline HCl hydrate (Lot No. 63 F 2052, Bristol Laboratories, Syracuse, N.Y.) was used. Paper chromatography in all three buffer systems indi-

cated that the sample contained only a trace of EATC; none could be detected by column chromatography. Integration of the bands corresponding to protons H_a and H_a¹ (Structures I and II) in the 100-Mc.p.s. NMR spectrum of a DMSO-d₆ solution of the sample indicated that the amount of ATC was on the order of 23 times as much as the amount of EATC.

4-Epianhydrotetracycline Sulfate—4-Epianhydrotetracycline sulfate (Lot No. 57 F 536, Bristol Laboratories) was used. Paper chromatography of this compound in all three systems indicated that only a trace of ATC was present; none could be detected by column chromatography. Integration of the bands corresponding to protons H_a and H_a¹ (Structures I and II) in the 100-Mc.p.s. NMR spectrum of a DMSO-d₆ solution of the sample indicated that the amount of EATC was on the order of 10 times as much as the amount of ATC. However, the presence of traces of one or more other compounds was indicated.

Samples—All of the TC samples used in this study had been received as part of the antibiotic certification program.

RESULTS AND DISCUSSION

Because pharmaceutical dosage forms of TC contain a number of other ingredients, the column chromatographic procedure and the screening method were tested for interference from such materials. Phenyltoloxamine, aspirin, phenacetin, caffeine, salicylamide, and chlorothen citrate did not interfere with either method. Amphoterin B, neomycin, nystatin, oleandomycin, and triacetyloleandomycin had no detectable effect on the results of the column chromatographic procedure. Although novobiocin caused the EATC band to follow the ATC band quite closely in the column chromatographic procedure, it did not affect the results. However,

amphotericin B and nystatin, both of which absorb light at 430 mμ, caused unduly high results in the screening method when they were present in concentrations comparable to those found in commercial products. For this reason, TC products containing amphotericin B or nystatin were tested by the column chromatographic method.

A survey was conducted to find out how much ATC and EATC were present in fresh TC powder. As shown in Table I, the ATC + EATC content of 38 samples of fresh TC HCl bulk material from 11 manufacturers ranged from 0.11 to 2.06%. However, all of the six results over 1% were obtained with material from one manufacturer. Table II shows the total ATC + EATC found in newly manufactured TC PO₄ analyzed by the method of Dijkhuis (15). All of the five samples tested contained between 1 and 2% ATC + EATC.

Another survey was made of the ATC and EATC present in newly manufactured samples of various TC dosage forms. Table III shows that of 22 TC HCl tablets tested, only five contained more than 1% total ATC + EATC. These five samples were produced by one manufacturer and contained less than 2% ATC + EATC. As shown in Table IV, all but two of the 49 TC capsules tested contained less than 2% total ATC + EATC. Table V shows that only

two of the 12 fresh TC syrups tested contained more than 1% of either ATC or EATC.

It can thus be seen that the amounts of ATC and EATC found in fresh TC products were quite low. On the basis of these results, limits of 2% EATC in TC powders and 3% EATC in finished TC products have been proposed for inclusion in the *Code of Federal Regulations* (20).

Several studies were conducted to determine the stability of TC products under various conditions. In one study, TC syrups were examined for ATC and EATC after they had been stored for different periods of time. The solid matter in the syrups was either in suspension or easily resuspendable. As shown in Table VI, there is some correlation between loss of biological potency and increase in ATC and EATC content.

In another study, the ability of the TC antibiotics to resist unfavorable storage conditions of elevated temperature and high humidity was investigated. The TC samples were stored at 37° in desiccators containing water (100% relative humidity) or a saturated sodium bromide solution (66% relative humidity) in the desiccant chamber. The samples were tested for potency by the microbiological turbidimetric method (18) and for degradation products by the paper chromatographic method on paper moistened with McIlvaine's buffer, pH 3.5, and by the column chromatographic method.

Several conclusions may be drawn from the data presented in Tables VII and VIII. Demethylchlortetracycline (DMCTC) is the most stable of the TC derivatives when stored under 100% relative humidity at 37°; it showed no loss of potency after storage for 1 month. Chlortetracycline (CTC) is somewhat less stable than DMCTC; after 1 month at 37° and 100% relative humidity, the potency of CTC powder had diminished by 17% and that of capsule material by 14%. Neither CTC nor DMCTC showed evidence of anhydrolite degradation products by the paper chromatographic method. However, TC was less stable; TC products stored 1 month at 37° and 100% relative humidity gave visible evidence of degradation by becoming partially liquid and turning dark brown. Potency losses of from 17 to 79% occurred, and the column chromatographic procedure revealed ATC levels ranging from 2.2 to 7.1% and EATC levels ranging from 3.3 to 14.1%. Paper chromatography indicated that approximately one-half of the TC was converted to the inactive epimer form, ETC. Rolitetracycline (RTC) was even more unstable. Storage at 37° and 100% relative humidity resulted in almost complete destruction of this antibiotic; the only recognizable fragment was a small amount of the epimeric form of RTC. Paper chromatography of degraded oxytetracycline indicated the possible presence of an anhydrolite product.

TC HCl powder and dosage forms were quite stable when stored 2 months at 66% relative humidity and 37°, as shown in Table IX. Only a small fraction of the TC was converted to the anhydro forms. However, TC HCl with added citric acid was almost completely inactivated and formed large amounts of ATC and EATC. Citric acid thus has an adverse effect on TC stability. TC PO₄ is somewhat

^a On paper moistened with McIlvaine's buffer, pH 3.5.

less stable than TC HCl under conditions of 37° and 66% relative humidity; TC PO₄ products stored under these conditions had potency losses ranging from 25 to 40% and small amounts of ATC and EATC were present.

The effects of other active ingredients on the stability of TC PO₄ were also investigated. Samples from two lots of TC PO₄ capsules made by the same manufacturer were stored under adverse and control conditions for 3 years. One lot (A) contained TC PO₄ and no other active ingredients; the other lot (B) contained TC PO₄, phenyl-

toloxamine citrate, aspirin, phenacetin, and caffeine. Control capsules were stored at room temperature in closed bottles, and the test capsules were stored under adverse conditions in open beakers in a desiccator at 32°. The desiccant chamber was filled with a saturated solution of Na₂Cr₂O₇ to ensure a constant relative humidity of 63%. At intervals the capsules were tested for ATC and EATC content. As shown in Table X, the test capsules of both lots at all times contained greater amounts of ATC and EATC than the control capsules; and at all times, Lot B contained greater amounts of ATC and EATC than did Lot A. The final potency of Lot A after being stored under adverse conditions was 24.4% of the labeled potency; after being stored under control conditions, it was 80% of labeled potency. The final potency of Lot B after being stored under adverse conditions was 13.4% of labeled potency; under control conditions, it was 85%. The combination of phenyltoloxamine citrate, aspirin, phenacetin, and caffeine apparently had some additional deteriorating effect on the stability of TC PO₄ capsules stored under adverse conditions.

NMR Analysis of Synthetic Corticosteroids of the 1,4-Dien-3-one Type

HAJRO W. AVDOVICH, PAUL HANBURY, and BRUCE A. LODGE

Abstract ☐ A procedure for the analysis of synthetic corticosteroids of the 1,4-dien-3-one type is described. The method is based upon NMR spectroscopy. Spectra are determined in dimethyl sulfoxide containing an internal reference substance, fumaric acid. Both bulk drugs and formulations can be assayed using this method, and comparison is made with results obtained from official assays on the steroids and their formulations. The average deviation obtained in the NMR method was 0.6%. A procedure for water-soluble 1,4-dien-3-ones is also described. This method uses triethylamine hydrochloride as an internal standard.

Keyphrases ☐ Corticosteroids, 1,4-dien-3-one type—analysis ☐ NMR spectroscopy—analysis ☐ Fumaric acid—internal standard

Synthetic corticosteroids of the 1,4-dien-3-one type are at present assayed (1, 2) by colorimetric methods based on the reduction of certain tetrazolium derivatives by the α -ketol side chain at C-17. Such methods do not distinguish between 1,4-dien-3-ones and related corticosteroids of the 4-en-3-one type, which may be present as impurities and which frequently possess different corticoid activity to that desired in the 1,4-dien-3-one. NMR spectroscopy affords a method of distinguishing easily between the two groups of steroids. 1,4-Dien-3-ones possess three vinylic protons, of which the chemical shift usually differs from that of the single vinylic proton of 4-en-3-ones. It is, therefore, theoretically possible to detect the two groups of compounds in the presence of each other and, hence, to develop a much more specific assay procedure.

Present methods used in the determination of prednisolone sodium phosphate (PSP) (1, 2) are also relatively nonspecific. The BP method (1) for the bulk drug relies upon dissolution in water and measurement of the extinction of the solution at 247 m μ ; for

the formulation, it uses a colorimetric procedure based on a condensation of the steroid with isoniazid. The USP method (2), for both the bulk drug and the formulation, uses alkaline phosphatase to hydrolyze the phosphate ester, followed by extraction of the liberated prednisolone into methylene chloride and measurement of the absorbance of the steroidal solution at 241 mμ.

EXPERIMENTAL

Spectra were obtained at 60 Mc.p.s. using an analytical NMR spectrometer (Varian A-60A). A sweep time of 50 sec. for a chart width of 500 c.p.s. was used for all integrals. A r. f. power of 0.25 milligauss (nominal dial setting) was found to give the maximum integral amplitude (3) and was used for the integrations. Tetramethylsilane in chloroform was used as an external reference to measure chemical shifts.

Procedure (Water-Insoluble Compounds)—Bulk Drug—Approximately 100 mg. of steroid was accurately weighed and dissolved in 1 ml. of dimethyl sulfoxide containing fumaric acid (25.40 mg./ml.). The NMR spectrum was integrated 5 times in each direction through the region shown (Fig. 1).

Dosage Forms—Tablets—Twenty 5-mg. or ten 8-mg. tablets were powdered and refluxed for 15 min. with 50 ml. of 95% ethanol. The mixture was filtered, the residue and filter pad were washed with 50 ml. of 95% ethanol, and the combined filtrate was evaporated to dryness by flash evaporation. The residue was dissolved in 1 ml. of dimethyl sulfoxide containing fumaric acid (25.40 mg./ml.). The NMR spectrum was integrated as for the bulk drug.

Injections—Four milliliters (25 mg./ml.) or 2 ml. (40 mg./ml.) of aqueous suspension was carefully measured into a 50-ml. round-bottom flask and evaporated to dryness. One milliliter of dimethyl

sulfoxide containing fumaric acid (25.40 mg./ml.) was added to the residue, and the whole was carefully mixed to effect dissolution of the steroid in the solvent. Some of the residue (preservative, suspending agents) was not soluble in the dimethyl sulfoxide and remained adhered to the wall of the flask. A clear solution was obtained, and the NMR spectrum was determined as for the bulk drug.

Procedure (Water-Soluble Compounds)—Bulk Drug—Approximately 100 mg. of PSP, previously dried *in vacuo* at 105°, was accurately weighed in a glass-stoppered flask, to which was added about 10 mg. of pure triethylamine hydrochloride, also accurately weighed. The mixture was dissolved in the minimum amount of D₂O (0.5–1.0 ml.). The NMR spectrum was obtained in the usual way (Fig. 2), the signals of interest being integrated 5 times in each direction. The signals at 2.42τ (for PSP) and 6.78τ (for triethylamine hydrochloride) were used as a basis for the assay.

Formulation—Four milliliters of injection of PSP was accurately measured into a 50-ml. round-bottom flask, and the solvent was removed by flash evaporation. Approximately 10 mg. of triethylamine hydrochloride (accurately weighed) was added to the flask, and the mixture was dissolved in the minimum amount of D₂O. The NMR spectrum was obtained and integrated as for the bulk drug.

Calculations—Bulk Drug—

amount of steroid (mg.) =

$$\frac{\text{E.W. (steroid)}}{\text{E.W. (standard)}} \times \frac{\text{I (steroid)}}{\text{I (standard)}} \times \text{weight of standard} \quad (\text{Eq. 1})$$

where E.W. is the molecular weight divided by the number of protons in the signal chosen and I is the integral height.

Tablets—As for the bulk drug, then:

$$\text{amount of steroid/tablet} = \frac{\text{total weight (steroid)}}{\text{no. of tablets in sample}} \quad (\text{Eq. 2})$$

Table II—Recovery of Steroids from Excipient Mixtures

Mixture	Steroid	Amount Added, mg.	Amount Found, mg.	%
1	Prednisone	97.6	96.3	98.7
2	Prednisone	137.3	135.9	98.9
3	Prednisone	137.0	135.0	98.6
4	Triamcinolone	124.4	125.2	100.6
5	Triamcinolone	106.3	106.9	100.6

Injectations—As for bulk drug, then:

$$\text{amount of steroid (mg./ml.)} = \frac{\text{total weight (steroid)}}{\text{no. of ml. in sample}} \quad (\text{Eq. 3})$$

RESULTS AND DISCUSSION

The NMR method, based on the 60 Mc.p.s. spectrum and using an internal standard, has been shown (4) to be suitable as an assay procedure for meprobamate and chemically related substances. The spectrum of a steroidal 1,4-dien-3-one is rather complicated, however, and an internal standard must be chosen with great care, since there are few spaces in the spectrum into which a reference signal might fit. To be of use as a standard, a substance should be an easily purified solid, freely soluble in the solvent of choice. It should not react with the solvent or the substrate and should possess a recognizable, isolated signal in a suitable region of the spectrum. Fumaric acid was chosen as an internal reference standard for use with water-insoluble 1,4-dien-3-ones, because its NMR spectrum in dimethyl sulfoxide shows a single sharp signal at 3.1 τ , which fits well into the spectrum of the steroids. Figure 1 shows the part of the spectrum utilized in the analysis; the signals occur at approximately 2.1 τ (doublet, C-1 proton), 3.6 τ (doublet, C-2 proton), and 3.7 τ (singlet, C-4 proton).

Also shown in Fig. 1 is the position of the signal from the vinylic proton in a steroidal 4-en-3-one (4.1 τ). Partial spectra were obtained from prepared mixtures containing 2, 5, and 10% of 4-en-3-one in 1,4-dien-3-one to show the intensity of the signal from the impurity. This signal can be seen to be well removed from the primary assay signal (2.1 τ) and the standard signal (3.1 τ).

The results obtained from the analysis of eight reference steroids are shown in Table I. In two cases, there was very little material available, and only one analysis could be carried out on each. Nevertheless, the results obtained from fluocinolone acetonide and triamcinolone acetonide are both within the average deviation from the mean, which for 30 samples is 0.6%. Eleven of the 30 results are outside the average deviation, which is the equivalent of one standard deviation. This does not appear to be important for practical purposes, however, since the overall range of results is 98.8–101.6%. The NMR method thus appears to be suitable for the assay of bulk steroids of the 1,4-dien-3-one type.

Table II shows that recovery of prednisone and triamcinolone from mixtures with lactose and starch is reproducible and almost complete. The extraction procedure thus appears to be suitable for use in the determination of steroids in dosage forms.

Table III shows the results obtained from some commercial dosage forms of the steroids under consideration. The NMR

Figure 2—Partial NMR spectrum of PSP + triethylamine hydrochloride in D_2O .

procedure for tablets is simpler than the colorimetric method because no weighing of the tablets is involved. Recovery of the steroid from the powdered tablets in the colorimetric method involves several extractions of an aqueous suspension of the powder with chloroform, followed by dilution of the chloroform solution. An aliquot is taken, and the chloroform is removed by evaporation on a steam bath; then the residue is dissolved in ethanol. The NMR procedure consists of refluxing with 95% ethanol, filtration, and removal of the solvent by flash evaporation. The residue is dissolved in 1 ml. of the stock solution of fumaric acid in dimethyl sulfoxide. The stock solution was stored in a cool, dark place for several months without deterioration. One problem frequently encountered in extracting drugs from powdered tablets into chloroform is that of emulsion formation. Such emulsions are sometimes very stable, and separation of all the chloroform solution is difficult. This problem does not enter into the NMR procedure at all.

The result obtained from Brand C, a prednisone tablet, requires some comment. The colorimetric method was carried out 8 times on this product, using a variety of water–chloroform ratios in the extraction. However, the results showed only 90% of the labeled amount, whereas the NMR procedure showed 98%. The reason for this low result may be that some very bad emulsions were obtained, even when a large excess of chloroform over water was used. The pairs of results obtained from the other five types of tablets compare very well.

Reproducibility of sampling was the chief problem in assaying the injectable preparations, which were both aqueous suspensions; however, the results are all well within the official limits (1, 2). No emulsion problems were encountered with these suspensions, in spite of the presence of suspending agents in the formulations. In the NMR procedure, not all of the dried formulation was soluble in dimethyl sulfoxide, but this apparently did not present any

Table III—Analysis of Dosage Form by NMR and Colorimetric Methods

Mean % = 100.1 SD = 0.95				

problems of recovery based on a comparison of the two pairs of results. It was found, for the formulations studied, that the excipients did not interfere with the NMR method; hence a minimum of cleanup is required.

The NMR procedure, as described, is specific for steroidal 1,4-dien-3-one in the presence of related 4-en-3-ones. This cannot be said of the colorimetric method, which works equally well with other steroids containing the α -ketol side chain. Indeed, it has been shown in this laboratory that such common pharmaceutical aids as ascorbic acid and lactose also produce the color under the reaction conditions used. Since it has been shown (5) that samples of corticosteroids of the 1,4-dien-3-one type sometimes contain significant amounts of related 4-en-3-one precursors, a more specific assay procedure is perhaps desirable.

PSP is a water-soluble corticosteroid and, therefore, the solvent of choice for NMR is D₂O. The almost inevitable presence of a strong signal of 5.3 τ (H₂O/HOD) with its attendant spinning side bands presents a considerable problem, since it reduces the space available in which to put a reference signal. Triethylamine hydrochloride was found to be a suitable internal standard, fulfilling all the conditions described for such substances.

The 60-Mc.p.s. spectrum of PSP in D₂O (Fig. 2) shows a broad doublet at 2.42 τ (J = 10 c.p.s.), being the signal from the vinylic proton at C-1 in PSP. This signal was compared with that produced by the six equivalent methylene protons of triethylamine hydrochloride at 6.78 τ (quartet, J = 7.5 c.p.s.).

In addition to the steroid, the commercial sample of PSP injection contains nicotinamide, phenol, sodium hydroxide, sodium

bisulfite, and disodium edetate. Some interference is caused with the signal at 2.42 τ (C-1 proton), making accurate integration impossible. However, the signals at 3.66 τ (doublet, J = 10 c.p.s., C-2 proton) and 3.93 τ (singlet, C-4 proton) are unaffected. The total integral for the two protons was used in the determination, with the necessary correction being made to the calculation.

Results obtained from the analysis of eight samples of PSP are shown in Table IV.

A sample of injection of PSP labeled to contain the equivalent of 20 mg. of prednisolone/ml. was analyzed twice by the NMR method and each time found to contain 18.8 mg./ml., and once by the USP method (2), giving 19.1 mg./ml.

For the injectable sample, the NMR method requires much less manipulation than the official UV method (2) and is also relatively more specific. Comparison of the results obtained for analysis of the commercial preparation showed the two methods to be in good agreement.

CONCLUSION

Synthetic corticosteroids of the 1,4-dien-3-one type can be assayed satisfactorily by means of NMR spectroscopy, even in the presence of related 4-en-3-one precursors. Because of the sensitivity of present NMR spectrometers, the method is chiefly of value for raw material analysis; it is, however, easily adapted for composite tablet assays and for the assay of injectable preparations.

Quantitative Spectrophotometric Methods for Determination of Sodium Hypochlorite in Aqueous Solutions

A. HUSSAIN*, P. TRUDELL, and A. J. REPTA

Abstract □ Two simple spectrophotometric procedures for the quantitative estimation of hypochlorite in commercially available sodium hypochlorite solutions are presented. One method is based directly on the absorbance of hypochlorite in alkaline aqueous media. The other method takes advantage of the quantitative reaction of hypochlorite and ammonia in alkaline solution to form chloramine, which has a higher molar absorptivity. Results of the spectrophotometric assays are compared with results obtained by the titrimetric procedure of NF XII.

Keyphrases □ Sodium hypochlorite determination—aqueous solutions □ Chloramine determination—Na hypochlorite analysis □ Molar absorptivity—Na hypochlorite, chloramine □ UV spectrophotometry—analysis

Of the various methods available for quantitative determination of sodium hypochlorite in aqueous solution, most are the volumetric or gravimetric type (1-4). All of these methods are relatively laborious, time-consuming, and expensive to do on a routine basis. The method described in the NF XII, while giving good precision and accuracy, requires the preparation of several solutions, some of which must be standardized (1).

The purpose of this work was to develop procedures equally sensitive compared to the NF method, which could be used routinely for the quantitative determination of sodium hypochlorite. The facts that hypochlorite ion has an absorbance maximum at 292.5 $m\mu$ in alkaline aqueous solution (5) and that the absorbance shows a direct relationship to concentration of hypochlorite were utilized in one procedure. The other procedure is based on the quantitative reaction of hypochlorite with ammonia to yield chloramine (6), which has an absorbance maximum at 244.3 $m\mu$ that is also linearly related to concentration.

EXPERIMENTAL

Reagents—Commercially available sodium hypochlorite solutions were used. Hypochlorous acid solutions were prepared by the method of Higuchi *et al.* (7). Reagent grade ammonium hydroxide (58%) (Mallinckrodt) was diluted with distilled water to yield a 20% ammonium hydroxide solution. All water was distilled from acid permanganate solution in an all-glass still.

Spectrophotometric measurements were carried out using a Cary model 14 spectrophotometer. A Beckman pH meter was used for all pH measurements.

Procedures—*Spectral Changes of Hypochlorous Acid as a Function of pH*—Solutions containing 2.13×10^{-3} *M* hypochlorous acid at various pH values were prepared. The spectral changes were determined by examining the UV spectra from 400 to 250 $m\mu$.

Standardization of Hypochlorous Acid Solutions—A suitable volume (3 ml.) of hypochlorous acid solution at 25° was pipetted into a stoppered conical flask and diluted with about 100 ml. of water. One milliliter of glacial acetic acid and 2 g. of potassium

iodide were then added, and the stoppered flask was placed in the dark for 5-10 min. The liberated iodine was then titrated with standard sodium thiosulfate solution, using 1 ml. of starch solution as an indicator.

Iodometric Determinations of Sodium Hypochlorite—These determinations were carried out according to a modification of the procedure described in NF XII. The modification consisted of pipetting 3 ml. of the sample at 25° rather than weighing it.

Spectrophotometric Method I—The molar absorptivity of hypochlorite was determined as follows. Solutions containing concentrations ranging from 8.73×10^{-4} to 34.92×10^{-4} *M* sodium hypochlorite were prepared by pipetting 1, 2, 3, and 4 ml. of a standardized hypochlorous acid solution into 100-ml. volumetric flasks. Two milliliters of 10% sodium hydroxide solution and 75 ml. of distilled water were then added to each flask, and the solutions were allowed to equilibrate at 25°. After equilibrating, the solutions were brought to volume with distilled water at 25°. A plot of the absorbance of each solution in a 1-cm. stoppered cell at 292.5 $m\mu$ versus concentration was used to calculate the molar absorptivity of hypochlorite ion.

The hypochlorite content of commercial bleaches was determined by pipetting 1 ml. of bleach at 25° into a 200-ml. volumetric flask and adding 175 ml. of water and 1 ml. of 10% sodium hydroxide solution. The solution was then equilibrated at 25° and brought to volume with distilled water of the same temperature. Its absorbance at 292.5 $m\mu$ was then determined against a similarly prepared solution containing no bleach. Using the molar absorptivity and a molecular weight at 74.5 g./mole for sodium hypochlorite, the concentration of sodium hypochlorite (in mg./ml.) of bleach solution was calculated.

Spectrophotometric Method II—The molar absorptivity of chloramine was determined by preparing concentrations of chloramine varying from 8.73×10^{-4} to 34.92×10^{-4} *M*. This was done by pipetting 1, 2, 3, and 4 ml. of a standardized hypochlorous acid solution (at 25°) into four 100-ml. volumetric flasks, followed by addition of about 75 ml. of distilled water and 2 ml. of 10% sodium hydroxide solution. The flasks were then equilibrated at 25° in a water bath. To one of the solutions was added 2 ml. of 20% ammonium hydroxide, and the solution was brought to volume with distilled water. The absorbance was measured immediately at 244.3 $m\mu$ in a 1-cm. stoppered cell using a suitable blank. Each of the remaining solutions was treated in an identical way. A plot of absorbance versus concentration was made, and the molar absorptivity was calculated.

Determination of hypochlorite content of commercial bleaches was made by pipetting 1 ml. of bleach at 25° into a 200-ml. volumetric flask. The sample was diluted with 175 ml. of distilled water and 1 ml. of 10% sodium hydroxide solution. The resulting solution was equilibrated at 25°. Two milliliters of 20% ammonium hydroxide solution was then added to the flask, and distilled water was added to bring the solution to a volume of 200 ml. The absorbance was then immediately measured at 244.3 $m\mu$ against a blank which was prepared in the same way except the bleach was omitted.

DISCUSSION

Spectrophotometric Method I—Since this method was based on the absorbance-concentration relationship of hypochlorite ion, it was necessary to determine the minimum pH required to ensure that all hypochlorous acid was converted to hypochlorite ion. Therefore, several solutions containing identical amounts of hypochlorous acid were adjusted to various pH values, and their

Figure 1—UV spectral changes of 2.13×10^{-3} M hypochlorous acid solutions as a function of pH. λ_{\max} is 292.5 $m\mu$.

spectra were obtained by scanning from 400 to 250 $m\mu$. It was found that at pH > 10, all hypochlorous acid had been converted to the hypochlorite ion. These data are shown in Fig. 1. All solutions subsequently used in the determination of the absorptivity and in analysis of hypochlorite were made such that pH > 10.

From Fig. 1, it was also determined that $\lambda_{\max} = 292.5$. When absorbance at λ_{\max} was plotted against pH (Fig. 2), a typical sigmoid-shaped curve was obtained. From Fig. 2, the pKa of hypochlorous acid was found to be 7.50, which agrees well with the value of 7.53 previously reported (8).

When the absorbance values at 292.5 $m\mu$ of a series of hypochlorite solutions were plotted against their concentrations, a linear relationship was found. From these data the molar absorptivity was calculated ($\epsilon = 360 \pm 2 \text{ M}^{-1} \text{ cm}^{-1}$).

The quantitative determination of hypochlorite in commercial bleach solution was done by pipeting a 1-ml. sample at 25° into a 200-ml. volumetric flask, adding excess alkali, and bringing to volume with water at 25°. The absorbance of the diluted solution was measured at 292.5 $m\mu$ against a blank. The concentration in milligrams of sodium hypochlorite per milliliter of bleach was calculated according to the following equation:

$$\text{mg. of NaOCl/ml. of bleach} = A \times MW \times V_D / \epsilon V_S \quad (\text{Eq. 1})$$

where: A = absorbance at 292.5 $m\mu$
 ϵ = molar absorptivity of hypochlorite (at 292.5 $m\mu$)
 $= 360 \text{ M}^{-1} \text{ cm}^{-1}$
 MW = molecular weight of NaOCl = 74.5
 V_D = total volume of diluted solution (in ml.)
 V_S = volume of bleach sample solution used (in ml.)

The stability of the solutions was checked, and no change in absorbance at 292.5 $m\mu$ was observed over a 2-hr. period.

Spectrophotometric Method II—An earlier report (6) has shown that hypochlorous acid in alkaline solution reacts rapidly in the presence of excess ammonia to form chloramine quantitatively according to the following scheme: $\text{NH}_3 + \text{HOCl} \rightarrow \text{NH}_2\text{Cl} + \text{H}_2\text{O}$.

Figure 2—Absorbance at 292.5 $m\mu$ of 2.13×10^{-3} M hypochlorous acid solutions as a function of pH.

This information was used as the basis for the indirect determination of hypochlorite. Figure 3 shows the difference in spectra between hypochlorite solution at pH > 10 and a similar solution to which excess ammonia has been added to form chloramine. The λ_{\max} shifted from 292.5 $m\mu$ for hypochlorite to 244.3 $m\mu$ for chloramine. When various concentrations of hypochlorous acid were treated with ammonium hydroxide at pH > 10, and the absorbance at 244.3 was plotted against the concentration of chloramine (which is equimolar with hypochlorite), a linear relationship was observed. From the slope of the line, the molar absorptivity was calculated to be $459 \pm 3 \text{ M}^{-1} \text{ cm}^{-1}$. Actual determinations of sodium hypochlorite in commercial bleach samples were similarly

3	NF ^a	5	59.7–60.2	59.7 ± 0.2
3	Spectrophotometric method I ^b	5	60.0–60.3	60.1 ± 0.2
3	Spectrophotometric method II ^c	5	59.1–59.5	59.3 ± 0.2

^a Used volume at 25° rather than weighing sample in NF assay. ^b Measured as hypochlorite at 292.5 m μ . ^c Measured as chloramine at 244.3 m μ .

carried out, and the concentration of sodium hypochlorite in milligrams per milliliter of bleach was calculated according to Eq. 1 where now A = absorbance of chloramine at 244.3 m μ , and ϵ = molar absorptivity of chloramine = 459 M⁻¹ cm.⁻¹.

When the absorbance of chloramine solutions was observed over a period of time, no significant changes were seen in 4–5 min. However, 1–2% decreases in absorbance were observed after 30 min. To minimize the experimental error due to the instability of chloramine, all solutions were prepared up to the point where the ammonium hydroxide was to be added. At this point, one solution at a time was taken and to it were added the ammonium hydroxide and distilled water to bring it to volume. The absorbance was then immediately measured.

RESULTS AND CONCLUSIONS

The hypochlorite content of three different bleach solutions was determined by the NF method and the two spectrophotometric methods; the results are shown in Table I. The results obtained for each sample are in good agreement for all three analytical methods.

The simplicity and ease of the spectrophotometric methods as opposed to the NF method would seem to suggest the former as the methods of choice in the determination of hypochlorite in aqueous solution. In addition, the spectrophotometric methods allow for analysis of much more dilute solutions than the NF method. For example, if a 10-cm. cell and the expanded scale of the Cary 14 spectrophotometer were used, concentrations as low as several micrograms per milliliter could be determined. This could be extremely useful, especially when applied to the determination of active chlorine in water.

Improved Self-Programming Automated Tablet-Coating System

ALLEN HEYD and JOSEPH L. KANIG

Abstract □ The usefulness of a monitoring system based on moisture sensing is established as a means of automating a tablet-coating process. A radio frequency absorption system was employed to measure continuously the state of dryness of the tablet mass and to indicate when the tablets reached a predetermined satisfactory end-point. The moisture-sensing apparatus was found to monitor the drying rate accurately after the tablets had been sprayed. The analyzer readings were shown to be directly related to conditions of relative humidity existing in the environment surrounding the coating pan. The instrument was extremely sensitive and permitted a constant readout of drying rate and moisture content by means of a specially constructed probe placed within the tablet mass.

Keyphrases □ Tablet-coating system—self-programming, automated □ Automated tablet coating—radio frequency system, moisture measurement □ Diagram—automated tablet-coating system □ Moisture analysis—tablet-coating rate control

One important factor in a tablet-coating process is the drying of the tablet mass after each application of a coating solution. The rate of liquid loss dictates the time period between tablet-coat applications. One does not know if the rate of liquid loss is constant for each application during a coating process, or if the application of successive coats lengthens or shortens the drying time. It becomes a matter of subjective evaluation to determine whether or not a tablet mass is sufficiently dry before the next application. When an automatic timed procedure is used, it is based on the assumption that the drying rate is constant for each cycle of the process. The validity of this assumption has never been clearly established. Drying rates are different for each type of coating solution and are also influenced by tablet shape, tablet size, and batch size. A contention underlying this investigation was that an automatic timed procedure does not take into account either inherent or environmental conditions which may exercise an effect during the coating process and may vary the drying time. In taking these inherent or environmental changes into account, a system must be able to monitor the drying rate continuously and utilize the degree of dryness for controlling an automated process.

Automated tablet-coating systems that have been suggested to date are time controlled (1–6) with the length of each step in the coating cycle determined by a preset timer. Therefore, such systems are insensitive to environmental changes. When an automated system is created around a timed procedure, it must be programmed specifically for all the variables indicative

of the properties of a particular batch. Each major variation in size, shape, weight, number, and other features of a tablet batch may require a separate and different program. A system that follows the drying rate, however, may prove to be independent of most of these variables. This report presents a description of an automated tablet-coating system which is entirely programmed and controlled by the moisture content of the tablet mass.

EXPERIMENTAL

Materials—The core tablets used in this investigation consisted of dicalcium phosphate dihydrate¹ lubricated with 1.5% magnesium stearate.² Tablets weighing 400 mg. were compressed with 1.01-cm. (0.40-in.) standard concave punches and used without further treatment.

The coating solution used in all the experiments was an 85% (w/v) syrup solution. The solution was colored with 0.1% (w/v) amaranth.³

Equipment—The schematic diagram in Fig. 1 illustrates the overall design and arrangement of the equipment which made up the programmed automated tablet-coating system.

The coating solutions were delivered by an airless spray system (A).⁴ The pump model used (the "President") had a 28:1 pressure ratio. Two spray guns (B) (Graco automatic Hydra-Spray guns, model 205-163) were suspended inside a 96.52-cm. (38-in.) baffled coating pan (C) in such a position that the spray was directed perpendicular to the surface of the tumbling tablets for maximum, uniform coverage. The guns were suspended from steel tubing which was mounted on the pump chassis. A high-pressure fluid heater (D) (Graco model 206-580, series A), 240 v., was mounted on the rear of the spray system and connected to the fluid lines between the pump and the spray guns. The fluid passing through the guns could then be heated to a desired temperature before it was sprayed. A circulating system (E) (Graco Restrict-A-Flo) was utilized to accomplish continuous fluid circulation for maintaining uniform temperature and homogeneity of the coating liquid. Two timers⁵ (F) were mounted on the automatic spray-system control panel. These timers were connected to energize the spray-on and drying cycle. The dry cycle timer was utilized only when the system was manually controlled. The timers were also interconnected with the moisture monitoring-programming device so the entire process could be evaluated for its applicability to automation. The instrument used to measure relative humidity during the coating experiments was a wet-dry bulb psychrometer.⁶ Exhaust (G) was supplied with a portable vacuum,⁷ and a blower-heater system⁸ was used as the source of forced air (H).

The instrument selected to measure the state of dryness of the tablet mass was the HFR-6E Moisture Analyzer.⁹ The Analyzer (I) operates on the principle of high-frequency conductance caused by power absorption of the material being tested. Power absorption or conductance is the only electrical property which gives accurate indications of moisture content (7). The Analyzer was adapted for in-process control of the various components of the coating system and for continuous readout of tablet moisture content. This was accomplished by replacement of the regular conductance meter with a contact-conductance meter which energized the spray cycle timer. Auxiliary switches were also incorporated into the Analyzer which activated the blower-heater and the exhaust system at the proper coating cycle intervals. A digital contact meter on the Analyzer was set to predetermine the total number of coats applied, after which it deenergized the entire coating apparatus. L-shaped and cup-shaped electrodes (J, K) were used to determine sample moisture content automatically and manually, respectively. Analyzer meter readings did not significantly differ

when using either electrode under the same set of conditions. The cup electrode was used only during calibration curve preparation.

Moisture Calibration Curve—A freshly prepared 200-lb. batch of tablets was wetted with 2000 ml. coating solution.

The tablets were allowed to tumble for 20 min. in an open pan without heat, forced air, or exhaust to achieve uniform wetting. Subsequently, three samples were taken at 15-min. intervals from different areas in the pan with the manual Analyzer electrode receptacle. Readings were taken after manipulation of the control switches on the Analyzer panel until a minimum reading on the contact meter (radio frequency conductance) was obtained. The readings in terms of units indicated the dielectric loss and, consequently, the moisture content of the tablet mass. Twenty intact tablets taken from each sample were weighed and placed in 50 ml. of anhydrous methanol, reagent grade, for 12 hr. Five milliliters of each methanol-water sample was then tested for total moisture content using the Karl Fischer method (8).

To establish a calibration curve, readings were plotted against percent moisture on a semilog graph since energy loss due to moisture is a first-order process (7). The resulting curve (Fig. 2), determined by the method of least squares, was then used to interpret readings in terms of actual tablet moisture content. This calibration curve is valid for all volumes of aqueous solution delivered. Therefore, the volumes used in the investigation were appropriate for each experiment.

Automated Coating Procedure—Two hundred pounds of freshly compressed tablets was placed in the coating pan. The automatic electrode was positioned in the tablet mass in such a manner that liquid from the spray nozzle was applied downstream in relation to tablet flow and electrode insertion. Tablet attrition on the electrode walls prevented the buildup of coating solution; therefore, electrode readings were not affected. An equilibrium meter reading of 22, corresponding to 2.2% moisture, was taken and designated as batch dryness for each experiment in the investigation. This reading was arbitrarily chosen to indicate batch dryness because it was extremely difficult to obtain lower readings within an optimum time period. The coating apparatus was put into operation by closing a master switch on the Analyzer. The contact meter indicating dryness activated the spray cycle timer (F). The timer energized a solenoid valve which, in turn, activated the automatic spray guns, allowing the flow and atomization of coating liquid. At the end of the spray cycle time, the solenoid was deenergized and the forced air and exhaust units were energized by the Analyzer. The sequence of events was repeated only when the Analyzer indicated that the predetermined degree of dryness was reached in the tablet mass. On completion of each spray cycle, the digital counter registered one coat. This coating procedure was carried out for repeated coats in each experimental portion of this investigation.

Sensitivity to Moisture Loss—Analyzer sensitivity to moisture loss was determined under four conditions: (a) at 29°; (b) at 29° with exhaust, (c) at 29° with forced air and exhaust; and (d) with forced air at 50° and exhaust.

Figure 4—Relative humidity versus drying time.

The spray cycle timer was set for a 60-sec. interval to deliver 600 ml. of coating liquid and was energized manually. The wetted tablets were tumbled for 10 min. prior to manual sample testing for moisture to assure uniform distribution of coating solution. Sample readings were taken every minute after the equilibration period until a constant moisture content was attained. The coating room temperature was 29° at 60% relative humidity for the series of experiments. Each condition was carried out in duplicate with a fresh batch of tablets.

Sensitivity to Relative Humidity—The automated coating procedure was carried out on freshly prepared batches of tablets for 5 consecutive days. During this time, the ambient relative humidity varied from 15 to 60%. Coating experiments were also carried out at five controlled relative humidity range levels: 15–25 to 55–65%. Each level consisted of 10% units from a low of 15 to a high of 65% relative humidity. These relative humidity levels were attained by atomizing water into the coating-room environment. Spray cycles of 10-sec. duration, delivering 100 ml. of coating solution per cycle, were used. Moisture readings were taken every minute after an initial 3-min. equilibration period until the base reading of 22 was attained.

Sensitivity to Changes in Spray Cycle Time—These experiments were performed at a temperature of 29° and 40% relative humidity to test Analyzer sensitivity to changes in spray cycle time (change in total volume delivered). Spray cycles were begun using a 10-sec. interval and then increased by 5- or 10-sec. increments to a 30-sec. interval. Forced air at 50° was used for drying the tablet mass. Meter readings were taken every 5 min. until a plateau was reached, indicating tablet dryness.

Reproducibility of Coating Cycles—Several coating cycles were run using spray cycles of 30-sec. duration to deliver 300 ml. of coating liquid. The experiments were carried out in triplicate under conditions of 50% relative humidity at a temperature of 29°. Moisture readings were taken every minute after a 5-min. equilibration period until a plateau was reached.

RESULTS AND DISCUSSION

Sensitivity to Moisture Loss—Figure 3 shows that the Analyzer followed moisture loss with time as drying of the tablet mass occurred.¹⁰ The differing drying curve characteristics also indicate

Table I—Effect of Relative Humidity on Drying Time

	Day				
	1	2	3	4	5
Average relative humidity, %	59.3	34.7	27.2	37.5	51.6
Average drying time, min.	18.2	10.0	9.0	11.5	15.0

Table II—Effect of Spraying Cycle Time on Drying Time

Spray Cycle Time, sec.	Drying time, min.
10	10.0
15	13.75
20	19.5
30	28.0

the sensitivity of the instrument to varying drying conditions. It can be seen that forced air significantly increased the drying rate of the tablets. A plateau (batch dryness) was reached in approximately 22 min. as opposed to approximately 40 min. with and without forced air, respectively (Curves C and D versus A and B). Exhaust had no significant effect on the rate of moisture loss, as is shown by Curves A and B. The exhaust system could very well have been eliminated from the coating apparatus and would only be of use for collecting dust from an enclosed coating system. There was no significant difference in drying rate when comparing forced air at 29 and 50°, Curves C and D, respectively. Therefore, the major driving force for moisture loss from the surface of the wet tablets was the volume of forced air.

Sensitivity to Relative Humidity—The data in Table I show a decrease in drying time with a decrease in the relative humidity surrounding the coating apparatus. The Moisture Analyzer was quite sensitive to these changes in drying time, and a surprisingly good linear relationship was found between relative humidity and drying time when the data were plotted as a 10-unit range in percent relative humidity versus time (Fig. 4).

The Analyzer clearly indicated that there was a change in drying time as the relative humidity surrounding the coating system changed.

Sensitivity to Changes in Spray Cycle Time—Table II shows that the Analyzer was sensitive to a change in moisture when the spray cycle times were varied. It is evident that as the spray cycle time increased, there was a corresponding increase in drying time.

Reproducibility of Coating Cycles—The reproducibility of the coating cycle is quite evident in Fig. 5. In each case, a plateau was reached at approximately 11 min., after which the curves were linear and parallel, indicating approach to dryness.

The importance of using a moisture-monitoring device in tablet coating is illustrated in Figs. 3–5. There was an immediate indication of drying rate and drying time for the tablet mass under specific environmental and tablet mass conditions (Figs. 3 and 4). The state of the drying condition was no longer evaluated subjectively with the attendant, inherent human error; but it was evaluated continuously, quantitatively, and reproducibly as shown in Fig. 5.

In addition, the Analyzer can function as a built-in fail-safe mechanism to correct immediately the drying program of the

Figure 5—Reproducibility of coating cycles.

¹⁰ Data points for Figs. 3 and 5 were omitted for the purpose of clarity.

coating process should there be a failure in one component of the systems such as in the spray delivery timer. Even though timed devices may contain fail-safe mechanisms, such a timed coating process would have to be terminated and reprogrammed manually.

SUMMARY

An automated tablet-coating system was designed which is self-programming and based on the rate of moisture loss. The Moisture Analyzer, which programmed the system, was revealed to be extremely sensitive to the presence of moisture and to moisture loss in the tablet mass. The system quickly adjusts to any change in spray cycle time and also shows a high degree of reproducibility between cycles under similar conditions.

A high degree of sensitivity of the drying cycles to changes in the environmental humidity was also demonstrated by the apparatus. It is, therefore, felt that a moisture-sensing device should be utilized when considering an automated tablet-coating system for production.

Monitoring Volatile Coating Solution Applications in a Coating Pan

RUSSELL J. LANTZ, Jr.*, ALAN BAILEY, and MANFORD J. ROBINSON

Abstract □ Equipment and methods are presented for recording temperature patterns resulting from the evaporation of volatile coating solutions applied to pellets in a rotating pan. These patterns are interpreted in regard to run-to-run replication, effect of application and drying rate, and coating solution distribution. The applicability of this equipment and methodology to control the coating of solid particles is discussed.

Keyphrases □ Coating application, pellets—monitoring method □ Volatile coating solutions—application monitoring □ Diagram—pellet coating equipment with monitor □ Thermal patterns—pellet coating

Sutaria (1) has noted that, until recently, pharmaceutical coating processes were an art because of the apathy shown toward studying the many variables involved in these processes. Sutaria's extensive bibliography indicates that efforts to define and control these variables are now underway and, in some cases, have resulted in the semiautomation of certain aspects of the coating process.

The purpose of this preliminary report is to add to this knowledge by presenting data on methods found useful for monitoring the application of volatile coating solutions to pellets in a rotating pan.

The application and evaporation of coating solutions containing volatile solvents, e.g., acetone, alcohol, and chloroform, produce measurable temperature changes in a bed of pellets in a rotating pan. By placing a thermocouple and thermistors in the pellet bed and recording the temperature changes during coating, it is possible

Figure 1—Equipment diagram.

to discern and control certain events and/or trends taking place during the coating process.

EXPERIMENTAL

Equipment and Instrumentation—The coating process was performed in a Stokes 91.4-cm. (36-in.) coating pan.¹ The volume of air moving across and through the pellet bed was monitored at the exhaust with a Dwyer pitot tube and an air velocity meter No. 400.² The temperature of the coating solutions was controlled in a 30-l., electrically heated, feed tank. The feed tank temperature was monitored with an Alnor pyrometer³ coupled to a standard

coating process should there be a failure in one component of the systems such as in the spray delivery timer. Even though timed devices may contain fail-safe mechanisms, such a timed coating process would have to be terminated and reprogrammed manually.

SUMMARY

An automated tablet-coating system was designed which is self-programming and based on the rate of moisture loss. The Moisture Analyzer, which programmed the system, was revealed to be extremely sensitive to the presence of moisture and to moisture loss in the tablet mass. The system quickly adjusts to any change in spray cycle time and also shows a high degree of reproducibility between cycles under similar conditions.

A high degree of sensitivity of the drying cycles to changes in the environmental humidity was also demonstrated by the apparatus. It is, therefore, felt that a moisture-sensing device should be utilized when considering an automated tablet-coating system for production.

Monitoring Volatile Coating Solution Applications in a Coating Pan

RUSSELL J. LANTZ, Jr.*, ALAN BAILEY, and MANFORD J. ROBINSON

Abstract □ Equipment and methods are presented for recording temperature patterns resulting from the evaporation of volatile coating solutions applied to pellets in a rotating pan. These patterns are interpreted in regard to run-to-run replication, effect of application and drying rate, and coating solution distribution. The applicability of this equipment and methodology to control the coating of solid particles is discussed.

Keyphrases □ Coating application, pellets—monitoring method □ Volatile coating solutions—application monitoring □ Diagram—pellet coating equipment with monitor □ Thermal patterns—pellet coating

Sutaria (1) has noted that, until recently, pharmaceutical coating processes were an art because of the apathy shown toward studying the many variables involved in these processes. Sutaria's extensive bibliography indicates that efforts to define and control these variables are now underway and, in some cases, have resulted in the semiautomation of certain aspects of the coating process.

The purpose of this preliminary report is to add to this knowledge by presenting data on methods found useful for monitoring the application of volatile coating solutions to pellets in a rotating pan.

The application and evaporation of coating solutions containing volatile solvents, e.g., acetone, alcohol, and chloroform, produce measurable temperature changes in a bed of pellets in a rotating pan. By placing a thermocouple and thermistors in the pellet bed and recording the temperature changes during coating, it is possible

iron-constantan thermocouple. The coating solutions were pumped by a Grover pump,⁴ which delivered 130 psig. pressure to a No. 650067 Spraying Systems⁵ T-Jet nozzle mounted on a Spraying Systems 24 AU Auto Jet valve assembly.⁶ The spraying and drying cycles were timed with a stopwatch, and the "start" and "stop" of the spray nozzle were controlled by an on-off switch in series with a Skinner electric valve.⁷ Ambient conditions were recorded with a Bristol thermo-humidograph.⁸

An Hitachi 165 recorder⁹ fitted with a standard iron-constantan thermocouple, placed 3.8 cm. (1.5 in.) deep in the pellet bed and 17.9 cm. (7 in.) in from the pan rim, was used to record pellet bed temperature at this point. The recorder temperature range was from 4 to 21°.

A second recorder,⁹ with two type A-21 amplifiers, was used to amplify the signals from two thermistors¹⁰ (nominal resistance: 2000 ohms at 25°). To obtain a range of 13–16° with each amplifier, the thermistors were placed in one arm of a standard Wheatstone bridge, where all arms were at equal resistance at 14°. One thermistor was placed beside the iron-constantan thermocouple, while the second thermistor was moved to different points on the pellet-bed surface. The two separate recording setups were used to give the advantage of the wide temperature range coverage of one recorder and the detailed or expanded scale of a small temperature range recorder, and to provide a reference check of one recorder against the other.

Figure 1 shows the equipment setup.

Materials—Sugar pellets, 16–30 mesh, were used for each coating run. Special denatured No. 30 alcohol was the volatile solvent used in preparing the coating solution.

Procedure—For each coating run, a 50-kg. charge of pellets was placed in the coating pan preset to rotate at 20 r.p.m. The coating solution was prepared, heated, and maintained at 65 ± 3°. A 2-min. spray and 2-min. dry cycle was used until the pellets were wetted

and the bed temperature dropped to approximately 15°. The time cycle was then changed to a 1-min. spray and a 3-min. drying period, or a 1-min. spray and a 4-min. drying period, to maintain an equilibrium between the amount of coating solution applied and the rate of evaporation. A sample data sheet and program for coating solution application and pellet drying are seen in Tables I and II, respectively.

Some coating runs were made under near identical conditions to determine if identical thermal patterns could be obtained. In other runs, coating application rates and pellet drying times were varied. The temperature profile across the pellet bed and the circulation of coating solution to the back of the coating pan were also determined. Sixteen coating runs were made to accumulate and recheck the data obtained.

RESULTS AND DISCUSSION

Typical thermal patterns, taken at the same point in the pellet bed with the thermocouple and thermistor setups, are shown in Fig. 2. These identical curves show good uniformity from cycle to cycle in the temperature rise that accompanies the heated coating solution application and the evaporative cooling which occurs during the drying period. The range between the maximum and minimum temperature usually averaged 0.3–0.4° within a normal spray and dry cycle (the lower curve).

Coating runs performed on different days, following nearly identical conditions and procedures, show almost identical thermal traces throughout each run. This is illustrated in Fig. 3, where portions of the trace of each run are shown early and late in the coating process. A comparison of the thermal patterns made early in the run with those made late in the run shows a difference in the heating portion of the curve, which represents the coating solution application. It is possible that the leveling off or temperature decrease at one point in the heating curve may be caused by a partial dissolution of the heavier coating accumulated late in the run as new coating solution is applied. This effect is shown more clearly in an expanded thermal trace of one cycle in Fig. 4.

It was found that a variation in coating solution application rates and/or pellet drying times caused distinguishable differences in the

Figure 3—Run-to-run duplication of thermal patterns.

pellet-bed thermal patterns. In Fig. 5 the upper and lower thermal traces show the effect of high and low coating solution application rates, and the middle thermal trace represents a more normal application and drying rate. High application rates of coating solution result in a continuous decrease in temperature during drying, with an overall downward trend in pellet-bed temperature; the low application rate of coating solution shows just the opposite effect. The normal application rate curve illustrates a system in equilibrium, in which the coating solution solvent application rate balances the solvent evaporation rate with no upward or downward trend in pellet-bed temperature.

If the pellets are subjected to an extended period of drying, or if only small amounts of coating solution are applied, two stages of drying, namely the "constant rate period" and the "falling rate period" (2, 3), are revealed by the thermal traces of these pellet beds. In the constant rate period, unbound solvent is removed from a saturated surface at a constant rate under constant conditions. The second stage or falling rate period proceeds after the critical solvent level has been reached,¹¹ and it is controlled by the internal movement of the solvent to the surface of the pellets. This stage is characterized by a diminishing solvent evaporation rate under constant conditions. In Fig. 6, the constant rate period is shown as a constant decrease in pellet-bed temperature, while the second stage or falling rate period is shown as a gradual increase in pellet-bed temperature.

The distribution of coating solution in a rotating pan is always of concern, because of the poor product circulation patterns set up in some coating pans, including those with improper baffle designs. Improper positioning of the spray nozzle can also result in maldistribution of the coating solution. A means of evaluating coating solution distribution in a rotating pellet bed is illustrated in Figs.

Figure 4—Temperature drop during coating solution application.

¹¹ The point where the surface no longer remains saturated.

Figure 5—Effects of coating solution application rate and drying.

7-9. Figure 8 shows four pellet-bed surface thermal patterns taken at points shown in Fig. 7. Assuming that the magnitude of pellet-bed temperature change is an indication of the amount of coating solution present, it is evident that Position B, just forward of the nozzle, E, receives the most coating solution, followed by Position C just behind the nozzle. Position A receives the third highest quantity of coating solution, while Position D, at the back of the coating pan, receives the least amount. Thermal patterns in Fig. 9, taken at the rear of this particular coating pan in Position D (Fig. 7), indicate that the amount of coating solution reaching this area depends in part on the coating solution application rate.

Measurement of temperature changes should be applicable to any pan coating process (including the coating of pellets and granules and the film coating of tablets) when coatings containing volatile solvents are used. Records of thermal patterns may be particularly useful in determining the day-to-day variability of one coating operator and/or the operator-to-operator variability for a single coating process.

Information which could reduce operator variability can be obtained, in part, from such a series of thermal pattern recordings. This technique may also turn out to be useful in coating process automation. Recording the thermal changes on magnetic tape and running a "playback" of the tape with proper circuitry and control¹² should permit automatic regulation of the pan coating process.

Figure 6—Thermal patterns indicating two stages of drying.

¹² This technique is more feasible if raw materials and ambient conditions can be held constant during the coating of each batch of solid particles.

Figure 7—Nozzle and thermistor positions in the coating pan.

The recording of temperature profiles across a bed of solid particles during coating may also be correlated with final product results to help in evaluating the design of coating pans and/or baffles for a particular product. This same technique should also be useful in selecting the proper spray nozzle design and determining its position in a coating pan.

SUMMARY

This preliminary report describes a method for measuring temperature changes encountered during the application of volatile coating solutions to pellets in a rotating pan. These temperature changes develop characteristic patterns during the periods of coating solution application and pellet drying, and these patterns are

Figure 8—Distribution of coating solution in the pellet bed.

Figure 9—Coating solution circulation to the back of the coating pan.

replicable. Distinguishable differences in thermal patterns were found when coating solution application rates and pellet drying times were varied. Thermal traces from extended pellet drying times revealed two stages of drying. Temperature changes recorded at several points on the pellet-bed surface demonstrated differences in coating solution distribution to the pellets.

This method of measuring solid particle-bed temperature changes in a rotating pan should be applicable to the control of day-to-day and operator-to-operator variability; to the automation of the coating process; and to an evaluation of the design of coating pans, baffles, and auxiliary equipment.

Correlations between changes in pan coating conditions and their effects on final product characteristics using this technique will be considered in another paper.

Enhancement of Radioresistance in Mice Treated with Diphenylhydantoin

H. LEVAN*, P. GORDON†, and S. STEFANI*

Abstract □ Diphenylhydantoin, a pharmaceutical compound of the same chemical class as magnesium pemoline, is found to exhibit significant protection against ionizing radiations. It is suggested that the mechanism of the radioprotective action of diphenylhydantoin is related to its influence on nucleic acid metabolism rather than to its anticonvulsant effects on the brain.

Keyphrases □ Diphenylhydantoin—radioresistance enhancement, mice □ Radiation protection—diphenylhydantoin effect, mice □ Irradiation, mice—enhancement of lifespan, diphenylhydantoin effect

Recently, the radioprotective effect of magnesium pemoline, a central nervous system (CNS) stimulant (1–4), has been investigated and reported from these laboratories. These encouraging results led to the studies of other compounds of the same chemical class as magnesium pemoline, among these diphenylhydantoin (DPH). Although pemoline and DPH do not have similar pharmacological actions on the most commonly employed screening system, pemoline is, in fact, 5-phenylpseudothiophene and has been reported to exert effects similar to DPH and other phenylhydantoins on aspects of learning behavior in the rat and on the enzyme system DNase I (5, 6). Because DPH is a relatively nontoxic drug currently in use, while magnesium pemoline still falls in the category of an experimental drug of restricted use, it was felt that the exploration for radioprotective effects exerted by DPH, similar to those of pemoline, might have both theoretical and practical value. In this report, the enhancement of the lifespan of irradiated mice treated with DPH is reported.

METHOD

CF₁ male mice, 50–60 days old, were used. The animals were housed in air-conditioned quarters and had free access to food and water. The experiments started about 10 days after their arrival from the supplier (Carworth Farm). Three hundred mice were divided randomly into two groups. Each group was then divided into 15 cages of 10 animals per cage. A second control group of 60 untreated mice was also used to observe possible pseudomonas infection. The experimental group was treated with 3 mg./kg. of DPH, intraperitoneal route, approximately 15–20 min. before 750 r whole-body X-irradiation; the control group was treated with a 0.3% suspension of tragacanth. Tragacanth was also used to prepare the DPH solution.

Irradiation was carried out with a Maxitron 400 kvp. X-ray machine at 80-cm. target-skin-distance (TSD) and an average exposure rate of 80 r/min. The TSD was determined by measuring the distance between the target and the horizontal level in the cage where the backs of the mice were exposed. The animals were not free to move around in the cage during irradiation. Total exposure was measured by a Victoreen Condenser R-Meter placed in the cage used to irradiate the animals. A turntable rotating at 5 r.p.m.

Figure 1—Survival curves for two groups of CF₁ mice treated with DPH and tragacanth and exposed to 750 r of X-irradiation. Key: ●—●, control (tragacanth); and ○—○, experimental (3 mg./kg. DPH).

was used to ensure uniform distribution of the radiation field. Less than 3% difference in the total exposure received by the two groups was observed.

The animals spent their postirradiation days in the same cage placed at the same position as before irradiation. Cautious measures were taken to assure minimal changes in the environmental factors between preirradiation and postirradiation periods. The experiment was replicated consecutively three times so that a total of 900 mice was used. Mortality was observed up to 30 days for each cage, and the total results were averaged for each of the two groups from all three experimental runs. Statistical analysis of the three combined experimental results was done according to Mewissen (7). The data plotted were thus based on the mortality of 900 animals.

RESULTS AND DISCUSSION

No unusual symptoms or sickness were observed in the 60 untreated, nonirradiated control mice. Figure 1 clearly demonstrates a prolongation of survival of mice treated with DPH. All mortalities in the control group occurred within 10 days. By the 19th day after radiation exposure, all animals in this group had died while over 60% of the animals treated with DPH still survived. Over a period of 2 weeks, the survival in the experimental group decreased from 100 to 55%, and no further mortality was observed after the 24th postirradiation day. Most animals in both groups died between the 11th and 14th day after radiation exposure. The highest mortality of the control group was 30%, 13 days after irradiation, versus 13% for the DPH-treated group 12 days following radiation exposure.

Although Laird and Fonner (8) have reported a protective effect of DPH in the hyperacute radiation syndrome wherein death is from convulsion, two aspects of the present experimental design required that the authors postulate a mechanism of action for DPH in this experiment employing X-irradiation at 750 r that is distinct from its classical anticonvulsant effect. The exposure to radiation

employed is one where death is delayed for more than 1 week and is ascribable to hematopoietic depression rather than to CNS effects. Mortality in the experiments of Laird and Fonner occurred following exposures in the 10,000-r range 2–3 days postirradiation and was associated with convulsions, which was not the case in this experiment. Furthermore, DPH was given in this experiment in a single injection at a dose level one-fourth the anticonvulsant dose in mice (9) and would certainly not be expected to exert any anticonvulsant activity 10 days following drug administration.

Potentially important nonanticonvulsant actions of the DPH drug group have been identified by Gordon *et al.* and include anti-leukemic activity (5) and enhancement of the deteriorated learning and memory characteristic of very old animals (10, 11). Furthermore, both DPH and pemoline have been identified by this group as markedly potentiating the activity of the enzyme DNase 1, while DPH has been found by Shafer (12) to increase markedly the turnover of DNA in normal liver. Thus, DPH may exert the radioprotective action reported here by effects on nucleic acid metabolism, which are in no simple way related to its anticonvulsant action on the brain.

Continuing investigations will include exploring the capacity of DPH to exert radioprotective effects when given after radiation because such an effect for DPH has been observed in these laboratories when it is given within the 1st hour. Further, in a series of preliminary experiments, DPH exerted an effect similar to that of pemoline (5-phenylpseudo-hydantoin) in altering the growth pattern of Ehrlich carcinoma while prolonging the lifespan of tumor-bearing animals (13–15). The fact that DPH and pemoline have a similar chemical structure and exert similar effects on a nucleic acid-metabolizing enzyme suggests the link between biological effects shared by these two compounds.

Erythrina sp. III: Chemical Constituents of *Erythrina suberosa* Roxb. Seeds

HARKISHAN SINGH and AMRIK SINGH CHAWLA

Abstract □ A phytochemical investigation of *Erythrina suberosa* seeds has resulted in the isolation of erythraline, erysodine, erysotrine, and hypaphorine. This is the first time that erysotrine has been found to occur naturally, although it is well known as a conversion product of other eryso-alkaloids. The alkaloidal constituents were found to vary in different seed collections. The fatty acid composition of the seed oil was examined, and the sterol part from the unsaponifiable matter was found to be composed of sitosterol, stigmasterol, campesterol, and cholesterol.

Keyphrases □ *Erythrina suberosa* seeds—phytochemistry, chemical constituents □ Mass spectroscopy—identification □ IR spectrophotometry—identification □ TLC—identification

In India, *Erythrina stricta* Roxb., *E. suberosa* Roxb., and *E. variegata* Linn. var. *orientalis* (Linn.) Merrill (syn. *E. indica* Lam.) have been used in the indigenous system of medicine for various ailments (1).

The authors have started a systematic study of *Erythrina* species growing in India. There have been no earlier reports of chemical investigations of *E.*

suberosa and *E. stricta*. Hypaphorine (I) has been isolated from the seeds of *E. variegata* var. *orientalis* (2–6), and Folkers and Koniuszy (6) obtained erythraline

(II; $R_1, R_2 = -CH_2-$) from the seeds. Subbaratnam (5) isolated a neutral entity, $C_{24}H_{50}O_2$, m.p. 82–84°. The fatty acids present in the seeds have been studied (3, 7). The bark of *E. variegata* var. *orientalis* has been investigated by various workers (3, 8, 9), and preliminary studies on the leaves (3, 10) have been made.

Recently, the present authors fractionated the petroleum ether extract of *E. suberosa* bark into wax esters, alcohols, and acids; alkyl ferulates; and stigmasterol, sitosterol, campesterol, and cholesterol (11). In this paper, results from an investigation on the chem-

employed is one where death is delayed for more than 1 week and is ascribable to hematopoietic depression rather than to CNS effects. Mortality in the experiments of Laird and Fonner occurred following exposures in the 10,000-r range 2–3 days postirradiation and was associated with convulsions, which was not the case in this experiment. Furthermore, DPH was given in this experiment in a single injection at a dose level one-fourth the anticonvulsant dose in mice (9) and would certainly not be expected to exert any anticonvulsant activity 10 days following drug administration.

Potentially important nonanticonvulsant actions of the DPH drug group have been identified by Gordon *et al.* and include anti-leukemic activity (5) and enhancement of the deteriorated learning and memory characteristic of very old animals (10, 11). Furthermore, both DPH and pemoline have been identified by this group as markedly potentiating the activity of the enzyme DNase 1, while DPH has been found by Shafer (12) to increase markedly the turnover of DNA in normal liver. Thus, DPH may exert the radioprotective action reported here by effects on nucleic acid metabolism, which are in no simple way related to its anticonvulsant action on the brain.

Continuing investigations will include exploring the capacity of DPH to exert radioprotective effects when given after radiation because such an effect for DPH has been observed in these laboratories when it is given within the 1st hour. Further, in a series of preliminary experiments, DPH exerted an effect similar to that of pemoline (5-phenylpseudo-hydantoin) in altering the growth pattern of Ehrlich carcinoma while prolonging the lifespan of tumor-bearing animals (13–15). The fact that DPH and pemoline have a similar chemical structure and exert similar effects on a nucleic acid-metabolizing enzyme suggests the link between biological effects shared by these two compounds.

Erythrina sp. III: Chemical Constituents of *Erythrina suberosa* Roxb. Seeds

HARKISHAN SINGH and AMRIK SINGH CHAWLA

Abstract □ A phytochemical investigation of *Erythrina suberosa* seeds has resulted in the isolation of erythraline, erysodine, erysotrine, and hypaphorine. This is the first time that erysotrine has been found to occur naturally, although it is well known as a conversion product of other eryso-alkaloids. The alkaloidal constituents were found to vary in different seed collections. The fatty acid composition of the seed oil was examined, and the sterol part from the unsaponifiable matter was found to be composed of sitosterol, stigmasterol, campesterol, and cholesterol.

Keyphrases □ *Erythrina suberosa* seeds—phytochemistry, chemical constituents □ Mass spectroscopy—identification □ IR spectrophotometry—identification □ TLC—identification

In India, *Erythrina stricta* Roxb., *E. suberosa* Roxb., and *E. variegata* Linn. var. *orientalis* (Linn.) Merrill (syn. *E. indica* Lam.) have been used in the indigenous system of medicine for various ailments (1).

The authors have started a systematic study of *Erythrina* species growing in India. There have been no earlier reports of chemical investigations of *E.*

suberosa and *E. stricta*. Hypaphorine (I) has been isolated from the seeds of *E. variegata* var. *orientalis* (2–6), and Folkers and Koniuszy (6) obtained erythraline

(II; $R_1, R_2 = -CH_2-$) from the seeds. Subbaratnam (5) isolated a neutral entity, $C_{24}H_{50}O_2$, m.p. 82–84°. The fatty acids present in the seeds have been studied (3, 7). The bark of *E. variegata* var. *orientalis* has been investigated by various workers (3, 8, 9), and preliminary studies on the leaves (3, 10) have been made.

Recently, the present authors fractionated the petroleum ether extract of *E. suberosa* bark into wax esters, alcohols, and acids; alkyl ferulates; and stigmasterol, sitosterol, campesterol, and cholesterol (11). In this paper, results from an investigation on the chem-

Table I—Contents of Fatty Acids Present in *E. suberosa* Seed Oil

Fatty Acid	Percent Weight	Percent Mole
Myristic acid	Traces	
Palmitic acid	12.2	13.4
Stearic acid	2.4	2.4
Oleic acid	38.3	39.2
Linoleic acid	24.7	25.4
Arachidic acid	3.5	3.2
Eicosenoic acid	4.5	4.4
Behenic acid	11.3	9.6
Docosenoic acid	Traces	
Lignoceric acid	3.1	2.4

ical constituents of *E. suberosa* seeds are reported. Three collections, made from Dehradun, Mandi, and Joginder Nagar in India, have been examined; a preliminary communication about the alkaloidal constituents of the seeds has been published (12).

From the powdered seeds, the oil was separated through extraction with petroleum ether. The physical and chemical characteristics of the oil and the chemical characteristics of the separated fatty acids were determined. On spectrophotometric estimation, the oil revealed the presence of 22.9% of diene acids calculated as linoleic acid, 43.7% of mono-ene acids calculated as oleic acid, and 33.4% of saturated fatty acids (found by difference). The fatty acid content in terms of percent weight and percent mole as estimated by GLC of the methyl esters is listed in Table I.

The unsaponifiable matter of the seed oil yielded a sterol material, which the GLC of the trimethylsilyl (TMS) ethers showed to be a mixture of sitosterol (67%), stigmasterol (20%), campesterol (12%), and cholesterol (1%).

The Dehradun seed powder was defatted with petroleum ether and the marc extracted with ethanol. The petroleum ether extract yielded an alkaloidal part (Fraction A). The ethanol extract gave a chloroform-soluble part (Fraction B), which on chromatographic resolution gave a crystalline base identified as erythraline (II; $R_1, R_2 = -CH_2-$). Fraction A, which was resinous, gave erythraline hydriodide. The aqueous alkaline layer remaining after removal of Fraction B from the ethanol extract was acidified, refluxed, and extracted with chloroform to give Fraction C, which did not yield crystalline material. The aqueous layer yielded a water-soluble base identified as hypaphorine (I).

The Mandi seed collection gave Fraction D from the petroleum ether extract, and Fractions E and F from the ethanol extract, representing "free" and "liberated" alkaloidal parts. Fraction D yielded a crystalline hydrochloride which appeared to be erysotrine (II; $R_1 = R_2 = CH_3$) hydrochloride according to elemental and UV data. Fraction F gave crystalline erysodine (II; $R_1 = H$, $R_2 = CH_3$). Contrary to earlier observations (13), it was possible to prepare the hydrochloride of the isolated erysodine. Chromatography of Fraction E led ultimately to crystalline erysotrine hydrochloride and erysodine. A confirmation of the identity of isolated erysotrine hydrochloride came from a mass spectrum of the liberated base from the salt.

The base indicated significant peaks at m/e 313 (molecular ion M^+ ; 33% intensity of base peak), 298 ($M^+ - CH_3$; 35%), and 282 ($M^+ - CH_3O$; base peak), which compared with the authentic specimen. Hypaphorine was also isolated from the Mandi seeds.

Because of the alkaloidal variations found in the Dehradun and Mandi collections of *E. suberosa* seeds, a third collection, from Joginder Nagar, was investigated. These seeds also yielded the "free" bases erysotrine and erysodine but no erythraline.

The difference in the alkaloidal variations mentioned may be attributed to differences in climatic or soil conditions, and the two plants possibly may belong to different strains. The other aspect of interest is the isolation of erysotrine because never before has erysotrine been found to occur naturally, although it is well known as a conversion product of other erysoalkaloids.

EXPERIMENTAL

Plant Material¹—The seeds were procured² from Dehradun (Uttar Pradesh, India), and also collected from Mandi and Joginder Nagar (Himachal Pradesh, India). The seeds were reduced to moderately coarse powder.

Extractives—The seed powder (Dehradun) (25 g.) was extracted successively in a continuous extraction apparatus, and the percent extractives was determined: petroleum ether (60–80°), 8.10%; benzene, 0.51%; ether, 0.07%; chloroform, 0.64%; acetone, 0.84%; ethanol, 18.20%; and water, 5.30%.

Extraction and Study of Oil—The seed powder (Dehradun) (500 g.) was extracted with petroleum ether (60–80°) for 15 hr. to yield 40 g. of the oil, which had the following characteristics: sp. gr. 25°/25°, 0.9483; n_D^{25} 1.4690; iodine value, 74.6; acid value, 8.6; saponification value, 173; and unsaponifiable matter, 1.6%.

The mixed fatty acid fraction (iodine value, 80.9; saponification equivalent, 281) obtained from the oil was found to have a total diene composition and mono-ene composition of 22.9 and 43.7%, respectively, as determined by the alkali isomerization method of Hilditch *et al.* (14) and using reference values of Hilditch *et al.* (15). By difference the saturated fatty acids come to 33.4%.

The mixed fatty acids were converted to their methyl esters (16). The IR spectrum of the methyl esters showed bands at 2997 cm^{-1} (olefinic C—H stretching); 2918 and 2846 cm^{-1} (for CH_2 and CH_3); 1740 cm^{-1} (C=O stretching); and 1230, 1185, and 1160 cm^{-1} (C—O stretching for esters).

The methyl esters were analyzed by GLC on a polyester column [20% diethylene glycol succinate on diatomite³ 2.44 m. (8 ft.) \times 0.49 cm. (0.19 in.), 215°] with a thermal conductivity detector. The peak areas were measured by triangulation and the results are given in Table I.

The unsaponifiable part of the seed oil was separated in the usual way. A chromatographic resolution on an alumina column gave a sterol fraction, m.p. 139°. The IR spectrum showed a band at 3440 cm^{-1} (broad, associated O—H stretching) and a weak but very diagnostic peak at 972 cm^{-1} for the *trans*-disubstituted double bond of stigmasterol.

The sterol fraction, when resolved as its TMS ether on an SE-30 column [1% on Anakrom SD, 3.04 m. (10 ft.) \times 0.32 cm. (0.125 in.), 260°], proved to be a mixture of sitosterol (67%), stigmasterol (20%), campesterol (12%), and cholesterol (1%). A standard mixture of TMS ethers of the corresponding sterols was used for identification of the peaks.⁴

Isolation and Detection of Alkaloids—Dehradun, Mandi, and Joginder Nagar seeds were investigated separately.

¹ The authenticity of the seeds was certified by Dr. T. S. Sareen, Curator, Department of Botany, Panjab University.

² Through M/s Pratap Nursery and Seed Stores, Dehradun.

³ Chromosorb W, Johns-Manville.

⁴ These data were obtained through Dr. J. W. Rowe, USDA Forest Products Laboratory, Madison, Wis.

Dehradun Seeds—The seed powder (2.0 kg.) was extracted with petroleum ether (60–80°) in a continuous extraction apparatus. The basic components were removed from the petroleum ether extract by shaking with 2% w/v sulfuric acid. The acid layer (1 l.) was made alkaline with a dilute ammonia solution (150 ml.) and extracted with chloroform. The chloroform extract was worked up to give a residue (0.93 g., Fraction A).

The marc was extracted with ethanol in a continuous extraction apparatus. The residue (300 g.) remaining after evaporation of the solvent was repeatedly treated with 2% w/v sulfuric acid. The acid layer (2 l.) was washed with chloroform (3 × 300 ml.) to remove the nonalkaloidal matter. The acid extract was made alkaline with a dilute ammonia solution (350 ml.) and extracted with chloroform (10 × 300 ml.). The chloroform extract was washed with water, dried over anhydrous sodium sulfate, and evaporated to yield a residue (5.7 g., Fraction B).

Fraction B was chromatographed over alumina (Merck, 170 g.). Elution with benzene gave a sticky solid mass (3.0 g.), which was repeatedly crystallized from absolute ethanol to give a base, m.p. 111–113° [lit. (6) erythraline, m.p. 106–107°].

Anal.—Calcd. for $C_{18}H_{19}NO_3$: N, 4.71. Found: N, 5.11. $[\alpha]_D^{20} + 192.5^\circ$ (c, 0.78, $CHCl_3$) [lit. (6) $[\alpha]_D^{20} + 211.8^\circ$ (c, 0.944, EtOH)]; UV λ_{max}^{MeOH} 292 m μ (log ϵ 3.6) [lit. (17) 292 m μ (log ϵ 3.6)].

The base showed no depression on determining mixed melting point with authentic erythraline. The base formed a hydrobromide, m.p. 250–251° dec. [lit. (17) erythraline hydrobromide, m.p. 246°].

Anal.—Calcd. for $C_{18}H_{19}NO_3 \cdot HBr$: C, 57.16; H, 5.33; Br, 21.13; N, 3.70. Found: C, 57.47; H, 5.30; Br, 21.25; N, 3.56. UV λ_{max}^{MeOH} 290 m μ (log ϵ 3.6). The IR spectra of the base hydrobromide and authentic erythraline hydrobromide were identical.

The hydrochloride of the base was prepared in the usual way and crystallized from dry ether–absolute ethanol to give an entity, m.p. 251–252° dec.

Anal.—Calcd. for $C_{18}H_{19}NO_3 \cdot HCl$: C, 64.79; H, 6.04; Cl, 10.63; N, 4.20. Found: C, 64.66; H, 6.64; Cl, 10.80; N, 4.19.

Fraction A was not resolvable on an alumina column. Its hydriodide, m.p. 247–248° dec., was prepared and showed no depression in melting point on admixture with the hydriodide of erythraline isolated from Fraction B [lit. (6) erythraline hydriodide, m.p. 252–253° dec.]. The IR spectra were also superimposable.

A portion of the aqueous layer left after removal of Fraction B was acidified with dilute sulfuric acid to pH 1.0. It was refluxed for 3 hr., made alkaline with dilute ammonia solution, and extracted with chloroform (5 × 200 ml.). The yield of the residue, after complete solvent removal, was 0.8 g. (Fraction C). It was chromatographed over alumina, but no pure base or salt could be isolated.

The other portion of the aqueous layer was acidified and precipitated with Dragendorff's reagent. A part of the separated precipitate (35 g.) was decomposed with moist silver carbonate (15 g.) and processed to obtain a crystalline material. It was recrystallized from ethanol to give a base, m.p. 250° dec. [lit. (18) hypaphorine, m.p. 253–254°].

Anal.—Calcd. for $C_{14}H_{18}N_2O_2$: C, 68.27; H, 7.37; N, 11.37. Found: C, 67.81; H, 7.11; N, 11.10. The base showed no depression on determining mixed melting point with authentic hypaphorine, and the IR spectra of both were identical.

The base formed a hydrochloride, m.p. 231–232° dec. [lit. (19) hypaphorine hydrochloride, m.p. 234–235°].

Anal.—Calcd. for $C_{14}H_{18}N_2O_2 \cdot HCl$: C, 59.48; H, 6.77; Cl, 12.54; N, 9.91. Found: C, 59.10; H, 6.63; Cl, 12.42; N, 9.80.

The hydrobromide, m.p. 233° dec. [lit. (20) hypaphorine hydrobromide, m.p. 225°], and nitrate, m.p. 221–222° dec. [lit. (18) hypaphorine nitrate, m.p. 223.5–224.5°], of the base were also prepared.

Mandi Seeds—The seed powder (4.8 kg.) was extracted with petroleum ether (60–80°) and the extract was worked as described previously to give an alkaloidal entity (2.5 g., Fraction D). The marc was extracted with ethanol, and the extract was processed to give alkaloidal Fraction E (14 g.).

A benzene-soluble portion (11 g.) of Fraction E was resolved on an alumina column (330 g.). Elution with benzene first gave a syrupy mass (3.0 g.) and then a solid residue (1.5 g.) which crystallized from acetone to give a base, m.p. 208–210° [lit. (13) erysodine, m.p. 204–205°].

Anal.—Calcd. for $C_{18}H_{21}NO_3$: C, 72.22; H, 7.07; N, 4.68. Found: C, 72.34; H, 6.95; N, 4.77. $[\alpha]_D^{20} + 220.8^\circ$ (c, 0.98, $CHCl_3$) [lit. (13) $[\alpha]_D^{20} + 248^\circ$ (c, 0.311, EtOH)], UV λ_{max}^{MeOH} 285 m μ (log ϵ 3.6)

[lit. (17) 285 m μ (log ϵ 3.6)]. The base showed no depression on determining mixed melting point with authentic erysodine. A mixture with the latter was inseparable on TLC, and the IR spectra were identical.

The hydrochloride was prepared by treating absolute ethanolic solution of the base with ethanolic hydrochloric acid. It was crystallized from dry ether–absolute ethanol to give an entity, m.p. 217–218° dec.

Anal.—Calcd. for $C_{18}H_{21}NO_3 \cdot HCl$: C, 64.40; H, 6.61; Cl, 10.56; N, 4.17. Found: C, 64.66; H, 6.68; Cl, 11.02; N, 4.30.

The syrupy mass was picked up with dry ether and made slightly acidic with ethanolic hydrochloric acid. The separated mass was repeatedly crystallized from dry ether–absolute ethanol to give a product, m.p. 206–208° [lit. (21) erysotrine hydrochloride, m.p. 205–206°].

Anal.—Calcd. for $C_{19}H_{23}NO_3 \cdot HCl$: C, 65.22; H, 6.91; Cl, 10.14; N, 4.01. Found: C, 65.34; H, 7.26; Cl, 10.30; N, 4.02. UV λ_{max}^{EtOH} 232 m μ (ϵ 19,800) and 284 m μ (ϵ 3490).

A part of the aqueous layer left after separation of alkaloidal Fraction E was hydrolyzed and worked as for Fraction C to obtain 2.1 g. (Fraction F) of the “liberated” base. The latter was resolved over alumina (53 g.). Elution with chloroform yielded a solid residue (1.1 g.), which crystallized from acetone to give a base, m.p. 208–210°, identified as erysodine.

Anal.—Calcd. for $C_{18}H_{21}NO_3$: C, 72.22; H, 7.07; N, 4.68. Found: C, 72.46; H, 7.04; N, 4.90.

The aqueous layer left after the removal of the “free” (Fraction E) and “liberated” (Fraction F) bases gave hypaphorine when worked in the usual way.

Fraction D (2.5 g.) was chromatographed over alumina (75 g.). Elution with benzene gave a syrupy mass (1.25 g.), which gave an alkaloidal hydrochloride, m.p. 203–204°, identified as erysotrine hydrochloride.

Anal.—Calcd. for $C_{19}H_{23}NO_3 \cdot HCl$: C, 65.22; H, 6.91; N, 4.01. Found: C, 65.24; H, 6.93; N, 3.90.

Joginder Nagar Seeds—This collection, when worked in the same manner as Mandi seeds, led also to the isolation of erysodine and erysotrine, the latter obtained as the hydrochloride.

The isolated bases and salts were identified by comparison with authentic specimens.⁵

NMR Analysis of Some Alkyl *p*-Hydroxybenzoates

F. SHIHAB, W. SHEFFIELD, J. SPROWLS, and J. NEMATOLLAHI*

Abstract □ By applying NMR spectrometry, a number of solutions containing unknown quantities of two or three alkyl *p*-hydroxybenzoates (parabens) in 60% polyethylene glycol in water were analyzed for quantification of the individual parabens. The method was found to be accurate, facile, and rapid and seems to possess a promising potential for applicability in related fields of pharmaceutical analysis.

Keyphrases □ Parabens—NMR analysis □ Alkyl *p*-hydroxybenzoates—NMR analysis □ NMR spectroscopy—analysis

The antibacterial and antifungal properties of esters of *p*-hydroxybenzoic acid (parabens) have been of interest to pharmaceutical scientists for the past few decades. Methyl, propyl, butyl, and benzyl parabens have been investigated individually or in combination in pharmaceutical research and development.

A literature survey revealed that UV spectrophotometry is the most widely used method for a quantitative analysis of the parabens (1). This technique has proved quite satisfactory in the quantification of a single paraben, but it is not sufficient for the analysis of a mixture of parabens in solution. This is due to the fact that most parabens possess nearly identical λ_{max} values.

Procedures such as column chromatography (2) and GLC (3) have been reported for the analysis of parabens. The former procedure is time consuming and laborious. If esters are in an aqueous solution, the silylation technique, which should precede injection onto the column, together with other problems inherent to GLC makes the latter procedure less desirable and casts some doubts upon the accuracy of the results.

An exploratory attempt on the applicability of NMR spectrometry for the analysis of parabens revealed the method to be both rapid and accurate and the procedure quite simple.

EXPERIMENTAL

The parabens used in the experiments were all reagent grade. The general procedure for preparing the standard solutions consisted of placing an accurately weighed quantity of the desired

Figure 1—The NMR spectrum of a mixture of benzyl paraben and methyl paraben in PEG-H₂O. Standard benzyl paraben is depicted at 110 c.p.s. offset.

ester in a volumetric flask, dissolving, and adjusting the volume with 60% polyethylene glycol (PEG) 400 in water. This vehicle was also used for preparing the solution of the paraben mixtures. Adoption of this solvent was due to its routine use in some other aspects of the research and to illustrate the point that the analysis does not require deuterated solvents.

The NMR spectra were determined using a Varian A-60 NMR spectrophotometer at an ambient temperature.

RESULTS AND DISCUSSION

Depicted in Fig. 1 is the NMR spectrum of a mixture of benzyl paraben and methyl paraben in 60% PEG in water. Benzyl paraben contains two doublets at δ 6.85 and δ 7.85, which are the results of spin-spin coupling of two pairs of phenyl protons, in two different magnetic environments, in the *p*-hydroxybenzoate moiety of the ester molecule (Structure I). The singlet at δ 7.3 results from the phenyl protons of the benzyl moiety. The two doublets of benzyl paraben superimpose on the doublets of methyl paraben.

NMR Analysis of Some Alkyl *p*-Hydroxybenzoates

F. SHIHAB, W. SHEFFIELD, J. SPROWLS, and J. NEMATOLLAHI*

Abstract □ By applying NMR spectrometry, a number of solutions containing unknown quantities of two or three alkyl *p*-hydroxybenzoates (parabens) in 60% polyethylene glycol in water were analyzed for quantification of the individual parabens. The method was found to be accurate, facile, and rapid and seems to possess a promising potential for applicability in related fields of pharmaceutical analysis.

Keyphrases □ Parabens—NMR analysis □ Alkyl *p*-hydroxybenzoates—NMR analysis □ NMR spectroscopy—analysis

The antibacterial and antifungal properties of esters of *p*-hydroxybenzoic acid (parabens) have been of interest to pharmaceutical scientists for the past few decades. Methyl, propyl, butyl, and benzyl parabens have been investigated individually or in combination in pharmaceutical research and development.

A literature survey revealed that UV spectrophotometry is the most widely used method for a quantitative analysis of the parabens (1). This technique has proved quite satisfactory in the quantification of a single paraben, but it is not sufficient for the analysis of a mixture of parabens in solution. This is due to the fact that most parabens possess nearly identical λ_{max} values.

Procedures such as column chromatography (2) and GLC (3) have been reported for the analysis of parabens. The former procedure is time consuming and laborious. If esters are in an aqueous solution, the silylation technique, which should precede injection onto the column, together with other problems inherent to GLC makes the latter procedure less desirable and casts some doubts upon the accuracy of the results.

An exploratory attempt on the applicability of NMR spectrometry for the analysis of parabens revealed the method to be both rapid and accurate and the procedure quite simple.

EXPERIMENTAL

The parabens used in the experiments were all reagent grade. The general procedure for preparing the standard solutions consisted of placing an accurately weighed quantity of the desired

Figure 1—The NMR spectrum of a mixture of benzyl paraben and methyl paraben in PEG-H₂O. Standard benzyl paraben is depicted at 110 c.p.s. offset.

ester in a volumetric flask, dissolving, and adjusting the volume with 60% polyethylene glycol (PEG) 400 in water. This vehicle was also used for preparing the solution of the paraben mixtures. Adoption of this solvent was due to its routine use in some other aspects of the research and to illustrate the point that the analysis does not require deuterated solvents.

The NMR spectra were determined using a Varian A-60 NMR spectrophotometer at an ambient temperature.

RESULTS AND DISCUSSION

Depicted in Fig. 1 is the NMR spectrum of a mixture of benzyl paraben and methyl paraben in 60% PEG in water. Benzyl paraben contains two doublets at δ 6.85 and δ 7.85, which are the results of spin-spin coupling of two pairs of phenyl protons, in two different magnetic environments, in the *p*-hydroxybenzoate moiety of the ester molecule (Structure I). The singlet at δ 7.3 results from the phenyl protons of the benzyl moiety. The two doublets of benzyl paraben superimpose on the doublets of methyl paraben.

By comparison of the integral values of the peak of the standard to those of the unknown, the concentration of each paraben in the mixture was calculated. The following examples illustrate the calculation of the concentration of individual parabens in mixtures as PEG-water solutions.

The abbreviations used are: standard = st; unknown = u; singlet integral value = SIV; doublet integral value = DIV; triplet integral value = TIV; molarity = M ; methyl, ethyl, propyl, butyl, and benzyl paraben = MePab, EtPab, PrPab, BuPab, and BzPab, respectively.

Calculation of Concentration of Methyl Paraben and Benzyl Paraben Present in Unknown Quantities as a Mixture in PEG-Water—See Fig. 1. The standard was a known concentration of benzyl paraben solution.

$$\frac{(\text{SIV})_{\text{BzPab}}}{(\text{SIV})_{\text{st}}} \times (M)_{\text{st}} = (M)_{\text{BzPab}} \quad (\text{Eq. 1})$$

$$4/5 \times (\text{SIV})_{\text{BzPab}} = (\text{DIV})_{\text{BzPab}} \quad (\text{Eq. 2})$$

$$\text{total } (\text{DIV})_{\text{u}} - (\text{DIV})_{\text{BzPab}} = (\text{DIV})_{\text{MePab}} \quad (\text{Eq. 3})$$

$$\frac{(\text{DIV})_{\text{MePab}}}{(\text{DIV})_{\text{st}}} \times (M)_{\text{st}} = (M)_{\text{MePab}} \quad (\text{Eq. 4})$$

Quantification of a mixture of any alkyl paraben mixed with benzyl paraben can be carried out by a similar procedure.

Calculation of Concentration of Methyl Paraben and Propyl Paraben Present in Unknown Quantities as a Mixture in PEG-Water—The standard was a known concentration of methyl paraben solution.

$$4/3 \times (\text{TIV})_{\text{PrPab}} = (\text{DIV})_{\text{PrPab}} \quad (\text{Eq. 5})$$

$$\text{total } (\text{DIV})_{\text{u}} - (\text{DIV})_{\text{PrPab}} = (\text{DIV})_{\text{MePab}} \quad (\text{Eq. 6})$$

$$\frac{(\text{DIV})_{\text{MePab}}}{(\text{DIV})_{\text{st}}} \times (M)_{\text{st}} = (M)_{\text{MePab}} \quad (\text{Eq. 7})$$

$$\frac{(\text{DIV})_{\text{PrPab}}}{(\text{DIV})_{\text{st}}} \times (M)_{\text{st}} = (M)_{\text{PrPab}} \quad (\text{Eq. 8})$$

5. {CH ₃ CH ₂ Ph	0.7500 0.3000	0.7484 0.3000
6. {CH ₃ n-C ₃ H ₇ CH ₂ Ph	0.5000 0.2500 0.1500	0.5000 0.2516 0.1500

Figure 2—The NMR spectrum of a mixture of ethyl paraben and propyl paraben in PEG-H₂O.

PEG-Water—The standard was a known concentration of benzyl paraben solution.

$$\frac{(\text{SIV})_{\text{BzPab}}}{(\text{SIV})_{\text{st}}} \times (M)_{\text{st}} = (M)_{\text{BzPab}} \quad (\text{Eq. 9})$$

$$4/5 \times (\text{SIV})_{\text{BzPab}} = (\text{DIV})_{\text{BzPab}} \quad (\text{Eq. 10})$$

$$\text{total } (\text{DIV})_{\text{u}} - (\text{DIV})_{\text{BzPab}} = (\text{DIV})_{\text{MePab} + \text{PrPab}} \quad (\text{Eq. 11})$$

$$4/3 (\text{TIV})_{\text{PrPab}} = (\text{DIV})_{\text{PrPab}} \quad (\text{Eq. 12})$$

$$(\text{DIV})_{\text{MePab} + \text{PrPab}} - (\text{DIV})_{\text{PrPab}} = (\text{DIV})_{\text{MePab}} \quad (\text{Eq. 13})$$

$$\frac{(\text{DIV})_{\text{PrPab}}}{(\text{DIV})_{\text{st}}} \times (M)_{\text{st}} = (M)_{\text{PrPab}} \quad (\text{Eq. 14})$$

$$\frac{(\text{DIV})_{\text{MePab}}}{(\text{DIV})_{\text{st}}} \times (M)_{\text{st}} = (M)_{\text{MePab}} \quad (\text{Eq. 15})$$

A summary of the precision of the experimental procedure is depicted in Table I.

As long as one of the two parabens in a mixture contains a discernible characteristic resonance peak, the individual esters can be determined quantitatively by NMR. Analysis of a mixture of ethyl and propyl paraben, whose triplet peaks are not superimposed, can be cited as an example and is depicted in Fig. 2.

Determination of Ethanol in an Elastomeric Matrix by Gas Chromatography

HARRIS I. TARLIN

Abstract □ A gas chromatographic procedure is described for the complete separation and quantitative determination of trace amounts of ethanol in the presence of nine common pharmaceutical compounds. By using a column containing an ethylvinylbenzene polymer, the occluded ethanol content of a single dosage unit can be determined in 8 min.

Keyphrases □ Ethanol, traces—separation, determination, elastomeric matrix, GLC □ Elastomeric matrix—ethanol separation, determination □ GLC—separation, determination

Ethanol has been determined by gas chromatography in liquid cough syrups (1) on a column of styrene-divinylbenzene polymer¹ and in blood (2–5) on a column of ethylvinylbenzene polymer.² This polymer has also been used to determine ethanol by gas chromatography in a variety of pharmaceuticals such as paregoric, mercurochrome, elixer phenobarbital, and antihistamine syrups (6). To date, there have been no studies reported in the literature concerning the determination of ethanol in a pharmaceutical dosage form comprising a water-soluble elastomeric material.

This report describes a simple, rapid method for determining ethanol which was occluded in an elastomeric matrix containing lidocaine, propylene glycol, sorbitol, sodium saccharin, polyvinyl alcohol, polyvinylpyrrolidone, gelatin, methylparaben, propylparaben, and common coloring and flavoring agents. The method was developed as part of a quality control program to determine the presence and quantity of ethanol in the finished dosage form prepared from a liquid mixture of the aforementioned components, which was subjected to heat above the boiling point of ethanol during processing.

EXPERIMENTAL

Instruments—A Perkin-Elmer model 811 gas chromatograph with a flame-ionization detector was used. The sensitivity of the detector was 0.005 C./g. The 1.82-m. (6-ft.) glass column, i.d. 0.32 cm. (0.125 in.), o.d. 0.63 cm. (0.25 in.), was packed with ethylvinylbenzene polymer 50/80 mesh, using a vibrator and conditioned for 18 hr. at 200° with helium gas flowing through the column. A small pledget of glass wool was placed in each end of the column. The

Table II—Ethanol Content of Three Batches of Product

	No. of Dose Units	Alcohol Content, $\mu\text{l./unit}$
Batch 1	4	0.05
	11	0.10
	2	0.15
	6	0.20
	2	0.25
Batch 2	13	0.00
	12	0.05
Batch 3	23	0.00
	1	0.05
	1	0.25

following gauge pressures were used: helium, 30; hydrogen, 15; and compressed air, 40. The flow rate through the column was 64 ml./min. The column temperature was 122° and the injector temperature was 185°. A Bristol Dynamaster Strip-Chart recorder with a chart speed of 2.54 cm. (1 in.)/min. was used.

Standard Solution—A stock solution containing 1 $\mu\text{l.}$ of 95% ethanol³/ml. was prepared by pipeting 2.0 ml. of alcohol into a 2-l. volumetric flask and diluting to the mark with distilled water.⁴ Standard solutions containing 0.3, 0.5, 1.0, and 5.0 $\mu\text{l.}$ of ethanol/10 ml. were prepared by pipeting 0.3, 0.5, 1.0, and 5.0 ml. of stock solution, respectively, into 10-ml. volumetric flasks and diluting to the mark with water. Five microliters of each standard was injected.⁵ Table I shows the relationship of peak height⁶ to alcohol concentration.

A single dosage unit of 5 cm.² of the solid elastomer mixture was cut into two pieces and introduced into a 10-ml. volumetric flask containing 5 ml. of water. The pieces were dissolved with vigorous shaking, and the flask was diluted to the mark with water. Five microliters of the prepared solution was injected. This procedure was carried out for 74 additional dosage units. Ethanol concentrations were calculated as follows: $\mu\text{l. of ethanol/dosage unit} = \text{peak height} \times \text{av. } \mu\text{l. of ethanol/10 ml./unit of peak height}$.

A standard containing 1 $\mu\text{l.}$ of ethanol/10 ml. of solution was injected throughout this investigation. An evaluation of 10 injections of the standard indicated that steady-state operating conditions were maintained ($p = 0.06$ for 2S).

Identification of the Ethanol Peak—The ethanol peak was qualitatively identified by the following enrichment method: 8 ml. of a solution consisting of 1 dissolved dosage unit/10 ml. (containing 0.025 $\mu\text{l.}$ of ethanol/ml.) was pipetted into a 10-ml. volumetric flask containing 1 $\mu\text{l.}$ of ethanol. The flask was diluted to the mark with water. The solution thus prepared contained 1.2 $\mu\text{l.}$ ethanol/10 ml. The expected peak height was 13.0, and the expected retention⁷ distance was 16.98 ± 0.22 cm. Following are the results of two trials:

	Peak Height	Retention Distance, cm.
Trial 1	13.5	16.9
Trial 2	12.8	16.7

³ Ethyl alcohol USP, 95%, U.S. Industrial Chemical Co. Referred to as ethanol in the following text.

⁴ Referred to as water in the following text.

⁵ All samples in this study were injected with a 10- $\mu\text{l.}$ Hamilton syringe.

⁶ All peak heights in this study were measured on chart paper which was divided into 100 equal units.

⁷ The retention distance is the distance in centimeters between the leading slope of the water peak and the maxima of the peak under investigation. The average retention distance for 5 standard ethanol solutions was 16.98 ± 0.22 cm.

This experiment indicated that the observed peak was due to ethanol. A similar procedure was used to identify the first major peak. The peak resulted from the organic impurities in water.

RESULTS AND DISCUSSION

Table II shows a summary of the ethanol content of the three batches studied. The column material used in this investigation has outstanding separation properties for volatile, low-molecular weight compounds and was particularly valuable for this study since no signals were observed from any of the compounds in the dosage form except ethanol.

Antimicrobial Activity of Some β -Nitrostyrenes

LEONARD R. WORTHEN and HOWARD W. BOND

Abstract □ Nine compounds were tested for antimicrobial activity, and eight of these exhibited varying spectra of inhibition.

Keyphrases □ β -Nitrostyrene derivatives—antimicrobial activity □ Antimicrobial activity, evaluation— β -nitrostyrene derivatives □ Paper disks—microbe-inhibition analysis

In the course of synthesizing some chemical compounds for testing as potential molluscicides, a number of β -nitrostyrene compounds were prepared. This report indicates the preliminary results obtained from testing nine of these compounds, seven of which are new (1), for antibacterial and antifungal activity.

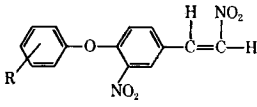

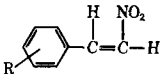

The antimicrobial activity of β -nitrostyrenes has been previously noted by several workers, including Schales and Graefe (2), Bocobo *et al.* (3), and Huitric *et al.* (4).

An impregnated filter paper disk on an inoculated agar plate was selected as the testing method. This technique has the advantage over the hole or cup method because the solvent can be evaporated from the saturated paper disks prior to placing them on the inoculated agar plate. In this manner, any potential antimicrobial effects from the solvent used can be avoided.

EXPERIMENTAL

Materials and Methods—The test organisms used included the following: *Staphylococcus aureus*, strain 209, ATCC 6538; *Escherichia coli*, ATCC 4157; *Pseudomonas aeruginosa*, ATCC 10145; *Bacillus subtilis*; *Proteus vulgaris*; *Aspergillus niger*, ATCC 9642; *Trichophyton mentagrophytes*, ATCC 9129; and *Candida albicans*, ATCC 10231. The melted test agar media were inoculated with 0.1 ml. of a 24-hr.-old bacterial culture grown in nutrient broth or a 0.1 ml. saline suspension of a 48-hr.-old fungal culture grown on Sabouraud's agar. Nutrient agar was employed for the bacterial tests

and Sabouraud's agar for the fungal tests. All bacterial cultures were incubated at 35° and the fungal cultures at room temperature. The filter paper disks (12.7-mm. diameter) were saturated with 0.1 ml. of a 1:1000 concentration of the compounds to be tested; the solvent was allowed to evaporate before the disks were placed, in duplicate, on the seeded plates. Ethanolic solutions of eight of the compounds were used. The other compound [*m*-(2-nitrovinyl)-phenyl acetate] was employed as a suspension in pyridine. Disks impregnated with an equal amount of the solvent only were dried and used as controls and in no instance exhibited any inhibition. The zones of inhibition were read at the end of 24 hr. of incubation for the bacteria and 48 hr. for the fungi. The results are tabulated in Table I.

DISCUSSION

Nine β -nitrostyrene derivatives were tested by the paper disk method for antimicrobial activity. Of the six 3-nitro-4-substituted phenoxy- β -nitrostyrenes tested, the parent compound had the widest spectrum. The pentachloro derivative was effective against *S. aureus* only, and the pentabromo derivative was inactive. None of these compounds had any activity against *P. vulgaris* or *P. aeruginosa*.

The three ring-substituted β -nitrostyrenes tested all showed good activity against the test organisms. Of particular significance is their activity against the *Proteus* and *Pseudomonas* species tested. One limitation with the most active compound tested, *m*-acetoxy- β -

nitrostyrene, was the inability to solubilize it in common organic solvents, even at a 1:1000 concentration. It was placed on the paper disk as a 1:1000 suspension. The results of the tests of the latter series of compounds warrant further study of other derivatives of this group.

Solvent Effects in the NMR Spectra of Cyano Compounds

EDWARD E. SMISSMAN and ALEXANDROS C. MAKRIYANNIS

Abstract □ Novel solvent effects in the NMR spectra of certain cyano compounds are reported. A change in the splitting pattern of the methylene groups of *N*-cyano-*N*-methylarylethylamines with a change in solvent was observed in open-chain alkyl cyano compounds containing a terminal aromatic ring.

Keyphrases □ Solvent effects—NMR spectra, cyano compounds □ Cyano compounds, NMR—solvent effects □ NMR spectra—solvent effects, cyano compounds

During the synthesis of a number of *N*-cyano-*N*-methylarylethylamines (1), it was observed that the NMR spectra exhibited dramatic changes when the solvent was changed from either carbon tetrachloride or deuteriochloroform to benzene. These changes involved: (a) a strong upfield shift in the singlet signal due to the *N*-methyl protons, and (b) a strong upfield shift of the multiplets due to the four methylene protons, accompanied by a pronounced change in the splitting pattern of the multiplet in all of the compounds where rotation was possible about the C—C bond of the ethylamine. The only compound examined which did not show the change in splitting pattern was *N*-cyanotetrahydroisoquinoline (Compound 5). The observations from the examined spectra are summarized in Table I.

structures of compounds listed in Table I

and Sabouraud's agar for the fungal tests. All bacterial cultures were incubated at 35° and the fungal cultures at room temperature. The filter paper disks (12.7-mm. diameter) were saturated with 0.1 ml. of a 1:1000 concentration of the compounds to be tested; the solvent was allowed to evaporate before the disks were placed, in duplicate, on the seeded plates. Solvent Effects in the NMR Spectra of Cyano Compounds

EDWARD E. SMISSMAN and ALEXANDROS C. MAKRIYANNIS

Abstract □ Novel solvent effects in the NMR spectra of certain cyano compounds are reported. A change in the splitting pattern of the methylene groups of *N*-cyano-*N*-methylarylethylamines with a change in solvent was observed in open-chain alkyl cyano compounds containing a terminal aromatic ring.

Keyphrases □ Solvent effects—NMR spectra, cyano compounds □ Cyano compounds, NMR—solvent effects □ NMR spectra—solvent effects, cyano compounds

During the synthesis of a number of *N*-cyano-*N*-methylarylethylamines (1), it was observed that the NMR spectra exhibited dramatic changes when the solvent was changed from either carbon tetrachloride or deuteriochloroform to benzene. These changes involved: (a) a strong upfield shift in the singlet signal due to the *N*-methyl protons, and (b) a strong upfield shift of the multiplets due to the four methylene protons, accompanied by a pronounced change in the splitting pattern of the multiplet in all of the compounds where rotation was possible about the C—C bond of the ethylamine. The only compound examined which did not show the change in splitting pattern was *N*-cyanotetrahydroisoquinoline (Compound 5). The observations from the examined spectra are summarized in Table I.

structures of compounds listed in Table I

Table I—Solvent Effects on Chemical Shifts in the NMR of Cyano Compounds

Compound	Solvent	Chemical Shift (δ)	
		N—CH ₃	—CH ₂ —CH ₂ —

12	CCl ₄		Triplet; 3.51 (J = 6 c.p.s.)
12	C ₆ H ₆		Multiplet; 1.99–2.70
			Triplet; 2.79 (J = 6 c.p.s.)
			Multiplet; 1.14–1.84

There appears to be no long-range coupling effects between the methylene protons and the protons of the aromatic ring in any of these aryethylamines. Decoupling experiments were performed on Compounds 1, 3, and 4 by irradiating the aromatic region of the spectra. This had no effect on the splitting pattern of the methylene groups when either deuteriochloroform or benzene was utilized as the solvent.

The NMR spectrum of phenylbutyronitrile (Compound 10) exhibited equally strong solvent effects, involving upfield shifts accompanied by pronounced changes in the patterns of the methylene signals. The spectra of the alkyl cyano compounds β -chloropropionitrile (Compound 11) and γ -bromobutyronitrile (Compound 12) exhibited upfield shifts of equal magnitude with no change in the splitting pattern, whereas *N,N*-dimethylphenethylamines showed no significant solvent effects in their NMR spectra.

These solvent effects, therefore, appear to be due to the cyano group and can be explained on the basis of a collision complex between the benzene ring and the cyano group. Similar collision complexes have been postulated by Hatton and Richards (2) and have been applied to explain the solvent effects caused by benzene with *N*-methyl formamide (3) and several ketones (4, 5). The general upfield shifts in the case of the non-aromatic protons can be attributed to the anisotropy of the magnetic susceptibility of benzene. The change in the

splitting pattern of the methylene peaks, which is observed with all of the open-chain alkyl cyano compounds containing a terminal aromatic ring (Compounds 1–4, 6, 7, 10), can be attributed to: (a) a decrease in the shielding effect of benzene when the methylene groups are further removed from the cyano group, and (b) conformational changes accompanying the change in solvent.

Monomolecular Film Properties of Some Cellulose Esters

JOEL L. ZATZ and BEVERLY KNOWLES

Abstract □ Cellulose acetate butyrate, cellulose acetate stearate, and cellulose acetate phthalate have been studied as monolayers at the air-water interface. Monolayers of the first two were virtually unaffected by changes in subphase pH, whereas the last one, cellulose acetate phthalate, exhibited large differences under the same conditions. Certain monolayer properties of the cellulose esters have been used to interpret the behavior of these polymers as free films and enteric coatings.

Keyphrases □ Cellulose esters—monomolecular film properties □ Film properties, monomolecular—cellulose acetate butyrate, cellulose acetate stearate, cellulose acetate phthalate □ Polymer monolayers—as model for enteric, film coatings

An approach that has provided information on the properties of film-forming polymers is the study of these materials as monolayers at the air-water interface (1). Such studies give insight into the molecular structure of polymers (1, 2) and may be used to investigate interaction of polymers with other substances, such as plasticizers (3).

Among the polymers used as coatings for pharmaceutical dosage forms, the cellulose esters represent an important group. These materials have previously been studied as free films and as coatings applied to tablets. Antonides and DeKay (4) evaluated various cellulose derivatives for possible use as enteric coatings. Patel *et al.* (5) studied water vapor transmission through free films of cellulose esters as a function of temperature and film thickness. Lachman and Drubulis (6) reported the influence of plasticizers on water vapor transmission through free films of cellulose acetate phthalate.

This study is concerned with the monomolecular film properties of three esters of cellulose, cellulose acetate phthalate (CAP), cellulose acetate butyrate (CAB), and cellulose acetate stearate (CAS). By adjusting the pH of the subphase to values of either 3 or 6.5 before spreading the polymer film, it was possible to assess the effect of a large change in environmental pH on the properties of each polymer studied.

EXPERIMENTAL

Materials and Apparatus—The cellulose derivatives were purchased¹ and purified further to remove residual monomers and other possible contaminants. CAP (32% phthalyl) was purified by precipitation from solution in benzene-ethanol, 1:1, using *n*-hexane as the nonsolvent. The polymer mass was washed with *n*-hexane and dried *in vacuo* at 30° to constant weight. As a result of this procedure, the free phthalic acid content of the polymer was reduced from an initial value of 1.3% w/w to a negligible level. Similarly, CAB (17% butyryl) was precipitated from solution in ethyl acetate by *n*-hexane. The precipitate was washed with *n*-hexane and dried *in vacuo* at 50° to constant weight. CAS was sus-

pending in *n*-hexane, repeatedly washed with that solvent, and dried *in vacuo* at 50°. Water was deionized and then distilled in an all-glass still. The organic liquids employed were of reagent grade and were found to be free of surface-active contaminants (7). The inorganic materials employed were of reagent grade and were not further purified. The Teflon surface balance has already been described (8). Surface pressure was determined by the Wilhelmy plate method.

Procedure—The pH of the subphase was adjusted using HCl to obtain a pH of 3 or a buffer system containing K₂HPO₄ and KH₂PO₄ to obtain a pH of 6.5. The ionic strength of each solution used as subphase was adjusted to 0.1 M using KCl. The polymer under investigation was dissolved in a suitable solvent, and the solution was applied to the surface by means of an Agla micrometer syringe. CAB was dissolved in methylene chloride, CAS in benzene, and CAP in a isopropanol-benzene mixture, 1:1. Preliminary experiments showed that essentially the same results were obtained using other spreading solvents (isopropanol-methylene chloride for CAP and methylene chloride-benzene for CAB). After spreading the polymer, 10 or 15 min. was allowed for equilibration. Then the area available to polymer molecules was slowly decreased (at a rate of about 0.02 m.²/mg./min.); surface pressure was determined as a function of available surface area. All studies were carried out at room temperature (25 ± 0.7°).

RESULTS

Plots of surface pressure as a function of available surface area (π -A curves) for the cellulose esters studied are presented in Figs. 1-3. Each plot is based on at least three independent experiments. The reproducibility was such that at a given surface area, the surface pressure found in each experiment was within 0.6 dyne/cm. of the average value plotted in Figs. 1-3.

The π -A curves for CAB are shown in Fig. 1. The results with a subphase pH of 3.2 were nearly identical with those at a pH of 6.5. Monolayers of CAB collapsed to form a stringy, tenacious coagulum.

Some difficulty was encountered in spreading CAS at the surface. Droplets of spreading solution formed from the tip of the Agla syringe appeared to lose their clarity after a few seconds because of polymer adsorption and precipitation at the surface of the drop. Certain proteins are known to behave in a similar manner (9). Since all of the polymer was not in solution when applied to the surface, it is possible that the CAS was not completely spread. The π -A results, given in Fig. 2, show a slight variation in surface pressure as a function of pH. However, at a given surface area, the difference in surface pressure is always less than 2 dynes/cm. and

Figure 1—Surface pressure (π)-area (A) isotherms of CAB at two subphase pH values: ▽, pH = 3.2; and △, pH = 6.5.

¹ Eastman Organic Chemicals, Rochester, NY 14650

Figure 2—Surface pressure (π)-area (A) isotherms of CAS at two subphase pH values: \square , pH = 3.2; and \circ , pH = 6.5.

is probably the result of experimental error. The two curves in Fig. 2 are quite similar and indicate that no significant change in the properties of CAS occurs when the subphase pH is changed from 3.2 to 6.5.

Quite another result is obtained for CAP monolayers (Fig. 3). At a pH of 3.1, the π - A curve exhibits a condensed region at areas smaller than about 0.8 m.²/mg. In the same region, the monolayer on a subphase of pH 6.5 appears to be much more expanded. Monolayer collapse pressure at a pH of 3.1 is 16.6 dynes/cm. The corresponding value for a pH of 6.5 is 11.4 dynes/cm. At a pH of 3.1, the extrapolated area at zero pressure of the film is 0.89 m.²/mg., increasing to 1.56 m.²/mg. at a subphase of pH of 6.5.

DISCUSSION

Monolayers of CAB and CAS were virtually unaffected when subphase pH was raised from about 3 to 6.5, whereas large changes occurred in the monolayer properties of CAP. These changes may reflect an alteration in conformation at the interface, which CAB and CAS do not undergo. Therefore, it may be inferred that neither CAB nor CAS could function as an effective enteric coating. Because the properties of these polymers are independent of pH, tablet disintegration could occur in: (a) either the stomach or small intestine, or (b) neither the stomach nor small intestine. For both of these polymers, the second alternative was actually found to be the case (4).

Figure 3—Surface pressure (π)-area (A) isotherms of CAP at two subphase pH values: \square , pH = 3.1; and \circ , pH = 6.5.

Table I—Some Properties of Unionized Cellulose Esters

Polymer	Collapse Pressure, dynes/cm.	Extrapolated Area at Zero Pressure, m. ² /mg.
CAB	7.0	0.82
CAS	19.4	0.74
CAP	16.6	0.89

The change in monolayer properties of CAP with pH is due to the presence of the ionizable carboxyl group in the phthalate moiety, which is presumably uncharged at a pH of 3.1 but negatively charged at a pH of 6.5. The satisfactory performance of CAP as an enteric coating has been ascribed to its insolubility in the strongly acid stomach fluids, where the polymer is uncharged, and its corresponding solubility in the weakly acid small intestine, in which the polymer is charged (10).

A very important property of polymer coatings is permeability to moisture. Moisture permeates polymer films by simple diffusion and by an additional mechanism involving clustering of water molecules about polar centers (11). In a series of related polymers, the most hydrophobic will generally exhibit the lowest moisture permeability.

It is instructive to compare the collapse pressures of the unionized cellulose esters as given in Table I. Collapse pressure, a measure of monolayer stability, is dependent on the balance between adhesional and cohesive forces in the film (12). In a series of compounds, those that exhibit strong intermolecular interactions will have higher collapse pressures. The most important contribution to monolayer stability appears to arise from van der Waals' interactions between hydrophobic groups. Thus, for a group of monolayers of similar constitution, monolayer collapse pressure may be taken as a qualitative measure of "hydrophobicity." Such a relationship has been demonstrated for the half-esters of poly-(methyl vinyl ether/maleic anhydride) (3). Based on collapse pressure values, one may conclude that CAS is more hydrophobic than CAB and that films of CAS should be less permeable to moisture than films of CAB. This predicted order is in agreement with experimental results (5). CAP differs from the other cellulose derivatives studied because it contains an additional polar group, the carboxyl group. Its presence would be expected to increase the interaction of CAP with the subphase and to influence the monolayer collapse pressure. For this reason the collapse pressure of monolayers of CAP should, strictly speaking, not be compared with those of CAB and CAS to predict relative moisture permeability of films. Nevertheless, values for both collapse pressure (Table I) and moisture resistance (5) increase in the order CAB, CAP, CAS.

By using polymer monolayers as a model for enteric and film coatings, a great deal of basic information may be obtained within a relatively short time. This new approach may be utilized in the evaluation of new polymers and of polymer mixtures as potential coating materials, and it will hopefully result in the introduction of novel formulations with superior properties.

Triazolines VI: Evaluation of 1,5-Diaryl- Δ^2 -1,2,3-triazolines and Arylidene Anilines for Herbicidal Activity

PANKAJA K. KADABA

Abstract □ A large number of 1,5-diaryl- Δ^2 -1,2,3-triazolines and arylidene anilines (from which the triazolines are derived) have been examined for the first time for herbicidal activity. Although the majority of the compounds as a class showed no activity, those bearing 3 or 4 halogen substituents evinced slight activity in post-emergence tests.

Keyphrases □ 1,5-Diaryl- Δ^2 -1,2,3-triazolines—herbicidal activity □ Arylidene anilines—herbicidal activity □ Herbicidal activity—1,5-diaryl- Δ^2 -1,2,3-triazolines, arylidene anilines

Studies in the author's laboratories on solvation effects and the role of protic-dipolar aprotic solvents in 1,3-cycloaddition reactions (1-5) have helped pave the way to the proper understanding and application of solvation energy to assist bimolecular cycloaddition reactions. Thus, the accelerating effect of water on the 1,3-cycloaddition of diazomethane to Schiff bases (arylidene anilines) (I) has led to a versatile general method for the synthesis of the rarely encountered Δ^2 -1,2,3-triazolines (II) (3, 6) (Scheme I). By carrying out

Scheme I

the addition reaction in aqueous dioxane solutions, a variety of previously unknown 1,5-diaryl-1,2,3-triazolines have been obtained in good yields. Earlier methods of syntheses (7, 8) have either failed to give a triazoline adduct or have yielded only insignificant amounts of the products. As a result, there is no reference in the literature to any studies on the biological properties of this group of heterocyclic compounds. The cycloaddition reaction in aqueous dioxane solutions has now made a large number of 1,2,3-triazolines readily available in sufficient quantities to permit, for the first time, a detailed screening of these compounds for biological activity. In this paper, a brief report on the results of screening for herbicidal activity is presented.

About 30 1,5-diaryl-1,2,3-triazolines (II) bearing one or two substituent groups on the C-phenyl and/or the N-phenyl and the respective arylidene anilines (I), from which the triazolines are derived, were screened for preemergence, postemergence, and defoliant activities. Although the majority of the 1,2,3-triazolines and arylidene anilines showed no activity, compounds bearing 3 or 4 halogen substituents evinced slight activity. The latter compounds caused visible chlorosis, contact and formative effects, and necrosis in the broad-leaf species in postemergence applications; the cereals, however, were unaffected. Both cereals and broadleaf species also were not affected in preemergence or defoliant tests.

EXPERIMENTAL

The 1,5-diaryl-1,2,3-triazolines and arylidene anilines containing such substituents as the nitro, chloro, bromo, methyl, methoxy, or carbalkoxy groups on the C-phenyl and/or the N-phenyl ring, in the *o*-, *m*-, or *p*-positions (with the exception of the carbalkoxy groups, which were present only in the *p*-position of the N-phenyl ring) were previously prepared in the author's laboratory (1-6). The *p*-aminobenzoic esters necessary for the preparation of the arylidene *p*-aminobenzoates were synthesized, in a convenient one-step reaction, by refluxing the *p*-aminobenzoic acid with excess alcohol in the presence of commercial boron trifluoride ethyl ether as the catalyst (9).

The test compounds were dissolved in acetone containing 0.5% polysorbate 20¹ and sprayed vertically onto potted seedlings aged 7 days from planting at the time of treatment. The spray volume used was 12 ml. directed evenly over 3 sq. ft. of area, and the spray rates were such that applications equivalent to 0.1 and 1 lb./acre were obtained. Each rate was applied to 12 pots simultaneously (two pots of each of the six species used). Observations were then made from four plants of each broadleaf species (two plants per pot) and 20 plants of each cereal species (10 plants per pot) at intervals of 1-2, 5, and 10-14 days for individual visual effects, the latter comprised of abscission, chlorosis, contact and formative effects, curvature, galling, killing, necrosis, abnormal pigmentation, quilling, adventitious root formation, and stunting.

Compounds bearing one or two halogen atoms, either alone or in conjunction with another group, showed little activity. Those bearing 3 or 4 halogen atoms, either alone or otherwise, produced visual effects, the tetrahalogen compounds being more powerful. Among those tested, 1-(3,4-dichlorophenyl)-5-(2,4-dichlorophenyl)-1,2,3-triazoline and 2,4-dichlorobenzylidene-3-chloroaniline appeared to be the most active and produced a greater variety of visual effects in a greater variety of crops than any of the other compounds.

Preparation and Antitumor Activity of Some Schiff Bases of 2'-Amino-4',5'-dichlorobenzenesulfonanilide and 2'-Amino-*p*-toluenesulfonanilide

JOHN H. BILLMAN and ROBERT L. SCHMIDGALL

Abstract □ Series of variously substituted salicylaldehyde Schiff bases and 2-substituted-*p*-[*N,N*-bis(2-chloroethyl)amino]benzaldehyde Schiff bases of 2'-amino-4',5'-dichlorobenzenesulfonanilide and 2'-amino-*p*-toluenesulfonanilide have been prepared and screened for antitumor activity. None of the compounds showed appreciable activity against L-1210 leukemia.

Keyphrases □ 2'-Amino-4',5'-dichlorobenzenesulfonanilide, Schiff bases—synthesis, antitumor activity evaluation □ 2'-Amino-*p*-toluenesulfonanilide, Schiff bases—synthesis, antitumor activity evaluation □ Antitumor activity evaluation—2'-amino-4',5'-dichlorobenzenesulfonanilide, 2'-amino-*p*-toluenesulfonanilide □ IR spectrophotometry—structure, analysis

Woolley *et al.* (1-3) have shown that 4',5'-dichloro-2'-nitrobenzenesulfonanilide (*Ia*) is effective in permanently curing some spontaneous mammary cancers of mice. Evidently the not very toxic *Ia* functions as an antimetabolite of 1,2-dimethyl-4,5-diaminobenzene and inhibits the biosynthesis of vitamin B₁₂, which is synthesized by the spontaneous cancers but not by the hosts (4). 2'-Amino-4',5'-dichlorobenzenesulfonanilide (*Ib*) was also apparently active but much less potent than *Ia*.

In view of the antitumor activity or at least accessibility to the tumor site of *Ia* and *Ib* plus the convenient handle of the primary amino group of *Ib* for further structural modifications, it was decided to prepare some derivatives of Type II. Twelve of these derivatives (Table I) were conveniently synthesized (Scheme I) by condensing the desired aldehyde with *Ib*, which was prepared from the corresponding *o*-phenylenediamine and arylsulfonyl chloride. The aldehydes employed were those substituted salicylaldehydes and 2-substituted-*p*-[*N,N*-bis(2-chloroethyl)amino]benzaldehydes which have previously shown antitumor activity

X = -Cl, -H R = -H or -CH₃ R' = substituted phenyl

Scheme I

either in their own rights or in easily hydrolyzed derivatives (5-15). It was hoped that these new azomethine derivatives (II) would be even more potent antineoplastic drugs than either the active parent amine *Ib* or the active aldehyde alone.

It is well known that a majority of tumors contain cells with a lower pH than cells in normal tissues. Fitch and Voegtlin (16) also have shown that the administration of glucose to tumor-bearing animals can produce an even lower pH value for the tumor cells. Since Schiff bases are one class of compounds that hydrolyze readily *in vitro* under mildly acidic conditions,

such compounds probably could be hydrolyzed selectively by the tumor cells to liberate the active aldehydes to serve as alkylating agents at the same time as the active amine is freed to act as an antimetabolite.

Even if hydrolysis of the Schiff bases does not occur at the tumor site, the compounds might still be active. Ross *et al.* (10) have pointed out that the azomethine linkage in these compounds can be regarded as an

isostere of two cytotoxic agents: the azo compounds and the stilbenes.

Seventeen Schiff bases (IV) (Table II) of 2'-amino-*p*-toluenesulfonanilide (III) were also prepared (Scheme I), using the same or similar aldehydes as were used in the synthesis of Compounds II. Here, if the derivatives IV undergo hydrolysis in the mildly acidic tumor cells, the active aldehydes could still be liberated to serve as

alkylating agents but the freed amine (III) would not have any antitumor activity (17). Thus, the primary functions of III would be to serve as a carrier of the active aldehydes to the tumor site and to direct them into the cellular metabolism. III could also serve as a protector of the aldehydes and prevent their destruction through oxidation, reduction, or whatever before they reached the tumor cells where they could be freed to function as antitumor agents.

Antitumor evaluation of the compounds in Tables I and II was carried out¹ using the test system for leukemia L-1210 (intraperitoneal). No appreciable activity was shown by any of the compounds in Tables I and II with this particular test system.

EXPERIMENTAL²

2'-Amino-4',5'-dichlorobenzenesulfonanilide, Ib—Seventy-five grams (0.424 mole) of 4,5-dichloro-*o*-phenylenediamine was suspended in 800 ml. of a 3:2 ethanol-water mixture and cooled to 0–5° in an ice bath. With vigorous stirring and maintenance of the temperature at 0–5°, 61.8 g. (0.350 mole) of benzenesulfonyl chloride was added dropwise over 5 hr. After complete addition, the stirring was continued for 4 hr. with the ice bath removed. Three hundred milliliters of 2.0 *N* hydrochloric acid was then added, and the mixture was stirred another hour. Suction filtration of the reaction mixture provided a wine-red solution and a purple-gray precipitate. The solid was recrystallized from 2-propanol with the hot mother liquor being decolorized with activated charcoal. White crystals of Ib were obtained after two further recrystallizations from 2-propanol. Yield: 44.8 g., 40.4%. M.p. (lit.) 158° (2); (obs.) 163–165°. IR absorptions, μ : —NHSO₂—, 3.10, 7.60, and 8.64; —NH₂, 2.90, 3.00, and 6.20.

Anal.—Calcd. for C₁₂H₁₀Cl₂N₂O₂S: N, 8.83. Found: N, 8.80.

Recovery of 22.8 g. of 4,5-dichloro-*o*-phenylenediamine was effected by neutralization of the wine-red solution with 50% aqueous sodium hydroxide.

2'-Amino-4',5'-dichlorobenzenesulfonanilide Schiff Base Derivatives, II (Table I)—The synthesis of this series of compounds is illustrated by the preparation of 2'-{[5-(*n*-hexyl)salicylidene]amino}-4',5'-dichlorobenzenesulfonanilide. To a stirring solution of 2.30 g. (0.00730 mole) of 2'-amino-4',5'-dichlorobenzenesulfonanilide in 50 ml. of absolute ethanol was added dropwise, over 15 min., 1.50 g. (0.00750 mole) of 5-(*n*-hexyl)salicylaldehyde (18) dissolved in 75 ml. of absolute ethanol. The mixture was refluxed for 15 min., chilled, and filtered. The tan solid obtained was recrystallized from 2-propanol to give fluffy, light-yellow crystals. Yield: 3.20 g., 86.5%. M.p. 135.5–137.5°.

Anal.—Calcd. for C₂₅H₂₆Cl₂N₂O₃S: N, 5.54. Found: N, 5.53.

2'-Amino-*p*-toluenesulfonanilide, III—A solution of 48.7 g. (0.450 mole) of *o*-phenylenediamine in 300 ml. of a 1:1 aqueous ethanol mixture was cooled to 0–5° in an ice bath. Over a span of 3 hr., 57.2 g. (0.300 mole) of *p*-toluenesulfonyl chloride was added in small portions with rapid stirring at 0–5°. The stirring at 0–5° was continued for another hour after the addition was completed; then the ice bath was removed. Two hundred fifty milliliters of 2.0 *N* hydrochloric acid was added, and stirring was continued for 60 min. at room temperature. After the disubstituted compound had been removed by suction filtration, the clear, dark-red filtrate was neutralized with 50% aqueous sodium hydroxide until a precipitate began to form. To complete the neutralization, solid sodium bi-

carbonate was slowly added with stirring until the evolution of carbon dioxide ceased. The mixture was chilled thoroughly in an ice bath and then filtered with suction. The resulting off-white solid was recrystallized from 2-propanol to give fluffy, white crystals of III. Yield: 63.8 g., 81.1%. M.p. (lit.) 114° (19), 135–136° (20), 142° (21); (obs.) 139–140°. IR absorptions, μ : —NHSO₂—, 3.16, 7.60, and 8.78; —NH₂, 2.91, 3.00, and 6.19.

Anal.—Calcd. for C₁₃H₁₄N₂O₂S: N, 10.68. Found: N, 10.65.

2'-Amino-*p*-toluenesulfonanilide Schiff Base Derivatives, IV (Table II)—The following synthesis for 2'-{[2-fluoro-4-(*N,N*-bis(2-chloroethyl)amino)benzylidene]amino}-*p*-toluenesulfonanilide is typical of the procedure used for preparing this series of compounds. Five and twenty-five hundredths grams (0.0200 mole) of 2'-amino-*p*-toluenesulfonanilide was dissolved in 50 ml. of dry methanol. To this was added dropwise, with stirring, a second solution of 5.03 g. (0.0220 mole) of 2-fluoro-4-[*N,N*-bis(2-chloroethyl)amino]benzaldehyde (13) contained in 75 ml. of hot methanol. The addition took 15 min. and was followed by 30 min. of refluxing. The reaction mixture was cooled in an ice bath and filtered to obtain a dirty yellow solid. Recrystallization of this solid from a 4:1 2-propanol-acetonitrile mixture afforded bright-yellow crystals which were moderately light sensitive. Yield: 7.70 g., 75.5%. M.p. 163–164°.

Anal.—Calcd. for C₂₄H₂₄Cl₂FN₃O₂S: N, 8.26. Found: N, 8.19.

² All melting points were taken in open capillaries on a Thomas-Hoover melting point apparatus and are uncorrected. The elemental analyses were performed by Midwest Microlab, Inc., Indianapolis, Ind. The IR spectra were determined in KBr disks on a Perkin-Elmer Infracord spectrophotometer. Aldehydes and other starting materials used were either reagent grade or were purified by distillation or recrystallization from appropriate solvents.

Mechanism of Action of Retinyl Compounds on Wound Healing II: Effect of Active Retinyl Derivatives on Granuloma Formation

K. H. LEE and THEODORE G. TONG

Abstract □ The naturally occurring retinyl derivatives that promote wound healing as measured by their effects on tensile strength of healing wounds also stimulate granuloma formation induced by cotton pellets. The hexosamine and hydroxyproline contents in the granuloma affected by retinyl derivatives are also increased. The mechanisms of action of retinyl derivation on wound healing are discussed.

Keyphrases □ Retinyl compounds—effect on granuloma formation □ Granuloma formation—retinyl derivatives, effects □ Wound healing—mechanism of action, retinyl derivatives

Previous reports have shown that a few retinyl derivatives promote wound healing, and these compounds also reverse the wound-healing retardation action of anti-inflammatory agents (1–3). It is well known that inflammation and mucopolysaccharide synthesis are the two important features which are essential for subsequent healing.

One commonly used method for studying the anti-inflammatory action of drugs is measuring antigranulation effect with the cotton pellet method of Meier *et al.* (4). This method involves subcutaneous implanting of cotton pellets and measuring the size of the granuloma induced after a few days. Anti-inflammatory agents reduce the size or weight of granuloma as compared with that of the control. In the present study, it is found that those retinyl derivatives that promote healing increase the size or weight of the granuloma. These active retinyl derivatives are “inflammatory agents.”

The promotion of mucopolysaccharide synthesis action of vitamin A in granulation tissue of an open wound has been demonstrated earlier (1). In the present study, it is found that both hexosamine and hydroxyproline contents in the granulomas of retinoic acid-treated animals are considerably higher than those of the controls. The mechanisms of action of retinyl derivatives on wound healing are discussed.

EXPERIMENTAL

Materials and Special Chemicals—Materials and chemicals used in this study included the following: crystalline hydroxy-L-proline;¹ retinoic acid,¹ all *trans*, Sigma grade, Type XX; synthetic crystalline, β -carotene,¹ Sigma grade, Type I; crystalline lycopene,¹ Blakeslea trispora origin; prednisone;² β -ionone³ (n_D^{20} 1.584); α -ionone³ (n_D^{20} 1.5030); glucosamine HCl,⁴ reagent grade; 2,4-pentanedione⁴ (acetylactone), reagent grade; *p*-dimethylaminobenzaldehyde,⁴ reagent grade; dental cotton rolls,⁵ size 1; polyvinyl sponge;⁶

and retinyl palmitate⁷ (400,000 units/g.). β -Ionone, as purchased, was a pure preparation, while α -ionone contained 31% of β -ionone. The isomer was satisfactorily separated by using a preparative gas chromatograph as described previously (3). The *p*-dimethylaminobenzaldehyde was twice recrystallized according to the procedure of Adams and Coleman (5).

METHODS

Implantation of Cotton and Polyvinyl Disks—The effect of retinyl compounds on granuloma formation in rats was evaluated with cotton pellet and polyvinyl sponge methods (4, 6). Cotton pellets are disks sliced from dental cotton rolls with a sharp razor blade. Disks weighing 20 ± 0.5 mg. were selected and placed in Petri dishes for sterilization in a steam autoclave for 40 min. The sterilized cotton disks were handled with sterilized instruments and an aseptic technique. Polyvinyl sponges were also prepared in the form of disks. The block of polyvinyl sponge was sliced with a heavy-duty butcher's cold-meat slicer into 3-mm. thick slices. A cork borer, 11 mm. in diameter, was used to cut the slices into uniform disks. The disks were then thoroughly washed with distilled water to remove the preservative and moistening agents. The washed disks were dried at 65° for 48 hr. Disks weighing 22 ± 0.5 mg. were selected and placed in Petri dishes for sterilization in a steam autoclave for 40 min.

Growth of granulation tissue into cotton pellets was induced by subcutaneous implantation at two symmetrical dorsolateral sites on Sprague-Dawley male rats weighing 120 ± 5 g. under ether anesthesia.

The cotton pellet implanted on the right side contained the retinyl compound, and the cotton pellet implanted on the left side served as the control. The compound was introduced to the pellet as its ether solution. The ether was completely evaporated before implantation. On the 7th day after implantation the animals were killed with ether and the body weights were taken. The granulomas were carefully removed and were weighed rapidly on a torsion balance.⁸ After drying in an oven at 65° for 48 hr., the dried slices were weighed again.

In other experiments, two cotton disks without drug were implanted dorsolaterally and retinoic acid sodium salt was given orally or intraperitoneally on the day before the operation and on the 2nd day after the operation. On the 7th day after implantation, the granulomas formed were carefully removed, and their wet weights and dry weights were measured as described previously.

For polyvinyl sponge experiments, large Sprague-Dawley male rats weighing 230 ± 5 g. were used. Four sponge disks were implanted subcutaneously at symmetrical dorsolateral sites. Two disks containing drug and two control disks were implanted diagonally 2 cm. from each other. Prednisone was given orally on the day before the operation and also on the 2nd day after the operation. The dosage was 2.5 mg. per rat per day. On the 7th day after implantation, the granulomas were carefully removed and treated as already described.

Chemical Analysis—Individual dry disks were weighed and placed in a Pyrex 13 \times 100-mm. culture tube with 1 ml. of 6 *N* HCl. The tube was sealed *in vacuo*, and the content was hydrolyzed at 140° in a constant-temperature heating block for 3 hr.⁹ After cooling to room temperature, the seal of the tube was broken and the content was carefully neutralized with 6 *N* NaOH. The content was then filtered with the aid of suction. The original tube and the

filter were rinsed several times with small portions of distilled water. The filtrate was brought to 10.0 ml. Aliquots were taken for hydroxyproline and glucosamine analyses. Samples containing 5–15 mg. of hydroxyproline were analyzed according to the method described by Neuman and Logan (7). Aliquots of the filtrate containing 0.010–0.030 mg. of glucosamine were analyzed according to the method of Elson and Morgan as modified by Boas (8).

RESULTS

The effects of retinoic acid and vitamin A on cotton pellet-induced granuloma are shown in Table I. Preliminary tests have been done to determine the proper amount of each compound to be used for appreciable, measurable effects. Either 6000 I.U. of retinyl palmitate or 2 mg. of retinoic acid is required to give about 50% increase in granuloma formation as compared with the control.

Both the wet weight and the dry weight of the granuloma induced by cotton pellets are about the same when either drug is applied. The granulomas of the controls are also similar in weight. The ratios of the granuloma induced by cotton pellets impregnated with either drug to the controls are all about 1.5. These differences are highly significant as determined by the Student *t* test ($p < 0.001$). These results clearly demonstrate that retinyl derivatives increase the size of granuloma induced by the cotton pellet. These results also indicate that retinyl palmitate and retinoic acid are of the same potency. Retinyl palmitate and retinoic acid also had the same activity when tensile strengths of healing wounds were compared

(9). In both cases the rats gained body weight at a normal rate, which indicates that the amount of drug used was not showing any toxic effect.

The effects of the sodium salt of retinoic acid, given orally or intraperitoneally, on cotton pellet-induced granuloma are shown in Table II. Group I involves 18 rats receiving no drug. The average wet weight and dry weight of granuloma are about 212 and 29 mg., respectively. These values are about the same as those of the controls shown in Table I. This fact indicates that the implantation of a cotton pellet impregnated with 2 mg. of retinoic acid or 6000 I.U. of retinyl palmitate did not influence the size of their controls. In Group II, six rats were given sodium retinoate orally. The average wet weight and dry weight are significantly larger than those of Group I animals. In Group III, all six rats received sodium retinoate intraperitoneally; their granulomas are about the same as those of Group II animals but are significantly larger than those of the controls.

The effect of prednisone on granulomas induced by retinoic acid-impregnated polyvinyl sponge is shown in Table III. Group I rats received no oral administration of prednisone. The average wet and dry weights of all of the granulomas induced by polyvinyl sponges impregnated with 2 mg. of retinoic acid were 390.9 and 54.8 mg., respectively. The average wet and dry weights of granuloma induced by polyvinyl sponges were 289.5 and 32.9 mg., respectively. The ratio of wet and dry weights of the granulomas induced by retinoic acid-impregnated and control polyvinyl sponges was about 1.5. Group II rats were treated exactly as those of Group I, except prednisone was given to the rats on the day before the opera-

IV	6	α -Ionone, 25 mg.	+49	252.0 \pm 6.6	228.8 \pm 3.8	1.1		27.5 \pm 2.2	28.1 \pm 1.7	1.0	

tion and also on the 2nd day after the operation. The average wet and dry weights of the granulomas induced by polyvinyl sponges impregnated with 2 mg. of retinoic acid were 340.0 and 46.3 mg., respectively. These weights are about 20% less than those of the animals receiving no prednisone (Group I). The wet and dry weights of the granulomas induced by polyvinyl sponges without retinoic acid were 240.5 and 27.8 mg., respectively. These weights are also about 20% less than those of the Group I animals. This experiment demonstrated again that retinoic acid enhanced granuloma formation induced by polyvinyl sponges and its activity was inhibited by prednisone. This also confirms the previous findings with another independent method: that prednisone inhibits and retinoic acid promotes healing (2, 3).

The effects of a few retinol-related, naturally occurring compounds in cotton pellet-induced granuloma are shown in Table IV. β -Carotene (Group I) enhances granuloma formation induced by the cotton pellet. It is almost as active as retinoic acid. Lycopene (Group II) has the same structure as β -carotene, except that it has an open trimethyl cyclohexene ring. It is not active. β -Ionone is active while α -ionone is not (Groups III and IV). The activities of these compounds on granuloma formation are essentially the same as their activities on the tensile strength of healing wounds (3).

The total hexosamine contents in the granulomas induced by cotton pellets in the presence and absence of 2 mg. of retinoic acid were 124.0 \pm 3.5 and 94.0 \pm 2.3 mcg., respectively. The dry weights of the respective granulomas were 55.4 \pm 2.1 and 35.5 \pm 0.8 mg. The hydroxyproline contents of the experimental and control granulomas were 259.2 \pm 7.3 and 200.0 \pm 8.5 mcg., respectively.

DISCUSSION

Inflammation and mucopolysaccharide synthesis are the two known important features in wound healing. Anti-inflammatory agents retard healing by their anti-inflammatory and inhibitory actions on mucopolysaccharide synthesis (2, 10-12). Retinol and a few retinyl derivatives can reverse the wound-healing retardation action of a number of anti-inflammatory agents (3, 10). This fact illustrates an important pharmacological principle of using an agent (retinol) to modify the untoward effect of a useful drug (anti-inflammatory agent). Retinol, or either one of the active retinyl derivatives alone, promotes healing (2, 3).

Meier *et al.* (4) introduced a method that makes quantitative studies of the action of cortisone on connective tissue possible. These workers used the cotton pellet as a foreign body to induce granuloma formation. Application of cortisone resulted in a diminution of granuloma size, which can be expressed quantitatively by determining its fresh and dry weights. Cortisone was effective by local as well as by general application, similar concentrations producing the same degree of inhibition of granuloma formed. Since then, this method has been extensively used for assaying steroid and nonsteroid anti-inflammatory agents. Retinol and retinyl derivatives that promote healing cause an increased granuloma mass induced by cotton pellets.

It is interesting to point out that this is the first demonstration of an agent given orally, intraperitoneally, or locally enhancing granuloma formation. This phenomenon definitely shows again the effect of retinol or its active retinyl derivatives and anti-inflammatory agents. It seems justified to call these retinyl compounds

"inflammatory agents."

Grindlay and Waugh (6) used essentially the same implantation method to study tissue regeneration, except that they used polyvinyl sponges. The protein, lipid, and mucopolysaccharide contents of the granuloma have been studied.

Jackson *et al.* (13) pointed out that repair of connective tissue is the most basic feature in wound healing, and they used the formation of granuloma induced by polyvinyl sponges to study healing. Sandberg and Zederfeldt (14) found that the rate of gain in tensile strength and hydroxyproline in granuloma was directly related in both rats and rabbits. The results of the present experiment show that only those retinyl derivatives that are active in increasing tensile strength also increase the size and weight of granuloma induced by either the cotton pellet or polyvinyl sponge. Granuloma formation is a useful quantitative method to study wound healing.

The promotion of mucopolysaccharide synthesis action of retinol in granuloma tissue of an open wound has been reported (1). In the present study, both total hexosamine and hydroxyproline contents were increased in the granuloma induced by the cotton pellet impregnated with retinoic acid.

The results obtained in this study suggest that retinol and active retinyl derivatives promote healing by inducing inflammation and increase mucopolysaccharide synthesis mechanisms of action.

Action of Antibiotics on Respiratory Tract II: Dicloxacillin

G. BENZI*, F. BERTE, E. BERMUDEZ, and E. ARRIGONI

Abstract □ Dicloxacillin antagonizes *in vitro* the acetylcholine-, histamine-, and barium chloride-induced spasms on the dog bronchial chain. Against the histamine or acetylcholine contraction, dicloxacillin is about 2–3 times less active than ephedrine, about 2000–4000 times less active than isoprenaline, and about 5–6 times more active than ampicillin. *In situ*, the intravenous injection of dicloxacillin induces a decrease of the respiratory frequency with a moderate increase in ventilation.

Keyphrases □ Dicloxacillin—respiratory tract, effects □ Antibiotics, dicloxacillin—effect, respiratory tract □ Bronchospasm—comparison antibiotics, effects

Studies on the ampicillin action on the respiratory tract showed that *in vitro* the antibiotic antagonizes the barium chloride-, histamine-, and acetylcholine-induced spasms on the dog bronchial chains. *In situ*, the antibiotic induces at first a prompt but short increase in ventilation; subsequently, a lesser but persistent activity remains for 2 or 3 hr. (1). The plan of the present research was to study the dicloxacillin action on the airways *in vitro* and *in vivo*. The isoxazolyl group of semisynthetic penicillins has been useful in the therapy of infections caused by penicillase-producing staphylococci (2–7) and, collaterally, possesses a myolytic action on the rabbit-isolated duodenum, jejunum, and ileum; on the guinea-pig-isolated bronchial muscle; and on the rat-isolated intestine (8). Furthermore, dicloxacillin induces a relaxation *in vitro* and *in vivo* of both the terminal bile duct and ureter, normal or hypertonized by various spasmogenic agents (9, 10). The intrabiliary perfusion with dicloxacillin inhibits *in situ* the stimulation of the peripheral end of the right supradiaphragmatic vagus (9), while the perfusion into the ureter with the antibiotic induces no effect on the electrical stimulation of the hypogastric and pelvic nerves (10).

METHODS

The experiments were performed in the dog both *in vitro* and *in situ*. The following were used: dicloxacillin sodium monohydrate, of which amounts are expressed in terms of 3-(2,6-dichlorophenyl)-5-methyl-4-isoxazolyl-penicillanic acid; ampicillin sodium salt, of which amounts are expressed in terms of D(-)-6-(α -amino- α -phenylacetamido)-penicillanic acid; *dl*-isoprenaline hydrochloride; and *l*-ephedrine hydrochloride, the amounts of which are expressed in terms of the base.

Experiments *In Vitro*—Bronchi of 38 mongrel dogs of either sex (weighing 6.6–11.4 kg.) were removed immediately after death. All tissues were carefully dissected and cut into rings, which were tied together in chains with loops of thread. The mucosa was removed to allow for greater freedom of movement of the muscle; the cartilage in each ring was cut so that only the smooth muscle bands were left joining each ring together (11). Four to six rings were suspended in a 50-ml. organ bath containing Tyrode solution gassed with 95% oxygen and 5% carbon dioxide; the temperature was 36.5–37.3°. The tonus level of the preparations was continuously recorded by a strain-gauge lever, giving a magnification of $\times 15$ to 20, tension 200 mg., writing on a kymograph

Figure 1—Log dose-response curve of dicloxacillin action against the stimulation by barium chloride. The ordinate shows the inhibition percent of the contracting action by barium. The concentrations of the antibiotic (mcg./ml.) are plotted on the abscissa in logarithmic scale. The vertical lines indicate standard errors of the means. Six preparations at each dose level.

drum. The preparations were left 2 hr. before any drugs were given. Three submaximal doses of acetylcholine were administered, until regular responses were obtained, before any doses of acetylcholine itself or other agonists were tested. The action of dicloxacillin (25–400 mcg./ml.) was evaluated against the stimulation by barium chloride (100–400 mcg./ml.); for the construction of the dose-response curve, dicloxacillin activity was taken as the percent inhibition of the recorded response area by barium chloride stimulation during a 20-min. period of contact.

For comparative assay with other *in vitro* bronchodilators, the activity of dicloxacillin (200–3200 mcg./ml.), ampicillin (2000–16,000 mcg./ml.), *l*-ephedrine (200–1600 mcg./ml.), and *dl*-isoprenaline (0.125–2.0 mcg./ml.) was evaluated against the stimulation by acetylcholine chloride (0.2–2.0 mcg./ml.) and histamine acid phosphate (1.0–10.0 mcg./ml.). Two dose levels of agonist and antagonist were usually used; the agonist doses were left in contact with the preparation for 0.5–1.0 min. Dicloxacillin and ampicillin were introduced into the bath 10 min., and ephedrine and isoprenaline 30 sec., before the acetylcholine or histamine doses. The ED_{50} , the slope of the curve, the potency ratio, and their 95% confidence limits were calculated (12).

Experiments *In Situ*—The experiments were carried out on 28 mongrel dogs of either sex (weighing 12.4–16.8 kg.) preanesthetized with urethan (0.4 g./kg. i.p.). Anesthesia was induced and maintained by chloralose (80 mg./kg. i.v.); the arterial blood pressure was measured from a cannula inserted into a femoral artery; the intestinal movement and tone were recorded by a rubber balloon inserted into the jejunum. During the succinylcholine chloride (1 mg./kg. i.v.) action, an intratracheal Warne tube was set in place. Through this tube, a little rubber balloon was pushed into a primary or, if possible, secondary bronchus under X-ray examination. Arterial blood pressure and intestinal and respiratory activity were recorded by a Physioscript EE12 Schwarzer polygraph.

Table I—Dog Bronchial Chain *In Vitro*: ED₅₀, Slope Function of Line (S) and Estimated Relative Potency (ERP), with 95% Confidence Limits, of *dl*-Isoprenaline, *l*-Ephedrine, Ampicillin, and Dicloxacillin against Stimulation by Acetylcholine Chloride (0.2–2 mcg./ml.) and Histamine Acid Phosphate (1.0–10.0 mcg./ml.)

Ephedrine	450 (214–945)	2.83 (0.97–8.20)	10 (3.4–29.5)
Ampicillin	4600 (2090–10,120)	2.53 (0.70–9.10)	1 D
Dicloxacillin	1000 (416–2400)	3.47 (0.77–15.61)	4.6 (1.41–14.95)

^a ED₅₀ = dose (mcg./ml.) of bronchodilator necessary to reduce by 50% the contraction produced by acetylcholine or histamine. ^b S = fold change in dose required to produce a unit standard deviation change in response along the line; thus $S = \text{antilog } s = \text{antilog } 1/b$, where b and s are, respectively, the slope constant and standard deviation of a line relating log dose of antagonist and probit percent reduction of agonist activity. ^c D = ampicillin and compared drugs differ significantly in potency ($p < 0.05$).

Dicloxacillin (0.25–8.0 mg./kg.) was administered intravenously by a polystan tube inserted into the femoral vein. Two submaximal doses of *dl*-isoprenaline or *l*-adrenaline were given intravenously until regular responses were obtained before any doses of dicloxacillin were tested. To analyze the mechanism of action, dicloxacillin was tested also after: (a) cutting the vagi, and (b) treatment with atropine sulfate (2–3 mg./kg. s.c.), dibenamine hydrochloride (3–6 mg./kg. i.v.), D(–)INPEA¹ (4–8 mg./kg. i.v.), methysergide maleate (20–40 mg./kg. s.c. + 10 mg./kg. i.v.), chlorpheniramine maleate (2–4 mg./kg. s.c.), cyproheptadine hydrochloride (200–400 mcg./kg. i.v.), hexamethonium bromide (200–400 mcg./kg. i.v.), or morphine hydrochloride (4–8 mg./kg. i.v.).

RESULTS AND DISCUSSION

Dicloxacillin (25–400 mcg./ml.) reduces or inhibits the stimulation by barium chloride on the dog bronchial chains *in vitro*; the log dose–response curve is indicated in Fig. 1.

The comparative assay of dicloxacillin, ampicillin, isoprenaline, and ephedrine action against the stimulation by acetylcholine or histamine is indicated in Table I and shows that dicloxacillin is more active than ampicillin in reducing the agonist-induced spasm. It is possible to observe that against histamine- or acetylcholine-induced contraction, dicloxacillin is about 2–3 times less active than ephedrine, about 2000–4000 times less active than isoprenaline, and about 5–6 times more active than ampicillin.

Dicloxacillin, as ampicillin (1) and aminophylline (11), is more effective in preventing a histamine than an acetylcholine bronchospasm. Obviously, it is impossible to correlate directly the present results with clinical conditions, the *in vitro* studies being limited to denervated portions of the airways while many bronchoconstrictive stimuli act, at least in part, *via* reflex mechanisms.

¹ D(–)-1-(4-Nitrophenyl)-2-isopropylaminoethanol HCl.

Figure 2—Action of dicloxacillin intravenously on the ventilation of a dog in situ. From top to bottom: tracing recorded by a balloon inserted into the bronchus; blood pressure (mm. Hg). 1 = control condition; 2 = 5 min. after injection intravenously of 2 mg./kg. of dicloxacillin; 3 = 15 min. later; 4 = 30 min. later; 5 = 60 min. later; 6 = 75 min. later; 7 = 90 min. later; and 8 = 120 min. later.

In situ, the intravenous injection of 0.25–8 mg./kg. of dicloxacillin induces a decrease of the respiratory frequency with a moderate increase in ventilation, as illustrated in Fig. 2. No change in systemic blood pressure occurs during the 2–3 hr. of the antibiotic action on the airways. The comparative evaluation of the action of dicloxacillin and ampicillin upon the dog ventilation is summarized in Fig. 3; ampicillin acts mainly on the depth of respiration, while dicloxacillin acts on the rate.

To analyze the mechanism of action of dicloxacillin *in situ*, it should be noted that: (a) the pressure recorded by the bronchial balloon technique reflects merely the effects of lung volume changes

Figure 3—Dog ventilation in situ: range of the percent changes (on ordinate) both in amplitude of the recorded tracing and in frequency of the respiratory rate at various periods of observation (on abscissa, in min.) after the intravenous injection of dicloxacillin (0.25–8 mg./kg.) and ampicillin (1.25–80 mg./kg.).

on the intrathoracic airways, primarily reflecting changes in tidal volume; (b) the pretreatment with morphine antagonizes the action of the antibiotic; (c) the dicloxacillin activity is unaffected by the pretreatment with atropine, dibenamine, INPEA, methysergide, chlorpheniramine, cyproheptadine, and hexamethonium; and (d) the action of the antibiotic persists after cutting of the vagi.

Consequently, only *in vitro* is it possible to note the myolytic activity of the antibiotic on the bronchial musculature, while *in vivo* it is more likely that dicloxacillin, as ampicillin, induces at least in part an action on the medullary respiratory center.

Spectrographic Determination of Traces of Cobalt in Vitamin B₁₂ Preparations

Keyphrases ☐ Cobalt determination—vitamin B₁₂ dosage forms ☐ Emission spectrograph, direct—analysis

Sir:

The assay methods available for determination of vitamin B₁₂ fall into four groups: biological, microbiological, chemical, and radioactive (1-3). Most of these methods are time consuming or difficult to perform, and often large samples must be taken for analysis.

A quick and simple analytical assay was needed for evaluation of active ingredients in pharmaceutical preparations containing vitamin B₁₂ or its analogs, using only a few centigrams of the test substance.

We have developed a direct emission spectrographic method for rapid analysis of vitamin B₁₂ in biological materials, where the amount of nonvitamin B₁₂ cobalt is negligible. The method is based upon the cobalt content of cyanocobalamin (C₆₃H₈₈CoN₁₄O₁₄P, 4.35% Co in dry form). Mineralization, fusion, or ashing of organic substances is superfluous in this determination; separation or extraction of traces of Co is similarly unnecessary.

One milliliter of a liquor containing 25-125 mcg. vitamin B₁₂/ml. (corresponding to 1.1-5.4 mcg. Co/ml.) is mixed with 0.1 g. spectroscopically pure graphite powder and evaporated to dryness at 105°. Or, approxi-

mately 0.05 g. powdered solid sample is thoroughly mixed with 0.1 g. graphite powder. Then 20 mg. of this mixture or the residue is vaporized in a cupped carbon electrode, using a 14-amp. d.c. arc, and the spectrographic plate is measured as usual (4).

The entire procedure takes about 30 min. for a single determination. In batch analyses the time required is considerably reduced.

The results of this determination are expressed in terms of anhydrous cyanocobalamin. When less stable but more naturally occurring forms of vitamin B₁₂, like hydroxocobalamin and metabolically active coenzyme B₁₂, are also present in the test solution, total vitamin B₁₂ activity is directly obtained in this method (calculated as cyanocobalamin equivalents).

Fraudulent addition of inorganic cobalt interferes with this assay.

The most sensitive cobalt line in the UV region, at 3435.5 Å, is chosen as the analytical line. Its intensity is suitable for the range 1-5 mcg. Co/ml. which is usually encountered in pharmaceutical preparations.

There are few ions that interfere with this determination, and it may be termed as specific. However, the intensity of the cobalt line is increased several times in the presence of organic matter existing usually in vitamin preparations. A similar increase of line intensity is observed in flame photometry when using solutions made with combustible organic solvents like methanol or methyl isobutyl ketone (5). For this reason, standard powders are made according to the "addition method," in which increasing amounts of Co are added to the same solution that is being analyzed (4). This "standard addition method" is equivalent, by its nature, to a recov-

on the intrathoracic airways, primarily reflecting changes in tidal volume; (b) the pretreatment with morphine antagonizes the action of the antibiotic; (c) the dicloxacillin activity is unaffected by the pretreatment with atropine, dibenamine, INPEA, methysergide, chlorpheniramine, cyproheptadine, and hexamethonium; and (d) the action of the antibiotic persists after cutting of the vagi.

Consequently, only *in vitro* is it possible to note the myolytic activity of the antibiotic on the bronchial musculature, while *in vivo* it is more likely that dicloxacillin, as ampicillin, induces at least in part an action on the medullary respiratory center.

Spectrographic Determination of Traces of Cobalt in Vitamin B₁₂ Preparations

Keyphrases ☐ Cobalt determination—vitamin B₁₂ dosage forms ☐ Emission spectrograph, direct—analysis

Sir:

The assay methods available for determination of vitamin B₁₂ fall into four groups: biological, microbiological, chemical, and radioactive (1-3). Most of these methods are time consuming or difficult to perform, and often large samples must be taken for analysis.

A quick and simple analytical assay was needed for evaluation of active ingredients in pharmaceutical preparations containing vitamin B₁₂ or its analogs, using only a few centigrams of the test substance.

We have developed a direct emission spectrographic method for rapid analysis of vitamin B₁₂ in biological materials, where the amount of nonvitamin B₁₂ cobalt is negligible. The method is based upon the cobalt content of cyanocobalamin (C₆₃H₈₈CoN₁₄O₁₄P, 4.35% Co in dry form). Mineralization, fusion, or ashing of organic substances is superfluous in this determination; separation or extraction of traces of Co is similarly unnecessary.

One milliliter of a liquor containing 25-125 mcg. vitamin B₁₂/ml. (corresponding to 1.1-5.4 mcg. Co/ml.) is mixed with 0.1 g. spectroscopically pure graphite powder and evaporated to dryness at 105°. Or, approxi-

mately 0.05 g. powdered solid sample is thoroughly mixed with 0.1 g. graphite powder. Then 20 mg. of this mixture or the residue is vaporized in a cupped carbon electrode, using a 14-amp. d.c. arc, and the spectrographic plate is measured as usual (4).

The entire procedure takes about 30 min. for a single determination. In batch analyses the time required is considerably reduced.

The results of this determination are expressed in terms of anhydrous cyanocobalamin. When less stable but more naturally occurring forms of vitamin B₁₂, like hydroxocobalamin and metabolically active coenzyme B₁₂, are also present in the test solution, total vitamin B₁₂ activity is directly obtained in this method (calculated as cyanocobalamin equivalents).

Fraudulent addition of inorganic cobalt interferes with this assay.

The most sensitive cobalt line in the UV region, at 3435.5 Å, is chosen as the analytical line. Its intensity is suitable for the range 1-5 mcg. Co/ml. which is usually encountered in pharmaceutical preparations.

There are few ions that interfere with this determination, and it may be termed as specific. However, the intensity of the cobalt line is increased several times in the presence of organic matter existing usually in vitamin preparations. A similar increase of line intensity is observed in flame photometry when using solutions made with combustible organic solvents like methanol or methyl isobutyl ketone (5). For this reason, standard powders are made according to the "addition method," in which increasing amounts of Co are added to the same solution that is being analyzed (4). This "standard addition method" is equivalent, by its nature, to a recov-

ery test. Therefore, experiments for the complete recovery of added vitamin B₁₂ are not necessary in this assay.

The cobalt line is measured against the background of the plate, using a densitometer. To prepare standard synthetic powders, 0.1, 0.2, 0.3, and 0.4 ml. of a standard cobalt solution containing 10 mcg. Co/ml. [49.38 mg. cobalt nitrate, Co(NO₃)₂·6H₂O, dissolved in 1000 ml. distilled water] are added to four 1-ml. portions of the vitamin solution being analyzed. Each sample is treated as mentioned previously, after mixing with 0.1 g. graphite powder.

An atomic absorption spectrophotometer may be used for this determination. While freedom of interference is better in emission spectrography, because of the higher resolving power of the large spectrographs used, the sensitivities of detection are of the same order of magnitude. Although the atomic absorption method may be superior in rapidity and probably precision, we can mention the following points in favor of emission spectrography:

1. Solid samples can be analyzed directly after drying and grinding with graphite powder.

2. Solvent extraction is not needed for the range of cobalt concentration usually encountered in biological materials.

3. The spectrographic plate is a valuable and permanent record of analytical data, enabling a complete qualitative and quantitative check at any time. This fact is particularly important in legal cases.

In the authors' opinion, emission spectrography and atomic absorption must be used simultaneously and concurrently for the exact determination of traces of metals in biological materials. Their respective results for every metal should doublecheck each other.

In the spectrographic procedure, a "National" carbon cupped electrode, type L 3900, is used as the lower electrode, and a "National" L 3957 is used as the counter electrode. The charge weighed into the cavity is 20 mg. The distance between electrodes, or analytical gap, is 3 mm., which is further increased to 6 mm. during arcing. A d.c. arc, 14-amp., generated from N.S.L. Spec Power,¹ is used as the excitation source. The time of exposure is set to 13 sec., during which up to 3 mcg. of Co in 20 mg. dry residue is completely volatilized. Prearcing is not necessary. A Bausch & Lomb Large Littrow spectrograph is used for this assay, with a fixed slit of 20-μ width and 3-mm. height. The spectrographic plate is Kodak No. 1, size 4 × 10 in., which is developed and dried using a N.S.L. processor. It is measured with a N.S.L. reader (densitometer).

The characteristic curve of the plate is obtained by plotting a preliminary curve, using an iron arc spectrum taken with a two-step filter. This method of plate calibration seems to have a satisfactory precision, because random scatter of experimental points is compensated for in drawing the preliminary curve. The characteristic curve is practically unchanged for a period of laboratory work. Concentrations are plotted against intensities on ordinary graph paper.

By taking three spectra from each powder, a precision of ±10% was attained.

A large number of vitamin B₁₂-containing preparations such as liver extract and liver injection were analyzed by this method. It was also used to follow separation or purification steps in manufacturing processes (fermentation, extraction, etc.). To indicate the precision obtained, we are giving here the results of a routine determination. The analysis of a vitamin B₁₂ preparation claimed to contain 40 mcg. vitamin/ml. gave the following results: 1.7, 1.8, 2.0, 2.0, 1.6, and 2.0 mcg. Co/ml. in six different plates. The mean value, 1.85, multiplied by 100/4.35 = 23 gives 42 mcg. cyanocobalamin/ml.

Synthesis of O-Alkyldihydroxyacetone and Derivatives

Keyphrases ☐ O-Alkyldihydroxyacetone, derivatives—synthesis ☐
IR spectrophotometry—structure ☐ GLC—identity

Sir:

Recently, Snyder and coworkers (1-4) proposed a biochemical pathway and identified intermediates that demonstrated the biosynthesis of O-alkyl ether bonds in glycerolipids from fatty alcohols and dihydroxyacetone-P in cell-free systems. This new metabolic scheme included O-alkyldihydroxyacetone and O-alkyldihydroxyacetone-P as intermediates. We have now further substantiated the previously reported biochemical reaction sequence (3) by the chemical synthesis of one of the intermediates, namely O-alkyldihydroxyacetone (I) (R = octadecyl or hexadecyl) (Scheme I). This preliminary communication describes the synthesis of I which can exist as a keto-enol tautomer; the properties of I are identical with those of the ¹⁴C-O-alkyldihydroxy-

IR spectrophotometry—structure ☐ GLC—identity

Sir:

Recently, Snyder and coworkers (1-4) proposed a biochemical pathway and identified intermediates that demonstrated the biosynthesis of O-alkyl ether bonds in glycerolipids from fatty alcohols and dihydroxyacetone-P in cell-free systems. This new metabolic scheme included O-alkyldihydroxyacetone and O-alkyldihydroxyacetone-P as intermediates. We have now further substantiated the previously reported biochemical reaction sequence (3) by the chemical synthesis of one of the intermediates, namely O-alkyldihydroxyacetone (I) (R = octadecyl or hexadecyl) (Scheme I). This preliminary communication describes the synthesis of I which can exist as a keto-enol tautomer; the properties of I are identical with those of the ¹⁴C-O-alkyldihydroxy-

¹ National Spectrographic Laboratories Inc., Cleveland, Ohio.

Scheme 1

acetone synthesized enzymically by microsomes (4), thereby confirming it as an intermediate in the biosynthesis of these new and metabolically important ether-linked keto lipids.

We have prepared structures with the following general formulas:

Two synthetic routes were investigated in the synthesis of 1-*O*-octadecyl-2,2-dimethoxy-3-hydroxypropane (II). In the first procedure, acetyl dihydroxyacetone dimethyl ketal was synthesized (5) and then converted to 1-*O*-trityl-2,2-dimethoxy-3-hydroxypropane (III), which had the correct elemental analysis; m.p. 127–128°.

Anal.—Calcd. for $\text{C}_{24}\text{H}_{46}\text{O}_4$: C, 76.16; H, 6.92. Found: C, 76.40; H, 7.01.

IR spectrum: 3500 cm^{-1} (OH), 2920 cm^{-1} (C—H), 1600 cm^{-1} (trityl), 1085–1140 cm^{-1} (—C—O—C—).

Compound III was reacted with octadecyl bromide in the presence of powdered KOH in benzene (6), resulting in 1-*O*-octadecyl-2,2-dimethoxy-3-*O*-trityl propane (IV). IR spectrum showed loss of OH band absorption, 2920 cm^{-1} (C—H, substantial increase in aliphatic CH band absorption), 1085–1140 cm^{-1} (—C—O—C—). Hydrogenolysis of IV with 15% Pd/C in dioxane at 40° and 60 p.s.i. resulted in I.

Anal.—Calcd. for $\text{C}_{21}\text{H}_{42}\text{O}_3$: C, 73.63; H, 12.36. Found: C, 73.59; H, 12.29.

IR spectrum: 3420 cm^{-1} (OH), 2920 cm^{-1} (C—H), 1725 cm^{-1} (—C—C—C—), 1085–1140 cm^{-1}

(—C—O—C—). NMR in CDCl_3 showed no methoxy singlet, and the assignments of fragments in the mass spectra were comparable to that of the keto-enol form of I, m.p. 87–89°.

In the second synthetic scheme, batyl alcohol was benzoylated in the presence of pyridine and the crude mono derivative was oxidized with dimethyl sulfoxide and dicyclohexylcarbodiimide in the presence of trifluor-

acetic acid (7). This afforded 1-*O*-octadecyl-3-*O*-benzoyl-2-propanone, V.

Anal.—Calcd. for $\text{C}_{28}\text{H}_{46}\text{O}_4$: C, 75.29; H, 10.38. Found: C, 75.26; H, 10.29, m.p. 52–53°.

Compound V was then ketalized to afford 1-*O*-octadecyl-2,2-dimethoxy-3-*O*-benzoylpropane, VI, which was further confirmed with IR. Compound VI was base hydrolyzed to give 1-*O*-octadecyl-2,2-dimethoxy-3-hydroxypropane (II).

Anal.—Calcd. for $\text{C}_{23}\text{H}_{48}\text{O}_4$: C, 71.08; H, 12.45. Found: C, 70.82; H, 12.33. IR spectrum showed 3470 cm^{-1} (OH), 2920 cm^{-1} (C—H), 1085–1140 cm^{-1} (—C—O—C—). NMR δ 3.25 [s, 6. (OCH₃)], m.p. 29–31°.

The two synthetic preparations of *O*-alkyldihydroxyacetone were reduced with LiAlH_4 to the corresponding *O*-alkylglycerol, and GLC of the isopropylidene derivatives demonstrated that they had the same retention time as the isopropylidene derivative of authentic batyl alcohol. Acid hydrolysis of the ketone-containing lipids produced octadecanol; periodate oxidation produced *O*-alkylglycolic acids, and they could be reduced with LiAlH_4 to *O*-alkylethyleneglycols. These reactions and the details for identifying the products have been described (4). Further work on these ether-linked keto-lipids is in progress in our laboratories.

REVIEWS

Legal Medicine Annual. Edited by CYRIL H. WECHT, M.D., J.D. Appleton-Century-Crofts, 440 Park Ave., New York, NY 10016, 1969. 442 pp. 16.7 × 24.4 cm. Price \$14.00.

This book contains 22 monographs by 26 authors covering various aspects of forensic medicine. The largest part of the book is devoted to a discussion of professional liability and forensic toxicology. The remainder of the book is rounded out with a discussion of criminal responsibility, organ transplantation, and abortion laws.

Two chapters that deserve special mention are: *Chapter 8*, dealing with the preparation for trial in drug liability cases. The author gives an excellent discussion of how probing an attorney's inquiry can be into the facts and responsibilities for adverse drug reactions.

Chapter 5 gives a clear overview of the medicolegal problems of hospital liability and the extent to which the courts are forcing hospitals to exercise increasing control over medical staff conduct. While this chapter focuses on potential liability of the medical staff, it is clear that members of the paramedical staff, such as, clinical pharmacists and nurses can face the same types of potential liability.

A book of this nature would not be of interest to the pharmaceutical scientist or pharmacy practitioner unless he has a strong interest in medicolegal problems.

Physician's Book Compendium. Edited by MAX CELNIK. Physician's Book Compendium, Inc., 25 West 45th St., New York, NY 10036, 1969. xxvi + 846 pp. 17 × 23.5 cm. Price \$29.50.

While the idea behind the "Physician's Book Compendium" of compiling into one source all books from the medical field and giving pertinent bibliographic information is sound and would have useful applications, the product of this idea falls considerably short of its goal, as stated in the Preface, of being "an indispensable reference volume."

Probably the first objectionable feature that the user would notice is the inserts of business reply cards, provided for ordering books. The thickness of these inserts, and their location interspersed throughout the text, makes flipping pages difficult. The next annoyance is the numerous pages of advertisements scattered throughout the volume; they seem to be out of place in a book of this type. The very fact that this book costs nearly thirty dollars and is filled with ads, in itself, might be objectionable to some purchasers of this book.

Had both of these aforementioned materials been placed at the beginning or end of the book, the usefulness of the book would have been somewhat increased, as well as bettering its appearance.

The paragraph summaries, which are not provided for all books, read like the publicity flyers sent out by the publishers. No attempt could be discerned to evaluate or critique any book, an omission which certainly detracts from the value of the compendium. This omission is particularly significant with regard to the older books.

With just a quick check of the section on "Pharmacology," it was noted that nearly half of the books included were published before 1964. One cannot help but wonder if these are all significant, classic books, or if they were included to fill out the space available.

The inclusion of books with a popular approach or nature tends to diminish any remnant image of a scholarly attempt at compiling a technical work.

The use of the same type face, although admittedly a little larger, for both the subheads within sections and the authors' last names adds to the reader's confusion.

While there is apparently a need for this type of book and the editors have made an initial step, it would be difficult, if not impossible, to recommend this book for general use.

Staff Review ■

Contraception: The Chemical Control of Fertility. Edited by DANIEL LEDNICER. Marcel Dekker, Inc., 95 Madison Ave., New York, NY 10016, 1969. xiv + 269 pp. 15.5 × 24 cm. Price \$13.75.

This is an excellent book for researchers who are entering the field of female antifertility. It contains six chapters which deal with biology and chemistry of steroidal and nonsteroidal agents. Each chapter is authored by men who are well versed in their respective fields.

Chapter One introduces the reader to the reproductive cycle of the human female and discusses the interplay between the hypothalamus, pituitary, and ovary.

Chapters Two and Four emphasize the biology of steroidal and nonsteroidal compounds that are either being used as contraceptive agents or have been evaluated in animals. Chapter Two in particular discusses in detail the mode of action and the rationale for selecting the present steroidal contraceptive agents. Chapter Four, on the other hand, primarily emphasizes the biology of nonsteroidal estrogens and antiestrogens. The chemistry is also divided in two chapters. Chapter Three covers the synthesis and the biological activity of various 19-norsteroids and progesterone-like compounds. Other chemical antifertility agents, referred to as nonsteroidals, are discussed in Chapter Five. The free use of flow diagrams and isolated structures brings to light the various routes and rationale that medicinal chemists have explored over the past decade.

Finally, the big plus for the book is the chapter on Assays and Screens. The author has compiled various methods that have been employed by a number of workers in screening for antifertility agents. The use of tissue slides enhances the appreciation of a novice for these assays.

All in all, the book is well written and the chapters are well coordinated. It does have, however, many typographical errors especially in Chapter Five. A chapter on "absorption, excretion, and metabolism" of existing contraceptive agents, in my opinion would have contributed immensely. Also, some mention of male antifertility would have been in order even though the editors did explain its omission in the Preface. The book can certainly be recommended for advanced graduate students and researchers in the field of contraception.

Isolation and Identification of Drugs (in pharmaceuticals, body fluids and post-mortem material). Edited by E. G. C. CLARKE. The Pharmaceutical Press, 17 Bloomsbury Square, WC-1, London, England. U. S. distributor: Rittenhouse Book Store, 1706 Rittenhouse Square, Philadelphia, PA 19103, 1969. xxii + 870 pp. 14.8 × 22.6 cm. Price \$39.00.

Clarke has drawn into monograph form drug identification methods, properties, metabolism, and toxicology. Most of this vast amount of information was available previously in assorted compilations but this book is the first large-scale collation of data of greatest interest to toxicologists, biochemists, pharmacists, pathologists, and forensic and pharmaceutical chemists. There is a clear need for this compilation and one can only regret the rapid obsolescence inherent in these active areas of research. All the more for this admirably printed and bound volume. The book was produced by the Pharmaceutical Society of Great Britain as a companion volume to the *Extra Pharmacopoeia*.

The essence of the work is the Monograph. Most concern commercial drug substances but some pesticides, herbicides, and hallucinogens are included. Unfortunately, the editor does not state criteria for selection or a cutoff date so one wonders at the absence of some recent, noted drugs. As most important compounds are listed, there is little loss in scope of coverage when transplanted to this country. Each monograph ideally contains statements or paragraphs on title, pharmacologic category, synonyms, trade names, structure, physical properties, screening tests, extraction, coded chromatographic systems, UV and IR absorption, references to

REVIEWS

Legal Medicine Annual. Edited by CYRIL H. WECHT, M.D., J.D. Appleton-Century-Crofts, 440 Park Ave., New York, NY 10016, 1969. 442 pp. 16.7 × 24.4 cm. Price \$14.00.

This book contains 22 monographs by 26 authors covering various aspects of forensic medicine. The largest part of the book is devoted to a discussion of professional liability and forensic toxicology. The remainder of the book is rounded out with a discussion of criminal responsibility, organ transplantation, and abortion laws.

Two chapters that deserve special mention are: *Chapter 8*, dealing with the preparation for trial in drug liability cases. The author gives an excellent discussion of how probing an attorney's inquiry can be into the facts and responsibilities for adverse drug reactions.

Chapter 5 gives a clear overview of the medicolegal problems of hospital liability and the extent to which the courts are forcing hospitals to exercise increasing control over medical staff conduct. While this chapter focuses on potential liability of the medical staff, it is clear that members of the paramedical staff, such as, clinical pharmacists and nurses can face the same types of potential liability.

A book of this nature would not be of interest to the pharmaceutical scientist or pharmacy practitioner unless he has a strong interest in medicolegal problems.

Physician's Book Compendium. Edited by MAX CELNIK. Physician's Book Compendium, Inc., 25 West 45th St., New York, NY 10036, 1969. xxvi + 846 pp. 17 × 23.5 cm. Price \$29.50.

While the idea behind the "Physician's Book Compendium" of compiling into one source all books from the medical field and giving pertinent bibliographic information is sound and would have useful applications, the product of this idea falls considerably short of its goal, as stated in the Preface, of being "an indispensable reference volume."

Probably the first objectionable feature that the user would notice is the inserts of business reply cards, provided for ordering books. The thickness of these inserts, and their location interspersed throughout the text, makes flipping pages difficult. The next annoyance is the numerous pages of advertisements scattered throughout the volume; they seem to be out of place in a book of this type. The very fact that this book costs nearly thirty dollars and is filled with ads, in itself, might be objectionable to some purchasers of this book.

Had both of these aforementioned materials been placed at the beginning or end of the book, the usefulness of the book would have been somewhat increased, as well as bettering its appearance.

The paragraph summaries, which are not provided for all books, read like the publicity flyers sent out by the publishers. No attempt could be discerned to evaluate or critique any book, an omission which certainly detracts from the value of the compendium. This omission is particularly significant with regard to the older books.

With just a quick check of the section on "Pharmacology," it was noted that nearly half of the books included were published before 1964. One cannot help but wonder if these are all significant, classic books, or if they were included to fill out the space available.

The inclusion of books with a popular approach or nature tends to diminish any remnant image of a scholarly attempt at compiling a technical work.

The use of the same type face, although admittedly a little larger, for both the subheads within sections and the authors' last names adds to the reader's confusion.

While there is apparently a need for this type of book and the editors have made an initial step, it would be difficult, if not impossible, to recommend this book for general use.

Contraception: The Chemical Control of Fertility. Edited by DANIEL LEDNICER. Marcel Dekker, Inc., 95 Madison Ave., New York, NY 10016, 1969. xiv + 269 pp. 15.5 × 24 cm. Price \$13.75.

This is an excellent book for researchers who are entering the field of female antifertility. It contains six chapters which deal with biology and chemistry of steroidal and nonsteroidal agents. Each chapter is authored by men who are well versed in their respective fields.

Chapter One introduces the reader to the reproductive cycle of the human female and discusses the interplay between the hypothalamus, pituitary, and ovary.

Chapters Two and Four emphasize the biology of steroidal and nonsteroidal compounds that are either being used as contraceptive agents or have been evaluated in animals. Chapter Two in particular discusses in detail the mode of action and the rationale for selecting the present steroidal contraceptive agents. Chapter Four, on the other hand, primarily emphasizes the biology of nonsteroidal estrogens and antiestrogens. The chemistry is also divided in two chapters. Chapter Three covers the synthesis and the biological activity of various 19-norsteroids and progesterone-like compounds. Other chemical antifertility agents, referred to as nonsteroidals, are discussed in Chapter Five. The free use of flow diagrams and isolated structures brings to light the various routes and rationale that medicinal chemists have explored over the past decade.

Finally, the big plus for the book is the chapter on Assays and Screens. The author has compiled various methods that have been employed by a number of workers in screening for antifertility agents. The use of tissue slides enhances the appreciation of a novice for these assays.

All in all, the book is well written and the chapters are well coordinated. It does have, however, many typographical errors especially in Chapter Five. A chapter on "absorption, excretion, and metabolism" of existing contraceptive agents, in my opinion would have contributed immensely. Also, some mention of male antifertility would have been in order even though the editors did explain its omission in the Preface. The book can certainly be recommended for advanced graduate students and researchers in the field of contraception.

Isolation and Identification of Drugs (in pharmaceuticals, body fluids and post-mortem material). Edited by E. G. C. CLARKE. The Pharmaceutical Press, 17 Bloomsbury Square, WC-1, London, England. U. S. distributor: Rittenhouse Book Store, 1706 Rittenhouse Square, Philadelphia, PA 19103, 1969. xxii + 870 pp. 14.8 × 22.6 cm. Price \$39.00.

Clarke has drawn into monograph form drug identification methods, properties, metabolism, and toxicology. Most of this vast amount of information was available previously in assorted compilations but this book is the first large-scale collation of data of greatest interest to toxicologists, biochemists, pharmacists, pathologists, and forensic and pharmaceutical chemists. There is a clear need for this compilation and one can only regret the rapid obsolescence inherent in these active areas of research. All the more for this admirably printed and bound volume. The book was produced by the Pharmaceutical Society of Great Britain as a companion volume to the *Extra Pharmacopoeia*.

The essence of the work is the Monograph. Most concern commercial drug substances but some pesticides, herbicides, and hallucinogens are included. Unfortunately, the editor does not state criteria for selection or a cutoff date so one wonders at the absence of some recent, noted drugs. As most important compounds are listed, there is little loss in scope of coverage when transplanted to this country. Each monograph ideally contains statements or paragraphs on title, pharmacologic category, synonyms, trade names, structure, physical properties, screening tests, extraction, coded chromatographic systems, UV and IR absorption, references to

quantitative methods, dose, metabolism, and an abstract of the referenced toxicology literature.

Following the monographs are individual collations of each identity test. Drugs are grouped under the standard chromatographic systems. Melting points, UV maxima, and IR bands are listed numerically with the drugs entered opposite. Color test data are compiled by observed reaction. Such devices are familiar and welcome to those experienced in qualitative organic analysis. Hundreds of IR spectra are reproduced, six to a page, and the transparent plastic bookmark carries wavelength and wavenumber grids to be superimposed on the spectra. This is attractive, but of questionable value in view of the difficulty in obtaining sufficiently pure samples and the ready availability of spectra elsewhere. Problems caused by the polymorphism of some categories of drugs also are not signaled. Appendixes include preparation of many reagents, description of color tests, the bibliography, and a good index.

Ten introductory chapters supply general discussion in support of the contents of the monographs. The first chapter contains rapid screening procedures for drug types known to account for most of drug ingestion cases brought to hospitals. Subsequent chapters discuss the three monograph chromatographies, spectrophotometric techniques, the older color and crystal tests, extraction procedures, and drug metabolism. At first notice, Smith's chapter on patterns of drug metabolism may appear unrelated to some readers. Further thought reveals the necessity of knowing excretion and metabolic aspects of drugs in humans. Little value to haphazard searching of the wrong tissues or fluids for evidence of a drug or more commonly, overlooking major metabolites while searching only for unchanged drug. An observation may be made that the monographs and tables are concerned with unchanged drugs and the general omission of metabolite identification is a weakness in this work. This is partly editorial, but also reflects the limited information in this area.

The major weakness of the volume lies in the area of sample isolation. As now offered, the book is largely one of identification methods. Common clean-up techniques aren't presented in a usable form. Isolation methods from pharmaceuticals just aren't treated. It is not a text for isolation and purification of samples.

Clarke's compilation is a practical fusion of qualitative organic analysis and toxicology in monograph form. The reference value of this work is unquestionable. This and the several innovations strongly recommend the volume to laboratories handling compounds of biomedical interest.

Marine Pharmacology. By MORRIS H. BASLOW. Williams and Wilkins Co., Baltimore, MD 21202, 1969. xiv + 286 pp. 18 × 26 cm. Price \$19.75.

The text represents the first comprehensive coverage of the embryonic field of marine pharmacology. It is the outgrowth of the author's interest in this field developed from a graduate course on the subject presented at the University of Hawaii for three years. In its comprehensive overview coverage, one finds chapters ranging from the antibiotic activity of sea water, through the biodynamic principles of various phyla of microorganisms, algae, sponges, jellyfish, marine worms, molluscs, arthropods, echinoderms, and finally culminating in the various higher vertebrates.

Since no other basis for classification is yet reasonable, the taxonomic one used by the author is very effective. Each chapter on a particular phylum is logically arranged and follows a smooth progression of subcategories so designed as to point out bioactive data in an easily readable fashion. References are at the end of each chapter and are numerous and current. For example, the chapter on blue-green algae starts with a brief consideration of the characteristics of the group and the history of reviews on the subject then proceeds through the known chemistry performed on bioactive algal principles, the pharmacology and toxicity of their active substances, and a conclusion based on the potential for the development of useful drugs or other agents from the phylum.

The chapters are profusely illustrated with tables containing pertinent condensed data from numerous investigators. Many

chemical structures of known substances are also given as well as reproductions of kymograph and physiograph recordings of effects of the more important marine principles on various test organisms. The final chapter summarizes in table form (10 pages), the pharmacological potential of substances isolated from marine organisms. The index is excellent and complete so that one can start with the name of an organism, the chemical principle, or type of activity and find a summary on these as well as appropriate references in the current scientific literature.

The text is to be highly recommended for use by pharmacologists, pharmaceutical chemists, and pharmacognosists as a prime reference on the subject. The main, and perhaps only, undesirable feature is the high price for this publication. If the publishers wish to make it readily available at all levels of interest, the price should be reduced considerably. In addition, the first eight pages (two of which contain four-color photographs of marine organisms), are printed on glossy paper while the remainder of the text is printed on less expensive yellowish stock paper.

Marine Pharmacology. By MORRIS H. BASLOW. Williams and Wilkins Co., Baltimore, MD 21202, 1969. xiv + 286 pp. 18 × 26 cm. Price \$19.75.

The text represents the first comprehensive coverage of the embryonic field of marine pharmacology. It is the outgrowth of the author's interest in this field developed from a graduate course on the subject presented at the University of Hawaii for three years. In its comprehensive overview coverage, one finds chapters ranging from the antibiotic activity of sea water, through the biodynamic principles of various phyla of microorganisms, algae, sponges, jellyfish, marine worms, molluscs, arthropods, echinoderms, and finally culminating in the various higher vertebrates.

Since no other basis for classification is yet reasonable, the taxonomic one used by the author is very effective. Each chapter on a particular phylum is logically arranged and follows a smooth progression of subcategories so designed as to point out bioactive data in an easily readable fashion. References are at the end of each chapter and are numerous and current. For example, the chapter on blue-green algae starts with a brief consideration of the characteristics of the group and the history of reviews on the subject then proceeds through the known chemistry performed on bioactive algal principles, the pharmacology and toxicity of their active substances, and a conclusion based on the potential for the development of useful drugs or other agents from the phylum.

The chapters are profusely illustrated with tables containing pertinent condensed data from numerous investigators. Many

chemical structures of known substances are also given as well as reproductions of kymograph and physiograph recordings of effects of the more important marine principles on various test organisms. The final chapter summarizes in table form (10 pages), the pharmacological potential of substances isolated from marine organisms. The index is excellent and complete so that one can start with the name of an organism, the chemical principle, or type of activity and find a summary on these as well as appropriate references in the current scientific literature.

The text is to be highly recommended for use by pharmacologists, pharmaceutical chemists, and pharmacognosists as a prime reference on the subject. The main, and perhaps only, undesirable feature is the high price for this publication. If the publishers wish to make it readily available at all levels of interest, the price should be reduced considerably. In addition, the first eight pages (two of which contain four-color photographs of marine organisms), are printed on glossy paper while the remainder of the text is printed on less expensive yellowish stock paper.

NEW JOURNALS

Comparative and General Pharmacology. Edited by G. A. KERKUT and G. N. WOODRUFF. Sciencetechnica Ltd., 823-825 Bath Road, Bristol, England BS4 5NU, 1970. i + 128 pp. 18 × 24.5 cm. Price: Annual Subscription \$40, Single Copies \$11. (English)

This quarterly journal will publish original research on all aspects of pharmacology with special emphasis on comparative pharmacology. Occasional review articles and short communications will also be published. The editor, Professor G. A. Kerkut, is in the Department of Physiology and Biochemistry, University of Southampton, Southampton, England. ■

NOTICES

Pharmaceutical Handbook. Edited by R. G. TODD. The Pharmaceutical Press, 17 Bloomsbury Square, W. C. 1 London, England, 1970. xv + 702 pp. 12.5 × 19 cm. Price \$9.50.

Chirurgenverzeichnis. By BURKLE DE LA CAMP. Springer-Verlag, Heidelberger Platz 3, 1 Berlin 33, Germany, 1970. viii + 1088 pp. 14.5 × 21 cm. Price \$20.90. (German)

Gas-Liquid Reactions. By P. V. DANCKWERTS. McGraw-Hill Book Co., 330 West 42nd St., New York, NY 10036, 1970. xiii + 276 pp. 15.5 × 23.5 cm. Price \$11.50.

Methods of Biochemical Analysis, Vol. 18. Edited by D. GLICK. Wiley, 605 Third Ave., New York, NY 10016, 1970. vi + 421 pp. 15 × 23.5 cm. Price \$16.50.

Ingredient X. The Production of Effective Drugs. By LOUIS C. SCHROETER. Pergamon Publishing Co., Maxwell House, Fairview Park, Elmsford, NY 10523, 1969. vii + 157 pp. 13.5 × 20.5 cm. Price \$7.75.

Mutation as Cellular Process. Edited by G. E. W. WOLSTENHOLME and MAEVE O'CONNOR. J. & A. Churchill Ltd., 104 Gloucester Place, London, England, 1969. xi + 244 pp. 15.5 × 23.5 cm.

Homeostatic Regulators. Edited by G. E. W. WOLSTENHOLME and JULIE KNIGHT. J. & A. Churchill Ltd., 104 Gloucester Place, London, England, 1969. viii + 327 pp. 15.5 × 23.5 cm.

Foetal Autonomy. Edited by G. E. W. WOLSTENHOLME and MAEVE O'CONNOR. J. & A. Churchill Ltd., 104 Gloucester Place, London, England, 1969. x + 326 pp. 15.5 × 23.5 cm.

Microbiologie Industrielle et Genie Biochimique. By P. SIMON and R. MEUNIER. Masson et Cie, 120 Boulevard Saint-Germain, Paris, France, 1970. vi + 567 pp. 16.5 × 25 cm. Price 180 fr. (French)

quantitative methods, dose, metabolism, and an abstract of the referenced toxicology literature.

Following the monographs are individual collations of each identity test. Drugs are grouped under the standard chromatographic systems. Melting points, UV maxima, and IR bands are listed numerically with the drugs entered opposite. Color test data are compiled by observed reaction. Such devices are familiar and welcome to those experienced in qualitative organic analysis. Hundreds of IR spectra are reproduced, six to a page, and the transparent plastic bookmark carries wavelength and wavenumber grids to be superimposed on the spectra. This is attractive, but of questionable value in view of the difficulty in obtaining sufficiently pure samples and the ready availability of spectra elsewhere. Problems caused by the polymorphism of some categories of drugs also are not signaled. Appendixes include preparation of many reagents, description of color tests, the bibliography, and a good index.

Ten introductory chapters supply general discussion in support of the contents of the monographs. The first chapter contains rapid screening procedures for drug types known to account for most of drug ingestion cases brought to hospitals. Subsequent chapters discuss the three monograph chromatographies, spectrophotometric techniques, the older color and crystal tests, extraction procedures, and drug metabolism. At first notice, Smith's chapter on patterns of drug metabolism may appear unrelated to some readers. Further thought reveals the necessity of knowing excretion and metabolic aspects of drugs in humans. Little value to haphazard searching of the wrong tissues or fluids for evidence of a drug or more commonly, overlooking major metabolites while searching only for unchanged drug. An observation may be made that the monographs and tables are concerned with unchanged drugs and the general omission of metabolite identification is a weakness in this work. This is partly editorial, but also reflects the limited information in this area.

The major weakness of the volume lies in the area of sample isolation. As now offered, the book is largely one of identification methods. Common clean-up techniques aren't presented in a usable form. Isolation methods from pharmaceuticals just aren't treated. It is not a text for isolation and purification of samples.

Clarke's compilation is a practical fusion of qualitative organic analysis and toxicology in monograph form. The reference value of this work is unquestionable. This and the several innovations strongly recommend the volume to laboratories handling compounds of biomedical interest.

CONCLUDING REMARKS.....	1230

... Concepts are extremely useful to the human mind, but concepts may change and change very fast. What remains are the facts, the experimental facts, the discoveries. If a new concept leads to a discovery, you may award a prize without hesitation. But a concept without a discovery would have little chance. Concepts are instruments in scientific research. They help you to make new discoveries.

If they don't, they have no justification. And the only way you can prove the justification of a concept—the correctness of a concept—is to see if it not only explains already known facts, but also leads to a new and unexpected discovery. That proves that there is something new in the concept....

Arne Tiselius
(Nobel Laureate)

Adrenergic drugs can almost serve as a prototype for the classical development of a group of medically active compounds. The initial lead arises from the observation of physiological activity associated with a natural product. Eventually, the chemical structure of the active substance is revealed, synthetic analogs are prepared, and their pharmacological activities are determined. An empirical body of structure-action relationships develops as a result of these studies, which leads to the synthesis of more compounds and, as knowledge of structural chemistry and pharmacological mechanisms becomes more refined, ideas concerning the relationship of chemical structure and pharmacological action become less empirical.

All these steps have been followed in developing the area of adrenergic drugs to its present state. It is particularly notable that the lead compound, epinephrine, is optically active. The early syntheses leading to racemic material and the pharmacological evaluation of the racemate made it apparent that some stereoselectivity was involved since the racemate was less active than the optically active natural product. Thus, at a very early stage in the development of adrenergic drugs, steric effects were observed. It is surprising that more resolutions were not performed and absolute configurations were not determined for many of the major synthetic analogs until recently. However, some attempts have

been made to review natural asymmetry and pharmacologic action (1, 2). The current revival of interest in this area makes it desirable to review what is known about steric effects and adrenergic agents.

A detailed discussion of adrenergic mechanism would be out of place here, but a brief review of some basic concepts is essential for any meaningful discussion of steric aspects.

Ahlquist (3) suggested the terms α and β for two different types of adrenergic receptors. This classification was based on the comparative effectiveness of the compounds epinephrine, norepinephrine, and isoproterenol on various tissues. In those tissues where the order of activity was epinephrine \geq norepinephrine \gg isoproterenol, the receptors were called α and associated with excitation or contraction. In tissues where the order was isoproterenol \gg epinephrine \geq norepinephrine, the receptors were designated β and associated with inhibition of function or relaxation. The validity of this concept, at least with respect to certain tissues, has been supported by experiments with selective antagonists, some of which block only α -effects and some of which block only β -effects. Other types of adrenergic receptors have been suggested, but most of the experimental work to date has been done with so-called α -agonists and β -agonists and their respective antagonists. A more complete discussion of the concepts of α - and β -receptors may be found in a recent publication (4).

The concept of direct and indirect action has received ample experimental verification. In its simplest sense, it suggests that sympathomimetic agents may act: predominantly directly, that is, at the effector site; predominantly indirectly, by releasing endogenous norepinephrine; or by a combination of these processes. Actually, there is evidence that the mechanism of action of indirect-acting sympathomimetic amines is more complex. Many indirect acting agents appear to block the uptake of norepinephrine as well as cause its release (5).

Regardless of the intricacies of the mechanism of action of indirect-acting sympathomimetic agents, it is important to keep in mind that drugs which are closely related structurally, such as the phenethylamines, may produce pharmacologically identical effects by different mechanisms. Analyses of structural or stereochemical requirements for activity are considerably complicated by this fact, and comparative studies of sympathomimetic amines done prior to the establishment of this concept must be reevaluated in modern terms.

Uptake of catecholamines by adrenergic nerves has been shown to proceed against a concentration gradient, and it seems that a saturable active transport system is involved. Iversen (6) has defined two uptake processes: uptake₁ and uptake₂. Uptake₁ is operative at low perfusion concentrations, accumulated norepinephrine is not readily washed out by perfusion with norepinephrine-free medium, and the process appears to be stereoselective for the enantiomers of both norepinephrine and epinephrine. Uptake₂ is operative at higher concentrations. The uptake is characterized by rapid washout of accumulated norepinephrine and complete lack of stereoselectivity. After exogenous catecholamines pass through the neuronal membrane, they may be retained by storage granules inside the neurone. There is

considerable evidence for the existence of more than one pool of stored catecholamines within the neurone. Perhaps the most complete information available deals with norepinephrine storage granules isolated from bovine splenic nerves and the adrenal medulla (7). The ability of these isolated storage granules to accumulate the isomers of norepinephrine, epinephrine, and some related compounds has been studied and will be discussed later.

Before leaving the subject of uptake and storage, the effects of cocaine and reserpine must be mentioned. These two drugs have been widely used as pharmacological tools in the study of adrenergic mechanisms. Cocaine apparently acts by inhibiting uptake of catecholamines and related compounds at the adrenergic neurone membrane. On the other hand, reserpine appears to exert its effect on the intraneuronal storage mechanisms and acts to prevent accumulation of norepinephrine or related compounds. Reserpine does not affect neuronal membrane uptake. The recently published monograph by Iversen (6) provides a detailed and extensively documented discussion of various aspects of the uptake and storage processes.

STEREOCHEMICAL NOTATION

Any discussion of stereochemical aspects of drug action must involve the proper use of notation to identify and specify the actual three-dimensional characteristics of the molecules considered. The small capital letters D and L are generally used to denote the configuration of an asymmetric carbon atom (Structure I) in a molecule of the type:

The molecule is oriented so that the number 1 carbon of the principal chain is at the top in the usual Fischer projection (8). This is sometimes stated differently, that is, that the carbon in the highest oxidation state is at the top, but since this would be the number 1 carbon, there is no conflict between these statements. If, when the molecule is so oriented, X is on the right, the configuration is said to be D; if X is on the left, the term L is used. These letters should *never* be used to denote sign of rotation. In many cases the lower case letters *d* and *l* (*dextro* and *levo*) have been used to specify sign of rotation, but this can lead to ambiguities. Some authors, particularly in the biological literature, use the upper case and lower case symbols interchangeably. For example, in some studies of sympathomimetic amines, the more active enantiomer of norepinephrine has been referred to as the L-isomer. In these cases, this means levorotatory; but most chemists would interpret this as meaning the "L" configuration, and the L isomer of norepinephrine is dextrorotatory. This example should suffice to show that when either upper case or lower case symbols of this type are used, the reader cannot be sure which enantiomer is being discussed.

The most reliable notation for specifying absolute configurations is usually referred to as the "sequence

rule." This method has been described in the literature (9) and has been widely accepted. An important distinction between the sequence rule and DL nomenclature is that while the symbols D and L relate the configuration of a molecule to some arbitrary standard, the sequence rule notation is self-consistent for the molecule in question but cannot be used to relate a series of compounds. This can be most clearly seen by considering the following compounds (Structures II and III):

These two compounds are obviously related configurationally and have the same absolute configuration. However, due to the difference in atomic number of the substituents, L-alanine has the S-configuration while L-cysteine has the R-configuration.

Medicinal chemists and pharmacologists are often interested in describing structure-action relationships in a series of structurally related drugs. When this is done, it makes little difference which method is used to describe the compounds evaluated as long as the method is unambiguous. For this reason, the symbols D, L, *d*, and *l* should not be used in these cases. Rotations, if desired, should be indicated by either (+) or (−), and absolute configurations by either R or S. Throughout this review, isomers are identified by the signs (+) or (−).

FACTORS COMPLICATING INTERPRETATION OF RESULTS

In every review or symposium, it has become increasingly important to discuss factors that can influence the interpretation of results. This review on optical isomers cannot be an exception. First and most important, when the activity of (−)- and (+)-isomers is compared, it is assumed that both forms are pure. However, this may not be the case. The activity ratios between (−)- and (+)-isomers of isoproterenol were reported as 11.8 for cat blood pressure (10) and 87.45 for dog blood pressure (11). Subsequently, Lands *et al.* (12) obtained higher activity ratios, 1000 for cat blood pressure and 450 for dog blood pressure. They pointed out that constant specific rotation or melting point is not the best criterion for optical purity, but that constant biological activity is.

Occasionally, pharmacologic activity of (−)- and (+)-isomers is expressed in mcg./kg. or mcg./ml. If both isomers have identical salts, it should not influence the calculation of the activity ratio. However, if one isomer is bitartrate salt and the other is hydrochloride salt, it will obviously affect the expression of the activity ratio. Hence, the dose or concentration should be expressed in molar terms, which necessitates knowing the molecular weight of a given drug. Further, it is interesting to know that different physical forms can have different biologic activity. Lands *et al.* (12) found that (+)-isoproterenol as a bitartrate salt is more toxic than when given as a base dissolved with dilute hydrochloric acid. Unfortunately, where the isomers are obtained from outside sources,

frequently the physical form of the isomers is not explicitly stated.

Pharmacologic activity of the sympathomimetic agents at adrenergic synapses is complicated by functional integrity of the uptake site (or transfer site) or storage site or by the presence of both α- and β-adrenergic receptors. The enzymes, dopamine-β-hydroxylase, monoamine oxidase (MAO), and catechol-*o*-methyl transferase (COMT), further complicate the situation. Optical isomers of adrenergic drugs are known to interact differently with many of these factors that influence pharmacologic activity. Depending upon the objective of the investigator in a given problem dealing with optical isomers, the following modifications can be made:

1. Reserpine pretreatment can be given to an animal to eliminate stored norepinephrine. Sufficient time must be allowed between reserpine pretreatment and depletion of endogenous norepinephrine. Korol *et al.* (13) studied optical isomers of octopamine on the cardiovascular system of the dog and concluded that both isomers of octopamine are acting directly. However, only 1 hr. was allowed between reserpine treatment and testing of the isomer. It is well known that during the early phase of action of reserpine, the effects of tyramine or phenethylamine are potentiated.

2. Cocaine can be used to inhibit uptake at the adrenergic neuronal membrane.

3. If the pharmacologic effects of closely related agents such as (+)-isomers and corresponding deoxy derivatives¹ are to be studied, it is important that the enzyme, dopamine-β-hydroxylase, be inactivated by a suitable inhibitor. Many deoxy derivatives are good substrates for this enzyme. Shore (14) and Patil *et al.* (15) used a similar approach when activity of deoxy derivatives was compared with corresponding (−)- or (+)-isomers.

4. Comparative pharmacologic effects of α-methylated and non-α-methylated sympathomimetic amines should be studied under the influence of MAO inhibitor because the latter amines are quickly inactivated by enzyme monoamine oxidase. Selection of monoamine oxidase can add one more variable in experimental design. The enzymatic action can be avoided by studying α-methylated amines only.

5. Although in some tissues the role of COMT in termination of pharmacologic effect of (−)-norepinephrine may be negligible, its role for that of (+)-isomer is yet undefined. Recently, fairly stable inhibitors of this enzyme were available. Comparison of activity of both isomers of norepinephrine in the presence of cocaine and under the influence of COMT inhibitor should give a better idea regarding the activity ratio of these antimers. It is difficult to talk about the receptor level when drug effects on a complex parameter such as blood pressure are studied. Studies on isolated tissues are better for controlling the variables.

6. While studying α-adrenergic receptors, β-receptors should be blocked by a suitable β-blocker which has a minimal α-adrenergic blocking property. Rat vas

¹ Amine without β-hydroxyl group. The term deoxy derivative will be used interchangeably with the other name of the amine, for example, deoxymetaraminol or α-methyl-*m*-tyramine.

deferens, seminal vesicles, rabbit aorta, cat spleen, mouse spleen, and cat nictitating membrane are generally used for testing α -adrenergic drug activity. Guinea pig atria, trachea, and rat uterus are generally used for testing β -adrenergic activity. If desired, different tissues from the same species could be used. Every test tissue has its own characteristic. Some sympathomimetic amines produce tachyphylaxis (acute tolerance), and the rate of tachyphylaxis varies with different isomers (16, 17). Two tachyphylactic amines, therefore, cannot be assayed on the same tissue. This introduces some variability in testing procedure and, hence, in the interpretation of results. By taking care of variables in experimental design, facts are clearly exposed. Furchgott (18) has critically evaluated various problems in a study of adrenergic drugs.

Frequently, biological activity of a single isomer is derived from that of the racemic form. However, some wrong assumptions may be made. Various possibilities can occur:

1. Only one isomer is active while the other isomer is practically inactive; for example, (–)-isopropylmethoxamine is a potent β -adrenergic blocker on trachea while (+)-isopropylmethoxamine is practically inactive (15).

2. One isomer is relatively more active than the other isomer. Both the isomers of sotalol are active in blocking β -adrenergic receptors. The pA_2 value for the (–)-isomer is 6.8 and that of the (+)-isomer is 5.15. The effect is stereoselective² (19).

3. Both the optical isomers can be equiactive. On the isolated rat vas deferens, isomers of hydroxyamphetamine produce equal effects which do not differ from racemic hydroxyamphetamine (20).

4. A given isomer may not produce any apparent effect, but it may be antagonistic to the pharmacological effects of other isomers. Luduena (21) reported that (+)-isoproterenol antagonizes the effects of (–)-isoproterenol.

5. Similarly, Fielden and Green (22–24) found that (+)-*N*-(1-phenethyl)guanidine has little effect of its own but antagonizes the potent adrenergic neurone-blocking effect of the (–)-form.

6. A very unusual finding reported by Porter *et al.* (25) is that racemic α -methyl-*p*-tyrosine causes greater depletion of norepinephrine from tissues than either isomer alone. In other words, the racemic form can behave as the third molecular species.

Occasionally, the relationship between the activity of (+)- and (–)-isomers may be different when different parameters are used. (+)- β -Hydroxyphenethylguanidine has about one-quarter the norepinephrine-depleting activity of the (–)-isomer. However, as compared to the (–)-form, the (+)-isomer is more effective in preventing ptosis caused by the adrenergic neurone-blocking agent. Such findings might be very useful in analyzing the mechanism of drug action. These observations clearly state that the norepinephrine depletion caused by the drug and the antagonism of the adrenergic neurone blockade are two different mechanisms (26).

Over the years, radiolabeled agents have facilitated research projects on adrenergic drugs, but they also have

Scheme I

added another complication. Many labeled sympathomimetic drugs are only available in racemic form. When single desired isomers of high specific activity become available, it will be necessary to reevaluate some previous studies with the racemic form. The role of single molecular species then will be clarified.

BIOSYNTHESIS

The biosynthetic pathway by which norepinephrine and epinephrine are formed has been intensively studied, and a recent review summarizing this work has appeared (27).

All of the work to date has confirmed the original postulation of Blaschko (28) with respect to the major pathway in animals (Scheme I).

The substrates for the first two steps are optically active compounds. Dopamine, while not optically active, yields an optically active product, (–)-norepinephrine, which can then be converted to another optically active compound, (–)-epinephrine. Each of these reactions may, therefore, exhibit some stereochemical features which will be considered at this point.

Tyrosine → Dihydroxyphenylalanine

The action of tyrosine hydroxylase has been studied by several groups, and the properties of the enzyme have been defined (29). D-Tyrosine, tyramine, DL-*m*-tyrosine, and L-tryptophan were found to be inactive as sub-

² This term is preferred over stereospecificity.

strates, indicating a high degree of structural and stereochemical specificity (30).

Dopa → Dopamine

The enzyme responsible for this conversion is best known as dopadecarboxylase, although the term aromatic L-amino acid decarboxylase is probably more correct (31). As this name suggests, the enzyme is stereospecific because L-aromatic amino acid does not decarboxylate D-dopa (28, 32, 33). It has been shown, however, that D-dopa is converted to dopamine *in vivo*, presumably by conversion to the keto acid followed by transamination to give L-dopa (34).

In addition, it has been demonstrated (35) that the enzymatic decarboxylation of amino acids proceeds with retention of configuration. Obviously, this point is not a major one in the reaction $\text{dopa} \rightarrow \text{dopamine}$, since dopamine contains no asymmetric carbons. It is of major importance, however, in the reaction of α -methylated amino acids, where both the substrate and the product contain asymmetric carbon atoms. The α -methylated analogs of many sympathomimetic amines have been the subject of widespread interest because of their ability to act as false adrenergic transmitters (36).

Biochemically active α -methyldopa has been shown to have the S-configuration (37). This corresponds to the L-configuration of dopa. Decarboxylation of this compound with retention of configuration should yield α -methyldopamine, which also has the S-configuration (Scheme II).

The observation that decarboxylation of L- α -amino acids produces dextrorotatory α -methylamines (38), coupled with the proof that the absolute configuration of levorotatory α -methyldopamine (not the natural metabolite) is R (39), establishes the absolute configuration of the natural metabolite as S and serves as proof for the retention of configuration in the α -methyl series.

Dopamine → Norepinephrine

This transformation is catalyzed by the enzyme dopamine- β -oxidase, whose properties have been recently reviewed (40).

The substrate specificity of dopamine- β -oxidase is rather low. In the case of the conversion of dopamine to norepinephrine, substrate stereospecificity is not a factor since the substrate contains no asymmetric carbons. The product, (–)-norepinephrine, has the R-configuration.

In the case of substrate with an α -methyl group,

substrate stereospecificity is involved, and several studies have demonstrated that only one enantiomer is β -hydroxylated (41–44).

In the series under discussion, where the sequence rule priorities of functional groups remain essentially the same, those enantiomers with the S-configuration at the β -carbon are active substrates while those with the R-configuration are not. The introduction of the hydroxyl group at the β -carbon is apparently stereospecific, yielding compounds whose absolute configurations at the β -carbon are the same as R(–)-norepinephrine. Thus, S(+)- α -methyldopamine is converted to α S, β R(–)- α -methylnorepinephrine.

Norepinephrine \rightleftharpoons Epinephrine

This interconversion is catalyzed by phenethanolamine-N-methyltransferase, which can utilize both enantiomers as substrates, those with the R-configuration showing greater activity (45).

SELECTIVITY OF UPTAKE AND STORAGE MECHANISM FOR OPTICAL ISOMERS

After reviewing different papers on this subject, a need for consistent terminology became evident. For the sake of uniformity, the term accumulation is preferred over deposition, uptake site over transfer site, and release over efflux or chemorelease. In many instances the drug was injected by various routes, and tissue accumulation was observed at a fixed time. This type of tissue accumulation will not distinguish between accumulation by adrenergic nerve endings and extra-neuronal uptake. Further, uptake by nerve endings is a two-stage process: (a) uptake by neuronal membrane in the cytoplasm, and (b) uptake by granular membrane into granules.

In 1963, Kopin and Bridgers (46) investigated the biological differences in (–)- and (+)-isomers of norepinephrine. Rats were subcutaneously injected with equal amounts of either the (±)-norepinephrine- ^{14}C and (±)-norepinephrine- ^3H or the (–)-norepinephrine- ^{14}C and (±)-norepinephrine- ^3H solutions. Animals were killed 1 or 24 hr. later; the ^3H – ^{14}C ratio in hearts and spleens was determined. From these experiments, the relative role of (–)- and (+)-norepinephrine in tissue uptake and retention was defined. They concluded that both isomers are bound to the tissue to the same extent, and that the disappearance of (+)-norepinephrine- ^3H is more rapid than that of (–)-isomer. Subsequently, Maickel *et al.* (47) reported that 5 min. after the intravenous injection of (±)-norepinephrine- ^3H , the ratio of (–)-norepinephrine- ^3H –(+)-norepinephrine- ^3H in the rat heart was 11:1. This ratio indicated a higher affinity of uptake mechanism for (–)-norepinephrine. The lack of detection of selectivity of the uptake mechanism by Kopin and Bridgers (46) was then due to methodology. Maickel *et al.* (47) separated the isomers of norepinephrine- ^3H by an isotope dilution technique. Kopin and Bridgers tested the differences after 1 hr. as compared to 5 min. by former investigators.

More details on the kinetic analysis of uptake of norepinephrine isomers were presented by Iversen (48). Isolated rat heart was perfused for various times with

different concentrations of norepinephrine isomers. The initial rates of uptake by various concentrations obeyed Michaelis-Menton kinetics. On the basis of the Michaelis constant, K_m , (+)-norepinephrine has only one-sixth the affinity for uptake as has (–)-norepinephrine. It is interesting, however, that the v_{max} for (+)-norepinephrine is higher than that for the (–)-isomer. Under similar experimental conditions, when hearts were perfused for 5 min. at 100 ng./ml. of epinephrine isomers, the tissue accumulation of (+)-epinephrine was only one-third as compared to that of (–)-epinephrine (49). This indicated differences in uptake for isomers of epinephrine. Although accumulation of (–)-norepinephrine in the adrenergic neurone is considered to be an active process (*i.e.*, against a concentration gradient), Born (50) has argued against this concept. The uptake of (–)-norepinephrine in the human erythrocytes occurs by simple diffusion. This process is also stereoselective (51). However, in contrast to the accumulation of (–)-norepinephrine in the adrenergic neurone, the accumulation in the erythrocytes is not inhibited by cocaine. Thus there appears to be some differences between the process of accumulation in these two systems. Selectivity of accumulation of norepinephrine isomers was also studied in the guinea pig heart (52). After intravenous injection of 1 μ mole/kg. of the appropriate isomer in the anesthetized guinea pig, the norepinephrine content in the heart and aortic blood was examined. One minute after injection the net uptake of (–)-norepinephrine by the heart was higher than that of (+)-norepinephrine. However, 60 min. afterwards, the net uptake for both isomers appeared to be the same. Possibly because of the small number of observations and the large variability in results, selectivity in uptake might not have been detected.

Westfall (53) used a systematic approach to study the stereoselectivity of epinephrine accumulation in the rat heart. After equal intramuscular doses, 1 mg./kg., both (–)- and (+)-epinephrine caused a greater accumulation of (–)-isomer in the heart, with concomitant greater loss of endogenous norepinephrine. The granular fraction exhibited greater selectivity than other tissue fractions from the heart. Selectivity in accumulation of the physiologically more active isomer of epinephrine was also demonstrated in the mouse heart (54). Approximately 1 hr. after 2-mg./kg. doses, *i.p.*, of epinephrine isomers, the accumulation of (+)-isomer was only one-third of that of (–)-isomer. In mouse femoral muscle, the accumulation difference between (–)- and (+)-isomers was very small.

Work demonstrating the stereoselectivity of norepinephrine isomer uptake and storage has continued to be reported. At relatively high concentrations of norepinephrine isomers, Mueller and Schideman (55) were unable to demonstrate the stereoselectivity in the particular fractions of cat atria. Reinvestigation of the problem with a modified technique eventually did show the differences at low concentrations of these isomers (56). The accumulation of total tritium from (\pm)-norepinephrine was relatively more inhibited by unlabeled (–)-isomer. Green and Miller (57) reported that *in vitro* labeled epinephrine accumulates in the rat uterus and that (–)-norepinephrine causes greater re-

lease of labeled epinephrine while (+)-norepinephrine is significantly less effective. These results indicate a possible stereoselectivity for uptake and/or release in norepinephrine isomers. Tissue perfusion provides a better test system to demonstrate selectivity for uptake than studies in intact animals with various routes of administration. Kirpekar and Wakade (58) used perfused cat spleen to investigate several factors influencing norepinephrine uptake. When (+)-norepinephrine was infused at 0.51 mcg./min. into the arterial supply of the spleen, 55% of the infused amount was recovered in the venous effluent. The recovery for that of (–)-norepinephrine was only 34%. Results indicate a 66% accumulation of (–)-norepinephrine by spleen and only 45% for (+)-norepinephrine.

Greater accumulation of exogenous norepinephrine can be demonstrated in the tissues if endogenous norepinephrine is depleted by a suitable agent which does not drastically block or impair the storage mechanism. Mackenna (59) used prenylamine-treated rabbits to study the uptake of norepinephrine and epinephrine isomers. After injection of 0.41 mg./kg. *i.m.* of either isomer, as compared to (+)-isomers, the accumulation and retention of (–)-isomers in the heart were higher, with longer duration. Similarly, von Euler and Lishajko (60) investigated the uptake of catecholamines in rabbit hearts depleted by decaborane. When the (–)- and (+)-epinephrines were given with (–)-norepinephrine, simultaneously and in equal amounts, relative to the uptake of (–)-norepinephrine the uptake of (–)-epinephrine was 2–3 times greater than that of (+)-epinephrine. It is suggested that when isomers are taken up in specific stores, the (–)- and (+)-isomers are released at the same rate.

The amine uptake in adrenergic nerve granules from bovine splenic nerves deserves special comment, since the study of specificity of uptake on such a simple system is more meaningful. The spontaneous depletion of endogenous norepinephrine from bovine splenic nerve granules is prevented more by (–)-norepinephrine than by the (+)-isomer. The amine uptake is enhanced by adenosine 5'-triphosphate (ATP). It is concluded that uptake is stereoselective at low concentrations (1 mcg./ml.) for naturally occurring isomers of both norepinephrine and epinephrine (61). The "affinity ratio," (–)-norepinephrine-(+)-norepinephrine, is reported as 5.9:1 (62).

However, reuptake of spontaneously released norepinephrine from the surrounding medium previously distorted the calculations of the affinity ratio of norepinephrine isomers. Von Euler and Lishajko (63) overcame this difficulty by studying the affinity ratio for uptake in the presence of potassium ferricyanide, an agent which continuously removes norepinephrine from the incubation medium of adrenergic nerve granules. The mean value for the affinity ratio found by the new method was 9.4. In the partially purified preparation of norepinephrine storage granules from rat heart, Potter and Axelrod (64) tried to demonstrate the affinity differences between isomers of norepinephrine. However, the differences did not appear to be great or significant.

Under proper conditions, condensation of formaldehyde with tissue catecholamines produces green fluores-

cent adrenergic nerves. Reserpine pretreatment depletes norepinephrine and, hence, fluorescence disappears. It can be reinstituted in the nerves by a suitable catecholamine. In catecholamine-depleted rat iris and salivary glands, after equal doses of either isomers of norepinephrine, an identical fluorescent intensity was observed in the nerves (65–67). Since the method is semiquantitative, small differences in the uptake might not have been detected. The optical isomers may differ in the rate of uptake and show identical accumulation at the end of a fixed time interval. On the other hand, it may be that the uptake mechanism in the rat iris and salivary gland and that in the heart are dissimilar. In his recent study, Iversen (68) was unable to observe differences between (–)- and (+)-isomers of amphetamine in regard to the affinity in the rat iris, but the same isomers showed a 20-fold difference in heart tissue. On this basis, he concluded that the uptake mechanism in two tissues from the same species may be different.

Although (–)- and (+)-isomers of (±)-*erythro*-levonordefrin³ are resolved, (±)-pseudolevonordefrin or (±)-*threo*-levonordefrin are as yet unresolved. Hence, the question regarding stereospecificity of the levonordefrin molecule for uptake and storage is only partly answered. Muscholl and Lindmar (69) compared the uptake and binding of (–)-levonordefrin and (±)-*threo*-levonordefrin in the perfused rabbit heart. Like (–)-levonordefrin, (±)-*threo*-levonordefrin was readily taken up and retained by the heart with concomitant equivalent loss of norepinephrine. While initial uptake for (–)-levonordefrin, (±)-levonordefrin, and (±)-*threo*-levonordefrin appeared to be the same, their release rates were different. Similarly, in the mouse heart at various times after injection of 20 mcg./kg. i.v. of (±)-*threo*-³H-levonordefrin or either (±)-*erythro*-³H-levonordefrin, there was essentially equal uptake of both *erythro*- and *threo*-levonordefrin (70). But (±)-*threo*-levonordefrin (half-life, 20 hr.) appeared to leave faster than the (±)-*erythro*-form (half-life, 72 hr.). In the catecholamine-depleted rat iris, Patil and Jacobowitz (71) studied reinstitution of fluorescence caused by isomers of levonordefrin. It was observed that (–)- and (+)-levonordefrin produced equal fluorescence intensity, indicating possible equal affinity for uptake and/or storage sites. However, even higher doses of (±)-*threo*-levonordefrin failed to produce fluorescence in the nerves. Thus, histochemical evidence in rat iris is against that found in the heart. As previously stated, it is very likely that uptake characteristics are very different in the two tissues.

Under the influence of the MAO inhibitor, mialamide, the release of labeled (±)-*erythro*-levonordefrin from the mouse heart is not influenced, while (±)-*threo*-levonordefrin is virtually lost after 18 hr. (72). During the first 6 hr. after infusion, (±)-*erythro*-*N*-methyl-levonordefrin⁴ retained by the heart was lost with a half-time of 5 to 6 hr. Likewise, (±)-*threo*-*N*-methyl-levonordefrin was taken up by heart and spleen. However, the concentrations did not decrease exponentially with time and the initial rates of loss were greater than

those observed with (±)-*erythro*-*N*-methyl-levonordefrin (73, 74). Histochemical work of Patil and Jacobowitz (71) indicates that (±)-*erythro*-*N*-methyl-levonordefrin restores the fluorescence in catecholamine-depleted rat iris, while (±)-*threo*-*N*-methyl-levonordefrin does not. These findings are similar to those for (±)-*erythro*- and (±)-*threo*-levonordefrin.

Shore and Alpers (75) developed a sensitive and specific fluorometric method for the estimation of metaraminol in tissues. Since chemical methods do not distinguish between optical isomers of metaraminol, it has provided a valuable tool for studying stereoselectivity of these molecules. It was observed (76) that after injection of 50 mcg./kg. i.v. of either (–)-metaraminol, (+)-metaraminol, or (±)-deoxymetaraminol, only (–)-metaraminol was retained in the rat heart for up to 24 hr. The tissue concentration of (+)-metaraminol and (±)-deoxymetaraminol fall sharply 10–15 min. after administration. Lack of accumulation of (–)-metaraminol in immunosympathectomized animals indicated that accumulation of (–)-metaraminol in normal animals was in sympathetic nerves only. Intracellular distribution of these agents in different fractions from the heart revealed that (–)-metaraminol displaces heart norepinephrine and is significantly associated with particulate cell fraction, whereas (±)-deoxymetaraminol neither depletes norepinephrine nor is associated significantly with cell particles. Although (+)-metaraminol does not deplete norepinephrine, it shows some association with cell particles (77). *In vitro*, rabbit heart slices also exhibit selective accumulation of (–)-metaraminol over (+)-metaraminol or (±)-deoxymetaraminol. Pretreatment of these slices with imipramine or ouabain markedly inhibited accumulation of both isomers of metaraminol (78). Reserpine pretreatment does not prevent accumulation of (–)- and (+)-metaraminol. But, combined treatment of reserpine and ouabain markedly prevents the accumulation of (–)-metaraminol more than ouabain alone. A similar combination is not synergistic for prevention of the accumulation of (+)-metaraminol. On this basis, it is suggested that reserpine, perhaps by creating local ionic imbalance in the cell, allows ouabain to exert a greater effect on the local Na⁺-K⁺-ATPase-amine pump-linked mechanism which normally allows the (–)-form of catecholamine to be accumulated more rapidly than the (+)-form (79). Both in the normal and the reserpine-pretreated heart slices, the washout rate for amines is (±)-deoxymetaraminol > (+)-metaraminol > (–)-metaraminol. However, amines are washed out more easily in the reserpine-pretreated animals (80). Using (±)-metaraminol-³H, Lundborg (81) and Lundborg and Stitzel (82) elaborated on the stereoselectivity of (–)- and (+)-metaraminol in the different tissue fractions from mouse heart. The two isomers of metaraminol were able to displace (±)-metaraminol-³H from subcellular fractions of the mouse heart when given 15 min. after administration of the labeled amine. The (–)-form was more effective. If unlabeled isomers were given 24 hr. after (±)-metaraminol-³H, only the (–)-isomer was an effective agent. In the adrenal medullary granules, (–)-metaraminol was more effective in preventing the uptake of (±)-metaraminol-³H than the (+)-form (83).

^a Drugs were administered 60 min. after intravenous ^3H -NE. ^b Two hours after drug administration. Data after Daly *et al.* (89).

Histochemically, the accumulation of isomers of dopa has been studied in several tissues. The number of green fluorescent enterochromaflinlike cells that could be induced by administration of the (+)-isomer of dopa was usually smaller than that after the (-)-isomer (84). The transport of amino acid into islet cells of the rat pancreas was selective, since accumulation of (+)-dopa could not be demonstrated histochemically even after pretreatment with nialamide. In contrast to this, fluorescence developed in the exocrine cells, both after administration of (-)- and (+)-dopa (85, 86). Similarly, the parafollicular cells of mouse thyroid (87) and the endothelial cells in the capillaries of mouse brain (88) selectively accumulate the (-)-isomer of dopa. When the rat iris is incubated with (-)- or (+)-dopa, a marked diffused fluorescence is seen after (-)-dopa, while (+)-dopa is selectively accumulated in the iris capillaries.⁵

STERIC STRUCTURE-ACTIVITY RELATIONSHIPS FOR RELEASE OR DEPLETION OF ENDOGENOUS AMINES BY SYMPATHOMIMETIC AGENTS

Tissue norepinephrine-depleting effects of certain isomers are described in the previous section. Many studies, which are summarized in this section, were designed for obtaining information regarding a structural requirement for releasing biogenic amines. Daly *et al.* (89) investigated the norepinephrine-releasing potencies of a wide variety of sympathomimetic amines and related compounds. Endogenous cardiac norepinephrine was prelabeled with 5 μC . of (±)-norepinephrine-7- ^3H with a compound that caused loss of tritiated norepinephrine. Relative activities of some selected agents are presented in Table I. It is clear that monophenolic or diphenolic amines with 1R stereo-

chemistry are better at depleting cardiac norepinephrine than are corresponding isomers with 1S stereochemistry. Nonphenolic amines, in general, were very weak in depleting norepinephrine-7- ^3H . (+)-Deoxynorephedrine appeared to be a better depleting agent than (-)-deoxynorephedrine. Because enzymes in biotransformation of these agents were not inhibited, it is open to question whether observed differences between (+)- and (-)-deoxynorephedrine are valid. Loss of asymmetry by substitution of one more α-methyl group in deoxynorephedrine and deoxyephedrine made molecules very weak in depleting cardiac ^3H -norepinephrine.

Shore (14) compared the norepinephrine-depleting activity of various sympathomimetic amines in which a limited number of optical isomers was included. Drugs were given intraperitoneally to rats; 3 hr. later the change in heart norepinephrine was measured. Drugs used were optical isomers of *p*-hydroxyamphetamine, levonordefrin, and metaraminol. The structure-activity relationships showed again that (-)-metaraminol (1R) in relatively low doses, 1 mg./kg., is the most effective in depleting cardiac catecholamines. Higher doses of deoxymetaraminol (10 mg./kg.) were also effective in lowering the tissue norepinephrine, but this activity was inhibited by benzyloxyamine, an inhibitor of dopamine-β-hydroxylase.

In the isolated perfused rat heart, after labeling endogenous norepinephrine stores, release of tritiated norepinephrine by optical isomers of catecholamines was investigated by Nash *et al.* (90). The release rate for (-)-isomers of norepinephrine, epinephrine, and isoproterenol was higher than for corresponding (+)-isomers. *In vivo*, tyramine is rapidly converted to its β-hydroxylated product, octopamine. Carlsson and Waldeck (91) used this approach to study structure-activity relationships for release of ^{14}C -octopamine that was formed from ^{14}C -tyramine. Mice were injected with 0.2 mg./kg. i.v. of ^{14}C -tyramine. Fifteen minutes was allowed for conversion of ^{14}C -tyramine to ^{14}C -octopamine. Various amines were injected, and after 15 min. the loss of ^{14}C -octopamine from the heart was determined. The steric structure-activity relationship for releasing ^{14}C -octopamine is very similar to that for releasing norepinephrine.

Availability of all four isomers of ephedrine enabled Abdallah *et al.* (17, 92) to investigate the norepinephrine release by these agents. In the perfused rabbit heart, (-)-ephedrine is more effective in both the rate-accelerating effect and releasing the cardiac norepinephrine in the perfusate. However, at equivalent doses, (+)-ephedrine, (-)-pseudoephedrine, and (+)-pseudoephedrine released approximately the same amount of norepinephrine in perfusate, but their heart rate-accelerating effects were not the same.

Recently, synthesis, resolution, and pharmacology of (±)-*threo*-metaraminol and related agents have been carried out by Saari *et al.* (93), Torchiana *et al.* (44), Waldeck (94), and Carlsson *et al.* (95). (-)-α-Methyl-dopamine (deoxylevonordefrin) is approximately 3 times as potent as its (+)-form in causing norepinephrine depletion from mouse heart, while for similar effects (+)-α-methyl-*m*-tyramine is more active than its (-)-form. A reasonable and logical explanation for the

⁵ B. Hamberger and T. Malmfors, personal communication, 1969.

higher norepinephrine-depleting effects of (+)- α -methyl-*m*-tyramine (deoxymetaraminol) is that this agent is converted to (–)-metaraminol, which is a very potent agent in depleting endogenous norepinephrine. The (–)-form may not undergo similar biotransformation; in addition, the (–)-form might be inactive as such. The norepinephrine-depleting effects of the (–)- and (+)-forms of α -methyldopamine are quite opposite to those of isomers of α -methyl-*m*-tyramine. Under *in vitro* conditions when (+)-forms are incubated with semipurified dopamine- β -hydroxylase from bovine adrenal medulla, the corresponding (–)-forms of amine metabolites [namely (–)-levonordefrin from (+)- α -methyldopamine and (–)-metaraminol from (+)- α -methyl-*m*-tyramine] can be obtained. The (–)-forms of both α -methyldopamine and α -methyl-*m*-tyramine failed to yield corresponding β -hydroxylated products. This indicates that marked norepinephrine-depleting effect of (–)- α -methyldopamine might be caused by the parent molecule itself. Furthermore, it is probable that dopamine- β -hydroxylase is also inhibited by this agent. However, exogenous administration of (±)-*threo*-levonordefrin can cause dose-dependent reduction of cardiac norepinephrine, with a concomitant fall of blood pressure in rats (96). As compared to (±)-*threo*-levonordefrin, (±)-*threo*-metaraminol appears to be much less active in depleting cardiac norepinephrine from the heart.

So far, only a limited number of optical isomers have been studied. Validity of any structure–activity relationship can only be studied by investigating structurally similar isomers on one system under well-controlled experiments. Norepinephrine depletion should not only be studied at equimolar doses but at a dose which will cause equivalent depletion or release. The former criterion is easier than the latter one.

INHIBITION OF UPTAKE

Several drugs are known to inhibit the uptake of exogenous norepinephrine into the sympathetic nerve endings. In the isolated perfused rat heart, Burgen and Iversen (97) made a systematic study of chemical structure of sympathomimetic amines and its relationship to inhibition of (±)-¹⁴C-norepinephrine uptake. Similarly, in the perfused rabbit heart, Muscholl and Weber (98) studied the inhibition of uptake of levonordefrin by some sympathomimetic amines. The following generalizations can be made regarding steric structure–action relationships: (a) In phenolic amines, deoxy derivatives are more potent than their corresponding (–)-isomers which are in turn more potent than (+)-isomers. (b) In nonphenolic amines such as ephedrine and norephedrine, deoxy derivatives are also more potent than (–)-isomers. But in the latter case, the situation is complicated by two asymmetric carbons. (c) (+)-Deoxynorephedrine is about 20 times more potent in inhibiting norepinephrine uptake than that of (–)-deoxynorephedrine. (d) (+)-Norpseudoephedrine is more potent than either (–)-norephedrine or (+)-deoxynorephedrine (Table II). Ross and Renyi (99) investigated effects of a series of amines on accumulation of (±)-norepinephrine-³H in cortex slices from mouse brain. As in the

Table II—Inhibition of Norepinephrine Uptake by Sympathomimetic Amines in the Rat Isolated Heart

Agent	Steric Configuration	ID ₅₀ , ^a M	Relative Inhibition of Uptake ^b
Phenethylamine	—	1.1×10^{-6}	1.00
(–)-Norepinephrine	1R	2.7×10^{-7}	4.07
(+)-Norepinephrine	1S	1.4×10^{-6}	0.78
Deoxynorepinephrine	—	1.7×10^{-7}	6.50
(–)-Epinephrine	1R	1.0×10^{-6}	1.10
(±)-Epinephrine	—	1.4×10^{-6}	0.78
Deoxyepinephrine	—	7.6×10^{-7}	1.45
(–)-Levonordefrin	1R,2S	2.0×10^{-7}	5.50
(±)-Levonordefrin	—	4.2×10^{-7}	2.60
(±)-Deoxylevonordefrin (methyldopamine)	—	1.8×10^{-7}	6.10

heart, uptake of tritiated norepinephrine resembles that of the enzymatic reaction according to Michaelis-Menton. In a concentration-dependent manner, various sympathomimetic amines prevented accumulation of tritiated norepinephrine in brain slices. However, the slopes of these dose–response curves varied considerably. Isomers, (–) and (+), of metaraminol exhibited distinct differences; the (–)-form was more potent. At the lowest concentration, 0.1 mcg./ml. of (–)-norepinephrine and (±)-norepinephrine, the inhibition of uptake was identical. This possibly indicates that (–)- and (+)-isomers of norepinephrine may not differ in preventing accumulation of tritiated norepinephrine. It is difficult to understand why isomers of metaraminol continue to exhibit stereospecificity at various concentrations while isomers of norepinephrine, amphetamine, and norphenylephrine did not differ in this respect.

Independently and simultaneously, Thoenen *et al.* (100) and Ross *et al.* (101) have observed that tissue accumulation of labeled nonphenolic agents such as amphetamine, norephedrine, and phenylethanolamine are not influenced by cocaine. They have suggested that tissue accumulation of nonphenolic amines is a function of their physical–chemical properties, while that of monophenolic or diphenolic amines is a function of the hydroxyl group. These studies suggest that some precautions are needed in comparing uptake inhibition by phenolic and nonphenolic amines. It is reasonable to compare activity of (–)- and (+)-isomers on any single parameter because their physical–chemical properties are identical. However, to make any generalizations regarding steric structure–activity, a study of a large number of antimeric pairs of both phenolic and nonphenolic amines is required.

IMPLICATIONS OF UPTAKE, STORAGE, INHIBITION OF UPTAKE, AND RELEASE OF ADRENERGIC DRUGS

Endogenously released or exogenously administered (–)-norepinephrine is mainly inactivated by rapid uptake into the adrenergic nerve endings. (+)-Norepineph-

Figure 1—Stereoselective potentiation of isomers of levonordefrin by cocaine (5 mg./kg. i.v.) in the spinal cat. Data in part obtained from Tye *et al.* (109).

rine has very little affinity for both uptake and storage site (see *Inhibition of Uptake*). The physiologic implications of these findings are reflected in the transmitter economy. The naturally occurring (–)-norepinephrine and (–)-epinephrine are most efficiently utilized. One important concept that has emerged from the study of uptake and storage mechanisms is the concept of “false neurochemical transmitters.” It is possible to substitute a molecule which is weaker than the natural neurohormone in activating pharmacologic receptors. These agents have proved to be very valuable substances in the treatment of hypertension. The classical example is that of α -methyldopa. The biotransformation and the formation of the false neurochemical transmitter are discussed in the previous section.

Because of modern instrumentation and laboratory facilities, many research projects are being carried out at a much faster rate than they were 20–30 years ago. There is also no doubt that many recent studies are better designed than before; however, it is of historical importance to comment on early reports concerning optical isomers of various adrenergic drugs. Tainter (102) and Luduena *et al.* (103) reported that pressor effects of isomers of norepinephrine and epinephrine were potentiated by cocaine. On the other hand, pressor effects of (+)-levonordefrin and (+)-phenylephrine were unaffected or desensitized by cocaine (104, 105). The intestinal smooth muscle of an unanesthetized dog is relaxed by (–)-norepinephrine and (–)-epinephrine. This effect was potentiated by cocaine, while that of (+)-isomers was unaffected or slightly antagonized by cocaine (106).

Trendelenburg (107) and Trendelenburg *et al.* (108) studied sensitization by cocaine for (–)- and (+)-isomers of norepinephrine and epinephrine. The cat nictitating membrane effect caused by (–)-isomers was sensitized more than the corresponding (+)-isomers. Independently, Tye *et al.* (109) also investigated the influence of cocaine on the isomers of norepinephrine, epinephrine, levonordefrin, and phenylephrine. In both normal and catecholamine-depleted cats, the nictitating membrane and blood pressure effects of (–)-isomers were sensitized by cocaine. When studied similarly, the effects of (+)-isomers were less sensitized or desensitized. Unequal potentiation of optical isomers was explained on the basis of previously reported un-

equal rates of uptake of these agents into the adrenergic neurone. In terms of the structure–activity relationship, it is clear that 1R stereochemistry is necessary for stereoselective or stereospecific sensitization by cocaine. However, the role of the β -hydroxyl group becomes secondary, if the molecule is heavily substituted on nitrogen. (–)-Isoproterenol has 1R stereochemistry at C₁ but is not potentiated by cocaine. Draskóczy and Trendelenburg (110) found that over the wide range of concentrations, (–)- or (+)-norepinephrine is removed from perfusate by the heart at approximately equal rates. In the same tissue, however, cocaine did produce marked stereospecific supersensitivity in favor of the (–)-isomer. Since perfused rabbit heart did not exhibit stereospecific uptake and since cocaine did not potentiate (+)-norepinephrine, they proposed that the lack of potentiation of (+)-norepinephrine by cocaine is caused by low potency of this isomer, which exerts pharmacological effects only in concentrations that saturate the uptake mechanism. The effect of cocaine becomes negligible when the uptake site is saturated (111). It was also demonstrated that in the lower concentration, (+)-norepinephrine, which caused little effect, markedly potentiated the positive inotropic effects of the (–)-isomer. According to these observations, the stereospecificity of the sensitizing effect of cocaine can no longer be ascribed to differences in the rate of uptake of the isomers. Seidehamel *et al.* (112) selected dopamine in an attempt to determine the importance of the positional role of the β -hydroxyl group. This agent is structurally similar to norepinephrine, except it lacks the β -hydroxyl group. The sensitization of the nictitating membrane to these agents produced by cocaine has the following sequence: (–)-norepinephrine > dopamine = (+)-norepinephrine. West *et al.* (113) also attempted to explain the unequal potentiation by cocaine of (–)- and (+)-isomers of norepinephrine, metaraminol, and octopamine in relation to degree of uptake. Cocaine-induced supersensitivity in atria and the rate of uptake occurred in a diminishing fashion: (–)-norepinephrine > (+)-norepinephrine > (–)-metaraminol > (–)-octopamine > (+)-metaraminol > (+)-octopamine. Here, again, saturation of uptake rather than rates of uptake might be an important factor in explaining the rank order. Desipramine, a cocaine-like agent, is reported to produce stereoselective sensitization of norepinephrine isomers on rat vas deferens (114). Two other agents, namely prenylamine (115) and α, α' -bis(dimethylammoniumacetaldehyde diethylacetal)-*p, p'*-diacetylbi-phenylbromide (DMAE), also behave like cocaine (116). These agents markedly potentiate pressor effects of (–)-norepinephrine and produce little or no potentiation of (+)-norepinephrine. In anesthetized cat nictitating membrane, after the administration of DMAE or cocaine, Wong and Long (116) did not observe a stereospecific sensitization for (–)- and (+)-epinephrine. Thus, it appears that stereospecific or stereoselective sensitization after cocaine or cocaine-like agents would be best demonstrated in an antimer which exhibits high isomeric ratio in activation of pharmacologic receptors, as well as high affinity difference for uptake sites [e.g., (–)- and (+)-isomers of levonordefrin] (Fig. 1). As compared to other antimers, the isomeric

ratio and difference in uptake for (–)- and (+)-epinephrine are small. Hence, it may be difficult to obtain a clearcut separation by sensitizing effects of one isomer over another.

Before leaving this section, it should be emphasized that stereoselective potentiation of norepinephrine isomers by a given agent should not be taken as a criterion for cocaine-like effects. A ganglionic blocker, mecamylamine, which does not resemble cocaine in any respect, also causes stereoselective potentiation of norepinephrine isomers (117) (Fig. 2).

Various drug treatments and surgical procedures are known to produce supersensitivity to certain sympathomimetic agents. For further information, readers are referred to an excellent review on this subject (118). Surgical removal of sympathetic ganglia causes degeneration of postganglionic fibers. A few days after the procedure, there is a marked loss of transmitter. The end organ continues to develop a supersensitivity, at least until the 28th postoperative day (119). Denervation supersensitivity has two components: (a) cocaine-like and (b) nonspecific, such as described for decentralization. With any agent that interferes with the release of the neurotransmitter, the end organ develops a supersensitivity which is more like that produced by surgical decentralization. Chronic treatment with reserpine produces a decentralization type of supersensitivity.

The idea of utilizing optical isomers of sympathomimetic amines to study supersensitivity caused by denervation can be traced to as early as 1939 (120). However, it was only after the role of these agents for uptake, binding, and release had been clarified that they became useful tools for analysis of various types of supersensitivities. Trendelenburg (107) reported that 7 days after excision of the superior cervical ganglia of a cat, the denervated nictitating membrane was nearly 100 times more sensitive to (–)-norepinephrine than the corresponding normal side of the same animal. The sensitivity to (+)-norepinephrine, on the other hand, increased only by a factor of 3.5. Soon after this, it was realized that the variable tone of the denervated nictitating membrane of the spinal cat, determined under ether, complicates the accurate estimation of supersensitivities (121). Seidehamel *et al.* (122), therefore, studied the various types of supersensitivities in both normal spinal cat as well as preparations in which tone of the nictitating membrane was reduced to a relatively stable level by acute treatment with reserpine. It was concluded that supersensitivities caused by decentralization and chronic treatment with reserpine cause stereoselective potentiation in favor of (–)-norepinephrine. However, denervation supersensitivity appeared to be nonstereoselective, because both isomers of norepinephrine were equally sensitized by this procedure. The role of COMT becomes important when uptake mechanism is lost. Thus, during the investigation of stereoselectivity and nonstereoselectivity of denervation supersensitivity, the enzyme COMT should be inhibited by a stable enzyme inhibitor like tropolone. Langer *et al.* (119) reported equal sensitizing effects of dopamine and (+)-norepinephrine. Green and Fleming (123) observed that denervated cat spleen *in vitro* produced three- to fourfold potentiation of (–)-norepinephrine, while that

Figure 2—Stereoselective potentiation of isomers of norepinephrine (NE) by mecamylamine (3-min. incubation). Isolated rat *vas deferens* was the test organ. Vertical lines are SEM. Data from Patil *et al.* (117). Key: —, control; ---, with mecamylamine, 3×10^{-4} M; ●, (–)-NE; and ○, (+)-NE. $n = 8$.

of (+)-isomer was slightly desensitized. The supersensitivity resulting from chronic reserpine treatment could not be demonstrated in this tissue. Failure to demonstrate such a sensitivity *in vitro* was attributed to the isolational procedural stress. From these reports it appears that the whole problem of change in the activity of optical isomers of norepinephrine in relation to denervation supersensitivity deserves reinvestigation under well-controlled experimental conditions. After denervation, if there is a qualitative change in α -adrenergic receptors (*i.e.*, change in the configuration), it should be reflected in isomeric ratios of norepinephrine. Hence, the isomeric ratio after denervation should be different from that in the normal tissue after administration of cocaine (124).

After a series of well-controlled experiments in reserpine-pretreated spinal cat, Trendelenburg (125) reported an interesting finding with (–)- and (+)-isomers of norepinephrine. During nerve stimulation, after equieffective doses of isomers of norepinephrine, the nictitating membrane effects of (–)-norepinephrine were potentiated more than those of the (+)-isomer. These observations were explained on the basis that during nerve stimulation, injected (–)-norepinephrine is immediately available for release. The (+)-isomer has less affinity for the uptake site and, therefore, will not be stored. Hence, no potentiation will result.

Many sympathomimetic amines and related agents inhibit the uptake of norepinephrine into the sympathetic nerve endings. This implies that relatively more concentration of norepinephrine will then be available for activation of pharmacologic receptors. Since various sympathomimetic amines displayed varying inhibition of uptake of norepinephrine (97), it was anticipated that different sympathomimetic amines should produce varying potentiation of norepinephrine effects. In the isolated rat *vas deferens*, Swamy *et al.* (126) studied potentiation of (–)-norepinephrine by (+)- and (–)-amphetamine. At all concentrations, 10^{-7} – 10^{-5} M, of amphetamine, the potentiation of exogenous norepinephrine was identical. In the presence of amphetamine, responses to the effects of endogenously released norepinephrine can be potentiated. Day (127) carried out ex-

periments on the isolated guinea pig vas deferens. The effects of (+)-, (-)-, and (\pm)-amphetamine were compared on the maximal response to sympathetic nerve stimulation over the frequency range 2–50 pulses/sec., using both pre- and postganglionic stimulation. It was found that both optical isomers and racemic mixture produced identical results. Thus, it appears that on vas deferens, isomers of amphetamine produce identical potentiation of exogenous or endogenous norepinephrine.

Swamy *et al.* (128) used a systematic pharmacologic approach to define some stereochemical characteristics of uptake site. An assumption was made that potentiation of exogenous norepinephrine is a faithful reflection of the ability of molecules to inhibit the uptake of norepinephrine. Only metabolically stable α -methylated amines were selected. Two isolated tissues from rat, vas deferens and right atria, were used to study the potentiating abilities of these agents. On both tissues at relatively low concentrations, 10^{-6} M, these drugs produced a potentiation of exogenous norepinephrine. The isomers were ranked according to their abilities to potentiate norepinephrine. In the isolated rat vas deferens, there was not a clearcut separation of steric structure and ability to potentiate norepinephrine. (-)-Metaraminol, which has the highest affinity for uptake site in the heart, was ranked 20th on the vas deferens. (-)-Amphetamine, which has a poor affinity for uptake, was ranked first. Rat vas deferens contains mainly α -adrenergic receptors. A given sympathomimetic amine can compete for both uptake and direct α -adrenergic receptors. If a given agent has higher affinity for both uptake and direct sites, then observed potentiation may not be a true reflection of the amine to inhibit uptake. In other words, norepinephrine, which is spared, will not produce its full effect on α -adrenergic receptors which might be occupied by the amine. In the isolated rat atria, which mainly contains β -adrenergic receptors, the isomers of various amines exhibited distinct stereochemical differences: (a) (-)-metaraminol ranked first in 20 agents tested; (b) (-)-isomers of norephedrine, ephedrine, and metaraminol ranked higher than their corresponding (+)-isomers; and (c) deoxy derivatives, such as α -methyl-*m*-tyramine, α -methyldopamine, amphetamine, and methamphetamine, ranked higher than their corresponding β -hydroxylated (+)-isomers. Thus, if potentiation is the faithful reflection of ability of an amine to inhibit uptake of (-)-norepinephrine, the obvious conclusion is that uptake characteristics differ in rat vas deferens as compared to atria. This view would be consistent with a recent report by Iversen (68).

As early as 1923, Gottlieb (129) studied the optical isomers of cocaine for local anesthetic activity. But a complete steric structure-activity of the cocaine molecule for inhibition of norepinephrine uptake is yet to be defined. Synthesis and/or resolution of these agents appear to be the main task. Schmidt *et al.* (130) investigated central and peripheral effects of (-)-cocaine and (+)-pseudococaine. Only (-)-cocaine was effective in both, producing central sympathetic stimulation and potentiating epinephrine. It can be concluded from these experiments that (+)-pseudococaine might not be an effective inhibitor of epinephrine uptake. However,

(-)-cocaine and (+)-pseudococaine have identical local anesthetic properties. This indicates that inhibition of uptake and local anesthetic effects may not be causally related. (-)-Norepinephrine-potentiating activity of close structural analogs of cocaine, tropacocaine, and pseudotropacocaine was investigated on the isolated rat vas deferens (131). Pseudotropacocaine appeared to be slightly more active than tropacocaine. Both of these agents were only 1/30th–1/100th as active as (-)-cocaine. The effects of tyramine were affected differently. A large body of evidence indicates that cocaine, norepinephrine, and tyramine compete for the same site at the adrenergic nerve endings. As expected, effects of norepinephrine were equally shifted by cocaine to the left and right, respectively. However, tropacocaine and pseudotropacocaine did not affect norepinephrine and tyramine response to an equal degree. Tropacocaine caused a slight shift of norepinephrine responses to the left. On the other hand, the same concentration of tropacocaine markedly shifted the effects of tyramine to the right with reduction in maxima. Pseudotropacocaine did not affect tyramine at all, but the effect of norepinephrine was slightly potentiated. These results indicate that a noncompetitive interaction of tropacocaine and pseudotropacocaine with receptors in the adrenergic nerves cannot be excluded.

Because of two asymmetric centers, the antidepressant drug methylphenidate can be exhibited in four stereoisomeric forms. Clinically, only the (\pm)-*threo*-form is used. The (\pm)-*erythro*-form is devoid of central effects. Buckner *et al.* (132) evaluated comparative peripheral effects of (\pm)-*erythro*- and (\pm)-*threo*-forms of methylphenidate. On the rat vas deferens in potentiating (-)-norepinephrine at equiactive concentrations, (\pm)-*erythro*-methylphenidate has 1/300th the activity as that of the (\pm)-*threo*-form. A histochemical technique demonstrated that in rat iris the (\pm)-*threo*-form markedly inhibited uptake of levonordefrin while the (\pm)-*erythro*-form was without effect. Implications of these findings are that if CNS stimulant effects are causally related to inhibition of uptake of norepinephrine, a greater potency of (\pm)-*threo*-methylphenidate over that of the (\pm)-*erythro*-form explains its higher CNS stimulant activity. The absolute configurations, methylphenidates, pipradrols, and pheniramines, have been determined recently (133).

MECHANISM OF ACTION OF "INDIRECTLY" ACTING β -HYDROXYLATED (+)-ISOMERS AND THEIR CORRESPONDING DEOXY DERIVATIVES

Muscholl (5) has pointed out that "indirectly" acting amines not only cause release of stored norepinephrine but also cause inhibition of reuptake of released norepinephrine. Previously, Patil *et al.* (20) observed that in the normal vas deferens, indirectly acting deoxy derivatives always produced a greater magnitude of pharmacologic effects than their corresponding β -hydroxylated (+)-isomers. For example, deoxylevonordefrin (α -methyldopamine) produced greater effects than (+)-levonordefrin. These results were explained on the basis that deoxy derivatives enter the intraneuronal stores at a faster rate and displace the stored norepinephrine at a faster rate than the corresponding β -hydrox-

ylated (+)-isomer. An incorrectly oriented alcoholic hydroxyl group in (+)-isomer was believed to cause hindrance in uptake of these agents. However, it can be argued that both deoxy derivative and (+)-isomer are taken up at an equal degree and displace equal amounts of norepinephrine. The higher activity of deoxy derivatives then can be explained by greater inhibition of reuptake by the agent. The lower activity of the (+)-isomer is caused by its ability to inhibit the reuptake of released norepinephrine.

A series of experiments was done to test the cocaine-like effect of indirectly acting agents in the reserpine-pretreated rat vas deferens. The concentrations of deoxy derivative and (+)-isomer were the same as those in which they exhibit unequal pharmacological effects on the normal tissue. The deoxy derivative and corresponding (+)-isomer were tested on the contralateral vas deferens of the same reserpine-pretreated rat. It was observed that the deoxy derivative and corresponding (+)-isomer caused equal potentiation of exogenous norepinephrine (134). These observations strengthen the original suggestion that in the rat vas deferens greater indirect effects of the deoxy derivative over the corresponding (+)-isomer is caused by either faster uptake of the agent and/or faster displacement of norepinephrine. The (+)-isomer possibly lacks both effects. This hypothesis is illustrated in Fig. 3.

Since tissue accumulation of nonphenolic amines is not affected by cocaine (100, 101), a very basic question was raised. "Do all indirectly acting agents release the stored norepinephrine by the same mechanism?" Experiments were designed on the rat vas deferens to seek the answer. A group of phenolic and nonphenolic amines was selected. From previous studies (20), it was also known that certain indirectly acting amines produce different maximal effects. To get some clue regarding similarity and dissimilarity of closely related indirectly acting agents, their maximal effects were superimposed. Phenolic amines and nonphenolic amines did show dissimilar behavior. Thus, the results support the hypothesis that all indirectly acting agents do not act by the same mechanism.

PHARMACOLOGICAL EFFECTS OF OPTICAL ISOMERS OF ADRENERGIC DRUGS— α - AND β -ADRENERGIC AGONISTS

Great credit should go to Cushny (135–137) for his pharmacologic studies on the optical isomers of various substances. He has carefully documented earlier reports concerning optical isomers of many naturally occurring substances (135). Soon after the presence of the epinephrine was demonstrated in adrenal medulla, Cushny (136) examined the pressor effects of naturally occurring (–)-epinephrine and synthetic (±)-epinephrine in the anesthetized dog. The (±)-epinephrine was one-half as active as (–)-epinephrine. From these experiments, it became evident that optical isomers of epinephrine showed selectivity in pharmacologic effects. In the following year, 1909, Cushny (137) compared individual (–)- and (+)-isomers of epinephrine. He found that the (+)-isomer was 1/12th–1/15th as active as (–)-isomer in raising blood pressure.

Figure 3—Illustration of a possible cause of low activity of (+)-isomers when compared with the corresponding deoxy derivatives. Since exogenous norepinephrine (●) is equally potentiated by "indirectly" acting (+)-isomers and their corresponding deoxy derivatives, the inhibition of reuptake of endogenously liberated neurohormone may be the same for both agents. Thus, higher rate of neuronal uptake and/or increase in the basic release mechanism may be the cause for higher amplitude of contraction of deoxy derivative over that of (+)-isomer. In (+)-isomers the OH-group may be incorrectly oriented with respect to transport mechanisms, and the rate of transport, therefore, is slower than that of the corresponding deoxy derivative where such a group is absent. $R = H, R' = OH, R'' = CH_3, R''' = CH_3$. Reproduced, with permission, from Patil et al., *Arch. Int. Pharmacodyn. Ther.*, **189**, 32(1969), and St. Catherine Press, Brugge, Belgium.

The single most important contribution in explaining the behavior of optical isomers toward the specific pharmacologic receptors came from the reports of Easson and Stedman (138). The theory was proposed that in an asymmetric molecule like (–)-epinephrine, three of the four groups linked to the asymmetric carbon are concerned in the attachment with the receptor. These groups are: (a) the basic nitrogen; (b) the aromatic group (with *m*- and *p*-hydroxyl groups which determine the intensity of attachment); and (c) the alcoholic hydroxyl group. In the (+)-isomer, since the alcoholic hydroxyl group is oriented in the wrong position, only two-point interaction is expected. This view was strengthened by the fact that deoxyepinephrine, which lacks the alcoholic hydroxyl group, is equiactive with (+)-epinephrine. This theory was elaborated by Blaschko (139) and Beckett (140). It can be illustrated as shown in Fig. 4. On guinea pig ileum, Wilson (141) tested (–)-epinephrine and (+)-epinephrine. According to this theory, the (–)-isomer was more active than the (+)-isomer and epinine was equiactive to (+)-epinephrine. However, Badger (142) collected the results from a number of reports and pointed out that in many cases the activity of deoxy derivatives and (+)-isomers was

Figure 4—Suggested interactions of optical isomers of epinephrine and deoxyepinephrine with adrenergic receptors [after Easson and Stedman (138), Belleau (199), and Beckett (140)]. According to Easson and Stedman, the correct orientation of the β -hydroxyl group of (–)-isomer results in higher activity while incorrect orientation of this group in (+)-isomer or the lack of the group in deoxy derivative would result in lesser but equal intensity of effect. In other words, (+)-isomer acts as if the β -hydroxyl group is missing (140).

not in harmony with the Easson-Stedman hypothesis. For many years, Badger's argument against the theory remained unanswered.

In the meantime, the concept of directly and indirectly acting amines has been widely accepted. Patil *et al.* (20, 143) selected a series of (–)- and (+)-isomers and their deoxy derivatives of sympathomimetic amines in order to test the Easson-Stedman hypothesis. Vas deferens from normal as well as reserpine-pretreated rats were used for the experiments. On the normal vas deferens, the (–)-isomer was always more active than the (+)-isomer, but many corresponding deoxy derivatives were more active than (+)-isomers. When the endogenous norepinephrine in the vas deferens was depleted by reserpine treatment, a very interesting result was obtained. The (–)-isomers retained their higher activity, as in normal tissue, but many (+)-isomers and corresponding deoxy derivatives appeared to have large, unequal, indirect components of action. Both the (+)-isomer and the deoxy derivative were equiactive in the reserpine-pretreated tissues. Results are illustrated in Fig. 5. In other words, in catecholamine-depleted tissues, results were in harmony with the Easson-Stedman hypothesis. These observations suggest that the hypothesis holds true for sites of direct action only (α - or β -adrenergic).

From this study, another question emerged. When catecholamine stores are intact, why are deoxy derivatives more active than the (+)-isomers? A possible explanation is that in (+)-isomers, orientation of the β -hydroxyl group is such that it may cause hindrance of transfer from extraneuronal sites to intraneuronal sites, thereby liberating lesser amounts of neurohormone at slower rates. With the deoxy amines, which lack the β -hydroxyl group, there is no such hindrance to transfer and these amines will be taken up by the storage site more easily and produce greater pharmacologic effects because of a faster rate of release of neurohormone. (This view is discussed and illustrated in a previous section.) Even *in vivo* systems, after depletion of catecholamines, (+)-isomers, and their deoxy derivatives, appear to produce equal pharmacologic effects (16, 144, 145). Dopamine causes biphasic or vasodepressor response in the anesthetized rabbit. Under similar conditions, (+)-norepinephrine produces a pressor effect. It was

anticipated that a similar activity difference could be detected on the rabbit aorta. Although the shapes of the dose-response curves of (+)-norepinephrine and dopamine were slightly different, the ED_{50} values were similar (146). (–)-Norepinephrine causes relaxation of the rat fundus strip. Both (+)-norepinephrine and dopamine have some 1/250th the activity of (–)-norepinephrine.⁶ The activities of (+)-norepinephrine and deoxynorepinephrine are identical, indicating a possible similar interaction of these drugs as suggested by Easson and Stedman. Furthermore, this theory holds true for the drug effects on skeletal muscle (147).

By use of isomers of norepinephrine, an attempt has been made to characterize the nature of the receptor material. Because cell walls are composed of phospholipids, it is implied that these lipids might be involved in the transport of drug in the adrenergic neurone or in the interaction of drugs at the pharmacologic receptors. For the *in vitro* system, isomers of norepinephrine failed to show differences in their interaction with lecithin (148). This is in contrast to the well-known stereoselectivity of the pharmacologic receptors. Failure of an *in vitro* system to demonstrate a difference should not be taken as evidence against the implication of phospholipids as the receptor material.

On the basis of similar patterns of potency of agonists and dissociation constants of antagonists, Furchgott (18) suggested that α -adrenergic receptors in rabbit aorta, muscle from the corpus of the stomach, and duodenum appear to be of a single type. This suggestion can be reexamined on the basis of activity ratio of optical isomers and the activity ratio of (+)-isomers and the deoxy derivative. If α -adrenergic receptors are identical in different tissues under proper conditions, one should obtain a similar isomeric potency ratio in all these tissues (124). Furthermore, if the Easson-Stedman hypothesis is true for interaction of agonists with α -adrenergic receptors, the activity of (+)-isomers and deoxy derivatives should be identical. Data in Table III are obtained from different reports, because the criteria for obtaining an isomeric ratio for antimers of norepinephrine are relatively constant.

⁶ J. R. Vane, personal communication, 1969.

Figure 5—Dose-response curves of (—●—) (-)-levonordefrin (—○—) (+)-levonordefrin (---○---) (+)-deoxylevonordefrin in normal and reserpine-pretreated rat vas deferens. Note that the Easson and Stedman hypothesis only holds true in catecholamine-depleted tissue. Data after Patil and Jacobowitz (71).

Fortunately, the isomeric ratios for isomers of norepinephrine from seven different test preparations containing mainly α -adrenergic receptors were readily available. In tissues which contain a high density of adrenergic nerves, the isomeric ratio for norepinephrine should be compared in the presence of cocaine. It can be seen from Table III that within the limits of experimental error, the isomeric ratios for norepinephrine isomers are approximately equal. Furthermore, the activities of (+)-norepinephrine and deoxynorepinephrine were approximately equal. On the basis of this data, new experiments were designed to test the validity of this concept. It was observed that after block of uptake by cocaine, isomeric ratios of norepinephrine on rat vas deferens, seminal vesicles, rabbit aorta, ileum, and spleen are equal (151). Since stereoselectivity is one of the best established properties of receptors, determination of isomeric ratios should provide an excellent criterion to differentiate the receptors. It seems probable, therefore, that the α -adrenergic receptors in all of the mentioned tissues are of a single type. The suggestion by van Rossum (149) regarding different types of α -adrenergic receptors in different tissues appears less tenable.

Conversely, if β -adrenergic receptors are of dissimilar types, the isomeric potency ratio of a given pair of isomers in different tissues containing β -adrenergic receptors should be different (124). The isomeric ratios between (-)- and (+)-norepinephrine for rate-accelerating effects in atria from cat, dog, rabbit, and guinea pig are 60, 10, 10, and 30, respectively.⁷ Different isomeric ratios from different species, at least in part, might be a reflection of unequal density of adrenergic innervation. Unfortunately, the effects of isomeric potency ratios are only available from two tissues, heart and bronchioles (Table IV).

Blinks (155) investigated (-)- and (+)-isomers of norepinephrine, epinephrine, and isoproterenol and their deoxy analogs, dopamine, epinine, and deoxyisoproterenol, respectively. Even in the tissues containing β -adrenergic receptors, guinea pig atria, the results were in accordance with the Easson-Stedman hypothesis. Deoxyisoproterenol and (+)-isoproterenol are equipotent weak agonists of β -adrenergic receptors. Both of these agents also have an identical α -adrenergic receptor blocking activity (156, 157). Similarity of interactions of (-)-, (+)-, and their deoxy derivative in tissue containing both α - and β -adrenergic receptors suggests that many molecular features of these sites must be similar. The dissimilarity between α - and β -adrenergic receptors becomes apparent when effects of (-)- and (+)-levonordefrin and (+)-deoxylevonordefrin are examined on both of the adrenergic receptors. (+)-Deoxylevonordefrin and (+)-levonordefrin are equiactive on the reserpine-pretreated rat vas deferens; while on the guinea pig trachea, (+)-deoxylevonordefrin is far more active than (+)-levonordefrin (71).

Apart from these observations, some qualitative differences between deoxy derivatives and (+)-isomers have been reported. Evidence suggests that there may be receptors for initiation of renal vasodilation which are affected by dopamine (deoxynorepinephrine). The renal vasodilatory effects of dopamine are not blocked by any classical antagonist, while those of (+)-norepinephrine are blocked (158). Similarly, it appears from the report of van Rossum (149) that deoxysynephrine causes stimulation of the rabbit jejunum, while (+)-synephrine causes inhibition. On any given tissue, the deoxy derivative and (+)-norepinephrine may interact identically with pharmacologic receptors, as suggested by Easson and Stedman; but if only the deoxy derivative liberates other substances such as histamine or serotonin, then the observed activity difference of (+)-isomer and the deoxy derivative may not appear equal.

⁷ J. R. Blinks, personal communication, 1969.

Table III—Relative Activities of Optical Isomers of Norepinephrine (NE) and Deoxynorepinephrine (Dopamine) on Various Tissues which Mainly Contain α -Adrenergic Receptors

^a A dose that will cause equivalent effect was selected as a criterion for calculation of dose ratio. ^b Reserpine, 3–5 mg./kg. i.p., was used to deplete catecholamine. ^c Reserpine, 0.1 mg./kg./day for 14 days.

Reuter and Wollert (159) studied the effects of isomers of some sympathomimetic amines on contractility and ⁴⁵Ca-uptake in isolated guinea pig atria. As compared to (+)-isomers, (–)-isomers of epinephrine and synephrine were more potent in producing contractility and influx of ⁴⁵Ca. It was concluded that increase of Ca-influx during excitation is responsible for the positive inotropic effects of these agents. If there is a transport system at the site of pharmacologic receptors, it seems likely that calcium is required in transport of these amines at the receptors for the effect; and since (–)-isomers are more effective than (+)-isomers, it seems possible that calcium and a correctly oriented alcoholic hydroxyl group together with basic nitrogen can form a chelate that is to be transported more effectively. The role of divalent metals and their chelates in relation to pharmacologic effects of sympathomimetic amines and their optical isomers should provide an interesting chapter on future

developments in understanding the basic mechanisms of drug action. The possible role of metals in the transport of norepinephrine has been discussed by Colburn and Maas (160, 161).

OPTICAL ISOMERS OF NONPHENOLIC AMINES

Since the discovery of ephedrine, many closely related amines have been synthesized and tested for sympathomimetic effects. In early days, the main interest in nonphenolic amines was caused by their central stimulant and prolonged pressor effects. The classical work of Badger and Dale (162) describes pressor activity of many structurally similar amines. Along with these developments, the optical isomers of some nonphenolic amines were also investigated. Many earlier studies were semiquantitative. Hence, an attempt to obtain a coherent summary except for blood pressure effects was a failure. A short report regarding the pressor effects of the isomers is presented in Table V. The pressor effects of nonphenolic amines are now recognized as being mediated through the release of catecholamines from the sympathetic nerve endings. Readers interested in earlier studies regarding optical isomers of nonphenolic amines are urged to read other reports (169–174).

Among nonphenolic amines, the ephedrine isomers present a unique opportunity to study steric structure-activity relationships. Although heart rate and pressor effects of naturally occurring (–)-ephedrine were considered as mixed actions, the investigation of all four isomers of ephedrine revealed that this property is not shared by (+)-ephedrine, and for (+)-pseudoephedrine was mainly “indirect” through the release of endogenous norepinephrine (16). De Meyts and Cession-Fossion (175) extended these observations in rats, that pressor effects of (–)-ephedrine were direct as well as indirect while those

of (+)-pseudoephedrine were mainly indirect. Fifty milligrams per kilogram, i.p., of (–)-ephedrine caused a significant decrease in myocardial catecholamines in rats, while under similar conditions (+)-pseudoephedrine was inactive. Both (–)-ephedrine and (+)-pseudoephedrine did not influence adrenal catecholamines. Light *et al.* (176) examined the vascular effects of ephedrine isomers in dogs. The intraarterial injection of (–)-ephedrine reduced the blood supply to all vascular beds studied, in contrast to the dilation produced by (–)-pseudoephedrine. Renal and vertebral arterial flows were increased and the carotid flow decreased by the (+)-isomers of both ephedrine and pseudoephedrine. Limb flow increased by (+)-ephedrine but decreased by the (+)-pseudoephedrine. These vascular effects probably indicate the indirect or direct activation of either α - or β -adrenergic receptors.

The pattern of the indirect pharmacologic activity of all four ephedrine isomers in the rat vas deferens appears as (–)-ephedrine > (+)-ephedrine \geq (+)-pseudoephedrine \gg (–)-pseudoephedrine. The pattern of the potentiation of exogenous norepinephrine by these agents in the reserpine-pretreated tissues also appears to be the same (Table VI). On the isolated rabbit aorta, (–)-ephedrine produces a marked contractile effect while other isomers produce little or no effect (177).

(–)-Ephedrine was introduced in therapeutics as a bronchodilator drug (178) and has been widely used as such. Tye *et al.* (179) investigated the effects of ephedrine isomers on tracheal smooth muscle of guinea pig. All isomers appear to be partial agonists and (–)-ephedrine and (–)-pseudoephedrine were mainly direct acting, the smooth muscle relaxant effects of (+)-ephedrine and (+)-pseudoephedrine were considerably reduced by reserpine-pretreatment. Propranolol, a β -adrenergic blocker, reduced the effects of all isomers. Ephedrines were studied in the presence of tone induced by methacholine. Muscle relaxant effects, therefore, may partly be attributed to competition of ephedrine molecules with that of methacholine.⁸

Pendular movements of rabbit ileum are inhibited only by (–)-ephedrine; the other three isomers produce little or no effect and are antagonistic to the α -adrenergic inhibitory effects of (–)-norepinephrine. The stereospecificity in such antagonism is not very marked. For example, (+)-ephedrine and (–)-pseudoephedrine vary considerably in steric structure, but produce similar antagonistic effects to (–)-norepinephrine (181). (–)-Phenylethanolamine produces inhibition of the rabbit ileum. (+)-Phenylethanolamine and the deoxy derivative, phenethylamine, do not have intrinsic activity, but both agents produce an equal antagonism to norepinephrine effects (182). These observations are consistent with the Easson-Stedman hypothesis (138).

LaPidus *et al.* (183) pointed out the stereochemical similarities between (–)-ephedrine and (–)-pseudoephedrine. In both of these molecules, the functional groups, the phenyl ring, β -hydroxyl group, and the amino group could fit the same three points on a hypothetical receptor. In the anesthetized cat, the pressor and nictitating membrane effects of (–)-ephedrine were

Table VI—Effects of “Indirectly” Acting Ephedrine Isomers on the Normal Vas Deferens and the Potentiation of Norepinephrine Responses by the Same Agents in the Reserpine-Pretreated Tissues

promptly terminated by (–)-pseudoephedrine. The pretreatment of an animal with (–)-pseudoephedrine can also prevent the effects of (–)-ephedrine (177). However, the antagonism by (–)-pseudoephedrine can be extended to other indirectly acting amines such as amphetamine and tyramine. The antagonism between (–)-ephedrine and (–)-pseudoephedrine on the cat nictitating membrane or blood pressure may even be physiological.

Because the pattern of effects of ephedrine isomers varies so greatly from one tissue to another, Kier (184) postulated a pattern of complementary features which represent the α -adrenergic receptor that is activated by ephedrine isomers. Molecular orbital calculations were used to map α -adrenergic receptors. These calculations present an interesting theoretical approach which would gain more recognition if the hypothesis were tested over a wide variety of related molecules and by some experimental means.

Several attempts were made to synthesize the ephedrinelike molecules with a rigid structure. Yelnosky and Katz (185) reported a sympathomimetic action of *cis*-2-amino-4-methyl-5-phenyl-2-oxazoline. Comparison of the structure of this agent with that of ephedrine illustrates a marked similarity in the functional groups. The pharmacological effects are also similar to ephedrine's. Meyer *et al.* (186) synthesized norephedrine homologs, 2-aminotetralol, with a rigid molecular structure. Like norephedrine, this agent could exist in four possible isomers: (+), (–)-*cis*-form and (+), (–)-*trans*-form. Only the *cis*-form was effective as a pressor agent. (+)-*cis*-2-Aminotetralol was about 5 times as active as (–)-*cis*-2-aminotetralol. The arrangement of functional groups in (+)-*cis*-2-aminotetralol was claimed to be like that in the most active form of norephedrine. It should be emphasized that higher pressor potency of these two agents reflects their possible catecholamine-releasing effects. Smismann and Chappell (187) reported on conformationally rigid derivatives of ephedrine. Pharmacological testing on the isolated rat vas deferens revealed that there were no intrinsic effects from all of the agents. However, in 10⁻⁴ M concentrations, effects of exogenous norepinephrine were

⁸ R. F. Furchgott, personal communication, 1969.

potentiated. This potentiation indicates that these agents possibly interact with uptake sites. Bulky substituents possibly retard the catecholamine-releasing activity which is seen in the parent ephedrine molecules. It would be interesting to synthesize and test the conformationally rigid analogs of catecholamines such as norepinephrine and epinephrine.

TACHYPHYLAXIS (ACUTE TOLERANCE)

It is outside the scope of this report to review various theories or explanations for tachyphylaxis. Only work pertinent to the optical isomers will be referred to. In the early years, tachyphylaxis to the sympathomimetic amines, such as ephedrine or amphetamine was said to be caused by receptor saturation (188). But when the various sites such as uptake, binding, and direct action were known, it was important to explain the phenomenon of tachyphylaxis in relation to these sites. Abdallah *et al.* (17) studied tachyphylaxis to the ephedrine isomers in the perfused rabbit heart and found that under identical experimental conditions, the rate of development of tachyphylaxis varied with the isomers. (–)-Ephedrine was the most potent tachyphylactic isomer studied. The correlation between norepinephrine recovered in the perfusate and loss of chronotropic effect was not parallel. None of the isomers significantly influenced the total cardiac norepinephrine. *In vivo*, at “equipressor” doses, the tachyphylactic tendencies for ephedrine isomers were (+)-pseudoephedrine > (+)-ephedrine > (–)-ephedrine (16), which is the reverse of the ranking observed *in vitro*. This ranking might be caused by differing disposal rates for the ephedrine isomers *in vivo*; but since cardiovascular reflexes may so greatly influence blood pressure, comparisons between *in vitro* and *in vivo* data are difficult to make. There are some doubts regarding participation of adrenal medulla during ephedrine tachyphylaxis (189). However, in an anesthetized cat, pretreatment with a total of 6 mg./kg. of *N,N*-diisopropyl urea, *N'*-isoamyl urea, and *N'*-diethylaminoethyl urea (P. 286), a specific adrenal medullary blocker, did not influence the pressor effects or the tachyphylactic effects caused by ephedrine isomers (190). If a given indirectly acting amine has a greater affinity for the uptake sites and is not washed off the tissue during perfusion, it may inhibit its own uptake during subsequent injections. This inhibition will result in a reduced displacement of catecholamines from storage sites and a consequent diminishing of tissue response. Similar suggestions have been made earlier by Blaschko (191) and Fawaz and Simaan (192). In other words, different rates of development of tachyphylaxis may be indicative of an amine's ability to prevent its own uptake into the sympathetic nerve endings.

Hanna (193) and Harvey *et al.* (194) found that the tachyphylactic tendencies of amphetamine isomers on dog blood pressure and on rabbit aortic strips were the same for both isomers. The major structural difference between amphetamine and ephedrine is that the latter possesses an alcoholic hydroxyl group. The different rates of development of tachyphylaxis observed with ephedrine isomers in this study may well depend on the orientation of this group. (+)-Pseudoephedrine, a *threo*-isomer, appeared to be less tachyphylactic than

(–)-ephedrine and (+)-ephedrine, which are both *erythro*-isomers. Lindmar *et al.* (74) have reported that (±)-pseudo dihydroxyephedrine, a *threo*-form, is washed off the heart more easily than (±)-dihydroxyephedrine, an *erythro*-form. (+)-Pseudoephedrine's lack of tachyphylactic power then may well be caused by its *threo*-conformation which allows it to be more easily washed off. These observations lead to the conclusion that the relative orientation of the β-hydroxyl group and the α-methyl group must be of critical importance in the development of tachyphylaxis in the ephedrine isomers.

Hornykiewicz and Obenaus (195) elaborated on some of the previous observations regarding tachyphylaxis to direct acting amines. In the anesthetized rats, infusion of large amounts of (+)-epinephrine, (+)-norepinephrine, epinine, and (–)- or (+)-phenylephrine induces tachyphylaxis to vasopressor effects of (–)-epinephrine, (–)-norepinephrine, and tetraethylammonium. The tachyphylactic potency of the amines was (–)-phenylephrine > epinine > (+)-norepinephrine = (+)-epinephrine > (+)-phenylephrine. Other peripheral effects of (–)-isoproterenol and (–)-epinephrine were also reduced by infusion of (+)-epinephrine. From these results, it was concluded that tachyphylaxis could result from saturation of α- or β-adrenergic receptors by less active isomers of catecholamines and related agents. In the isolated heart of *venus mercenaria*, (–)-norepinephrine produces negative inotropic effects. The repetition of the same dose produces tachyphylaxis. Optical isomers of amphetamine and ephedrine can prevent the tachyphylactic effects caused by (–)-norepinephrine. (–)-Ephedrine was found to be more potent than (+)-ephedrine, and (+)-amphetamine was found to be more potent than (–)-amphetamine (196, 197).

Thus, it appears that sympathomimetic amines can produce tachyphylaxis by the following mechanism or combination of the following mechanisms: (a) depletion of small available stores of norepinephrine; (b) inhibition of their own uptake by neuronal membrane; (c) saturation of α- and/or β-adrenergic receptors; and (d) slow excretion or metabolic disposition. The optical isomers of sympathomimetic amines provide a good tool for exploring various mechanisms of sympathomimetic amines.

α-ADRENERGIC BLOCKERS

At present, very little information is available regarding steric aspects of the reversible competitive antagonist of α-adrenergic receptors. Therefore, our knowledge regarding α-adrenergic receptor antagonists is derived solely from irreversible blockers. Nickerson (198) suggested that in the case of β-haloalkylamines, the development of a stable drug receptor bond can be related directly to the chemical reactivity of ethylenimium intermediate formed at physiological pH. Belleau (199) later introduced a concept of isosterism. He suggested a similarity of interaction of (–)-norepinephrine and ethylenimium ion from *N*-(2-chloroethyl)dibenzylamine at the α-adrenergic receptor. It is of interest to note that the suggested interaction of agonist, (–)-noradrenaline, with the α-adrenergic receptor is essentially the same as that postulated by Easson and Stedman (138).

Belleau and Triggle (200) synthesized and resolved two optical isomers of *N,N*-dimethyl- β -chlorophenethylamine.

Equipotent antiadrenaline effects of the two isomeric forms of *N,N*-dimethyl- β -chlorophenethylamine indicate a possible common reactive symmetric molecular species at adrenergic receptors (Scheme IIIa). Similarly, *cis*- and *trans*-isomers of *N*-methyl-*N*-(2'-phenoxypropyl)-2-chloroethylamine yield similar reactive molecular species, and hence they are approximately equipotent with respect to the reactive α -adrenergic site (Scheme IIIb)

Scheme IIIa, b—Common reactive ethylenimium ion from the optical isomers of *N,N*-dimethyl- β -chlorophenethylamine and *N*-methyl-*N*-(2'-phenoxypropyl)-2-chloroethylamine, respectively.

(201). There are several thought-provoking reviews available on this subject (202–205).

β -ADRENERGIC BLOCKERS

Since the introduction of dichloroisoproterenol as an antagonist to the inhibitory effects of catecholamines, a number of structurally related chemicals have been synthesized and tested for β -adrenergic blocking properties. All of those agents which produced significant β -adrenergic blockade have asymmetric carbon or carbons. The optical isomers of dichloroisoproterenol (206), pronethalol (206, 207), propranolol (208–211),

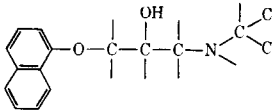

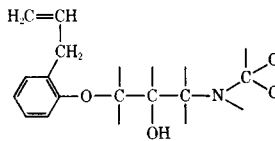

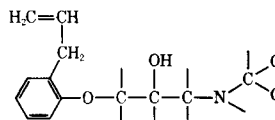

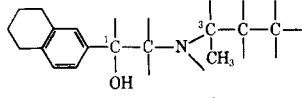

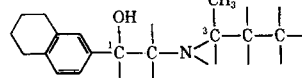

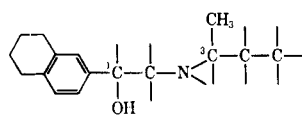

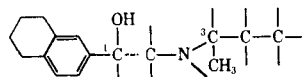

methoxamine and its derivatives (15, 19, 212), INPEA (213–215), α -methyl-INPEA (216), sotalol (19, 217), butedrine (218–221), and H56/28 (222) have been synthesized, resolved, and tested for pharmacologic activity. The chemical structure and β -adrenergic blocking properties are summarized in Table VII. Examination of data in Table VII reveals that all potent β -blockers markedly resemble the agonists (–)-isoproterenol. The points of similarities are: (a) substitution on the phenyl ring; (b) alkyl substitution on the nitrogen; and (c) alcoholic group in correct stereochemistry with the receptor (1R or D-configuration). The stereochemistry of the alcoholic hydroxyl is the same as that in (–)-isoproterenol. This structural requirement implies that β -adrenergic blockers are relatively more specific in their attachment to the β -receptor than α -adrenergic antagonists to the α -receptors. However, there is a marked similarity between interaction of α - and β -adrenergic agonists with their respective receptors. Substitution of the methyl group adjacent to the carbon-carrying alcoholic hydroxyl group can hinder the effective interaction of agonist or antagonists with the receptor. For example, (–)-pseudobutamine fulfills all the structural requirements for a β -adrenergic blocker, but it does not appear to block β -adrenergic receptors. A very interesting study on the conformational aspects of the ephedrine isomers has been carried out by Portoghesi (223). He states that: "It appears significant that (–)-ephedrine is the only isomer which possesses both 1R configuration and the C-methyl group which projects above the plane of phenethylamine moiety. The (–)-pseudoephedrine also possesses the 1R stereochemistry necessary for direct action, but the C-methyl group is oriented below the plane. It is conceivable that the methyl group in the latter isomer hinders effective interaction with the receptor." In terms of this conformational analysis of ephedrine isomers, it becomes apparent why (–)-ephedrine blocks β -adrenergic receptor and (–)-pseudoisomer does not. Similar explanations may hold true for the isomers of methoxamine, isopropylmethoxamine, butoxamine, and α -methyl-INPEA in which there are two asymmetric centers like those in the ephedrine molecule. The actual conformations of these molecules at the receptors are not yet known. Butedrine also has two asymmetric centers, but the methyl substitution is very remote from that of the important functional alcoholic hydroxyl group. As a consequence, it does not appear to influence the interaction of the alcoholic hydroxyl group with the β -adrenergic receptor. Butedrine 1R, 3R and 1R, 3S are almost equiactive.

(–)-Propranolol is more potent in antagonizing isoproterenol-induced tachycardia while its (+)-isomer is much less active. The deoxy analog of propranolol is approximately as active as (+)-propranolol (208). Thus, β -adrenergic blockers are in line with Easson and Stedman's suggestions regarding interactions of asymmetric molecules with the receptors. However, many exceptions appear to have emerged, particularly when a given molecule has more than one asymmetric center in which the nonfunctional group may hinder the attachment of functional groups to receptors. The location of adrenergic receptors in tissue is not known. If β -

receptors are inside the cell and if there is another transport system at the sites of direct action, then it becomes of primary importance to establish a structural requirement for such a system before the Easson-Stedman theory can be rejected.

Different types of β -receptors complicate interpretation of structure-activity study from one tissue to another (224, 225). Substitution of $-\text{CH}_3$ group on α -carbon is known to decrease ability of molecules to block β -receptors in the heart. The β -adrenergic receptors in the skeletal muscle are classified as Type β_2 . Tremors of skeletal muscles produced by infusion of catecholamines in man are blocked by (\pm)-propranolol but are unchanged by (+)-propranolol (226). Whether all these β -receptors are different or whether the effects are due merely to physical-chemical properties of β -blockers is not known.

In addition to blocking β -adrenergic receptors, many of these blockers produce direct myocardial depression. Levy and his colleagues (227–230) attempted to correlate the physical-chemical properties with the cardiac effects of various β -blockers and their isomers. However, there appears to be no simple relationship between *in vitro* β -adrenergic blocking action and myocardial depressant effects.

On the other hand, the inhibition of Ca^{++} uptake in cardiac sarcoplasmic reticulum fractions by (–)- and

(+)-propranolol correlates with their ability to decrease cardiac contractility (231).

Recently, Serrano and Hardman (232) suggested that a nonionized form of the drug might be essential for the production of β -adrenergic blockade. While this suggestion will require further proof, an interesting experiment could be made by testing (–)- and (+)-isomers of β -adrenergic blockers. Since pK_a values of (–)- and (+)-isomers are identical, regardless of change in pH, the relative number of nonionized forms of both drugs should be the same. This would indicate that the difference in pharmacological activity between (–)- and (+)-isomers should remain the same at different pH values.

An attempt has been made to characterize the nature of the β -adrenergic receptor in the guinea pig atria (233). A potent and long-acting β -blocker, propranolol, was used as a tool to tag the receptors. However, uptake of the less active (+)-propranolol was the same as that of the more potent racemate or (–)-isomer. This nonspecific uptake indicates that the antagonist was largely bound to nonspecific sites and that the amount of antagonist bound to the specific sites must be very small. Thus, attempts to identify the pharmacologic receptors have achieved limited success.

Because of their antiarrhythmic effect, there has been considerable clinical interest in β -adrenergic blockers. However, the mechanism of antiarrhythmic action of

these drugs is complicated by their local anesthetic, "quinidineline," and β -adrenergic blocking effects. Results clearly indicate that adrenergically induced cardiac arrhythmias can be promptly terminated by low doses of (–)-isomers of β -adrenergic blocker. On the other hand, much higher and nearly equivalent doses of both (–)- and (+)-isomers of β -adrenergic blockers are required to prevent or prolong the cardiac arrhythmia induced by ouabain (234–241). Posttetanic potentiation of cat soleus is equally depressed by optical isomers of the β -blocker. On this basis, Standaert *et al.* (242) suggested that termination of digitalis-induced arrhythmia might be a neural phenomenon. In the guinea pig, when arrhythmias were produced by infusion of ouabain, Dohadwalla *et al.* (243) showed that (\pm)-propranolol is slightly more effective than (+)-propranolol. They attributed this unequal antiarrhythmic effect to the unequal β -adrenergic blocking property and not to the local anesthetic effect. Stickney and Lucchesi (244) elaborated on the ventricular arrhythmias elicited in dogs by central administration of acetylcholinesterase inhibitor. Racemic propranolol, but not (+)-propranolol, attenuated the arrhythmias caused by the glycoside.

Some β -adrenergic blockers are known to have a hypotensive effect in man. Kelliher and Buckley (245) studied the possible mechanism of this hypotensive effect. When administered directly into the left lateral ventricle of cat, both (+)- and (\pm)-propranolol produced nearly equal hypotensive effects. It was concluded that the central hypotensive effect is independent of β -adrenergic blockade. This study should be extended to the other optical isomers which are not local anesthetics. Furthermore, prevention of adrenergically induced arrhythmias may not necessarily be related to local anesthetic effects of β -blockers. For example, (–)-sotalol lacks local anesthetic effect but is a very effective agent in preventing the adrenergically induced arrhythmia. The mechanism of termination of nonadrenergically induced arrhythmia is yet to be clarified. Both the isomers of propranolol cause equal myocardial depression and the local anesthetic effect is also identical. In order to separate local anesthetic effect from quinidine-like effect, the use of deoxypropranolol has been suggested by Ariens (246). Parmley and Brunwald (247) compared myocardial depressant and antiarrhythmic properties of (\pm)-propranolol, (+)-propranolol, and quinidine. Their study suggests that (+)-propranolol might be a very useful drug in the treatment of certain arrhythmias where β -adrenergic blockade is not desired. Quinidine lowers arterial blood pressure, while (+)-propranolol is without such a clinically undesired effect.

Peripheral vascular effects of propranolol isomers have been studied in the anesthetized dog. Direct intracoronary injections of small doses, in the anesthetized dog, of (+)-propranolol produces transitory reduction in coronary vascular resistance; under similar conditions, (–)-propranolol only increases coronary vascular resistance. This increased resistance may be a reflection of β -blocking effect of (–)-isomer (248). Both isomers of propranolol, when injected directly in the external iliac artery, increased blood flow through the artery to the same extent. This effect is, however, at-

tributed to the local anesthetic effects of the agents (249).

Studies on effects of isomers of adrenergic drugs on metabolic processes are relatively few. Isoproterenol is very potent in releasing free fatty acids *in vitro* from adipose tissue. The (+)/(–) isomeric ratio is approximately 4000 (250). β -Adrenergic blockers competitively inhibit the free fatty acid mobilization stimulated by the adrenergic agents. (–)-Isomers of INPEA, isopropylmethoxamine, and methoxamine are some 100 times more potent than their (+)-isomers (251–255). High concentrations of both (–)- and (+)-INPEA equally reduced the incorporation of labeled glucose in the fat cells. Thus, the phenomenon appears to be nonspecific and unrelated to the β -adrenergic blockade (256).

Any adrenergic drug with a basic chemical structure such as phenethylamine exhibits a variety of characteristic effects at adrenergic synapses. β -Adrenergic blockers are basically derivatives of phenethylamines. It is possible, therefore, that β -receptor antagonists can interact at the same two points (Sites A and B), as suggested for *N*-(2-chloroethyl)dibenzylamine, and can protect α -receptors from the latter (Fig. 6). This two-point interaction would occur equally well with (–)- or (+)-isomers of β -antagonists, and thus the degree of stereoselectivity in protection of α -receptors by β -receptor antagonists would not be marked (257). If β -adrenergic blockers compete with norepinephrine for α -adrenergic receptors, these agents should shift the dose-response curve for norepinephrine to the right in a parallel fashion. Most agents, except isomers of H56/28, produced a potentiation of the effects of exogenous norepinephrine and shifted the curve to the left. This paradoxical observation can be explained by differential interplay between two main factors operative at sympathetic neurones: (a) inhibition of uptake, and (b) competition at α -adrenergic receptors. Whenever effects of norepinephrine are potentiated by a given blocker, the optical isomers do not differ in this respect. It indicates that inhibition of uptake of norepinephrine by (–)- and (+)-isomers of β -blocker must be similar. Results from biochemical studies tend to support this notion. Either in the adrenergic nerve granule or in the perfused heart, inhibition of uptake of exogenous norepinephrine or epinephrine by (–)- and (+)-isomers of β -blocker is similar (258–261). Since (–)- and (+)-isomers of β -blocker do not differ in either competition at α -receptor or inhibition of uptake and since (–)-isomers are the most potent blockers, the observed effects are not causally related to β -adrenergic blockade. Furthermore, on rabbit aorta, where uptake of agonist is not a critical factor in the determination of competitive antagonism, the pA_2 values of (–)- and (+)-INPEA are equal (262).

All four optical isomers of butedrine were also investigated (263) on the rat vas deferens. Phenylephrine was used as agonist. In the presence of butedrine, the dose-response curve of phenylephrine was depressed. The pD_2' values for noncompetitive antagonism varied from 3.7 to 4.20. This indicates a very small difference in butedrine isomers for the noncompetitive interaction with α -agonists, hence, unrelated to their β -blocking properties.

β -Adrenergic blockers are known to enhance the respiratory difficulty in asthmatics. With the aid of the optical isomers of INPEA, Murmann (264) attempted to analyze the underlying mechanism. He found that except in one species of mice, LD_{50} of histamine was not significantly altered by pretreating mice with either isomer of INPEA. He tentatively, then, suggested that β -adrenergic blockade may not be the cause for the enhancement of respiratory difficulty in asthmatics. However, it appears that in the bronchioles, when the smooth muscle relaxation is blocked by β -adrenergic blockers, there could be bronchoconstriction caused by overpowering of parasympathetics, as well as that of α -adrenergic receptors. Hence, in order to define the role of β -adrenergic blockade in asthmatics, two types of experiments remain to be done: (a) to see if (+)-isomers of INPEA will enhance the bronchoconstriction in asthmatics; and (b) to compare endotracheal pressure changes after pretreatment of either (-)- or (+)-isomers of β -blockers in experimental animals. The two phases of nicotinic blood pressure effects of acetylcholine in atropine-pretreated animals are well known. The first phase, caused by stimulation of sympathetic ganglia, is selectively antagonized by (-)-INPEA, while (+)-INPEA is ineffective. It is concluded that selective β -adrenergic blockade might be involved at the level of sympathetic ganglia (215).

METABOLIC ASPECTS

Only a limited number of reports concerning this facet are available at present. Epinephrine increases blood sugar; this effect is stereoselective in favor of (-)-isomer. In rabbits, 0.05 mg./kg. of (-)-epinephrine and 1 mg./kg. of (+)-epinephrine produce approximately an equivalent rise in the blood sugar. The effects of the (+)-isomer are transitory, while those of the (-)-isomer last many hours (265). Bowman and Raper (266) studied drugs affecting carbohydrate metabolism on contractions of the rat diaphragm. Potassium-induced depression of the skeletal muscle contraction is readily reversed by sympathomimetic agents. In this respect, (-)-norepinephrine and (-)-epinephrine are 500–1000 times more potent than their respective (+)-isomers. These effects, as they claim, are probably caused by activation of the β -receptor. Anderson and Chen (267) screened the hyperglycemic action of 40 amines. After equimolar doses (0.1 ml. of 0.1 M i.v.) in rabbits, the rise in blood sugar was determined. According to this test, the activity of ephedrines was: (-)-pseudoephedrine > (+)-ephedrine = (+)-pseudoephedrine > (-)-ephedrine. The differences between (-)-pseudoephedrine and (-)-ephedrine were striking. The onset of action of (-)-pseudoephedrine was very slow and as much as 40 min. was required for the peak effects. On the other hand, only 10 min. was required for the peak effects of the less active (-)-ephedrine.

A highly attractive hypothesis regarding the role of cyclic 3',5'-AMP in response to catecholamines has been put forward by Sutherland and his colleagues (268–270). It has been suggested that cyclic 3',5'-AMP plays an essential role in the hyperglycemic response

Figure 6—(a) The initial interaction of the ethylenimium ion from N-(2-chloroethyl)dibenzylamine ($R = C_6H_5CH_2$) and the α -adrenergic receptor as suggested by Belleau (199) and Triggle (202). (b) The possible interaction of β -adrenergic blockers like INPEA (where $R = NO_2$) and explains the protective action of β -adrenergic blockers against block by N-(2-chloroethyl)dibenzylamine. Note that the β -hydroxyl group is not involved and thus explains a similar protective effect of (-)- and (+)-INPEA. Reproduced with permission from Patil et al., *J. Pharmacol. Exp. Ther.*, 163, 309(1968), and the Williams & Wilkins Co., Baltimore, MD 21202

to epinephrine, principally through its effect on phosphorylase. Furthermore, it has been suggested that cyclic 3',5'-AMP might also be involved in the positive inotropic effects of catecholamines in the heart. The ability of (-)-isoproterenol, (-)-epinephrine, and (-)-norepinephrine to stimulate formation of cyclic 3',5'-AMP and to produce positive inotropic responses is of a similar nature. (-)-Epinephrine, as compared to its (+)-isomer, is much stronger both in formation of cyclic 3',5'-AMP and in positive inotropic effects. Recently, Weiss and Costa observed a stereospecific activation of adenylylase (271).

McNeill and Brody (272) determined the stereoselectivity of norepinephrine isomers for rat cardiac phosphorylase. Although both forms activated the enzyme to the same extent, (+)-norepinephrine was found to be 1/30th as active as its (-)-form. Thus, adenylylase and cyclic 3',5'-AMP and phosphorylase exhibit stereoselectivity.

A study of the metabolic fate of optical isomers provides an interesting approach to elucidating the nature of various mechanisms that are involved in biotransformation and excretion of the drugs. Considering the specificity of various enzymes, it is unlikely that optical isomers are handled identically by the body. Development of a sensitive and specific analytical method, however, poses a problem. Many methods that are available today do not distinguish between (-)- and

^a $\mu\text{mole of HCHO/min./mg. protein.}$ ^b The K_m and ν_{max} values shown are the mean values determined from two or three experimentally independent $1/v$ versus $1/s$ plots. The experimental points on each of these plots represented the mean of duplicate rate measurements for each substrate level. The standard error of the mean for the values in the table was about 10%. Data from Dann (282).

(+)-isomers of the drug. Hence, the metabolic fate of (-)- and (+)-isomers from the injected racemate cannot be precisely studied.

The fate and urinary excretion of amphetamine isomers have been studied in various species and in man. Although total urinary excretion of these drugs is pH dependent, the differences in the excretion pattern are not great (273–275). Gunne (276) used the gas chromatographic resolution method (277) for amphetamines and found that after administration of (\pm)-amphetamine, all subjects excreted approximately equal amounts of both isomers during the first 12 hr. Urine collected after 12 hr. contained a continually decreasing proportion of the (+)-isomer. This slow excretion might be a reflection of

higher tissue deposition of (+)-amphetamine (or its metabolites) over that of (-)-amphetamine (42). In rats, 2 days after dosing with equal amounts of (+)- and (-)-amphetamine, the quantity of *p*-hydroxyamphetamine is 48 and 63% of the initial dose, respectively. Relatively more (+)-*p*-hydroxyamphetamine is converted to its β -hydroxylated product, (-)-*p*-hydroxynorephedrine (43) by enzyme dopamine- β -hydroxylase; hence less (+)-*p*-amphetamine will appear in the urine. It is interesting, however, that the ring-hydroxylating enzyme does not appear to show selectivity for amphetamines. This lack of selectivity is in contrast to the fact that (-)-ephedrine is ring hydroxylated while (+)-ephedrine is not (278). There are marked species differences in the metabolism of amphetamine isomers. Axelrod (279) reported that an enzyme system in rabbit liver microsomes catalyzes the deamination of amphetamine to yield phenylacetone and ammonia. This enzyme system prefers (-)-amphetamine as substrate. However, neither (-)- nor (+)-amphetamine is metabolized by a microsomal preparation of rat liver (280). The urinary excretion kinetics of a close structural analog of amphetamine, methamphetamine, was also studied in man (276, 281). The excretion patterns of (+)- and (-)-methamphetamine are similar. Most of the drug is excreted unchanged in 24 hr.; however, a very small amount of the drug is *N*-demethylated. Because more (+)-amphetamine occurs in the urine after (\pm)-methamphetamine, it is suggested that enzymatic *N*-demethylation may be stereospecific. Similarly, (-)-ephedrine is *N*-demethylated while (+)-ephedrine is not (278). Recently, Dann (282) has investigated demethylation rates of ephedrine isomers. Isolated rabbit liver microsomes were used to determine the enzymatic kinetics. It was found that the ν_{max} is the same for all ephedrine isomers, but K_m values for (-)-ephedrine and (-)-pseudoephedrine were approximately twice those of (+)-ephedrine and (+)-pseudoephedrine (Table VIII).

MAO and COMT are the two major enzymes intimately involved in adrenergic drug effects. Although stereochemical substrate specificity was not detected in the early semipurified enzymatic preparations (283–286), it is now demonstrated that indeed these enzymes do show selectivity for the (-)-isomers of norepinephrine, epinephrine, and *m*-octopamine which are better substrates than their corresponding (+)-isomers (287). Kynuramine oxidation by rat liver monoamine oxidase was inhibited more by (+)-isomers (2S) of amphetamine, 2,4-dichloroamphetamine, 4-chloro-*N*-methylamphetamine, than their corresponding (-)-isomers (288). Although available reports indicate that both (-)- and (+)-epinephrine are equally good substrates for COMT (289, 290), a more definite study is needed to establish the stereoselectivity in the highly purified enzyme.

CNS EFFECTS

In 1939, Alles reported that (+)-amphetamine was much superior to its (-)-isomer in antagonizing chloral hydrate hypnosis in rabbits (291). Later, Prinzmetal and Alles (292) confirmed these observations in humans. They concluded that (+)-amphetamine was 2–4 times as

active as (–)-amphetamine in producing CNS stimulation. Tainter *et al.* (293) studied analeptic potency of a series of sympathomimetic amines in rats against hypnotic action of tribromoethanol, chloral hydrate, and pentobarbital. The time required for recovery of the corneal and righting reflexes after a fixed dose of the hypnotic was compared with that observed under the same conditions when various of the supposed analeptics were administered also. Both (–)- and (+)-ephedrine (60 mg./kg.) did not produce any analeptic effects. However, (–)-pseudoephedrine produced a shortening of some of the reflexes under tribromoethanol and chloral hydrate which indicated that with this isomer there was a definite analeptic power. Fairchild and Alles (294) systematically investigated the locomotor activities of all optical isomers of ephedrine, norephedrine, and amphetamine. In mice, the central locomotor activity of the most potent (+)-amphetamine was assigned as 1. The activity ratios of (–)-amphetamine, (+)-norpseudoephedrine, (–)-ephedrine, and (–)-norpseudoephedrine were 4.2, 10, 24.4, and 42.8, respectively. Other isomers, (–)-norephedrine, (+)-norephedrine, (–)-pseudoephedrine, (+)-pseudoephedrine, and (+)-ephedrine, were considered as less effective as central locomotor stimulants and produced measurable activity only at doses approaching lethal amounts. Schulte *et al.* (295) used the jiggle cage to record the central activity of various sympathomimetic amines in rats. When compared at threshold, stimulant doses of (+)-amphetamine were 8 times as potent as its (–)-form. Both forms of pseudoephedrine were much less active than (–)-ephedrine.

The ratio of central stimulant activity using (+)- and (–)-methamphetamine varies from 4 to 8, with the (+)-form more active (296). This activity difference is the same as that exhibited between isomers of amphetamine.

Considering the complexity of the CNS, more than one criterion is needed to obtain a full profile of central stimulant activity. Lanciault and Wolf (297) carefully examined the neuropharmacological properties of the ephedrine isomers. Several standard techniques, including low-frequency electroshock and chemoshock threshold determinations, hexobarbital sleep-time alteration, and a behavioral rating scale, were employed. It was concluded that (–)- and (+)-ephedrine were considerably more potent than (–)- and (+)-pseudoephedrine. None of these agents affected the hexobarbital sleep-time. Interestingly enough, in one test, a given stimulant raises a threshold while the same agent in other tests lowers the seizure threshold. For example, (±)-amphetamine raises the seizure threshold of the low-frequency electroshock test while pentylenetetrazol seizure threshold is lowered by (±)-amphetamine. According to both tests, low-frequency electroshock and chemoshock threshold determinations, (–)- and (+)-ephedrine were more potent than (–)- and (+)-pseudoephedrine. In rabbits, however, (+)-amphetamine was more effective in raising the threshold to electrical convulsions and (–)-amphetamine and (–)- and (+)-ephedrine did not produce any change (298).

Central effects of the optical isomers of phenolic amines such as norepinephrine and epinephrine have been investigated (299). Since these agents produce marked

pressor effects, there is the problem of separating peripheral effects from central effects. Moreover, these amines penetrate very poorly into the CNS. To overcome this difficulty, drugs were applied iontophoretically in order to study responses to brainstem neurones in decerebrate cats. The effects of (–)-norepinephrine on the firing rate of spontaneously active neurones have been found to conform to certain well-defined patterns. There are two types of patterns observed with (–)-norepinephrine, excitatory and/or inhibitory. (+)-Norepinephrine inhibited certain neurones which were also inhibited by (–)-norepinephrine; but on neurones excited by (–)-norepinephrine, its effect was weaker or absent. Thus, the excitatory effect shows stereoselectivity whereas inhibitory effect does not. The classical adrenergic blockers did not modify the responses. It is concluded that receptors for norepinephrine on brainstem neurones are of more than one kind and that they do not fit into the α - and β -classification applied to peripheral receptors (300).

An interesting approach to the study of central effects of catecholamines which do not pass the blood-brain barrier is to study them in young chickens where the blood-brain barrier is imperfect or nonexistent. Dewhurst and Marley (301, 302) used this approach to examine central effects of certain phenolic amines. The behavioral, electrocortical, and electromyographic activities were recorded. The phenolic amines produced depressant effects. Levonordefrin was at least 4 times as potent as the (+)-form. (–)-Norepinephrine was twice as potent as (+)-norepinephrine; however, dopamine was more potent than (–)-norepinephrine or (+)-norepinephrine. This pattern differs from that of peripheral sites where (+)-norepinephrine and dopamine are almost equiactive. The nonphenolic amines, such as amphetamine, produced excitatory effects. The (+)-form was more active than the (–)-form of amphetamine.

β -Adrenergic blockers produce variable effects on the CNS. With the aid of optical isomers of INPEA, Murmann *et al.* (303) concluded that, since both isomers were equipotent in producing CNS stimulation and since only one isomer is a potent β -adrenergic blocker, the central effects of β -blocker are unrelated to the blockade of β -adrenergic receptors.

The role of endogenous catecholamines in the peripheral effects of many nonphenolic amines is well defined. However, controversy still exists regarding the role of endogenous catecholamines in central effects of amphetamine and related agents. Wolf *et al.* (304) investigated optical isomers of several nonphenolic amines in the normal, reserpine-pretreated, and α -methyl-*m*-tyrosine-pretreated mice. Ability of the drug to lower chemoconvulsive threshold was used as an index of the central activity. All agents except (–)-pipradrol and (–)-pseudoephedrine demonstrated significant central effects. Reserpine pretreatment lowered the chemoconvulsive threshold to (+)-amphetamine, (–)-amphetamine, (+)-pipradrol, (–)-ephedrine, and (+)-ephedrine, while that after (+)-pseudoephedrine, (–)-norephedrine, and (+)-norpseudoephedrine was not affected. On the other hand, in the α -methyl-*m*-tyrosine-pretreated animals, the chemoconvulsive thresholds

after (+)-amphetamine, (–)-amphetamine, (–)-ephedrine, and (+)-pseudoephedrine were increased. Results from α -methyl-*m*-tyrosine-pretreated animals were assumed to be a better reflection of central catecholamine depletion. It was concluded that central effects of (+)- and (–)-amphetamine, (–)-ephedrine, and (+)-ephedrine possess large indirect components in their activity while those of (+)-pipradrol, (–)-norephedrine, and (+)-norpseudoephedrine are mainly direct. The effects of the optical isomers of amphetamine were also investigated on brain dopamine levels (305, 306), tissue respiration (307), and liver monoamine oxidase inhibition (284). However, both forms of amphetamine isomers produced similar results, indicating that these effects are not causally related to the central effects.

Infusion of (–)- α -methyldopa into the vertebral artery of the cat produces lowering of the blood pressure while (+)- α -methyldopa produces no such effect (308).

No clearcut structure–activity relationship as yet can be formulated for the central effects of sympathomimetic amines. In spite of this, as in the periphery, there are many agents which exhibit stereoselectivity in their central effects.

Amphetamine is well known to produce aggregation toxicity in mice. This effect is more pronounced with (+)-amphetamine. The potency ratio of the isolated/aggregated LD₅₀ is 4.9 for (+)-amphetamine and 1.2 for (–)-amphetamine. There was a marked dose-dependent reduction of the brain and heart norepinephrine content after (+)- or (–)-isomers of amphetamine. It was, however, only after the administration of (+)-isomer in aggregated mice that the norepinephrine-depleting effect was enhanced. Hence, it was concluded that the release of endogenous stores of norepinephrine plays a role in the enhanced toxicity of (+)-amphetamine in mice (309). Selectivity of aggregation toxicity was also studied for ephedrine isomers. Except for (+)-pseudoephedrine, all isomers of ephedrine exhibited this phenomenon, but in a magnitude which is much lower than that of (+)-amphetamine (310). The LD₅₀ potency ratio (isolated/aggregated) for the most potent ephedrine isomer was only 1.5.

There has been considerable clinical interest in the anorexigenic response of the drugs affecting the CNS. A reliable eating response can be obtained on injection of small quantities of (–)-norepinephrine into the rostral hypothalamus of the rat. (+)-Norepinephrine induces a negligible response, indicating a stereoselective effect. Booth (311) postulated that α -adrenergic modulation of postsynaptic activity by norepinephrine from the nerve ending is involved in the hypothalamic control of feeding in the rat. The stereoselectivity in the feeding behavior for isomers of norepinephrine was also observed by Margules (312). Roszkowski and Kelley (313) developed a screening method for assessing drug inhibition of feeding behavior. (+)-Amphetamine is very effective in producing an inhibition of broth consumption in rats. (–)-Amphetamine was ineffective. Abdallah (314) found (–)-ephedrine to be the most potent of the ephedrine isomers in causing a reduction of food intake in mice. Several other reports indicate that the (+)-form of amphetamine is more of an appetite depressant than the (–)-isomer (315–317). Between the isomers there is

cross-tolerance to the anorexigenic effect (318). Thus, it has been difficult to separate the central stimulant effects from the anorexigenic effects of these agents.

Greater loss of sodium from tissue could cause a great loss of body water which in turn reduces the weight of an animal. Because isomers of amphetamine do not significantly differ from one another in causing sodium loss, it cannot be an important factor in the weight-reducing effect of (+)-amphetamine (319).

The potent CNS-stimulating effect of (+)-amphetamine can be demonstrated by increased oxygen consumption in morphine-pretreated dogs or in humans. In this respect, (–)-amphetamine is much less active than the (+)-form (320, 321). *p*-Chloro-substituted amphetamines show some promise as anorexigenic agents. (+)-*p*-Chloroamphetamine is less of a central stimulant but is a longer-acting anorexigenic agent than (+)-amphetamine (322). (–)-*p*-Chloroamphetamine is more active than (–)-amphetamine; both agents are less active than their respective (+)-forms. The anorexigenic effect of (+)-*p*-chloroamphetamine is unrelated to depletion of brain serotonin because both optical isomers are equally effective in causing depletion of brain serotonin (323). Phenmetrazine and phendimetrazine are known to be effective anorexigenic agents. There is an interesting stereochemical relationship between ephedrine and the phenmetrazine molecule (324, 325). Most observations to date tend to support the view that the anorexigenic effect of (+)-amphetamine may be of central origin.

CONCLUDING REMARKS

An attempt is made to survey a highly scattered and occasionally fragmentary literature on the optical isomers of adrenergic drugs. The facts from the old literature as well as those from the recently published manuscripts are blended in a proper perspective. At adrenergic synapse, stereoselectivity has been observed for: (a) all biosynthetic pathways; (b) transport in adrenergic neurone; (c) prevention of uptake at the neurone; (d) binding and retention in the granule; (e) enzyme monoamine oxidase; and (f) pharmacologic α - and β -adrenergic receptors. Previously, adrenergic blockers were used to classify the pharmacologic receptors. However, blockers don't have to react with the exact configuration of the receptor. In addition, physical–chemical properties of one blocker could differ from those of the other. So far as (–)- and (+)-isomers are concerned, their physical–chemical properties are identical. The evidence obtained from blockers could be regarded as an indirect one. Agonists have to interact with the exact configuration of the receptor to produce the pharmacologic effect. The isomeric activity ratio should serve as a better criterion to differentiate receptors. Even if the adrenergic receptor is isolated, its similarity to that in the tissue will not be proven until isomeric affinity ratios are obtained and compared with the isomeric activity ratio. Thus, optical isomers provide a valuable tool to analyze drug effects at basic levels.

RESEARCH ARTICLES

Interaction of Isoniazid with Magnesium Oxide and Lactose

WEN-HUNG WU, TING-FONG CHIN, and JOHN L. LACH

Abstract □ Interactions of isoniazid with magnesium oxide and with lactose were investigated in the solid state. In the isoniazid-magnesium oxide system, chemisorption as well as physical adsorption of isoniazid molecules onto the magnesium oxide surface was confirmed by diffuse reflectance spectroscopic data. An absorption maximum due to chemisorbed isoniazid molecules was found to occur at 325 mμ, whereas physical adsorption was detected at 268 mμ. The mechanism of surface chemisorption is different from that of the formation of the isoniazid-metal-ion complex in solution. The browning reaction of the isoniazid-lactose system in solid state

was also studied using diffuse reflectance spectroscopy. The rates of browning at 95, 100, 105, and 110° were followed by measuring the reflectance at 450 mμ. From the data obtained, the approximate time needed for browning to be perceptible has been predicted. TLC separations of the reaction products confirmed the presence of isonicotinoyl hydrazones of lactose and hydroxymethylfurfural.

Keyphrases □ Isoniazid interaction—magnesium oxide, lactose □ Lactose-isoniazid systems—browning rates □ Magnesium oxide, chemisorption—isoniazid □ Diffuse reflectance spectroscopy—analysis □ IR spectrophotometry—identity

Difficulties in formulating a new pharmaceutical dosage form have often been experienced because of the interactions between the supposed inert adjuvants and the active ingredient itself. Although the nature and intensity of these interactions vary, such interactions may alter the stability, dissolution rate, and, consequently, the absorption of the drug. A literature survey

indicates that such interactions involving the formation of complexes have been studied extensively in aqueous solution; relatively few studies have been carried out in the solid state.

Stearic acid and calcium stearate have been shown by Kornblum and Zoglio (1) to catalyze the degradation of aspirin. Ribeiro *et al.* (2) studied the influence of lubri-

RESEARCH ARTICLES

Interaction of Isoniazid with Magnesium Oxide and Lactose

WEN-HUNG WU, TING-FONG CHIN, and JOHN L. LACH

Abstract □ Interactions of isoniazid with magnesium oxide and with lactose were investigated in the solid state. In the isoniazid-magnesium oxide system, chemisorption as well as physical adsorption of isoniazid molecules onto the magnesium oxide surface was confirmed by diffuse reflectance spectroscopic data. An absorption maximum due to chemisorbed isoniazid molecules was found to occur at 325 mμ, whereas physical adsorption was detected at 268 mμ. The mechanism of surface chemisorption is different from that of the formation of the isoniazid-metal-ion complex in solution. The browning reaction of the isoniazid-lactose system in solid state

was also studied using diffuse reflectance spectroscopy. The rates of browning at 95, 100, 105, and 110° were followed by measuring the reflectance at 450 mμ. From the data obtained, the approximate time needed for browning to be perceptible has been predicted. TLC separations of the reaction products confirmed the presence of isonicotinoyl hydrazones of lactose and hydroxymethylfurfural.

Keyphrases □ Isoniazid interaction—magnesium oxide, lactose □ Lactose-isoniazid systems—browning rates □ Magnesium oxide, chemisorption—isoniazid □ Diffuse reflectance spectroscopy—analysis □ IR spectrophotometry—identity

Difficulties in formulating a new pharmaceutical dosage form have often been experienced because of the interactions between the supposed inert adjuvants and the active ingredient itself. Although the nature and intensity of these interactions vary, such interactions may alter the stability, dissolution rate, and, consequently, the absorption of the drug. A literature survey

indicates that such interactions involving the formation of complexes have been studied extensively in aqueous solution; relatively few studies have been carried out in the solid state.

Stearic acid and calcium stearate have been shown by Kornblum and Zoglio (1) to catalyze the degradation of aspirin. Ribeiro *et al.* (2) studied the influence of lubri-

cant type and concentration of the lubricant in the decomposition of aspirin in APC tablets. In most cases, an increase in lubricant concentration caused a corresponding increase in decomposition. The most striking effect was observed with calcium stearate, stearic acid, and magnesium stearate. It is conceivable that the metallic salts of these weak organic acids catalyze aspirin degradation: however, the catalytic effect brought about by stearic acid alone suggests that some other mechanism(s) may also be operative. The influence of antacid compounds and tablet diluents on the stability of aspirin has also been investigated by Bandelin and Malesh (3). The authors reported that there is no relationship between the solubility of the adjuvants and the decomposition of aspirin. For example, a highly insoluble magnesium trisilicate produced a high rate of decomposition, while calcium gluconate, a very soluble salt, was less reactive.

Adsorption of antibiotics on antacid materials has been studied by several authors (4, 5). Blaug and Gross (6) showed that the adsorption of some anticholinergic drugs on magnesium trisilicate was so strong that complete desorption was difficult. Chulski and Forist (7), studying the effects of some solid buffering agents on prednisolone, found that the steroid was adsorbed by magnesium trisilicate and that magnesium oxide produced a first-order degradation of the steroid.

Although these studies dealing with drug-adjuvant interactions covered different types of drugs and adjuvants, the nature of the interactions involved and their reaction mechanisms were not fully discussed. This is probably attributable to the fact that reactions in the solid state are usually complex, complicated by numerous parallel and consecutive reactions. However, more important has been the lack of available effective and dependable instrumentation for the study of such interactions in the solid state.

Guillory *et al.* (8) reported on thermal methods using differential thermal analysis (DTA) for the detection of interactions occurring between solid components of pharmaceuticals. Drug-adjuvant interactions in the solid state have been investigated by Lach and Bornstein (9-11), Bighley (12), and McCallister (13), using diffuse reflectance spectroscopy (DRS). The authors covered a wide range of active medicinal agents including antibiotics, analgesics, and anticoagulants. The adjuvants investigated included both metallic and nonmetallic compounds. The degree of strength of the interactions between drugs and adjuvants was interpreted from the spectral shifts observed.

Since the clinical response of any solid dosage form depends not only on the accurate labeled amount of medicament present but also on its actual availability to the patient once administered, a study of these solid-state interactions is of prime importance in an understanding of the formulation of therapeutically effective dosage forms. The purpose of this investigation was to study drug-adjuvant interactions, since drug availability might be significantly altered as a result of these solid-solid interactions. Since isoniazid (INH) does form chelates in solution with various metallic ions (14-16), it is highly probable that similar type interactions would occur on the surface of metallic-containing adjuvants commonly employed in the preparation of solid dosage

forms. It is also probable that INH would undergo other types of surface interactions. An investigation dealing with these aspects was therefore undertaken.

EXPERIMENTAL

Reagents—The following were used: isoniazid,¹ recrystallized from 95% ethanol, m.p. 171-172°; MgO USP,² heavy, average size 30 μ ; KBr,³ spectroscopic grade; lactose monohydrate,² A.R., m.p. 201-202°; silica gel G⁴ for TLC; deuterium oxide⁴ for spectroscopy, 99.75%; 5-hydroxymethylfurfural,⁵ recrystallized from a mixed solvent consisting of equal volumes of ether and petroleum ether, m.p. 31-32°; methanol,² A.R.; and methylene chloride,⁶ A.R.

Apparatus—All diffuse reflectances were measured using a spectrophotometer⁷ equipped with reflectance attachment. The cell consists of a square aluminum block, an aluminum back cover, and two metal bolts. A piece of circular quartz,⁸ 3.17 cm. (1.25 in.) in diameter and 0.16 cm. (0.064 in.) in thickness, is fitted into the front side of the block. The detailed dimensions are shown in Fig. 1. The powder compartment is shown as the shaded area. The other apparatus used were: recording spectrophotometer;⁹ IR spectrophotometer;¹⁰ vacuum oven;¹¹ dry oven,¹² analytical, low gradient; heater and circulator,¹² equipped with microset thermoregulator;¹³ submersion rotator;¹⁴ and TLC apparatus.¹⁵

General Procedure for Sample Equilibration—Specified quantities of a drug and an adjuvant were accurately weighed on an analytical balance and transferred into a suitable size amber-colored bottle, which held enough void volume for sample mixing after the powders and solvent (10 ml. solvent/1 g. adjuvant) were added. After the cap was replaced, the bottle was fixed on the rotator and tumbled for 24 hr. at room temperature (25°). The content was poured into a mortar and dried at 25° in a vacuum oven. After the bulk of the solvent was driven off, the powder was thoroughly triturated and then dried again at 35° under vacuum. Finally, the sample was cooled in a vacuum desiccator over calcium sulfate.

Reflectance Measurement—The prepared sample was packed into a cell. Since the process of packing has been reported (17) to cause fluctuation in reflectance reading, it is essential to maintain the same condition for every sample packed. In all cases, pure adjuvant itself was used as a white standard (18).

Preparation of Deuterated INH—One gram of INH was dissolved in 10 ml. of D₂O, and the clear solution was transferred to an ampul which was sealed after the air was replaced by nitrogen. The ampul was allowed to stand in the dark for 24 hr., and the D₂O was evaporated under vacuum until completely dry.

Browning of INH-Lactose Solid System—According to the previously stated procedure, a sample containing 15 mg. INH/1 g. lactose was equilibrated in CH₂Cl₂. For purposes of comparison, lactose containing no INH was treated in the same manner. After the reflectance spectra were taken, both samples were heated at 100 \pm 0.5° in a dry oven. At various time intervals, the samples were transferred to a desiccator containing calcium sulfate and allowed to cool for 15 min.; the reflectance spectra were then taken. The same experiment was carried out also at 95, 105, and 110°.

Browning of INH-Lactose Mixture in Solution—Three solutions were prepared by dissolving: (a) 150 mg. INH, (b) 150 mg. INH and 10 g. lactose, and (c) 10 g. lactose, respectively, in small amount of water and made to 100-ml. volume. Five milliliters each of the solutions was filled into 10-ml. ampuls and sealed. These ampuls were heated at 100 \pm 0.1° in an oil bath; at various time intervals, one ampul containing the respective solution was removed. The reaction was quenched by quick cooling, 1 ml. each of the content was diluted

to 100 ml., and the transmittance spectra were taken from 220–340 $m\mu$.

Preparation of Isonicotinoyl Hydrazone of Hydroxymethylfurfural (INH-HMF)—One gram HMF was dissolved in 8 ml. of methanol and diluted with an equal volume of water. To this solution was added 1 g. of INH and diluted with 5 ml. of water. The clear solution was heated to boiling and then chilled in a refrigerator. The precipitate was filtered and recrystallized from 45 ml. of 50% ethanol, using charcoal as a decolorizing agent. The light-yellow needles obtained were again recrystallized and finally dried at 30° under vacuum, m.p. 216–218° (corrected). $\lambda_{\text{max}}^{\text{H}_2\text{O}} = 320 \text{ m}\mu$, $d_{320}^{\text{H}_2\text{O}} = 2697.0$. Elemental analysis showed the following:

	C	H	N
Theoretical	58.77	4.52	17.14
Determined	58.86	4.63	17.09

TLC—Silica gel G plates (0.25 mm.) were developed by a solvent mixture made by diluting 60 ml. methanol with CHCl_3 to 125 ml. Air-dried plates were then examined under UV light and also exposed to iodine vapor.

RESULTS AND DISCUSSION

INH-MgO System—DRS of various samples, containing 3, 7, 10, 13, and 16 mg. INH/1 g. MgO and equilibrated in methanol according to the general procedure previously described, are shown in Fig. 2. In each spectrum, two absorption maxima were observed, one at 268 $m\mu$ and the other at 325 $m\mu$. However, the transmittance spectrum of INH in aqueous solution showed only one absorption maximum at 262 $m\mu$. The influence of solvent polarity on this maximum was small, since λ_{max} in CHCl_3 was also found at the same wavelength. It was also observed (Fig. 2) that the intensity increase of the maximum at 268 $m\mu$ as a function of drug concentration was much greater than that for the maximum at 325 $m\mu$.

These intensity relationships (Table I) are represented by the observed reflectances and expressed as a remission function, which is also referred to as the Kubelka-Munk equation (19):

$$f(r_\infty) = \frac{(1 - r_\infty)^2}{2r_\infty}$$

where r_∞ is a measured reflectance. As seen in the last column of Table I, a comparison of the ratio $f(r_\infty)_{268}/(r_\infty)_{325}$ indicates that this

13	3.82×10^{-3}	43.7	0.3627	54.0	0.1959	1.85
16	4.71×10^{-3}	38.3	0.4970	49.8	0.2530	1.97

concentration effect was considerably more significant for the 268 $m\mu$ maximum than for the other at 325 $m\mu$. If one assumes that the appearance of these two maxima is due solely to the INH molecules adsorbed onto the MgO surface and that the forces involved in this interaction for these adsorbed molecules are comparable, then this ratio for these two maxima should not change. Theoretically, the ratio of absorbances as well as remission functions at two different wavelengths should be equal to the ratio of the molar absorptivity at the respective wavelengths and should be a constant. Since this is not the case here, it is more likely that the maxima at 268 and 325 $m\mu$ are the results of INH molecules being adsorbed by several different mechanisms.

Figure 3 shows a plot of remission function, $f(r\infty)$, versus concentration expressed in mole fraction, i.e., mole INH/mole MgO. Although fluctuation of data was rather significant, it was possible to observe that an approximately linear relationship did exist between the remission function and concentration at 268 $m\mu$, whereas at 325 $m\mu$ the remission function approached a plateau. Since in physical adsorption, multiple-layer adsorption may occur, this intensity increase for the 268- $m\mu$ maximum with an increase in concentration may be assigned to physical adsorption of INH molecules. This assignment might well be supported by the bathochromic effect observed, which has also been reported by several workers (9, 20) in such adsorption. The second maximum at 325 $m\mu$ may be due to chemisorbed INH molecules. Since chemisorption is known to occur only to the extent of formation of a monolayer on the adsorbent surface, the adsorbed molecules in excess of this amount (multiple-layer) no longer contribute to the intensity of a maximum due to chemisorption, as is seen in the maximum at 325 $m\mu$ which gradually shows a plateau at higher concentration and a decrease in the clarity of the peak.

From the molar absorptivity of INH, $a_{262}^{H_2O} = 518.0$, the maximum at 262 $m\mu$ can be assigned to a $\pi \rightarrow \pi^*$ transition of the conjugated system in the INH molecule. There is then a possibility of assigning the weaker maximum at 325 $m\mu$ in the reflectance spectrum to the $n \rightarrow \pi^*$ transition of the carbonyl group. This is not possible, however, since the intensity of the $n \rightarrow \pi^*$ transition can never exceed that of the $\pi \rightarrow \pi^*$, so the 325- $m\mu$ maximum should be always weaker than the 268- $m\mu$ maximum. However, this was not observed when the experimental conditions were altered.

To study further the nature of these maxima, 15 mg. of INH/1 g.

of MgO was triturated in a mortar for 10 min. and packed into a cell; the reflectance spectrum was then taken at different time intervals. The results are shown in Fig. 4. As is evident from this figure and contrary to Fig. 2, the intensity ratios, $f(r\infty)_{268}/f(r\infty)_{325}$, determined within the time interval studied were smaller than 1; as time increased, these ratios gradually decreased and then slowly increased. These relationships between ratios and time calculated from Fig. 4 are shown in Fig. 5, and they may be explained in the following manner. Immediately after the trituration, both chemisorption and physical adsorption have occurred. However, the extent of adsorption in both cases is far from the equilibrium state, as may be observed by a comparison of Fig. 2 and Fig. 4. Consequently, at this stage, except for some of the INH molecules that have been removed from the surface of the INH crystals and chemisorbed onto MgO surface, the rest of the INH molecules remain intact in the crystalline form. However, as the time interval lengthens, some INH molecules become separated from the INH crystalline surface due to particle collision or surface diffusion, and they undergo chemisorption with the large unsaturated MgO surface. This is reflected in the increase in the intensity of the 325- $m\mu$ maximum in the diffuse reflectance spectrum. Statistically speaking, it is probable that some of these free INH molecules may also be adsorbed physically to other already chemisorbed molecules, so that the intensity of the maximum at 268 $m\mu$ increases but at a much slower rate. This is indicated in Fig. 4, which shows this ratio decrease during the first 66 hr. However, beyond this period the ratio begins to increase. This is probably due to the fact that the unsaturated MgO surface sites are, for the most part, satisfied by the chemisorbed layer of INH molecules and that additional molecules liberated from the INH crystal surface are now physically adsorbed to this layer. If the system just discussed is allowed to attain equilibrium by storage for a sufficient period of time, the reflectance values would be comparable to that of the sample equilibrated in a solvent. Zeitlin *et al.* (18) have confirmed this aspect in their study.

The assignment of the two maxima was further supported by a study that involved equilibration and solvent elution of the drug from the adjuvant surface. Each sample was prepared by equilibrating 5 g. of MgO with 200 mg. of INH dissolved in 50 ml. of methanol and CH_2Cl_2 , respectively. The sample was then filtered with gentle

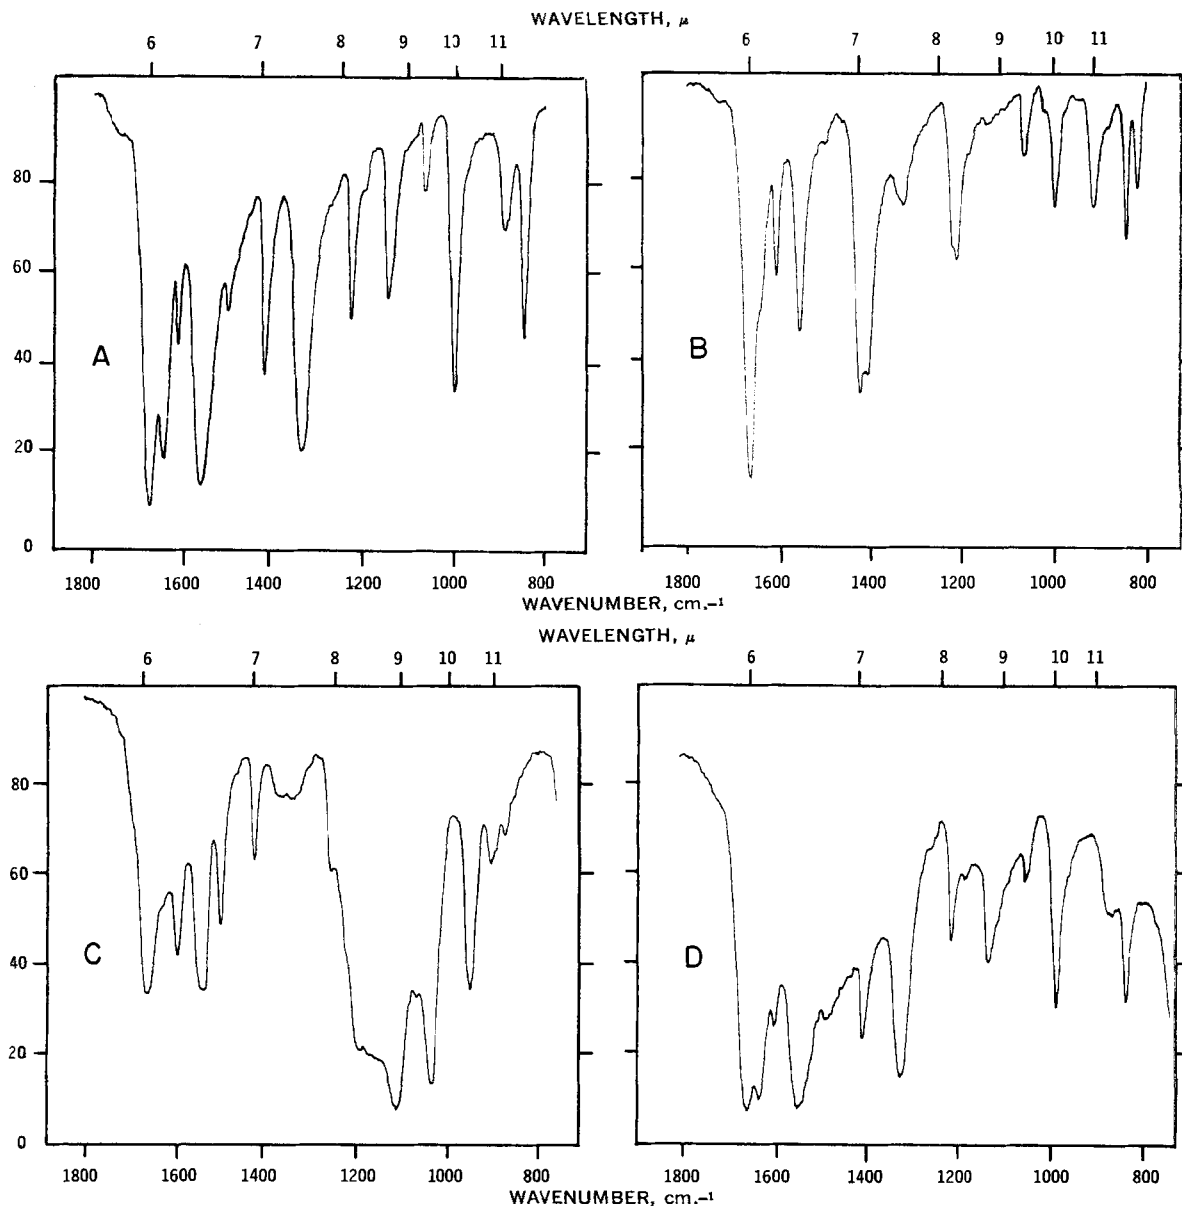

Figure 7—IR spectra of isoniazid (A), deuterated isoniazid (B), isoniazid-copper complex (C), and isoniazid adsorbed on magnesium oxide (D).

suction, followed by slow elution with 200 ml. of the respective solvent used in equilibration, and dried at 35° in a vacuum drying oven. Differential thermal spectrograms of these samples indicated that no solvent residue remained. DRS of these samples are shown in Fig. 6. As can be seen, the absorption intensities for the 268-m μ maxima are weaker than for the 325-m μ maxima, and the ratios, $f(r\infty)_{268}/f(r\infty)_{325}$, are less than 1. This is contrary to the ratios calculated from Fig. 2 and listed in Table I. This finding is significant and is due to the fact that in this elution process, physically adsorbed INH molecules are more easily removed than those that are due to chemisorption.

The possibility that this 325-m μ maximum is due to the existence of inter- or intramolecular complexes within the crystal lattice of the INH particle is unlikely in view of the fact that these equilibrated samples were thoroughly eluted with the respective solvents. Under such conditions the presence of crystalline INH particles is very limited.

In their studies dealing with the determination of dissociation or formation constants of INH complexes, various workers (21–24) have reported that spectral shifts of INH solutions do occur with a change in pH. At a pH above 11.6, the 262-m μ maximum is shifted to 300 m μ and is due to ionization of the INH tautomer (Scheme I).

No strong maximum at 325 m μ was observed even at very high pH values. In view of the fact that the pH of a saturated MgO aqueous solution is approximately 10.3, it is highly improbable that the 325-m μ maximum observed in the solid INH-MgO system discussed is due solely to the pH effect. It is interesting to note here that the diffuse reflectance spectrum of a mixture of MgO and INH-Cu complex [the complex prepared according to the procedure of Foye and Duvall (15)] did show a small hump in this 300-m μ region. This would be expected since, in the postulated copper complex structure,

Figure 8—DRS showing the browning of lactose at 100°. (The numbers shown are time in hours.)

ionization of the INH tautomer is necessary prior to its formation. The absence of this 300-m μ hump, as seen in Figs. 2, 4, and 6, does suggest that a mechanism or mechanisms other than that involved in the formation of the INH-Cu complex in solution is operative in the INH-MgO equilibrated system. The formation of an INH-Mg complex in solution has not been reported.

These observations are also supported by the IR spectra shown in Fig. 7. Spectra A, B, and C were taken after mixing 1 mg. of INH, deuterated INH, and INH-Cu complex, respectively, with 150 mg. of KBr. Spectrum D was taken of a thoroughly triturated mixture of 1 mg. INH and 3 mg. MgO. This sample was placed in a vacuum desiccator over calcium sulfate for 30 hr. and mixed with 150 mg. of KBr. Spectra A, B, and D portray a strong carbonyl stretching band, ν C=O at 1665 cm.⁻¹; C exhibits only a weaker band at 1655 cm.⁻¹, which is probably due to ν C=N rather than the ν C-I=O. Comparison of A and B at 1636 cm.⁻¹ reveals the fact that the 1636-cm.⁻¹ band in A is responsible for the bending vibration of an amino group, δ -NH₂. Because this amino group bending vibration disappears

Figure 9—DRS showing the browning of isoniazid-lactose system at 100°. (The numbers shown are time in hours.)

Figure 10—Relationship between reflectance and dilution of browned substance obtained from heating the isoniazid-lactose system at 100° for 182 hr.

upon deuteration, it is absent in B. The same band is still present in D but not C. Therefore, it may be assumed that the -NH₂ groups in A and D exist in the same free form, while in C it is quite different, probably because of the formation of a coordination bond between cupric ion and the lone pair electrons on the amino nitrogen. However, the most confirmatory evidence is obtained at 1330 and 1110 cm.⁻¹, which may be assigned to ν C-N and ν C-O bands, respectively. Again A and D give the same spectra while C is variant. It is quite natural that Spectrum D shows the 1330-cm.⁻¹ band, even if INH has reacted with MgO in a manner similar to that of the INH-Cu complex, because the 1 mg. of INH used is in excess of the amount needed to interact with the surface of the 3 mg. of MgO present. However, the complete absence of a band at 1110 cm.⁻¹ indicates that the carbonyl double bond in Spectrum D is still intact. On the other hand, Spectrum C displays a strong ν C-O band at 1110 cm.⁻¹, which coincides well with the postulated structure of this INH-Cu complex. Hence, it may be concluded that, contrary to that of the INH-Cu complex, the interaction of INH with MgO does not induce significant alteration in the molecular structure of INH. Thus the interaction, as well as the formation of the new UV maximum at 325 m μ in the diffuse reflectance spectrum, is the result of a mechanism different from that involved in this INH-Cu complex.

One possibility is that a donor-acceptor mechanism is operative in this INH-MgO interaction. It is known that the pyridine ring itself is a good donor. This donor capacity, however, might be somewhat reduced by the presence of a carbonyl group that exhibits a negative inductive effect. This effect would not be too significant if one considers the counterbalancing effect of the hydrazide group which may supply enough flow of electrons into the carbonyl group. Electron affinities of many compounds are not well known. However, if the energy level of the antibonding molecular orbital of MgO lies lower

Figure 11—The rates of browning of lactose at 95, 100, 105, and 110°.

Figure 12—The rates of browning of the isoniazid-lactose system at 95 and 100°.

than the antibonding orbital of the conjugated system in the INH molecule, there is a possibility that a π -electron of INH will be transferred to the low-lying antibonding orbital of MgO instead of to the higher energy antibonding orbital of its own. This could happen when the two molecular orbitals approach close proximity to each other so that the overlapping of molecular orbitals actually occurs. Such a situation would require strong adsorption of a substrate onto an adsorbent surface, that is, chemisorption rather than physical adsorption. The immediate consequence of this type of electron transfer is the appearance of a resultant two-charged species which, in turn, would attract each other much more than the original two polar molecules. This does indicate the complexity of surface interactions since both chemisorption and physical adsorption are operative.

INH-Lactose System—The reflectance spectra of both lactose and the INH-lactose system are shown in Fig. 8 (Curve O) and Fig. 9 (Curve O). As is evident in Fig. 8 (Curve O), lactose has not been influenced by this equilibration process. Figure 9 (Curve O), which represents the spectrum of the equilibrated INH-lactose sample, shows a broad maximum at 265 $m\mu$ and shoulders at both sides of the maximum. Because of the lack of well-separated maxima in the spectrum of the INH-lactose system as compared to that of MgO, a study dealing with concentration effects with respect to intensity changes and spectral shifts was not successful.

Heating of the equilibrated lactose and INH-lactose samples in an oven at $100 \pm 0.5^\circ$ did produce changes in the DRS spectra, as shown in Figs. 8 and 9, as well as browning of the samples. Although no absorption maximum was initially seen in the equilibrated lactose system containing no drug, a maximum did appear at about 275 $m\mu$ after heating. In the INH-lactose system, this thermal effect broadened the maximum at 265 $m\mu$. Since no maximum appeared in the visible region of the spectra in Figs. 8 and 9, selection of a proper wavelength at which the extent of browning was to be measured was next undertaken. For this purpose, the darkened sample was subjected to serial dilutions with lactose, and the reflectance spectra were taken. When the remission function, $f(r_\infty)$, versus extent of dilution was plotted at 400, 450, and 500 $m\mu$, respectively, all

showed straight-line relationships as illustrated in Fig. 10, showing the exact conformity with an equation described by Wendlandt and Hecht (25):

$$f(r_\infty) = \frac{2.303 \cdot a \cdot C}{S} \quad (\text{Eq. 2})$$

where a is the molar absorptivity, C is the molar concentration, and S is the scattering coefficient.

The reflectance at 450 $m\mu$ was arbitrarily chosen and employed in the subsequent reflectance measurements for the investigation of the rate of browning in the solid systems. The results are shown in Figs. 11-13. Careful examination of each curve revealed that it consists of two portions. In the first stage of the browning reaction, which in most cases occurred between 0-50 hr., a sigmoidal curve was obtained; in the second stage, an almost straight-line relationship with time was observed. From these two distinct patterns in the reflectance data, it may be assumed that two fundamentally different mechanisms are probably operative. Since each lactose molecule contains 1 molecule of water which may have a direct relationship in the first stage of this browning reaction, a study of the dehydration aspect of lactose was carried out at the same temperature ranges. The results showed that, except at 95°, the complete dehydration of lactose occurred within about 50 hr., which coincided with the time necessary for the completion of the sigmoidal portion of the curve. During this stage of browning, it appears that a true solution phase is formed locally between the water liberated from lactose monohydrate, and that this dehydrated lactose and INH then proceed to react to form: (a) a condensation product of lactose and INH, and (b) various carbonyl compounds through stepwise degradation of lactose. This initial reaction can be regarded as being in a solution phase and not the so-called solid-solid reaction in the true sense of the meaning.

During the second stage of browning, the reaction may be considered essentially in the solid state. From the straight-line relationship obtained between remission function and time, the browning reaction may be assumed to follow an apparent zero-order rate law; from the slope, the rate constants, k , were calculated and are listed in Table II. However, since the actual reaction is very complicated and many different types of reaction nuclei may be formed during the

Figure 14—Temperature dependence of apparent zero-order rate constant for browning reactions of the isoniazid-lactose system (A) and lactose alone (B).

first stage of the browning reaction, these, along with other nuclei generated in this second stage, may then proceed to form various products. Therefore, the apparent rate constant, *k*, in this case does not have the usual kinetical significance. It does, however, represent a total overall reaction and does enable the approximate estimation of the rate of reaction at the other temperatures. From the data in Table II, an Arrhenius plot was attempted (Fig. 14). From the curves obtained instead of the usual straight lines, it is obvious that the reaction mechanisms are not consistent throughout the temperature range studied, and this reflects the complexity of the browning reaction. When the curves are extrapolated to room temperature, assuming that the curves do not change their curvature, it is possible to estimate the approximate time required for the extent of browning to be perceptible. Since lactose showed a convex curve that does not intersect with a vertical line down through a point at 25°, it would appear that this browning of lactose would require an infinite time to occur. Brownley and Lachman (26) reported that lactose remained white after storage for 36 months under ambient conditions. On the other hand, the equilibrated mixture of INH and lactose showed a concave curve. From the intersect with the vertical line at 25°, log *k* was determined and the time required for initial browning to be perceptible, assuming *r*_∞ = 90%, was calculated as approximately 4 years. In this calculation, it is assumed that the straight-line portion of the curve passes through the origin. This 4-year stability of the INH-lactose system will certainly be reduced to some extent when the sample is exposed to excessive moisture. Ritschel and Rahman (27) and Horikoshi and Himuro (28) drew attention to the fact that atmospheric moisture did accelerate the browning of INH tablets.

Since it is well known that browning of many compounds, such as food and food products, is also faster in the presence of moisture, the browning of the INH-lactose system was carried out in solution for purposes of comparison and to isolate reaction products where possible. Prior to heating, Solutions *a* and *b* showed absorption at 262 mμ, which is due to INH as mentioned before (see *Browning of INH-Lactose Mixture in Solution*). Solution *c* did not show any absorbance. After heating, Solution *a* showed a shoulder at about 300 mμ. Solution *b*, which is a mixture of INH and lactose, showed a new strong absorption at 320 mμ. Solution *c* exhibited an intense maximum at 283 mμ, which was identified by TLC as 5-hydroxymethylfurfural (HMF). The new maximum at 320 mμ in Solution *b* was believed to be the result of a reaction between INH and HMF, which was confirmed by TLC using prepared INH-HMF as a standard. The compound INH-HMF has been prepared differently by Knotz (29). Since both HMF and INH-HMF were found to obey Beer's law within 0–0.6 mg. HMF/100 ml. H₂O and 0–0.8 mg. INH-HMF/100 ml. H₂O,¹⁶ the quantities of INH-HMF and HMF produced in Solutions *b* and *c* were determined from the spectra and are listed in Table III. This table indicates that the rates of appearance of both INH-HMF and HMF were approximately equal. From these results, it is assumed that HMF, which is formed from the degradation of lactose in aqueous solution, reacts instantly with INH to form INH-HMF. The high reactivity of both species was substantiated by the fact that swift precipitation of INH-HMF was observable as moderately concentrated solutions of both species were mixed together. Also, an almost theoretical yield was obtained in the preparation of INH-HMF.

Figure 15—Thin-layer chromatogram showing thermal degradation products of the isoniazid-lactose system. Key: *a*, INH-HMF, *R*_f = 0.85, pink spot under UV light, brown spot by I₂ vapor; *b*, INH-L, *R*_f = 0.12, brown spot by I₂ vapor; *c*, methanol extract of degradation products in solid state; *d*, methanol extract of degradation products in solution; *e*, HMF, *R*_f = 0.96, black spot under UV light, brown spot by I₂ vapor; and *f*, INH, *R*_f = 0.62, brown spot by I₂ vapor.

Since INH-HMF was found in solution degradation, it was interesting to know whether the same compound was also formed in the solid system. Identification of the reaction products in the solid state was carried out using TLC. The highly darkened solid sample was first extracted with anhydrous methanol and then spotted on a plate. Simultaneously, methanol solutions of INH, INH-HMF, HMF, and isonicotinoyl hydrazone of lactose (INH-L) were also spotted. INH-L was tested since Yamamoto and Tanaka (30) reported its formation in INH tablets. The compound was prepared according to a method described by the same authors. The results of TLC are shown in Fig. 15. The presence of INH-HMF and INH-L was evident in this figure. The isolation and confirmation of INH-HMF were carried out first by concentration of a large quantity of methanol extract. This concentrate was then streaked onto a 3.0-mm. thick preparative plate and developed as before. Using UV light as a guide, the pink-color band was scraped off and extracted with anhydrous methanol. The extract was concentrated, diluted with an equal volume of water, and then purified; it showed the same UV and IR spectra when compared with the prepared INH-HMF. Since the quantity of INH-HMF formed in the solid system was very small, many difficulties were encountered in its quantitative determination; consequently, attempts to correlate the rate of browning and the rate of formation of INH-HMF in the solid system were unsuccessful.

The mechanisms of the Maillard-type browning reactions involving glucose and glycine have been discussed in detail by several authors (31, 32); a stepwise reaction scheme was proposed. A simplified reaction scheme is shown in Scheme II A. Although the mechanisms involved in the reactions between sugars and amino acids might resemble the present system, the results from the present studies showed some discrepancies. The degradative mechanisms have been modified and are given in Scheme II B. In the reaction of the INH-lactose system, the formation of INH-HMF may not completely rely on INH-L as a source. Since the formation of INH-L and HMF needs approximately the same conditions, i.e., high temperature and humidity, and since the reactivity of HMF is high, the formation of INH-HMF from INH and HMF is also possible. As shown in Scheme II A, most workers have considered that an equilibrium exists between A + HMF and A + HMF. However, this is not conceivable, except in the presence of catalyst which may promote the hydrolysis of INH-HMF. In fact, the whole process of the browning reaction may be expected to be much more complicated than the proposed scheme, since many parallel pathways may exist in this process. Recently, Mitsuda *et al.* (33) reported that electron spin

¹⁶ With the aid of small amount of methanol.

Scheme II—Mechanisms of browning reactions. Key: Scheme A, described by Keeney and Bassette (32); and Scheme B, modified

resonance spectroscopy revealed that a free radical reaction was found operative in the aminocarbonyl reaction of food browning.

Although the interaction of INH and lactose does not proceed to an appreciable degree under ambient conditions, the situation may become significant under moderate temperature and moisture conditions as those found in tropical or subtropical climates. It should also be recognized here that during wet granulation procedures, in which both INH and lactose are exposed to higher temperatures and excessive moisture, these degradation aspects cannot be overlooked.

As has been pointed out by Bernstein *et al.* (34), none of the INH derivatives, including hydrazones, is more active on a molar basis than INH itself. It is also interesting to speculate here as to the tuberculostatic activity of darkened tablets of INH-HMF and INH-L itself.

The INH-HMF prepared in this study has been evaluated for its antitubercular activity.¹⁷ Preliminary *in vitro* results using the standard NCBC plate method indicate that INH-HMF and INH have approximately comparable activity. However, due to the fact that their physicochemical properties are sufficiently different (for example, aqueous solubility) and that even if the *in vitro* tests appear to be comparable, it does not necessarily mean that they are clinically equivalent. For example, Kakemi *et al.* (35) studied absorption of INH and its derivatives from the gastrointestinal tract and found that the INH-L is hardly absorbed. A recognition of these INH-lactose reactions and their effects on drug availability and therapeutic response is therefore necessary in the formulation of satisfactory INH dosage forms.

Behavior of Erythrocytes in Various Solvent Systems VI: Water-Tetramethylurea

DONALD E. CADWALLADER and JANIS R. PHILLIPS*

Abstract □ Hemolytic behavior of human erythrocytes in water-tetramethylurea (TMU) solutions was investigated. TMU freely permeates human red blood cells; however, hemolysis can be prevented by the inclusion of 0.9% sodium chloride in solutions containing up to 8% TMU. The addition of sodium chloride to solutions containing more than 8% TMU did not prevent hemolysis, discoloration, and precipitation of blood components. Divalent and trivalent anions gave greater protection against hemolysis than did the sodium chloride. When possible, the data were used to calculate van't Hoff *i* values for sodium chloride in aqueous solutions.

Keyphrases □ Erythrocytes, behavior—water-tetramethylurea system □ Hemolysis, erythrocytes—water-tetramethylurea system □ Tetramethylurea-sodium chloride system—erythrocyte hemolysis □ Isotonic coefficients—tetramethylurea-water systems

It is well known that to prepare a safe and efficacious injection, it is sometimes necessary to employ a mixed solvent system consisting of water and a nonaqueous solvent. For this reason, investigations have been made to study the hemolytic effects of aqueous solutions of glycerin, propylene glycol, and liquid polyethylene glycols on rabbit and human erythrocytes, and the hemolytic effects of aqueous dimethylsulfoxide and liquid amides on human erythrocytes (1-5).

This report is concerned with the investigation of water-tetramethylurea (TMU) systems. TMU is a dipolar aprotic solvent and possesses a number of desirable solvent properties. The solvent and reagent properties of TMU have been reviewed by Luttringhaus and Dirksen (6). The solvent has a mild and pleasant odor, a high degree of stability, low reactivity, a high boiling point (177.6°), and a water-white color. It also has the property of being completely miscible with water, alcohols, ether, benzene, chlorinated hydrocarbons, and many other polar and nonpolar solvents.

Due to the possible use of TMU as a drug solvent, Dixon *et al.* carried out toxicity studies on TMU (7). In their studies, TMU was also tested for central nervous system (CNS) pharmacological properties and the ability to increase survival time of tumor-bearing mice due to structural similarities between TMU and drugs capable of producing these effects. It was reported that the acute LD₅₀ of TMU for mice was 2230 mg./kg. i.v. and 2920 mg./kg. given orally. Toxic doses were lower with the monkey, the drug being lethal at doses as low as 750 mg./kg. i.v. TMU was found to possess weak anti-convulsant and tranquilizer activity, and it produced a significant increase in median survival time of mice bearing a plasma cell tumor.

It was the purpose of this investigation to observe the behavior of human erythrocytes in TMU solutions. In each experiment the hemolytic method was utilized. By comparison of standard hemolysis curves obtained for human blood in aqueous saline solutions and those

Table I—Values of *i* for Sodium Chloride in Various Water-TMU Solutions, Calculated from Concentrations Causing 25, 50, and 75% Hemolysis of Human Erythrocytes*

* Each value is an average of at least two blood samples.

obtained from experiments using sodium chloride-water-TMU solutions, it was possible to calculate the hemolytic isotonic coefficients for sodium chloride in various water-TMU solutions.

EXPERIMENTAL

Materials—TMU (Aldrich Chemical Co.) had a specific gravity of 0.972 and was 99% pure. All electrolytes and nonelectrolytes employed in this study were reagent grade.

Collection of Blood—The blood samples used for all experiments were obtained from the forearm veins of a 22-year-old male Caucasian donor. Fresh blood samples were used in all experiments. Approximately 10 ml. of blood was obtained from the donor and placed in a 50-ml. round-bottom flask containing 10-15 glass beads. The flask was rotated gently for about 5 min.; then the blood was decanted into a 50-ml. conical flask and aerated by swirling the flask gently for about 5 min.

Preparation of Solutions—All of the TMU solutions were volume-in-volume percentage preparations. Sodium chloride solutions were prepared on a weight-in-volume basis. Data from a previous paper [*viz.*, Table I, (2)] were used in the preparation of isotonic solutions of calcium chloride, sodium citrate, sodium bromide, sodium sulfate, and sodium tartrate. All pH adjustments were made using Sorensen isotonic buffer systems. Distilled water was used to prepare all solutions.

Quantitative Determination of Percent Hemolysis—In each experiment, the hemolytic method was used to determine the degree of hemolysis of erythrocytes in the TMU solutions. This quantitative method is based on the fact that a hypotonic solution liberates oxyhemoglobin in direct proportion to the number of cells hemolyzed. Into each of two test tubes was transferred 5 ml. of standard sodium chloride solution (0.34%, 0.35% . . . 0.45%, 0.46%) and 5 ml. of the mixed solvent system being tested. After the test tubes were brought to a constant temperature by placing in a water bath (37 ± 1°), 0.05 ml. of blood was pipeted into each tube. Each tube was then inverted several times to ensure thorough mixing and allowed to remain 45 min. at 37°. The absorbance of the supernatant liquid after centrifuging was measured using a Klett-Summers photoelectric colorimeter equipped with a No. 54 filter. To find the percent hemolysis, these absorbance readings were divided by the absorbance readings for 0.05 ml. of blood in 5 ml. of distilled water (standard for 100% hemolysis) and multiplied by 100. A blank, made by placing 0.05 ml. of blood in 5 ml. of 0.9% sodium chloride solution, was used to cancel any light absorbance inherent to the blood sample. Since all solutions of TMU were slightly turbid, TMU solutions corresponding to the concentration range of test solutions were used as blanks to cancel any absorbance that might be caused as a result of this turbidity. Both the standard and the blanks were subjected to the same conditions of standing for 45

Figure 1—Hemolysis of human erythrocytes after 45 min. at 37° in various TMU-saline solutions.

min. at 37° followed by centrifuging. A pH meter (Corning model 7) was used for all pH measurements.

Calculations of *i* Values—Through use of the hemolytic method, concentrations of sodium chloride and the TMU solutions giving the same degree of hemolysis could be determined. Once these concentrations were ascertained, it was possible to calculate isotonic coefficients (*i* values) through use of the following equation:

$$\left(\begin{array}{c} i \text{ value for NaCl} \\ \text{in water} \end{array} \right) \left(\begin{array}{c} \text{g. of NaCl in} \\ \text{100 ml. of water} \end{array} \right) = \left(\begin{array}{c} i \text{ value for NaCl} \\ \text{in TMU soln.} \end{array} \right) \left(\begin{array}{c} \text{g. of NaCl in} \\ \text{100 ml. of TMU soln.} \end{array} \right) \quad (\text{Eq. 1})$$

The value of *i* for sodium chloride was taken as 1.86, which is the accepted *i* value for 0.9% sodium chloride in water (8).

Curves showing the degree of hemolysis in sodium chloride-water solutions and sodium chloride-water-TMU solutions were plotted on rectangular coordinate graph paper. From these curves, it was possible to determine the concentrations of sodium chloride in g./100 ml. of water and the TMU solvent causing 25, 50, and 75% hemolysis. These values were inserted into Eq. 1, thereby giving the values of *i* for sodium chloride in a particular water-TMU solution at concentrations producing 25, 50, and 75% hemolysis. The various *i* values of TMU solutions are shown in Table I.

Preparation of Hemolysis Curves—Approximately 25 experiments employing human blood were carried out. A standard hemolysis curve (Fig. 1) was constructed from the average readings of these experiments. Hemolysis curves of the various TMU solutions were constructed using the *i* values previously calculated (Table I). Through rearrangement of Eq. 1 to give

$$\left(\begin{array}{c} \text{g. of NaCl in 100} \\ \text{ml. of TMU soln.} \end{array} \right) = \frac{\left(\begin{array}{c} 1.86 i \text{ value for} \\ \text{NaCl in water} \end{array} \right) \left(\begin{array}{c} \text{g. of NaCl in 100 ml.} \\ \text{of water causing 25\%} \\ \text{hemolysis} \end{array} \right)}{\left(\begin{array}{c} i \text{ value for NaCl in} \\ \text{TMU solution} \end{array} \right)} \quad (\text{Eq. 2})$$

the grams of sodium chloride per 100 ml. in a TMU solution causing 25% hemolysis were calculated. Similar calculations were carried out at 50 and 75% hemolysis. By plotting these three points, the hemolysis curves for the various TMU solutions were constructed (Fig. 1). From these hemolysis curves (Fig. 1), the amounts of sodium chloride preventing hemolysis of 50% of the erythrocytes (or where 50% hemolysis occurred) in various TMU solutions were determined, and the results are shown in Fig. 2.

RESULTS

In this study it was found that complete hemolysis of human erythrocytes occurred in 0.0–100% TMU solutions after 45 min. at 37°. Upon addition of 0.9% sodium chloride, hemolysis of human erythrocytes was essentially prevented (less than 5%) in solutions containing 0.0–8% TMU. Hemolysis greatly increased in solutions containing 9–12% TMU even with 0.9% sodium chloride. These results are shown in Fig. 3.

Figure 2—Amount of sodium chloride preventing hemolysis of 50% of human erythrocytes in various TMU solutions at 37°.

Reddish-brown solutions resulted when blood was added to 0.9% saline solutions containing 15–16% TMU. More pronounced discoloration and/or precipitation occurred in solutions containing higher concentrations of TMU. Solutions containing 50% TMU revealed a brownish-green color with no precipitation, while those at 75% showed a brown precipitate in addition to the brownish-green color.

It was possible to modify the fragility of human erythrocytes through the addition of hypotonic quantities of sodium chloride (0.34%, 0.35% . . . 0.45%, 0.46%) to various water-TMU solutions. When blood was added to saline solutions containing 0.0–7% TMU, typical sigmoidal hemolysis curves resulted (Fig. 1). These curves were constructed in the manner described in the *Experimental* section of this report utilizing the data presented in Table I.

Calculations of *i* values for sodium chloride in various water-TMU solutions were accomplished through use of Eq. 1 and are shown in Table I.

The pH readings for the TMU solutions were within a range of 5.1–7.0. Addition of isotonic phosphate buffer reduced hemolysis (less than 5%) in solutions containing as much as 10% TMU (Fig. 3).

Aqueous TMU solutions containing isotonic quantities of calcium chloride (1.15%) and sodium bromide (1.51%) gave results similar to those described for the TMU-saline solutions. Addition of sodium citrate (1.84%), sodium sulfate (1.27%), and sodium tartrate (1.61%) reduced hemolysis, producing trace hemolysis in solutions containing as much as 10.5% TMU. The hemolysis curves for TMU solutions containing these divalent and trivalent anion salts were similar to the mentioned curve for phosphate buffer (Fig. 3).

DISCUSSION

From the experimental data gathered in this study, it can be seen that TMU freely permeates human red blood cells and, therefore, offers no protection to these cells from hemolysis. Upon addition of

Figure 3—Hemolysis of human erythrocytes after 45 min. at 37° in various TMU solutions containing 0.9% sodium chloride or pH 7.0 isotonic Sorensen buffer.

0.9% sodium chloride, complete hemolysis can be prevented in the TMU solutions containing up to 8% TMU. Since addition of 0.9% sodium chloride to these TMU solutions prevents hemolysis and since addition of hypotonic quantities of sodium chloride to these solutions (and TMU solutions of lower concentration) prevents complete hemolysis, the lysis of red cells in solutions containing 7% or less TMU can be attributed to osmotic hemolysis.

There is a critical concentration for TMU at which addition of 0.9% sodium chloride will not prevent hemolysis and/or precipitation of blood components. The transition from nonhemolytic concentrations to destructive concentrations is rather abrupt, as shown by the hemolysis curve in Fig. 3.

Further destruction of red cells occurs as TMU concentrations are increased above the critical concentration. This is apparent as the color changes from reddish-brown to greenish-brown with a brown precipitate.

The van't Hoff factor or isotonic coefficient can be expressed as the ratio of any colligative property of a real solution to that of an ideal solution of a nonelectrolyte (9). The isotonic coefficients (*i* values) for aqueous solutions containing 3 and 6% TMU were found to be less than 1.86. This is evidence that these concentrations offer no protection to human erythrocytes against osmotic hemolysis. However, *i* values calculated for 1 and 7% TMU were slightly higher than 1.86, indicating that these strengths contribute slightly to the tonicity of the extracellular aqueous solutions. This is shown graphically when the concentration of TMU is plotted against the amount of sodium chloride preventing hemolysis of 50% of the erythrocytes (Fig. 2). No *i* values were calculated for 8% TMU solutions since this concentration gave very erratic results and appears to be too critical an area for determination of *i* values.

Upon first observations, pH of the TMU solutions appeared to have some effect upon the solution's tendency to damage human red blood cells, since addition of pH 7.0 Sorensen phosphate buffer considerably reduced hemolysis in solutions containing up to 12% TMU (Fig. 3). However, it did not seem that the reduction of hemolysis was due to the pH effect since the pH range (5.1–7.0) of plain aqueous TMU solutions was near neutral, especially in the higher concentrations. Through further experiments using isotonic quantities of other salts, it was determined that divalent and trivalent anions gave greater protection against hemolysis than did the 0.9% sodium chloride. Therefore, it was surmised that the effect of hemolysis reduction with the phosphate buffer system was due to its phosphate anion properties, not its pH-limiting properties.

In a series of papers (10–15) concerning the hemolysis of human erythrocytes in relation to lattice structure of water, Good es-

tablished the idea that the effect of a solute upon the structural properties of the water lattice is basic to the mechanism of hemolysis. He found that large simple anions produce simple steric distortion and electrostatic screening which disturb the lattice locally and free water molecules which will tend to associate themselves with a malonamide stabilized zone. Thus the fluidity of the extracellular phase is reduced and hemolysis is slower. Therefore, the large anion will inhibit hemolysis by contributing free water molecules to the malonamide-stabilized lattice. Divalent and trivalent anions used in these studies could possibly act in a similar way whereby they inhibit hemolysis by contributing free water to a TMU-stabilized lattice.

Coumermycin A₁—Biopharmaceutical Studies I

HAROLD L. NEWMARK and JULIUS BERGER

Abstract □ Coumermycin A₁, as the free acid or simple salts, is poorly absorbed from the gastrointestinal tract of animals and humans. It is not appreciably degraded in the fluids of the gastrointestinal tract. Mixture of coumermycin with certain additives, such as sugar amines, can significantly enhance oral absorption in dogs, as measured by the increased blood levels achieved. *N*-Methylglucamine, in a 1:4 ratio of antibiotic to *N*-methylglucamine, enhances blood levels 5–15-fold over the antibiotic alone in both dogs and humans.

Keyphrases □ Coumermycin A₁—absorption, oral administration □ Blood levels, coumermycin A₁—formulation effect □ Stability, coumermycin A₁—gastrointestinal tract □ Microbiological analysis—coumermycin A₁

Coumermycin A₁ is a highly potent antibiotic whose antimicrobial spectrum qualitatively resembles that of novobiocin (1–4). Tests *in vitro* and subcutaneously in mice indicated antibacterial activity, particularly against Gram-positive organisms, at concentrations and doses far lower than for novobiocin (*i.e.*, 1/10 to 1/30). However, early trials of the antibiotic orally in humans gave very poor or nondetectable blood levels (5–7). Blood levels far lower than 1 mcg./ml. were achieved even on doses up to 2 g./day, although several forms of the antibiotic were tested, including the water-soluble disodium salt (7), enteric coating (5, 7), and mixing with polyethylene glycol 300 (Carbowax 300) (7). The total amount of antibiotic accounted for in body fluids, calculated at the maximum blood levels achieved, represented less than 0.1% of the total oral drug intake in these clinical studies.

For mice, the toxicity expressed as LD₅₀ in mg./kg. for coumermycin has been reported to be p.o., > 4000 (1); i.p., 183 (1); s.c., 380 (1); and i.m., 500 (8). The median curative dose in experimental *Staphylococcus aureus* (Smith) infection in mice has been reported (1, 3) as 0.13 mg./kg. s.c. and 4.3 mg./kg. p.o. Comparable data were reported by others (10). These large differences in toxicity and activity depending on the route of administration strongly suggest poor absorption. The problem of achieving elevated coumermycin blood levels thus can be posed as one of faulty or poor absorption from the gastrointestinal (GI) tract or of instability of the

drug on oral administration. Since the preferred route for antibiotic administration is oral, it was considered essential before embarking on clinical trials to attempt to achieve improved blood levels by this route. The dog was chosen as a test animal since it had been found useful in studies of similar problems with novobiocin (9). Considering the *in vitro* antimicrobial activity of coumermycin in the presence of blood serum, a blood level of at least 1 mcg./ml. was somewhat arbitrarily selected as a desirable goal to allow for a reasonable safety factor, pending eventual clinical verification.

MATERIALS AND METHODS

Blood Level Assays—Early studies were performed using an antibiotic bioassay employing serial broth dilutions of 2- or 3-fold, with *Staphylococcus aureus* as the test bacterium. Results of this method had the inherent and substantial potential error of the factor of dilution. During the course of the work, an agar diffusion cup-plate antibiotic bioassay was developed which had a precision of better than ±20% (4). Blood samples (serum) were diluted in 20% dimethylsulfoxide–3% aqueous phosphate buffer solution, pH 6.3, to a concentration which gave inhibition zones against the test organism *S. aureus* within the proper dose–response range (0.5 mcg./ml.). The standard coumermycin monosodium salt was similarly diluted in control blood serum. Quantitative evaluations were obtained as described in (4). Most of the data reported are with the latter method, unless otherwise indicated.

Administration of Drug to Dogs—For oral studies, dogs fasted 12–18 hr. were administered a single dose of about 5 mg./kg. of coumermycin monosodium salt as a fine powder (average diameter 7 μ) in gelatin capsules. Blood samples were taken at various time intervals as indicated later. It was found that administering an oral dose of water to the dog immediately after the drug dose gave higher and more consistent results. Both males and females were used, since no sex-related difference in response was found.

A parenteral aqueous solution of the monosodium salt of coumermycin A₁ was prepared to contain 20 mg./ml. of coumermycin A₁ monosodium salt (Ro 5-4645/10), 10% *N,N*-dimethyl acetamide, 10% ethanol, 40% propylene glycol, and 1.5% benzyl alcohol in water for injection. This solution was injected intravenously at a drug dose of about 10 mg./kg. Blood samples were taken and the sera assayed as previously indicated.

EXPERIMENTAL

Coumermycin A₁ (formerly also known as sugardomycin D-1a or notomycin), mol. wt. 1110, has the chemical structure (2, 4) shown as I.

I

It is a bishydroxycoumarin with two weakly acidic groups, $pK_a = 5.8-6.2$ depending on solvent. [Kawaguchi *et al.* (1, 2) reported the pK_a as 7.76 in 75% dioxane-water and 6.35 in 75% dimethyl formamide-water.] The pyrrole groups have very weak acidic properties, pK_a above 11. The drug is sensitive to hydrolysis and rearrangement in strongly alkaline solution. A 1% solution of the soluble disodium salt has a $pH \sim 10$. This contrasts with novobiocin, pK_a about 3.8, which forms a readily soluble monosodium salt which is only slightly alkaline (9).

Coumermycin free acid has no melting point but decomposes at about 245° , as does the crystalline monosodium salt (8). Coumermycin is soluble in aqueous alkali (*i.e.*, above $pH 10$), dioxane, dimethylformamide, and dimethylacetamide, and moderately soluble in acetone, methyl isobutyl ketone, methyl ethyl ketone, and ethyl acetate. It is poorly soluble in ethanol, methanol, isopropyl alcohol, chloroform, and benzene, and essentially insoluble in carbon tetrachloride, petroleum ether, and neutral and acidic water. It has a slight solubility in aqueous 6 *N* urea. When dissolved in aqueous alkali and neutralized with dilute acid, precipitation is rapid to form a dense particulate solid. Similarly, dilution of organic solvent solutions (*e.g.*, dimethylacetamide) with water results in rapid precipitation. In dilute aqueous alkali solution, coumermycin has strong surfactant properties. These stability, solubility, and physicochemical properties were taken into consideration in the selection of additives to be tested for enhancement of absorption of the drug.

Stability—To determine the importance of the stability of the antibiotic on blood levels, the effect of several experimental conditions was investigated.

Recovery from Blood In Vivo—The parenteral solution of the drug was injected intravenously into dogs at ~ 10 mg./kg. Blood samples were taken and the sera were bioassayed. The results were as follows (average of two dogs):

Time after Injection, hr.	Blood Levels (Dilution Assay), ¹ mcg./ml.
0	0
0.5	160
1.0	160
2.0	70
4.0	70
24.0	3

Assuming a blood volume about 8% of the dog body weight, the peak level of 160 mcg./ml. in blood is about 1.3 times the administered dose. This is essentially 50–200% recovery of the injected drug, considering the errors of the method used. The results thus indicate that the drug was not rapidly destroyed nor eliminated from the blood.

In the Gastrointestinal Tract—In Vitro—An aqueous solution of the freshly prepared disodium salt of coumermycin was added to freshly prepared gastric juice USP to give a concentration of 20 mcg./ml. Full antibiotic activity (dilution bioassay) was maintained when incubated for 4 and 7 hr., respectively, at 37° .

In Vivo—The pyloric sphincter of a dog was tied off surgically. A dose of 500 mg. of coumermycin monosodium salt was administered orally. Blood samples were taken periodically from the gastropiploic vein leading from the stomach, as well as samples of the gastric contents by aspiration into a syringe with saline. The bioassay results indicated essentially 100% retention of activity in the gastric contents for 4 hr., while the blood samples (1, 2, and 4 hr.) showed <1 mcg./ml.

These tests indicated that coumermycin is relatively stable in the GI tract, certainly in the stomach, and is not destroyed rapidly by the low pH (about 1.5) or enzymes of gastric juice *in vitro* or *in vivo*. It also appears stable to intestinal juice (pH about 8) *in vitro*.

Solubility—It was hypothesized that a system that would solubilize coumermycin at the pH range of the GI tract in aqueous solution would permit more efficient absorption. Several different approaches were made.

Table I—Coumermycin Blood Levels in Dogs after Single 5-mg./kg. Oral Dose (Antibiotic Content) in Different Formulations

^a Numbers in parentheses are the ratio of the weights of the components used in the test preparation in order of listing. ^b Assays performed by serial dilution method. ^c Administered at 50 mg./kg.

Soluble Salts or Ion-Pairs—A series of disubstituted salts or ion-pairs of coumermycin was prepared and their aqueous solutions neutralized by dilute acid to $pH 7$. Most of these cases resulted in rapid precipitation of free coumermycin or its monosubstituted salt in the form of dense particles. These included magnesium, sodium, calcium (insoluble), aluminum (insoluble), diethanolamine, triethanolamine, lysine, glycine, trishydroxymethyl aminomethane (THAM), proline, leucine, and choline.

Sugar Amines—When aqueous solutions of coumermycin in dilute alkali are neutralized in the presence of sugar amines, a gel is formed rather than dense particles. This is analogous to the “gel-like” precipitate of amorphous novobiocin formed on careful acidification of its sodium salt solution, as reported previously (8). In particular, *N*-methylglucamine (NMG) aqueous solutions with coumermycin produce aqueous gels on neutralization with acid. A 2.5% solution of coumermycin with 10% NMG (pH about 11) will form an opalescent, solid gel on neutralization by dilute HCl or dilute acetic acid. These gels do not appear to have appreciable crystalline coumermycin. Similar behavior can be observed with glucosamine, *N*-acetylglucosamine, and *N*-acetylgalactosamine. A large molar excess of the sugar amine appears to be required.

Complexing Agents—Coumermycin contains two hydroxycoumarin groups that are potentially capable of forming soluble complexes with polyoxyethylene groups. Indeed, Kawaguchi *et al.* (7) claimed some slight success in using polyethylene glycol 300 (Carbowax 300) to enhance blood levels. It was found that solutions of coumermycin monosodium salt in dimethylacetamide with a series of substances containing polyethylene glycol units, including some nonionic surfactants, did form micellar, slightly opalescent dispersions on dilution with water. These include

¹ It should be pointed out again that the serial broth dilution method, employed in this early exploratory experiment, is subject to a potential twofold error and is probably most likely the reason that the 1- and 4-hr. blood values did not “appear” to decline from the preceding values.

Table II—Coumermycin Blood Levels^a in Humans after Single 250-mg. Oral Dose

Preparation	Blood Levels, mcg./ml., Hours after Dose				
	0	2	4	8	24

polysorbate 80, an emulsifying agent (Emulphor EL-620), a propylene glycol derivative (Pluronic F-68), polyethylene glycol 300, polyethylene glycol 4000, and polyethylene glycol monoricinoleate.

Formulations—A summary is presented in Table I of the data obtained for blood levels in dogs administered different formulations of coumermycin designed to give enhanced levels. A review of these results in dogs resulted in the selection of NMG formulation with the monosodium salt of coumermycin for trial in humans, using a 1:4 weight ratio equivalent to about 1:20 molar ratio. Although higher ratios of NMG to coumermycin increased the blood levels of drug in dogs, practical limitations such as capsule size led to the choice of 1:4 for clinical capsules. NMG has the practical advantages of being commercially available, nonhygroscopic, and chemically stable.

Capsules containing 50 mg. of coumermycin (monosodium salt) with 200 mg. of NMG were tested in humans in comparison to capsules of micronized coumermycin monosodium salt alone. The capsules were administered as a single oral dose of 250 mg. of coumermycin to six humans in each group. The results are presented in Table II.

DISCUSSION

The blood level data presented of coumermycin with NMG in dogs and humans clearly show the enhancement of absorption produced by this additive. At a ratio of 1:4 (drug-NMG), both dogs and humans show a 5–15-fold enhancement of oral absorption of coumermycin as measured by blood levels achieved. This effect is produced by simple physical mixture of the two ingredients in capsules. This represents about a 20 molar ratio of NMG to coumermycin. *In vitro*, this mixture dissolves in water to form a solution at pH 10.5–11.0, which in turn gives a gel-like noncrystalline mass on acidification. Presumably, a similar dissolution and then acidification to form a gel occur in the stomach after oral administration. The resultant gel probably has a greatly enhanced surface area to aid in absorption of coumermycin from the GI tract.

The blood levels achieved with the 1:4 mixture in dogs at 5 mg./kg. p.o. are roughly comparable to those achieved with the same mixture at 250 mg./human p.o. (approximately equivalent to 4

mg./kg.). This substantiates the choice of dogs as a test animal for biopharmaceutical studies of coumermycin.

The NMG mixture with coumermycin rapidly achieves blood levels appreciably higher than the 1 mcg./ml. originally desired on single doses of 250 mg./human, and levels above 1 mcg./ml. are maintained for over 12 hr.

SUMMARY

Coumermycin A₁, as the free acid or simple salts, is poorly absorbed from the GI tract of animals and humans. It is not appreciably degraded in the fluids of the GI tract. Mixtures of coumermycin with certain additives, such as sugar amines, can significantly enhance oral absorption in dogs, as measured by the increased blood levels achieved. NMG, in a 1:4 ratio of antibiotic to NMG, enhances blood levels 5–15-fold over the antibiotic alone in both dogs and humans.

Coumermycin A₁—Biopharmaceutical Studies II

HAROLD L. NEWMARK, JULIUS BERGER, and J. THURØ CARSTENSEN

Abstract □ Coumermycin monosodium salt in a 1:4 w/w mixture with *N*-methylglucamine is absorbed with an efficiency of about 20–25% in dogs and humans after oral administration. This is 5–15-fold the oral absorption efficiency of the drug alone. On intravenous or oral administration, blood levels decline exponentially after 3–4 hr. in dogs and after 4–6 hr. in humans; the half-lives of these declines are 8–9 hr. in dogs and 8–10 hr. in humans. Blood levels well over 1 mcg./ml. are readily achieved on oral dosage of 4–5 mg./kg. in dogs and humans.

Keyphrases □ Coumermycin A₁—biopharmaceutical characteristics □ Blood levels, coumermycin A₁—administration route effect □ Distribution—coumermycin A₁ □ Microbiological analysis—coumermycin A₁

The antibiotic coumermycin A₁, as the free acid or most simple salts, is poorly absorbed from the gastrointestinal (GI) tract of dogs and humans. In a previous paper, the authors reported that a mixture of the monosodium salt with *N*-methylglucamine (NMG) (1:4 by weight) in capsules enhanced blood levels on oral administration in dogs and humans by 5–15-fold (1). The present studies were made to determine the biopharmaceutical characteristics of this preparation *in vivo*.

EXPERIMENTAL

Materials and Methods—Oral and parenteral preparations were formulated in the following manners. Gelatin capsules of micronized coumermycin A₁ monosodium salt were prepared containing 50 mg. of drug and designated Capsules A. Capsules containing a mixture of 50 mg. of micronized coumermycin A₁ with 200 mg. of NMG were made and designated Capsules B. A fresh parenteral solution of coumermycin A₁, 50 mg./ml., was prepared in a solvent consisting of 30% propylene glycol, 10% ethyl alcohol, 1% benzyl alcohol, 0.5% NMG, and water for injection, with the pH adjusted

Figure 1—Coumermycin blood levels in dogs after a single oral dose, 5 mg./kg., of: A, capsules of coumermycin alone; and B, capsules of coumermycin + NMG (1:4). Each group represents the average of six dogs.

Figure 2—Coumermycin blood levels in humans after a single oral dose, 4 mg./kg., of: A, capsules of coumermycin alone; and B, capsules of coumermycin + NMG (1:4). Each group represents the average of six subjects.

to 9.4 by sodium hydroxide. In the parenteral solution, there is only a minimal amount of NMG, the ratio of drug to NMG being 1:0.1 or 1/40 of the ratio in the capsules.

Studies in Dogs—Dogs, each weighing about 10 kg., fasted 12–18 hr., were given capsules of drug formulation to provide the equivalent of about 5 mg./kg. Blood samples were taken at intervals and assayed microbiologically by a cup-plate assay for coumermycin concentration (1). Oral absorption efficiency was tested as follows: the parenteral formulation was administered intravenously at 0.5 and 2.5 mg./kg., respectively, to two dogs. Six other dogs were each given orally a single Capsule B. Blood samples were taken at intervals and measured for coumermycin concentration.

The parenteral preparation also was used to permit examination of the difference in blood levels achieved after intramuscular and intravenous administration, measured 1 hr. after injection, in comparison with the oral levels. The effect of repeated daily intravenous injection also was examined after administration at three different dosage levels.

Studies in Humans—Six human subjects were given a single oral dose of five Capsules A, representing a dose of approximately 4 mg./kg. of drug alone. Six other human subjects were given a single oral dose of five Capsules B, similarly representing a dose of approximately 4 mg./kg. of drug content, but in the presence of NMG. Blood samples were taken at intervals and measured microbiologically for coumermycin concentration. For the study of oral absorption efficiency in humans, a single human adult subject (L.R.) was injected intravenously with 50 mg. of coumermycin in parenteral solution; samples of blood were taken periodically for measurement of coumermycin concentration. Subsequently, the same subject was retested with a dose of 100 mg. i.v. In some experiments with dogs and humans, samples of urine and stools were also examined for the presence of excreted, unchanged antibiotic.

RESULTS AND DISCUSSION

The results of a single dose, oral administration, of antibiotic with and without NMG are presented for dogs in Fig. 1 and for humans in Fig. 2. The effect of NMG in enhancing the oral absorption, as indicated by elevation of blood levels, is clearly indicated. From the individual values and comparison of the area under the curves, the enhancement by NMG appears to be in the range of 5–15-fold over the drug alone in both dogs and man. The post-absorptive half-life is calculated to be about 10 hr.

Figure 3—Blood levels of coumermycin in dogs after 2.5-mg./kg. i.v. dose (A), 0.5-mg./kg. i.v. dose (B), and 2.5 mg./kg. p.o. (C). Data are presented in semilogarithmic form, the linear form of the corresponding equations being indicated in the two intravenous curves. The area under the oral curve is estimated in a linear graph (not shown).

The efficiency of absorption of coumermycin in the NMG mixture can be calculated from the data of Fig. 3 in dogs and of Fig. 4 in humans. As pointed out by Riegelman *et al.* (2), a peripheral compartment may be detected only in the early phases subsequent to administration of a drug. By considering the present case a two-compartment, open-system model:¹

the equation governing the time-dependent concentration should be: $C_p = A \cdot \exp(-\alpha \cdot t) + B \cdot \exp(-\beta \cdot t)$, with a value extrapolated to zero time of $C_p^0 = A + B$.

The parameters, A , B , α , and β , may now be evaluated from the curves by the feathering technique. The parameter values found are indicated in Figs. 3 and 4.

Once the parameters in the double-exponential decay curve are known, the forward and reverse diffusion constants k_{12} and k_{21}

Figure 4—Blood levels of coumermycin in man after 100-mg. i.v. dose (A), 50-mg. i.v. dose (B), and 250 mg. p.o. (C). The data are presented in linear form, and the appropriate least-squares equations indicated. The area under Curve C can be estimated by graphical means.

and the disposition constant k_{el} may be determined readily. Values of these for dog (from Fig. 3) and man (from Fig. 4) are listed in Table I.

The amount of drug in the tissue compartment (T) at time t is governed by the differential equation:

$$\frac{dT}{dt} = k_{12}[A \cdot \exp(-\alpha \cdot t) + B \cdot \exp(-\beta \cdot t)] - k_{21}T \quad (\text{Eq. 2})$$

This is readily solved, using the integrating factor $\exp(k_{21}t)$ and imposing the initial condition that $T = 0$ at $t = 0$ yields the solution:

$$T = \frac{A \cdot k_{12}}{k_{21} - \alpha} [\exp(-\alpha \cdot t) - \exp(-k_{21}t)] + \frac{B \cdot k_{12}}{k_{21} - \beta} [\exp(-\beta \cdot t) - \exp(-k_{21}t)] \quad (\text{Eq. 3})$$

This quantity integrated over time is used here as a measure of absorption, *i.e.*,

$$I = \int_0^\infty T dt = \frac{A \cdot k_{12}}{[k_{21} - \alpha]} \cdot \left[\frac{1}{\alpha} - \frac{1}{k_{21}} \right] + \frac{B \cdot k_{12}}{[k_{21} - \beta]} \cdot \left[\frac{1}{\beta} - \frac{1}{k_{21}} \right] \quad (\text{Eq. 4})$$

Values of this measure of absorption (I) as found in dog and man are listed in Table I.

It is noted that, in the dog, absorption is linearly related to dose (188 = 5.42), whereas proportionality is not quite as apparent in man. In the latter case, however, I depends strongly on the accuracy of $k_{21} - \alpha$ and $k_{21} - \beta$. All dose-independent constants (k_{12} , k_{21} , k_{el} , α , and β) correlate well from low to high dosage. However, only a few points in time are used here, and the values in Table I, at best, should only be used for qualitative comparison. As reported by Wagner and Northam (3), the distribution volumes, when calculated in this fashion, are likely to be overestimates.

Equation 4 cannot be used for estimation of absorption by the oral route, but an insight into the physiological availability of the oral dosage form may be gained by use of the absorption definition of Wagner and Nelson (4), *i.e.*, by determining the area (a) under the curve in Fig. 4 (in linear presentation). In this manner, a value of 19 mcg.-hr./ml. is obtained for the 250-mg. p.o. dose. This is comparable to the 50-mg. i.v. data in Table I, implying a 20% efficiency *via* the oral route.

Similar figures are obtained in the case of the dog, where values are: $A_\infty = 138$ mcg.-hr./kg.-ml. for 2.5 mg. i.v.; $A_\infty = 29$ mcg.-hr./kg.-ml. for 0.5 mg./kg. i.v.; and 52 mcg.-hr./kg.-ml. for 5 mg./kg. p.o., so that 5 mg./kg. p.o. is equivalent to about 1 mg./kg. i.v., yielding an efficiency of about 20% *via* the oral route. A more straightforward procedure is to assume that the curve of the 5-mg./kg. p.o. dose, after 4 hr., is approximately equivalent to a hypothetical curve of the 1.25-mg./kg. i.v. dose, obtained by interpolation between 0.5-mg. and 2.5-mg./kg. i.v. doses, *i.e.*, 25% efficiency. Similar treatment of the data in Fig. 4 may be made,

20	Intramuscular	74
10	Intravenous	85

^a Each value represents the average of two dogs.

indicating that in humans the oral absorption efficiency of the coumermycin in the mixture with NMG is approximately 20–25%. These figures, of course, are estimates since the two compartments are actually not in steady state of equilibrium throughout the cited period.

The intravenous curves in humans (Fig. 4) show that the early (0.5 hr. after dose) values are essentially dilutions of the drug in the blood volume. Thus, 50 mg. i.v. in a human adult with about 5 l. of blood and fluid in equilibrium with it calculates to 10 mcg./ml. which is what was obtained. A similar calculation for the 100-mg. case yields a value of 20 mcg./ml. as compared to the 18 mcg./ml. actually found. It is noted that it requires 3–4 hr. in dogs and 4–6 hr. in humans before the $A \cdot \exp(-\alpha \cdot t)$ -term becomes negligible; after this period the blood level, of course, declines in a conventional first-order fashion. As seen from the limited data here, the overall half-life in humans on 50- and 100-mg. intravenous dose appears somewhat longer than the overall half-life in dogs.

Table II summarizes the data obtained with blood levels in dogs after intramuscular and intravenous administration as measured 1 hr. after the dose. The results suggest some retardation of movement of the drug from the intramuscular site. Thus, it appears that at least twice the dose by the i.m. route is required to achieve the same blood levels as those obtained 1 hr. after i.v. dosing.

The effect of repeated daily i.v. injections of coumermycin A₁ on blood levels in dogs is shown in Table III. Levels were measured 1 hr. after the first, fifth, and tenth daily injection. These data suggest that on i.v. administration, increasing dosage increases blood levels after the first dose but not linearly. After the initial dose, the subsequent increase in blood levels after repeated dosage is greater than the multiple of dose increase. This suggests decreased migration of the drug out of the blood into tissue stores with increased repeated dosage, possibly approaching saturation of these tissues at higher dosage.

Bioassay of urine samples from dogs or humans, even after high blood levels were achieved, indicated the presence of little or no

intact coumermycin A₁. On the other hand, substantial amounts of drug were found in the feces of dogs and humans. These data will be reported later.

SUMMARY AND CONCLUSIONS

Coumermycin monosodium salt in a 1:4 w/w mixture with NMG is absorbed with an efficiency of about 20–25% in dogs and humans on oral administration, based on the assumption of a two-compartment open model. This is 5–15-fold the oral absorption efficiency of the drug alone. On intravenous or oral administration, blood levels decline exponentially after 3–4 hr. in dogs and 4–6 hr. in humans; the half-lives of these declines are 8–9 hr. in dogs and 8–10 hr. in humans. Blood levels well over 1 mcg./ml. are readily achieved on oral dosage of 4–5 mg./kg. in dogs and humans.

Acetylcholine Tachyphylaxis in Isolated Rabbit Atrium and Its Relation to Norepinephrine Stores

M. DAVID MacFARLANE* and THEODORE KOPPANYI

Abstract □ Large concentrations of acetylcholine, in the presence of atropine, are known to produce positive inotropic and chronotropic responses in isolated, spontaneously beating rabbit atria. This response is due to release of norepinephrine from atrial tissue. After repeated concentrations of acetylcholine (100 mcg./kg.), in the presence of atropine (3 mcg./kg.), were added to the bath fluid at 10-min. intervals, the usual stimulatory responses to acetylcholine were not detected; *i.e.*, the tissue was tachyphylactic to the actions of acetylcholine. If acetylcholine, in the presence of atropine, was given at intervals of more than 20 min., tachyphylaxis could not be observed. To investigate a possible link between acetylcholine tachyphylaxis and a decrease in the amount of norepinephrine available for release by acetylcholine, the atria were exposed to norepinephrine after acetylcholine tachyphylaxis was produced. Norepinephrine was allowed to remain in contact with tachyphylactic atrial tissues for 5 min. before being washed out. Acetylcholine now elicited its usual stimulatory effect. Epinephrine was also capable of restoring the response of tachyphylactic atria to acetylcholine. Atria excised from rabbits that were pretreated with reserpine did not respond to either acetylcholine or tyramine. When these preparations were incubated with norepinephrine, there was no return of the stimulatory response to acetylcholine, although the response to tyramine was restored.

Keyphrases □ Acetylcholine tachyphylaxis—isolated atrium, rabbit □ Norepinephrine stores, relationship—acetylcholine tachyphylaxis □ Reserpine effect—acetylcholine, tyramine activity □ Atropine effect—acetylcholine tachyphylaxis

Tachyphylaxis is the phenomenon in which repeated administration of a drug to a test system at short time intervals leads to progressively smaller and smaller responses induced by the drug (1). Indirectly acting sympathomimetic amines such as amphetamine (2), tyramine (3), and ephedrine (4), as well as cocaine (5), owe their adrenergiclike effects to release of endogenous norepinephrine from the test tissue, and the tissue develops tachyphylaxis due to the gradual depletion of essential norepinephrine stores (6).

It has been demonstrated that large doses of acetylcholine (ACh), when given either in the presence or absence of atropine, released norepinephrine (NE) from isolated cardiac tissue (7, 8). This release has also been shown for indirectly acting sympathomimetic amines (9). Because of this similarity between the indirectly acting sympathomimetic amines and ACh, the authors attempted to produce tachyphylaxis to the positive inotropic and chronotropic actions of ACh on the isolated spontaneously beating rabbit auricles.

It has also been demonstrated by Cowan *et al.* (1, 3, 4) that after production of tachyphylaxis to indirectly acting sympathomimetic amines, an exposure of the tachyphylactic tissue to NE restores, to a lesser or greater degree, the responses to subsequent challenges with the drug. Therefore, the effect of an exposure of ACh-tachyphylactic atrial tissue to NE and epinephrine (E) was tested. Additionally, the absence of responses to ACh in the tachyphylactic preparation was

compared to the absence of response to ACh observed in atrial tissues taken from rabbits that were pretreated with reserpine.

It has been proposed (6, 10, 11) that cardiac tissue has a number of storage compartments for NE and that the different compartments may be induced to release this neurohumor by different stimuli. In these studies, the authors also attempted to differentiate between compartments from which ACh and tyramine release NE.

METHODS

All experiments were performed on the isolated, spontaneously beating rabbit atria. Male albino rabbits, weighing 1.2–2.3 kg., were sacrificed by a blow to the nape of the neck. The heart was then rapidly excised and placed in oxygenated Locke solution of the following composition (in g./l.): NaCl, 9.0; KCl, 0.42; CaCl₂ (dihydrate), 0.24; NaHCO₃, 0.5; and dextrose, 2.0. The right and left atria were separated together from the ventricles and, after washing and removal of excess tissue, were mounted in a 40-ml. organ bath filled with Locke solution at $30 \pm 1^\circ$ through which 100% O₂ was continuously bubbled.

One end of the atrial preparation was attached to a Starling heart lever, loaded to exert a tension of 1 g., which recorded the amplitude of atrial contractions on a smoked paper kymograph. The rate of contraction was recorded using a Thorp impulse counter calibrated so that 1 mm. of deflection was equal to one contraction.

A 1-hr. period was allowed for equilibrium before the experimental protocol was initiated.

The animals used in the studies requiring pretreatment with reserpine were given 5 mg./kg. *i.p.* 20–24 hr. prior to the experiment.

Statistical analysis of the experimental data was carried out as described by Batson (12). A probability of 5% ($p = 0.05$) was considered maximum for statistical significance.

The following drugs were used in this study: acetylcholine bromide,¹ *l*-adrenaline (*l*-epinephrine) bitartrate,¹ atropine sulfate,² levarterenol (*l*-NE) bitartrate monohydrate,³ tyramine hydrochloride,⁴ and reserpine USP⁵ (ampuls, 2.5 mg. base/ml.).

The concentrations of drugs, with the exception of reserpine, were expressed in terms of their respective salts. The concentrations of the solutions were such that it was not necessary to add more than 0.3 ml. of the drug solution to the bath fluid.

RESULTS

Dose-response curves to ACh were determined by exposing the atria to progressively increasing concentrations of ACh. ACh was added to the organ bath 3 min. after an addition of atropine (3 mcg./ml.); each addition of ACh was followed by a 30-min. period with numerous washes prior to repetition of the described procedure.

The dose-response curve to ACh (Fig. 1) shows that the force and rate of atrial contraction increased in a linear fashion with increasing concentrations of ACh up to 100 mcg./ml., after which the change in rate decreased with increasing doses of ACh until a negative chronotropic response became apparent.

Table I—Responses of Isolated Rabbit Atria ($n = 8$) to ACh (100 mcg./ml.), in the Presence of Atropine (3 mcg./ml.), before and after the Production of Tachyphylaxis

Parameters Measured	Control Values	Change from Control Values	
		Control Response to ACh \pm SE	Response to ACh \pm SE after Production of Tachyphylaxis
Force ^a	22 \pm 2.1	+9 \pm 1.0	-5 \pm 1.3 ^c
Rate ^b	126 \pm 7.8	+36 \pm 4.2	-12 \pm 2.4 ^c

^a Mean force in mm. ^b Mean rate in beats/min. ^c Comparison of responses to ACh before and after tachyphylaxis; $p = 0.05$ or less.

The stimulatory response to ACh (100 mcg./ml.), in the presence of atropine (3 mcg./ml.), was characterized by a very short latent period (2-4 sec.) followed by a marked stimulation of both force and rate. After reaching their maximum, the parameters started to return to control levels; when this occurred the bath fluid was exchanged repeatedly. These responses could be reproduced many times when ACh and atropine were given at 30-min. intervals. Results from all subsequent experiments are compared with these described responses.

Production of Tachyphylaxis to ACh—For the demonstration of true tachyphylaxis, certain criteria must be satisfied. The same concentration of ACh must be administered at equal time intervals, and all measured parameters must be allowed to return to predrug levels prior to the next administration of the challenging agent. A concentration of 100 mcg./ml. of ACh was used and was preceded for 3 min. by atropine (3 mcg./ml.). An interval of 10 min. between ACh responses was found to be optimal for the production of tachyphylaxis. When the time interval between responses was prolonged to 20 min. or longer, tachyphylaxis could not be produced. The response to ACh lasted about 1 min.; thus there was a sufficient time interval between drug additions to allow all parameters to return to control levels.

Using these experimental conditions, complete or nearly complete tachyphylaxis was produced following the administration of four doses of ACh. The response of atria to the administration of ACh was considered to be tachyphylactic when the preparation no longer produced an augmentation of atrial contractions. In most experiments, augmentation was replaced by depression. Table I summarizes the measurements obtained in the production of tachyphylaxis.

When the aforementioned schedule of drug additions was continued throughout the duration of the experiment, a spontaneous return of the normal positive inotropic and chronotropic response to ACh could not be observed. However, if after the production of tachyphylaxis the administration of ACh was discontinued for a minimum of 35-45 min., a spontaneous return of the normal response to ACh was observed.

After the establishment of tachyphylaxis to ACh, the indirectly acting sympathomimetic amine, tyramine (5 mcg./ml.), was added to the atrial bath and produced its characteristic augmentation of atrial contractions. Thus, the authors have found no evidence of cross tachyphylaxis between the stimulatory actions of ACh and tyramine.

Reversal of Tachyphylaxis to ACh by Catecholamines—Since the stimulatory response of atria to additions of ACh is the result of a release of NE (7), the development of tachyphylaxis may be attributed to a decrease in the availability of releasable NE and, there-

Figure 1—Dose-response curve to ACh in the presence of atropine (3 mcg./ml.). Key: \circ , force \pm SE; \bullet , rate \pm SE.

fore, should be modified, or perhaps reversed, by exposure to this amine.

Tachyphylaxis was produced in the manner previously described. Upon production of tachyphylaxis, the atria were incubated with NE (0.025 mcg./ml.) for 5 min. The NE was then washed out and the response to ACh was tested in the presence of atropine. The NE incubation procedure did not interrupt the 10-min. interval between additions of ACh. Table II demonstrates the effect of NE incubation upon the tachyphylaxis to the stimulatory response to ACh. As can be seen, restoration of the normal positive inotropic and chronotropic response was attained. Figure 2 is a tracing of a typical experiment of this type.

Since incubation with NE proved to be effective in restoring the stimulatory response to ACh in tachyphylactic atria, another catecholamine, E (0.025 mcg./ml.), was employed under similar conditions. Table II shows the results of these experiments. The response of the atria to ACh, following E incubation, was restored to control levels as it was following incubation with NE.

Effect of Other Agents upon the Response of Atria to ACh—Atria were excised from rabbits that had received reserpine⁸ (5 mg./kg. i.p.) 24 hr. prior to the experimental procedure. In these preparations, the addition of ACh in the presence of atropine failed to produce a positive inotropic and chronotropic response. This was instead supplanted by a negative inotropic and chronotropic response. When reserpine-pretreated atria were incubated with NE (0.025 mcg./ml.) in the manner previously described, there was no restoration of the normal stimulatory response to ACh as was observed in the tachyphylactic atria. Table III summarizes the results of these experiments. However, a restoration of the response to tyramine in reserpine-pretreated atria could be demonstrated following incubation with NE.

DISCUSSION

The positive inotropic and chronotropic effect of ACh on the atropine-pretreated atria is a well-known phenomenon (13-15). Hoffman *et al.* (14) and Middleton *et al.* (16) have proposed that this atrial stimulation is a result of release of an epinephrinelike substance from cardiac tissue, either due to ganglionic stimulation or release from chromaffin tissue. The investigations of Richardson and Woods (7) and of Angelakos and Bloomquist (8) have established that this epinephrinelike substance is, in fact, NE. Thus, one must come to the conclusion that ACh exerts its stimulatory action *via* release of NE in the atropine-pretreated isolated rabbit atria.

Table II—Effect of Incubation with Catecholamines upon Responses of Tachyphylactic Isolated Rabbit Atria to ACh (100 mcg./ml.) in the Presence of Atropine (3 mcg./ml.)

Parameters Measured	Control Values	Catecholamine, CA, 0.025 mcg./ml.	Change from Control Values		
			Tachyphylactic Response to ACh before CA \pm SE	Control Response to CA \pm SE	Response to ACh after CA \pm SE

Figure 2—Effect of NE upon tachyphylaxis to large doses of ACh in isolated rabbit atria.

The upper tracing measures contractile force and the lower tracing depicts atrial rate. The horizontal bracketed line represents 1 min. The drugs were added at the black dots; ACh, 100 mcg./ml.; At, atropine, 3 mcg./ml.; NE, 0.025 mcg./ml. At the arrows the bath fluid was exchanged three times while the kymograph was arrested. The first two doses of ACh illustrate the response of the tachyphylactic atria to this drug. The third dose of ACh illustrates the response after incubation with NE.

While some experimental evidence (17–19) supports the proposal that ganglionic stimulation is the mechanism by which ACh exerts its effect, results of other studies suggest that this mechanism is not an adequate explanation. Anatomical and histological studies have shown that, although intrinsic ganglia are present in the atria, these structures are all parasympathetic and not sympathetic (20–22). Hirsch *et al.* (23) and Cooper (24), using cardiac transplantation techniques to ensure complete denervation, indicate that ganglionic stimulation by ACh is an unlikely mechanism for the positive inotropic and chronotropic effect in such preparations. Studies using the formaldehyde vapor-condensation technique have shown that there is little or no fluorescence in the atria after sympathetic denervation (25). Lee and Shideman (26), using cat papillary muscle, have demonstrated that, in atropine-pretreated preparations, large doses of ACh produced positive inotropic and chronotropic responses. Careful histological studies of these papillary muscles have shown no ganglia to be present; only sympathetic nerve endings were observed.

It is extremely unlikely, therefore, that ACh produces its stimulatory action by acting through the stimulation of intrinsic sympathetic ganglia in the atria. It is more likely that it is acting by the release of NE from the postganglionic neurons. This may be accomplished in a manner similar to that described by Burn and Rand (27).

In view of this evidence and present experimental data, it would seem more meaningful and correct to characterize the actions of ACh and other nicotinic agents on the atria as indirect actions rather than nicotinic effects. The term nicotinic implies sympathetic ganglionic stimulation, and this is clearly not applicable to atria.

Cowan *et al.* (3, 4), Maengwyn-Davies (28), and Maengwyn-

Davies *et al.* (2, 29) have substantiated the general theory of Koppányi (30) that drugs whose action depends upon the liberation of biogenic substances will show tachyphylaxis due to the gradual depletion of releasable biogenes. Indirectly acting ACh meets these stipulations and is indeed tachyphylactogenic on the rabbit atrium, as are the other indirectly acting atrial stimulants.

Incubation of the atria with NE restores the usual indirect response to ACh, which is lost during tachyphylaxis, presumably by replacement of essential catecholamines. The authors have also shown that E, as well as NE, can reverse the tachyphylaxis to ACh. The restoration of the response to ACh by E is in full agreement with the observations of Potter (31) who showed that E and NE are equally well bound to isolated storage granules. Therefore, in these experiments, E may have acted as a "false transmitter." Another explanation might be that of Raab and Gigue (32) who proposed that E may displace some NE from storage sites and then be demethylated to NE.

There seems to be some question as to whether there is a depletion of NE when the stimulatory response to ACh is absent. Using somewhat different methods, Torchiana and Angelakos (33) have demonstrated that when the stimulatory response to ACh in atropinized preparations was absent, there was no significant depletion of NE from the atrial tissue. Furthermore, they have shown that ACh administered to nonatropinized cardiac tissue causes a liberation of NE, accompanied by an increase rather than a decrease in cardiac catecholamines, without, of course, a positive inotropic and chronotropic response (8). This failure to demonstrate a depletion of NE could be interpreted in two ways. First, these authors administered acetylcholine at 20-min. intervals. At this time interval, there could be a restoration of liberated catecholamines by the atrial tissue since the present authors have shown that ACh administered at 20–30-min. intervals failed to produce tachyphylaxis. Secondly, the ACh releasable store may be small, and depletion of this store would not give a significant reduction in the total catecholamine content of the atria. These proposals may gain support in the observations that the atria is still responsive to tyramine while tachyphylactic to ACh. Moreover, there must be some depletion of NE, as indicated by the observation that tachyphylaxis to ACh is reversed by incubation of the atria with this neurohormone.

In atria excised from reserpine-pretreated rabbits, all agents acting by the release of NE are ineffective. The authors have shown this to be true for ACh, just as it has been shown for nicotine (34), DMPP (35), and tyramine (3). This lack of response in all cases is most probably a result of the depletion of NE by reserpine (36). In the studies reported here, however, atria from reserpine-pretreated rabbits which showed no indirect stimulating response to ACh could not be made to respond upon incubation with catecholamines while the response to tyramine was reinstated. This difference in behavior of indirectly acting ACh and of tyramine and DMPP in atria from reserpine-pretreated animals could be explained by the depressant action of ACh (Table III) and the lack of such depressant action by tyramine. The depressant effect of ACh may be due to stimulation of receptor sites not occupied by atropine, resulting in atrial depression (37).

The lack of cross tachyphylaxis between ACh and tyramine, and the restoration of the response to tyramine but not to ACh in reserpine-pretreated atrium, indicate that these two agents release NE from different stores. When the ACh-releasable store is apparently depleted, the tyramine-releasable store is still unaffected.

The results seem to indicate that there is no uptake of NE by the ACh-releasable compartment in reserpinized atria. If NE was taken up, some would probably be released by ACh, with the result (which is not observed) being a reduction or reversal of the depressant response to ACh. The reserpine-pretreated atria was, however, capable of taking up and releasing NE, as indicated by the restoration of the atrial response to additions of tyramine.

The contrast between the effects of reserpine pretreatment and tachyphylaxis on the atrial response to ACh is quite perplexing. In the case of tachyphylaxis, the negative inotropic and chronotropic effects of large, oft-repeated doses of ACh can be easily converted into atrial stimulation by incubation with catecholamines; thus the tachyphylaxis can be explained by the loss of essential catecholamines. These ACh-releasable catecholamines probably represent only a small fraction of the total catecholamines, because tachyphylaxis is reversed by allowing the atrial preparation to stand without further additions of ACh for 35–45 min.

Table III—Effect of Incubation with NE (0.025 mcg./ml.) on Responses of Reserpine-Pretreated* ($n = 5$) Isolated Rabbit Atria to ACh (100 mcg./ml.) in the Presence of Atropine (3 mcg./ml.)

Effect of Sex on Penicillin Blood Levels in Dogs

JOHN W. POOLE*

Abstract □ Studies concerned with the oral absorption characteristics of dicloxacillin from various pharmaceutical formulations in beagle dogs suggest that the female of this species shows consistently higher and more prolonged blood serum levels of the antibiotic than the corresponding male. An investigation was initiated to determine the extent of this phenomenon with respect to sodium dicloxacillin monohydrate and other penicillins. The results of these studies suggest that the monobasic penicillin molecules show blood serum level variations after oral administration that are related to the sex of the animal, while a similar correlation does not appear to exist for the amphoteric penicillins. Determination of the biological half-life of the various penicillins in the male and female after intravenous administration indicates that no sexual differences occur with respect to the disappearance of active drug from the blood.

Keyphrases □ Penicillin blood levels—dogs □ Sex effect, dogs—penicillin blood levels □ Blood levels, half-life, corticosteroids—sex effect, dogs □ Microbiological test method—analysis

Minor sexual differences in drug response among the animals of a species are frequently encountered in toxicity experiments. For example, L-thyroxine produces a

more pronounced depressant effect on weight gain in male than in female rats (1), and the toxicity of hypoglycemic agents is enhanced in female and male rats pretreated with diethylstilbestrol (2). These differences are sometimes quite significant. For example, the antibiotic acetoxycyclohexamide was shown by Pallotta *et al.* (3), in acute and subacute tests, to be about four times as toxic for young female rats as it is for males. In many cases, these differences in response between the sexes can be traced to differences in enzyme activities and rate of metabolism. Male rats metabolize hexobarbital much faster than do females, and the average sleeping time of the male after receiving the drug is only about one-fourth that of the female (4, 5). Recently, in a report by Kernohan and Todd (6), it was suggested that women bleed more readily than men during heparin therapy. A similar conclusion, that women have a higher risk of bleeding with heparin than do men, was made from the studies of Jick *et al.* (7).

The results obtained in a series of investigations on the effect of dosage-form variables on biological avail-

Effect of Sex on Penicillin Blood Levels in Dogs

JOHN W. POOLE*

Abstract □ Studies concerned with the oral absorption characteristics of dicloxacillin from various pharmaceutical formulations in beagle dogs suggest that the female of this species shows consistently higher and more prolonged blood serum levels of the antibiotic than the corresponding male. An investigation was initiated to determine the extent of this phenomenon with respect to sodium dicloxacillin monohydrate and other penicillins. The results of these studies suggest that the monobasic penicillin molecules show blood serum level variations after oral administration that are related to the sex of the animal, while a similar correlation does not appear to exist for the amphoteric penicillins. Determination of the biological half-life of the various penicillins in the male and female after intravenous administration indicates that no sexual differences occur with respect to the disappearance of active drug from the blood.

Keyphrases □ Penicillin blood levels—dogs □ Sex effect, dogs—penicillin blood levels □ Blood levels, half-life, corticosteroids—sex effect, dogs □ Microbiological test method—analysis

Minor sexual differences in drug response among the animals of a species are frequently encountered in toxicity experiments. For example, L-thyroxine produces a

more pronounced depressant effect on weight gain in male than in female rats (1), and the toxicity of hypoglycemic agents is enhanced in female and male rats pretreated with diethylstilbestrol (2). These differences are sometimes quite significant. For example, the antibiotic acetoxycyclohexamide was shown by Pallotta *et al.* (3), in acute and subacute tests, to be about four times as toxic for young female rats as it is for males. In many cases, these differences in response between the sexes can be traced to differences in enzyme activities and rate of metabolism. Male rats metabolize hexobarbital much faster than do females, and the average sleeping time of the male after receiving the drug is only about one-fourth that of the female (4, 5). Recently, in a report by Kernohan and Todd (6), it was suggested that women bleed more readily than men during heparin therapy. A similar conclusion, that women have a higher risk of bleeding with heparin than do men, was made from the studies of Jick *et al.* (7).

The results obtained in a series of investigations on the effect of dosage-form variables on biological avail-

Figure 1—Mean blood serum concentration of dicloxacillin in male and female beagle dogs after oral administration of 250-mg. doses.

ability of dicloxacillin in beagle dogs indicated that the female of this species demonstrated consistently better utilization of this drug than the corresponding male. This was shown by higher peak blood serum levels and greater areas under the blood serum level-time curves after oral administration of the antibiotic to female dogs than after similar dosing to the males. A study was initiated to determine the extent of this phenomenon with respect to penicillin compounds as a class.

Specifically, the blood serum levels attained after oral administration of the monobasic penicillins, dicloxacillin and nafcillin, and the amphoteric penicillin, ampicillin, to male and female beagle dogs were determined. The biological half-lives of these drugs in this species were also determined in both sexes after intravenous administration of these compounds. In addition, the results obtained with several other penicillins used in various studies designed to evaluate dosage-form variables have been considered with respect to a difference in biological utilization of these agents between male and female beagle dogs.

EXPERIMENTAL

Compounds—The following were used: ampicillin, anhydrous (Wyeth Laboratories, C-10575); sodium nafcillin monohydrate (Wyeth Laboratories, W-663989); and sodium dicloxacillin monohydrate (Wyeth Laboratories, C-10651).¹

Procedure—The general procedure used in the blood serum level studies follows. Six dogs, three of each sex, were utilized in each experiment. The test animals were dosed with the appropriate drug in a strict crossover manner. The dogs were fasted overnight; the antibiotic was administered by means of a stomach tube, followed by a standard amount of distilled water. Blood samples were drawn at the appropriate times postadministration and analyzed by a microbiological method utilizing *Sarcina lutea* as the test organism.

In studies in which the drug was administered intravenously, the penicillin was dissolved in an appropriate amount of physiological saline solution just prior to administration.

RESULTS AND DISCUSSION

In a series of investigations concerned with the effect of dosage-form variables on the biological utilization of dicloxacillin, oral administration of the various dosage forms containing this agent to female beagle dogs resulted in significantly higher and greater area under the blood serum level-time curves than after similar administration to male animals of the same species. A typical example of such a study is shown in Fig. 1. In this instance the female animals showed a mean peak serum level of the antibiotic

Figure 2—Mean blood serum concentrations of dicloxacillin in male and female beagle dogs after oral administration of 25-mg./kg. doses.

of 3.7 mcg./ml., while the male animal showed a mean peak serum level of 2.2 mcg./ml. The areas under the blood serum level-time curves calculated for each sex were 1.20 and 3.34 mcg./ml. \times hr. for the male and female dogs, respectively. These results were influenced to some extent by the fact that discrete dosage units containing 250 mg. of the active moiety were administered to each animal in a crossover experiment. Because the females were, generally, slightly smaller than the male animals, this factor may have had a significant effect on the results observed. In addition, the possibility that the females used were "good" absorbers of this agent and the males "poor" absorbers was also considered.

To rule out the significance of these factors, a study was designed in which a 25-mg./kg. dose of penicillin was administered to the two sexes of this species in the form of a powder slurried in water. All the animals used in the initial experiments were omitted from this study. In addition to dicloxacillin, two other penicillins were included in the study, nafcillin and anhydrous ampicillin.

Figure 2 illustrates the difference in blood serum levels attained in this experiment with male and female animals after administration of dicloxacillin at the 25-mg./kg. dose. These results are in agreement with the earlier data obtained utilizing this drug in pharmaceutical dosage forms. The females in this instance showed a mean peak serum level of 5.4 mcg./ml., while the mean level with the males was 2.5 mcg./ml. Similarly, the areas under the blood serum level-time curves were determined to be 4.96 and 1.72 mcg./ml. \times hr. for the female and male animals, respectively.

Figure 3 shows the results obtained when nafcillin was administered at the 25-mg./kg. level to beagle dogs of both sexes. In this instance, the females attained a mean peak serum level of 0.68

Figure 3—Mean blood serum concentrations of nafcillin in male and female beagle dogs after oral administration of 25-mg./kg. doses.

¹ Dosage forms of the several penicillins employed in these studies were prepared by the Development Section of the Pharmacy Research and Development Division, Wyeth Laboratories, Inc.

Figure 4—Mean blood serum concentrations of ampicillin in male and female beagle dogs after oral administration of 25-mg./kg. doses.

mcg./ml., while the males showed a mean peak serum level of 0.40 mcg./ml. The areas under the blood serum level-time curves for the females and males were calculated to be 0.81 and 0.46 mcg./ml. \times hr., respectively.

However, as shown in Fig. 4, after administration of anhydrous ampicillin to animals of both sexes, no significant difference in mean peak serum levels attained or in the area under the blood serum level-time curves between the sexes was observed. The mean peak serum levels attained in this case were 12.1 and 12.2 mcg./ml., and the areas under the blood serum level-time curves were 21.8 and 26.0 mcg./ml. \times hr. for the males and females, respectively. Table I summarizes the mean peak serum levels and curve areas obtained in this investigation. The blood serum level data obtained in this study indicate that the monobasic penicillins, such as dicloxacillin and nafcillin, show a significant difference in biological utilization of these agents between male and female beagle dogs. The results obtained with the amphoteric penicillin, ampicillin, did not demonstrate any significant differences in blood serum levels between the sexes.

The results obtained in subsequent experiments utilizing pharmaceutical dosage forms of penicillin G, a monobasic penicillin, and Wy-4508 [6-(1-aminocyclohexanecarboxamido)penicillanic acid], an amphoteric penicillin, are in agreement with the results summarized in Table I.

Figure 5 shows the mean blood serum levels obtained for penicillin G in male and female beagle dogs after oral administration of 500 mg. of the drug as buffered tablets. As was the case with the monobasic penicillins, the female showed a significantly better overall biological utilization of this agent than did the male animal. A mean peak serum level of 58 units/ml. was attained in the females, while a mean peak serum level of 25 units/ml. was noted in the males. Similarly, the areas under the blood serum level-time curves for the female and male animals were determined to be 80 and 48 units/ml. \times hr., respectively.

Figure 6 illustrates the results obtained in a study of male and female beagle dogs after oral administration (250 mg.) of a pharmaceutical formulation of the amphoteric penicillin, Wy-4508. The results show that there is no significant difference in the blood serum levels attained between the male and female animals or in the overall biological utilization of this agent after such administration. The peak serum levels obtained were 31.5 mcg./ml. for the male and 27.5 mcg./ml. for the female. The areas under the blood serum level-time curves were 36.0 and 36.6 mcg./ml. \times hr. for the males and females, respectively.

One possible mechanism by which the observed sex difference in blood serum levels could be explained is a difference in elimination rate (biological life) for the monobasic penicillins in the males and females. To test this possibility, an intravenous dose of the two

Table I—Peak Blood Serum Level and Areas under Blood Serum Level-Time Curve after Oral Administration of Various Penicillins (25 mg./kg.) to Male and Female Beagle Dogs

Compound	Peak Level, mcg. ml.		Area under Curve, mcg./ml. \times hr.	
	Male	Female	Male	Female
Nafcillin ^a	0.40	0.68	0.46	0.81
Dicloxacillin ^a	2.5	5.4	1.72	4.96
Ampicillin	12.1	12.2	21.8	26.0

^a Administered as the sodium salt of the monohydrate.

Figure 5—Mean blood serum concentrations of penicillin G in male and female beagle dogs after oral administration of 500-mg. doses.

monobasic penicillins, nafcillin and dicloxacillin, along with the amphoteric penicillin, ampicillin, was administered to beagle dogs of each sex and the blood serum level decay followed. The dogs used in this study were the same animals employed in the oral absorption studies with these penicillins. The biological half-life for ampicillin in both sexes was similar, as was expected, on the basis of the oral blood level data. The average half-life values were 35 and 34 min. for the male and female, respectively. However, neither of the monobasic penicillins, dicloxacillin or nafcillin, employed in this study showed a difference in the biological half-life for the male and female animals. The average biological half-life for nafcillin was determined to be 10 min. in each sex, while administration of dicloxacillin resulted in an average biological half-life of 16 min. for the male and 18 min. for the female. The results of these studies are summarized in Table II, where the average biological half-life for the various penicillin products in the male and female animals is listed along with the range of half-lives obtained. These results indicate that the differences in peak serum levels and areas under the blood serum level-time curves noted for the male and female dogs with monobasic penicillins are apparently not related to a difference in elimination rate of these drugs in the two sexes. Other possible mechanisms which may be involved in the differences in serum levels noted are: (a) a difference in the metabolism of the monobasic penicillins in the gut wall of the male and female animals or (b) a difference in acidity in the gastrointestinal tract of the male and female beagle dogs. This latter hypothesis could account for the lack of any sex difference noted with amphoteric penicillins which would not be as sensitive to the acid environment of the gastrointestinal tract as monobasic penicillins.

Figure 6—Mean blood serum concentrations of Wy-4508 in male and female beagle dogs after oral administration of 250-mg. doses.

Table II—Biological Half-Life of Various Penicillins in Male and Female Beagle Dogs after Intravenous Administration

Sex	Half-Life, min.		
	Nafcillin ^a	Dicloxacillin ^a	Ampicillin
Male	10 (9–11) ^b	16 (12–20) ^b	35 (29–39) ^b
Female	10 (9–11) ^b	18 (15–22) ^b	34 (28–38) ^b

^a Administered as the sodium salt of the monohydrate. ^b Range of half-life observed.

In any event, the sex of the test animal should be considered in studies concerned with *in vivo* effects of monobasic penicillins in which dogs, particularly beagles, are used. The effect of the animal's sex on the biological utilization of such compounds in other species and in human subjects is not known at this time. Studies in humans are of interest since differences of the magnitude observed in the animal studies may be clinically significant.

SUMMARY

The biological utilization, as demonstrated by blood serum levels and area under the serum level-time curves, for a series of penicillin compounds in male and female beagle dogs has been determined. Results obtained indicate that the female of this species attained a higher mean peak serum level and a greater area under the blood serum level-time curve than did the male after oral administration of the monobasic penicillins studied: dicloxacillin, nafcillin, and penicillin G. The amphoteric penicillins employed, ampicillin and Wy-4508, showed no significant difference in blood serum levels or curve areas after oral administration to male or female beagle dogs. There was no significant difference between the sexes in the elimination rate (half-life) of the monobasic penicillins, sodium dicloxacillin monohydrate and sodium nafcillin monohydrate, or of the amphoteric penicillin, ampicillin, after intravenous administra-

tion, which rules out this factor as an explanation for the difference in serum levels noted. A possible reason for the sex difference in serum levels in beagle dogs may be due to a difference in acidity of the gastrointestinal tract and/or to a difference in the gut wall metabolism of the monobasic penicillins in the male and female of this species.

Pharmacokinetic Analysis of Potentiating Effect of Phenylbutazone on Anticoagulant Action of Warfarin in Man

ROBERT A. O'REILLY* and GERHARD LEVY†

Abstract □ Warfarin is eliminated more rapidly but its anticoagulant effect is increased by concomitant administration of phenylbutazone. Pharmacokinetic analysis by recently developed techniques shows that the prewarfarin synthesis rate and the normal degradation of prothrombin complex activity are not affected by phenylbutazone, but that this drug has a pronounced effect on the relationship between synthesis rate of prothrombin complex activity and plasma-warfarin concentration. These observations are consistent with the assumption that phenylbutazone competitively displaces warfarin from nonspecific binding sites in the plasma and tissues (particularly the liver) and thereby increases the interaction of the anticoagulant with its pharmacologic receptor and metabolizing enzyme system.

Keyphrases □ Warfarin activity—phenylbutazone effect □ Phenylbutazone effect, warfarin activity—pharmacokinetics □ Pharmacokinetics—phenylbutazone potentiation, warfarin activity □ Biologic half-life, warfarin—phenylbutazone effect

Drug interactions are usually of three types. A drug may increase or decrease the elimination rate constant of another by stimulating or inhibiting drug metaboliz-

ing enzymes, by changing urine pH or the flow rate of urine or bile, and/or by affecting the distribution of the other drug in the body. Another type of drug interaction involves the potentiation or inhibition of the pharmacologic effect of one drug by another without measurably affecting its kinetics of elimination. The third type of drug interaction is one where the gastrointestinal absorption of one drug is increased or decreased by the other. The coumarin anticoagulants exemplify all three of these effects. Induction of microsomal enzymes by heptabarbital increases the rate of elimination of warfarin and bishydroxycoumarin without affecting the relationship between anticoagulant effect and plasma-coumarin concentration in man (1, 2). Heptabarbital apparently also decreases the gastrointestinal absorption of bishydroxycoumarin (3) by mechanisms which are still being studied.

A particularly interesting interaction is that between warfarin and phenylbutazone. The former is more rapidly eliminated in the presence of phenylbutazone, but its anticoagulant effect in man is increased (4).

Female	10 (9–11) ^b	18 (15–22) ^b	34 (28–38) ^b

^a Administered as the sodium salt of the monohydrate. ^b Range of half-life observed.

In any event, the sex of the test animal should be considered in studies concerned with *in vivo* effects of monobasic penicillins in which dogs, particularly beagles, are used. The effect of the animal's sex on the biological utilization of such compounds in other species and in human subjects is not known at this time. Studies in humans are of interest since differences of the magnitude observed in the animal studies may be clinically significant.

SUMMARY

The biological utilization, as demonstrated by blood serum levels and area under the serum level-time curves, for a series of penicillin compounds in male and female beagle dogs has been determined. Results obtained indicate that the female of this species attained a higher mean peak serum level and a greater area under the blood serum level-time curve than did the male after oral administration of the monobasic penicillins studied: dicloxacillin, nafcillin, and penicillin G. The amphoteric penicillins employed, ampicillin and Wy-4508, showed no significant difference in blood serum levels or curve areas after oral administration to male or female beagle dogs. There was no significant difference between the sexes in the elimination rate (half-life) of the monobasic penicillins, sodium dicloxacillin monohydrate and sodium nafcillin monohydrate, or of the amphoteric penicillin, ampicillin, after intravenous administra-

tion, which rules out this factor as an explanation for the difference in serum levels noted. A possible reason for the sex difference in serum levels in beagle dogs may be due to a difference in acidity of the gastrointestinal tract and/or to a difference in the gut wall metabolism of the monobasic penicillins in the male and female of this species.

Pharmacokinetic Analysis of Potentiating Effect of Phenylbutazone on Anticoagulant Action of Warfarin in Man

ROBERT A. O'REILLY* and GERHARD LEVY†

Abstract □ Warfarin is eliminated more rapidly but its anticoagulant effect is increased by concomitant administration of phenylbutazone. Pharmacokinetic analysis by recently developed techniques shows that the prewarfarin synthesis rate and the normal degradation of prothrombin complex activity are not affected by phenylbutazone, but that this drug has a pronounced effect on the relationship between synthesis rate of prothrombin complex activity and plasma-warfarin concentration. These observations are consistent with the assumption that phenylbutazone competitively displaces warfarin from nonspecific binding sites in the plasma and tissues (particularly the liver) and thereby increases the interaction of the anticoagulant with its pharmacologic receptor and metabolizing enzyme system.

Keyphrases □ Warfarin activity—phenylbutazone effect □ Phenylbutazone effect, warfarin activity—pharmacokinetics □ Pharmacokinetics—phenylbutazone potentiation, warfarin activity □ Biologic half-life, warfarin—phenylbutazone effect

Drug interactions are usually of three types. A drug may increase or decrease the elimination rate constant of another by stimulating or inhibiting drug metaboliz-

ing enzymes, by changing urine pH or the flow rate of urine or bile, and/or by affecting the distribution of the other drug in the body. Another type of drug interaction involves the potentiation or inhibition of the pharmacologic effect of one drug by another without measurably affecting its kinetics of elimination. The third type of drug interaction is one where the gastrointestinal absorption of one drug is increased or decreased by the other. The coumarin anticoagulants exemplify all three of these effects. Induction of microsomal enzymes by heptabarbital increases the rate of elimination of warfarin and bishydroxycoumarin without affecting the relationship between anticoagulant effect and plasma-coumarin concentration in man (1, 2). Heptabarbital apparently also decreases the gastrointestinal absorption of bishydroxycoumarin (3) by mechanisms which are still being studied.

A particularly interesting interaction is that between warfarin and phenylbutazone. The former is more rapidly eliminated in the presence of phenylbutazone, but its anticoagulant effect in man is increased (4).

^a Sodium warfarin, 1.5 mg./kg. body weight, alone and on the 4th day of phenylbutazone administration, 200 mg. three times a day. ^b All males. ^c Based on least-squares regression analysis of log C_p values > 1 mg./l. ^d Listed only to facilitate description of the data. These values are a complex function of the amount absorbed and of the kinetics of absorption, distribution, and elimination.

This is unusual since more rapid elimination of a drug generally results in a decrease in its total pharmacologic effect (unless the drug is activated by metabolism). For example, the total anticoagulant effect of warfarin is decreased by enzyme inducers such as heptabarbital (1). Recently developed pharmacokinetic techniques (5) now permit a more detailed assessment of the mechanism of potentiation of warfarin by phenylbutazone.

EXPERIMENTAL

A single dose of sodium warfarin, 1.5 mg./kg. body weight, was administered orally to six normal subjects. Plasma-warfarin concentrations and prothrombin complex activity were determined daily for 5 days or more. The same experiment was carried out also during phenylbutazone (PB) administration (200 mg. orally three times a day for at least 8 days). Warfarin was administered on the 4th day of PB administration. Additional details of the study are described elsewhere (4, 6).

THEORETICAL

The theory and methodology for relating the anticoagulant effect of warfarin to its concentration in the plasma have been described in detail in a previous report (5) and will only be summarized here. Coumarin anticoagulants interfere with the synthesis of vitamin K-dependent blood-clotting factors (Factors II, VII, IX, and X) but do not affect their degradation. There is no direct relationship between prothrombin complex activity (P) and warfarin concentration in the plasma (C_p), because the former represents the net effect of the synthesis of various clotting factors and their degradation. Thus,

$$R_{\text{net}} = R_{\text{syn.}} - R_{\text{deg.}} \quad (\text{Eq. 1})$$

where R_{net} is the net rate of change in P , $R_{\text{syn.}}$ is the rate of synthesis,

and $R_{\text{deg.}}$ is the rate of degradation of P . Since $R_{\text{deg.}} = k_d P$,

$$R_{\text{net}} = R_{\text{syn.}} - k_d P \quad \text{or} \quad R_{\text{syn.}} = R_{\text{net}} + k_d P \quad (\text{Eq. 2})$$

where k_d is the apparent first-order degradation rate constant for P . Prior to the administration of a coumarin anticoagulant,

$$R_{\text{syn.}}^0 = k_d P^0 \quad (\text{Eq. 3})$$

In the clinical range of C_p and $R_{\text{syn.}}$, there is an essentially linear relationship between $R_{\text{syn.}}$ and log C_p which, as has been shown previously (5), is described by the relationship

$$R_{\text{syn.}} = R_{\text{syn.}}^0 + m \log C_{p \text{ min.}} - m \log C_p \quad (\text{Eq. 4})$$

where $C_{p \text{ min.}}$ is the hypothetical minimum effective C_p . A plot of $R_{\text{syn.}}$ versus log C_p has a slope of $-m$ and extrapolates to $C_{p \text{ max.}}$ at $R_{\text{syn.}} = 0$. P and C_p are determined experimentally as a function of time. Administration of a synthesis-blocking dose of warfarin (such that $R_{\text{syn.}} = 0$) yields k_d . The change of P with time determines R_{net} . $R_{\text{syn.}}$ can then be calculated by means of Eq. 2. Least-squares regression analysis of $R_{\text{syn.}}$ as a function of log C_p yields m and $C_{p \text{ max.}}$

RESULTS

PB significantly decreased ($p < 0.01$ by paired t test) the biologic half-life of warfarin from an average of 64 hr. to an average of 40 hr. (Table I). The extrapolated initial C_p was higher during PB administration in five of the six subjects, but the difference was not statistically significant. P^0 was 100% of normal in all subjects in the control period and during PB administration. Also, PB had no effect on k_d and, therefore, did not change $R_{\text{syn.}}^0$ (Table II).

The relationship between $R_{\text{syn.}}$ and log C_p was profoundly altered by PB. In three of the six subjects the relationship remained approximately linear, but the slope of the regression line ($-m$) decreased appreciably (e.g., Fig. 1). In the other three subjects, data obtained during PB administration show slight curvature (e.g., Fig. 2). Despite

this, and merely for facilitating a summary of the results, regression lines were fitted also to these data by the method of least squares. This summary is presented in Table III. There was a highly significant ($p < 0.01$) decrease in m during PB administration but no statistically significant change in C_p max. (by paired t test), although five out of six values were lower during PB administration. Figure 3 shows the results obtained in Subject N-31 in the present study, as well as the results of three additional experiments with warfarin alone. C_p values in the additional experiments were determined spectrophotometrically, while all C_p values in the present study were determined by fluorometry.

DISCUSSION

The biologic half-life of warfarin was significantly decreased during PB administration. PB is a known inducer of drug-metabolizing enzymes (7) but, due to its pronounced affinity to plasma proteins (8), it also displaces warfarin from protein-binding sites (6). There is evidence that decreased plasma protein binding increases the elimination rate constant of coumarin anticoagulants by increasing their concentration at biotransformation sites in the liver (9, 10). On the other hand, PB and bishydroxycoumarin (and, therefore, presumably also warfarin) may be metabolized by the same enzyme system (11); therefore, there may occur mutual inhibition of biotransformation. Thus the observed effect of PB on the elimination of warfarin may be the net result of more than one type of effect, and its direction and magnitude may depend on the dose and duration of PB administration.

The lack of effect of PB on P^0 , k_d , and, therefore, on R_{syn} ,⁰ shows that PB has no apparent effect on the blood-clotting system. On the other hand, the relationship between R_{syn} and C_p is considerably changed by PB. Unfortunately, the fluorometric assay for warfarin [which had to be used in this study because PB interferes with the spectrophotometric assay (6)] is not totally specific for unchanged warfarin and is affected also by one or more of its hydroxylated metabolites (12). Particularly the lower C_p values (*i.e.*,

the values obtained late in the experiment) are, therefore, somewhat higher than those obtained by spectrophotometry. Consequently, as is exemplified in Fig. 3, the regression lines are steeper (and m values larger) than when C_p is determined spectrophotometrically. However, this has little effect on the relative relationships between R_{syn} and C_p with and without PB.

The effect of PB is unlike that produced by the enzyme inducer heptabarbital (1) and differs also from the pattern observed in a subject who is genetically resistant to warfarin (13). Heptabarbital stimulates the biotransformation of warfarin and, therefore, decreases C_p ; but the anticoagulant effect at a given C_p is the same during control periods and during heptabarbital administration, *i.e.*, the "concentration-response" relationship is not altered (1). In the resistant subject, the slope of the R_{syn} versus $\log C_p$ plot is normal, but the regression line is displaced laterally to a higher C_p max. value (13).

PB affects mainly the slope ($-m$) of the R_{syn} - $\log C_p$ plot. Qualitatively, this suggests that PB competitively displaces warfarin from nonspecific protein-binding sites in the plasma and tissues¹ and thereby affords more extensive interaction of the anticoagulant with its pharmacologic receptor in the liver. The more rapid elimination of warfarin during PB administration is consistent with this reasoning, since warfarin is eliminated by biotransformation in the liver and the elimination rate of the anticoagulant is a function of its concentration in the liver. The warfarin-PB interaction is an interesting example of the simultaneous occurrence of two separate effects, enhanced elimination (which ordinarily would decrease the total pharmacologic effect) and potentiation of the pharmacologic

Figure 2—Effect of phenylbutazone on the relationship between R_{syn} and C_p in Subject N-22. Key: ○, control; and ●, with phenylbutazone.

Figure 3—Effect of phenylbutazone on the relationship between R_{syn} and C_p in Subject N-31. Key: ○, control; and ●, with phenylbutazone. Shown also are data for four other control experiments in which C_p was determined spectrophotometrically. The regression line for the control results was fitted to all the experimental data.

¹ Note, for example, the qualitative similarity between the effect of a constant concentration of displacing agent on the protein binding of a drug at various concentrations (Fig. 3 in Reference 14) and the effect of a presumably relatively constant body level of PB on the activity of warfarin as found in the present study.

action of warfarin. Both of these effects seem to be due primarily to a change in the distribution of warfarin in the body.

Diffuse Reflectance Studies of Solid-Solid Interactions

JOHN L. LACH and LYLE D. BIGHLEY*

Abstract □ Tetracycline and its derivatives, bishydroxycoumarin, and methantheline bromide have been studied by diffuse reflectance spectroscopy for possible solid-solid interactions with various metallic adjuvants. Examination of the spectra of some of these drug-adjuvant systems show rather small spectral changes, while other spectra show large bathochromic and hyperchromic changes, new band formation, and visual color changes which are indicative of charge-transfer interactions. Although these interactions vary in variety and intensity, they may significantly alter the availability and activity of the medicinal agent in pharmaceutical dosage forms.

Keyphrases □ Solid-solid interaction—determination □ Diffuse reflectance spectroscopy—solid-solid interaction analysis □ Tetracyclines, methantheline bromide, bishydroxycoumarin—metal-ion interactions □ Metal ions—tetracyclines, —methantheline bromide, —bishydroxycoumarin—interactions

Many articles in the pharmaceutical and medical literature deal with the problem of physiologically inactive tablet and capsule formulations. Lach and Bornstein (1), by the use of diffuse reflectance spectroscopy (DRS), have postulated that the apparent inactivity may be due in part to adsorption of the active principle onto an inert adjuvant. They have shown that solid-solid interactions do indeed exist between various chemical entities and a wide variety of adjuvants commonly found in pharmaceutical dosage forms. Although some of the interactions may be of the weak variety, they may, nevertheless, be sufficient to alter the absorption and availability of the medicinal agent.

The study of solid-solid interactions is of interest because of the effects that adjuvants may exhibit when incorporated into pharmaceutical dosage forms. These effects may include: (a) changes in the nature and in-

tensity of biological activity caused by complexation with the active ingredient (2); (b) modifications of the physical state, particle size, and/or surface area of the drug available to the absorption sites (3); or (c) changes in the stability of the active principle (4-7).

The purposes of this study were to continue the investigation of solid-solid interactions of a number of drugs and to gain a better insight into the nature of these interactions.

EXPERIMENTAL

Reagents—Oxytetracycline hydrochloride,¹ tetracycline hydrochloride,² chlortetracycline hydrochloride,² demethylchlortetracycline hydrochloride,² methantheline bromide,³ bishydroxycoumarin,⁴ magnesium trisilicate, ferric phosphate, aluminum hydroxide, tribasic calcium phosphate, and talc were used.

Apparatus—The following were used: Beckman model DU spectrophotometer with a diffuse reflectance attachment (1), constant-temperature water bath with rotating spindles, 150-ml. amber vials with caps, Parafilm,⁵ and a glass desiccator with anhydrous calcium sulfate.⁶

Procedure—*Preparation of the Tetracyclines*—Thirty milligrams of active ingredient (tetracycline HCl, oxytetracycline HCl, chlortetracycline HCl, and demethylchlortetracycline HCl) was weighed for every 2 g. of adsorbent (pharmaceutical adjuvant) used. The powders were placed in 150-ml. amber vials, and 25 ml. of distilled water was added as the dispersion medium. The vial was then covered with Parafilm and capped. Equilibration was allowed to proceed for 2 hr. at 30 ± 0.5° to effect interaction. After equilibration, the suspension was filtered under vacuum and the powder dried

in vacuo over anhydrous calcium sulfate. The DRS spectra of the samples were then determined, using magnesium carbonate as the standard.

Preparation of Methantheline Bromide and Bishydroxycoumarin—Sixty milligrams of active ingredient was weighed for every 2 g. of adsorbent. The powders were placed in 150-ml. vials, 10 ml. of distilled water was added to each vial, and equilibration was allowed to proceed as described previously. After equilibration, the dispersion medium was removed by drying *in vacuo* over anhydrous calcium sulfate. The DRS spectra of the samples were determined, using magnesium carbonate as the reference standard.

Preparation of the Control—The control for each experiment was prepared by physically mixing 2 g. of the adsorbent with the indicated amount of dried active ingredient, using a mortar and pestle for the trituration. The DRS of the control was then determined, using magnesium carbonate as the reference standard.

RESULTS AND DISCUSSION

Tetracycline-Adjuvant Interactions—Throughout the following discussion of the different drug-adjuvant systems, a qualitative interpretation of the results will be given because the theory and mechanism of solid-solid interactions are not fully understood at present. However, the authors feel a qualitative interpretation is of value in view of the fact that drug-adjuvant interactions do occur in the solid state. Furthermore, it is important to recognize, prior to dosage formulation, that such surface interactions may occur.

Since Lach and Bornstein (1) showed that oxytetracycline undergoes solid-solid interaction with various adjuvants, since cobalt and nickel complexes of tetracycline and two of its analogs were prepared and their spectral properties studied (8), and because the metal chelation aspects of tetracycline complexes have been investigated extensively in solution (9-13), a DRS study of the various tetracycline-metallic-containing excipients was undertaken. The objective was to determine whether significant spectral differences existed between the different derivatives and whether DRS changes observed in these antibiotic-exipient interactions could be correlated with respect to reported formation constants (9).

Figure 1, which shows the DRS of chlortetracycline hydrochloride and magnesium trisilicate, is an example of the interaction exhibited by tetracycline and its derivatives with this adjuvant. Examination of the figure shows that Spectrum B, which represents the equilibrated sample, has undergone a significant change from that of the physical mixture of the two components (A) and also from the spectrum of the pure drug (C). In addition to these spectral differences, other evidence that an interaction had taken place was noted by a change of color from white or faintly yellow in the physical

Figure 2—DRS composite of equilibrated tetracyclines (30 mg.) and magnesium trisilicate (2.0 g.). Key: A, tetracycline HCl; B, chlortetracycline HCl; C, oxytetracycline HCl; and D, demethylchlortetracycline HCl.

Figure 3—DRS of tetracycline HCl (30 mg.) and ferric phosphate (2.0 g.). Key: A, control; B, equilibrated sample; C, pure tetracycline HCl with no adjuvant present; and D, pure ferric phosphate with no drug present.

mixture to a straw yellow in the equilibrated sample. The spectral and color changes occurred with all four tetracycline derivatives. It should be noted here that only in the tetracycline series were the equilibrated samples filtered first and then vacuum dried. Removal of the soluble tetracycline species from solution by the excipient under study further indicates the strength of the interaction.

The equilibrated samples of the tetracycline-magnesium trisilicate series all show a bathochromic shift between 450 and 400 $m\mu$ and decreased reflectance throughout the visible and UV region. New band formation is seen at approximately 315 $m\mu$ in each case. This band may be considered to be the result of an interaction of the adsorbent with the tetracyclines where the adsorbent facilitates the clarification of an existing peak in this region, or it might represent the reflectance spectrum of a film of drug adsorbed onto the surface of magnesium trisilicate. The suggestion that this peak may be a clarification of an already existing peak can be seen by examining the transmittance spectra of the pure compounds in basic media (1). However, the reflectance spectra of the pure compounds (Spectrum C) do not show a maximum at this wavelength.

It appears that chemical rather than physical interactions have occurred since the spectral changes associated with physical adsorption are usually in the order of 5-10 $m\mu$, while the maximum changes observed here approach 40-45 $m\mu$. This, together with color formation, strongly suggests chemisorption.

Figure 2 shows the composite spectra of the various equilibrated tetracycline-magnesium trisilicate systems. With the exception of small intensity differences and small changes in the bathochromic shifts, the spectra of the equilibrated samples are very similar.

The spectra in Fig. 3 show the tetracycline hydrochloride-ferric phosphate system, which is typical of the spectra of the tetracycline derivatives with this adjuvant. Visual evidence of an interaction was again manifested by color changes. The physical mixtures were faint yellow while the equilibrated samples were tan. An examination of the spectra of the equilibrated samples in the 700-400- $m\mu$ region, as compared to the physical mixtures, shows bathochromic shifts of the order of 130 $m\mu$ and large intensity changes. Both of these changes are strongly indicative of chemisorption.

Although no differences were observed between the control and equilibrated samples over much of the UV region because of complete absorption by ferric phosphate, it is not unreasonable to assume that spectral changes would also be observed in this region if these samples were diluted with a nonabsorbing material.

Figure 4 shows the spectra of demethylchlortetracycline hydrochloride-aluminum hydroxide. These spectra are again typical of the interaction of the tetracycline series with this adjuvant. The spectra of the equilibrated samples (B) are considerably different from those of the physical mixtures (A). While the physical mixtures showed only limited absorption from approximately 450-350 $m\mu$,

Table I—Formation Constants and DRS Bathochromic Shifts of Various Tetracycline–Metal Systems

Tetracycline Derivative	log K' (1:1 Complex)	log K'' (2:1 Complex)	log K_s (Overall)	DRS Bathochromic Shift, $m\mu$
Aluminum Ion				
Tetracycline	7.4	6.4	19.2	98.0
Chlortetracycline	7.2	ppt.	18.0	87.5
Oxytetracycline	7.0	ppt.	18.0	98.0
Ferric Ion				
Tetracycline	9.9	8.6	25.3	130
Chlortetracycline	9.4	7.2	22.2	125
Oxytetracycline	9.6	7.2	22.5	140
Magnesium Ion				
Tetracycline	—	—	—	57
Chlortetracycline	—	—	—	44
Oxytetracycline	3.8	—	—	45

the equilibrated samples exhibited significant absorption from 500–220 $m\mu$.

The drug concentration of 30 mg. per 2 g. of adjuvant was maintained here, since Lach and Bornstein (1) found that at this concentration the reflectance spectrum presumably represents the chemisorbed single layer. They found that when the drug–adjuvant ratio was increased, the bands in the reflectance spectrum broadened with a limit approaching the spectrum of the pure tetracyclines.

In addition to exhibiting absorption over a wider wavelength range than the physical mixtures, the equilibrated samples showed a bathochromic shift of approximately 80 $m\mu$ and a color change from white or faint yellow in the physical mixtures to an intense yellow. These spectral and visual changes are indicative of a chemical interaction of the drug molecules with the available active surface sites.

The large bathochromic shifts observed in these DRS studies of tetracycline–metallic adjuvant systems have also been reported to occur in solution spectra in the presence of metallic ions. Conover (10) has stated that there is a large bathochromic shift of the characteristic long wavelength UV absorption of solutions of tetracycline and its derivatives in an excess of many bivalent and trivalent metallic ions. He reports that these solution band displacements vary quantitatively with various metals, but qualitatively the effects are comparable. It should be pointed out that the observed bathochromic shifts and the nature of the DRS spectra also vary with various metallic adjuvants. However, the spectra of the various tetracycline derivatives for any given metal-containing adjuvant are comparable, which is reasonable and expected.

The bathochromic changes observed in the DRS spectra of these antibiotic–metallic adjuvant interactions were compared with reported formation constants (9) for the metal complexes of the tetracyclines (Table I). Since the present studies deal with surface interactions for which the stoichiometry of the interaction spectrum cannot be determined, a comparison was made between the bathochromic shifts observed in these interactions and log K_s values. K_s has been defined by Albert and Rees (9) as the product of all the partial constants. The bathochromic shifts were determined at a reflectance value between 700 and 380 $m\mu$ which exhibited the maximum change.

A comparison of the magnitude of the bathochromic shifts and the changes in the formation constants indicates some correlation,

Figure 5—DRS of bishydroxycoumarin (60 mg.) and magnesium trisilicate (2.0 g.). Key: A, control; B, equilibrated sample; and C, pure bishydroxycoumarin with no adjuvant present.

Figure 6—DRS of bishydroxycoumarin (60 mg.) and aluminum hydroxide (2.0 g.). Key: A, control; B, equilibrated sample; and C, pure bishydroxycoumarin with no adjuvant present.

because the ferric-containing adjuvant exhibits a larger bathochromic shift than the aluminum-containing adjuvant which, in turn, is larger than the magnesium-containing adjuvant. This is in agreement with the formation constants reported for these ions, since the value for the ferric ion is larger than the aluminum ion, which is larger than the magnesium ion. Although it is interesting that the observed DRS changes do parallel the reported formation constant values for these ions, it is difficult at this time to make a quantitative comparison.

Studies were also conducted to determine whether these drug–adjuvant interactions occurred when physical mixtures were exposed to humid conditions. Dried, physically mixed samples of the tetracyclines and magnesium trisilicate were placed on evaporating dishes in a moisture chamber, which consisted of a wax-sealed desiccator in which the desiccant had been replaced by water. The samples were allowed to stand in this moisture chamber for 4 hr., after which they were removed and dried *in vacuo* over anhydrous calcium sulfate. The spectra of these compounds were determined and found to resemble those shown in Fig. 1. The primary differences observed were that the bathochromic and intensity changes were not as pronounced, nor was the peak at 315 $m\mu$ as clearly defined. Possibly the spectral differences between water-equilibrated samples and samples exposed to humid conditions reflect an incomplete interaction such as an interaction of only the surface molecules. It is reasonable to assume that with the equilibration technique, a greater degree of interaction may occur with more pronounced spectral changes, because more surface area is exposed during the procedure.

Interaction of Methantheline Bromide and Bishydroxycoumarin with Various Metallic Adjuvants—The study of bishydroxycoumarin and methantheline bromide for possible drug–adjuvant interactions was prompted by reported therapeutic discrepancies of solid dosage forms of bishydroxycoumarin and certain quaternary compounds (14, 15).

The adjuvants chosen for this study were selected on the basis of the metal fraction which they contain and/or because of their usage in pharmaceutical formulations. Sixty milligrams of active principle was mixed with 2 g. of adjuvant, since studies with 30 mg. of active compound showed no absorbance in either the physical mixtures or the equilibrated samples.

Spectral data presented in Fig. 5 show the bishydroxycoumarin–magnesium trisilicate system. These spectra, as well as the interaction of bishydroxycoumarin with aluminum hydroxide (Fig. 6) and talc (Fig. 7), are representative of a chemisorption interaction. The spectrum of the equilibrated bishydroxycoumarin–tribasic calcium phosphate system, however, is unchanged from the spectrum of the physical mixture.

The equilibrated magnesium trisilicate (Fig. 5), aluminum hydroxide (Fig. 6), and talc (Fig. 7) systems all show a rather large bathochromic shift between 375 and 310 $m\mu$, as well as a hyper-

Figure 9—DRS of methantheline bromide (60 mg.) and tribasic calcium phosphate (2.0 g.). Key: A, control; B, equilibrated sample; and C, pure methantheline bromide with no adjuvant present.

chromic change throughout the UV region. In the magnesium trisilicate and talc systems, there is a smaller bathochromic change involving a band at 250 $m\mu$, which has shifted to 255 $m\mu$ in the equilibrated samples. Since this particular band shift in the bishydroxycoumarin systems occurs only with the magnesium-containing adjuvants, it may indicate chelation of bishydroxycoumarin with magnesium.

Studies involving methantheline bromide and talc (Fig. 8), tribasic calcium phosphate (Fig. 9), and aluminum hydroxide (Fig. 10) showed small bathochromic shifts but rather large intensity changes. However, the interaction with magnesium trisilicate (Fig. 11) appears to be indicative of chemisorption. As in the bishydroxycoumarin-adjuvant systems, no color changes were observed when the samples were equilibrated.

Although it is evident from the spectral data presented that these interactions will vary in intensity, the spectral differences have not been correlated with bioavailability. Desorption and bioavailability experiments of these drug-excipient interactions are currently underway to gain a better understanding of the significance of such interactions.

The chemical properties of the various adjuvants may also influence the spectral changes observed with the methantheline bromide and bishydroxycoumarin systems. The availability of the metal portion in various adjuvants may differ since some surfaces are thought to be more saturated than others. The valency requirements of surface atoms may be more fully satisfied by bonding with nearby atoms, thus making them less available for chemisorption. Nor can hydration effects be overlooked, because hydration may also satisfy the valency requirements of the metallic portion and thereby decrease the number of active sites available for interaction.

Figure 10—DRS of methantheline bromide (60 mg.) and aluminum hydroxide (2.0 g.). Key: A, control; B, equilibrated sample; and C, pure methantheline bromide with no adjuvant present.

Figure 11—DRS of methantheline bromide (60 mg.) and magnesium trisilicate (2.0 g.). Key: A, control; B, equilibrated sample; and C, pure methantheline bromide with no adjuvant present.

A possible explanation for the bishydroxycoumarin-adjuvant interactions may be one of chelation. Further studies are in progress with respect to this hypothesis, and subsequent publications will deal with the mechanism of these interactions.

The therapeutic differences observed in presumably equivalent dosage forms may be due, in part, to surface interactions of the type described in this study. These interactions may exert an effect on the dissolution rate, as preliminary studies currently underway have indicated, and subsequently reduce the gastrointestinal absorption rates.

While it is recognized that drug release from pharmaceutical dosage forms is a complex phenomenon, the fact that surface interactions occur with various inactive adjuvants makes it imperative that the effect of these interactions on drug release be studied. Perhaps a more scientific approach to formulation through a knowledge of drug-adjuvant interactions could prevent many of the discrepancies observed in the therapeutic efficacy of pharmaceutical dosage forms.

Dissolution Behavior and Solubility of Anhydrous and Dihydrate Forms of Wy-4508, an Aminoalicyclic Penicillin

JOHN W. POOLE* and C. KANTA BAHAL

Abstract □ Anhydrous and dihydrate forms of an aminoalicyclic penicillin (Wy-4508) were compared for solubility in distilled water at temperatures ranging from 7 to 60°. Differences were noted in the physical-chemical properties of these two forms. Below the transition temperature, 61°, the anhydrous form was found to be significantly more soluble than the dihydrate. In addition, the solubility of the anhydrous crystal was shown to be inversely related to temperature. The thermodynamic properties noted for the two forms of the antibiotic have been experimentally evaluated.

Keyphrases □ Penicillin, aminoalicyclic (Wy-4508)—anhydrous, dihydrate forms, solubility □ Temperature effect—aminoalicyclic penicillin solubility □ Dissolution—aminoalicyclic penicillin, anhydrous, dihydrate □ Thermodynamic properties—amhydrous, dihydrate aminoalicyclic penicillin

Many organic and inorganic compounds exist in separate crystalline forms having different physical-chemical properties. Higuchi (1) has pointed out that the resulting variation in thermodynamic properties associated with the differences in crystal forms may be of considerable pharmaceutical importance. The present report is concerned with an investigation of the differences in the physical-chemical properties of two forms of an aminoalicyclic penicillin, Wy-4508 [6-(1-amino-cyclohexanecarboxamido)penicillanic acid] (I).

Specifically, the solubilities in distilled water of the anhydrous and dihydrate forms of this penicillin were determined, and the thermodynamic properties of these two compounds were experimentally evaluated.

Much of the past work reported on the physical-chemical properties of crystalline hydrates has been concerned with inorganic compounds, as illustrated by the studies of Taylor and Henderson (2) on various hydrates of calcium nitrate and of Hill (3) on calcium sulfate. Recently, several investigations concerned with studies of organic molecules in the anhydrous and hydrated forms have been reported. Two of the hydrated forms of phenobarbital, as well as the anhydrous form, were examined by Eriksson (4) for apparent solubility in water as a function of time. Shefter and Higuchi (5) reported the relative dissolution rates of solvated and nonsolvated crystalline forms of several types of compounds of pharmaceutical interest, including steroids and xanthenes. These workers also determined the thermodynamic properties of several crystal systems. In a recent report by the present authors (6), the dissolution and solubility behavior of anhydrous and trihydrate

forms of the semisynthetic penicillin, ampicillin, was reported.
