The dissolution profiles for sodium pentobarbital in a vacuum-dried microcapsular state is shown in Fig. 4. As may be expected, the results of release studies for sodium pentobarbital from the untableted powders showed a tendency to be greater at higher pH values. It may be seen that in a 45-min. period about 13.7 mg. (90%) of the encapsulated sodium pentobarbital was released to the phosphate buffer and the H₂O media while only about 11.4 mg. (75%) was released to the medium containing HCl.

Although dissolution studies for the spray-dried material were carried out in the three media previously mentioned, only those results for HCl are shown (Fig. 5). The release patterns are very similar to those obtained for other media and show that the vacuum-dried microcapsular powder initially releases sodium pentobarbital more quickly than the spray-dried material.

It was thought that since the vacuum-dried material had to be scraped from the collection vessel and then spatulated in order to obtain a powder, that some of the capsules might have been disrupted and that this led to the greater release. The spray-dried material, on the other hand, was free flowing as it was collected. For these reasons, further work was done using only the spray-dried powder.

When the microcapsular material was tableted, without lubricants or other adjuvants, both the disintegration of the tablet and the ability of the liquid medium to wet the tablet seemed to play an

Figure 8—A comparison of the release relationship of tablets of approximately 2 hardness in two liquid media. Key: ○, in 0.1 *N* HCl; and △, in 0.1 *M* PO₄.

Figure 9—A comparison of the release relationship of microcapsular tablets of three different hardnesses in 0.1 M PO_4 liquid media. Key: ○, 8 hardness; △, 5 hardness; and □, 2 hardness.

important role in release of active ingredient. It was expected that disintegration and/or wetting would not appreciably be affected from liquid to liquid. However, as indicated in Figs. 6–8, there apparently is some disintegrating or wetting action since the release of sodium pentobarbital is slightly more rapid in acid solution; this is contrary to the trend found in Fig. 4.

Figures 6–8 demonstrate the release of sodium pentobarbital from the microcapsules. Although a first-order release is not justified except by the trend of the data, first-order rates are used for purposes of comparison. A comparison of these figures indicates that the differences in rate from one dissolution medium to the other became greater as the hardness of the tablet tested decreased. These differences in rate of release are shown more clearly in Fig. 9. Figure 9 is a comparison of the release rate of tablets of various hardness. It can be seen that the more rapid release rates were found in the softer tablets with the greater difference between tablets of hardness 5 and 2.

Table I is a compilation of slopes and significant data for the release of sodium pentobarbital from tablets of various hardnesses and the several liquid media. The mechanism of release (9, 10) probably involves leaching of the sodium pentobarbital through a network of nylon fibers constituting the microcapsule.

SUMMARY

The studies reported here demonstrate that interphasal polymerization can be used to prepare nylon-membrane microcapsules. It has also been shown that a free-flowing powder can be obtained by spray drying slurries of microcapsules.

When the free-flowing powder was tableted, it was observed that changes in release rate could be controlled by varying hardness. It was also observed that vacuum drying yielded capsule material of different appearance and release characteristics from spray-dried microcapsular material.

Although a statistical evaluation of particle size was carried out, there could be no significance attached to the range found. However, examination of the effect of size of particle on release rate is presently being investigated.

Pyrrolidine-Substituted Nicotine Analogs: Synthesis and Pharmacology

WARREN HANKINS* and ALFRED BURGER

Abstract □ (—)5',5'-Dimethylnicotine (I) was synthesized in one step from (—) cotinine; it had approximately 0.03 times the mouse toxicity of nicotine but did not cause the same qualitative toxic signs as nicotine; it stimulated and then depressed autonomic ganglia (anesthetized dog) and directly affected the respiratory center and the cardiovascular system. The total synthesis of 5,5-dimethyl-2-(3-pyridyl)-Δ¹-pyrroline (V) and its 1-oxide (VI) was performed. Compound V was hydrogenated to 2,2-dimethyl-5-(3-pyridyl)pyrrolidine (II), and this was converted to its 1-propyl homolog. Compound VI was reduced to 2,2-dimethyl-1-hydroxy-5-(3-pyridyl)pyrrolidine (VIII).

Keyphrases □ Nicotine analogs, pyrrolidine substituted—synthesis □ Pharmacology—pyrrolidine-substituted nicotine analogs □ NMR spectroscopy—structure □ Mass spectroscopy—identity □ Nitron—synthesis, reactions

Because of the blocking action of neighboring methyl groups upon the piperidine-nitrogen in pempidine (1), the authors undertook a study of derivatives with sterically crowding methyl groups in the pyrrolidine ring of nicotine.¹ Of compounds which have been studied pharmacologically, 5'-methylnornicotine (2), and nicotine analogs with alkyl groups in the pyridine ring, including 4- and 6-methylnicotine (3, 4), and 2-(or 6-) alkyl-1,2-(or 1,6-)dihydro-1-methylnicotine compounds (5) may be mentioned; the latter paralyzed the respiratory center but lowered the dog's blood pressure.

THEORETICAL

In this work, (—) cotinine was treated with excess MeMgI to give (—) 5-(3-pyridyl)-1,2,2-trimethylpyrrolidine [(—)5',5'-dimethylnicotine (I)].

The corresponding 1-*nor* compound [(±)5,5-dimethyl-2-(3-pyridyl)pyrrolidine] (II) was synthesized as follows. Methoxide-induced condensation of 3-dimethylamino-1-(3-pyridyl)-1-propanone (III) with 2-nitropropane, and hydrogenation of the resulting 4-methyl-4-nitro-1-(3-pyridyl)-1-pentanone (IV) gave 5,5-dimethyl-2-(3-pyridyl)-Δ¹-pyrroline (V) together with 5,5-dimethyl-2-(3-pyridyl)-Δ¹-pyrroline-1-oxide (VI) (6). The pyrroline V was then hydrogenated to II.

Confirmation of structures V and VI rested on chemical reactions and spectra (see *Experimental*). Propionylation of II followed by reduction of the resulting amide gave 2,2-dimethyl-1-*n*-propyl-5-(3-pyridyl)pyrrolidine (VII), the propyl homolog of I. Furthermore,

the nitron VI could be reduced to 2,2-dimethyl-1-hydroxy-5-(3-pyridyl)pyrrolidine (VIII).

The nicotine homolog I (as the dihydrochloride) was tested (Dr. Marvin J. Bleiberg of Woodard Research Corp.) and compared to nicotine (dihydrochloride and sulfate) under identical test conditions which are described in the *Experimental* section. The LD₅₀ ratios in the mouse for I (I·2HCl, LD₅₀ 11.0 mg./kg., 95% confidence limits) and nicotine were approximately 30.6, i.e., I was about 0.03 times as toxic as nicotine. The confidence intervals of the LD₅₀'s for each compound show that the dose-mortality curves are virtually parallel. However, toxic signs such as Straub tail, tremors, eyelid ptosis, and mydriasis, which were seen at lethal doses of nicotine, were not observed with I.

The MED₅₀ to obtain a pharmacodynamic effect in the mouse are (95% confidence limits) 0.018 mg./kg. for nicotine·2HCl, and 1.8 mg./kg. for I·2HCl, respectively; thus the potency ratio of nicotine/I is 100.0. There was evidence of ganglionic stimulation expressed by a greater rise in blood pressure caused by dimethylphenylpiperazinium iodide (DMPP) for I; in a dog receiving atropine before all but the initial dose of I, 0.200 mg. of I caused a marked rise in blood pressure equivalent to 0.016 mg. of nicotine sulfate. This is consistent with the potency ratio in the mouse. A ganglionic blocking action after large doses of I was suggested by the progressive depression of the blood pressure rise after AcCh following increasing doses of I. A direct effect on the respiratory center and on the cardiovascular system was indicated by the increased depth of respiration and the large blood pressure rise following injection of I.

The odor of I (free base) was very similar to, if not indistinguishable from, that of nicotine.

EXPERIMENTAL

Melting points were determined with a Thomas-Hoover apparatus and are uncorrected. IR spectra were obtained on a Perkin-Elmer 337 spectrophotometer, NMR spectra on a Perkin-Elmer R-20 instrument (60 M c.p.s.), mass spectra with a Hitachi-Perkin-Elmer RMU-6E instrument (see Table I). IR and NMR spectra were taken on all compounds and were consistent with the proposed structures; they are listed only if not essentially identical with those tabulated by Castagnoli *et al.* (7). NMR spectra (p.p.m.) were measured in CDCl₃ (TMS as standard) or in D₂O (DSS as standard), respectively. Microanalyses were performed by Galbraith Laboratories, Knoxville, Tennessee.

Pharmacological Methods—Mice of the HA/ICR strain, random breed (2 per dose level), received I at one-half log-dose intervals i.v. Observations included the standard pharmacologic profile in

¹After completion of both the synthetic and pharmacologic work (*vide infra*) the authors learned of an article by Castagnoli *et al.* (7) who had synthesized several of the compounds described in this paper [(±)I, II, V, VI, VIII] by a completely different route. For this reason, the authors' experimental report lists only those data that differ significantly from those of the California authors (7).

Table I—Mass Spectra (70 ev.) m/e

Compound	M^+	Fragmentation M minus ()
I	190	175 (CH_3)
II	176	161 (CH_3)
V	174	159 (CH_3)
		146 ($\text{CH}_2=\text{CH}_2$)
VI	190	175 (CH_3)
		173 (OH)
VII	218	203 (CH_3)
		189 (C_2H_5)
VIII	192	177 (CH_3)
		174 (H_2O)

dose range studies, number of mice reacting, time of onset of the pharmacologic signs, their degree and severity, and the time for recovery. LD_{50} and MED_{50} (both at 95% confidence limits) were estimated.

For tests in the dog, two mongrel dogs which were housed in temperature-controlled quarters, conditioned to the laboratory, and previously given canine distemper vaccine, were used. Food was withheld for 18–24 hr. prior to anesthesia (phenobarbital sodium, 140 mg./kg., i.v. or i.p.). The trachea was exposed and cannulated in order to maintain the respiratory airway. The right common carotid artery was exposed and cannulated to record blood pressure by means of an E and M pressure transducer, connected to an E and M physiograph. The anticoagulant was benzo fast pink (1.66 g./l. of 9% saline). Bilateral electrodes, placed on the skin next to the lower ribs, recorded the respiratory excursions by means of an impedance pneumograph; the EKG was recorded on a separate channel of the physiograph. Injections of the test material (and of nicotine dihydrochloride as a standard) were administered through a cannula inserted into a femoral vein; each injection was washed with Krebs-Ringer solution. In addition to graded increasing doses of I (dihydrochloride) and of the standard, Dog No. 1 also received dimethylphenylpiperazinium iodide, acetylcholine chloride, and atropine sulfate before a final dose of nicotine sulfate. Dog No. 2 also received epinephrine, ACh, and atropine.

Chemistry—(–)-1,2,2-Trimethyl-5-(3-pyridyl)pyrrolidine (I)—To a solution of MeMgI [from 106.5 g. (0.75 mole) of MeI and 18.2 g. (0.75 mole) of Mg in dry ether (300 ml.) under N_2] was added (–) cotinine (8) (26.4 g., 0.15 mole) in dry benzene (40 ml.). Ether was removed by distillation and replaced by benzene, and the solution was refluxed at 65–75° under N_2 for 24 hr. (9). The reaction mixture was poured into ice water, the basic mixture was steam distilled, and the distillate (3–4 l.) was acidified and evaporated under vacuum. The residual oil was made basic, extracted (ether), and dried well (Na_2SO_4). Evaporation of the ether yielded 5 g. (17%) of a brown liquid. The colorless dihydrochloride, prepared in ether, was recrystallized from ethanol–ether, m.p. 258–260°.

Anal.—Calcd. for $\text{C}_{12}\text{H}_{20}\text{Cl}_2\text{N}_2$: C, 54.8; H, 7.6; N, 10.6. Found: C, 55.0; H, 7.8; N, 10.4.

The yellow dipicrate was obtained in, and recrystallized from, ethanol, m.p. 210–212°: $[\alpha]_{\text{D}}^{25} = 76.9^\circ$ (c 0.13, ethanol).

Anal.—Calcd. for $\text{C}_{24}\text{H}_{24}\text{N}_8\text{O}_{14}$: C, 44.4; H, 3.7; N, 17.3. Found: C, 44.4; H, 3.8; N, 17.1.

4-Methyl-4-nitro-1-(3-pyridyl)-1-pentanone (IV)—A solution of sodium methoxide (3 g., 0.054 mole) in methanol (40 ml.) was added gradually to a stirred solution of 3-dimethylamino-1-(3-pyridyl)-1-propanone (III) (10.7 g., 0.05 mole) (10) and 2-nitropropane (31 g., 0.35 mole) in methanol (60 ml.) (11). After slight heating for 10 min. the stirred solution was heated to boiling, and dimethylamine was removed by distilling off about 10 ml. of methanol over a period of 20 min. Solvent and excess nitropropane were then removed under reduced pressure, the residue was taken up in water (100 ml.) containing a few drops of 10% NaOH solution, and IV crystallized on cooling. It was recrystallized from ethanol. The colorless crystals weighed 7.6 g. (68%), m.p. 73–75°.

Anal.—Calcd. for $\text{C}_{11}\text{H}_{14}\text{N}_2\text{O}_3$: C, 59.5; H, 6.3; N, 12.6. Found: C, 59.7; H, 6.4; N, 12.5.

Reduction of IV—A solution of IV (8.4 g., 38 mmoles) in absolute ethanol (40 ml.) and 2 g. of W-7 Raney nickel (12) was hydrogenated at an initial pressure of 3.6 kg./cm.² for 24 hr. Standard workup yielded 6.5 g. of crude reduction product which was chromatog-

raphed on magnesium silicate.² Elution with ether gave 5,5-dimethyl-2-(3-pyridyl)- Δ^1 -pyrrolidine (V) (4.6 g., 69%); elution with ether–methanol (9:1) gave 5,5-dimethyl-2-(3-pyridyl)- Δ^1 -pyrrolidine-1-oxide (VI) (0.9 g., 12%).

Compound V separated from ether as colorless crystals, m.p. 43–44°; it had previously been described as an oil (7).

Anal.—Calcd. for $\text{C}_{11}\text{H}_{14}\text{N}_2$: C, 75.8; H, 8.1; N, 16.1. Found: C, 75.8; H, 8.1; N, 16.2.

The nitron VI had m.p. 75–76° after recrystallization from ether or hexane, and vacuum drying.

Anal.—Calcd. for $\text{C}_{11}\text{H}_{14}\text{N}_2\text{O}$: C, 69.5; H, 7.4; N, 14.7. Found: C, 69.3; H, 7.4; N, 14.6.

IR (KBr) 3400 cm^{-1} [the band at 3660 cm^{-1} reported by Castagnoli *et al.* (7) was not observed].

1-Hydroxy-2,2-dimethyl-5-(3-pyridyl)pyrrolidine (VIII)—A suspension of LAH (200 mg.) in dry ether (50 ml.) was added gradually over a period of 15 min. to a warm stirred solution of VI (0.5 g., 2.6 mmoles) in dry ether (150 ml.) and the mixture was refluxed for 18 hr. After dropwise decomposition with water, the ether layer was dried (MgSO_4) and evaporated in vacuum. VIII (0.3 g., 62%) crystallized from ether, m.p. 127–128°. IR (KBr) 3170 cm^{-1} ; the band at 3580 cm^{-1} (7) was not observed.

Anal.—Calcd. for $\text{C}_{11}\text{H}_{16}\text{N}_2\text{O}$: C, 68.7; H, 8.4; N, 14.6. Found: C, 68.6; H, 8.5; N, 14.3.

2,2-Dimethyl-5-(3-pyridyl)pyrrolidine (II)—A solution of V (3 g.) in absolute ethanol (30 ml.) was hydrogenated at 3.82 kg./cm.² with 1.5 g. of 10% Pd-C for 7 hr. Standard workup gave a residual oil which was converted to its dihydrochloride in ether. The salt was recrystallized from ethanol–ether, m.p. 135–137°. Drying over P_2O_5 raised the m.p. to 210–212°.

Anal.—Calcd. for $\text{C}_{11}\text{H}_{16}\text{N}_2 \cdot 2\text{HCl} \cdot \text{H}_2\text{O}$: C, 49.4; H, 7.5; N, 10.5. Found: C, 49.6; H, 7.3; N, 10.4.

Reconversion of the dihydrochloride to the base with sodium carbonate solution and ether extraction gave a clear liquid. The yellow dipicrate, formed in and recrystallized from ethanol, had m.p. 185–186°.

Anal.—Calcd. for $\text{C}_{23}\text{H}_{22}\text{N}_8\text{O}_{14}$: C, 43.5; H, 3.5; N, 17.7. Found: C, 43.7; H, 3.3; N, 17.5.

2,2-Dimethyl-1-n-propyl-5-(3-pyridyl)pyrrolidine (VII)—A mixture of II (1.5 g.), propionic acid (2.5 ml.), and propionic anhydride (2.5 ml.) was refluxed for 1 hr. and then cooled and poured into ice water. The solution was made strongly basic with 50% KOH solution, extracted with ether, and the extract was dried (MgSO_4) and evaporated. The crude 2,2-dimethyl-1-propionyl-5-(3-pyridyl)pyrrolidine (1.4 g.), dissolved in dry ether (30 ml.), was added to LAH (0.5 g.) in dry ether (25 ml.) with stirring. After refluxing for 4 hr. the mixture was worked up [water (1.5 ml.), 10% NaOH (1.5 ml.), water (5 ml.), ether extraction, drying (MgSO_4), evaporation]. Yield of clear oil VII was 1.2 g. The dihydrochloride, prepared in dry ether, was recrystallized from ethanol–ether, m.p. 245–247°. NMR (D_2O) δ 0.78 (t, 3, CH_3 of propyl), 1.3 (m, 2, CH_2 of propyl), 1.52 (s, 3, CH_3), 1.66 (s, 3, CH_3), 2.6 (m, 4, protons at C-3 and C-4 of pyrrolidine), 3.2 (m, 2, $\text{N}-\text{CH}_2$), 5.07 (q, 1, proton at C-2), 8.1–9.15 (4, pyridinium salt pattern).

Anal.—Calcd. for $\text{C}_{14}\text{H}_{22}\text{N}_2 \cdot 2\text{HCl}$: C, 57.7; H, 8.3; N, 9.6. Found: C, 57.4; H, 8.1; N, 9.4.

The yellow dipicrate was obtained in and recrystallized from ethanol, m.p. 205–206°.

Anal.—Calcd. for $\text{C}_{26}\text{H}_{28}\text{N}_8\text{O}_{14}$: C, 46.2; H, 4.1; N, 16.6. Found: C, 46.3; H, 4.2; N, 16.4.

Synthesis of Sugar Moiety Substituted Nucleosides I: 9-[3-*O*-(*n*-Hexyl)- α,β -D-xylofuranosyl]adenine and 9-[3-*O*-(*n*-Hexyl)-5-deoxy- α,β -D-xylofuranosyl]adenine

DANIEL H. MURRAY and JOHN PROKOP

Abstract ☐ Isopropylidene-D-xylose was covered *via* the 5-trityl compound to a 3-*O*-(*n*-hexyl) derivative. Following detritylation, benzoylation, and acetolysis, condensation with chloromercuri-6-benzamidopurine in the presence of titanium tetrachloride gave a crude nucleoside mixture. After deacylation, the mixture of anomeric nucleosides was resolved on ion-exchange resin (Bio-Rad AGI) to give 9-[3-*O*-(*n*-hexyl)- α -D-xylofuranosyl]adenine and 9-[3-*O*-(*n*-hexyl)- β -D-xylofuranosyl]adenine. Similarly, isopropylidene-5-deoxy-D-xylose was converted to a 3-*O*-(*n*-hexyl) derivative. Acetolysis and condensation with chloromercuri-6-benzamidopurine followed by deacylation and resolution on ion-exchange resin led to isolation of 9-[3-*O*-(*n*-hexyl)-5-deoxy- α -D-xylofuranosyl]adenine and 9-[3-*O*-(*n*-hexyl)-5-deoxy- β -D-xylofuranosyl]adenine.

Keyphrases ☐ Nucleosides, sugar moiety substituted—synthesis, isolation, separation ☐ 3-*O*-(*n*-Hexyl)adenine derivatives—synthesis, isolation ☐ Column chromatography—separation ☐ IR—identification ☐ UV spectrophotometry—identification ☐ Polarimetry—identification

In a continuing series of investigations, the authors have been exploring the structural features of the sugar moiety of adenine nucleosides required for interaction with the enzyme adenosine deaminase and/or inhibition of whole cells (1, 2). Other groups as well have devoted considerable attention to this area of study, particularly the laboratories of LePage (3), Schaeffer (4), and Bloch (5), among others. Compositely, the results of many studies such as those cited suggest that the 3'-hydroxyl group is usually not an important participant in an interaction with enzymes by which an adenine nucleoside may function as an *inhibitor* rather than as a *substrate*.

Recently, Baker (6) has collated many examples of the application of a principle he enunciated earlier (7): that a group which is found not to be important in interaction with an enzyme may be an ideal candidate for further modification with even quite bulky groups,

including those which may react covalently with an enzyme to yield an active site directed, irreversible inhibitor. Both Baker (8) and Schaeffer (9) have now prepared a number of such irreversible inhibitors.

To date there seems not to have been any attempt to apply the implications of the Baker principle to "unimportant" groups on the sugar moiety of nucleosides. As noted, the 3'-hydroxyl would appear to be such a group. The present and following reports describe the syntheses of a number of 3'-*O*-substituted nucleosides whose availability will allow a beginning to be made in assessing the practicality of designing an active site directed, irreversible inhibitor of a sugar moiety substituted type.

Initially, the *n*-hexyl substituent was selected since not only could it serve as the carrier of an alkylating function, but of itself might enhance binding of the nucleoside through interaction with potentially accessible hydrophobic regions on susceptible enzymes. That such a hydrophobic region exists on adenosine deaminase has been demonstrated by Schaeffer and Vogel with a series of 9-alkyl substituted adenines (10). Xylofuranosyladenine (3c) and 5'-deoxyxylofuranosyladenine (11), both of which show affinity toward adenosine deaminase, were selected as candidates for 3'-*O*-substitution. The present paper, therefore, reports the syntheses of the 3'-*O*-(*n*-hexyl) derivatives of these two nucleosides.

PROCEDURES

Etherification of 1,2-*O*-isopropylidene-5-*O*-triphenylmethyl-D-xylofuranose (12) (I, Scheme I) with 1-chlorohexane in the presence of potassium hydroxide gave the 3-*O*-(*n*-hexyl) derivative (II) as a noncrystallizing syrup in quantitative yield. Attempts to remove the trityl group by hydrogenolysis over palladium black or palladium-on-charcoal were unsuccessful. This group, however, was readily removed in good yield when II was refluxed in an aqueous ethanolic solution of acetic acid. The resulting distillable syrup (III) was contaminated with 8% of triphenylcarbinol which could be removed by

Synthesis of Sugar Moiety Substituted Nucleosides I: 9-[3-*O*-(*n*-Hexyl)- α,β -D-xylofuranosyl]adenine and 9-[3-*O*-(*n*-Hexyl)-5-deoxy- α,β -D-xylofuranosyl]adenine

DANIEL H. MURRAY and JOHN PROKOP

Abstract □ Isopropylidene-D-xylose was covered *via* the 5-trityl compound to a 3-*O*-(*n*-hexyl) derivative. Following detritylation, benzoylation, and acetolysis, condensation with chloromercuri-6-benzamidopurine in the presence of titanium tetrachloride gave a crude nucleoside mixture. After deacylation, the mixture of anomeric nucleosides was resolved on ion-exchange resin (Bio-Rad AGI) to give 9-[3-*O*-(*n*-hexyl)- α -D-xylofuranosyl]adenine and 9-[3-*O*-(*n*-hexyl)- β -D-xylofuranosyl]adenine. Similarly, isopropylidene-5-deoxy-D-xylose was converted to a 3-*O*-(*n*-hexyl) derivative. Acetolysis and condensation with chloromercuri-6-benzamidopurine followed by deacylation and resolution on ion-exchange resin led to isolation of 9-[3-*O*-(*n*-hexyl)-5-deoxy- α -D-xylofuranosyl]adenine and 9-[3-*O*-(*n*-hexyl)-5-deoxy- β -D-xylofuranosyl]adenine.

Keyphrases □ Nucleosides, sugar moiety substituted—synthesis, isolation, separation □ 3-*O*-(*n*-Hexyl)adenine derivatives—synthesis, isolation □ Column chromatography—separation □ IR—identification □ UV spectrophotometry—identification □ Polarimetry—identification

In a continuing series of investigations, the authors have been exploring the structural features of the sugar moiety of adenine nucleosides required for interaction with the enzyme adenosine deaminase and/or inhibition of whole cells (1, 2). Other groups as well have devoted considerable attention to this area of study, particularly the laboratories of LePage (3), Schaeffer (4), and Bloch (5), among others. Compositely, the results of many studies such as those cited suggest that the 3'-hydroxyl group is usually not an important participant in an interaction with enzymes by which an adenine nucleoside may function as an *inhibitor* rather than as a *substrate*.

Recently, Baker (6) has collated many examples of the application of a principle he enunciated earlier (7): that a group which is found not to be important in interaction with an enzyme may be an ideal candidate for further modification with even quite bulky groups,

including those which may react covalently with an enzyme to yield an active site directed, irreversible inhibitor. Both Baker (8) and Schaeffer (9) have now prepared a number of such irreversible inhibitors.

To date there seems not to have been any attempt to apply the implications of the Baker principle to "unimportant" groups on the sugar moiety of nucleosides. As noted, the 3'-hydroxyl would appear to be such a group. The present and following reports describe the syntheses of a number of 3'-*O*-substituted nucleosides whose availability will allow a beginning to be made in assessing the practicality of designing an active site directed, irreversible inhibitor of a sugar moiety substituted type.

Initially, the *n*-hexyl substituent was selected since not only could it serve as the carrier of an alkylating function, but of itself might enhance binding of the nucleoside through interaction with potentially accessible hydrophobic regions on susceptible enzymes. That such a hydrophobic region exists on adenosine deaminase has been demonstrated by Schaeffer and Vogel with a series of 9-alkyl substituted adenines (10). Xylofuranosyladenine (3c) and 5'-deoxyxylofuranosyladenine (11), both of which show affinity toward adenosine deaminase, were selected as candidates for 3'-*O*-substitution. The present paper, therefore, reports the syntheses of the 3'-*O*-(*n*-hexyl) derivatives of these two nucleosides.

PROCEDURES

Etherification of 1,2-*O*-isopropylidene-5-*O*-triphenylmethyl-D-xylofuranose (12) (I, Scheme I) with 1-chlorohexane in the presence of potassium hydroxide gave the 3-*O*-(*n*-hexyl) derivative (II) as a noncrystallizing syrup in quantitative yield. Attempts to remove the trityl group by hydrogenolysis over palladium black or palladium-on-charcoal were unsuccessful. This group, however, was readily removed in good yield when II was refluxed in an aqueous ethanolic solution of acetic acid. The resulting distillable syrup (III) was contaminated with 8% of triphenylcarbinol which could be removed by

Scheme I

chromatography on silica gel. Benzoylation of III in the usual manner gave a quantitative yield of IV as a syrup. Acetolysis of IV gave the 1,2-diacetate (V) again as a syrup in quantitative yield. Condensation of V with chloromercuri-6-benzamidopurine (VI) in the presence of titanium tetrachloride resulted in a crude anomeric mixture of blocked nucleosides (VII) obtained as a glass. Without further purification, VII was deacetylated with methanolic sodium methoxide, and the crude reaction products were chromatographed on ion-exchange resin¹ using 60% aqueous methanol. Rechromatographing the partially separated nucleosides gave the pure α and β anomers (VIII and IX, respectively) as crystalline solids in yields of 5.0% and 63%, respectively (from V).

In a similar manner, 5-deoxy-1,2-*O*-isopropylidene-D-xylofuranose (II) (X, Scheme II) was hexylated to give XI in 83% yield as a distillable liquid. Acetolysis of XI gave the 1,2-diacetate (XII) as a liquid which was coupled with VI in the presence of titanium tetrachloride. The resulting crude blocked nucleosides (XIII), obtained as a syrup, were deacetylated and chromatographed as before. The pure crystalline α and β nucleosides (XIV and XV, respectively) were isolated, after rechromatographing the partially overlapping peaks, in yields of 5.8% and 36%, respectively (from XII).

R = *n*-hexyl
Bz = benzoyl
Ac = acetyl

Scheme II

The anomeric assignments of these nucleosides were made by application of Hudson's rules of isorotation as shown in Table I. So far as is known, no exceptions to these rules have been found for 9-glycofuranosyladenines. In addition, condensation reactions with 2-acyloxy intermediates (such as V and XII), even under titanium tetrachloride conditions, are known to obey the *trans* rule of Baker for nucleosides (1, 13); that is, the preponderant anomer will have a C1', C2' *trans* configuration of substituents. The yields shown in Table I confirm these assignments.

¹ Bio-Rad AGI \times 8 (OH) is a more purified form of Dowex 1 supplied by Bioradlabs, New York, N. Y.

Table I—Specific Rotations and Yields of Nucleosides

Nucleoside	$[\alpha]_D^{25}$ (MeOH)	% Yield	Anomeric Assignment
VIII	$-0.6 \pm 0.2^\circ$	5.0	α
IX	-49.8°	63	β
XIV	$+0.5 \pm 0.2^\circ$	5.8	α
XV	-61.7°	36	β

The biological activity of the nucleosides reported in this paper is currently under investigation. The results will be the subject of a future report.

EXPERIMENTAL²

3-*O*-(*n*-Hexyl)-1,2-*O*-isopropylidene-5-*O*-triphenylmethyl-*D*-xylofuranose (II)—A mixture of 4.32 g. of 1,2-*O*-isopropylidene-5-*O*-triphenylmethyl-*D*-xylofuranose (I) (12), m.p. 116–118°, 7.0 ml. of 1-chlorohexane, 3.0 g. of powdered potassium hydroxide,³ and 5 ml. of benzene were stirred and heated under reflux overnight while protected from moisture. The cooled mixture was partitioned between 70 ml. of ether and 30 ml. of water. The organic phase was separated and washed further with water (2 × 30 ml.), then dried (MgSO₄), filtered, and evaporated at 0.05 mm. pressure and 55° for 3 hr. to give a stiff, yellow syrup which failed to crystallize; yield, 5.17 g. (100%). IR analysis showed a substantial increase in aliphatic C—H absorption at 3000–2860 cm.⁻¹ (addition of hexyl) and complete loss of hydroxyl absorption at 3450 cm.⁻¹; $[\alpha]_D^{25} -25.4^\circ$ (c 3.25, MeOH), $[\alpha]_D^{25} -41.7^\circ$.

Anal.—Calcd. for C₃₃H₄₀O₅: C, 76.71; H, 7.80. Found: C, 76.33; H, 7.39.

3-*O*-(*n*-Hexyl)-1,2-*O*-isopropylidene-*D*-xylofuranose (III)—A mixture of 25.8 g. of II, 400 ml. of ethanol, 280 ml. of water, and 120 ml. of glacial acetic acid was heated under reflux for 2 hr. (complete solution occurred in 30 min.). After evaporation of the solvents, the residue was dissolved in 300 ml. of chloroform and washed with 100 ml. of 1 *N* sodium hydroxide solution and two 100-ml. portions of water. The chloroform solution was evaporated to dryness and the residue diluted with 75 ml. of methanol and stored overnight at 5°. Triphenylcarbinol, 9.99 g. (77% of theory), was removed by filtration. The filtrate was evaporated to dryness and the residue distilled, giving the crude product (contaminated with triphenylcarbinol as shown by TLC) as a colorless, viscous liquid in a yield of 12.6 g. (92%), b.p. 135–145°/0.04 mm. A 3.0-g. sample of this material was chromatographed on 70 g. of silica gel using benzene and gave 0.25 g. (8%) of triphenylcarbinol. Further elution with absolute ethanol gave the desired product (2.68 g.), which was distilled to give 2.53 g. (78% overall) of III as a colorless liquid, b.p. 128–134°/0.03 mm.; $\bar{\nu}_{\text{max}}^{\text{film}}$ (cm.⁻¹) 3500 (OH), strong bands in the 3000–2850 region (aliphatic C—H of hexyl) and 1375 (doublet, isopropylidene); $[\alpha]_D^{25} -33.2^\circ$ (c 3.31, MeOH), $[\alpha]_D^{25} -39.6^\circ$.

Anal.—Calcd. for C₁₄H₂₆O₅: C, 61.29; H, 9.55. Found: C, 61.23; H, 9.70.

5-*O*-Benzoyl-3-*O*-(*n*-hexyl)-1,2-*O*-isopropylidene-*D*-xylofuranose (IV)—To a stirred solution of 1.74 g. (6.4 mmoles) of pure III in 10 ml. of pyridine was added dropwise 1.0 ml. (8.7 mmoles) of benzoyl chloride below room temperature. The mixture was stored overnight at 5° in a stoppered flask and then quenched by the addition of 10 drops of water. After 30 min., the reaction was diluted with 50 ml. of chloroform and washed with 50 ml. of water, 50 ml. of aqueous-saturated sodium bicarbonate, and 50 ml. of water; it was then dried (MgSO₄), filtered, and evaporated to dryness. Traces of pyridine were removed from the residue by codistillation *in vacuo* with two 10-ml. portions of toluene. The resulting light-amber syrup was held for several hours at <1 mm. pressure; yield, 2.39 g. (100%); $\bar{\nu}_{\text{max}}^{\text{film}}$ (cm.⁻¹) loss of 3500 absorption (OH), 1725

(benzoate C=O), 1375 doublet (isopropylidene), 1280 (benzoate C—O—C), 710 (phenyl).

Anal.—Calcd. for C₂₁H₃₀O₆: C, 66.64; H, 7.99. Found: C, 66.51; H, 7.80.

1,2-*Di-O*-acetyl-5-*O*-benzoyl-3-*O*-(*n*-hexyl)-*D*-xylofuranose (V)—To a stirred solution of 5.46 g. of IV in 58 ml. of glacial acetic acid and 6.4 ml. of acetic anhydride was added dropwise, at 15–20°, 2.8 ml. of concentrated sulfuric acid. The reaction was allowed to stand overnight in a stoppered flask and was then poured, with stirring, into 200 ml. of cold 10% aqueous sodium acetate. After 1 hr., the mixture was extracted with four 50-ml. portions of chloroform. These extracts were combined and washed with 200 ml. of water, 200 ml. of aqueous-saturated sodium bicarbonate, and 200 ml. of water; they were then dried (MgSO₄), filtered, and evaporated to dryness at 0.05 mm. pressure and 50° to give an almost colorless syrup; yield, 6.00 g. (99%); $\bar{\nu}_{\text{max}}^{\text{film}}$ (cm.⁻¹) 1750 (acetate C=O), 1725 (benzoate C=O), 1375 singlet (C-methyl), 1280 (benzoate C—O—C), 1220 (acetate C—O—C), 710 (phenyl).

Anal.—Calcd. for C₂₂H₃₀O₈: C, 62.54; H, 7.16. Found: C, 63.34; H, 7.19.

9-[3-*O*-(*n*-Hexyl)- α - and β -*D*-xylofuranosyl]adenine (VIII and IX, respectively)—A mixture of 2.28 g. (5.4 mmoles) of V, 2.56 g. (5.4 mmoles) of chloromercuri-6-benzamidopurine (I) (VI), 2.6 g. of diatomaceous earth,⁵ and 100 ml. of ethylene dichloride was distilled until 25 ml. of distillate had been collected. After cooling to room temperature, a solution of 0.60 ml. (5.4 mmoles) of titanium tetrachloride in 6 ml. of ethylene dichloride was added dropwise and the mixture was heated under reflux overnight while protected from moisture. To the cooled reaction was added 10 ml. of aqueous-saturated sodium bicarbonate with vigorous stirring, followed by additional solid sodium bicarbonate in small portions until a neutral reaction was obtained. After filtration through a diatomaceous earth pad, the filtrate was evaporated to dryness. A solution of the residue in 50 ml. of chloroform was washed with 50 ml. of 30% aqueous potassium iodide and 50 ml. of water, then dried (MgSO₄), filtered, and evaporated to dryness at 0.05 mm. pressure and 50° to give the crude, blocked nucleosides (VII) as an amber glass; yield, 2.90 g. (89); $\bar{\nu}_{\text{max}}^{\text{film}}$ (cm.⁻¹) 1750 (acetate C=O), 1725 (benzoate C=O), 1700 shoulder (amide C=O), 1610, 1580 (C=C and C=N), 1280 (benzoate C—O—C), 1225 (acetate C—O—C), 710 (phenyl).

A solution of 2.57 g. of VII in 50 ml. of 0.1 *N* methanolic sodium methoxide was heated under reflux for 3 hr. The cooled reaction was neutralized with acetic acid and evaporated to dryness. Methyl benzoate was removed by codistillation *in vacuo* with three 10-ml. portions of water. The residue was dissolved in 75 ml. of 50% aqueous ethanol and chromatographed on a column (38 mm. × 50 cm.) of ion-exchange resin using 60% aqueous methanol.⁶ The partially separated peaks⁷ corresponding to the anomeric nucleosides were each rechromatographed under the same conditions to give the pure isomers. The α -anomer (VIII) eluted first, and evaporation of the solvents gave 84 mg. (5.6%) of a crystalline solid, m.p. 174–177°. Recrystallization from 50% aqueous methanol gave the pure compound, m.p. 180–181°; $[\alpha]_D^{25} -0.6^\circ \pm 0.2^\circ$ (c 1.07, MeOH), $[\alpha]_D^{25} +0.5^\circ \pm 0.2^\circ$; $[\alpha]_D^{25} +34.1^\circ$; $\lambda_{\text{max}}^{\text{9.5\% EtOH}}$ 260 (ε 15,000).

Anal.—Calcd. for C₁₆H₂₅N₅O₄: C, 54.68; H, 7.17; N, 19.93. Found: C, 54.65; H, 7.13; N, 19.87.

The β -anomer (IX) eluted next and amounted to 1.06 g. (71%) after removal of the solvents, m.p. 159–160°. Two recrystallizations from aqueous methanol gave the analytical sample, m.p. 160–160.5°; $[\alpha]_D^{25} -49.8^\circ$ (c 1.21, MeOH), $[\alpha]_D^{25} -60.1^\circ$; $\lambda_{\text{max}}^{\text{9.5\% EtOH}}$ 260 (ε 15,100).

Anal.—Calcd. for C₁₆H₂₅N₅O₄: C, 54.68; H, 7.17; N, 19.93. Found: C, 54.87; H, 6.94; N, 19.48

5-Deoxy-3-*O*-(*n*-hexyl)-1,2-*O*-isopropylidene-*D*-xylofuranose (XI)—A stirred mixture of 10.4 g. of 5-deoxy-1,2-*O*-isopropylidene-*D*-xylofuranose (II) (X), m.p. 68–70°, 42 ml. of 1-chlorohexane, 30 ml. of benzene, and 18 g. of powdered potassium hydroxide were heated under reflux overnight while protected from moisture. The cooled mixture was partitioned between 300 ml. of ether and 100 ml.

² All evaporations were conducted *in vacuo* in a Buchler-type evaporator at 40–45° unless specified otherwise. Melting points were determined on a Mel-Temp apparatus and are uncorrected. The IR, UV, and polarimetric determinations were made using Perkin-Elmer models 337, 202, and 141, respectively.

³ Obtained from the Riverside Chemical Co., Inc., North Tonawanda, N. Y.

⁴ Galbraith Laboratories, Knoxville, Tenn., performed the elemental analyses.

⁵ Celite, Johns Manville, New York, N. Y.

⁶ Practical grade methanol was entirely satisfactory.

⁷ Since these chromatograms generally required 2–3 days of continuous operation, the eluate was conveniently monitored by the use of an ISCO model UA equipped with a recorder operating at 1.27 cm. (0.5 in.)/hr.

of water. The ether layer was further washed with water (2×100 ml.), dried (MgSO_4), filtered, and evaporated to dryness. The resulting liquid was vacuum distilled, giving 12.9 g. (83%) of XI as a colorless distillate, b.p. $75-80^\circ/0.02$ mm.; $\bar{\nu}_{\text{max}}^{\text{film}}$ (cm^{-1}) loss of 3500 band (OH), several strong bands at 3000–2850 (aliphatic C—H of hexyl), 1375 doublet (isopropylidene); $[\alpha]_{\text{D}}^{25} -28.3^\circ$ (c 1.22, MeOH), $[\alpha]_{\text{D}}^{25} -33.1^\circ$.

Anal.—Calcd. for $\text{C}_{14}\text{H}_{26}\text{O}_4$: C, 65.08; H, 10.14. Found: C, 64.81; H, 10.18.

1,2-Di-O-acetyl-5-deoxy-3-O-(n-hexyl)-D-xylofuranose (XII)—To a stirred solution of 11.5 g. of XI in 180 ml. of glacial acetic acid and 21.3 ml. of acetic anhydride was added dropwise, at $15-20^\circ$, 8.5 ml. of concentrated sulfuric acid. The reaction was stored overnight at room temperature in a stoppered flask, then poured into 650 ml. of cold 10% aqueous sodium acetate with stirring. After 40 min., the mixture was extracted with four 125-ml. portions of chloroform. The combined extracts were washed with 300 ml. of water, 300 ml. of aqueous-saturated sodium bicarbonate, and 300 ml. of water; dried (MgSO_4); filtered; and evaporated to dryness at 0.1 mm. pressure and 50° to give XII as a pale-yellow liquid; yield, 13.7 g. (101%); $\bar{\nu}_{\text{max}}^{\text{film}}$ (cm^{-1}) 1750 (acetate C=O), 1375 singlet (C-methyl), 1220 (acetate C—O—C).

Anal.—Calcd. for $\text{C}_{15}\text{H}_{26}\text{O}_6$: C, 59.58; H, 8.67. Found: C, 60.11; H, 8.87.

9-[5-Deoxy-3-O-(n-hexyl)- α - and β -D-xylofuranosyl]adenine (XIV and XV, respectively)—A mixture of 4.82 g. (16 mmoles) of XII, 7.57 g. (16 mmoles) of chloromercuri-6-benzamidopurine, 8 g. of diatomaceous earth, and 290 ml. of ethylene dichloride was distilled until 55 ml. of distillate had been collected. The mixture was cooled to room temperature and a solution of 1.8 ml. (16 mmoles) of titanium tetrachloride in 9 ml. of ethylene dichloride was added dropwise. The reaction was heated under reflux 20 hr. while protected from moisture. After cooling, 20 ml. of aqueous-saturated sodium bicarbonate was added with vigorous stirring, followed by additional solid sodium bicarbonate in small portions until a neutral reaction was obtained on pH paper. The mixture was filtered through a diatomaceous earth pad, the cake washed with two 50-ml. portions of ethylene dichloride, and the combined filtrate and washings were evaporated to dryness. A solution of the residue in 100 ml. of chloroform was washed with 100 ml. of 30% aqueous potassium iodide, 100 ml. of aqueous-saturated sodium bicarbonate, and 100 ml. of water; it was then dried (MgSO_4), filtered, and evaporated to dryness at 0.1 mm. pressure and 55° to give the crude, blocked nucleosides (XIII) as a pale-brown syrup; yield, 6.82 g. (89%); $\bar{\nu}_{\text{max}}^{\text{film}}$ (cm^{-1}) 1750 (acetate C=O), 1700 (amide C=O), 1225 (acetate C—O—C), 710 (phenyl).

A solution of 6.81 g. of XIII in 100 ml. of 0.1 *N* methanolic sodium methoxide was heated under reflux for 2.5 hr. while protected from moisture. The cooled reaction was neutralized with acetic acid and the solvent evaporated. Methyl benzoate was removed by co-distillation of the residue with three 20-ml. portions of water *in vacuo*. A solution of the residue in 70 ml. of 80% aqueous methanol was divided into two equal portions, each of which was chromatographed on a column (58 mm. \times 50 cm.) of ion-exchange resin (200–400 mesh) using 60% aqueous methanol. The resulting chromatogram showed a minor UV absorbing peak followed by a major peak with some overlapping of the two materials. These overlap

regions were combined from the two runs and rechromatographed to give the cleanly separated isomers. The first peak to elute, the α -anomer (XIV), gave white needles after evaporation; yield, 0.31 g. (6.5%). Recrystallization from 30 ml. of 50% aqueous methanol gave fine white needles, m.p. $139-140^\circ$; $[\alpha]_{\text{D}}^{25} +0.5^\circ \pm 0.2^\circ$ (c 1.11, MeOH), $[\alpha]_{\text{D}}^{25} +1.2^\circ \pm 0.2^\circ$, $[\alpha]_{\text{D}}^{25} +39.1^\circ$; $\lambda_{\text{max}}^{\text{95\% EtOH}}$ 260 (ϵ 15,400).

Anal.—Calcd. for $\text{C}_{16}\text{H}_{25}\text{N}_5\text{O}_8$: C, 57.29; H, 7.51; N, 20.88. Found: C, 57.01; H, 7.53; N, 20.58.

The major peak, the β -anomer (XV), gave 1.91 g. (40%) of white crystals on evaporation, m.p. $149-151^\circ$. Recrystallization from 45 ml. of 65% aqueous methanol gave white needles, m.p. $150-151^\circ$; $[\alpha]_{\text{D}}^{25} -61.7^\circ$ (c 1.29, MeOH), $[\alpha]_{\text{D}}^{25} -75.2^\circ$; $\lambda_{\text{max}}^{\text{95\% EtOH}}$ 260 (ϵ 15,600).

Anal.—Calcd. for $\text{C}_{16}\text{H}_{25}\text{N}_5\text{O}_8$: C, 57.29; H, 7.51; N, 20.88. Found: C, 57.46; H, 7.67; N, 20.93.

Potential Antineoplastics II: 1-Thiocarbamoyl-3-methyl-4-arylhydrazono-2-pyrazolin-5-ones, 2-Amino-4-phenyl-5-arylazothiazoles, and *N*-Phenyl-*N'*-2(4-phenyl-5-arylazothiazolyl)thiocarbamides

H. G. GARG and R. A. SHARMA

Abstract □ A series of 1-thiocarbamoyl-3-methyl-4-arylhydrazono-2-pyrazolin-5-ones, 2-amino-4-phenyl-5-arylazothiazoles, and *N*-phenyl-*N'*-2(4-phenyl-5-arylazothiazolyl)thiocarbamides have been prepared for evaluation as antineoplastic agents. The 1-thiocarbamoyl-3-methyl-4-arylhydrazono-2-pyrazolin-5-ones and 2-amino-4-phenyl-5-arylazothiazoles were synthesized by coupling of appropriate aryldiazonium salts with 1-thiocarbamoyl-3-methyl-2-pyrazolin-5-one and 2-amino-4-phenylthiazole, respectively. The *N*-phenyl-*N'*-2(4-phenyl-5-arylazothiazolyl)thiocarbamides were obtained by condensing phenylisothiocyanate with 2-amino-4-phenyl-5-arylazothiazoles. The hydrazone-keto structures to 1-thiocarbamoyl-3-methyl-4-arylazo-2-pyrazolin-5-ones have been based on the IR spectral data. The intermediates required in these syntheses are also described.

Keyphrases □ 1-Thiocarbamoyl-3-methyl-4-arylhydrazono-2-pyrazolin-5-ones—synthesis □ 2-Amino-4-phenyl-5-arylazothiazoles—synthesis □ *N*-Phenyl-*N'*-2(4-phenyl-5-arylazothiazolyl)thiocarbamides—synthesis □ IR spectrophotometry—structure

There has been a growing interest, during the last few years, in compounds containing the $N^*-N^*-S^*$ or $O^*-N^*-S^*$ tridentate ligand system (1–5) or arylazo grouping (6, 7). This interest stems mainly from certain interesting carcinostatic activities of heterocyclic carboxaldehyde thiosemicarbazones and the interfering action of 5-arylazopyrimidines with nucleic acid synthesis. Moreover, various Schiff bases from benzaldehyde nitrogen mustards and thiazoleamines have been reported to possess antitumor activity (8–10). As a part of a general study¹ directed toward the development of antineoplastics (11), the above-mentioned rationale led to examination of the synthesis and properties of three series of compounds having these mixed structural features—*viz.*, 1-thiocarbamoyl-3-methyl-4-arylhydrazono-2-pyrazolin-5-ones and 2-amino-4-phenyl-5-arylazothiazoles having $N^*-N^*-S^*$ ligand and arylazo grouping and *N*-phenyl-*N'*-2(4-phenyl-5-arylazothiazolyl)thiocarbamides having $N^*-N^*-S^*$ ligand and arylazo grouping and a modified azomethine linkage. It was hoped that these series might afford compounds that would be relatively less toxic to normal cells and have a better chemotherapeutic index.²

THEORETICAL

The most satisfactory route to 1-thiocarbamoyl-3-methyl-4-arylhydrazono-2-pyrazolin-5-ones (II) has been found to be the

prior synthesis of 1-thiocarbamoyl-3-methyl-2-pyrazolin-5-one (I) and its subsequent coupling with diazonium salts. The required intermediate (I) is obtained in excellent yield by the cyclization of ethyl 3-oxobutylate- β -thiosemicarbazone in liquid ammonia at room temperature. This in turn is prepared from ethyl acetoacetate and thiosemicarbazide (12) (see Scheme I). The products are all highly colored crystalline derivatives which are summarized in Table I.

The precursor for 2-amino-4-phenyl-5-arylazothiazoles, 2-amino-4-phenylthiazole (III), has been obtained by the condensation of acetophenone and thiourea in presence of iodine (13). The arylazo group at C-5 has been introduced by the condensation of the corresponding diazonium salts with III. The different 2-amino-4-phenyl-5-arylazothiazoles so obtained are crystalline substances and are summarized in Table II.

Boiling equimolar quantities of phenylisothiocyanate, prepared according to the procedure of Dains *et al.* (14), and 2-amino-4-phenyl-5-arylazothiazoles in benzene on a steam bath gives the *N*-phenyl-*N'*-2(4-phenyl-5-arylazothiazolyl)thiocarbamides in yields exceeding 60% (Table III).

It is interesting to note that the 1-thiocarbamoyl group is thermolabile in 1-thiocarbamoyl-3-methyl-4-arylhydrazono-2-pyrazolin-5-ones, and the cleavage of the thiocarbamoyl residue results in the products being the *N*-1-unsubstituted-3-methyl-4-arylhydrazono-2-pyrazolin-5-ones (15).

The structures assigned to 1-thiocarbamoyl-3-methyl-4-arylazo-2-pyrazolin-5-ones need some comments as they can theoretically exist as one or more of the four possible structures (see structures of II).

Possible Structures of Compound II

The IR spectra of all the compounds show bands characteristic of cyclic $C=O$ frequency (16) (1660 cm^{-1} region) and $C=N$ — NH — $N=N$ —vibration (17) (1550 cm^{-1} region) (Table IV). This evidence unequivocally excludes Structures IIa, IIb, and IIc from consideration and supports hydrazone-keto Structure IId for all 1-thiocarbamoyl-3-methyl-4-arylhydrazono-2-pyrazolin-5-ones.

¹ A preliminary report of a portion of this work appeared in abstracts, Joint Convention of the Chemical Research Committee (C.S.I.R.) Institution of Chemists (India), and Society of Biological Chemists (India), Hyderabad-7 (India), 1969, p. 22.

² These compounds have been submitted for testing to Dr. H. B. Wood, Jr., National Institutes of Health, Bethesda, Md., the results of which will be reported elsewhere.

Scheme I

EXPERIMENTAL³

1-Thiocarbamoyl-3-methyl-2-pyrazolin-5-one—Thiosemicarbazide hydrochloride (12.7 g., 0.1 mole) was dissolved in water (30 ml.) and mixed with acetoacetic ester (13 ml., 0.1 mole). Ethyl 3-oxobutyrates- β -thiosemicarbazone separated after 15 min. and recrystallized from ethanol as colorless needles, yield 19.09 g., 90%; m.p. 92–93° (from ethanol) [lit. (12) m.p. 93°].

The latter (50 g.) was suspended in liquid ammonia (25 ml.) and thoroughly stirred until it gradually dissolved. The mixture was then made acidic with concentrated HCl. 1-Thiocarbamoyl-3-methyl-2-pyrazolin-5-one precipitated and was recrystallized as colorless needles, yield 2.9 g., 76%; m.p. 181–182° (from DMF-ethanol) [lit. (12) m.p. 180°].

1-Thiocarbamoyl-3-methyl-4-(2-methoxyphenylhydrazono)-2-pyrazolin-5-one—*o*-Anisidine (2.5 ml., 0.02 mole) was dissolved in 3 N HCl (2.5 ml.) and cooled to 0°. Sodium nitrite (1.4 g., 0.02 mole) dissolved in water (20 ml.) was gradually added. The diazonium salt solution was filtered into a well-cooled, stirred mixture of sodium acetate (5 g.) and 1-thiocarbamoyl-3-methyl-2-pyrazolin-5-one (3.14 g., 0.02 mole) in acetic acid (50 ml.). 1-Thiocarbamoyl-3-

methyl-4-(2-methoxyphenylhydrazono)-2-pyrazolin-5-one started precipitating almost immediately. After standing for 2 hr., the precipitate was filtered, washed with water, and recrystallized as orange needles, yield 4.3 g., 82%; m.p. 210–211° (DMF-ethanol).

Anal.—Calcd. for C₁₃H₁₃N₅O₂S: C, 49.4; H, 4.4; N, 24.0; S, 11.0. Found: C, 49.0; H, 4.6; N, 23.6; S, 10.7.

By adopting a similar procedure as above, several 1-thiocarbamoyl-3-methyl-4-arylhydrazono-2-pyrazolin-5-ones, described in Table I, were obtained.

2-Amino-4-phenylthiazole—A mixture of acetophenone (24.0 ml., 0.2 mole), thiourea (30.4 g., 0.4 mole), and iodine (50.8 g., 0.2 mole) was heated overnight on a steam bath. This was cooled and extracted with ether (2 \times 25 ml.) to remove unreacted acetophenone and iodine. The residue was then dissolved in hot water and filtered to remove sulfur and other impurities. The solution was cooled somewhat (about 20°) and made alkaline with concentrated ammonia. The 2-amino-4-phenylthiazole thus precipitated was recrystallized as long colorless needles, yield 38.7 g., 65%; m.p. 145° (from H₂O-ethanol) [lit. (13) m.p. 147°].

2-Amino-4-phenyl-5-phenylazothiazole—Aniline (1.85 g., 0.02 mole) was dissolved in 3 N HCl (2.5 ml.) and cooled to 0°. Sodium nitrite (1.4 g., 0.02 mole) dissolved in water (25 ml.) was added. The diazonium solution was filtered to a well-cooled suspension of 2-amino-4-phenylthiazole (3.52 g., 0.02 mole) and sodium acetate (5 g.) in ethanol (50 ml.). After 2 hr., 2-amino-4-phenyl-5-phenylazothiazole was filtered and washed well with water. It was recrystallized as red needles, yield 4.5 g., 80%; m.p. 191–192° (from DMF-ethanol) [lit. (18) m.p. 195°].

Anal.—Calcd. for C₁₅H₁₂N₄S: C, 64.2; H, 4.2; N, 20.0; S, 11.4. Found: C, 63.7; H, 4.4; N, 19.6; S, 11.2.

Similarly prepared 2-amino-4-phenyl-5-arylazothiazoles are summarized in Table II.

N-Phenyl-N'-2(4-phenyl-5-phenylazothiazolyl)thiocarbamide—A mixture of phenylisothiocyanate (1.35 g., 0.01 mole) and 2-amino-4-phenyl-5-phenylazothiazole (2.80 g., 0.01 mole) in benzene (15 ml.) was refluxed for 6–8 hr. on a steam bath. The solvent was removed and the residue was repeatedly triturated with petroleum ether (b.p. 40–60°) and then with ether. The crystalline thiocarbamide thus obtained was recrystallized from DMF-ethanol as deep red needles, yield 3.1 g., 75%; m.p. 241–242°.

Anal.—Calcd. for C₂₂H₁₇N₅S₂: C, 63.6; H, 4.1; N, 16.8; S, 15.4. Found: C, 63.2; H, 4.5; N, 16.6; S, 15.1.

Similarly a number of *N*-phenyl-*N'*-2(4-phenyl-5-arylazothiazolyl)-thiocarbamides were prepared which are summarized in Table III.

Release of Medroxyprogesterone Acetate from a Silicone Polymer

T. J. ROSEMAN* and W. I. HIGUCHI†

Abstract □ The *in vitro* release of medroxyprogesterone acetate from a silicone rubber matrix was studied. A nonlinear dependence of release rate upon medroxyprogesterone acetate concentration within the matrix was found. Based upon a model system, equations were derived to explain this behavior and to include other parameters which may influence the release rate. Since the model, in part, is dependent upon a receding medroxyprogesterone acetate layer within the matrix, a photograph depicting depletion zones as a function of time is presented. In contrast to the T. Higuchi model for drug release, this model includes the boundary diffusion layer. Comparison of the two models suggested that when the boundary layer was considered, a better fit of experimental data to theory was found. The applicability of the model to an *in vivo* system is discussed. This study has suggested that the partition coefficient, diffusion coefficients, medroxyprogesterone acetate concentration within the polymer, and agitation conditions play important roles in the release process.

Keyphrases □ Medroxyprogesterone acetate release rate, *in vitro*—physicochemical factors □ Silicone rubber matrix—medroxyprogesterone acetate release □ Matrix boundary diffusion layer model—equations derived □ Partition coefficient—silicone, medroxyprogesterone acetate □ Vapor phase chromatography—determination

The use of a rubber material as a delivery system for various chemicals has been a subject of considerable interest. The B. F. Goodrich Co. (1) has recently incorporated toxic substances into a rubber matrix and observed effective antifouling activity for prolonged periods. Some therapeutic implications of silicone rubber as a drug delivery system have been described previously (2).

The advantage of silicone rubber as a dosage form for medroxyprogesterone acetate has been discussed by Mishell *et al.* (3). It was shown that medroxyproges-

terone acetate was readily absorbed from a vaginal device in sufficient quantity to inhibit ovulation. This drug delivery system promises to be a unique approach in the field of contraception.

Although other investigators (4, 5) have studied the diffusion of drugs across silicone membranes, an *in vitro* study on the release of a drug embedded in a silicone matrix has not been presented. Therefore, the present study was designed to investigate the physicochemical factors involved in the release of medroxyprogesterone acetate from a silicone matrix system. The interdependence of various parameters can be described by mathematical relationships based upon a physical model which is an extension of concepts set forth by Higuchi (6).

EXPERIMENTAL

Medroxyprogesterone acetate¹-silicone² cylinders, 4 cm. by 0.5 cm., were prepared by levigating the required amount of drug into the elastomer and polymerizing with catalyst. The mixture was then forced into prewashed vinyl tubing and allowed to cure. After the cylinders were removed from the tubing and weighed, 24 were mounted between two circular disks and secured in a 3-l. jacketed beaker. Figure 1 is a schematic diagram of the *in vitro* dissolution apparatus. Distilled water from eight 5-gal. carboys was pumped at a rate of about 60 l./day through a 37° water bath, which preheated the water, into the beaker. The effluent was discarded into a drain. This constant flow of water approximates a "perfect sink" condition, *i.e.*, there is no significant concentration build-up in the dissolution media. The same water bath provided 37° water which was continuously circulated through the walls of the beaker,

Release of Medroxyprogesterone Acetate from a Silicone Polymer

T. J. ROSEMAN* and W. I. HIGUCHI†

Abstract □ The *in vitro* release of medroxyprogesterone acetate from a silicone rubber matrix was studied. A nonlinear dependence of release rate upon medroxyprogesterone acetate concentration within the matrix was found. Based upon a model system, equations were derived to explain this behavior and to include other parameters which may influence the release rate. Since the model, in part, is dependent upon a receding medroxyprogesterone acetate layer within the matrix, a photograph depicting depletion zones as a function of time is presented. In contrast to the T. Higuchi model for drug release, this model includes the boundary diffusion layer. Comparison of the two models suggested that when the boundary layer was considered, a better fit of experimental data to theory was found. The applicability of the model to an *in vivo* system is discussed. This study has suggested that the partition coefficient, diffusion coefficients, medroxyprogesterone acetate concentration within the polymer, and agitation conditions play important roles in the release process.

Keyphrases □ Medroxyprogesterone acetate release rate, *in vitro*—physicochemical factors □ Silicone rubber matrix—medroxyprogesterone acetate release □ Matrix boundary diffusion layer model—equations derived □ Partition coefficient—silicone, medroxyprogesterone acetate □ Vapor phase chromatography—determination

The use of a rubber material as a delivery system for various chemicals has been a subject of considerable interest. The B. F. Goodrich Co. (1) has recently incorporated toxic substances into a rubber matrix and observed effective antifouling activity for prolonged periods. Some therapeutic implications of silicone rubber as a drug delivery system have been described previously (2).

The advantage of silicone rubber as a dosage form for medroxyprogesterone acetate has been discussed by Mishell *et al.* (3). It was shown that medroxyproges-

terone acetate was readily absorbed from a vaginal device in sufficient quantity to inhibit ovulation. This drug delivery system promises to be a unique approach in the field of contraception.

Although other investigators (4, 5) have studied the diffusion of drugs across silicone membranes, an *in vitro* study on the release of a drug embedded in a silicone matrix has not been presented. Therefore, the present study was designed to investigate the physicochemical factors involved in the release of medroxyprogesterone acetate from a silicone matrix system. The interdependence of various parameters can be described by mathematical relationships based upon a physical model which is an extension of concepts set forth by Higuchi (6).

EXPERIMENTAL

Medroxyprogesterone acetate¹-silicone² cylinders, 4 cm. by 0.5 cm., were prepared by levigating the required amount of drug into the elastomer and polymerizing with catalyst. The mixture was then forced into prewashed vinyl tubing and allowed to cure. After the cylinders were removed from the tubing and weighed, 24 were mounted between two circular disks and secured in a 3-l. jacketed beaker. Figure 1 is a schematic diagram of the *in vitro* dissolution apparatus. Distilled water from eight 5-gal. carboys was pumped at a rate of about 60 l./day through a 37° water bath, which preheated the water, into the beaker. The effluent was discarded into a drain. This constant flow of water approximates a "perfect sink" condition, *i.e.*, there is no significant concentration build-up in the dissolution media. The same water bath provided 37° water which was continuously circulated through the walls of the beaker,

Figure 1—Dissolution apparatus for silicone cylinders.

thereby maintaining a constant temperature during dissolution. The solution was agitated by an impeller which was driven by a Servodyne drive system.³ The impeller was situated in the center of the beaker and extended to the bottom of the cylinders. Its location was fixed for all experiments.

In order to quantitate the initial release rates, the effluent was collected, extracted, and assayed for its medroxyprogesterone acetate content by a modified USP procedure (7). The long time release data (1 week or greater) was obtained by withdrawing the cylinders and determining the residual medroxyprogesterone acetate content by vapor phase chromatography. The difference between the initial and final values gave the amount lost at any given time.

The zones of depletion were measured microscopically with a calibrated reticule. Cross-sectional slices of the cylinder were used for the measurement.

The partition coefficient of medroxyprogesterone acetate was determined by equilibrating flat sheets (about $7 \times 2 \times 0.05$ cm.) of the silicone material in a solution of tritium-labeled medroxyprogesterone acetate at 37° . Sheets were removed at 1-day and 4-day intervals to ensure that equilibrium had resulted. They were then extracted with methylene chloride and the solvent evaporated to dryness. After the addition of 15 ml. of Diotol counting solvent, the samples were counted in a liquid scintillation spectrometer.⁴ The partition coefficient was calculated by dividing the counts per volume in the equilibrated solution by counts per volume in the silicone sheet.

THEORETICAL CONSIDERATIONS

The mechanisms of drug release from various matrix systems have previously been discussed (6). It was assumed that the rate-limiting step was the diffusion of drug from the matrix (matrix controlled). Under certain conditions, it is conceivable that the rate of diffusion from the surface of the matrix to the surrounding bulk solution will make a significant contribution to the total diffusional process. Therefore, the mathematics for this system (matrix-boundary diffusion layer model) is presented for two geometric cases. The assumptions in the derivations are: (a) A pseudo-steady state exists; (b) $A \gg C_s$, the concentration of drug in the matrix is much greater than its solubility in the matrix; (c) the diffusion coefficients are constant; (d) diffusion is the rate-controlling step, rather than dissolution; (e) the diffusional process occurs through the matrix phase rather than through pores or channels within the matrix.

Planar Case—Figure 2 is a hypothetical diagram of the matrix-boundary diffusion layer model. The rate of diffusion across a plane of unit area is given by Fick's law,

$$G = -D \frac{dC}{dx} \quad (\text{Eq. 1})$$

where G is the rate of diffusion across the plane, dC/dx is the concentration gradient, and D is the diffusion coefficient. The amount depleted from the matrix per unit time per unit area becomes

$$\frac{dQ}{dt} = -G = \frac{D_e}{l} (C_s - C_s') \quad (\text{Eq. 2})$$

where C_s and D_e are the solubility and effective diffusion coefficient, respectively, in the matrix phase, C_s' is the concentration in the matrix at $x = 0$, and l is the diffusional distance (zone of depletion). The effective diffusion coefficient is given by

$$D_e = \frac{D_s \epsilon}{\tau} \quad (\text{Eq. 3})$$

where ϵ is the volume fraction of the matrix, τ is the tortuosity of the matrix, and D_s is the diffusion coefficient in the matrix phase. It follows that the rate of diffusion across the diffusion boundary layer (h_a) is given by

$$\frac{dQ}{dt} = \frac{D_a}{h_a} [C_a' - C_B(t)] \quad (\text{Eq. 4})$$

where D_a is the diffusion coefficient in the aqueous phase, C_a' the concentration in water at $x = 0$, and C_B the concentration at $x = h_a$. Equating Eqs. 2 and 4, under steady-state conditions, utilizing the relationship

$$K = \frac{C_a}{C_s} = \frac{C_a'}{C_s'} \quad (\text{Eq. 5})$$

where C_a is the solubility in the aqueous phase, and K is the partition coefficient, and solving for C_s' , the rate becomes

$$\frac{dQ}{dt} = \frac{D_e}{l} \left[C_s - \frac{C_s D_e h_a + D_a C_B(t)}{K D_a l + D_e h_a} \right] \quad (\text{Eq. 6})$$

For the condition $A \gg C_s$, where A is the concentration of drug in

Figure 2—Hypothetical diagram for the matrix-boundary diffusion layer model.

³ Cole Parmer, Chicago, Ill.

⁴ Packard Tri-Carb, Packard Instrument Co.

Figure 3—Schematic diagram of a cross-sectional view of a cylinder where $l = a_0 - a'$.

the matrix, the rate of release per unit area is

$$\frac{dQ}{dt} = A \frac{dl}{dt} \quad (\text{Eq. 7})$$

Equating Eqs. 5 and 6 and simplifying give

$$\left(Kl + \frac{D_e}{D_a} h_a \right) \int_0^l A dl = D_e C_s K \int_0^t dt + D_e \int_0^t C_B(t) dt \quad (\text{Eq. 8})$$

Integrating and setting $C_B = 0$ ("perfect sink" condition) the above reduces to

$$l^2 + \frac{2D_e h_a l}{KD_a} = \frac{2D_e C_s t}{A} \quad (\text{Eq. 9})$$

Since

$$Q = Al \quad (\text{Eq. 10})$$

Eqs. 9 and 10 define the Q versus t plots. When $l^2 \gg 2D_e h_a l / KD_a$, Eq. 9 reduces to the matrix-controlled process,

$$l^2 = \frac{2D_e C_s t}{A} \quad (\text{Eq. 11})$$

It follows that

$$Q = (2AD_e C_s t)^{1/2} \quad (\text{Eq. 12})$$

Equations 11 and 12 have been derived previously (6).

Cylindrical Case—The equations describing the release of a drug from a cylindrical matrix can be derived using the basic relationships that exist in the planar system. The amount (Q') depleted per unit time is

$$\frac{dQ'}{dt} = -2\pi h D_a a \frac{dC}{da} \quad (\text{Eq. 13})$$

where h is the height of the cylinder and a is the radius of the area under consideration. All other symbols have been defined previously. Since, according to Fig. 3, $C = C_s$ at $a = a'$ and $C = C_s'$ at $a = a_0$, integration of Eq. 13 yields

$$\frac{dQ'}{dt} = \frac{-2\pi h D_a (C_s' - C_s)}{\ln \frac{a'}{a_0}} \quad (\text{Eq. 14})$$

Figure 4—Total amount of medroxyprogesterone acetate released from silicone cylinders as a function of time for three concentrations. Key: $\circ = 3.0\%$; $\Delta = 12.0\%$; $\square = 24.0\%$.

Assuming $C_B = 0$, the rate of diffusion from the surface is given by

$$\frac{dQ'}{dt} = \frac{2\pi h a_0 D_a}{h_a} C_a' \quad (\text{Eq. 15})$$

After equating Eqs. 14 and 15, substituting Eq. 5, solving for C_a' , and rearranging, the rate becomes

$$\frac{dQ'}{dt} = \frac{2\pi h a_0 K D_a}{h_a} \left(\frac{D_e C_s h_a}{-K D_a a_0 \ln \frac{a'}{a_0} + D_e h_a} \right) \quad (\text{Eq. 16})$$

For $A \gg C_s$,

$$\frac{dQ'}{dt} = -2\pi h A a' \frac{da'}{dt} \quad (\text{Eq. 17})$$

Equating Eqs. 16 and 17:

$$\int_{a_0}^{a'} \left(K D_a a_0 \ln \frac{a'}{a_0} - D_e h_a \right) a' da' = \frac{K D_e C_s D_a a_0}{A} \int_0^t dt \quad (\text{Eq. 18})$$

Integration and substitution yield

$$\frac{a'^2}{2} \ln \frac{a'}{a_0} + \frac{1}{4} (a_0^2 - a'^2) + \frac{D_e h_a}{2 K D_a a_0} (a_0^2 - a'^2) = \frac{C_s D_e t}{A} \quad (\text{Eq. 19})$$

For the matrix-controlled system, this reduces to

$$\frac{a'^2}{2} \ln \frac{a'}{a_0} + \frac{1}{4} (a_0^2 - a'^2) = \frac{C_s D_e t}{A} \quad (\text{Eq. 20})$$

Figure 5—Rate as a function of time for three medroxyprogesterone acetate concentrations in silicone cylinders. Key: $\circ = 3.0\%$; $\Delta = 12.0\%$; $\square = 24.0\%$.

Figure 6—Three-week release rate from silicone cylinders versus medroxyprogesterone acetate concentration.

Since

$$Q' = \pi h A (a_0^2 - a'^2) \quad (\text{Eq. 21})$$

Eqs. 19 or 20 and 21 define the Q' versus t plots.

RESULTS AND DISCUSSION

Figures 4 and 5 show the amount of medroxyprogesterone acetate released (Q') and the rate of release respectively as a function of time for the silicone cylinders at three medroxyprogesterone acetate concentrations. It is interesting to note that the initial rates (Fig. 5) are relatively constant while at later times there is a nonlinear dependence of rate upon concentration. Figure 6 shows this dependence at 3 weeks. As the medroxyprogesterone acetate diffuses from the matrix, rather well-defined zones of depletion develop. An example of the zones at various times is illustrated in Fig. 7 for a transparent silicone material. Initially, the transparent material is rendered opaque by the presence of medroxyprogesterone acetate. As the medroxyprogesterone acetate diffuses from the matrix, clear zones result. The longer release times show the larger zones. The unique advantage of this system is that the zones can be measured directly. These then can be compared to theoretical values. The value of Q' can be evaluated from Eq. 21 as long as $A \gg C_s$.

Although Eq. 20 was not reported by Higuchi (6), its derivation follows from the other geometric cases which were presented for the release from a homogeneous matrix. Equation 19 represents an extension of Eq. 20 which includes the aqueous boundary diffusion layer. To compare the theories, the following values were assigned:

- C_a — The solubility of medroxyprogesterone acetate in water at 37° is 3.25×10^{-3} mg./ml.
- D_a — The diffusion coefficient in water was determined from the Sutherland-Einstein equation (8). The calculated value was 6.54×10^{-6} cm.²/sec.

Figure 7—Cross-sectional views of silicone (transparent) cylinders. Key: A = placebo; B = drug-filled initial; C = 1 week; D = 2 weeks; E = 3 weeks; F = 4 weeks.

Figure 8—Thickness of depletion zone as a function of time for medroxyprogesterone acetate-silicone cylinders. Curves drawn are based upon theoretical calculations for the matrix-controlled model. The symbols represent experimental data. Key: \circ = 3.0%; Δ = 12.0%; \square = 24.0%.

h_a — The thickness of the diffusion layer, calculated from the expression $h_a = D_a C_a / G_i$ where G_i is the initial rate, was 66.8×10^{-4} cm.

K — The value of K was determined to be 0.033 ± 0.003 .

The values of ϵ , volume fraction of the polymer, and τ , tortuosity, have not been given since these are incorporated into an effective diffusion coefficient. Due to the presence of vacuoles, drug, and filler, the value of ϵ will be less than one. The tortuosity factor accounts for indirect pathways that may result from presence of filler within the matrix.

Since $l = a_0 - a'$, Eqs. 19 and 20 were compared considering l as the variable. The continuous lines in Fig. 8 show l as a function of time as calculated from Eq. 20, for the matrix-controlled case, at three different medroxyprogesterone acetate concentrations. The value of D_s was chosen to be 2.0×10^{-7} cm.²/sec. to fit the data for $A = 30$ mg./cm.³ The symbols represent the experimental points. A similar plot is given in Fig. 9, the l values being calculated from Eq. 19, for the matrix-boundary diffusion layer model. In this case D_s was chosen to be 2.6×10^{-7} cm.²/sec. to fit the data for $A = 30$ mg./cm.³ Comparison of Figs. 8 and 9 indicates that the matrix-boundary diffusion layer model gives a better fit of theory with data. If Eq. 19 represents the correct model, then an increase in h_a should increase the time to reach a given l distance. Since h_a is dependent on hydrodynamic flow, a decrease in stirring rate should result in a higher h_a value. The effect of stirring for $A = 30$ mg./cm.³ is illustrated in Fig. 10. The corresponding h_a value, calculated from initial rate data for the 70 r.p.m. experiment, is 146×10^{-4} cm. Inserting this value back into Eq. 19 and recalculating l as a function of time resulted in good agreement of theory with experimentally measured l values. Further support of the matrix-boundary diffusion

Figure 9—Thickness of depletion zone as a function of time for medroxyprogesterone acetate-silicone cylinders. Curves drawn are based upon theoretical calculations for the matrix-boundary diffusion model. The symbols represent experimental data. Key: \circ = 3.0%; Δ = 12.0%; \square = 24.0%.

Figure 10—Thickness of depletion zone as a function of time for 3.0% medroxyprogesterone acetate-silicone cylinders. Key: Δ = 700 r.p.m.; \circ = 70 r.p.m.

layer model stems from an examination of initial rate data. For a purely matrix-controlled system, initial steady-state rates would be dependent upon $(A)^{1/2}$.⁵ Figure 5 shows that this is clearly not the case. The initial rates are relatively constant.

Although it appears that Eq. 19 is operating, it would be of interest to determine the limits of its applicability. Setting $\alpha = D_e C_s h_a / D_a C_a$ for the planar case Eq. 9 (recalling that $K = C_s / C_a$), it can be shown that when $\alpha \ll l$, variation in stirring rates would not affect the release rates, since the release of the drug would be matrix controlled. For drugs with high values for α , i.e., $\alpha \cong l$, the effects of agitation would be significant, and therefore the matrix-boundary diffusion layer model would apply. It can be seen that the values of C_s , D_e , C_a , and D_a determine which model is operating. An analogous situation exists in the area of the kinetics of dyeing (9). It would be expected that compounds of similar molecular size and weight would exhibit relatively constant D_e / D_a values. Since the C_s / C_a (K) ratios are more sensitive to molecular structure, they can vary quite markedly (10). This would suggest that the partition coefficient can substantially influence the drug release mechanism. It follows then that compounds which have relatively small K values would follow the matrix-boundary diffusion layer model, while those with large values would be solely matrix controlled. Future studies will be designed to explore the relationship of K to the release mechanism.

Analyses of *in vivo* data from medroxyprogesterone acetate-silicone vaginal devices suggest that the amount released per time per unit area is considerably less than the *in vitro* system. If it is assumed that the contributing factor⁶ to these results is a larger aqueous diffusion layer, then the *in vivo* data can be compared to theory by utilizing Eq. 19. Based upon the data, h_a can be estimated at 580×10^{-4} cm. This value can now be inserted back into Eq. 19 and utilizing Eq. 21, a theoretical plot of Q' versus t can be obtained, Fig. 11. All other parameters have been previously defined. The plot is made for four concentrations: 10 mg./cm.³, 20 mg./cm.³, 40 mg./cm.³, and 80 mg./cm.³. The symbols in Fig. 11 represent the *in vivo* data, determined by residual analyses of the device for its drug content. Considering the assumptions which were made, the agreement of theory with data is acceptable. It is interesting to note that the curves are initially similar while at 21 days the lower concentration gives a substantially lower dose of drug. It is apparent that the effect of concentration is relatively minor until the zones of depletion are sufficiently large.

CONCLUSIONS

A model system was presented for the release of a water-insoluble steroid, medroxyprogesterone acetate, embedded in a solid silicone

Figure 11—Release profiles for medroxyprogesterone acetate-silicone devices. Curves are theoretical while symbols are *in vivo* data. Key: \circ = 10 mg./cm.³-A; Δ = 20 mg./cm.³-B; \square = 40 mg./cm.³-C; \diamond = 80 mg./cm.³-D.

rubber. The experimental findings were not totally consistent with concepts already set forth for matrix systems. Therefore, a model was developed which considered the boundary diffusion layer. In this instance, equations were consistent with the experimental results. The amount of drug present within the matrix (A), the diffusion coefficients in the solid and aqueous phases, and the partition coefficient (K), were included. The dependence of the amount released (Q') upon A was in agreement with the values calculated from theory. It was suggested that the partition coefficient strongly influenced the release mechanism.

The applicability of the model to an *in vivo* system was also evaluated. Based on the assumption that the slower release observed *in vivo* was due to a larger boundary diffusion layer, plots were made for the theoretical *in vivo* release at four drug levels within the matrix. Except for the thickness of the diffusion layer, all parameters were the same as the *in vitro* system. The amount of medroxyprogesterone acetate lost after 3 weeks from vaginal devices was qualitatively in agreement with the theoretical values.

⁵ This can be derived from Eq. 12. It can also be shown that up to 50% release the plane surface is a good approximation for the cylindrical surface.

⁶ Other factors such as the formation of an interfacial layer or lack of "perfect sink" conditions could also be important.

Pharmacokinetic Profile of Trimethoprim in Dog and Man

S. A. KAPLAN, R. E. WEINFELD, S. COTLER, C. W. ABRUZZO, and K. ALEXANDER

Abstract □ A pharmacokinetic profile of trimethoprim was determined in man and in the dog. The dog was shown to absorb the drug completely, and distribute the drug into the tissues to a great extent. The low recovery of intact trimethoprim in the urine is indicative of biotransformation and/or alternate routes of excretion. The drug is eliminated in man with a half-life of 15–17 hr. In addition, steady-state blood levels were maintained on daily oral dosing over a 13-week period. The dog was shown to eliminate trimethoprim 4 to 5 times faster than man.

Keyphrases □ Trimethoprim—pharmacokinetic profile □ Pharmacokinetics, trimethoprim—man, dog □ Absorption, distribution—trimethoprim □ Fluorometry—analysis

Trimethoprim is an inhibitor of dihydrofolate reductase which potentiates the activity of sulfonamides against a wide variety of bacterial species (1,2).

Chemically, trimethoprim is 2,4-diamino-5-(3',4',5'-trimethoxybenzyl)pyrimidine with the following structural formula (Structure I):

Structure I

It is a weak difunctional base with both basic groups titrating almost simultaneously with a pKa of 7.2 (3).

This study was designed to elucidate the physiological disposition of trimethoprim in the dog following i.v. and oral administration and in man following single and chronic oral administration.

EXPERIMENTAL

In Vivo Dog Study—A 5.7-mg./kg. dose of trimethoprim was administered intravenously and orally 2 weeks apart to two different male dogs. Five-milliliter oxalated blood specimens were collected at the time intervals indicated in Table I. The total volumes of urine voided were collected at 24-hr. intervals from 0 to 48 hr. following i.v. administration and from 0 to 72 hr. following oral administration. All specimens were frozen for subsequent analyses.

Human Study—Clinical studies were conducted in two human female subjects.¹ Each subject was given a single oral 200-mg. dose of trimethoprim on Day 1. Repeated oral doses of 50 mg. q.i.d. at 7:00 a.m., 12 noon, 5:00 p.m., and 10:00 p.m. commenced on Day 8 and continued through the 7:00 a.m. dose of Day 22 of the study for Subject R. R. Subject M. H. began the repeated oral dosing of 50 mg. q.i.d. on Day 5 and continued only through the first dose of Day 8.

The dosing, blood, and urine sampling schedules are presented in Table II. Five-milliliter oxalated blood specimens were obtained, the total volume of urine voided was measured, and 50-ml. aliquots were frozen for subsequent analyses.

^a Nil is less than 0.1 mcg./ml.

In a separate study, a group of 13 healthy adult male volunteers² each received a dose of 50 mg. trimethoprim q.i.d. for 13 weeks. Blood specimens were obtained before and once weekly during drug administration, always at the same time of day with regard to drug administration, just prior to the first dose in the morning, and were frozen for subsequent analysis.

Analytical Methods—Trimethoprim was determined in the blood and urine by a specific spectrofluorometric procedure (4) with a sensitivity of 0.1 mcg./ml.

One-milliliter blood or urine (1 to 10 dilution) specimens were placed in 50-ml. glass-stoppered centrifuge tubes. The specimens were diluted with 7 ml. distilled water and 1 ml. of 1 N aqueous sodium carbonate solution. Ten milliliters of chloroform (reagent grade) was added, the tubes stoppered, and extracted gently for 10 min. on a reciprocating shaker. The stoppers were removed and the specimens were then centrifuged at 2000 r.p.m. for 10 min. The aqueous phase was aspirated and the chloroform washed with 5 ml. distilled water. The water was aspirated and an 8-ml. aliquot of the chloroform phase was transferred into a 15-ml. glass-stoppered centrifuge tube. Four milliliters of 0.01 N sulfuric acid was then added and the sample extracted by shaking and the phases separated by centrifuging for 10 min. each. A 3-ml. aliquot of the acid phase was placed in a fresh 15-ml. glass-stoppered centrifuge tube to which 1 ml. of a 0.1 M potassium permanganate solution in 0.1 N sodium hydroxide was added. The solution was mixed, and the test tube was stoppered and heated in a 60° water bath for 20 min. The tubes were cooled to room temperature and 0.1 ml. of a 37% formaldehyde solution (reagent grade) was added. The solution was mixed

and allowed to stand for 5 min. The solution was acidified by the addition of 1 ml. of 1 N sulfuric acid and extracted with 3 ml. of chloroform by shaking, and the phases were separated by centrifuging for 10 min. each. The aqueous phase was aspirated and the chloroform phase transferred to a small test tube.

The fluorescence of the chloroform extract was measured in a 1-cm. path. cell at 345 m μ in a Farrand spectrofluorometer (MK-1) with activation at 295 m μ . Duplicate control specimens of blood or urine and control specimens to which 5 and 10 mcg. of trimethoprim were added as internal standards were carried through the entire procedure. The concentrations in the unknown specimens were

Figure 1—Trimethoprim blood levels in Dog 1 following i.v. and oral administration. Key: 5.7 mg./kg. trimethoprim to Dog 1: ●—●, i.v.; and ×—×, oral.

calculated on the basis of the internal standard after correction for the control values.

RESULTS AND DISCUSSION

The dog blood level and urinary excretion data following i.v. and oral administration of trimethoprim are presented in Table I and Figs. 1 and 2. The pharmacokinetic profile of trimethoprim in the dog is summarized in Table III.

The human blood level data of the two subjects receiving both single and chronic administrations of the drug are presented in Table II and Figs. 3 and 4. The corresponding urinary excretion data are presented in Tables IV and V and Fig. 5. The pharmacokinetic profile following the single and chronic oral dosing of trimethoprim is summarized in Table VI. The blood level data of the subjects receiving trimethoprim daily over a 13-week period are presented in Table VII.

Theoretical Considerations—Following the intravenous injection of trimethoprim to two dogs, the resulting blood level curves could be adequately described by the biexponential equations as shown

Figure 2—Trimethoprim blood levels in Dog 2 following i.v. and oral administration. Key: 5.7 mg./kg. trimethoprim to Dog 2: ●—●, i.v.; and ×—×, oral.

^a $0.693/\text{constant}$ = half-life. ^b Calculated from absorption rate equation (6).

in Figs. 1 and 2. The first portion of the biexponential curve will be referred to as the fast disposition rate, with a rate constant α . The second portion of the curve will be referred to as the slow disposition rate, with a rate constant β . It should be noted that α and β are both hybrid rate constants, each influenced by all the individual processes of the disposition of the drug. The rate constant α reflects the distribution phase of the compound from the central to the peripheral (tissue) compartment. The rate constant β reflects the elimination rate of the drug from the body. The physiological

disposition of trimethoprim may therefore be defined in terms of the two-compartment open-system model shown in Scheme I (5):

Scheme I

Solution of the differential equations resulting from such a model yields the following integrated equation describing the blood level-time curve after a single intravenous injection as seen in Figs. 1 and 2:

$$C_p = Ae^{-\alpha t} + Be^{-\beta t}$$

where C_p is the concentration of drug in the plasma, and A and B are the ordinate axis intercepts.

The α and β are both hybrid rate constants reflecting all the individual rate processes; however, k_{12} , k_{21} , and k_{13} are individual rate constants calculable from this equation (5). The k_{12} and k_{21} are first-order rate constants of distribution and k_{13} is the sum of the simultaneous processes of biotransformation and excretion, all assumed to be first-order processes. This is the rate constant of the elimination reaction *per se*.

The absorption rate is calculated from the following relationship (6):

$$\left(\frac{A}{V_p}\right)_{tn} = C_{p_{tn}} + k_{13} \int_0^{tn} C_p dt + C_{T_{tn}}$$

which indicates that the amount absorbed per unit volume of distribution (A/V_p) at time tn equals the plasma level (C_p)_{tn} plus the tissue level (C_T)_{tn} plus the amount eliminated ($k_{13} \int_0^{tn} C_p dt$) at time tn .

In a two-compartment open-system model the total volume of distribution of the entire system (V_D)_{ss}, when calculated with reference to the concentration of drug in the central compartment, is the sum of the volume of the central compartment, V_p , and of the peripheral (tissue) compartment, V_T (7), where V_p = administered dose/ $A + B$ and (V_D)_{ss} = $V_p(k_{12} + k_{21})/(k_{21})$.

The volume of distribution can also be calculated using the equation as presented by Gibaldi *et al.* (8) and is referred to as (V_D) _{β} .

In this case, (V_D) _{β} = V_p/f where: $f = C_2/(C_2 + C_2^{-1})$, $C_2 = B/(A + B)$, and $C_2^{-1} = k_{12}/(\alpha - \beta)$.

Physiological Disposition of Trimethoprim in the Dog—The pharmacokinetic parameters summarized in Table III indicate that trimethoprim has fast disposition rate constants, α , of 6.6 and 13.6 hr.⁻¹, respectively, in Dogs 1 and 2. The slow disposition rate constants, β , were 0.187 and 0.281 hr.⁻¹ corresponding to half-

lives of 3.7 and 2.5 hrs, and reflect the apparent elimination rates of the drug from the body.

The volumes of the central compartment, V_p , were calculated to be 8.5 and 10.9 l., respectively. The total volumes of distribution, $(V_D)_{ss}$, of trimethoprim were calculated to be 184 and 154% of body weight in the two dogs, suggesting significant tissue uptake of trimethoprim. $(V_D)_\beta$ was calculated and found to be almost identical with the $(V_D)_{ss}$ calculation (Table III).

Only 18.8% of the intravenously administered dose was recovered as intact drug in the 0 to 48-hr. urine of Dog 1 and 29% in Dog 2, indicating biotransformation and/or alternate routes of excretion. Almost all the recovered trimethoprim was excreted in the urine during the 0 to 24-hr. interval.

The data indicate fairly rapid and complete absorption of the orally administered drug in the dog (Table III) with Dog 2

exhibiting a lag in the start of absorption. Absorption was essentially complete in 2 hr. in Dog 1 and in 3 hr. in Dog 2.

Physiological Disposition of Trimethoprim in Man—The pharmacokinetic profile following the administration of a single 200-mg. oral dose of trimethoprim to two subjects is presented in Table VI.

In relation to body weight the single doses represented 2.3 mg./kg. for M. H. and 3.4 mg./kg. for R. R.

In each case the blood level curves (Figs. 3 and 4) peaked at 4 hr. postadministration. Subjects R. R. and M. H. exhibited blood level peaks of 1.8 and 2.1 mcg./ml. and elimination rates of 4.0 and 4.6%/hr. corresponding to half-lives of 17.3 and 15 hr., respectively.⁴

Estimates of the volume of distribution following single oral

^a Mean of 13 weekly determinations.

doses were made by means of the area equation (9) and are presented in Table VI. It should be noted that $(V_D)_{\text{area}}$ has been shown to be mathematically identical to the $(V_D)_\beta$ term previously defined (8):

$$(V_D)_{\text{area}} = \frac{\text{amount of drug absorbed}}{\beta(\text{area})}$$

where complete absorption of the dose is assumed, β is the apparent elimination rate constant, and the (area) is the area under a blood level curve from time = 0 to time = ∞ . The percent volume of distribution for Subjects M. H. and R. R. were calculated to be 158 and 177% of body weight, indicative of tissue uptake and possible localization of the drug.

The percent of dose excreted as intact drug following oral administration of single 200-mg. doses as seen in Tables IV and V were 25.6 and 36.4% for Subjects M. H. and R. R., with urinary elimination rates of 3.6 and 3.7%/hr. corresponding to half-lives of 19.5 and 18.7 hr. (Fig. 5). The low recovery of the intact drug in the urine is an indication of biotransformation and/or alternate routes of excretion.

Twenty-four-hour urine specimens were collected during the chronic dosing period for the above two subjects and analyzed for intact trimethoprim. The results are presented in Tables IV and V. The daily intact trimethoprim urine levels ranged from 18 to 45% of the administered dose in Subject R. R. and from 9 to 20% in Subject M. H.

Following the chronic administration of 50 mg. trimethoprim q.i.d. (every 5 hr.) to Subjects M. H. and R. R., they exhibited minimum steady-state blood levels of approximately 1.5 and 2.2 mcg./ml., respectively, as indicated in Figs. 3 and 4.

It is interesting to note that the steady-state blood levels are achieved within 2–3 days of chronic administration and that the steady-state levels achieved on dosing 50 mg. q.i.d. (every 5 hr.) are approximately the same as the single dose, 200 mg., peak blood level. Estimated steady-state blood levels were calculated from the elimination rate data utilizing a q.i.d. dosing regimen of every 6 hr. based on the equations of Boxer *et al.* (10). The calculated steady-state minimum–maximum blood levels are 1.7–2.1 mcg./ml. for Subject M. H. and 2.0–2.6 mcg./ml. for Subject R. R. These simulated values are in excellent agreement with the experimental finding indicated above.

The trimethoprim blood levels reported in Table VII following the daily administration of 50 mg. q.i.d. for 13 weeks indicate

that steady-state levels were evident by the end of the 1st week of treatment and maintained throughout the experimental period. This finding is substantiated by the small standard error about the mean blood level in each subject which is consistent with steady-state conditions. This would, therefore, preclude drug cumulation or enzyme induction by trimethoprim over a 13-week period.

The mean minimum steady-state trimethoprim blood level of the 13 subjects was 1.1 mcg./ml. with a range from 0.33 to 1.84 mcg./ml. It should be noted that the subjects with the lower blood levels represented those with the higher body weights. The minimum steady-state trimethoprim blood levels seen in the 13-subject study group corresponds with the steady-state blood levels seen in the two-subject study group. In view of these findings one may predict blood levels resulting from multiple dosing, based on pharmacokinetic data obtained from a single dose.

In attempting to compare the disposition profiles of trimethoprim in the dog and in man, it appears that both species absorb the drug well and distribute the drug extensively into the tissues. However, differences are discernible in the rates of elimination of trimethoprim in that the dog eliminated the drug 4–5 times faster than the human Subjects M. H. and R. R.

SUMMARY

1. Trimethoprim appears to be absorbed well and is highly distributed in both the dog and man.
2. In two human subjects the intact drug was eliminated from the bloodstream with half-lives of 15 and 17.3 hr.
3. In man, 50 mg. administered q.i.d. every 5 hr. gives rise to a steady-state blood level approximately the same as the maximum blood level achieved with a single 200-mg. dose.
4. Steady-state blood levels were maintained on daily dosing over a 13-week interval.
5. The low recovery of the intact drug in the urine is indicative of a high degree of biotransformation and/or alternate routes of excretion.
6. The dog eliminated the drug 4 to 5 times faster than the two human subjects studied.

Two-Compartment Model for a Drug and Its Metabolite: Application to Acetylsalicylic Acid Pharmacokinetics

MALCOLM ROWLAND, LESLIE Z. BENET, and SIDNEY RIEGELMAN

Abstract □ A general solution is presented for solving the pharmacokinetic parameters which describe a drug and its metabolite in a two-compartment open model. The method is specifically applied to the treatment of plasma data for acetylsalicylic acid and its metabolite, salicylic acid, following intravenous administration of acetylsalicylic acid. The acetylsalicylic acid data were found to be adequately described by a model in which elimination occurs solely from the central compartment.

Keyphrases □ Model, two-compartment, open—pharmacokinetic parameters □ Kinetic equations—two-compartment open model □ Acetylsalicylic acid—pharmacokinetics □ Concentration-time curve areas, ratio—drug-metabolite

In a previous publication a comparison of two models was made in an attempt to describe the pharmacokinetics of acetylsalicylic acid (ASA) following an intravenous dose to man (1). An essential feature in both of these models was the distribution of ASA between a central and peripheral compartment while the comparison revolved around deciding whether metabolism to salicylic acid (SA) occurred exclusively in the central compartment (Model A) or in both compartments (Model B, Fig. 1). The third possibility, *i.e.*, metabolism solely in the peripheral compartment, was excluded as hydrolysis is known to occur in plasma, which is the reference system for the central compartment. In addition, it was tacitly assumed that Model A also described SA kinetics for an intravenous dose. Both models were simulated on an analog computer, and from the results it was suggested that only Model A adequately fitted the observed ASA and resultant SA plasma data. Subsequent re-examination of this problem shows that by using both the ASA and SA data, an analytical solution is available for determining all the rate constants for ASA in Model B.

DISCUSSION

Before proceeding with the specific problem, a number of pertinent points can be made relating to the above two simple models, A

and B. In either case the same biexponential concentration-time curve results from an intravenous dose of the drug into Compartment 1 and this is characterized by the exponents α' and β' together with the coefficients A' and B' as shown in Table I. (The double prime terms used in Model B are numerically equivalent to those in Model A, and serve only to distinguish between the models.) However, whereas these exponents and coefficients allow a complete solution of all the rate constants in Model A, *i.e.*, k_{21} , k_{12} , and k_{13} , only $(k_{21} + k_{24})$, $(k_{12} + k_{13})$, together with the product of k_{12} and k_{21} , can be calculated in Model B. Failure to recognize these boundary conditions in Model B resulted in an incorrect analysis of the analog computer calculations which appeared in Fig. 6 of Reference 1. Consequently, by just measuring the unchanged drug, it is impossible to obtain a solution for the specific rate constants in Model B. This may only be achieved by measuring the metabolite derived by biotransformation of the parent drug and by injection of this metabolite on a separate occasion. Such an approach, namely, following a drug and one of its metabolites was used in determining the model necessary to describe the pharmacokinetics of ASA. As expected the intravenous ASA data can be fitted by either Model A or B.

Enlarging this discussion leads to consideration of the more general situation which is represented in Model C (Fig. 2). Here elimination can proceed in both the tissue and peripheral compartments for drug and any metabolite that one measures. Despite this complexity, drug plasma levels still decline biexponentially, but with more rate constants involved in any one term in the equation describing these results (Table II). In this case, as in Model B, if drug alone is measured, it is only possible to calculate the sum of various rate constants, *i.e.*, $(k_{12} + k_{13} + k_{17})$ and $(k_{21} + k_{24} + k_{28})$ together with the product of k_{12} and k_{21} . Likewise, an injection of the metabolite only allows the solution of $(k_{43} + k_{46})$, $(k_{34} + k_{28})$ together with the product of k_{34} and k_{43} . An additional number of rate constants in Model C can, however, be solved by determining the fraction of a dose in Compartment 3 with time following the injection of the parent drug. The general form of this function can be readily derived by solving the differential equations which describe Model C and which are as follows:

$$\dot{F}_1 = -(k_{12} + k_{13} + k_{17}) \cdot F_1 + k_{21} \cdot F_2 \quad (\text{Eq. 1})$$

$$\dot{F}_2 = k_{12} \cdot F_1 - (k_{21} + k_{24} + k_{28}) \cdot F_2 \quad (\text{Eq. 2})$$

$$\dot{F}_3 = k_{13} \cdot F_1 + k_{43} \cdot F_4 - (k_{34} + k_{35}) \cdot F_3 \quad (\text{Eq. 3})$$

$$\dot{F}_4 = k_{24} \cdot F_2 + k_{34} \cdot F_3 - (k_{43} + k_{46}) \cdot F_4 \quad (\text{Eq. 4})$$

$$\dot{F}_5 = k_{35} \cdot F_3 \quad (\text{Eq. 5})$$

$$\dot{F}_6 = k_{46} \cdot F_4 \quad (\text{Eq. 6})$$

Table I—Various Parameters Which Define Models A and B in Fig. 1

	Model A	Model B
Plasma (blood) concentration time curve	$C_1 = A'e^{-\alpha't} + B'e^{-\beta't}$	$C_1 = A''e^{-\alpha''t} + B''e^{-\beta''t}$
Fraction of dose in central compartment	$F_1 = \frac{m_1}{\text{dose}} = \frac{C_1}{A' + B'}$ $= X'_{\alpha'}e^{-\alpha't} + X'_{\beta'}e^{-\beta't}$	$F_1 = \frac{m_1}{\text{dose}} = \frac{C_1}{A'' + B''}$ $= X''_{\alpha''}e^{-\alpha''t} + X''_{\beta''}e^{-\beta''t}$
Definition of terms with respect to the appropriate model	$X'_{\alpha'} = \frac{k_{21} - \alpha'}{\beta' - \alpha'}$ $\alpha' + \beta' = k_{12} + k_{13} + k_{21}$ $\alpha'\beta' = k_{13} \cdot k_{21}$	$X''_{\alpha''} = \frac{(k_{21} + k_{24}) - \alpha''}{\beta'' + \alpha''}$ $\alpha'' + \beta'' = (k_{12} + k_{13}) + (k_{21} + k_{24})$ $\alpha''\beta'' = (k_{12} + k_{13})(k_{21} + k_{24}) - k_{12} \cdot k_{21}$

Figure 1—Two-compartment open system in which elimination of drug, introduced into Compartment 1, occurs either from that compartment (Model A) or from both compartments (Model B).

$$\dot{F}_7 = k_{17} \cdot F_1 \quad (\text{Eq. 7})$$

$$\dot{F}_8 = k_{28} \cdot F_2 \quad (\text{Eq. 8})$$

$$\sum_{n=1}^8 F_n = 1 \quad (\text{Eq. 9})$$

$$F = \frac{m_3}{\text{dose}} = X_\alpha e^{-\alpha t} + X_\beta e^{-\beta t} + X_\gamma e^{-\gamma t} + X_\delta e^{-\delta t} \quad (\text{Eq. 10})$$

where

$$X_i = \frac{k_{13}(k_{21} + k_{24} + k_{28} - i)(k_{43} + k_{46} - i) + k_{12} \cdot k_{24} \cdot k_{43}}{(j - i)(k - i)(l - i)}$$

and i equals either α , β , γ , or δ , while j , k , and l are the superscripted values not equal to i ; i.e., $i = \alpha$:

$$X_\alpha = \frac{k_{13}(k_{21} + k_{24} + k_{28} - \alpha)(k_{43} + k_{46} - \alpha) + k_{12} \cdot k_{24} \cdot k_{43}}{(\beta - \alpha)(\gamma - \alpha)(\delta - \alpha)}$$

Letting $E_2 = k_{21} + k_{24} + k_{28}$; $E_4 = k_{43} + k_{46}$; $A_{13} = k_{12} \cdot k_{24} \cdot k_{43}$, \therefore

$$F = k_{13} \sum_{i=\alpha}^{\delta} \frac{(E_2 - i)(E_4 - i)}{(j - i)(k - i)(l - i)} e^{-it} + A_{13} \sum_{i=\alpha}^{\delta} \frac{1}{(j - i)(k - i)(l - i)} e^{-it} \quad (\text{Eq. 11})$$

Rearranging

$$\frac{F_3}{\sum_{i=\alpha}^{\delta} \frac{1}{(j - i)(k - i)(l - i)} e^{-it}} = \frac{\sum_{i=\alpha}^{\delta} [(E_2 - i)(E_4 - i)] e^{-it} / [(j - i)(k - i)(l - i)]}{\sum_{i=\alpha}^{\delta} e^{-it} / [(j - i)(k - i)(l - i)]} + A_{13} \quad (\text{Eq. 12})$$

Since α , β , γ , and δ are known, and the terms $(k_{21} + k_{24} + k_{28})$ and $(k_{43} + k_{46})$ can be determined from the values of the coefficients described in the intravenous data, it is possible to calculate at any given time all the summation terms in Eq. 11, and in the rearranged Eq. 12, an equation for a straight line. Also, since the corresponding values of F_3 may be derived directly from the experimental metabolite plasma data following injection of the parent drug, it is possible to calculate both of the time variable functions on either side of Eq. 12. A plot of these functions will then give a slope of k_{13} and an intercept equal to the product $k_{12}k_{24}k_{43}$. Therefore, even in this relatively complex model, the rate constant k_{13} , describing metabolism within the central compartment to the measured metabolite, can be determined.

Amount of Drug Loss from Compartments 1 and 2—In looking at the general model, it is equally important to know the fraction of the drug which is lost from Compartment 1 and Compartment 2, respectively. These values are simply given as follows:

$$\text{fraction drug lost from Compartment 1} = (k_{13} + k_{17}) \int_0^\infty F_1 dt \quad (\text{Eq. 13})$$

Table II—Various Parameters Which are Characteristic of Model C in Fig. 2

Concentration-time curve of drug in Compartment 1.	$C_1 = Ae^{-\alpha t} + Be^{-\beta t}$
Fraction of dose in Compartment 1.	$F_1 = X_\alpha e^{-\alpha t} + X_\beta e^{-\beta t}$
Definition of coefficient and exponents for drug introduced as a bolus via Compartment 1.	$X_\alpha = \frac{(k_{21} + k_{24} + k_{28}) - \alpha}{\beta - \alpha}$ $\alpha\beta = (k_{12} + k_{13} + k_{17}) \times (k_{21} + k_{24} + k_{28}) - k_{12} \cdot k_{21}$
Concentration-time curve of metabolite introduced as a bolus via Compartment 3.	$C_3 = Ce^{-\gamma t} + De^{-\delta t}$
Corresponding fraction of metabolite in Compartment 3.	$F_3 = X_\gamma e^{-\gamma t} + X_\delta e^{-\delta t}$
Corresponding definition of coefficient and exponents for metabolite.	$X_\gamma = \frac{(k_{43} + k_{46}) - \gamma}{\delta - \gamma}$ $\gamma + \delta = (k_{43} + k_{46}) + (k_{34} + k_{35})$ $\gamma\delta = (k_{43} + k_{46})(k_{34} + k_{35}) - k_{34} \cdot k_{43}$

fraction drug lost from Compartment 2 =

$$(k_{24} + k_{28}) \int_0^\infty F_2 dt \quad (\text{Eq. 14})$$

Since the values of F_1 and F_2 are given by:

$$F_1 = \frac{E_2 - \alpha}{\beta - \alpha} e^{-\alpha t} + \frac{E_2 - \beta}{\alpha - \beta} e^{-\beta t} \quad (\text{Eq. 15})$$

$$F_2 = \frac{k_{12}}{\beta - \alpha} e^{-\alpha t} + \frac{k_{12}}{\alpha - \beta} e^{-\beta t} \quad (\text{Eq. 16})$$

it follows that:

$$\text{fraction drug lost from Compartment 1} = \frac{(k_{13} + k_{17}) E_2}{\alpha\beta} \quad (\text{Eq. 17})$$

$$\text{fraction drug lost from Compartment 2} = \frac{k_{12}(k_{24} + k_{28})}{\alpha\beta} \quad (\text{Eq. 18})$$

Also, as expected, addition of Eqs. 17 and 18 and appropriate substitution shows that the sum of the fractions of drug lost from Compartments 1 and 2 is unity.

Clearance of Drug from Compartments 1 and 2—The total body clearance (TBC) of drug, defined by Eq. 19, is model independent for an i.v. dose no matter where drug loss occurs.

$$\text{TBC} = \frac{\text{dose}}{\int_0^\infty C_1 dt} \quad (\text{Eq. 19})$$

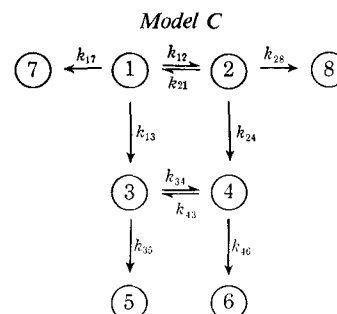

Figure 2—Compartmental model describing the distribution and elimination of a drug injected into Compartment 1, elimination proceeding by various routes from Compartments 1 and 2, with a metabolite, 3, undergoing analogous disposition.

Table III—Ratio of the Total Areas under the Metabolite Concentration–Time Curve following an Equimolar i.v. Dose of Drug and Metabolite

Case	Model		Ratio of Areas ^a	
	$k_{45} > 0$	$k_{46} = 0$	$k_{46} > 0$	$k_{46} = 0$
General	I 	VI 	I $\frac{k_{13}(k_{21} + k_{24} + k_{28})(k_{43} + k_{46}) + k_{12}k_{24}k_{43}}{\alpha\beta(k_{43} + k_{46})}$	VI $\frac{k_{13}(k_{21} + k_{24} + k_{28}) + k_{12}k_{24}}{\alpha\beta}$
$k_{28} = 0$	II 	VII 	II $\frac{k_{13}(k_{21} + k_{24})(k_{43} + k_{46}) + k_{12}k_{24}k_{43}}{\alpha\beta(k_{43} + k_{46})}$	VII $\frac{k_{13}(k_{21} + k_{24}) + k_{12}k_{24}}{\alpha\beta}$
$k_{17} = k_{28} = 0$	III 	VIII 	III $\frac{k_{13}(k_{21} + k_{24})(k_{43} + k_{46}) + k_{12}k_{24}k_{43}}{\alpha\beta(k_{43} + k_{46})}$	VIII 1
$k_{24} = k_{28} = 0$	IV 	IX 	IV $\frac{k_{13}}{k_{13} + k_{17}}$	IX $\frac{k_{13}}{k_{13} + k_{17}}$
$k_{17} = k_{24} = k_{28} = 0$	V 	X 	V 1	X 1

^a In the formulas, $\alpha\beta = E_1E_2 - k_{12} \cdot k_{21}$

Multiplying both sides of Eq. 13 by dose divided by V_1 , the volume constant for Compartment 1 [i.e., $V_1 = \text{dose}/(A + B)$], gives:

$$\frac{(\text{amount of drug lost from Compartment 1})}{V_1} = (k_{13} + k_{17}) \int_0^\infty C_1 dt \quad (\text{Eq. 20})$$

Rearranging Eq. 20 results in:

$$\text{clearance of drug from Compartment 1} = (k_{13} + k_{17}) V_1 \quad (\text{Eq. 21})$$

Subtracting Eq. 21 from Eq. 19 yields the clearance of drug from

Compartment 2, which may also be numerically given by:

$$\text{clearance of drug from Compartment 2} = (k_{24} + k_{28}) V_2 \quad (\text{Eq. 22})$$

where V_2 , the volume constant for distribution in Compartment 2 with reference to the concentration in Compartment 1, is defined as

$$V_2 = \frac{k_{12}}{E_2} V_1 \quad (\text{Eq. 23})$$

Although the volume terms V_1 and V_2 may not be equal to a real physiological space, the clearances from Compartments 1 and 2 (as defined in Eqs. 21 and 22) are measures of an actual clearance for organs and/or tissues within the body.

Area Analysis—Assuming that the rate constants defining the kinetics of the metabolite are independent of whether it is given directly or formed by the biotransformation of the parent compound, one can calculate the ratio of the total areas under the metabolite concentration–time curve in Compartment 3 following an equivalent dose of parent drug and metabolite on separate occasions. This is given by

$$\begin{aligned} \text{ratio of metabolite areas} &= \frac{\left[\int_0^\infty F_3 dt \right]_{\text{i.v. drug}}}{\left[\int_0^\infty F_3 dt \right]_{\text{i.v. metabolite}}} \\ &= \frac{k_{13}E_2E_4 + A_{13}}{\alpha\beta E_4} \quad (\text{Eq. 24}) \end{aligned}$$

Utilizing such an equation, it is possible to investigate the influence of the route and magnitude of elimination and distribution on the area under the metabolite curve. Several such cases are illustrated in Table III. Cases IX and X represent the well-known models in which elimination of the drug (and metabolite) occurs solely from

Figure 3—Plot of the time variable functions in Eq. 13, Subject A. Slope equal to k_{13} .

Table IV—Values Calculated to Test the Model Appropriate for ASA Pharmacokinetics

Subject	k_{13} (min. ⁻¹)		$k_{12}k_{24}k_{43}^b$	k_{24}^c	Fraction ASA Metabolized in Compartment 1 ^d	Fraction ASA Metabolized in Compartment 2 ^e

B	0.101/	0.095	3×10^{-4}	0.009	0.94	0.06
C	0.096/	0.110	-4×10^{-4}	-0.025	1.14	-0.14
D	0.105	0.095	2×10^{-4}	0.014	0.91	0.09

^a Taken from Reference 1. ^b Calculated by graphical methods utilizing Eq. 12. ^c Calculated using equations defined for Model B in Table I and graphical solution for k_{13} . ^d Calculated using Eq. 17 when $k_{17} = 0$. ^e Calculated using Eq. 18 when $k_{28} = 0$. / These values differ slightly from those reported previously (1) due to calculation errors.

the central compartment. Case IX is normally used to calculate the rate constant, k_{13} , when the sum ($k_{13} + k_{17}$) has been determined from previous i.v. data. When the ratio of areas is unity, it is impossible to distinguish between Cases V, VIII, and X. The remaining cases illustrate those conditions in which elimination of an unchanged drug also occurs from Compartment 2 and metabolite may or may not be eliminated from Compartment 4. Table III clearly shows that the corresponding area analysis cannot be used to calculate exclusively the rate constant k_{13} . Rather this ratio of areas under the metabolite concentration-time curve is a complex function which results from the interplay of all the constants in the appropriate model.

Examination of ASA Kinetics—Returning to the problem associated with the ASA data, the total area under the SA plasma concentration-time curve was the same following either injection of ASA or an equivalent dose of SA. Also, it has been reported that only approximately 1% of ASA is eliminated unchanged in the urine (2). These data, in themselves, suggest that all the models in Table III can be excluded with the exception of Cases V, VIII, and X. To distinguish Case VIII from the other two, it is necessary to determine whether the rate constant k_{24} exists. This was ascertained for each of the four subjects in the study (1) by graphically solving Eq. 12. The values for the fraction of the dose in Compartment 3 were obtained by dividing the plasma concentration values for SA by the sum of the coefficients C and D , i.e., $F_3 = C_3/C + D$, while each of the time variable summation terms was calculated at each time point. Figure 3 illustrates such a plot for Subject A of Reference 1. As expected, a straight line was obtained for this and the other subjects and resultant values for k_{13} are shown in Table IV together with the intercept $k_{12}k_{43}k_{24}$. In addition, the values for k_{13} , assuming Model A for ASA, are presented. As can be seen the intercept was essentially zero for all subjects, indicating that the term k_{24} is small since the other rate constants, k_{43} and k_{12} , must be positive and significant values as they are related to the distribution of ASA and SA where both of these drugs exhibit biexponential curves. Knowing k_{13} , it is also possible to obtain an exact solution of k_{24} for the ASA data by appropriate substitution into the defined terms for Model B in Table I. These values are presented in Table IV.

From the data in Table IV, it is obvious that the pathway designated by k_{24} may be considered of only minor importance in ASA pharmacokinetics. It is likely that the values reported for k_{24} and the "Fraction ASA Metabolized in Compartment 2" differ from zero only as a result of the errors inherent in the biological experiment. This is reinforced by the negative values calculated for Subject C. Consequently, we are led to the conclusion that Model A rather than Model B describes the ASA data, and this is confirmed by the close similarity between the values of the rate constant, k_{13} , determined by the graphical solution of Eq. 12 and those given by simple calculation based on Model A. Accordingly, as previously suggested

(1) the ASA i.v. data can be adequately described by the model in which elimination occurs solely in the central compartment. However, because the rate constant k_{24} appears to be zero, one cannot distinguish between Cases V and X where SA is eliminated exclusively from the central compartment or from both compartments. Obviously were the value of k_{24} a significant number, then k_{43} and hence k_{46} could have been calculated allowing the entire ASA model to be characterized.

TERMINOLOGY

n	refers to Compartment n .
C_n, M_n, F_n	are the corresponding concentration, mass, and fraction of administered dose of a species in compartment n .
k_{nm}	first-order rate constant for the transfer of species from Compartment n to m .
α, β, A, B	are the exponents and coefficients of the equation describing the changes with time for the species in Compartment 1 following an injection of drug into that compartment.
γ, δ, C, D	are the exponents and coefficients of the equation describing the changes with time for the species in Compartment 3 following an injection of metabolite into that compartment.
$\alpha, \alpha', \alpha'', \text{etc.}$	are numerically equivalent and the prime terms are solely used to distinguish between various models describing the observed data.
E_n	is the sum of all the rate constants out of compartment n .
A_{nm}	is the product of the rate constants involved in the alternate route between compartments n and m , i.e., $A_{13} = k_{12} \cdot k_{24} \cdot k_{43}$.

Comparison of Whole-Body Liquid Scintillometry, Radiography, and Clinical Chemical Tests in the Evaluation of the Effect of Chronic Corticoid Dosing on Calcium in Beagles

M. C. BHATTI*, S. M. SHAW, R. E. LEWIS, and J. E. CHRISTIAN

Abstract □ Chronic doses of 6 α -methylprednisolone were administered to beagles for 106 days to bring about changes in calcium balance. During the initial 64 days of corticoid treatment, no outstanding changes were observed in the blood levels of calcium, phosphorus, or alkaline phosphatase. Radiographic changes in the skeleton were not seen after 64 days of treatment. Significant changes in ^{45}Ca retention were detected by whole-body liquid scintillometry after only 13 and 28 days of corticoid administration. On day 64 of the study, the dosage of 6 α -methylprednisolone was increased. Decreased levels of calcium in blood plasma and increased levels of plasma alkaline phosphatase were observed after the dose of corticoid was increased. A great reduction in whole-body ^{45}Ca retention was also observed, and thinning of the cortices of the long bones of the legs was apparent. The results of the investigation indicate that whole-body liquid scintillation counting of ^{45}Ca is a sensitive indicator of alterations of calcium metabolism in relation to other diagnostic methodology.

Keyphrases □ Corticoid administration, chronic—Ca effect evaluation □ ^{45}Ca retention—chronic corticoid administration □ Scintillometry—analysis □ Atomic absorption spectroscopy—analysis

The diagnosis of pathologic conditions affecting the skeleton is difficult. Clinical chemical methods and radiography can rarely detect skeletal disease until a critical stage has developed. Routine radiographic methods are sensitive to rarefying osteopathies only after a 30–50% loss of skeletal mineral (1, 2). There is a definite need for superior diagnostic methodology.

Experimentation in this laboratory (3) and that conducted by others (4–10) have demonstrated that ^{45}Ca and whole-body counting techniques show great promise for the evaluation of skeletal calcification. The purpose of the present investigation was to compare the abilities of whole-body liquid scintillation counting of ^{45}Ca , routine clinical chemical methods, radiography, and ^{45}Ca specific activity determinations of bone sample for the detection of changes in calcium balance brought about in beagle dogs by chronic dosing with the corticoid, 6 α -methylprednisolone. Chronic administration of corticoid was chosen because one of the most serious complications of sustained glucocorticoid therapy is the development of osteoporosis (11). The development of osteoporosis from glucocorticoid administration is an insidious process, taking many months to become severe enough to be capable of clear radiological recognition (12, 13). Skeletal alterations resulting from corticoid treatment have been well documented in animals (14–16).

EXPERIMENTAL

Five pure-bred male beagles¹ were used for the investigation. The dogs were housed together in a large indoor kennel which per-

mitted them to exercise freely. The dogs were maintained on a balanced commercial diet.² Tap water was allowed *ad libitum*. At 10 weeks of age, each dog received 100 μc . of ^{45}Ca in two subcutaneous doses 2 days apart. Approximately 50 days were allowed for equilibration of the isotope with the stable skeletal calcium pool. At various intervals throughout the study, bone samples were obtained from each dog by amputation of the third digit of a foot. The first phalanx of each digit was analyzed for ^{45}Ca and total calcium.

The bone was air dried, weighed, and ashed in a muffle furnace. The ash was dissolved in 1 N HCl. Calcium determinations were carried out in triplicate by atomic absorption spectroscopy³ according to the methodology developed for the clinical use of the spectrophotometer (17, 18). Determinations of ^{45}Ca were made in triplicate by placing aliquots of the dissolved bone ash in a toluene modified XDC scintillator solution (19) and counting the samples with a Packard Tri-Carb scintillation spectrometer.⁴ An internal standardization procedure was utilized to correct the counting data for quenching (20).

Following the ^{45}Ca equilibration period, corticoid administration was initiated. Four of the dogs received a daily oral dose of 2 mg./kg. of body weight of 6 α -methylprednisolone for 63 days. On the 64th day, the corticoid dose for these four dogs was raised to 10 mg./kg. of body weight daily and maintained until day 106. The fifth dog served as a control and received doses of lactose in place of corticoid during the entire study.

Before and during corticoid administration, the dogs were radiographed at approximately 2-week intervals. The areas radiographed were the lumbar spine, foreleg, and mandible. All radiographs were made using regular-speed film and ultradetail intensifying screens.

Clinical chemical determinations were performed prior to and at various times during corticoid dosing. After 24 hr. of fasting, a 10-ml. sample of whole blood was obtained from the external jugular vein of each dog in heparinized syringes. Plasma alkaline phosphatase determinations were made using Phosphatase-Alkaline Quantitative.⁵ This simplified test for alkaline phosphate makes use of reagent tablets containing phenolphthalein phosphate substrate (21). The reagent tablets have been reported to produce results which are in excellent agreement with more sophisticated techniques for alkaline phosphatase determination (22–24). An analysis using a standardized enzyme solution⁶ was run with each series of alkaline phosphatase determinations as a check against errors in methodology. Serum inorganic phosphorus was determined with Hycel phosphorus reagent.⁷ A standardized serum⁸ was analyzed with each series of phosphorus determinations to assure against technical errors. Serum calcium was determined by adding 0.2 ml. of plasma to 5 ml. of a solution of 1% lanthanum as $\text{LaCl}_3 \cdot 7\text{H}_2\text{O}$ and 5% trichloroacetic acid in double distilled water. The mixture was centrifuged to precipitate the plasma proteins. The calcium contained in the supernatant was determined by atomic absorption spectroscopy. All clinical chemical determinations were made in triplicate. Each time clinical chemical analyses were conducted, the average value obtained for the corticoid-treated dogs was compared to the values for the control dog.

Figure 1—Plasma alkaline phosphatase levels. Key: ●, 6α-methylprednisolone-treated dogs; and ■, control dog.

A 4-pi whole-body liquid scintillation counter (3, 25) was used to determine whole-body retention of ^{47}Ca . Retention of ^{47}Ca was determined before corticoid administration and at four intervals during corticoid dosing. For each whole-body counting study, each dog was administered 0.2 μc . of ^{47}Ca intravenously into the external jugular vein. Fifteen minutes after isotope administration, ^{47}Ca retention was determined in each dog. This was considered to be time 0 and the count rate to be 100% retention of ^{47}Ca . Each dog was counted at given time intervals for 144 hr. after time 0. The ^{47}Ca retention values for the four corticoid-treated dogs were averaged at each time interval. Comparisons were made between the average retention values after various periods of corticoid dosing and the average retention values before corticoid dosing. Whole-body counting data were examined statistically using an analysis of variance and a Newman-Keuls Sequential Range test. At the termination of the study, the dogs were euthanized with pentobarbital, and necropsies were performed.

RESULTS AND DISCUSSION

During the period of corticoid dosing at a level of 2 mg./kg. of body weight, no outstanding changes were observed in the plasma alkaline phosphatase (Fig. 1), serum calcium (Fig. 2), or serum inorganic phosphorus (Fig. 3) levels of the treated dogs as compared to the control dog. No apparent radiographic changes in the treated dogs in relation to the control dog were observed at this lower dosage level of corticoid. However, by whole-body liquid scintillometry, it was possible to detect significant ($p = 0.01$) changes in ^{47}Ca whole-body retention in the dogs after 13 and 28 days of corticoid administration as compared to ^{47}Ca retention in the same dogs previous to the initiation of drug treatment (Fig. 4). At each time period investigated, statistical differences between whole-body ^{47}Ca retention curves occurred 60 hr. and thereon after ^{47}Ca administration. The results of the investigation during the period of corticoid dosing at a level of 2 mg./kg. illustrate the ability of whole-body liquid scintillation counting of ^{47}Ca to detect alterations of calcium

Figure 2—Serum calcium levels. Key: ●, 6α-methylprednisolone-treated dogs; and ■, control dog.

metabolism in the absence of radiographic and clinical chemical changes.

As may be seen in Fig. 4, after 54 days of corticoid administration at the lower dosage level the whole-body retention of ^{47}Ca began to approach the values observed before drug treatment. It appeared that the treated dogs were adapting to the pharmacologic effect of the drug. When the dosage level of 6α-methylprednisolone was raised to 10 mg./kg. of body weight, the whole-body retention of ^{47}Ca was found to be greatly decreased in the treated dogs in relation to ^{47}Ca retention in the dogs before corticoid treatment. Following the increase in dosage level the serum calcium in the treated dogs was decreased in relation to the control dog. Also, plasma alkaline phosphatase was elevated in the treated dogs as compared to the control dog. No conspicuous changes were observed in serum inorganic phosphorus during the entire study.

Radiographs taken at termination of the study (after 42 days of corticoid at a dose of 10 mg./kg. of body weight) showed thinning of the cortices of the long bones in the forelegs of the corticoid-treated dogs. Figure 5 illustrates the difference between the radiographic appearance of the long bones of the forelegs of the corticoid-treated dogs as compared to the control dog. It was also noted that the dogs treated with 6α-methylprednisolone developed curvature of the forelegs with the convex side anterior. Periosteal thickening of both the radius and the ulna on the concave side (posterior) occurred. In the middle third of the ulna there was an increased transverse trabecular pattern.

The ^{45}Ca specific activity of bone samples was expressed as c.p.m. ^{45}Ca /mg. Ca/g. bone. For each dog, the bone specific activity at the initiation of corticoid or control treatment was considered

Figure 4—Whole-body liquid scintillation determination of ^{47}Ca retention by dogs receiving chronic doses of 6α-methylprednisolone. Key: ●, dogs before corticoid treatment; ◇, dogs after 13 days of corticoid; □, dogs after 54 days of corticoid; △, dogs after 28 days of corticoid; and ○, dogs after 98 days of corticoid.

Figure 5—Radiograph of the foreleg. Key: A, dog after chronic doses of 6 α -methylprednisolone for 106 days; and B, control dog.

as 100% and subsequent samples were expressed as the percent of the initial specific activity remaining. After 59 days of corticoid dosing at a level of 2 mg./kg. of body weight, the specific activity of the bone samples from the treated dogs was 64% of the initial specific activity while the specific activity of the control dog was 59%. After a total of 106 days of corticoid dosing the specific activity of the bone samples from the treated dogs was 63% of the specific activity found previous to the initiation of corticoid administration while the specific activity of the control dog was 49%. Necropsy examinations at the termination of the study revealed no gross pathology in any of the dogs. However, gonadal atrophy was evident in the corticoid-treated dogs.

Whole-body liquid scintillation detection of ^{45}Ca retention in this investigation indicated that corticoid administration results in a decreased calcium retention. Collins *et al.* (26, 27) and Garrett *et al.* (28, 29) observed that chronic corticoid administration to beagle dogs resulted in decreased ^{45}Ca uptake by bone and an increased fecal excretion of ^{45}Ca . These workers concluded that de-

creased bone formation rather than increased destruction was the major effect of administered corticoids.

It would appear from the whole-body counting studies that either osteoblastic activity was depressed so that osteoclastic activity, normally held in balance, could show a greater net effect of resorption on bone, or that osteoclastic activity was enhanced resulting in increased bone resorption. Since osteoclasts have been shown to be associated with phosphatase enzymes (30), increased osteoclastic activity may account for the increased alkaline phosphatase levels observed in the corticoid-treated dogs. Conversely, the increased alkaline phosphatase levels may have been due to an increased osteoblastic activity attempting to heal bone damaged caused by the 6 α -methylprednisolone (31). However, Frost and Vilaneuva (32) examined the bones of a group of 21 human patients who had received cortisone or ACTH for more than 2 weeks. Only two cases showed normal osteoblastic activity. The remaining 19 cases showed depression or cessation of osteoblastic activity. Frost (32, 33) has concluded that human patients receiving phar-

macodynamic doses of corticoids go into negative calcium balance as a result of an unequal inhibition of both bone formation and bone resorption. The inhibition of formation is greater than the inhibition of resorption with the result that a negative skeletal balance ensues, leading to osteoporosis. In the present investigation, it is possible that an inhibition of bone formation by the corticoid may account for the decreased whole-body retention of ^{47}Ca and that inhibition of resorption may account for the increased retention of ^{46}Ca by the bone samples analyzed. The foreleg curvature developed by the dogs treated with 6α -methylprednisolone presents further evidence of inhibited bone formation. It has been shown in these laboratories that retardation of the distal ulnar epiphysis in dogs will result in curvature of the bones of the foreleg accompanied by periosteal thickening of these bones on the concave area.

SUMMARY

From these studies it can be seen that whole-body liquid scintillation counting of ^{47}Ca is a sensitive indicator of alterations of calcium metabolism in relation to other diagnostic methodology. During the first 64 days of corticoid treatment, no outstanding changes were observed in the blood levels of calcium, phosphorus, or alkaline phosphatase. Radiographic changes in the skeleton were not apparent after 64 days of treatment. However, it was possible to detect significant changes in ^{47}Ca retention by whole-body liquid scintillometry after only 13 days of corticoid administration. Significant radiographic and clinical chemical changes occurred only after elevated doses of corticoid were administered.

Heterogeneous Systems II: Influence of Partitioning and Molecular Interactions on *In Vitro* Biologic Activity of Preservatives in Emulsions

NAGIN K. PATEL* and JOYCE M. ROMANOWSKI

Abstract □ The preservative activity of *p*-hydroxybenzoic acid esters (parabens) in the presence of a polysorbate 80-sorbitan monooleate water system was found to be related to the concentration of the free or unbound paraben. Prediction of required preservative concentration for an emulsified system from a knowledge of oil-water partition coefficients and preservative-macromolecules binding data is illustrated. It was demonstrated by an *in vitro* microbiological procedure and using a glass dialysis cell that the fungistatic activity against *Aspergillus niger* of methyl- and propylparaben in emulsified systems was primarily a function of the free paraben concentration in the aqueous phase.

Keyphrases □ *p*-Hydroxybenzoic acid esters activity—partitioning, molecular interaction, effects □ Biological activity—emulsion preservatives *in vitro* □ Emulsions, effect—preservatives □ Inhibition determination—dialysis cell

Biological activity of antimicrobial agents in a heterogeneous system such as an emulsion is much more complex than in a simple aqueous medium. These agents, under the classification of preservatives, are incorporated in emulsified systems—medicinal, cosmetic, pharmaceutical, and nonpharmaceutical emulsions; ointments, creams, *etc.*—to protect against deterioration from bacterial and fungal attack. During the past 2 decades, pharmaceutical and cosmetic industries have recognized an increasing number of failures of the preservative to protect against microbial spoilage. This period coincides with the time during which nonionic emulsifiers, those containing polyoxyethylene groups and others, have become increasingly popular. A multiplicity of factors governs the efficacy of a preservative in the final formulation, and some notable reviews on the subject have appeared in the literature (1–5).

Emulsion and cream formulations contain a variety of ingredients which collectively form excellent substrates for microbial growth (6, 7). Under some conditions, fixed oils, fats (6, 7), hydrocarbon oils (8), the emulsifier (9), or the preservative (10) may be metabolized by certain microorganisms.

Previous investigations (11–16) have shown that many of the more commonly used preservatives in pharmaceutical and cosmetic emulsions are adsorbed to, bound to, or solubilized by nonionic emulsifiers in aqueous solution. The bound or solubilized (12) preservative in such a system has been shown to be devoid of antimicrobial activity (13, 15, 17, 18). In emulsified systems an additional factor, partitioning of the preservative between the oil and water phases, must be considered for the effective preservation of the entire formulation.

It is generally recognized that emulsified preparations containing different oil phases require higher concentra-

tion of preservatives (19) than normally used. The activity of some phenols in a two-phase system, liquid petrolatum–water, has been studied by Bean *et al.* (20). Recently, Anderson and Chow reported on the distribution and activity of benzoic acid in oil–water systems, emulsified with 0.1% polyoxyethylene lauryl ether¹ (21); the antifungal activity of benzoic acid was related to its concentration in aqueous phase.

As pointed out by Atkins (22), the problem of deterioration of cosmetic emulsion systems during storage, due to either mold formation or bacterial growth, is confined mainly to oil-in-water emulsions; it is rarely a problem with water-in-oil emulsions, the reason being that most troublesome organisms require an aqueous medium for favorable growth. In a water-in-oil emulsion, the water is surrounded by an inhospitable oil phase and this is not conducive to growth. The less common organisms which can infect the oil phase apparently do not cause product decomposition or spoilage, so that, even if they exist, their presence is not suspected (22). The most important factors affecting the activity of preservatives in oil-in-water emulsions containing nonionic emulsifying agents are those governing the availability of the preservatives in the aqueous phase. In such a system the preservative would partition into the oil phase and would also interact with the nonionic emulsifiers, thus reducing the activity of the preservative. The principal aim of this investigation was to show how the partition coefficient and binding data can readily and satisfactorily be used to determine the effective concentration in aqueous phase of methyl- and propylparaben in typical oil-in-water emulsions containing polysorbate 80² and sorbitan monooleate³ (or polysorbate 20⁴ and sorbitan monolaurate⁵) as emulsifying agents. It will also be demonstrated by an *in vitro* microbiological procedure that the activity of the preservatives is related to their concentrations in the aqueous phase. Selection of the oils was based on their varying oil–water partition coefficients (23).

THEORY

The theory behind the partitioning of a preservative in an oil–water system has been described in Part I (23). The equilibria con-

¹ Brij 35, marketed by Atlas Chemical Industries, Inc., Wilmington, Del.

⁵ Span 20, marketed by Atlas Chemical Industries, Canada, Ltd., Brantford, Ontario.

trolling the partitioning of a preservative between two phases and its binding to surfactant have also been discussed (2,12,13,15).

When a preservative distributes between oil and aqueous phases, the transfer is governed by its distribution coefficient or partition coefficient, D (23), as follows:

$$C_{oil} = DC_{H_2O} \quad (\text{Eq. 1})$$

where C_{oil} and C_{H_2O} are the preservative concentrations in oil and water phases at equilibrium. Assuming that the amount in the aqueous phase is active and if some transfers to the oil phase, sufficient additional preservative should be provided to maintain the required concentration in the water. Thus the total preservative, C_{ts} , to be added to a two-phase system can be calculated by knowing the usual concentration required in the aqueous phase (C_{H_2O}), and knowing the volume of each phase (V_{oil} and V_{H_2O}) and the distribution coefficient:

$$\text{total preservative} = C_{H_2O}V_{H_2O} + C_{oil}V_{oil} \quad (\text{Eq. 2})$$

Substituting the value of C_{oil} from Eq. 1:

$$C_{ts} = C_{H_2O}V_{H_2O} + DC_{H_2O}V_{oil} \quad (\text{Eq. 3})$$

If the preservative binds to the emulsifier in aqueous solution, the total preservative in water can be given by the following equation as described elsewhere (13, 15):

$$C_{H_2O} = RC_{H_2O} \quad (\text{Eq. 4})$$

where C_{H_2O} and C_{H_2O} are the concentrations of total (free + bound or solubilized) and free preservative in water, and R is the binding or solubilization constant as explained previously (13,15). The total preservative in this study was taken as the free plus the amount bound to or solubilized by the polysorbate-sorbitan ester dispersion.

If the failure of a preservative in a system consisting of oil and water phases emulsified with nonionic surfactants can be attributed to the partitioning as well as the binding of the preservative, the total quantity of the preservative which is theoretically needed for preservation, C_{ts} , can be computed by combining Eqs. 3 and 4 as represented by the following equation:

$$C_{ts} = C_{H_2O}(RV_{H_2O} + DV_{oil}) \quad (\text{Eq. 5})$$

In the present work it was assumed that the minimum inhibitory concentration of paraben in the absence of surfactants and oil corresponds to the concentration of free paraben.

MATERIALS

The oil phases and preservatives were the same as employed in earlier papers (15, 23). Polysorbate 80, polysorbate 20, sorbitan monooleate, and sorbitan monolaurate were commercial samples.

EXPERIMENTAL PROCEDURES

Determination of Interaction between Preservative and Nonionic Surfactants—Equilibrium dialysis method using a cellophane membrane⁶ was employed to determine this interaction, and the general approach and experimental procedure for this part have been detailed in previous communications (12, 24). Preliminary experimentation showed that this membrane (23) was impermeable to sorbitan monooleate. It was found previously to be impermeable to polysorbate 80 (16) and to the oils (23) used in this study. The general procedure was the same as that described earlier (24) with the following exception. A 10-ml. portion of aqueous polysorbate-sorbitan ester dispersion was pipetted into one of the compartments of the dialysis cell (24) and an equal volume of paraben solution was placed into the opposite compartment. In order to increase the total paraben content of the system, it was necessary in some cases to dissolve additional paraben in the dispersion. Overnight agitation of the assembled cells was sufficient for attainment of equilibrium. Any sorption of the parabens by the membrane and dialysis cells was found to be insignificant (25) under experimental conditions.

Table I— R Values Based on the Interaction Between Parabens and Macromolecules at 30°

Paraben	Macromolecules			<i>R</i> ^a
	Proportion	%	HLB	
Polysorbate 20–Sorbitan Monolaurate				
Methyl	92:8	5	16.0	3.84
Propyl	92:8	5	16.0	16.6
Polysorbate 80–Sorbitan Monooleate				
Methyl	70:30	5	11.8	3.44
Methyl	70:30	4	11.8	3.03
Methyl	58:42	5	10.5	3.15
Propyl	70:30	5	11.8	14.5
Propyl	58:42	5	10.5	15.5

^a Each R value represents an average of five to eight determinations.

After equilibration, an aliquot was removed from the nonmacromolecule side of the membrane and the concentration of the preservative was ascertained spectrophotometrically (16). Since the quantity of paraben added to the system was known, the amount on the macromolecule side was readily calculated by simple subtraction and the difference was taken as the amount bound or solubilized (12) by the macromolecules.

Preparation of Emulsion—The emulsions were prepared according to the formula 25% oil, 5% w/v emulsifier (4% in the case of castor oil), and sufficient distilled water or culture medium (as described in the following section) to make 100 ml. Because of high partitioning of propylparaben into almond oil and due to its high binding with the emulsifiers, 10% almond oil was used for microbiological work involving propylparaben-almond oil emulsion system. The emulsifier concentrations were selected to give the most stable emulsion with a minimum concentration of the emulsifying agents. Appropriate amounts of polysorbate 80 and sorbitan monooleate were blended to give the HLB (hydrophile-lipophile balance) values of: 10.5 for mineral oil, 16 for oleic acid, and 11.8 for almond oil and castor oil. Preliminary experiments using the procedure described in the literature (26) gave the above HLB values yielding the most stable emulsions. Polysorbate 80 was dissolved in warm aqueous phase, and sorbitan monooleate was dissolved in warm oil phase; both the phases were blended and passed 2-3 times through a hand homogenizer.

Microbiological Procedures—*Aspergillus niger*⁷ was selected as the principal microbe, and the synthetic culture medium used in this study was the same as described elsewhere (15).

Procedure for Dispersions—The minimum inhibitory concentrations (MIC) for methyl- and propylparaben were determined in the presence of dispersions of polysorbate 80 and sorbitan monooleate (or polysorbate 20 and sorbitan monolaurate) in culture medium. The emulsifiers were blended and aqueous dispersion was passed twice through a hand homogenizer. The binding data in terms of R values (total preservative/free preservative) as presented in Table I were used to predict the inhibitory concentration for the surfactant dispersions. The method of prediction and the general procedure have been described earlier (15). The growth of *A. niger* was observed for a 2-week period in the form of mycelial hyphae which were readily visible on the surface in the test tube.

Procedure for Emulsions—A convenient method for approximating the free preservative or the preservative in the aqueous phase in an emulsified system is an equilibrium dialysis technique which utilizes a membrane that permits the free passage of the preservative but is impermeable to the emulsifier and the oil. At equilibrium the activity of the preservative would be identical on both sides of the membrane; for reasonably dilute solutions, it may be assumed that the concentration of the free preservative on both sides of the membrane will be essentially equal. Thus, by placing an emulsion on one side of the membrane and determining the concentration of the free preservative on the opposite side, it is possible to approximate the concentration of free preservative in equilibrium with the emulsifier and the oil phase. Assumption is made that the

⁶ Fisher Scientific Co.

⁷ UAMH No. 1456, Provincial Laboratory of Public Health, Edmonton. Stock culture was grown on slants of potato dextrose agar.

Figure 1—Assembled dialysis cell containing emulsion in one compartment and culture medium in the other, separated by a cellophane membrane.

biologic activity of the preservative would parallel the concentration of free preservative.

A glass dialysis cell was constructed for growth studies; it consisted of two halves, each with a capacity of about 30 ml. Each half was prepared by fusing a 6-mm. ground-glass stopcock with the cylindrical end of a flat flange.⁸ To assemble the unit, a cellophane membrane was placed between the two halves and secured with the aid of a brass bracket. The assembled dialysis cell is portrayed in Fig. 1. Twenty milliliters of an appropriate concentration (0.065% methylparaben or 0.020% propylparaben) of the paraben in the culture medium was pipetted into one of the compartments. It should be noted that these concentrations correspond to the MIC of these agents for *A. niger* in the culture medium. The entire unit was sterilized by autoclaving at 15 lb. pressure for 15 min. (15). During sterilization, it was necessary to place the dialysis cell in a slant position with both ends kept open to avoid the rupture of the membrane due to pressure buildup at autoclaving temperature. The cell was allowed to attain room temperature with aseptic precautions and the compartment containing preservative solution was closed. Four such dialysis cells were prepared. A predicted inhibitory concentration of the preservative in the emulsion was computed using Eq. 5 and from the knowledge of binding and partition coefficient (23) data. A required amount of the preservative was dissolved in the emulsion. Three additional concentrations of the agent were prepared, one of which was lower and two higher than the above value (15). A 20-ml. sample of the emulsion was pipetted into the empty compartment of the dialysis cell. The unit was closed and equilibrated by overnight agitation at 30°.

The nonemulsion side of the dialysis cell was inoculated with two loopfuls of a spore suspension (15) of *A. niger*. The cells were incubated at 30°, and the growth in the form of mycelial hyphae was observed visually each day for a total period of 2 weeks. In some

Figure 2—Adsorption isotherms based on the interaction of methylparaben with 5% aqueous dispersion of surfactants. Key: A, polysorbate 80-sorbitan monooleate (58:42), HLB, 10.5; B, polysorbate 80-sorbitan monooleate (70:30), HLB, 11.8; and C, polysorbate 20-sorbitan monolaurate (92:8), HLB, 16.0.

cases there was a marked separation of the emulsion during incubation. This separation was prevented by agitation of the cells in a water bath at 30° during the 2-week period. Preliminary tests showed that the membrane was impermeable to *A. niger*, to any other organism which might be present in the emulsion, and to the emulsion itself. At the end of this experiment, a 1-ml. aliquot was moved from the nonemulsion side of the cell and the paraben content analyzed spectrophotometrically. The exact paraben concentration in the emulsion was then calculated.

RESULTS AND DISCUSSION

Interaction of Parabens with Surfactants—The interactions of methyl- and propylparaben with a dispersion of polysorbate 80 and

Figure 3—Adsorption isotherms based on the interaction of propylparaben with 5% dispersion of surfactants. Key: A, B, and C as defined in Fig. 2.

⁸ Quickfit FG 25.

sorbitan monooleate (or polysorbate 20 and sorbitan monolaurate) are shown in Figs. 2 and 3. These plots represent typical adsorption isotherms and similar isotherms for a methylparaben–polysorbate system have been reported (12). More useful data for the formulation work are presented in Table I. The ratio, R , of total/free paraben over the concentration range studied as shown in Figs. 2 and 3 is fairly constant. The results also demonstrate that varying proportions of the emulsifiers show a difference in the extent of binding. The R values can easily be obtained from these figures and the average of these values in each case was computed. The average R values are listed in Table I and have been found to be useful in computing the free preservative for a definite concentration of a macromolecule (15).

Inactivation by Surfactants Related to Binding—It has been established that parabens are inactivated in the presence of polysorbate 80 in aqueous solution due to binding or solubilization (12–15). A correlation between the predicted and experimental inhibitory concentrations of methyl- and propylparaben in the presence of 5% dispersion containing various proportions of polysorbate 80 and sorbitan monooleate (or polysorbate 20 and sorbitan monolaurate) is illustrated in Fig. 4. The proportion and the concentrations of the surfactants correspond to the HLB values and the concentrations used in the emulsions for microbiological work. The figure also shows the MIC of the parabens in the absence of the surfactants for the purpose of comparison.

As is evident, there is a significant inactivation of the parabens due to solubilization or binding by the surfactant dispersion. It can be noticed that the magnitude of inactivation increases from methyl- to propylparaben. This is reasonable since propylparaben is bound by the surfactants to a greater extent than methylparaben as shown in Figs. 3 and 4 and Table I (R values).

Correlation of the Binding and Partitioning Data with Inhibitory Concentrations—Figure 5 depicts a comparison of the experimental inhibitory concentrations of methyl- and propylparaben for emulsified systems and the concentrations predicted (using Eq. 5) from a knowledge of MIC in culture medium, the partitioning data, and the binding data. The results show that there is a reasonably good agreement between the predicted and experimental values. The difference in these values can be attributed to small variations in the partition coefficients and R values.

There are two factors responsible for the biologic availability of the antimicrobial agent in the emulsified system, namely the binding to the emulsifier and the partitioning into the oil. If one compares the magnitude of inactivation in Fig. 4 with that in Fig. 5, it is observed that for mineral oil emulsion the inactivation is due solely to the surfactants. This is to be expected since both methylparaben and propylparaben have mineral oil–water partition coefficient values lower than 1 (23). This might also explain the observed lower MIC values for both methyl- and propylparaben in

Figure 4—Comparison of predicted and experimental minimum inhibitory concentrations of parabens in the presence of 5% aqueous dispersion of surfactants. For comparison, the figure also shows the minimum inhibitory concentrations of the parabens in the absence of the surfactants. Key: A, B, and C as defined in Fig. 2.

Figure 5—Comparison of predicted and experimental minimum inhibitory concentrations of parabens in emulsified systems. Concentrations of oils and emulsifiers were 25% and 5% with the following exception: castor oil emulsion contained 4% total emulsifiers, and almond oil emulsion in the case of propylparaben consisted of 10% of the oil.

the case of mineral oil emulsions (Fig. 5) than those in the aqueous dispersion of the surfactants (Fig. 4).

The magnitude of inactivation of the parabens increased from oleic acid to almond oil to castor oil emulsion, primarily due to the increase in the partition coefficients of these oils. In Part I, the authors reported the oil–water partition coefficients for these oils as 4.4, 7.6, and 58, respectively. From the partitioning data, one would expect a greater difference in the MIC values of oleic acid and almond oil emulsions. However, this difference was reduced due to the higher binding capacity of the emulsifiers (Table I) in the case of oleic acid than those in almond oil emulsion. The greatest inactivation was observed in the case of castor oil emulsion because of the very high partitioning of methylparaben in this oil.

The degrees of binding and partitioning for propylparaben (23) are greater than those of methylparaben. Thus propylparaben was inactivated to a greater extent than methylparaben.

Although emulsions containing nonionic agents can be effectively preserved, there may be some practical limitations. The amount of preservative in emulsified systems with oil of high partition coefficient, and especially when the emulsifier has a high binding tendency, may affect the stability of the product or may be in the range to cause contact dermatitis (27) or may be prohibitive economically. Preliminary work indicated that the stability of emulsions containing nonionic surfactants which have a complexing tendency for parabens was seriously affected with increase in the concentration of paraben (28). Nevertheless, the knowledge of partitioning and binding data should permit evaluation in a product development laboratory so that the most efficient preservative is selected for a particular system. For example, it was found that the almond oil–water partition coefficients of methylparaben and sorbic acid were 7.5 and 3.3. Of the two preservatives, the nonionic emulsifier has less affinity for sorbic acid (15). Sorbic acid would be preferred as a preservative for vegetable oil emulsions, although pH of the system must be considered. Furthermore, as suggested by Riegelman (29), rather than using 5–10% of nonionic surfactants as the emulsifier, it would be advisable to attempt to formulate the emulsion with a much lower concentration of emulsifying agent and to attempt to stabilize the system with another agent with less affinity for the preservative.

Kinetics of Hydrus Aluminum Oxide Conversion in Mixtures of Amorphous Alumina Gels of Various Acid Reactivities

STANLEY L. HEM*, EMANUEL J. RUSSO, RICHARD J. HARWOOD†, BEHRAM H. TEJANI, SURENDRA M. BAHAL, and RALPH S. LEVI

Abstract □ Mixtures of two amorphous alumina gels of different acid reactivity change physically and chemically upon aging until a constant state is reached. The gels, when individually aged, retain their initial properties. The end-point appearance, viscosity, X-ray diffraction pattern, DTA thermogram, acid-insoluble fraction, and acid reactivity of the mixture are identical to those of the gel having the lower acid reactivity. The change in properties appears to be due to the conversion of the gel having the higher reactivity into the less reactive form. The rate of conversion is first-order, temperature-dependent, and directly dependent on the initial concentration of the less reactive gel.

Keyphrases □ Hydrus aluminum oxide conversion—kinetics □ Alumina gels, amorphous, effect— Al_2O_3 conversion □ X-ray diffraction—identity □ Calorimetry—analysis, gels

The physical and chemical properties of hydrus aluminum oxide depend on the nature of the reactants used in its formation (1, 2), the pH and temperature of

its precipitation (3–5), and the conditions under which it is aged (6, 7). The effects of mixing alumina gels of different physical and chemical properties have not been reported. Preliminary experiments in the authors' laboratories have indicated that when amorphous alumina gels of various acid reactivities are mixed, there are changes in the physical and chemical properties of the mixtures during aging. The purpose of the present study was to examine these changes in greater depth.

EXPERIMENTAL

Source of Gels—One alumina gel was prepared by the reaction of aluminum chloride with sodium carbonate and sodium bicarbonate at 25° and pH 5.8, according to the procedure of Papée *et al.* (8), and washed with deionized water until the concentration of chloride ion in the filtrate, as determined by the Volhard method (9), was less than 0.1%. This gel (I) possessed the full theoretical acid reactivity in terms of its Al_2O_3 content. Gels with reactivity less

^a Expressed as percent of theoretical acid-consuming capacity.

than theory were prepared by the addition of strong ammonia solution NF to aluminum chloride solutions at 25° and controlled pH. Gels reacting at 25% of theory (II) and 70% of theory (III) were obtained by precipitating at pH 7.7 and 4.9, respectively; washing as in (I); and aging until the end-point reactivity was reached (10). Aluminum hydroxide compressed gel (F-5000)¹ (IV) was obtained through normal commercial channels. This gel possesses 10% of theoretical acid reactivity. Aluminum hydroxide compressed gel (F-500)¹ (V) and aluminum hydroxide gel² (VI) were likewise obtained from commercial sources and were found to react stoichiometrically with 0.1 N HCl.

Gel Mixtures—Binary mixtures containing 4% w/w Al₂O₃ were prepared from the gels so as to contain various concentrations of the less acid-reactive components. Appropriate weights of I, II, and III were used, depending on the Al₂O₃ content. Gels IV, V, and VI

were diluted with distilled water to form 4% w/w suspensions prior to the preparation of the mixtures.

The mixtures were aged in sealed, screw-capped glass bottles at 60, 45, and 35°. The sample bottles were tared and the weight checked at every assay. No weight losses were noted.

Tests—The acid reactivity of each gel was described by its percentage of the theoretical acid-consuming capacity, based on the stoichiometric reaction of the Al₂O₃ with 0.1 N HCl. The precision of the USP acid-consuming capacity test (11) was improved by titrating to pH 3.5 rather than by using bromophenol blue T.S.

The X-ray diffraction pattern of each gel was obtained in the colloidal state by irradiating a sample in dialyzer tubing.

The insoluble gel fraction which remained after the acid-consuming capacity test was collected by filtration on a tared 0.45-μ Millipore filter.³ Two filters were used so that one could serve as a control. The control filter and the filter with the residue were dried to constant weight at 90° in a vacuum desiccator. The results were reported as the residue obtained from 1 g. of alumina gel.

The viscosity of the alumina gels was determined at 25° using the Haake Rotovisco,⁴ system mv. II, head 500, speed 162.

Thermograms of each alumina gel were obtained using a DuPont model 900 differential thermal analyzer.⁵ The gels were dried at 25° in a vacuum desiccator. A 2- to 3-mg. sample was introduced into a microcell and heated at a rate of 20° per min. to obtain the DTA thermograms.

RESULTS AND DISCUSSION

Mixtures of I and II—Initial Properties—Gels I and II differed physically and chemically in several significant aspects, as seen in Table I. X-ray diffractometer scans indicate that the solid material in the gels is noncrystalline. The broad diffuse band is typical of

**Figure 1**—Initial X-ray diffraction pattern of Alumina Gel I.**Figure 2**—Change in concentration of Alumina Gel I during aging of a mixture of 80% I and 20% II at 45°.

scattering by amorphous material (Fig. 1). Figure 1 is typical of the scans obtained for both individual gels and mixtures throughout this study. These properties of the individual gels did not change upon aging, even at elevated temperatures. The 1:1 mixture of I and II had properties equivalent to the sum of those of the individual gels. Subsequent examinations of this mixture were conducted to determine the changes which occurred during aging.

Changes in Acid Reactivity upon Aging—At 45°, all mixtures lost acid reactivity until a minimum (end-point) level was reached. For the 1:1 mixture of Gels I and II, this end-point level was 25% of theory and was observed after aging for 12 days at 45°. For mixtures of Gels I and II containing 10, 20, 40, or 50% of Gel II, prepared and aged at 35, 45, and 60° (Table II), the end-point reactivities were also 25% of theory. Since the end-point reactivity was independent of the temperature or the ratio of I to II, but was always identical to the acid reactivity of II, it is assumed that I converts to II during the aging of the mixtures.

Figure 3—Effect of percentage of II on the rate of change of I in a mixture of Alumina Gels I and II. Key: □, 60°; ●, 45°; and ■, 35°.

Under this assumption, the reactivity of mixtures of Gels I and II would be related to the amount of each present at time t by the following equation:

$$R_t = \frac{100I_t + 25[II_{init.} + (I_{init.} - I_t)]}{100}$$

where R_t = percent of theoretical acid-consuming capacity of the mixture at time t ; I_t = percent of I unchanged at time t ; $II_{init.}$ = percent of II in the initial mixture; $I_{init.}$ = percent of I in the initial mixture.

By rearranging the above equation, the amount of I present at any time in a mixture of I and II can be calculated and plotted. Such a plot shows that in a mixture initially containing 80% of I and 20% of II, I converts to II according to apparent first-order kinetics (Fig. 2).

Rate constants for the conversion of I to II in mixtures with various initial concentrations of II were calculated for mixtures aged at 35, 45, and 60°. The rate of conversion of I to II increased at all temperatures and was directly related to the initial concentration of II (Fig. 3).

The heat of activation for the conversion of I to II in a 1:1 mixture was calculated from Fig. 4 to be 26.2 kcal. mole⁻¹.

The effect of a change in temperature at which the acid reactivity test was conducted for the end-point mixture of I and II and for Gel II further indicates a conversion of I to II during aging. For example, the reactivity of II, which is 25% of theory at a test temperature of 37°, increased to 29.3% of theory when tested at 60°. The reactivity

Figure 4—Effect of temperature on the rate of change of I in a 1:1 mixture of Alumina Gels I and II.

Figure 5—Effect of aging of alumina gels on the weight of the acid-insoluble residues. Key: ●, 2:1 mixture of Alumina Gels I and II; and □, II.

of the end-point mixture of I and II also increased from 25 to 29.3% of theory when the test temperature was increased from 37 to 60°.

Effect of Aging on Other Physical and Chemical Properties—Table III shows that the physical and chemical properties of the 1:1 mixture of Gels I and II changed during aging at 45° until they reached the indicated end-point values. The end-point physical appearance, acid reactivity, residue remaining after the acid-consuming capacity test, and viscosity of the mixture were identical to those of Gel II. The same changes occurred in the 1:1 mixture of Gels I and II aged at 35 and 60° and in various other mixtures of I and II aged at various temperatures. The only effect of temperature or ratio of gels was to change the rate of conversion of I to II. In each instance, identical end-point properties were observed.

Acid-Insoluble Fraction after Aging—All gels having less than the theoretical acid-consuming capacity left an acid-insoluble residue at the completion of the acid-consuming capacity test. This residue was believed to consist of completely acid-refractory aluminum oxide. Its weight was determined during the aging at 45° of a 2:1 mixture of Gels I and II and of Gel II. The values obtained from triplicate assays, and the lines determined by least-squares analyses which best fit these points, are given in Fig. 5.

As shown in the figure, 8.6 mg. of acid-insoluble residue was recovered from 1 g. of a freshly prepared 2:1 mixture of Gels I and II containing 4% w/w Al_2O_3 . This agrees well with the expected result of 10 mg., which assumes that I leaves no residue and that II is 75% acid-insoluble. The weight of acid-insoluble residue increased as the mixture aged at 45° until a constant value of 27 mg. was reached, beginning at 13 days, which is approximately the same time that the acid reactivity of the mixture reached its end-point reactivity of 25% of theory. From this point on, the quantity of acid-insoluble residue recovered from the mixture was virtually identical to the weight of residue recovered from a 4% w/w suspension of II. For II, the acid-insoluble residue remained constant during aging. These data again indicate a conversion of I to II in the 1:1 mixture of Gels I and II.

Properties of Mixtures of Other Alumina Gels—To test the general hypothesis that in mixtures of amorphous alumina gels of various acid reactivities, the more reactive gel is converted into the less reactive, a series of mixtures were prepared and aged at 60° (Table IV). In all cases when two alumina gels of different acid reactivities were mixed, the mixture lost reactivity until it reached a constant end-point reactivity equal to that of the less reactive gel.

Clearly, in an aged mixture, the more acid-reactive gel is converted into the less reactive form. Since these gels are amorphous, the conversion does not involve a change in form but instead may be analogous to the polymorphic transformations which occur as a system converts to its more stable form upon aging. It can be assumed that a completely acid-refractory form is thermodynamically

Table IV—End-Point Acid Reactivity of Aged 1:1 Alumina Gel Mixtures^a

Alumina Gels in Mixture, together with % of Theoretical Acid-Consuming Capacity of Each Gel (in Parentheses)	% Theoretical Acid-Consuming Capacity after Mixture Aged at 60° for	
	2 Weeks	3 Weeks
I(100):II(25)	25	25
I(100):III(70)	68	69
III(70):II(25)	30	25
I(100):IV(10)	14	12
V(100):IV(10)	8	8
VI(100):IV(10)	8	8

^a All gels and the aged mixtures in this table were amorphous.

cally the most stable, and that acid reactivity and related properties are inversely proportional to the thermodynamic stability. Thus the observed conversion of the system reflects its attainment of the most stable state.

CONCLUSIONS

Mixtures composed of two individually stable amorphous alumina gels of different acid reactivities change physically and chemically upon aging until they reach a constant state. At this point, their properties are identical to those of the less acid-reactive gel. The same constant state is obtained independent of temperature, but the rate of change depends on temperature and on the initial concentration of the less reactive gel. It is hypothesized that the more acid-reactive gel converts to the less reactive gel according to apparent first-order kinetics. Since no changes in form are observed, the change may be thought of as analogous to the polymorphic transformations which occur as a system converts to its most stable state.

Determination of Radioactive-Labeled Codeine, Morphine, Dihydromorphine, and Their Metabolites in Biological Materials

S. Y. YEH and L. A. WOODS

Abstract □ Recoveries of ^{14}C -labeled morphine from aqueous solutions containing 1 to 500 ng. of drug (containing no ammonium ions) by extraction with three volumes of ethylene chloride containing 10, 20, or 30% of *n*-amyl alcohol were 82.9, 91, and 96%, respectively. Dihydromorphine was 79.1% extracted by ethylene chloride containing 30% *n*-amyl alcohol, and codeine, 97%, with all the above mentioned solvent mixtures. Complete hydrolysis of conjugated metabolites of morphine, codeine, or dihydromorphine was achieved by autoclaving samples in a portable autoclave at 18–20 lb. pressure for 2 hr. in a solution of 1.1 *N* HCl, or for 1 hr. in 2.2 *N* HCl, or 0.5 hr. in 3.3 *N* HCl. The conjugated metabolites were also completely hydrolyzed by treatment in a steam-jacketed autoclave at 20 lb. pressure for 0.5 hr. in 2.2 *N* HCl or 1 hr. in 1.1 *N* HCl. A procedure is described for the estimation of codeine and its metabolites, including morphine, in the same samples.

Keyphrases □ Codeine, metabolites—determination, biological samples □ Morphine, metabolites—determination, biological samples □ Dihydromorphine, metabolites—determination, biological samples □ Radioactive labeling—codeine, morphine, dihydromorphine, metabolites □ Scintillometry, liquid—analysis

Methods for determining codeine metabolites in biological samples have been described (1, 2). Johannesson and Woods (3) modified the procedure for estimating radioactive morphine (4, 5) to quantitate codeine metabolites in biological samples. Low recoveries of codeine metabolites, especially conjugated codeine and conjugated morphine, were obtained when using the hydrolysis procedure of Chernov and Woods (5) for biological samples. Incomplete hydrolysis of conjugated morphine in the early studies has been noted (6). The present paper describes conditions for complete hydrolysis of conjugated morphine, conjugated codeine, and conjugated dihydromorphine, and maximum extraction of codeine, morphine, and dihydromorphine in biological materials.

EXPERIMENTAL

Reagents—All reagents used were analytical grade. Toluene counting solution: 100 mg. of 1,4-bis-2(5-phenyloxazolyl)benzene (POPOP), and 3 g. of 2,5-diphenyloxazole (PPO) per liter of toluene; phenethylamine-methanol-toluene counting solution: 100 mg. of 1,4-bis-2(5-phenyloxazolyl)benzene (POPOP), 3 g. of 2,5-diphenyloxazole (PPO), 270 ml. of redistilled colorless phenethylamine (stored in an amber bottle less than 1 month after redistillation), 270 ml. of absolute methanol, and toluene to make 1 l.; naphthalene-dioxane counting solution (7): 60 g. of naphthalene, 4 g. of PPO, 200 mg. of POPOP, 20 ml. of ethylene glycol, 100 ml. of methanol, and dioxane to make 1 l.; NaOH solutions: 1.0–10.0 *N*; morphine carrier, 1 mg./ml. of morphine sulfate in distilled H_2O ; codeine carrier, 1 mg./ml. of codeine phosphate in distilled H_2O ; dihydromorphine carrier, 1 mg./ml. of dihydromorphine HCl in distilled H_2O ; N - $^{14}\text{CH}_3$ -morphine (5) solution in 0.01 *N* HCl; N - $^{14}\text{CH}_3$ -codeine (8) in 0.01 *N* HCl; N - $^{14}\text{CH}_3$ -dihydromorphine (9) in 0.01 *N* HCl; 40 and 4% anhydrous K_2HPO_4 solutions.

Determination of Free and Conjugated Morphine—*Estimation of Free Morphine*—Duplicates of 1-ml. aliquots of biological samples were placed in 40-ml. centrifuge tubes containing 1 ml. of H_2O and 0.5 ml. of nonlabeled morphine carrier. The samples were buf-

fered with 2 ml. of 40% K_2HPO_4 solution, shaken with 15 ml. of ethylene chloride containing 30% *n*-amyl alcohol in an International shaker at 280–300 oscillations per minute for 30 min., and centrifuged at 1700 r.p.m. for 15 min. The aqueous phase was removed by aspiration.¹ The organic layer was shaken by hand for 30 sec. with 5 ml. of 4% K_2HPO_4 solution. After the mixture was centrifuged for 15 min., the aqueous phase was removed by aspiration.

Ten-milliliter aliquots of the organic phase from each sample were transferred to 20-ml. scintillation-counting vials and evaporated to dryness on a Fisher slide-warmer at 55°. The residue was dissolved in 0.8 ml. *n*-amyl alcohol, 10 ml. of toluene counting solution was added, and the radioactivity of each sample was determined in a Nuclear-Chicago model 720 series liquid scintillator spectrometer for 3×10 min. Controls for background and known amounts of labeled morphine were run concurrently to serve as a check on the technique and the performance of the counter.

Known concentrations of 1–500 ng. of N - $^{14}\text{CH}_3$ -morphine were carried through the described extraction procedure and a linear relationship was obtained with the curve passing through the origin when net counts per minute (c.p.m.) or disintegrations per minute (d.p.m.) were plotted against the concentration. From the graph a factor converting c.p.m. or d.p.m. values to concentration was obtained for use in calculation of the drug present in biological materials.

Estimation of Total (Free plus Conjugated) Morphine—Duplicates of 1-ml. aliquots of biological samples, obtained after administration of morphine, were placed in 40-ml. centrifuge tubes containing 0.5 ml. of nonlabeled morphine. The mixture was autoclaved 1 hr. in 2.2 *N* HCl (final normality) at 18–20 lb. pressure in a portable autoclave (All-American portable pressure sterilizer, No. 25X, Wisconsin Aluminum Foundry Co.) and remained in the autoclave until the pressure dropped to 1–2 lb. The hydrolyzed samples were first carefully adjusted to pH 9 by saturating with NaHCO_3 powder and then buffered with 2 ml. of 40% K_2HPO_4 solution. The procedure for the determination of free morphine was then followed.

Conjugated morphine was calculated from the difference between the autoclaved and nonautoclaved biological samples.

Determination of Free Dihydromorphine and Conjugated Dihydromorphine—Free and conjugated dihydromorphine in biological specimens were determined according to the above procedure except using 0.5 ml. of nonlabeled dihydromorphine carrier instead of morphine carrier.

Determination of Codeine and Its Metabolites—*Estimation of Free Codeine plus Free Morphine*—Free codeine and the free morphine, metabolite of codeine in the biological samples, were estimated according to the procedure for determination of free morphine except that 0.5 ml. of nonlabeled codeine carrier instead of morphine carrier was used.

Estimation of Free Codeine—Free codeine in the biological samples was determined by modifying slightly the method for determination of free morphine and free codeine described above. Two milliliters of 0.5 *N* NaOH solution, instead of 2 ml. of 40% K_2HPO_4 solution, was added to the sample. The apparent morphine remaining in the aqueous phase as sodium morphinate was removed by aspiration. The organic phase was transferred to another tube and shaken with 4 ml. of 0.1 *N* NaOH solution instead of 4 ml. of 4% K_2HPO_4 solution. The counting procedure for determination of morphine was then followed.

Estimation of Total (Free plus Conjugated) Codeine and Total Morphine—Duplicates of 1-ml. aliquots of the biological samples were placed in 40-ml. centrifuge tubes containing 0.5 ml. nonlabeled

¹ If radioactivity remaining in the aqueous was to be estimated, this phase was completely separated and 0.5-ml. aliquots were counted with 10 ml. naphthalene-dioxane or phenethylamine-methanol-toluene solution.

Table I—Recovery of N - $^{14}\text{CH}_3$ -morphine, N - $^{14}\text{CH}_3$ -dihydromorphine, and N - $^{14}\text{CH}_3$ -codeine in Aqueous Solution with and without NH_4OH by Extraction with Ethylene Chloride Containing Varying Amounts of n -Amyl Alcohol^a

^a Samples contained 1 ml. of N - $^{14}\text{CH}_3$ -morphine (5080 \pm 107 d.p.m.) or N - $^{14}\text{CH}_3$ -dihydromorphine (8191 \pm 156 d.p.m.), or N - $^{14}\text{CH}_3$ -codeine (4778 \pm 79 d.p.m.) and 0.5 ml. nonlabeled drug carrier (1 mg./ml.), 2 ml. of 40% K_2HPO_4 solution and 1 ml. of distilled water or ammonium hydroxide solution as indicated. Quadruplicate samples were used for each experiment. ^b Duplicate samples were analyzed. ^c Four experiments (16 samples) were carried out. ^d Radioactivity in the aqueous phase of 4 out of 16 samples was measured in duplicate.

codeine carrier. The mixture was autoclaved in 2.6 N HCl at 18–20 lb. pressure in a portable autoclave for 1 hr. The hydrolyzed samples were carefully adjusted to pH 9.0 by saturating with NaHCO_3 powder and buffered with 2 ml. of 40% K_2HPO_4 solution. The procedure for estimation of free codeine and free morphine was then followed.

Estimation of Total Codeine—Total codeine in samples, which had been autoclaved and the pH adjusted to above 7.0, was estimated as free codeine.

Calculation of Codeine Metabolites—Free codeine was calculated from a standard curve prepared from known concentrations of N - $^{14}\text{CH}_3$ -codeine. Conjugated codeine was calculated from the difference between the samples determined for total codeine and for free codeine. Free morphine was estimated from the difference between samples extracted for free morphine plus free codeine and that for free codeine only. Conjugated morphine was obtained from the difference between samples analyzed for total morphine plus total codeine and for total codeine only, followed by the subtraction of the calculated amount of free morphine.

Estimation of Total Radioactivity—Total radioactivity in the sample was determined by counting 0.5-ml. aliquots with 10 ml. of naphthalene–dioxane counting solution or 10 ml. of phenethylamine–methanol–toluene solution. Toluene- ^{14}C was used as the internal standard. Disintegrations per minute (d.p.m.) of each sample were determined with the FORTRAN IV computer (10).

Statistical Evaluation—Duncan's new multiple-range test (11) was used for comparison of all the means.

RESULTS

Recoveries of Morphine, Dihydromorphine, and Codeine—The recoveries of morphine, dihydromorphine, and codeine from aqueous solution containing 0.5 mg. alkaloids and 1–500 ng. of radioactive-labeled drug by the described procedures were 96.0 \pm 1.8, 79.1 \pm 0.8, and 99.8–103.2%, respectively (Table I). The mean recoveries of morphine from aqueous solution containing 2.5 to 10.0 mg. of morphine were 94.0 \pm 1.5%. The results indicate that the solvent mixture is very efficient for extraction of these alkaloids.

The recovery of morphine from aqueous solution improved as the proportion of n -amyl alcohol was increased in the solvent mixture. Eighty-three percent of morphine was recovered with ethylene chloride containing 10% of n -amyl alcohol (Table I). One hundred-percent recovery of morphine with the same solvent mixture has also been reported (4). The higher recovery presumably was due to the salting-out effect of Na_2HPO_4 (5). The effect of saturation of NaCl or $(\text{NH}_4)_2\text{SO}_4$ on extraction of alkaloids from acidic solution has also been described (12). The presence of ammonium ions was found to decrease the extraction of morphine (Table I).

Separation of Codeine from Morphine—Codeine was extracted into the organic phase from an alkaline aqueous solution containing both codeine and morphine. The effect of alkalinity of the aqueous phase on the removal of morphine by the organic solvent mixture was such that it was necessary to add 2 ml. of 0.5 N NaOH solution and to transfer the organic phase to another tube to be washed with 4 ml. of 0.1 N NaOH solution.

Recoveries of morphine and codeine, or codeine alone, from samples containing known amounts of both codeine and morphine indicated that both codeine and morphine were quantitatively extracted into the organic phase when the pH of samples was adjusted to 9.0, and only codeine was extracted when the pH was adjusted to 12–13.

Hydrolysis of Conjugated Morphine, Dihydromorphine, or Codeine—The plasma, bile, and urine of dogs collected after s.c. injection of N - $^{14}\text{CH}_3$ -morphine and urine of rats after s.c. injection of N - $^{14}\text{CH}_3$ -codeine and N - $^{14}\text{CH}_3$ -dihydromorphine were used for hydrolysis studies. Autoclaving samples in 1.1 N HCl at 18–20 lb. pressure in a portable sterilizer for 0.5 hr. gave 60–70% hydrolysis of conjugated metabolites in biological samples. By increasing either the acid strength or the autoclaving time, hydrolysis of conjugated metabolites of each drug was increased (Tables II and III).

Complete hydrolysis of the morphine conjugate was achieved by autoclaving samples (a) in a portable autoclave at 18–20 lb. pressure in 3.3 N HCl for 0.5 hr., in 2.2 or 3.3 N HCl for 1.0 hr., or with 1.1, 2.2, or 3.3 N HCl for 2.0 hr. (Table II), or (b) in a steam-jacketed autoclave (American Sterilizer Co.) at 20 lb. pressure with 2.2 or 3.3 N HCl for 0.5 and 1.0 hr. or with 1.1 N HCl for 1.5 hr. (Table

^a Quadruplicate samples were autoclaved with HCl in a portable autoclave at 18–20 lb. pressure. The liberated drug was determined with the modified methyl orange dye method (16). ^b Three experiments with four samples each were done.

III). The recovery of morphine was lower than maximum when the samples were autoclaved with 2.2 or 3.3 *N* HCl in a steam-jacketed autoclave at 20 lb. pressure for 1.5 hr. and allowed to remain in the autoclave for 2 hr. (Table III). After extraction, the radioactivity remaining in the aqueous phase was approximately 10% of the total in the biological samples. This radioactivity may represent morphine altered chemically by the conditions of autoclaving.

Complete hydrolysis of isolated pure morphine-3-glucuronide, the major metabolite of codeine in rats or of morphine in rats, dogs, and man, and that of isolated pure morphine-3-ethereal sulfate, the major metabolite of morphine in cats, is accomplished under similar conditions as described above (Table IV).

Codeine-6-glucuronide, the major metabolite of the drug isolated from the urine of dogs (13), is hydrolyzed completely in 2.6 *N* HCl at 18–20 lb. pressure in a portable autoclave for 1 hr., or in 5.3 *N* HCl for 0.5 hr. (Table IV).

Determination of Radioactivity in Aqueous Samples—Total radioactivity was determined successfully by mixing 0.5-ml. aliquots of aqueous solutions, plasma, bile, urine, or fecal homogenate with either 10 ml. of dioxane-naphthalene solution or 10 ml. phenethylamine-methanol-toluene solution.

The results with the described procedure for analysis of *N*-¹⁴CH₃-codeine metabolites in the bile, urine, and fecal homogenate of rats have previously been reported (8).

DISCUSSION

The recovery of total morphine, dihydromorphine, or codeine by extraction with ethylene chloride containing *n*-amyl alcohol is dependent on complete hydrolysis of conjugated drug and the proper adjustment of pH and salt concentration in the hydrolyzed samples. Using NaOH solutions to adjust the hydrolyzed samples to pH 9–10 was somewhat tedious and laborious, involving some loss of samples due to testing the solution with pH paper. Ammonium hydroxide, instead of NaOH solution, had been used in these experiments to bring the hydrolyzed samples to pH 9–10. However, lower and inconsistent recovery of total morphine was observed, presumably due to the formation of ammonium morphinate salt which remained in the aqueous phase (Table I). The adjustment of autoclaved biological samples to pH 9 by saturating with NaHCO₃ was found to give most satisfactory results. The recovery of codeine was not affected by either the presence of NH₄OH ions in the system or by the amount of *n*-amyl alcohol.

Conditions used in previous studies for hydrolysis of conjugated morphine and its analogs varied considerably. The original work on hydrolysis of conjugated narcotics reported by Gross and Thompson (14) stated that 35–92% of the injected morphine could be recovered in the urine and feces of the dog after the biological samples had been autoclaved in 1.1 *N* HCl at 15 lb. pressure for 0.5 hr. Longer hydrolysis or use of stronger acid (up to 5.5 *N*) did not change the yield. The autoclave used by Gross and Thompson was presumed to be a steam-jacketed one. Identical conditions were

followed by most subsequent investigators (1, 15). Data have also been reported on hydrolysis of morphine conjugate in 1.1 *N* HCl in a steam-jacketed autoclave at 18 lb. pressure for 0.5 hr. (2, 16) or 25 min. (4); in 0.8 *N* HCl at 15–18 lb. pressure in a portable autoclave for 20 min. (5, 17); and in 4.1 *N* HCl on a boiling water bath for 0.5 hr. (18). The different results are probably due to the variability of hydrolysis conditions. The elevated temperature is prolonged in a steam-jacketed autoclave which has been switched off, while the temperature in a portable autoclave drops quickly to room temperature. Furthermore, the kinetics of degradation of morphine in aqueous solution have been shown to be dependent on the morphine concentration, on the concentration of oxygen, and on temperature (19).

The strength of the alkaline solution used by Johannesson and Woods (3) for extraction of codeine from aqueous solution containing codeine and morphine was found inadequate to remove morphine completely. In addition, with their procedure, 0.5 to 1.0 ml. of the alkaline solution residue remained on the top of the organic phase. Ten to twenty-five percent of the apparent morphine was extracted back to the organic phase when it was shaken with 4 ml. of 4% K₂HPO₄ solution. Conjugated morphine [45% of codeine injected in the rat (8)], a major metabolite of codeine, therefore would be mistakenly estimated as conjugated codeine.

Complexes of Ergot Alkaloids and Derivatives III: Interaction of Dihydroergocristine with Xanthine Analogs in Aqueous Media

H. V. MAULDING and M. A. ZOGLIO

Abstract □ The capacity of the poorly water-soluble ergot derivative, dihydroergocristine methanesulfonate, to form intermolecular complexes with caffeine, theophylline, and 7- β -hydroxypropyl-theophylline was studied. Upon inclusion of xanthine, dihydroergocristine exhibited elevated solubility at pH 6.65, a larger dissolution rate constant in 0.1 *N* HCl, and a change in partitioning-rate constants for transfer of the alkaloid from aqueous to organic phases. These alterations of physicochemical properties appear to be a consequence of mutual interaction between the two components in solution. The effect of dihydroergocristine was enhanced on enteral administration with each of the three complexing agents as measured on α -adrenergic blockade in cats. When tritiated dihydroergocristine was given orally to humans along with 7- β -hydroxypropyl-theophylline, blood levels went higher and stayed higher than when the alkaloid was administered alone. The same situation was true of total urinary excretion of tritium.

Keyphrases □ Ergot alkaloids—physicochemical analyses □ Dihydroergocristine, interacting—xanthine analogs □ Xanthine-dihydroergocristine complex formation—solubility effect □ Biological activity, dihydroergocristine—xanthines, effect □ Partitioning rates—dihydroergocristine-xanthine complex □ Colorimetric analysis—spectrophotometer

Previous studies in this area (1, 2) have attempted to correlate *in vitro* data with physiological responses observed on addition of caffeine and other xanthines to several ergot alkaloids and their congeners (3–5).

The present report is concerned with interactions occurring in solution between three complexing agents—caffeine, theophylline, and the soluble derivative 7- β -hydroxypropyl-theophylline—and dihydroergocristine methanesulfonate. Dihydroergocristine is one of the hydrogenated alkaloids of the ergotoxine group (6).

This work points to a good accord between physicochemical data derived from solubility, dissolution rate, and partitioning-rate studies and pharmacological results from human and animal investigations. The evidence appears to indicate complex formation leading to increased absorption rate, as well as the amount of absorption of many ergot derivatives in the presence of xanthines.

EXPERIMENTAL

Materials—Dihydroergocristine methanesulfonate¹ (mol. wt. 707.8) showed only traces of contaminants when subjected to thin-layer chromatography.

The various xanthines utilized were: 7- β -hydroxypropyl-theophylline,² m.p. 135–138°; theophylline,³ m.p. 272–274°; and caffeine anhydrous powder USP,⁴ m.p. 238°.

Melting points are uncorrected. Reagent grade chloroform (Mallinckrodt Chemical Works) was employed in the partitioning studies. A pH 6.65 buffer was made by dissolving 13.6 g. KH_2PO_4 in 500 ml. water, adjusting the pH with concentrated KOH, and diluting to 1 l. (ionic strength, 0.2).

The pH measurements were taken on a Metrohm pH meter and spectrophotometric data were obtained from a Cary model 14 spectrophotometer.

Partitioning Studies—A solution was prepared by placing dihydroergocristine methanesulfonate (150 mg.) in 950 ml. of pH 6.65 phosphate buffer, stirring magnetically for 30 min. to 1 hr, followed by filtration (Whatman No. 1 filter paper) into a flask immersed in a water bath maintained at 30°, and finally addition of pH 6.65 buffer to make 1 l. of solution.

This solution was immediately analyzed for dihydroergocristine (7) and read at 585 $m\mu$ (absorbance of 0.902 equivalent to 0.1 mg./ml.). The usual concentrations of alkaloid obtained in this manner were in the range of 0.06 to 0.09 mg./ml.; 500 ml. (half) of this solution of known concentration was kept and 500 ml. had xanthine added to it.

Fifteen milliliters of the freshly prepared aqueous phase—either with or without xanthine—was added carefully to 15 ml. chloroform in screw-capped vials (50 ml.). The vials were sealed and rotated at 6 r.p.m. in a 30° ($\pm 0.1^\circ$) water bath. Five-milliliter samples were taken at 3, 5, 7, 9, 11, 13, and 15 min. from the aqueous phase and analyzed for dihydroergocristine by the Van Urk method (7).

Solubility Studies—Dihydroergocristine (50 mg.) was placed in watertight, amber, screw-capped vials (50 ml.) containing exactly 10 ml. of pH 6.65 phosphate buffer and varying quantities of the three xanthines being considered. The vials were clamped onto the edge of metal disks (15-cm. diameter) mounted on a motor-driven shaft and rotated vertically at 6 r.p.m. in a constant-temperature bath, 30 $\pm 0.1^\circ$. After 24 hr., samples were taken using pipets with filters attached and analyzed for dihydroergocristine by the Van Urk method (7).

Figure 1—Solubilizing action of xanthine on dihydroergocristine in phosphate buffer (pH 6.65) at 30° for 24 hr. Key: \blacksquare , 7- β -hydroxypropyl-theophylline; \circ , caffeine; and Δ , theophylline.

Dissolution Rates—A 25-r.p.m. stirrer motor fitted with a 2.54-cm. propeller blade placed 4 cm. from the bottom of an 800-ml. beaker containing 500 ml. 0.1 N HCl solution was employed for these determinations. Dihydroergocristine (50 mg.) or the alkaloid in combination with xanthine, prepared by mixing 50 mg. alkaloid with 5 g. xanthine in a mortar, was placed into the stirred solution from a height of about 1.5 cm. The temperature was maintained at $37 \pm 0.1^\circ$ by immersing the beaker in a constant-temperature bath. Samples were withdrawn periodically for dihydroergocristine analysis in the usual manner (7).

RESULTS AND DISCUSSION

The solubility of dihydroergocristine methanesulfonate is elevated to some degree by all three xanthines examined at pH 6.65 as may be seen from Fig. 1. It is apparent (Fig. 1) that 7- β -hydroxypropyl-theophylline ultimately allows a greater solubilization of the alkaloid than caffeine or theophylline; however, this was not shown in concentrations greater than 50 mg./ml. xanthine because extremely large amounts are of little practical consequence. Caffeine leads to greater solubilization of the alkaloid than theophylline as it elevates the amount of dihydroergocristine in solution at this pH and temperature (30°) by almost 12 times, while theophylline increases the amount about 3 times. This was previously shown to be the situation with dihydroergotoxine (2). Curves as seen in Fig. 1 do not readily allow analysis by elegant treatments as those of Connors *et al.* (8, 9), thus leaving the exact nature of the complex in doubt.

It is recognized that dissolution rates of some solids may be the rate-limiting step in their absorption (10, 11). When ergot derivatives were subjected to dissolution-rate studies with and without the presence of xanthines, the rate constant was found to be increased nearly threefold in the first instance (1, 2, 5). The authors have previously found HCl (500 ml., 0.1 N) allows approximation of a first-order process with these substances. Figure 2 gives an example where a 100:1 ratio of 7- β -hydroxypropyl-theophylline to dihydroergocristine was utilized in the dissolution rate at a stirrer speed of 25 r.p.m. and 37°. The rate constants vary by a factor of 2.5:1 (0.053 to 0.138 min.⁻¹), which is in agreement with those previously reported (1, 2). Caffeine and theophylline gave almost the same ratios and results as those reported in Fig. 2 relative to the alkaloid, although they are not reported here. Therefore, for the conditions employed, there is evidence of a significant change in dissolution-rate constant on addition of xanthine to dihydroergocristine.

Figure 2—Effect of 7- β -hydroxypropyl-theophylline on the dissolution rate of dihydroergocristine in 0.1 N HCl (500 ml.) at 37° and 25 r.p.m. Key: \circ , the dissolution of dihydroergocristine, 50 mg.; and \bullet , the dissolution of dihydroergocristine, 50 mg., and 7- β -hydroxypropyl-theophylline, 5 g.

It was previously observed that xanthines had the effect of increasing the partitioning rate of ergot derivatives from an aqueous to an organic phase under certain conditions, although the equilibrium distribution was not disturbed (1, 2). Figure 3 gives an example of the action of 7- β -hydroxypropyl-theophylline in altering the partitioning rate of dihydroergotoxine methanesulfonate of which dihydroergocristine methanesulfonate is one of the three components (2). This phenomenon was noted with dihydroergocristine methanesulfonate itself in the presence of 7- β -hydroxypropyl-theophylline in a weight-weight ratio of 100:1 (xanthine-alkaloid) and the results may be seen in Fig. 4. The results in Fig. 4 show slopes of 2.5×10^{-2} min.⁻¹ and 5.1×10^{-2} min.⁻¹ for the alkaloid alone and with xanthine, respectively. Similar results were obtained with caffeine and theophylline and are not reported here. In 0.1 N HCl the rate was reversed as was found to be the case with ergotamine tartrate (1).

An investigation was made of the effect of increasing 7- β -hydroxypropyl-theophylline concentration on the partitioning-rate constants of dihydroergocristine methanesulfonate as the amount of xanthine goes from 0 to 500 times the weight of the ergot derivative

Figure 3—Effect of 7- β -hydroxypropyl-theophylline on the partitioning rate of dihydroergotoxine methanesulfonate from an aqueous (phosphate buffer, pH 6.65) to an organic phase (chloroform). Key: \bullet , dihydroergotoxine, 0.1 mg./ml.; \blacksquare , dihydroergotoxine, 0.1 mg./ml., and 7- β -hydroxypropyl-theophylline, 10.0 mg./ml.; ---, experimental run No. 1; and —, experimental run No. 2.

Dihydroergocristine methanesulfonate ^b	1	1	1	1	1	1
7- β -Hydroxypropyl-theophylline ^c	0	10	50	100	200	500
Rate constant $\times 10^{-2}$ min. ^{-1d}	2.5	3.0	4.4	5.1	5.8	6.6

^a All experiments carried out as mentioned in *Experimental* section with xanthine added after assay to determine alkaloid present. Concentrations of dihydroergocristine varied from 0.06 mg./ml. as mentioned.
^{b,c} Quantities given are measured on a weight to weight basis, i.e., 1:50 is 1 mg. dihydroergocristine and 50 mg. 7- β -hydroxypropyl-theophylline.
^d Rate constants and slopes thereof obtained by linear regression analysis from four experiments utilizing each ratio and run consecutively. Values were measured between 3 and 15 min.

in solution. The results are listed in Table I and show a general trend upward for the rate constants as the amount of xanthine is increased. A dose-effect relationship of this same type was encountered on enteral administration of dihydroergocristine to cats with a general increase in effect up to a 50:1 ratio (w/w) of xanthine to alkaloid followed by leveling up to a ratio of 200:1 (5).

Biological—The α -adrenergic blockade of dihydroergocristine methanesulfonate in cats was studied with and without xanthine present and this activity was enhanced on enteral administration of the alkaloid together with caffeine, theophylline, and 7- β -hydroxypropyl-theophylline. Significant increases in blocking action were noted at 7- β -hydroxypropyl-theophylline to dihydroergocristine ratios of 12.5:1 (w/w), the maximum effect being at 50:1 with no further increases on addition of excess complexing agent. This phenomenon was characterized by: (a) faster onset, (b) higher maximum, and (c) longer duration of action when the alkaloid and xanthine were administered concurrently. These differences were not encountered on i.v. dosing and are a result of increased dihydroergocristine absorption from the gut (5).

Tritiated dihydroergocristine was administered orally to five patients along with 7- β -hydroxypropyl-theophylline (1 mg. alkaloid and 100 mg. xanthine) and plasma levels were found to go higher and stay higher longer than when dihydroergocristine (1 mg.) was given alone. Total urinary tritium excretion was appreciably higher in the combination than in the case of the alkaloid itself; however, not much appears to be unchanged dihydroergocristine (5).

Effect of pH on the Micellar Properties of a Nonionic Surfactant

J. R. BLOOR*, J. C. MORRISON, and C. T. RHODES†

Abstract □ The effect of change in pH on the critical micelle concentration of a nonionic surfactant (Tween 40) has been investigated by surface tension and light-scattering methods. It is shown that a linear relationship exists between the free energy of micellization and pH. Significance of changes in the enthalpy and entropy of micellization are discussed. A computer program, written in Algol 803, is presented to convert raw experimental light-scattering data to micellar molecular weights. It is shown that both micellar molecular weight and the hydration per unit mass of surfactant decrease with increase in pH value. Interpretation of these results is discussed.

Keyphrases □ Nonionic surfactant—micellar properties, pH effect □ Micellar properties, nonionic surfactants—pH effect □ Surface tension method—pH effect, micelle concentration □ Turbidity method—pH effect, micelle concentration □ Refractive index—determination □ NMR—identification □ Computer program—conversion of light-scattering data to micellar molecular weights

Surfactants are widely used in pharmaceutical technology as wetting agents, solubilizers, and emulsifiers. Thus, studies of the properties of surfactants are of assistance in placing pharmaceutical formulation on a rational rather than an empirical basis (1). Also, naturally occurring surfactants, as found for example in bile and gastric juice, can have a significant effect upon drug absorption rates and other aspects of drug action (2). Kakemi *et al.* have attributed the retarded absorption of sulfonamides from aqueous solutions of a nonionic surfactant to micellar entrapment of drug (3). It has also been suggested that surface-active bile salts transport lipids by micellar solubilization (4). Surfactants can therefore play an important part in the biotransport of drugs. In the present paper the effects of pH upon a number of micellar properties of a nonionic surfactant are reported. This work forms part of a study of drug diffusion in micellar solution, further results of which will be published shortly (5). In addition to the value which the results reported in this paper have for diffusion studies, the data are of use in further elucidating the micellar structure of nonionic surfactants and in identifying the forces involved in micellar aggregation.

EXPERIMENTAL

Materials—A polyoxyethylene sorbitan monopalmitate¹ was characterized by NMR spectroscopy. The solvent used was D₂O, and the sodium salt of tetramethylsilane was used as the internal reference. Mean molecular surfactant formula was estimated by the method previously described by Rhodes (6).

The water used in this investigation was double distilled from an all-glass still.

Both the sodium chloride and benzene used in this work were of AnalaR grade.

Table I—Characterization of the Surfactant by NMR Spectroscopy

Formula Claimed by Manufacturers	Formula Calculated Using Methyl Protons as Reference	Formula Calculated Using Sorbitan Ring Protons as Reference
Alkyl protons 31 Polyoxyethylene protons 20	30 (.4) 20 (.0)	31 (.1) 19 (.5)

Surface Tension Measurements—The critical micelle concentrations (CMC) values of the surfactant at various temperatures and pH values were determined by use of a Du Nouy tensiometer (7). Experimental technique was checked by measuring the surface tension of water which was found to be 72.0 dynes cm.⁻¹ at 25°. This was in excellent agreement with the literature value (8). The temperature was controlled at all times to ±0.1° of that required.

Light Scattering—Turbidities were measured using a Brice-Phoenix Universal light-scattering photometer² using unpolarized incident light, wavelength 436 mμ, and a standard 30 × 30-mm. turbidity cell. Temperature during determination of turbidities was maintained at ±0.1° of that required. The photometer was calibrated against an opal glass diffuser as a primary reference standard. For benzene the observed Rayleigh ratio was found to be 48.8 × 10⁻⁶ cm.⁻¹ which was in good agreement with the previously reported value (9). All solutions were clarified by filtration through Millipore cellulose membrane filters (0.1 μm pore size). Dissymmetries $Z(I/45^\circ/I135^\circ)$ where I is the intensity of scattered light) were determined for each solution using a standard 40 × 40-mm. semioctagonal cell.

Refractive Index Measurements—The refractive indices of surfactant solutions were determined using a Hilger and Watts interference refractometer³ with ±0.1° temperature control. Calibration was effected using sodium chloride as standard (10).

RESULTS AND DISCUSSION

The results of the NMR characterization of the surfactant (Table I) show that the mean molecular formula determined experimentally is in good agreement with that stated by the manufacturers. Absence of signals, other than those assigned to the surfactant (5.8 p.p.m. sorbitan ring protons, 6.3 p.p.m. polyoxyethylene protons, 8.7 p.p.m. alkyl protons, and 9.1 p.p.m. terminal methyl protons), is supporting evidence for the manufacturers' formula.

Plots of surface tension and turbidity against surfactant concentration showed abrupt changes of slope at the CMC; typical results are shown in Figs. 1 and 2. Results obtained by the two methods are in good agreement with one another and literature values (11).

Table II records the CMC values for the surfactant at various pH values and temperatures. Methods for calculating the thermodynamic parameters of micellization from CMC values and solubilization data have been discussed in some detail by Molyneux *et al.* (12) and Humphreys and Rhodes (13). Subject to activity corrections, which for a nonionic surfactant are probably small, the free energy of micellization, ΔG_m , may be calculated by use of Eq. 1:

$$\Delta G_m = -RT \ln K \quad (\text{Eq. 1})$$

² Supplied by Techmation Ltd., London, England.

³ Supplied by Hilger and Watts Ltd., London, England.

¹ Tween 40, supplied by Honeywell-Atlas Ltd., Carshalton, England.

Figure 1—Surface tension as a function of log surfactant concentration at 25°.

where R is the gas constant, T the absolute temperature, and K the CMC expressed in terms of mole fraction. Figure 3 shows the ΔG_m values for the surfactant as a function of pH. A linear relationship between these two quantities is apparent. When data are available on the variation of K with temperature, it is possible to resolve ΔG_m into the enthalpic and entropic, ΔH_m and ΔS_m , factors by means of Eq. 2:

$$\Delta G_m = \Delta H_m - T\Delta S_m \quad (\text{Eq. 2})$$

Estimates of these quantities have been made (Table III). Because of the small temperature difference, 15°, used in this work, high-precision estimates of ΔH_m and ΔS_m are not possible. However, the values are of use for qualitative interpretation of micellar structure.

The average micellar molecular weight, \bar{M}_w , was determined from turbidities measured at 90° by extrapolating the Debye function to zero micellar concentration (14, 15):

$$H(C - C_0)/(\tau - \tau_0) = 1/\bar{M}_w \lim (C - C_0) \rightarrow 0 \quad (\text{Eq. 3})$$

where H is a constant for any given surfactant system under specified instrumental and environmental conditions, C is the surfactant concentration, C_0 is the CMC, τ is the turbidity at 90°, and τ_0 is the turbidity at 90° at the CMC. Plots of the Debye function against $(C - C_0)$ are governed by Eq. 4:

$$H(C - C_0)/(\tau - \tau_0) = 1/\bar{M}_w + 2B(C - C_0) \quad (\text{Eq. 4})$$

The term B , the second virial coefficient, represents the deviation from ideal behavior. The value of H is evaluated from Eq. 5:

$$H = \{32\pi^2 n^2 [(n - n_0)/C]^2\} / (3\lambda^4 N) \quad (\text{Eq. 5})$$

where C is the solution concentration in g./ml.; n is the refractive index of the solution, n_0 is the refractive index of the solvent, λ is the wavelength of the incident light in cm., and N is Avogadro's number.

A computer program has been written in Algol 803 to substitute raw input data, surfactant concentration, turbidities, refractive

Figure 2—Turbidity as a function of surfactant concentration at 25° and pH 2.1.

index measurements, and relevant constants into the above equations. Using least-squares procedures the program causes the determination of the best line for the refractive index against concentration plot and the plots of Debye function against concentration. Samples of input and output data together with the program are given in the Appendix. Dissymmetry ratios were always close to unity, less than 1.03. These values confirmed the clarity of the solutions and substantiated the validity of the experimental procedure. Debye plots are shown in Fig. 4.

Figure 5 shows that a substantial change in micellar molecular weight occurs with change in pH. The values of \bar{M}_w reported do not include water of hydration because the refractive index of the hydrated water is very close to that of the solvent. However, as shown in Fig. 6, the second virial coefficient shows a significant decrease in value with increase in pH. This shows that the solvent-solute interaction is greater at low pH values, indicating more micellar hydration than in alkaline solution. Thus, both the aggregation number and amount of water bound per unit mass of surfactant are greater in acid solution.

In interpreting these results the effect of pH upon water structure is probably a critical factor. There is evidence that sodium and hydroxyl ions are structure-formers which thus increase the extent of water structure around the monomeric surfactant (16).

Figure 3—Free energy of micellization at 25° as a function of pH.

Table II—Critical Micelle Concentrations of the Surfactant

Temperature	pH	Critical Micelle Concentration (molar) $\times 10^5$
25	2.1	6.5
25	5.0	4.1
25	7.4	3.7
25	9.2	2.6
25	12.1	2.2
40	2.1	4.9
40	12.1	1.4

Figure 4—Debye plots. Key: pH 2.1, ○; pH 5.2, ▲; pH 7.3, ●; pH 9.8, □; and pH 11.9, △.

Chloride ions, however, are considered to be structure-breakers. The observed values for entropy of micellization will, of course, be greatly dependent upon the extent of water structure around the monomeric surfactant, as well as the structure and order of the micelle. Since the micelle is hydrated to a greater extent in acid solution, it is most likely that the palisade layer has a more open and flexible, and thus less ordered, structure than at high pH values. It is thus unlikely that the micelle in acid solution has a lower configurational entropy than that in alkaline solution since the structure of the hydrocarbon core is very probably independent of pH (12). This discussion is supported by the experimentally observed values of ΔS_m , 5 e.u. at pH 2.1 and 18 e.u. at pH 12.1, the larger entropy change being provisionally assigned as due to the greater degree of water structure at higher pH.

The enthalpy of micellization may be further resolved as shown in Eq. 6:

$$\Delta H_m = \Delta H_m^1 + \Delta H_m^2 \quad (\text{Eq. 6})$$

where ΔH_m^1 is the enthalpy change associated with the hydrophobic part of the surfactant and ΔH_m^2 is the enthalpy change associated with the head group. The difference in the estimated ΔH_m at pH values 2.1 and 12.1 which are -6.7 and -3.4 kcal. mole $^{-1}$, respectively, may therefore be expected to be due to several factors. Wurzhmitt (17) has suggested that nonionic surfactants are in fact weakly cationic in nature. The ionic nature of the head group and the extent of palisade layer hydration may thus be expected to be pH dependent. Since a greater amount of water structure is believed to exist around the surfactant molecules at high pH, the enthalpy change associated with

Figure 5—Change in micellar molecular weight of surfactant with pH at 25°.

Table III—Thermodynamic Parameters Controlling the Micellization

pH	ΔG_m kcal. mole $^{-1}$	ΔH_m kcal. mole $^{-1}$	ΔS_m cal. mole $^{-1}$ $^{\circ}\text{K}^{-1}$
2.1	8.2	6.7	5
12.1	8.7	3.4	18

Figure 6—Variation of second virial coefficient with pH.

the destruction of this "iceberg sheath" (18) would be expected to be greater than at low pH values. However, the enthalpy values shown in Table III are greater at low pH. Thus the other factors involved must more than compensate for this effect.

The reasons for the higher aggregation number at low pH cannot be precisely delineated at the present time. It may be that geometric limitations imposed by the differences in hydration with pH play a significant role. For a spherical micelle, changes in the hydration and thus in the size of the palisade layer must be accompanied by alteration in the aggregation number if the density of the hydrocarbon core is to remain constant.

There is no reason to suppose that the nonionic surfactant investigated in this study is unique of its type. It is therefore probable that other nonionic surfactants show similar significant changes in micellar properties with pH. Further work is necessary to see if the hypotheses outlined in this paper are of general applicability. In particular, information about the pH dependence of the interaction with drugs and the effect upon drug diffusion and transport is of considerable pharmaceutical relevance.

APPENDIX

The following computer program converts experimental light-scattering data into micellar molecular weights. The comment statement in the programs defines the symbols and explains the form of the input data.

DRUG STANDARDS

Trifluoperazine Tablets: Alternative Methods of Analysis

J. R. WATSON, FUMI MATSUI, and W. N. FRENCH

Abstract □ Procedures utilizing a direct spectrophotometric measurement (such as described in the British Pharmacopoeia) for the analysis of trifluoperazine tablets suffer from several disadvantages. The possibility of excipient interference is not precluded and this factor, coupled with use of a fixed reference absorptivity value, can sometimes lead to erroneous results. Therefore, alternative assay procedures are required to assess accurately the drug content. Two such methods are described. The first is the acid-dye type and involves the partitioning of a trifluoperazine-bromocresol purple complex between an aqueous buffer pH 6 and benzene containing 1% isoamyl alcohol and subsequent measurement of the yellow-colored organic phase at 410 mμ. Acidic and neutral compounds as well as the common excipients do not interfere. The second method employs an alkaline siliceous earth column through which the drug is eluted into a chloroform-methanol-HCl system and the absorbance measured at 259 mμ. The precision and accuracy of the alternative methods, as well as the pharmacopoeial procedure are compared using commercial dosage forms and simulated drug-excipient mixtures.

Keyphrases □ Trifluoperazine tablets—analyses □ Acid-dye method—trifluoperazine analysis □ Column chromatography—analysis □ UV spectrophotometry—analysis □ Colorimetric analysis—spectrophotometer

The current BP method for the analysis of trifluoperazine hydrochloride tablets (1) involves dissolution of an aliquot sample of 20 powdered tablets and direct

spectrophotometric measurement of the filtrate at 256 mμ using a fixed reference absorptivity value. Although the method is satisfactory in most cases, it suffers from the disadvantage of possible interference from excipients and also from both inter- and intrainstrumental variations. The latter variations may be considerable (2, 3) and introduce unsuspected error into the assay. Therefore, alternative assay procedures which are relatively free from interference and instrumental variation are required on occasion for products with assay results that are suspect by the pharmacopoeial method.

While several methods have been reported in the literature as general procedures suitable for the analysis of piperazinyl phenothiazine drugs in pharmaceutical dosage forms and in biological media, there are virtually no data on their direct application to the analysis of trifluoperazine hydrochloride tablets. Blazek and Mares (4) determined drugs of the piperazinyl phenothiazine type gravimetrically by precipitation with silicotungstic acid or by electrochemical titration against the same reagent. Other electrochemical methods include controlled-potential coulometric analysis (5) and polarography (6), the latter being reported as having an accuracy of $\pm 5\%$ when applied to trifluoperazine hydro-

The second method employs an alkaline siliceous earth column through which the drug is eluted into a chloroform-methanol-HCl system and the absorbance measured at 259 mμ. The precision and accuracy of the alternative methods, as well as the pharmacopoeial procedure are compared using commercial dosage forms and simulated drug-excipient mixtures.

Keyphrases □ Trifluoperazine tablets—analyses □ Acid-dye method—trifluoperazine analysis □ Column chromatography—analysis □ UV spectrophotometry—analysis □ Colorimetric analysis—spectrophotometer

The current BP method for the analysis of trifluoperazine hydrochloride tablets (1) involves dissolution of an aliquot sample of 20 powdered tablets and direct

spectrophotometric measurement of the filtrate at 256 mμ using a fixed reference absorptivity value. Although the method is satisfactory in most cases, it suffers from the disadvantage of possible interference from excipients and also from both inter- and intrainstrumental variations. The latter variations may be considerable (2, 3) and introduce unsuspected error into the assay. Therefore, alternative assay procedures which are relatively free from interference and instrumental variation are required on occasion for products with assay results that are suspect by the pharmacopoeial method.

While several methods have been reported in the literature as general procedures suitable for the analysis of piperazinyl phenothiazine drugs in pharmaceutical dosage forms and in biological media, there are virtually no data on their direct application to the analysis of trifluoperazine hydrochloride tablets. Blazek and Mares (4) determined drugs of the piperazinyl phenothiazine type gravimetrically by precipitation with silicotungstic acid or by electrochemical titration against the same reagent. Other electrochemical methods include controlled-potential coulometric analysis (5) and polarography (6), the latter being reported as having an accuracy of $\pm 5\%$ when applied to trifluoperazine hydro-

chloride formulations. Quantitative paper chromatography involving colorimetric measurement at 610 $m\mu$ of the complex formed between the drug and potassium iodoplatinate after elution from the chromatogram was applied to several of the phenothiazine-type drugs by Nadeau and Sobolewski (7). Piperazinyl phenothiazine compounds could be detected in submicrogram quantities by gas chromatography (8) and spectrofluorometry (9), but these techniques have yet to be developed into precise analytical methods.

While the above procedures perhaps could be employed in some instances for the analysis of trifluoperazine hydrochloride tablets, in general they are not sufficiently rapid and accurate or else require the use of equipment which may not be readily available to the analyst.

In the present study, two alternative assay procedures were considered. The first assay procedure is of the acid-dye type and involves the partitioning of a trifluoperazine-bromocresol purple complex between an aqueous buffer of pH 6 and benzene containing 1% isoamyl alcohol, and subsequent measurement of the organic phase at 410 $m\mu$. The second method employs an alkaline-siliceous earth chromatographic column from which the drug is eluted with chloroform (10) and the absorbance measured at 259 $m\mu$. In addition, the use of ultrasonic energy was investigated as a rapid and convenient means to break up the solid dosage form and prepare the sample solution.

In order to measure the accuracy and precision of each technique and to compare against the direct UV procedure (BP method), stock sample solutions were prepared using the ultrasonic disintegration apparatus and aliquots of the filtered solution treated simultaneously by each of the assay procedures.

EXPERIMENTAL

A. Preparation of Sample Solutions—For each product examined, 10 tablets were selected at random and the active ingredient dissolved in a sufficient volume of 1% (v/v) HCl to give a concentration (based on label claim¹) of approximately 23.6 mg. of salt or the equivalent of 20 mg. of base per 100 ml. (i.e., 10 \times 1-mg. tablets in 50 ml, 10 \times 2 mg. in 100 ml., 10 \times 5 mg. in 250 ml., 10 \times 10 mg. in 500 ml., and 10 \times 20 mg. in 1000 ml.).

Disintegration of the tablets and dissolution of the drug were accomplished with an ultrasonic probe of 1.27-cm. (0.5-in.) diameter (clamped in a vertical position, tip downward) powered by a 200-w.

generator.² A basket assembly constructed of stainless steel wire mesh (30 mesh), 5.08 cm. (2 in.) in length and internal diameter slightly larger than the probe, was used to hold each tablet in the area of maximum sonic energy emission. A small rod attached to the basket assembly served as an arm to hold the basket in place during insonation.

In practice, each of the 10 tablets was insonated individually. The first tablet was placed in the wire basket assembly and the basket brought up over the probe so that the tablet came in contact with the tip. A beaker containing the appropriate amount of solvent was raised so that the basket was about half immersed. Ultrasonic energy was applied for 30 sec. at a power setting of 30% maximum with manual tuning for optimum output. This insonation process was repeated until all 10 tablets had been disintegrated. The resulting suspension was stirred briefly and then filtered through a 25-mm. membrane filter of 0.45- μ porosity (with a 1-mm. thick prefilter) using a 5-ml. syringe fitted with a continuous pipeting device. Aliquots of this solution after filtration were subsequently taken for analysis by the chromatographic column procedure, by direct UV measurement, and by the acid-dye technique.

Simulated drug–excipient mixtures were prepared by adding 10 ml. of a solution of trifluoperazine hydrochloride (accurately weighed and made up to a concentration of about 11.8 mg./10 ml. 1% HCl) to 25 ml. of filtered solution prepared as above from insonation of placebos, and adjusting the volume to 50 ml. with 1% HCl (final concentration approximately 23.6 mg. salt/100 ml.). For each successive mixture (Table I), the number of placebos was increased to give about 9% overestimation with the direct UV procedure.

B. Assay by Direct UV Measurement—An aliquot of the filtered sample solution prepared in Part A was diluted twentyfold with 1% HCl to give a concentration (based on label claim) of about 1.18 mg. of salt/100 ml. Dilution was facilitated by the use of an automatic dilutor³ adjusted for a diluent to sample solution ratio of 19:1. The absorbance of the final solution was measured at 256 $m\mu$ against a blank of 1% HCl. The average drug content per tablet was determined by comparison against the average absorptivity value obtained from three separate solutions containing trifluoperazine hydrochloride reference material. For each solution, about 50 mg. of standard (accurately weighed) was made to a volume of 250 ml. in 1% HCl. A twentyfold dilution was made as described with the automatic dilutor.

C. Assay by the Acid-Dye Technique—Reagents—(a) Buffer solution, pH 6.0 (McIlvaine): 7.37 ml. of 0.1 *M* citric acid plus 12.63 ml. of 0.2 *M* Na₂HPO₄. (b) Bromocresol purple (BCP) in buffer solution: bromocresol purple dissolved in buffer solution of pH 6.0 to give a concentration of 37.5 mg./100 ml. This solution was extracted with benzene containing 1% isoamyl alcohol until the extract was virtually colorless. (c) Photometric solvent: benzene (A.R.) containing 1% isoamyl alcohol (A.R.) by volume.

Procedure—An aliquot of the filtered sample solution prepared in Part A was diluted tenfold with 1% HCl to give a concentration (based on label claim) of about 118 mcg. of salt per 5 ml. A 5.0-ml. aliquot of this final solution was pipetted into a 42-ml. centrifuge tube along with 5.0 ml. of buffer pH 6, 5.0 ml. of BCP solution, and 10 ml. of photometric solvent (the latter dispensed from an automatic dispenser for convenience). The tube was stoppered and tumbled end-over-end for 5 min. in a device constructed to rotate 15 tubes simultaneously at 100 r.p.m. (alternatively, the stoppered tubes may be shaken vigorously by hand for 1 min.). After mixing, the tube was centrifuged for 2 min.; then the clear supernatant was decanted carefully into a clean dry cell for measurement of absorbance at 410 $m\mu$ against a blank prepared in the same manner using 5 ml. of 1% HCl. At the same time, 5.0 ml. of standard reference solution containing approximately 120 mcg. of trifluoperazine hydrochloride (accurately determined from the initial weighing) was carried through the assay procedure. The average drug content per tablet was determined by comparison of the absorbance of the sample solution against that of the standard reference solution.

D. Assay by the Alkaline-Siliceous Earth Column Procedure—Pretreatment of Diatomaceous Earth⁴—Acid-washed diatomaceous earth (100 g.) was placed in a 64 \times 150-mm. medium-porosity

¹ Tablets were labeled to contain trifluoperazine hydrochloride with the dosage level expressed as the equivalent amount of base.

⁴ Celite 545, Johns-Manville, New York, N. Y.

sintered-glass funnel and 1000-ml. portions of 1:1 hot (boiling) aqueous HCl passed through with the aid of gentle suction. Five hundred milliliters of hot water was then passed through, followed by 1000 ml. of hot 1 N NaOH, 500 ml. of chloroform, and 1000 ml. of water. The treated diatomaceous earth was dried for 15 hr. at 110°.

Preparation of Partition Columns—Six grams of the purified diatomaceous earth was mixed well with 2 ml. of 20% NaOH in a small beaker and the damp mass transferred to a 25 × 220-mm. glass column containing a pledget of glass wool at the base to support the diatomaceous earth. The mixture was firmly tamped to produce a column free of air pockets and irregularities.

Procedure—A 4.0-ml. aliquot of the filtered sample solution prepared in Part A was pipeted directly on the surface of the column and allowed to soak in. Water-washed chloroform (90 ml.) was then passed through the column and collected in a 100-ml. volumetric flask containing 8 ml. of methanol and 4 drops of concentrated HCl. The contents of the volumetric flask were made to volume with water-washed chloroform and the absorbance measured at 259 mμ against a blank prepared in the same manner. The average drug content per tablet was determined by comparison against the absorptivity of a reference standard solution prepared in the same manner.

RESULTS AND DISCUSSION

Sample Preparation—Spectrophotometric analysis of drugs in a solid dosage form involves two main steps: the first is to effect quantitative dissolution of the active ingredient from the tablet matrix and the second is to prepare the solution in a suitable form (*i.e.*, clarity and concentration) for final measurement. The techniques used to achieve these goals ultimately govern the overall accuracy and precision of the method.

The current pharmacopeial directive for extracting trifluoperazine hydrochloride from excipient material entails finely grinding 20 weighed tablets and shaking an aliquot of the powder equivalent to about 5 mg. of the drug for 15 min. with 5% HCl. The mixture is then made up to a specified volume with the same solvent, mixed, filtered, and the absorbance measured at 256 mμ. Several factors inherent to this type of sampling sequence tend to diminish the accuracy and precision of the analysis. First are the errors in weighing and those associated with mechanical loss and non-homogeneous grind. In some cases, there is the added problem of incomplete dissolution of the active drug because of insufficient particle breakup. The use of ultrasonic disintegration as a sampling tool not only precludes the above difficulties but is more rapid and less tedious than the conventional technique. The fact that 1% HCl invariably gave the same assay results as 5% HCl, and because the former acidity was more compatible with the requirements of the acid-dye extraction method and the alkaline-siliceous earth column procedure, militated against the use of the stronger pharmacopeial solvent. Before adopting the ultrasonic technique for routine analytical use, it was necessary to establish its feasibility for the phenothiazine drugs in general and trifluoperazine in particular because there are several well-documented cases in the literature where the ultrasonic field induced chemical changes in the sonified material. For example, the rate of hydrolysis of aspirin was increased when the drug was subjected to ultrasound (11, 12). Skauen (13) has reviewed other instances where ultrasonic waves under certain conditions affected the chemical integrity of medicinal compounds. Because of the lability of most compounds of the phenothiazine family, it was deemed essential to monitor the absence or presence of any destructive action on the trifluoperazine molecule associated with the high-energy emission from the probe. This was done by: (a) comparing the thin-layered chromatograms (14, 15) of powdered and sonified tablets; developing systems used were benzene-dioxane-aq. NH₃ (60:35:5) giving $R_f = 0.69$, and *n*-BuOH saturated with 1 N NH₃ giving $R_f = 0.51$; in no instance were any spots found in the sonified material which were not present in the powdered sample; and (b) comparing the assay results using the shakeout procedure against those using the ultrasonic-disintegration technique; within experimental error and content uniformity variations, these were in good agreement (usually within 2%). The data, therefore, gave no evidence to suggest any decomposition of any brand of trifluoperazine tablets resulting from exposure to ultrasonic energy under the conditions employed.

Figure 1—Effect of dye concentration on absorbance (varying quantity of dye but fixed concentration of drug).

The official compendium does not specify the type of filtration in the monograph for trifluoperazine tablets. With certain formulations where gravity filtration through Whatman No. 2 paper was employed, the filtrate appeared as a fine opalescent suspension, a situation which could conceivably lead to erroneously high results despite subsequent dilution. While the use of finer porosity paper usually eliminated this difficulty, the filtration step became excessively time consuming and, as a result, the possibility of drug decomposition became an important consideration. Suction filtration even through a thin pad of acid-washed diatomaceous earth was sometimes subject to clogging and was therefore not always satisfactory. Maximum clarity was readily achieved with the use of a membrane filter of micron-range porosity.

Methods—Under the experimental conditions of sample preparation, the effective dye concentration expressed as a molar ratio of dye to drug with the acid-dye technique was approximately 12:1. A plot of this ratio against absorbance is given in Fig. 1. With a fixed concentration of drug, in the case of trifluoperazine hydrochloride, the optimum dye concentration expressed in moles of dye per mole of drug is restricted to a relatively narrow band between 10:1 and 16:1. At lower ratios the color intensity was significantly decreased and was more sensitive to small variations in dye concentration, while higher ratios (*i.e.*, more concentrated dye solution) resulted in the formation of a precipitate. Beer's law was obeyed for drug concentrations in the range of 30 to 150 mcg./5 ml. of sample solution. All solutions which were analyzed by the acid-dye technique in this study fell within this concentration range.

The extent of partition of the drug-dye complex from an aqueous phase of given pH into the organic phase appears to be related to the molecular structure of the particular drug and dye. In the ideal situation, the pH values at which partition of the colored ion pair into the organic phase is a maximum and blank readings a minimum are coincident. This is rarely the case in practice but the pH should usually be kept as high as possible to prevent extraction of the sulfonic acid form of the dye into the organic layer. An optimum

buffer pH of 6.0 was indicated for the trifluoperazine-bromocresol purple system.

In the chromatographic method, the solvent system, methanol (8 ml.) containing concentrated hydrochloric acid (4 drops) and diluted to 100 ml. with water-washed chloroform, is completely transparent down to the cutoff point of 242 $m\mu$. In this solvent system, the absorption maximum for trifluoperazine is at 259 $m\mu$. Nine determinations of the absorptivity of trifluoperazine hydrochloride following partition through the alkaline-siliceous earth column gave an average value of 59.80 with a coefficient of variation of 1%. The commercial diatomaceous earth (see Footnote 4), which is often suitable as such for analysis by column chromatography, in this instance gave blank readings which were high and variable (0.072–0.114) and, as a consequence, was not satisfactory for use without further treatment. Washing with hydrochloric acid, then consecutively with aqueous alkali and chloroform to simulate the analytical conditions, led to almost total removal of UV-absorbing impurities and lowered the reference column absorbance values to 0.005 or less. This value, established by several replicate measurements on each treated batch of diatomaceous earth, was quite reproducible and was subtracted as a fixed quantity from the absorbance reading of each solution of the drug eluted from the column.

Results—Studies on the extent of the quantitative interference by excipient substances encountered with the direct spectrophotometric procedure for four brands of trifluoperazine tablets showed that the absorbance contribution of the water-soluble coating materials is generally negligible with the higher dosage forms but is significant at the 1-mg. level where the dilution factor is less. With some of these tablets, the drug content can be overestimated by 2.5%. With placebos of Brand V, for example, an absorbance measurement equivalent to approximately 5% interference was observed. The soluble (in 1% HCl) coating materials of Brands I–IV, and the soluble excipient substances of the placebos of Brand V, however, gave zero absorbance on spectrophotometric analysis by either of the two alternative methods.

To substantiate the validity of these results and to ascertain that complete drug recovery could be effected by the acid dye and the alkaline column procedures, several simulated drug–excipient mixtures were prepared from a stock solution of trifluoperazine hydrochloride and filtered excipient solutions made from sonification of placebos. The data in Table I clearly demonstrate that, as expected with the pharmacopeial method, the presence of excipient material in the simulated solutions resulted in varying levels of interference corresponding to the number of placebos employed, but that no detectable interference and essentially 100% recovery were achieved with all six solutions by the two alternative procedures.

Inspection of the results in Table II for nine commercial formulations shows that, where the extent of interference is about 2.5% or less, the direct spectrophotometric method is of comparable accuracy to that of the two proposed procedures. For most of the lot numbers examined, the assay values are comparable for all three assay procedures, except in the case of sample No. 8 where the degree of overestimation was about 6% by the direct UV method.

The above data underline the fact that with some trifluoperazine tablet formulations, the pharmacopeial method can give erroneously high results, and in these instances where suspicious assay results are encountered, the two alternative procedures described herein should prove useful to assess accurately the drug content.

Optimal Ferric Hydroxamate Method for Determination of Intact Pilocarpine

IRWIN S. GIBBS* and MURRAY M. TUCKERMAN

Abstract □ The ferric hydroxamate colorimetric method for lactones has been optimized for the determination of pilocarpine in the presence of its degradation product by careful control of pH, reagent concentration, and time to yield a method which has the following advantages of similar methods previously proposed: (a) direct sampling of the usual 1 or 2% solutions without dilution; (b) a stable blank with relatively low absorbance; and (c) production of a color with a minimal rate of fading, suitable for quantitative determination. Analysis of 20 independent sets of calibrations by linear regression analysis yields a regression coefficient of 0.98, an absorbance (y) intercept of -0.007 , and a slope of 0.51.

Keyphrases □ Pilocarpine solutions—analysis □ Ferric hydroxamic acid method—color formation □ Colorimetry analysis—spectrophotometer

Various analytical methods for the determination of pilocarpine hydrochloride have appeared in the literature including titrimetric (1-4), ion-exchange (5), colorimetric (6-12), and measurement of the UV absorption of the tetraphenylboride (13). For the routine quality control of pilocarpine hydrochloride ophthalmic solutions, the method of Brochmann-Hanssen *et al.* (12) appears most useful. The method consists of making the sample alkaline in the presence of hydroxylamine hydrochloride, allowing the reaction to proceed for a period of time, and adding ferric chloride to the acidified mixture to yield a colored ferric hydroxamate. After allowing the color to develop, the absorbance is read at 500 $m\mu$ in a suitable instrument. The advantages of this method are specificity for the intact lactone ring of the pilocarpine molecule and more than sufficient sensitivity.

In using the technique, this sensitivity has been found to be a burden because samples cannot be taken directly from the solutions of pilocarpine hydrochloride commonly appearing in commerce, thus entailing several dilutions during analysis of samples and preparation of calibration curves. In addition, variations in absorbance with time for treated samples, gas bubble formation on the walls of the cells, and the small volume of the final sample, making adequate rinsing of cells difficult, all serve to make this method less than ideal.

The proposed method reduces the disadvantages, allowing for direct sampling from aqueous solutions of pilocarpine hydrochloride in concentrations of 1 and 2% and yielding absorbance values which conform to the usual conditions for photometric measurement.

EXPERIMENTAL

Apparatus—The Cary model 15 recording spectrophotometer and the Gilford apparatus with the Beckman DUR monochromator were used for the absorbance measurements.

Samples—The samples consisted of aqueous solutions of pilocarpine hydrochloride USP XVII in a concentration of 0.7%.

Solutions used in the performance of the method suggested by Brochmann-Hanssen *et al.* (12) were 0.04%. The pilocarpine hydrochloride employed was assayed by the USP method (14), yielding a recovery of $99.85 \pm 0.11\%$.

Reagents—Hydroxylamine hydrochloride, 1 M in water; alkaline phosphate consisting of 10 volumes of 7% trisodium phosphate and 2 volumes of 3.5 M sodium hydroxide; and ferric chloride solution, 0.3 M in 0.1 N hydrochloric acid.

Proposed Method—Transfer an accurately measured volume of pilocarpine hydrochloride solution containing between 10 and 20 mg. of pilocarpine hydrochloride to a 25.0-ml. volumetric flask and add water to make approximately 10 ml. Add 1.0 ml. of 1 M hydroxylamine hydrochloride and 3.0 ml. of alkaline phosphate solution, mixing well after each addition, and allow the solution to stand for 10 min. Add 1.0 ml. of 5.25 M hydrochloric acid followed by 1.0 ml. of ferric chloride solution. Dilute with water after 10 min. and read the absorbance in a suitable spectrophotometer at 480 $m\mu$. A reagent blank is treated in the same manner. A calibration curve may be conveniently prepared by taking 1.00, 2.00, and 3.00 ml. of a 0.7% pilocarpine hydrochloride solution (which yields absorbance values equivalent to 0.35, 0.70, and 1.05% solutions, respectively) and treating in the described manner.

RESULTS

Twenty calibration curves were prepared as indicated on separate days. Each curve was prepared using fresh reagents and a fresh 0.7% pilocarpine hydrochloride standard solution. The following

Table II—Absorbance *versus* Time Obtained with Treated Sample (3.00 ml. of 0.7% Pilocarpine Hydrochloride) and Reagent Blank

22	0.532	0.011

significant values were obtained upon calculation using regression analysis: regression coefficient, 0.98; absorbance (y) intercept, -0.007 ; and slope, 0.51 .

Fading Rate—As has been pointed out (12, 15), ferric hydroxamic acid procedures, in general, yield unstable colors. Comparison of the change in absorbance with time between the proposed method and the Brochmann-Hanssen method for pilocarpine hydrochloride was rendered difficult by formation of gas bubbles on the walls of the cell immediately upon introduction of the sample when using the Brochmann-Hanssen technique. These bubbles grew larger with time. The colored solutions arising from the proposed method, however, are homogeneous and no difficulty was experienced.

Absorbance spectra of the solutions obtained with the Brochmann-Hanssen method showed a maximum at $500\text{ m}\mu$ as reported (12), while those of solutions obtained with the proposed method showed a slightly broader maximum in the region of $480\text{ m}\mu$. Recorded absorbance spectra obtained with the solutions treated in accordance with the Brochmann-Hanssen technique 10 and 20 min. after the initial spectrum invariably showed a total increase in absorbance at the wavelength of maximum absorption, although the $+20$ -min. spectrum sometimes showed a decrease in absorbance from that at $+10$ min. Recorded absorbance spectra of solutions obtained with the proposed method showed only a slight decrease in the absorbance maximum 10 and 20 min. after the initial spectrum.

Due to the paradoxical behavior of the solutions obtained in the Brochmann-Hanssen method and also to the fact that both the sample and blank are highly colored, the changes in absorbance with time of both samples and blanks were determined independently against water at $500\text{ m}\mu$. The same was done for solutions obtained with the proposed method at $480\text{ m}\mu$. The results are shown in Table I.

As can be seen, the method proposed by Brochmann-Hanssen *et al.* (12) yields rather large changes in absorbance with time for both the sample and blank. In addition, the overall net change in absorbance of the sample is not predictable with respect to direction or magnitude. On the other hand, the absorbance of the reagent blank used in the proposed method is constant within the limits of accuracy of the digital read-out meter of the Gilford apparatus employed. The absorbance of the sample obtained by the proposed method shows only a slight decrease over the time period studied.

In order to determine the optimal time period between combination of the sample with the reagents and determination of the absorbance, an absorbance *versus* time study for the sample and reagent blank was performed. Water was used to establish a baseline absorbance of 0. The results are shown in Table II.

As can be seen by perusal of Table II, the absorbance of the reagent blank again remains constant within the limits of accuracy of the instrument throughout the time period employed. The sample shows an initial accelerated fading, which is somewhat stabilized at approximately 10 min. following the addition of the ferric chloride solution. Thus, by following the directions given for the proposed method, the operator has sufficient time to make several solutions to volume, rinse the cells, and take absorbance readings without fear of significant fading during the time required.

CONCLUSIONS

A method has been proposed for the colorimetric analysis of aqueous solutions of pilocarpine hydrochloride which exhibits: (a) ease of sampling; (b) no change in absorbance of the reagent blank and only slight fading of the sample over the time suggested after addition of the last reagent required in sample treatment and reading of the sample absorbance; and (c) no gas bubble formation in the treated sample as was obtained with a previously proposed method (12).

While the proposed method has not been applied to samples of commercially available solutions, no marked deviations are expected in the results, provided that interfering substances are removed prior to sample treatment by methods similar to that prescribed by Brochmann-Hanssen *et al.* (12).

Fluorometric Determination of Salicylic Acid in Aspirin Products Including Noninterfering, Interfering, and Buffered Substances

NORMAN SHANE and DENNIS MIELE

Abstract □ A rapid, fluorometric method for the determination of salicylic acid in aspirin products in combination with noninterfering fluorescent substances, such as phenyltoloxamine citrate, glyceryl guaiacolate, and caffeine, interfering fluorescent materials, such as hydrogenated castor oil (Castorwax) and salicylamide, and buffering agents, such as aluminum glycinate and magnesium carbonate, gave accurate and precise results. The procedure is based on a simple dissolution of the crushed tablet in a pH 4.0 buffer solution and reading of the filtered solution at activation and fluorescent wavelengths of 310 and 410 m μ , respectively. An additional operation of a chloroform and buffer solution extraction is necessary when interfering substances are present. In the case of salicylamide, a constant background reading has to be subtracted; however, an accuracy of 95.5% was established. For nonaspirin salicylates in buffered-aspirin products, the procedure gave results similar to those reported by Guttman and Salomon.

Keyphrases □ Aspirin dosage forms—salicylic acid determination □ Salicylic acid determination—aspirin dosage form, buffered, unbuffered □ Interfering substances—salicylic acid determination □ Fluorometry—analysis

There are many methods in literature for the determination of small amounts of salicylic acid in aspirin and aspirin products. These involve colorimetry (1–3), chromatography (4–7), spectrophotometry (5–10), and titrimetry (11). Fluorometric determinations (12–14) have been described for the determination of salicylate in biological tissues by measurement of the characteristic fluorescence of the salicylate ion on exposure to UV light.

The present paper describes a simple, fast, fluorometric determination of salicylic acid in aspirin products. With no interference of other fluorescent compounds, separations are not necessary. The ingredients can be dispersed in a pH 4 buffer solution, filtered, and the salicylic acid content determined fluorometrically. With interfering substances that have solubility differences in organic systems, a simple extraction can be performed.

For buffered-aspirin tablets, a variety of methods (15–18) is described for the determination of total non-aspirin salicylates. By treating the sample with HCl-citric acid solution and extracting with chloroform and then with pH 4 buffer solution, the salicylate content can be determined fluorometrically. Results similar to the Guttman and Salomon method (18) were obtainable.

EXPERIMENTAL

Apparatus and Reagents—Fluorometer—A G. K. Turner Associates model 2 fluorometer with a 7-60 primary filter (band pass 310 m μ) and a No. 2A secondary filter (band pass 410 m μ) was used to obtain the fluorescent readings. A Beckman research pH meter was used to measure the pH of the buffer solutions.

A Beckman DK2 recording spectrophotometer was used to obtain spectra of the chloroform solution. The results for the buf-

fered-aspirin tablets were obtained on the Aminco-Bowman spectrofluorometer (4-8100). The activation and emission wavelengths were set at 310 and 410 m μ , respectively.

Materials—Spectral grade, analytical reagent chloroform (Merck & Co.) was used. All analgesic compounds, *i.e.*, acetylsalicylic acid, USP grade; salicylamide, NF grade; acetaminophen, NF grade; phenyltoloxamine citrate, USP grade; glyceryl guaiacolate, USP grade; salicylic acid, USP grade, were checked by IR spectrophotometry. Castor oil¹ was also used. The filter units employed in the experiment were Whatman folded filter paper No. 2V and the Millipore Swinnex-13 using celotat (cellulose acetate) No. ECPO-1300 filter.

Solutions—(a) pH 4 buffer; prepared by combining a ratio of 7.71 ml. of 0.2 M disodium hydrogen phosphate and 12.29 ml. of 0.1 M citric acid. (b) Seventeen milliliters of concentrated hydrochloric acid and 1000 ml. of 0.1 M citric acid.

Tablets—Powdered mixtures of the following composition were analyzed: (a) 325 mg. of aspirin; (b) 325 mg. of aspirin and 146 mg. of castor oil; (c) 195 mg. of aspirin, 130 mg. of salicylamide, 98 mg. of acetaminophen, and 65 mg. of caffeine; and (d) 325 mg. of aspirin, 97 mg. of magnesium carbonate, and 49 mg. of aluminum glycinate.

PROCEDURE

Absence of Interfering Substances—Calibration—To five 50-ml. volumetric flasks, 0.1, 0.2, 0.3, 0.5, and 1.0 mg. of salicylic acid were added. Buffer solution, pH 4, was added to each flask, which was then shaken for 30 sec. and filtered. Five milliliters of the filtered solution was added to a cell and placed in the fluorometer which was initially set to zero with the buffer solution. When a steady state was achieved (approximately 1 min.), readings were taken.

Method—A tablet was crushed and transferred to a 50-ml. volumetric flask. The contents were brought to volume with pH 4 buffer solution, shaken vigorously for 30 sec., and then filtered. Proceed as described in the previous calibration beginning: "Five milliliters of the filtered solution was added. . . ."

Presence of Interfering Substances—Calibration for Tablets Coated with Castor Oil—To five separators, 0.1, 0.2, 0.3, 0.5, and 1.0 mg. of salicylic acid were added. To each separator, 25 ml. of chloroform was added and shaken for 30 sec. The chloroform solution was extracted with three 15-ml. portions of buffer solution; the buffer extracts were transferred to a 50-ml. volumetric flask and adjusted to volume. Five milliliters of the solution was added to the cell and read in the fluorometer that had been previously standardized with buffer solution. Readings were taken at equilibrium.

A tablet was crushed and transferred to a 125-ml. separator. Proceed as described in the previous calibration beginning: "To each separator, 25 ml. of chloroform was added and shaken for 30 sec. . . ."

For tablets containing aspirin, acetaminophen, salicylamide, and caffeine, a tablet was crushed and put into a 50-ml. volumetric flask which was brought to volume with chloroform. The solution was shaken vigorously for 1 min. and transferred with as much residue material as possible to the separator, allowing a few seconds for the complete drainage of the flask. Fifty milliliters of buffer solution was then added, and the separator was shaken vigorously for 30 sec. The lower chloroform layer was completely drained, including as much filmy interface as possible. (The clarity of the division of the two layers is enhanced by gently swirling the flasks as the layers separate. This enables the trapped air bubbles in the chloroform layer to escape to the surface. If these bubbles do not disappear,

^a The average of salicylic acid found in recrystallized aspirin was 0.033%; this amount was used to calculate the weight found in the composition composed of both aspirin and added salicylic acid in Tables I and II.

they should be drained with the chloroform.) The buffer solution was transferred to a 100-ml. volumetric flask through the top of the separator. The separator was rinsed with an additional 10 ml. of buffer, which was then transferred to the previous flask that was brought to volume with additional buffer solution. The solution was filtered using the Millipore filter. Five milliliters of the filtered solution is read on the fluorometer that has been standardized with buffer solution. Two samples should be read, and if the readings differ by more than one unit, a third sample is required. Readings should be taken after allowing the instrument to equilibrate with the sample inside for 1 min.

For buffered-aspirin tablets containing aspirin, magnesium carbonate, and aluminum glycinate, a tablet was crushed and placed in a 125-ml. separator. HCl-citric acid solution, 25 ml., was added. After the effervescence ceased, two 25-ml. chloroform extractions of the mixture were made and saved. The combined chloroform extracts were then extracted with two 25-ml. portions of buffer. The buffer extracts were placed in a 100-ml. volumetric flask and brought to volume. Some of this aqueous solution was filtered, and a 5-ml. aliquot was added to the cell and read on the Aminco spectrofluorometer. Readings were taken after the instrument was equilibrated with the sample inside for 1 min.

RESULTS AND DISCUSSION

Studies of the fluorescent properties of salicylic acid as a function of pH show that the fluorescent spectra arise from different ionic forms (19). The stable spectrum of the acid arises from the singly ionized form. Figure 1 shows the plots of pH versus fluorescence

(19). At pH 4, the monosalicylate ion levels off in fluorescent intensity. The detection limit of the salicylic acid at pH 4 is around 0.1 p.p.m.

Aspirin shows a rate constant of about 0.1 day^{-1} at 17° at pH 4 (8). At room temperature during the time period of the above experiments, aspirin showed a negligible decomposition.

The determination of salicylic acid in aspirin products in these experiments is based on the fact that the aspirin compound does not fluoresce while salicylic acid does at pH 4. At this pH, aspirin decomposition is negligible. For the experiment on noninterfering substances, aspirin, having starch as the excipient, gave results as shown in Table I.

In the analysis of aspirin tablets coated with castor oil, the tablets were dissolved in chloroform and extracted with pH 4 buffer solution. The salicylic acid forms the monosodium salts with the buffer solution and remains in the aqueous layer. Results are shown in Table II.

For the determination of salicylic acid in tablets containing aspirin, salicylamide, acetaminophen, and caffeine, a fluorometric procedure was developed in which the ingredients were dissolved in chloroform, and aspirin and salicylic acid were extracted into a buffer solution. The interference of the major ingredient is limited by the chloroform extraction and the use of the buffer. Salicylic

**Figure 1—Plot of pH versus fluorescence for salicylic acid and salicylamide. Key:—, salicylic acid; and - -, salicylamide.**

acid can be determined with an accuracy of ± 0.15 mg. at levels of 1 mg. The values may be simply calculated from a suitable calibration curve.

The fluorometer is especially useful in the determination of very small amounts of salicylic acid in the presence of large amounts of the ingredients of the tablet because its fluorescence per unit weight is much larger than that of the active ingredients. If the amount of salicylic acid in the tablet is as small as 2 mg., it would represent only 1.6% of the respective standard amount of salicylamide, the only ingredient which exhibits fluorescence at this pH. Figure 1 shows the effect of pH *versus* fluorescence of a solution containing 1 mg. of salicylic acid and 10 mg. of salicylamide. The optimum condition for determining salicylic acid in the presence of salicylamide was at pH 4. The actual amount of the fluorescence of salicylamide is limited by chloroform extraction and buffer operation. The reading of the salicylamide is depressed because 90% of it has been removed. The ratio of anionic to undissociated species is 10:1 in both aspirin and salicylic acid and only 1:10⁴ in salicylamide, and it is the anionic species which fluoresces to the largest extent.

The background reading of the tablet has been carefully determined by using a large number of runs. Tablet mixtures were simulated by weighing the standard amounts of the four components. The quantity of salicylic acid in each of the two components (aspirin and salicylamide, which gave readings) were carefully determined. Neither acetaminophen nor caffeine gave fluorescence under the conditions of this analysis. The salicylic acid content of aspirin was determined by using an iron (III) complexing technique (20)—0.128 mg./195 mg. of aspirin. Using a titration in nonaqueous medium with methanolic potassium hydroxide, it was determined that there was a negligible amount of salicylic acid in salicylamide, and the reading of salicylamide was a result of salicylamide fluorescence. The observed background of the composed tablet is 32.5. The salicylic acid content of the composed tablet gave a reading of 1.2; therefore, the adjusted background is 31.3 (four components with no salicylic acid).

The observed readings of fresh commercial tablets varied from 32.5 to 35.8. Individual batches were consistent among themselves, alternating between 0.13 and 0.45 mg. of salicylic acid in the tablets.

The data, summarized in Table III, were acquired through the addition of salicylic acid to a weighed portion, equivalent to one tablet, of a powdered mixture made from 10 tablets. The tablet background was obtained from the measurement of a given amount of the mixture and subtracted from the observed reading to determine the increase resulting from the addition of salicylic acid. The data are plotted in Fig. 2.

The best straight line through the data points is obtained by using a least-squares method (21). The calculated straight line is where $y = 9.63x + 0.85$, y = adjusted fluorescence reading, and x = milligrams of salicylic acid added.

Adjusting the background and initial salicylic acid content, the equation can be solved to find the total amount of salicylic acid per tablet to give

$$x = y_1 - \frac{32.1}{9.63}$$

where y_1 is the observed fluorometer reading.

The average deviation of calculated values from the actual values is 0.06 mg., representing an average relative error of 2.00% with a standard deviation of 0.074; one can be 95.5% confident of being accurate to within 0.15 mg. and 99.7% confident of being accurate within 0.22 mg.

However, the deviations in the observed data are not the only errors involved. An error of ± 0.05 mg. is introduced by uncertainties in the fluorometer readings (readings are good only to ± 0.5 division). The major error is a result of the tolerance limits of the ingredients. Limits of $\pm 10\%$ significantly alter the readings of the background. This introduces an error of ± 0.3 mg. in the final determination of salicylic acid. However, as there are extremes, salicylamide and aspirin must both be either high or low by 10% to obtain such a large error; this large deviation is unlikely. This large error can only be eliminated by: (a) determining the salicylamide and aspirin contents of the tablets, and (b) adjusting the background accordingly.

By employing a high source intensity xenon lamp and a grating instrument rather than the one incorporating band filters and a

mercury lamp source (as used in these experiments), a more monochromatic system for maintaining an exact activation and fluorescent spectrum would permit a lesser background effect and a higher intensified signal at the appropriate selected wavelengths.

For buffered-aspirin tablets, Guttman and Salomon (18) indicated that current assays are unsuitable in the analysis of salicylic acid due to adsorption of acid by buffering components, and chloroform-insoluble buffering agents can catalyze a conversion of aspirin in chloroform solution to a compound determined as salicylic acid. They showed that treatment of the sample with citric acid monohydrate inhibited the problems. To convert the salts of salicylic acid, a strong acid was added. However, Guttman and Salomon indicated that the aspirin was degraded by this treatment in chloroform to salicylic acid during the time period required for sample dissolution and from the adsorption of aspirin to solids which hydrolyzed during the strong acid treatment. They circumvented the problems by treating the powdered buffered tablets with citric acid monohydrate. Separation of salicylic acid from aspirin was accomplished chromatographically in these procedures (16, 18).

Table IV shows the determination of salicylic acid in buffered-aspirin tablets by fluorescence and the Guttman and Salomon

Figure 2—Calibration curve for salicylic acid and powdered mixture containing aspirin, acetaminophen, salicylamide, and caffeine. Key: ○—○, least-squares straight line.

method. As shown in the table, there is no statistical difference between the methods with respect to the means and variances.

After the HCl-citric acid solution is added to the crushed tablet, a pH of 0.9–1 is observed. Slight effervescence occurs but subsides in less than 1–2 min. The extraction of the undissociated salicylic acid and aspirin by chloroform is then accomplished. The aspirin and salicylic acid are extracted from the chloroform solution by the buffer solution. The whole experiment takes about 10 min.

To ensure complete extraction of salicylic acid and aspirin into the chloroform solution, some of the aqueous phase was treated with 1 *N* NaOH and tested for the absence of salicylate fluorescence. Also, to be assured of complete extraction of salicylic acid from the chloroformic solution, some of the organic phase was run on the spectrophotometer to observe the absence of salicylic acid.

Gas-Liquid Chromatography of *d*-Biotin

V. VISWANATHAN, F. P. MAHN, V. S. VENTURELLA, and B. Z. SENKOWSKI

Abstract □ A rapid and specific gas chromatographic method has been developed for the detection and determination of *d*-biotin. This technique has been found applicable to agricultural premixes and pharmaceutical injectable preparations. After suitable preliminary extraction, the biotin silyl ester is prepared using bis-(trimethylsilyl)acetamide (BSA) reagent. The silyl ester of *d*-biotin exhibited good peak symmetry and a linear response when utilizing a hydrogen flame ionization detector with a 2% OV-17 column operated at a temperature of 190°. The conditions for the assay of *d*-biotin in several preparations are described employing *n*-octacosane as the internal standard. The standard deviation of the developed procedure under the conditions studied was $\pm 2.7\%$.

Keyphrases □ *d*-Biotin—determination □ Parenterals, agricultural premixes—*d*-biotin analysis □ *n*-Octacosane—internal standard □ GLC—analysis

d-Biotin is widely distributed in animals and plants and was first isolated from egg yolk (1). It is required in comparatively small amounts for the growth of bacteria, plants, and animals and appears to be related to the process of cell development. In 1940, György *et al.* (2) published their work on the identity of biotin. In the following 2 years, du Vigneaud *et al.* (3, 4) established the empirical and structural formulas. In 1943, Harris *et al.* (5) synthesized *d*-biotin (the naturally occurring form) and in 1949, Goldberg and Sternbach (6) patented their findings of a more economical synthesis.

While several microbiological techniques are currently employed for the determination of *d*-biotin, a comprehensive survey of the literature indicated that GLC had heretofore not been employed for quantitative analysis. A considerable number of satisfactory GLC procedures have been reported for various water-soluble vitamins. These procedures involve the preparation of the appropriate trimethylsilyl derivatives (ester or ether) prior to GLC analysis.

Carboxylic organic compounds, such as biotin, are not sufficiently volatile for direct analysis employing GLC. However, the chemical structure of *d*-biotin indicated the possibility of substituting the active hydrogen of the carboxyl group with a silyl group, thereby making the gas chromatographic analysis possible. Horning *et al.* (7) mentioned the qualitative response of *d*-biotin silyl ester in their study of urinary acids and related compounds.

This paper describes the quantitative GLC determination of *d*-biotin after the conversion to its silyl ester with bis-(trimethylsilyl)acetamide (BSA). The derivative is easily formed and serves very well for quantitative analysis. The linearity of detector response with concentration injected, reproducibility, recovery data, and procedures for handling several types of dosage forms are described.

method. As shown in the table, there is no statistical difference between the methods with respect to the means and variances.

After the HCl-citric acid solution is added to the crushed tablet, a pH of 0.9–1 is observed. Slight effervescence occurs but subsides in less than 1–2 min. The extraction of the undissociated salicylic acid and aspirin by chloroform is then accomplished. The aspirin and salicylic acid are extracted from the chloroform solution by the buffer solution. The whole experiment takes about 10 min.

To ensure complete extraction of salicylic acid and aspirin into the chloroform solution, some of the aqueous phase was treated with 1 *N* NaOH and tested for the absence of salicylate fluorescence. Also, to be assured of complete extraction of salicylic acid from the chloroformic solution, some of the organic phase was run on the spectrophotometer to observe the absence of salicylic acid.

Gas-Liquid Chromatography of *d*-Biotin

V. VISWANATHAN, F. P. MAHN, V. S. VENTURELLA, and B. Z. SENKOWSKI

Abstract □ A rapid and specific gas chromatographic method has been developed for the detection and determination of *d*-biotin. This technique has been found applicable to agricultural premixes and pharmaceutical injectable preparations. After suitable preliminary extraction, the biotin silyl ester is prepared using bis-(trimethylsilyl)acetamide (BSA) reagent. The silyl ester of *d*-biotin exhibited good peak symmetry and a linear response when utilizing a hydrogen flame ionization detector with a 2% OV-17 column operated at a temperature of 190°. The conditions for the assay of *d*-biotin in several preparations are described employing *n*-octacosane as the internal standard. The standard deviation of the developed procedure under the conditions studied was $\pm 2.7\%$.

Keyphrases □ *d*-Biotin—determination □ Parenterals, agricultural premixes—*d*-biotin analysis □ *n*-Octacosane—internal standard □ GLC—analysis

d-Biotin is widely distributed in animals and plants and was first isolated from egg yolk (1). It is required in comparatively small amounts for the growth of bacteria, plants, and animals and appears to be related to the process of cell development. In 1940, György *et al.* (2) published their work on the identity of biotin. In the following 2 years, du Vigneaud *et al.* (3, 4) established the empirical and structural formulas. In 1943, Harris *et al.* (5) synthesized *d*-biotin (the naturally occurring form) and in 1949, Goldberg and Sternbach (6) patented their findings of a more economical synthesis.

While several microbiological techniques are currently employed for the determination of *d*-biotin, a comprehensive survey of the literature indicated that GLC had heretofore not been employed for quantitative analysis. A considerable number of satisfactory GLC procedures have been reported for various water-soluble vitamins. These procedures involve the preparation of the appropriate trimethylsilyl derivatives (ester or ether) prior to GLC analysis.

Carboxylic organic compounds, such as biotin, are not sufficiently volatile for direct analysis employing GLC. However, the chemical structure of *d*-biotin indicated the possibility of substituting the active hydrogen of the carboxyl group with a silyl group, thereby making the gas chromatographic analysis possible. Horning *et al.* (7) mentioned the qualitative response of *d*-biotin silyl ester in their study of urinary acids and related compounds.

This paper describes the quantitative GLC determination of *d*-biotin after the conversion to its silyl ester with bis-(trimethylsilyl)acetamide (BSA). The derivative is easily formed and serves very well for quantitative analysis. The linearity of detector response with concentration injected, reproducibility, recovery data, and procedures for handling several types of dosage forms are described.

EXPERIMENTAL

Operational Parameters—The instrument used for this work was a Varian Aerograph model 204 B, equipped with a hydrogen-flame ionization detector. The column used was a stainless steel coil, 121.9 cm. (4 ft.) long and 3 mm. o.d., packed with 2% OV-17 on diatomite (Chromosorb G), AW/HMDS treated, 70/80 mesh. Prior to use, the column was flow conditioned at 225° for 16–20 hr. with a stream of nitrogen. The temperatures were: column, 190° (or adjusted accordingly to obtain a retention time of approximately 19 min. for *n*-octacosane); injector port, 275° with a Pyrex insert; detector, 275°. The flow rates were: carrier gas—nitrogen, 60 ml./min.; detector gas—hydrogen, 30 ml./min.; and air, 300 ml./min. All injections were made using a 10- μ l. Hamilton syringe with an injection volume of approximately 5 μ l. The instrument was operated at a range of 10 and 32 \times attenuation (or sufficient to obtain a 50% peak response on the recorder scale). The recorder used was 0–1 mv. (Texas Instrument) with a pen response of 0.4 sec. and a chart speed of 12 in./hr. All peak areas were measured using a disk integrator. Under the conditions stated the relative retention time of *d*-biotin silyl ester is 0.68 with respect to the internal standard, *n*-octacosane, which has a specific retention time of approximately 19 min. A sample chromatogram is shown in Fig. 1.

Reagents and Chemicals—Liquid phase phenylmethylsilicone fluid, OV-17, *n*-octacosane, and bis-(trimethylsilyl)acetamide (BSA) were commercial grade (Applied Science Laboratories, Inc.). The solid support, diatomite (Chromosorb G), AW/HMDS treated, 70/80 mesh, was used as purchased (F & M Scientific Corp.). All solvents were analytical reagent grade, requiring no further purification.

Standard Preparation—Internal Standard Solution—Five hundred milligrams of *n*-octacosane, accurately weighed into a 50-ml. volumetric flask, was dissolved and diluted to volume with *n*-hexane.

Reference Standard Solution—An accurately weighed 50-mg. portion of standard *d*-biotin was placed in a 50-ml. volumetric flask and treated with 5.00 ml. of bis-(trimethylsilyl)acetamide reagent. The flask was stoppered and heated on a steam bath with frequent agitation until the reaction was complete and the solution clear (approximately 20–30 min.). The mixture was cooled, 5.00 ml. of internal standard solution added, and the solution diluted to volume with *n*-hexane.

Sample Preparation—A. *d*-Biotin Premix: 1%—An accurately weighed portion of premix (equivalent to about 10 mg. of *d*-biotin) was placed in a 50-ml. centrifuge tube. Fifteen milliliters of absolute ethanol was added and the mixture warmed on a steam bath for 10 min., with occasional agitation. The mixture was centrifuged and the clear supernatant liquid transferred to a 125-ml. conical flask without disturbing the residue. The extraction was repeated four more times and the extracts combined. The combined extracts were evaporated to dryness on a steam bath under a stream of nitrogen. Exactly 2.0 ml. of bis-(trimethylsilyl)acetamide reagent was added. The vessel was stoppered and heated on a steam bath for 20–30 min. with frequent agitation. The sample preparation was cooled and 1.00 ml. of internal standard solution (containing 10 mg. of *n*-octacosane) was added. Quantitative transfer of the entire mixture into a 10-ml. volumetric flask was attained with the aid of *n*-hexane and the solution was diluted to volume with *n*-hexane (working sample solution).

B. *d*-Biotin Parenteral: 0.05%—A 20.0-ml. portion of sample preparation was transferred to a 125-ml. conical flask. Concentrated hydrochloric acid, 0.5 ml., and 30 ml. of anhydrous methanol were added. The solution was evaporated to dryness on a steam bath under a stream of nitrogen. Exactly 2.0 ml. of bis-(trimethylsilyl)acetamide reagent was added; the flask was stoppered and heated on a steam bath for 20–30 min. with frequent agitation. The solution was cooled and 1.00 ml. of internal standard solution (containing 10 mg. of *n*-octacosane) was added. The entire mixture was quantitatively transferred into a 10-ml. volumetric flask with the aid of *n*-hexane and diluted to volume with *n*-hexane.

Standard Calibration and Sample Analysis—Chromatographic preruns of several 5- μ l. injections of working standard solution was carried out in order to condition the column to determine the instrument sensitivity and the peak retention times.

Five-microliter volumes of the working standard and sample solutions, equivalent to approximately 5 mcg. of *d*-biotin, were alternately injected into the instrument using the aforementioned conditions. After the elution of the *n*-octacosane peak, the instru-

Figure 1—Standard chromatogram showing relative retention times of biotin TMS derivative and internal standard. Key: A, solvent; B, biotin TMS; and C, *n*-octacosane.

ment was ready for another injection. Duplicate samples and standards were chromatographed and the respective areas determined from the integrator trace.

Calculations—Response Factor for Biotin (RF_B)—

$$RF_B = \frac{A_B(\text{std}) \times C_O}{A_O(\text{std}) \times C_B}$$

where A_B = peak area of biotin in the working standard, A_O = peak area of *n*-octacosane in the working standard, C_O = mg. of *n*-octacosane per ml. of working standard, and C_B = mg. of biotin per ml. of working standard.

Concentration of Biotin—

$$\frac{A_B(\text{spl}) \times C_O \times 10}{A_O(\text{spl}) \times RF_B \times \text{spl taken (g. or ml.)}} = \text{mg. biotin/g. (ml.)}$$

where A is area, C is concentration, and RF_B is the response factor for biotin; 10 = dilution factor.

RESULTS AND DISCUSSION

Hexamethyldisilazane and trimethylchlorosilane in the ratio of 2:1 was found unsuitable for the silylation of biotin, while bis-(trimethylsilyl)acetamide reagent was found satisfactory for complete and rapid silylation. This behavior was also reported by Horning (7). The selection of diatomaceous earth (Gas Chrom G), AW/HMDS treated, was arbitrary and any support properly

Table I—*d*-Biotin Premix Recovery Data

silanized may be suitable for good peak symmetry and quantitative recovery. Results obtained using either copper tubing or stainless steel tubing were equivalent. *d*-Biotin forms a TMS derivative when the carboxyl group exists in the acidic form. The sodium salt of *d*-biotin did not yield a TMS derivative. Therefore, it is assumed that reaction takes place at the carboxyl group to form the biotin silyl ester. The reaction apparent in the derivatization can then take the following form:

Since the derivatization was shown to occur at the carboxyl center, concentrated hydrochloric acid was added to the parenteral sample prior to derivatization because the *d*-biotin present in the parenteral preparation is in a water-soluble salt form.

Figure 2—Linearity of response with concentration. Column: 2% OV-17 on Chromosorb G, length 121.9 cm. (4 ft.); temperature 190°; 5 μ l. injected; attenuation 32X. Micrograms of *d*-biotin injected as the silyl ester with the internal standard as a constant.

Linearity data for *d*-biotin-TMS ester versus *n*-octacosane as the internal standard are shown in Fig. 2. The minimum detectable level for the *d*-biotin-TMS ester was approximately 0.3 mcg. at range 10, 1X. The recovery of known amounts of *d*-biotin added to a sample premix is given in Table I.

Initially, 5 α -cholestane was chosen as the internal standard. However, it had a specific retention time of approximately 28 min. In order to reduce the chromatographic time, *n*-octacosane (C₂₈ hydrocarbon), which had a specific retention time of approximately 19 min. under the prescribed conditions, was preferable. In addition, the latter proved more economical.

Six replicates of a premix containing 10 mg. of biotin per gram showed a mean of 10.33 with a relative standard deviation from the mean of ± 0.28 . The precision (*ts*: 95%) was ± 0.71 (Table II).

Six replicates of a sample of injectable containing 0.500 mg. of *d*-biotin per milliliter showed a mean of 0.553 mg. with a relative standard deviation from the mean of ± 0.015 . The precision (*ts*: 95%) was ± 0.040 (Table II).

Table III shows the results of analyses of nine samples of *d*-biotin premix by the described GLC method compared to the microbiological assay and to the colorimetric procedure previously reported (8).

Investigation is still being carried out on the application of this procedure towards the determination of *d*-biotin, present in microgram levels, in multivitamin preparations. In these preparations, as well as certain types of premixes, additional suitable isolation techniques may be required in order to remove interfering components.

SUMMARY

A rapid and specific GLC technique has been developed for the detection and determination of *d*-biotin. The method involves the preparation of the TMS ester, addition of *n*-octacosane as an internal standard, and analysis employing a hydrogen-flame ionization detector. Conditions are outlined for the determination of *d*-biotin in premixes and in parenteral preparations.

Formulation and Computation of Compartment Models

CARL F. EVERT and MICHAEL J. RANDALL

Abstract □ In the formulation of compartment models for describing biological phenomena, two separate approaches have usually been employed for isotope dilution systems and systems for which no tracers are introduced. In the former, steady state is assumed to exist and small perturbations are introduced for solution of the system. In the latter, sets of simultaneous differential equations are solved for the complete time course of the drug kinetic system. For linear systems which can be described by first-order kinetics, it is shown that the isotope dilution problem can be cast into the more general approach of simultaneous linear differential equations and the restriction of steady state removed. Solutions to these equations are shown to be easily obtainable using the state-space approach. For systems in which linearity cannot be assumed, digital computer techniques are presented which greatly facilitate numerical solutions. These concepts are demonstrated with two examples. A third example shows how these concepts and others can be employed with isotope dilution to find the initial pool sizes and rate constants in a six-compartment system.

Keyphrases □ Models, compartment—formulation, computation □ Theoretical considerations—data fitting, models □ Kinetic equations—first-order model system □ Computer program—data fitting, models

The use of mathematical descriptions called models that seek to capture the essence of biological phenomena has been emerging over the last 20 years. These concepts have been widely reported in the literature from a general and theoretical point of view, as well as in relation to specific applications. Most frequently, some form of dynamic behavior has been of concern so that the areas of pharmacokinetics and radioactive tracers have been the major contributors of applications. From these sources two points of view have arisen. One is concerned with the dynamics of a system described by a set of differential equations and seeks to evaluate the time course of the substance as a steady state is approached. The other presumes that steady state exists and that small perturbations about this value are introduced in order to evaluate flow rates, dilution, *etc.* These two points of view have placed emphasis on different variables, and the formulation of the descriptions of the system behavior in terms of these different variables has given the appearance of different computational requirements. It will be shown for first-order systems that these differences are superficial and that new advances in computer algorithms and computing languages now provide conveniences not generally recognized or utilized in biological modeling.

COMPUTATION FOR COMPARTMENT MODELS

The observable behavior of the distribution, absorption, or elimination of drugs has led to the concept that a biological system

can be treated as if there were boundaries called "compartments" which separate the system into parts and that the drug or other material is transferred from one compartment to another in conformance with first-order kinetics. This assumes that the rate of change of material is proportional to the amount of material that is present in the compartment. The application of Fick's law in the case of diffusion can lead to similar sets of linear first-order differential equations. Although the assumption of first-order kinetics, linearity, and rate coefficients that are constants is clearly a gross approximation of a complex biological phenomenon, the approach has proved beneficial in numerous instances when it is utilized with discretion and understanding. The assumptions are so widely accepted that one textbook (1) states: "Most drugs disappear from the body in this fashion."

The use of mathematical models as an aid to the better understanding of biological phenomena requires that some form of computation be executed. While there have been advances from time to time in the conceptual features of modeling, little attention seems to have been paid to keeping the computational procedures up-to-date and to making the techniques more attractive to the biological researchers who could take advantage of modeling as a tool. Basic to a dynamic model is the solution of a set of differential equations. This job has been variously relegated to the analog computer or the digital computer. The work that has been assigned to the digital computer has been that of solving the equations by the techniques of numerical integration, the computation of statistical parameters, or perhaps some curve fitting. Most laboratories seem to have developed their own libraries of programs associated with modeling and, except for utilizing some common language such as FORTRAN, they appear to have overlooked the availability of general-purpose programs such as CSMP (Continuous System Modeling Program) (2). It is hoped that this paper will suggest some new approaches to meeting the computational requirements of modeling and thus reduce the effort required in the utilization of models for biological systems.

The recent emergence of the ideas of organizing the description of systems characterized by sets of first-order differential equations under the heading of "state space" has fostered the development of algorithms (3) which provide analytical solutions. The user is not required to manipulate matrices or to use the Laplace transform. The algorithms may be programmed for digital computers and thus provide the proper analytical form and the associated coefficients in a more convenient fashion than most other methods. This is also the form most familiar to those applying compartment theory, and the approach should therefore have appeal to anyone interested in biological dynamics. The use of the state-space formulation of the equations has the added advantages that it identifies the basic assumptions of linearity and clarifies the use of superposition. The state-space method yields solutions in functional form which gives the opportunity of locating maxima by differentiation and permits comparisons in terms of time constants. When comparing the functional solutions with experimental data points, one need only evaluate the function at the specific points in question. All other points need not be computed. An analog computer or numerical integration technique would continuously evaluate the complete range of the solution. There is the disadvantage, however, that when the system parameters are altered, an entirely new state-space solution must be executed, but corresponding disadvantages are present in obtaining the solutions of numerical integration procedures. Thus there are trade-offs in the computational aspects of modeling, and it is desirable to have alternative techniques available so that one may select the tool that is most appropriate for the requirements. An analog computer run generates a continuous solution in the desired range.

The analog computer is convenient for use in matching models to data when the number of parameters to be changed is small, say five or less. However, to evaluate a single point, the analog computer must compute a continuous solution at least to the desired point. Digital programs such as CSMP to be illustrated here have been written to simulate the operation of the analog computer. They are in fact conveniently packaged numerical integration routines with the ability to be interspersed with FORTRAN statements. With this program, one may run successive cases and make decisions automatically at the end of each case for purposes of optimization or curve fitting. Good initial estimates of system parameters will reduce the number of successive runs required. These analog simulators usually incorporate nonlinear components and thus provide a convenient way of solving nonlinear differential equations without special programming. Here again the solutions are in the form of tables of values or digitally plotted curves rather than explicit functions of the independent parameter. Evaluation of specific data points requires computation of all previous points. As a means of illustrating the use of CSMP and later the state-space approach, a problem which has been published (4) in a nonlinear formulation requiring extensive special programming will be reviewed. However, the ramifications of the method go far beyond this particular application.

The usual problem in drug dynamics seeks to evaluate the time course of the amount of drug in the various compartments of interest. The initial conditions are usually assumed to be zero except in the compartment into which the drug is introduced. The resulting formulation is a dynamic system with the drug being distributed among the compartments and perhaps being eliminated from the system at several points. The conditions of steady state may not be of particular interest because steady state could be the condition in which all the drug has been cleared from the system. The length of time for the system to reach steady state may be prohibitively long for clinical verification. The point of interest may well be the early rates of the dynamic behavior, and there may be little concern with the final conditions of steady state.

In the case of the mathematical description of phenomena in which radioactive tracers are of interest, the emphasis has been on the small variations from an existing steady state. In fact an effort is made not to disturb the steady state appreciably. This concept of steady state in a biological system does not mean that there is no exchange of material among the compartments, but rather that the amount transferred into a compartment in a given unit of time is exactly the same as the amount which leaves the compartment in the given unit of time. Thus there can be a flow of material in the system, and the point of interest is in establishing the flow rates or pool sizes through dilution measurements. Radioactive tracers are suited to this task because they are not distinguishable by the body from the parent substance. Tracers may be injected in small enough quantities so as not to upset the equilibrium conditions and yet in sufficient amount so as to be measurable. The usual measurement is that of specific activity. Therefore, it was a natural approach to formulate the description in these well-known terms. The equations have been published (4) before and are of the general form:

$$S_i \frac{da_i}{dt} = \sum_{j=1, j \neq i}^n \rho_{ij}(a_j - a_i)$$

where a_i = specific activity, ρ_{ij} = flow constant, and S_i = compartment size (amount of parent substance).

This formulation is most convenient when the conditions of steady state are met. However, when one wishes to investigate the behavior in nonsteady state, it requires that the equations be viewed as having time-varying coefficients. A solution which leads to a form of the generalized Riccati-type equation can be found in the reference given. The solution was re-presented by Rescigno and Segre (5). The system solved in these references was a three-compartment closed system. The flow constants were assumed fixed with the exception of one which was specified as a function of time.

The general form of these equations can be derived from the equations that describe the same system with first-order kinetics (see Appendix 1). The specific activity parameter is introduced by defining specific activity as $a = R/S$, differentiating and substituting for the derivatives of R and S in the equations. Here R is the amount of radioactivity and S is the amount of parent substance. If S is assumed to be constant, it can be associated with the first-order rate

constant to give a new coefficient ρ . However, if S changes with time and the new coefficients ρ are specified as constants, as in the example referred to, one is forced to allow the normally fixed-rate constant to vary. It is not clear what physical reality was intended to be represented in the example problem. Nevertheless, assume that a problem of this form is to be solved and its biological justification has been established. For the three-compartment closed system the equations for nonsteady state, when written in terms of specific activity, take the form:

$$S_1 \frac{da_1}{dt} = \rho_{12}(a_2 - a_1) + \rho_{13}(a_3 - a_1)$$

$$S_2 \frac{da_2}{dt} = \rho_{21}(a_1 - a_2) + \rho_{23}(a_3 - a_2)$$

$$S_3 \frac{da_3}{dt} = \rho_{31}(a_1 - a_3) + \rho_{32}(a_2 - a_3)$$

$$\frac{dS_1}{dt} = \rho_{12} - \rho_{21} + \rho_{13} - \rho_{31}$$

$$\frac{dS_2}{dt} = \rho_{21} - \rho_{12} + \rho_{23} - \rho_{32}$$

$$\frac{dS_3}{dt} = \rho_{31} - \rho_{13} + \rho_{32} - \rho_{23}$$

where S_i = amount of parent substance, a_i = specific activity, and ρ_{ij} = flow coefficients.

If some of the ρ 's are functions of time, it is necessary to carry out the simultaneous solution of these six differential equations. Any suitable numerical integration algorithm may be used. However, the Continuous System Modeling Program is typical of the family of similar programs available for such solutions. The program shown in Appendix 2 is all that is required to solve this problem. Problems of much greater complexity can be solved in the same fashion and require a minimum of effort or programming skill.

The formulation of the three-compartment closed system, when applied to a system with first-order kinetics, really falls into the more usual category of the nonsteady-state linear systems. Since in such systems the theorem of superposition is applicable, one may solve the equations for the behavior of the parent substance S , followed by the solution for the activity R . The division of the curve for R by that for S gives a curve of specific activity as a function of time. No assumption of steady state need be made in the formulation. The origins of the two curves which are to be divided may be offset relative to each other. That is to say, the system may be initially loaded with the unlabeled species so that all compartments have initial conditions or finite pool sizes at the time the radioactive tracer is introduced. In fact there may be little interest in how the system got to the condition which prevailed at the time of the introduction of the tracer. The subsequent values of specific activity are the important considerations. A complete example of a two-compartment closed model is carried out in the state-space form in Appendix 3. Note that the solution is in the form of a function of exponential terms. If the rate constants are known, they can be combined into numerical coefficients. Computer solutions of the state-space matrix \bar{A} , of course, require numerical values.

It commonly occurs that the rate constants of the system are not known and that an experiment must be conducted to evaluate these constants. Many papers have treated the problem of curve fitting of assumed functions or the iterative searching for unknown parameters. One of the basic uses of the tracer method is that of establishing pool size through the technique of introducing tracers and then computing the pool size from the dilution indicated by the specific activity. This is easily done in a single compartment or more complicated system, if the rate constants are known or where extensive measurements can be made. Unfortunately, in many systems some rate constants may be unknown or certain internal compartments are not accessible for measurement. The accompanying model considered in Appendix 4 is one in which it was desired to establish the pool size existing at the time of the introduction of the tracer and none of the rate constants was known. The approach was one that could be of benefit in most drug metabolism studies. A model was established based on the best judgment of what might be appropriate and an analytical solution was derived. The state-space numerical solution would have yielded the final exponential form if rate constant values were given. Nevertheless, here it was desirable to identify

the terms of each coefficient comprising the final solution form, and a complete derivation was made. The derivation developed showed that it would be possible to determine the desired quantities from clinical test data. Then to demonstrate that the procedure was feasible, a simulation of the model using assumed parameters was run and data were taken on the model which corresponded to the clinical data expected from the actual experiment. Then from these data the pool size and rate constants were evaluated and shown to agree with the assumed values. One, of course, is not assured that the model is a unique representation of the biological phenomena, but if the experimental data indicates that the model is acceptable, then the parameters can be evaluated. Thus, in this fashion one can be assured that an experiment is feasible and that it will yield the desired parameters. Additional knowledge was gained regarding the requirements for data collection in the clinical experiment, the sensitivity of the parameters in the model was determined, and the general level of confidence regarding the experiment was raised.

While there is no completely general approach to this kind of modeling, this example utilizes relationships that might be overlooked in some situations. Rate constants were separated, based on the final value of the compartment measurements, and the use of a derivative of the analytical form of the solution yielded a transcendental equation that gave the sum of two rate constants. The fortuitous circumstances inherent in this model were that there was an output compartment directly linked to the input compartment and the fact that the parent drug could be assayed as well as the specific activity measured.

CONCLUSIONS

These considerations have shown that it is not necessary to formulate the tracer kinetics for systems governed by first-order linear differential equations in the form of nonlinear equations in order to evaluate the nonsteady-state behavior in terms of specific activity. The solutions may be obtained routinely through the use of the state-space formulation for the separate evaluations of the parent substance and the radioactive tracer, followed by a division of the curves or data points if specific activity is desired. Furthermore, if the case for nonlinear formulation of nonsteady-state conditions is justified on some biological grounds, the solution can be conveniently obtained through the use of a continuous system modeling program such as CSMP which provides a numerical integration algorithm and suitable selection of nonlinear elements. The model in Appendix 4, chosen to exhibit the procedures mentioned above, also exhibited other important features. Through the use of final value and curve fitting or solution of transcendental equations, the initial pool size was evaluated in a model of three internal compartments. The usual model in which dilution techniques are used through the measurement of specific activity to evaluate pool size consists of a single internal compartment linked to an external excretory compartment. An interesting problem exists in the extension of this approach to more complex systems.

It is to be noted that the formalism of postulating a model, assuming parameters, and executing trial runs to produce simulated clinical data, followed by the use of the data to check the previously assumed parameters, provides an assurance that the entire process is well defined. In this fashion the requirements for data collection and processing may be set forth well in advance of the clinical phase of the experimentation.

APPENDIX 1

For an n -compartment, closed, first-order system, one can write

$$\frac{dS_i}{dt} = \sum_{j=1, j \neq i}^n K_{ij}S_j - \sum_{j=1, j \neq i}^n K_{ji}S_i \quad i = 1, 2, \dots, n$$

or

$$\frac{dS_i}{dt} = \sum_{j=1, j \neq i}^n K_{ij}S_j - K_{ji}S_i \quad i = 1, 2, \dots, n$$

where K_{ij} is the rate constant with units hours^{-1} for the transfer of substances S from compartment j to compartment i . S_i is the total amount of substance in compartment i with units of moles.

Scheme I—Three-compartment system.

One can write similar equations for the activity R_i of compartment i since the body will process labeled and unlabeled material in like manner. R has units of counts per minute.

$$\frac{dR_i}{dt} = \sum_{j=1, j \neq i}^n K_{ij}R_j - K_{ji}R_i \quad i = 1, 2, \dots, n$$

Specific activity a_i of compartment i is defined as

$$a_i = \frac{R_i}{S_i} \quad i = 1, 2, \dots, n$$

Differentiating,

$$\frac{da_i}{dt} = \frac{S_i(dR_i/dt) - R_i(dS_i/dt)}{S_i^2}$$

$$\frac{da_i}{dt} = \frac{1}{S_i} \frac{dR_i}{dt} - \frac{R_i}{S_i^2} \frac{dS_i}{dt}$$

Substituting for the derivatives of R_i and S_i results in

$$\frac{da_i}{dt} = \frac{1}{S_i} \sum_{j=1, j \neq i}^n K_{ij}R_j - K_{ji}R_i - \frac{R_i}{S_i^2} \sum_{j=1, j \neq i}^n K_{ij}S_j - K_{ji}S_i$$

$$\frac{da_i}{dt} = S_j \sum_{j=1, j \neq i}^n K_{ij} \frac{1}{S_i} \frac{R_j}{S_j} - K_{ji} \frac{1}{S_j} \frac{R_i}{S_i} - S_j \sum_{j=1, j \neq i}^n K_{ij} \frac{1}{S_i} \frac{R_i}{S_i} - K_{ji} \frac{1}{S_j} \frac{R_i}{S_i}$$

$$\frac{da_i}{dt} = S_j \sum_{j=1, j \neq i}^n \frac{K_{ij}}{S_i} a_j - \frac{K_{ji}}{S_j} a_i - \frac{K_{ij}}{S_i} a_i + \frac{K_{ji}}{S_j} a_i$$

$$S_i \frac{da_i}{dt} = \sum_{j=1, j \neq i}^n K_{ij}S_j(a_j - a_i)$$

If one defines $\rho_{ij} = K_{ij}S_j$ as a flow variable with variability due to S_j and not the rate constant K_{ij} ,

$$S_i \frac{da_i}{dt} = \sum_{j=1, j \neq i}^n \rho_{ij}(a_j - a_i)$$

If steady-state conditions exist, all S 's will be constant and ρ becomes a constant.

APPENDIX 2

For the system in Scheme I with the substances S_i at steady state, it is desired to find the specific activities a_i of each compartment after injecting one unit of labeled material into Compartment 1 at $t = 0$. One cannot resort to known general solutions of linear differential equations (see Appendix 3) because the flow "constant" $\rho_{23} = 1 - 5t$ makes the differential equations which describe the system have time-varying coefficients. For the system in Scheme I, one can write for the specific activities:

$$\frac{da_1}{dt} = \frac{1}{S_1} [\rho_{12}(a_2 - a_1) + \rho_{13}(a_3 - a_1)]$$

$$\frac{da_2}{dt} = \frac{1}{S_2} [\rho_{21}(a_1 - a_2) + \rho_{23}(a_3 - a_2)]$$

$$\frac{da_3}{dt} = \frac{1}{S_3} [\rho_{31}(a_1 - a_3) + \rho_{32}(a_2 - a_3)]$$

Figure 1—CSMP program.

where ρ_{23} is time varying.

For the substance S_i in each compartment the equations are:

$$\begin{aligned}\frac{dS_1}{dt} &= \rho_{12} + \rho_{13} - \rho_{21} - \rho_{31} = 0 \\ \frac{dS_2}{dt} &= \rho_{21} + \rho_{23} - \rho_{12} - \rho_{32} = -0.5 - 5t \\ \frac{dS_3}{dt} &= \rho_{31} + \rho_{32} - \rho_{13} - \rho_{23} = 0.5 + 5t\end{aligned}$$

The six equations shown can be solved simultaneously in a straightforward manner with numerical techniques by using a digital computer language such as CSMP which simulates an analog computer. The simple CSMP program required to solve the above equations is shown in Fig. 1. Integration is performed by using the CSMP function "INTGRL(IC,X)", where IC is the initial condition and X is the function to be integrated. The functions to be integrated such as da_1/dt , which is shown in DA1 in Fig. 1, are defined by FORTRAN IV statements and/or with other CSMP functions. Plots of functions may be called for as well as function values at discrete points. Results of the above example are shown in Figs. 2–4. It is important to note that the above approach makes solutions easily obtainable for a large class of problems. The assumption of steady state, for instance, could be removed and add little complexity to the CSMP program.

APPENDIX 3

Consider a two-compartment, closed, first-order system with initial conditions $S_1(0)$ and $S_2(0)$:

As in Appendix 1, one can write:

$$\begin{aligned}\frac{dS_1}{dt} &= K_{12}S_2 - K_{21}S_1 \\ \frac{dS_2}{dt} &= K_{21}S_1 - K_{12}S_2\end{aligned}\quad (\text{Eq. 1})$$

or in matrix form

$$\begin{bmatrix} \dot{S}_1 \\ \dot{S}_2 \end{bmatrix} = \begin{bmatrix} -K_{21} & K_{12} \\ K_{21} & -K_{12} \end{bmatrix} \cdot \begin{bmatrix} S_1 \\ S_2 \end{bmatrix} \quad (\text{Eq. 2})$$

which may be written as

$$\dot{\vec{S}} = \vec{A}\vec{S}$$

These equations are in the form of the canonical state equations for which solutions are well known (3). The solution is

$$\vec{S} = e^{\vec{A}t}\vec{S}_0$$

where \vec{S}_0 is a constant column vector

$$\begin{bmatrix} S_1(0) \\ S_2(0) \end{bmatrix}$$

of initial conditions. The matrix $e^{\vec{A}t}$ is defined as

$$e^{\vec{A}t} = \vec{I} + \vec{A}t + \cdots + \frac{\vec{A}^K t^K}{K!} + \cdots$$

where \vec{I} is an $n \times n$ identity matrix and \vec{A} is an $n \times n$ constant matrix, which, for this example, are rate constants as in Eq. 2.

All that is necessary for a complete analytical solution to Eq. 1 is evaluating $e^{\vec{A}t}$. Several methods suited to computer implementation exist in the literature (3), but the method of Laplace transforms will be used here for convenience. It can be shown (3) that $e^{\vec{A}t}$ is the inverse Laplace transform of the matrix

$$[s\vec{I} - \vec{A}]^{-1}$$

where s is the Laplace variable and \vec{I} is the identity matrix. One can write

$$[s\vec{I} - \vec{A}] = s \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} - \begin{bmatrix} -K_{21} & K_{12} \\ K_{21} & -K_{12} \end{bmatrix} = \begin{bmatrix} s + K_{21} & -K_{12} \\ -K_{21} & s + K_{12} \end{bmatrix}$$

Now,

$$[s\vec{I} - \vec{A}]^{-1} = \begin{bmatrix} \frac{(s + K_{12})}{s(s + K_{12} + K_{21})} & \frac{K_{12}}{s(s + K_{12} + K_{21})} \\ \frac{K_{21}}{s(s + K_{12} + K_{21})} & \frac{(s + K_{21})}{s(s + K_{12} + K_{21})} \end{bmatrix}$$

by normal methods. Taking the inverse Laplace transform yields¹

$$\begin{aligned}L^{-1}([s\vec{I} - \vec{A}]^{-1}) &= e^{\vec{A}t} \\ &= \begin{bmatrix} \frac{K_{12}}{K_{12} + K_{21}} + \frac{K_{21}}{K_{12} + K_{21}} e^{-(K_{12}+K_{21})t}; & \frac{K_{12}}{K_{12} + K_{21}} - \frac{K_{12}}{K_{12} + K_{21}} e^{-(K_{12}+K_{21})t} \\ \frac{K_{21}}{K_{12} + K_{21}} - \frac{K_{21}}{K_{12} + K_{21}} e^{-(K_{12}+K_{21})t}; & \frac{K_{21}}{K_{12} + K_{21}} + \frac{K_{12}}{K_{12} + K_{21}} e^{-(K_{12}+K_{21})t} \end{bmatrix}\end{aligned}$$

Thus the solutions for Eq. 2 can be written as

$$\begin{bmatrix} S_1 \\ S_2 \end{bmatrix} = \begin{bmatrix} \frac{K_{12}}{K_{12} + K_{21}} + \frac{K_{21}}{K_{12} + K_{21}} e^{-(K_{12}+K_{21})t}; & \frac{K_{12}}{K_{12} + K_{21}} - \frac{K_{12}}{K_{12} + K_{21}} e^{-(K_{12}+K_{21})t} \\ \frac{K_{21}}{K_{12} + K_{21}} - \frac{K_{21}}{K_{12} + K_{21}} e^{-(K_{12}+K_{21})t}; & \frac{K_{21}}{K_{12} + K_{21}} + \frac{K_{12}}{K_{12} + K_{21}} e^{-(K_{12}+K_{21})t} \end{bmatrix} \begin{bmatrix} S_1(0) \\ S_2(0) \end{bmatrix}$$

or

$$\begin{aligned}S_1 &= S_1(0) \left[\frac{K_{12}}{K_{12} + K_{21}} + \frac{K_{21}}{K_{12} + K_{21}} e^{-(K_{12}+K_{21})t} \right] + \\ &\quad S_2(0) \left[\frac{K_{12}}{K_{12} + K_{21}} - \frac{K_{12}}{K_{12} + K_{21}} e^{-(K_{12}+K_{21})t} \right] \\ S_2 &= S_1(0) \left[\frac{K_{21}}{K_{12} + K_{21}} - \frac{K_{21}}{K_{12} + K_{21}} e^{-(K_{12}+K_{21})t} \right] + \\ &\quad S_2(0) \left[\frac{K_{21}}{K_{12} + K_{21}} + \frac{K_{12}}{K_{12} + K_{21}} e^{-(K_{12}+K_{21})t} \right]\end{aligned}$$

¹ A matrix of the type

$$\begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}$$

is written as

$$\begin{bmatrix} 1; & 0 \\ 0; & 1 \end{bmatrix}$$

because of format restrictions.

Figure 4— $a_3(t)$ from CSMP program.

If one does not know $S_1(0)$ and $S_2(0)$ but knows them at some time, t_1 , earlier [e.g., 100 mg. of substance was injected into Compartment 1 with no initial substance in the system, then $S_1(t_1) = 100$ and $S_2(t_1) = 0$], one can use the above solutions with different initial conditions and evaluate at the later time which has been defined as zero to obtain $S_1(0)$ and $S_2(0)$.

If labeled substance is now injected into the system at $t = 0$, it is possible to write for the activities, as in Appendix 1,

$$\frac{dR_1}{dt} = K_{12}R_2 - K_{21}R_1$$

$$\frac{dR_2}{dt} = K_{21}R_1 - K_{12}R_2$$

The solutions to the above follow in the same manner as for the unlabeled substance S_1 , i.e.,

$$R_1 = R_1(0) \left(\frac{K_{12}}{K_{12} + K_{21}} + \frac{K_{21}}{K_{12} + K_{21}} e^{-(K_{12}+K_{21})t} \right) + R_2(0) \left(\frac{K_{12}}{K_{12} + K_{21}} - \frac{K_{12}}{K_{12} + K_{21}} e^{-(K_{12}+K_{21})t} \right)$$

$$R_2 = R_1(0) \left(\frac{K_{21}}{K_{12} + K_{21}} - \frac{K_{12}}{K_{12} + K_{21}} e^{-(K_{12}+K_{21})t} \right) + R_2(0) \left(\frac{K_{21}}{K_{12} + K_{21}} + \frac{K_{12}}{K_{12} + K_{21}} e^{-(K_{12}+K_{21})t} \right)$$

The above solutions could be obtained by other methods, but the state-space method has the advantage of being easily relegated to a computer. One can now obtain a complete analytical solution for the specific activities simply by dividing:

$$a_1 = \frac{R_1}{S_1} = \frac{R_1(0) \left(\frac{K_{12}}{K_{12} + K_{21}} + \frac{K_{21}}{K_{12} + K_{21}} e^{-(K_{12}+K_{21})t} \right) + R_2(0) \left(\frac{K_{12}}{K_{12} + K_{21}} - \frac{K_{12}}{K_{12} + K_{21}} e^{-(K_{12}+K_{21})t} \right)}{S_1(0) \left(\frac{K_{12}}{K_{12} + K_{21}} + \frac{K_{21}}{K_{12} + K_{21}} e^{-(K_{12}+K_{21})t} \right) + S_2(0) \left(\frac{K_{12}}{K_{12} + K_{21}} - \frac{K_{12}}{K_{12} + K_{21}} e^{-(K_{12}+K_{21})t} \right)}$$

and

$$a_2 = \frac{R_2}{S_2} = \frac{R_1(0) \left(\frac{K_{21}}{K_{12} + K_{21}} - \frac{K_{12}}{K_{12} + K_{21}} e^{-(K_{12}+K_{21})t} \right) + R_2(0) \left(\frac{K_{21}}{K_{12} + K_{21}} + \frac{K_{12}}{K_{12} + K_{21}} e^{-(K_{12}+K_{21})t} \right)}{S_1(0) \left(\frac{K_{21}}{K_{12} + K_{21}} - \frac{K_{12}}{K_{12} + K_{21}} e^{-(K_{12}+K_{21})t} \right) + S_2(0) \left(\frac{K_{21}}{K_{12} + K_{21}} + \frac{K_{12}}{K_{12} + K_{21}} e^{-(K_{12}+K_{21})t} \right)}$$

Note that the amount of radioactive drug injected must be added to $S_1(0)$ and $S_2(0)$ since S is defined as the total amount of drug present. Also note that the second term in the numerator of the a 's is zero if the labeled material is injected into Compartment 1 only, as is the usual case.

APPENDIX 4

In the following first-order compartment model each compartment contains an initial condition at time $t = 0$. Measurements are possible for Compartments 4, 5, and 6 only, and hence the initial conditions of Compartments 1, 2, and 3 are unknown. Also, all rate constants are unknown. It will be shown that all of the unknowns may be uniquely determined by using the method of isotope dilution.

One can write

$$\frac{dS_1}{dt} = -(K_{21} + K_{41})S_1$$

$$\frac{dS_2}{dt} = K_{21}S_1 - (K_{32} + K_{52})S_2$$

$$\frac{dS_3}{dt} = K_{32}S_2 - K_{63}S_3$$

The solutions to the above three equations are

$$S_1 = S_1(0)e^{-(K_{21}+K_{41})t}$$

$$S_2 = \frac{K_{21}S_1(0)}{(K_{52} + K_{32}) - (K_{21} + K_{41})} (e^{-(K_{21}+K_{41})t} - e^{-(K_{32}+K_{52})t}) + S_2(0)e^{-(K_{32}+K_{52})t}$$

$$S_3 = S_3(0)e^{-K_{63}t} + \frac{K_{32}S_2(0)}{(K_{52} + K_{32}) - K_{63}} (e^{-K_{63}t} - e^{-(K_{32}+K_{52})t}) + \frac{K_{21}K_{32}S_1(0)}{(K_{52} + K_{32} - K_{63})(K_{41} + K_{21} - K_{63})} \left(\frac{e^{-K_{63}t}}{e^{-(K_{32}+K_{52})t}} + \frac{e^{-(K_{32}+K_{52})t}}{(K_{63} - K_{32} - K_{52})(K_{41} + K_{21} - K_{32} - K_{52})} + \frac{e^{-(K_{41}+K_{21})t}}{(K_{63} - K_{41} - K_{21})(K_{52} + K_{32} - K_{41} - K_{21})} \right)$$

The above three equations describe the time dependency of mass.

Suppose an amount of labeled material is injected into Compartment 1 at $t = 0$. One can write rate equations for the amount of activity in each compartment as:

$$\frac{dR_1}{dt} = -(K_{41} + K_{21})R_1$$

$$\frac{dR_2}{dt} = K_{21}R_1 - (K_{32} + K_{52})R_2$$

$$\frac{dR_3}{dt} = K_{32}R_2 - K_{63}R_3$$

The solutions to the activity equations above are of the same form as the mass equation solutions except that no initial conditions of activity exist on any compartments except 1. Thus the solutions are

$$R_1 = R_1(0)e^{-(K_{21}+K_{41})t}$$

$$R_2 = \frac{K_{21}R_1(0)}{(K_{21} + K_{41}) - (K_{52} + K_{32})} (e^{-(K_{21}+K_{41})t} - e^{-(K_{32}+K_{52})t})$$

$$R_3 = K_{21}K_{32}R_1(0) \left(\frac{e^{-K_{63}t}}{(K_{52} + K_{32} - K_{63})(K_{21} + K_{41} - K_{63})} + \frac{e^{-(K_{32}+K_{52})t}}{(K_{63} - K_{32} - K_{52})(K_{21} + K_{41} - K_{32} - K_{52})} + \frac{e^{-(K_{21}+K_{41})t}}{(K_{63} - K_{41} - K_{21})(K_{32} + K_{52} - K_{41} - K_{21})} \right)$$

Now if specific activity is defined as

$$a = \frac{R}{S}$$

one has for Compartment 1

$$a_1 = \frac{R_1}{S_1} = \frac{R_1(0)}{S_1(0)} \frac{e^{-(K_{41}+K_{21})t}}{e^{-(K_{41}+K_{21})t}}$$

which is a constant. $K_{41}S_1$ and $K_{41}R_1$ can be measured so that

$$a_1 = \frac{K_{41}R_1}{K_{41}S_1}$$

can be determined. Since $R_1(0)$ and a_1 are known,

$$S_1(0) = \frac{R_1(0)}{a_1}$$

which is one of the unknowns to be determined. Note that one must subtract that amount of labeled substance introduced from the above value.

In addition it is possible now also to evaluate K_{41} from

$$K_{41} = \frac{K_{41}S_1(0)}{S_1(0)}$$

K_{21} may be determined from a curve fitting of the $K_{41}S_1$ data with K_{41} as the only unknown. K_{21} could also be determined from the final values of Compartments 4, 5, and 6, i.e.,

$$\frac{K_{41}}{K_{21}} = \frac{S_4(\infty)}{S_5(\infty) + S_6(\infty)}$$

The sum $(K_{32} + K_{52})$ can be found from a curve fit of the $K_{52}R_2$ data with the sum as the only unknown or by solving a transcendental equation derived as

$$K_{52}R_2 = \frac{K_{52}K_{32}R_1(0)}{(K_{21} + K_{41}) - (K_{52} + K_{32})} (e^{-(K_{41}+K_{21})t} - e^{-(K_{32}+K_{52})t})$$

$$\frac{dK_{52}R_2}{dt} = \frac{K_{52}K_{32}R_1(0)}{(K_{21} + K_{41}) - (K_{52} + K_{32})} (- (K_{41} + K_{21}) e^{-(K_{41}+K_{21})t} + (K_{32} + K_{52}) e^{-(K_{32}+K_{52})t})$$

at the time T_m , $K_{52}R_2$ reaches its maximum and $(dK_{52}R_2/dt) = 0$. Thus

$$(K_{41} + K_{21}) e^{-(K_{41}+K_{21})T_m} = (K_{32} + K_{52}) e^{-(K_{32}+K_{52})T_m}$$

which is a transcendental equation which must be solved iteratively. All terms are known except the sum $(K_{32} + K_{52})$.

The sum $(K_{32} + K_{52})$ may now be split into its parts by making use of the relationship

$$\frac{K_{52}}{K_{32}} = \frac{S_5(\infty)}{S_6(\infty)}$$

and thus K_{52} and K_{32} are determined explicitly. One can now deter-

mine the unknown initial conditions, $S_2(0)$. It is possible to measure

$$K_{52}S_2 = K_{52}S_2(0)e^{-(K_{32}+K_{52})t} + \frac{K_{52}K_{21}S_1(0)}{(K_{32} + K_{52}) - (K_{41} + K_{21})} (e^{-(K_{41}+K_{21})t} - e^{-(K_{32}+K_{52})t})$$

and thus at $t = 0$ one can be sure he is measuring $K_{52}S_2(0)$ alone. Since K_{52} is known,

$$S_2(0) = \frac{K_{52}S_2(0)}{K_{52}}$$

Only two unknowns remain for the system, $S_3(0)$ and K_{63} . K_{63} can be found with a curve fit of the measured $K_{63}R_3$ data with K_{63} as the only unknown, or one can solve another transcendental equation derived in a manner similar to the first.

From the $K_{63}S_3$ data at $t = 0$, one can find $K_{63}S_3(0)$ in the same manner as $K_{52}S_2(0)$ and hence

$$S_3(0) = \frac{K_{63}S_3(0)}{K_{63}}$$

Thus all unknowns have been uniquely determined. Two methods of evaluating several of the unknowns are possible and can be used as a check.

Some Derivatives of Phenethanolamine as MAO Inhibitors

J. N. WELLS and J. K. SHIELDS*

Abstract □ A series of *N*-methyl and *o*-alkyl phenethanolamine derivatives has been prepared and tested against monoamine oxidase *in vitro*. A substantial increase in MAO inhibition over that of the parent phenethanolamine derivatives was noted in the *o*-benzyl analogs.

Keyphrases □ Monoamine oxidase inhibition *in vitro*—phenethanolamine derivatives □ *N*-Methyl, *o*-alkyl derivatives—monoamine oxidase inhibition *in vitro* □ Inhibition analysis—radioactive content method

A previous report (1) from these laboratories indicated that 2-phenethylamino-1-phenylethanol (*Ia*) and 2-isopropylamino-1-phenylethanol (*Ib*) were good monoamine oxidase (MAO) inhibitors *in vitro*. A more recent investigation has shown that the *in vivo* duration of action of *Ia* is very short and characterized by potent CNS stimulant properties (2).

The purpose of the studies reported here was to improve the inherent MAO-inhibiting properties of *Ia* and *Ib* by structural modification. Based on the report (3) that etherification of the hydroxyl group in a hydrazinoalkanol series increased the *in vivo* potency, the authors have prepared a few ether and *N*-alkyl analogs of *Ia* and *Ib* and tested their effectiveness against MAO *in vitro*.

Scheme 1

CHEMISTRY

Preparation of *N*-methyl derivatives of *Ia* and *Ib* was accomplished by a standard reductive amination procedure (4).

Synthesis of the desired amino-ethers (*Va,b,c*) was accomplished via the corresponding α -bromophenylacetamide (II) (Scheme I). α -Bromoamides have been shown to form α -lactams when treated with an alkoxide (5). It was assumed that the α -lactam was formed as an intermediate in this sequence since product ratios and yields under various conditions correspond to those predicted from studies of α -lactam reactivity (6). For example, α -lactam formation could have occurred when the appropriate α -bromoamide (II) was reacted with an equimolar amount of either sodium methoxide or benzoxide suspended in the respective alcohol or benzene. However, yields of the ether-amides decreased when benzene was the solvent. This would be expected from proposed ring opening mechanisms attributing formation of the amino-ester (VI) to alkoxide attack on the carbonyl carbon of α -lactams and ether-amide (VII) formation to solvolysis of the α -carbon by an alcohol molecule (Scheme II) (5-8).

One experiment was conducted in an attempt to isolate both the products expected if an α -lactam was involved. When *N*-phenethyl α -bromophenylacetamide (IIa) was reacted with an equimolar amount of sodium benzoxide in ether at room temperature, both the amino-ester (VI, R' = CH₂-C₆H₅, R = CH₂-CH₂-C₆H₅) and ether-amide (IVa) were isolated. In no other case was an attempt made to recover the amino-ester or to quantify the yield. It is interesting to note that in the reaction of sodium methoxide with IIa, only the amino-ester (methyl α -phenethylaminophenylacetate) was isolated.

The desired amino-ether compounds (*Va,b,c*) were readily obtained by lithium aluminum hydride reduction of the corresponding ether-amides (IVa,b,c).

In Vitro Monoamine Oxidase Inhibition—Inhibition of monoamine oxidase *in vitro* was assessed by the method of Wurtman and Axelrod (9). The potential MAO inhibitor and the substrate (2-¹⁴C-tryptamine) were incubated with rat liver homogenate. After a suitable length of time the deaminated product (¹⁴C-indolacetic acid) was extracted and counted for its radioactive content. The compounds were screened at 5 × 10⁻⁴ M concentration as the hydrochloride salt by using: 1 ml. of a 10⁻³ M solution of the potential inhibitor, 0.625 ml. of phosphate buffer, 0.10 ml. (0.02 μ c.) of ¹⁴C-tryptamine substrate, and 0.25 ml. of rat liver homogenate to give a final volume of 2 ml. The degree of inhibition was compared to 5 × 10⁻⁴ M iproniazid standard. The results are given in Table I.

EXPERIMENTAL

Melting points were determined on a Buchi apparatus with open capillary tubes and are uncorrected. NMR spectra were obtained with a Varian Associates A-60-A spectrophotometer in CDCl₃ with tetramethylsilane as an internal standard. Combustion analyses were conducted by Galbraith Laboratories, Inc., Knoxville, Tenn. IR spectra were determined on a Perkin-Elmer model 21 spectrophotometer and were consistent with structures given.

***N*-Methyl-2-phenethylamino-1-phenylethanol Hydrochloride**—Formic acid (25.6 g. of 90%, 0.50 mole), formaldehyde (9.0 g. of 40%, 0.30 mole), and 2-phenethylamino-1-phenylethanol (24.1 g., 0.10 mole) were reacted by standard procedures (4). The product was isolated as the hydrochloride salt and recrystallized from hexane-acetone to give a white solid (8.6 g., 30%), m.p. 153-154°; NMR

Scheme II

(D₂O) δ 7.25 (m, 10, Ar), 5.25 (m, 1, CH), 3.22 (b m, 6, CH₂), 2.95 (s, 3, CH₃).

Anal.—Calcd. for C₁₇H₂₂ClNO: C, 69.97; H, 7.60. Found: C, 69.93; H, 7.76.

N-Methyl-2-isopropylamino-1-phenylethanol Hydrochloride—Formic acid (51.2 g. of 90%, 1.0 mole), formaldehyde (18.0 g. of 40%, 0.60 mole), and 2-isopropylamino-1-phenylethanol (35.8 g., 0.20 mole) were reacted as above. Recrystallization of the hydrochloride salt from hexane-acetone gave 16.5 g. (36%) of white solid, m.p. 134–135°; NMR (D₂O) δ 7.4 (s, 5, Ar), 5.15 (t, 1, CH), 3.7 (m, 1, CH), 3.25 (d, 2, CH₂), 1.27 (m, 6, CH₃).

Anal.—Calcd. for C₁₂H₂₀ClNO: C, 62.73; H, 8.77. Found: C, 62.86; H, 8.97.

N-Phenethyl- α -benzoxyphephenylacetamide (IVa)—Method A—N-Phenethyl α -bromophenylacetamide (11) (20.0 g., 0.06 mole) in 150 ml. of benzyl alcohol was added over 1 hr. to a heated solution of sodium benzoxide (7.8 g., 0.06 mole) in 50 ml. of benzyl alcohol. The mixture was heated under reflux for 10 hr. and then filtered. The filtrate was added to water and extracted with ether. The dried organic extract was evaporated *in vacuo* and the residue distilled under reduced pressure to remove benzyl alcohol. The thick residue solidified after 2 days. The solid was recrystallized from hexane to give 5.0 g. (23%) of white crystalline solid, m.p. 86–88°; NMR (CDCl₃) δ 7.25 (m, 9, Ar), 6.8 (b m, 1, NH), 4.75 (s, 1, CH), 4.40 (d, 2, CH₂), 3.5 (q, 2, NHCH₂), 2.75 (t, 2, CH₂).

Anal.—Calcd. for C₂₃H₂₈NO₂: C, 79.97; H, 6.71. Found: C, 79.75; H, 6.33.

Method B—N-Phenethyl- α -bromophenylacetamide (25.0 g., 0.08 mole) in 100 ml. of benzene was added dropwise to a suspension of 10.4 g. (0.08 mole) of sodium benzoxide in 100 ml. of benzene. After 24 hr. at room temperature the precipitate which had formed was removed and the filtrate was evaporated *in vacuo*. The solid residue was recrystallized from hexane to give 2.5 g. (9%) of white solid identical to that obtained by Method A.

N-Isopropyl- α -methoxyphenylacetamide (IVc)—Utilizing Method A above, N-isopropyl- α -bromophenylacetamide (40.0 g., 0.16 mole) was reacted to give 5 g. (15%) of recrystallized material, m.p. 51–56°; NMR (CDCl₃) δ 7.3 (m, 5, Ar), 6.43 (m, 1, NH), 4.51 (s, 1, CH), 4.0 (t, 1, CH), 3.3 (s, 3, OCH₃), 1.15 (m, 6, CH₃). This material was used without further purification.

N-Phenethyl- α -benzoxyphephenylacetamide (IVa) and Benzyl- α -phenethylaminophenylacetate—To a solution of sodium benzoxide (13.0 g., 0.10 mole) in ether was added in one portion an ether solution of N-phenethyl- α -bromophenylacetamide (32.0 g., 0.1 mole). After 1 hr. the solid was collected and discarded. Ethereal HCl was added dropwise to the filtrate. The precipitate was recrystallized from acetone-ethanol (4:1) to give 2.3 g. (6.2%) of VI·HCl, m.p. 224–225°.

The ether filtrate was evaporated *in vacuo*. The resulting residue was treated with water and extracted with ether. The ether extracts were dried and evaporated to give an oil which could not be purified. The aqueous phase was chilled and a precipitate formed. The solid was recrystallized from hexane to give 1.0 g. (2.1%) of IVa.

Attempted Synthesis of N-Phenethyl- β -methoxyphenethylamine Hydrochloride—Following Method B, N-phenethyl- α -bromophenylacetamide (32.0 g., 0.10 mole) was reacted with sodium methoxide (5.4 g., 0.10 mole) to give a crude solid, m.p. 222–225°. Without further purification (7.5 g., 0.028 mole) was reacted with lithium aluminum hydride according to the general reduction procedure. The product obtained was found to be 2-phenyl-2-phenethylaminoethanol hydrochloride, 1.7 g. (19%), m.p. 131–132°; NMR (CDCl₃) δ 6.40 (m, 10, Ar), 5.6 (m, 1, CH), 4.35 (m, 3, CH₂-OH), 3.15 (m, 4, CH₂-Ar, CH₂-N).

Table I—Results of *In Vitro* Screening for MAO Inhibition Using Rat Homogenate

Compound	% Inhibition
Iproniazid	100
Ia	36 \pm 7 ^{a, b}
Ib	36 ^c
Va	93 \pm 2 ^a
Vb	70 \pm 5 ^a
Vc	15 \pm 4 ^a
N-Methyl Ia	51 \pm 4 ^a
N-Methyl Ib	24 \pm 6 ^d

^a Triplicate determinations reported as the mean and average deviation from the mean value. ^b Found to be less active than previously reported (1). Dioxane was used in the earlier testing and if not properly purified would contain ethanol which has been reported to inhibit MAO *in vitro* (10). ^c Single determination. ^d Duplicate determinations reported as the mean and average deviation of an individual result from this mean value.

Anal.—Calcd. for C₁₆H₂₀ClNO: C, 69.18; H, 7.27. Found: C, 69.47; H, 7.24.

N-Phenethyl- β -benzoxyphephenylamine Hydrochloride (Va)—General Reduction Procedure—N-Phenethyl- α -benzoxyphephenylacetamide (8.0 g., 0.023 mole) suspended in 200 ml. of dry ether was added in 10-ml. portions to a suspension of lithium aluminum hydride (1.74 g., 0.046 mole) in 100 ml. of ether. The mixture was heated under reflux for 12 hr. and then 9.6 ml. of water was added. The resulting precipitate was removed by filtration and the ether filtrate dried. The ether was placed in a dry-ice acetone bath and dry ethereal HCl was added dropwise. The solid that precipitated was recrystallized from acetone-methanol (4:1) by cooling the solution to 0° to give 1.6 g. (19%) of pure Va·HCl, m.p. 136–137.5°; NMR (CDCl₃) δ 7.37 (m, 15, Ar), 5.15 (q, 1, CH), 4.5 (dd, 2, O-CH₂-Ar), 3.3 (m, 6, CH₂-N-CH₂-CH₂-Ar).

Anal.—Calcd. for C₂₃H₂₆ClNO: C, 75.08; H, 7.12. Found: C, 75.26; H, 7.21.

N-Isopropyl- β -benzoxyphephenylamine Hydrochloride (Vb)—N-Isopropyl- α -benzoxyphephenylacetamide (6.0 g., 0.021 mole) was reacted according to the general reduction procedure to give 1.3 g. (22%) of Vb, m.p. 188–189°; NMR (CDCl₃) δ 7.4 (m, 10, Ar), 5.17 (q, 1, CH), 4.5 (dd, 2, O-CH₂), 3.33 (m, 3, CH, N-CH₂), 1.5 (d, 6, CH₃).

Anal.—Calcd. for C₁₈H₂₄ClNO: C, 70.69; H, 7.91. Found: C, 70.39; H, 7.90.

N-Isopropyl- β -methoxyphenethylamine Hydrochloride (Vb)—N-Isopropyl- α -methoxyphenethylacetamide (5.0 g., 0.024 mole) was reacted according to the general reduction procedure to give 1.1 g. (20%) of Vc·HCl, m.p. 225–226°; NMR (D₂O) δ 7.3 (m, 5, Ar), 4.65 (m, 1, CH), 3.3 (m, 6, CH, N-CH₂, OCH₃), 1.50 (d, 6, CH₃).

Anal.—Calcd. for C₁₂H₂₀ClNO: C, 62.73; H, 8.77. Found: C, 62.61; H, 8.69.

DISCUSSION

From Table I it can be observed that *in vitro* inhibition of MAO by the benzyl ether compounds Va and Vb was substantially increased over that of the parent compounds (Ia and Ib). It is interesting to note that the methyl ether of 2-isopropylamino-1-phenylethanol causes a decrease in *in vitro* MAO inhibition from the parent compound which corresponds to observations in the hydrazinoalkanol series of Schuler and Wyss (3). Methylation of the nitrogen of the parent compounds increased MAO inhibition in one case (IIa) over the parent but decreased inhibition in relation to the parent with compound IIb. *In vivo* testing of these compounds will be carried out at a later date.

Some Cyclic Ketals and Acetals of Digitoxin, Digoxin, and Ouabain

KHALID S. ISHAQ and OLE GISVOLD

Abstract □ A new and milder method has been utilized to re-investigate the preparation, properties, and biological activities of the mono-*o*-isopropylidene (acetonides) derivatives of digitoxin, digoxin, and ouabain. The preparation, properties, and biological activities of the mono-*o*-ethylidene derivatives of digitoxin and digoxin also are described. The latter derivatives show greater activity than the former.

Keyphrases □ Digitoxin, digoxin cyclic ketals, acetals—synthesis □ Ouabain cyclic ketals, acetals—synthesis □ Bioanalysis—digitoxin, digoxin, ouabain derivatives □ TLC, paper chromatography—separation, identification □ UV spectrophotometry—identity

In a previous publication the preparation and activities of the mono-*o*-isopropylidene derivatives (glycoside acetonides) of digitoxin, digoxin, and ouabain have been reported (1). Their biological activities were much less than had been expected on the basis of their physical properties and, in the cases of digitoxin and of digoxin, the position of the isopropylidene group. Because these activities were so unexpectedly low, a reinvestigation of the preparation of these derivatives by much milder methods was sought and one such was found. Acetonation can be effected in a very short time at room temperature *via* the use of 2,2-dimethoxypropane, acetone, a trace of acid, and room temperature conditions. The yields are almost quantitative and derivatives readily can be crystallized. Bioassay of these derivatives prepared by this new, very mild method gave comparable results in the case of digoxin but not in the case of digitoxin or ouabain. The ease with which the isopropylidene derivatives (dioxolanes) of digitoxin and digoxin could be prepared *via* the use of ketal-interchange techniques suggested the preparation of other cyclic ketals and cyclic acetals (dioxolanes) to test further the contribution to activity such derivatives might exert. Because the isopropylidene group, even though it was the simplest type of a cyclic ketal and on the terminal digitoxose residue, reduced activity so markedly that the preparation of a cyclic acetal as a second type of a dioxolane derivative was investigated. The ethylidene derivative readily could be prepared *via* 1,1-

dimethoxyethane, acetaldehyde, a trace of acid, and room temperature conditions. Bioassays of these ethylidene derivatives *via* LD₅₀ intravenous assays in cats showed that mono-*o*-ethylidene digoxin had the same activity as that of acetyldigoxin whereas acetyldigitoxin was 2.35 times as active as mono-*o*-ethylidene digitoxin. Thus the activity (toxicity) of digitoxin was reduced to a greater extent by both types of derivatives than was the case with digoxin. Also it is of interest to note that the mono-*o*-ethylidene digoxin activity was the same as that of acetyldigoxin.

In the case of digoxin, its usefulness is improved in its acetyl derivatives.¹ Acetyldigoxin is considered by some to be the drug of choice because it is well absorbed orally, is less toxic to the CNS, and has a shorter duration of action than digitoxin or acetyldigitoxin. Acetyldigoxin was isolated directly from *Digitalis lanata* by Hopponen and Gisvold (2) in 1952, and its good oral absorption properties in cats were first reported by White and Gisvold (3).

It now appears that the physical properties of the monoethylidene derivative of digoxin, *i.e.*, *R_f* value measuring liposolubility, should enhance its degree of absorption upon oral administration. Its toxicity and duration of action would depend in part upon its distribution and metabolism *in vivo*. This derivative is sensitive to hydrolysis at condition below pH 7 but is quite stable above pH 7. Dioxolanes are usually stable *in vivo* and thus such derivatives of the cardiac glycosides might exert some interesting effects upon their metabolism *in vivo*. Increased stability without a significant increase in stereochemical bulk would be effected by the substitution of F for H in the ethylidene residue. Such investigations are now in progress.

Some Cyclic Ketals and Acetals of Digitoxin, Digoxin, and Ouabain

KHALID S. ISHAQ and OLE GISVOLD

Abstract □ A new and milder method has been utilized to re-investigate the preparation, properties, and biological activities of the mono-*o*-isopropylidene (acetonides) derivatives of digitoxin, digoxin, and ouabain. The preparation, properties, and biological activities of the mono-*o*-ethylidene derivatives of digitoxin and digoxin also are described. The latter derivatives show greater activity than the former.

Keyphrases □ Digitoxin, digoxin cyclic ketals, acetals—synthesis □ Ouabain cyclic ketals, acetals—synthesis □ Bioanalysis—digitoxin, digoxin, ouabain derivatives □ TLC, paper chromatography—separation, identification □ UV spectrophotometry—identity

In a previous publication the preparation and activities of the mono-*o*-isopropylidene derivatives (glycoside acetonides) of digitoxin, digoxin, and ouabain have been reported (1). Their biological activities were much less than had been expected on the basis of their physical properties and, in the cases of digitoxin and of digoxin, the position of the isopropylidene group. Because these activities were so unexpectedly low, a reinvestigation of the preparation of these derivatives by much milder methods was sought and one such was found. Acetonation can be effected in a very short time at room temperature *via* the use of 2,2-dimethoxypropane, acetone, a trace of acid, and room temperature conditions. The yields are almost quantitative and derivatives readily can be crystallized. Bioassay of these derivatives prepared by this new, very mild method gave comparable results in the case of digoxin but not in the case of digitoxin or ouabain. The ease with which the isopropylidene derivatives (dioxolanes) of digitoxin and digoxin could be prepared *via* the use of ketal-interchange techniques suggested the preparation of other cyclic ketals and cyclic acetals (dioxolanes) to test further the contribution to activity such derivatives might exert. Because the isopropylidene group, even though it was the simplest type of a cyclic ketal and on the terminal digitoxose residue, reduced activity so markedly that the preparation of a cyclic acetal as a second type of a dioxolane derivative was investigated. The ethylidene derivative readily could be prepared *via* 1,1-

dimethoxyethane, acetaldehyde, a trace of acid, and room temperature conditions. Bioassays of these ethylidene derivatives *via* LD₅₀ intravenous assays in cats showed that mono-*o*-ethylidene digoxin had the same activity as that of acetyldigoxin whereas acetyldigitoxin was 2.35 times as active as mono-*o*-ethylidene digitoxin. Thus the activity (toxicity) of digitoxin was reduced to a greater extent by both types of derivatives than was the case with digoxin. Also it is of interest to note that the mono-*o*-ethylidene digoxin activity was the same as that of acetyldigoxin.

In the case of digoxin, its usefulness is improved in its acetyl derivatives.¹ Acetyldigoxin is considered by some to be the drug of choice because it is well absorbed orally, is less toxic to the CNS, and has a shorter duration of action than digitoxin or acetyldigitoxin. Acetyldigoxin was isolated directly from *Digitalis lanata* by Hopponen and Gisvold (2) in 1952, and its good oral absorption properties in cats were first reported by White and Gisvold (3).

It now appears that the physical properties of the monoethylidene derivative of digoxin, *i.e.*, *R_f* value measuring liposolubility, should enhance its degree of absorption upon oral administration. Its toxicity and duration of action would depend in part upon its distribution and metabolism *in vivo*. This derivative is sensitive to hydrolysis at condition below pH 7 but is quite stable above pH 7. Dioxolanes are usually stable *in vivo* and thus such derivatives of the cardiac glycosides might exert some interesting effects upon their metabolism *in vivo*. Increased stability without a significant increase in stereochemical bulk would be effected by the substitution of F for H in the ethylidene residue. Such investigations are now in progress.

EXPERIMENTAL

The details of some of the paper chromatographic techniques used in these studies have been previously described (4). Thin-layer

¹ Marketed in Europe as Novadigal and Lanatinin.

chromatography (5) using silica gel and development with benzene–95% ethyl alcohol was used to good advantage. The Raymond reagent was used to detect the glycosides and their reaction products on both paper and silica gel.

Preparation of Isopropylidene Derivatives—The dry glycosides, digoxin, digitoxin, or ouabain (65 mg. each), were dissolved in 130, 65, and 60 ml., respectively, of dried acetone followed by the addition of 15 ml. of 2,2-dimethoxypropane. Dry hydrogen chloride, 12–14 bubbles, was added *via* a glass tube that had a 4-mm. internal diameter. The course of the reaction could be followed by the chromatographic examination of a few milliliters of the reaction mixture. At room temperature, 95 min., 90 min., and 27 hr., respectively, gave the optimum conversion to the desired derivative which was at least 90% in the case of digoxin and digitoxin and 80% plus in the case of ouabain. The remainder was the glycoside and a faster moving substance on TLC silica gel. Hydrogen chloride was chosen as the condensing agent because it readily could be removed under a vacuum on the Buchi during the removal of the acetone and excess 2,2-dimethoxypropane. This is a critical factor since non-volatile acids such as *p*-toluene sulfonic acid, although effective as a catalyst, are troublesome to remove and may lead to some cleavage of the acid-sensitive dioxolane derivatives.

Although conversion to the desired isopropylidene derivative was obtained in very high yield, preparation of a highly purified analytically pure sample *via* direct crystallization was not readily possible because of the formation of isomorphous crystals. Chromatographic purification on 1-mm. silica gel plates using benzene–95% ethyl alcohol (7:3) yielded analytically pure samples. Such samples gave a positive Raymond test, negative periodate-benzidine test (6), and showed a UV λ_{max} at 218 m μ . Thus the lactone ring was intact and the isopropylidene residue was on the terminal digitoxose residue. The R_f value of these analytically pure samples was the same as that obtained from the initial acetonated glycoside product.

Mono-*o*-isopropylidene digoxin after recrystallization from benzene and naphtha (Skellysolve B) melted at 241–244.5° with decomposition.

Anal.—Calcd. for mono-*o*-isopropylidene digoxin, $\text{C}_{44}\text{H}_{68}\text{O}_{14}$: C, 64.36; H, 8.34. Found: C, 64.13; H, 8.54.

Mono-*o*-isopropylidene digitoxin after recrystallization from benzene and naphtha melted at 243.5–246.5° with decomposition.

Anal.—Calcd. for mono-*o*-isopropylidene digitoxin, $\text{C}_{44}\text{H}_{68}\text{O}_{13}$: C, 65.65; H, 8.50. Found: C, 65.43; H, 8.36.

Mono-*o*-isopropylidene ouabain after recrystallization from methanol, benzene, and naphtha melted at 221–223° with decomposition.

Anal.—Calcd. for mono-*o*-isopropylidene ouabain, $\text{C}_{32}\text{H}_{48}\text{O}_{12}$: C, 61.55; H, 7.74. Found: C, 61.50; H, 7.96.

Preparation of Ethylidene Derivatives—Dry digoxin, 80 mg., was dissolved with the aid of heat in 170 ml. of dried methylene chloride in a 250-ml. three-necked flask fitted with a condenser equipped with a drying tube. The flask was cooled to 5° in an ice bath and 5 ml. of 1,1-dimethoxyethane added. Dried and cooled acetaldehyde, 10 ml., was added *via* a syringe and finally dry hydrogen chloride, 33–55 bubbles, was introduced *via* a glass tube having an internal diameter of 4 mm. After 17 hr. the solvents were removed under vacuum on the Buchi. Analysis *via* TLC on silica gel using benzene–95% ethyl alcohol (7:3) showed the presence of some digoxin R_f value 0.50 and two very closely moving substances having an average R_f value of 0.67. The latter might well be two con-

formers or isomers at the 2-position of the dioxolane ring. Purification *via* thick-layer silica gel plates as described above gave a crystalline product after crystallization from methanol, benzene, and water that melted at 128–148°; $[\alpha]_D^{22} = +9.6$ ($C = 0.5$ in methanol); λ_{max} at 218 m μ .

Anal.—Calcd. for mono-*o*-ethylidene digoxin, $\text{C}_{44}\text{H}_{66}\text{O}_{14}$: C, 63.99; H, 8.24. Found: C, 63.44; H, 8.53.

Because digitoxin was more soluble in methylene chloride, 80 mg. was dissolved in 40 ml. of methylene chloride and a 200-ml. three-necked flask was used. The remainder of the experimental conditions were the same as those used for the preparation of mono-*o*-ethylidene digoxin. The purified mono-*o*-ethylidene digitoxin was crystallized from methanol, benzene, and water. It melted at 113–127°; $[\alpha]_D^{22} = +8.5$ ($C = 0.5$ in methanol); λ_{max} at 218 m μ . Its R_f value on silica gel using benzene–95% ethyl alcohol (7:3) was 0.72. As in the case of the digoxin derivative, two very closely moving spots were obtained. Thus here also two conformers or isomers at the 2-position of the dioxolane ring are possible to account for the two very closely moving spots on TLC since the R_f value of digitoxin was 0.57.

Anal.—Calcd. for mono-*o*-ethylidene digitoxin, $\text{C}_{43}\text{H}_{66}\text{O}_{13}$: C, 65.29; H, 8.41. Found: C, 64.73; H, 8.62.

Bioassay² of the Glycoside Acetonides—The following mean $\text{LD}_{50} \pm \text{SE}$ mg./kg. was obtained: digoxin acetonide, 0.582 ± 0.04 (4 cats); digitoxin acetonide, 1.38 ± 0.03 (4 cats); ouabain acetonide, no minimum lethal dose could be reached (2 cats). Thus the digoxin acetonide was slightly more active than that previously reported whereas digitoxin acetonide was about 1.8 times as active as that previously reported. The inactivity of the ouabain acetonide differed from that previously reported which was 0.8837 ± 0.0714 (10 cats).

Bioassay² of the Glycoside Mono-*o*-ethylidene Derivatives—The following mean $\text{LD}_{50} \pm \text{SE}$ mg./kg. was obtained: mono-*o*-ethylidene digoxin, 0.375 ± 0.02 (4 cats), and mono-*o*-ethylidene digitoxin, 1.05 ± 0.06 .

Estimation of Steroid Solubility: Use of Fractional Molar Attraction Constants

J. A. OSTRENGA and C. STEINMETZ

Abstract □ The fractional molar attraction constant (f_p), an empirical constant related to the solubility parameter, was defined and chosen to be related to the solubilizing capacity of solvents for a given steroid because it was thought to assess the relative polarity of solvent molecules. Experimental solubilities for two steroids are reported which indicate that f_p may be a useful parameter for solubility estimations.

Keyphrases □ Steroid solubility—estimation □ Fractional molar attraction constants—steroid solubility □ X-ray diffraction—identification □ Scintillometry—analysis

The solubility of a drug in one or more components of a pharmaceutical dosage form is valuable information which can be used to characterize its behavior in such a physical system. The solubility is usually not difficult to determine and often it is one of a few physical parameters readily available to the formulator which can aid him in the design of suitable dosage forms. This is particularly true in the case of topical dosage forms and where the solubility of the active ingredient can be related to phenomena such as thermodynamic activity, vehicle release rate, dissolution rate, and apparent penetration rate.

THEORETICAL

Methods or techniques for estimating or predicting the solubilities of drugs in various pharmaceutical solvents have obvious practical implications. One of the most useful concepts has been that of the solubility parameter (δ) as defined by Hildebrand and Scott (1) in Eq. 1 for nonelectrolytes:

$$\delta = (E/V)^{1/2} = (EV)^{1/2}/V = F/V \quad (\text{Eq. 1})$$

where E is the molar cohesive energy, V the molar volume, and F the molar attraction constant (2). It was originally derived for regular solutions ($\Delta H > 0$) where a good solvent for a given solute has a δ value close to that of the solute according to

$$\Delta G_m = V_m \phi_1 \phi_2 (\delta_1 - \delta_2)^2 - T \Delta S_m \quad (\text{Eq. 2})$$

where ΔG_m is the free energy of mixing, T the absolute temperature, S_m the entropy for mixing, V_m the volume of the mixture, and ϕ the volume fraction of component 1 or 2. This requirement corresponds to fulfilling the thermodynamic condition that ΔG_m be large and negative for good mixing. Burrell (3) has explored its potential for application in the paint and polymer coatings industry. The main limitation, however, has been that the solubility parameter concept is strictly applicable only to nonpolar systems where dispersion or London forces are predominant and other forces such as those related to hydrogen bonding and polarity are absent. In attempting to increase its applicability, these other forces and their effects have been considered by Burrell (4) and Gardon (5) and have proven to be worthwhile efforts.

In the case of steroids one encounters a somewhat specific solubility problem regarding prediction or estimation. The solubility parameter is not very useful for estimating the solubilizing capability of solvents for steroids because the circumstances are such that certain assumptions associated with δ are no longer valid; namely, that the solutes are crystalline, and specific interactions become highly significant in defining the solubility characteristics

(both of these conditions tend to make $\Delta H < 0$). For steroids one finds that a proper hydrophilic-hydrophobic balance on the part of the solvent is associated with good solvent properties. That is, steroids are relatively insoluble in nonpolar solvents such as hexane and very polar solvents such as water but have appreciable solubility in solvents with partial polarity. This realization suggested that what is required is a parameter which assesses the fraction of the solvent molecule which can participate in the solubilization of a steroid and thereby hopefully place solvency on a common scale. This notion led to the defining of an empirical quantity called the fractional molar attraction constant (f_p). That is, since the presence of certain functional groups (e.g., esters, ketones, ethers, alcohols) play a critical role in governing the solubility capacity of solvents for steroids and since apparently the relative abundances of these groups are also important, the separation of δ into two components was considered according to Eqs. 3 and 4:

$$\delta = \delta_p + \delta_n = (F_p + F_n)/V \quad (\text{Eq. 3})$$

$$\delta_p = F_p/V; \delta_n = F_n/V \quad (\text{Eq. 4})$$

where δ_p and δ_n are the contributions made to δ by participating and nonparticipating functional groups, respectively. F_p and F_n are similarly defined for F ; that is, F_p is the sum of F for all participating groups in the solvent molecule and F_n is the corresponding sum for all nonparticipating groups ($F = F_p + F_n$). The fractional molar attraction constant then was defined as in Eq. 5.

$$f_p = \delta_p/\delta = F_p/(F_p + F_n) = F_p/F \quad (\text{Eq. 5})$$

In order to demonstrate the possible usefulness of f_p , the solubilities of two steroids in various solvents were determined at 25°. The steroids employed in this report were fluocinolone acetonide¹ and fluocinolide.²

EXPERIMENTAL

Materials—Cellosolve acetate,³ carbitol acetate,³ *n*-butyl carbitol,³ glyceryl triacetate,³ methyl cellosolve acetate,³ ethylene glycol diacetate,³ isopropyl myristate,⁴ cellosolve solvent,³ methyl cellosolve,³ diethylene glycol,³ propylene glycol,³ Ucar solvent LM,³ 1,4-butanediol,⁴ polyethylene glycol 400,³ carbitol,³ propylene carbonate,⁵ toluene (scintillation grade),⁶ PPO,⁷ POPOP,⁷ dioxane (scintillation grade),⁶ naphthalene,⁸ fluocinolone acetonide, and fluocinolide were used as received. All other materials were of analytical reagent grade. ¹⁴C-labeled (acetonide label) steroids were used in all determinations and were provided by the Institute of Organic Chemistry, Syntex Research, Palo Alto, Calif. The radioactive purity was checked by developing a radioactive sample on a TLC plate with chloroform-methanol (95:5 for the acetate and 100:5 for the alcohol) and then scanning on a Vanguard model 880-D glass plate scanner. These radiochromatograms indicated that the purity was $\geq 98\%$.

Solubility Determinations—Solubilities were determined in the various solvents in duplicate by one of two methods. In the first method, an excess quantity of radioactive steroid with known spe-

^a The most stable phase is the clathrate; values for the solubility of Phase I were obtained by extrapolation (see text). ^b Values obtained by extrapolation to 100% of solvent in a plot of log solubility versus percent solvent in water.

cific activity was added to approximately 10 ml. of each solvent in a culture tube. The preparations were capped, sealed with rubber tape, and agitated on a Vibro-Mixer⁹ at 25° in a thermostated bath until equilibrium was attained (2–5 days). All preparations were protected from the light. The only difference in the second method was that prior to agitation the preparations were heated to 60° to aid solubilization. Equivalent results were obtained by the two methods. Samples were withdrawn at appropriate times and passed through a suitable Gelman Metrical filter¹⁰ (13 mm., 0.2 μ). One milliliter of each filtrate was then analyzed on a liquid scintillation counter. Upon termination of the solubility experiments, the excess steroid was collected from each preparation by filtration and dried. X-ray powder diffraction patterns using copper K α radiations on a Stoe Weissenberg goniometer system with a 57.3-mm. diameter camera were obtained on each dried sample as a means for identifying the polymorphic phase at equilibrium.

Radiochemical Assays—The specific activities of the radiochemicals were 20.7 mc./mmole for both steroids. Samples of the filtrates for each solvent were assayed for steroid utilizing a Nuclear Chicago Unilux II liquid scintillation counter. One-milliliter samples were mixed directly with either 15 ml. of scintillation fluid consisting of 13 g. of PPO (2,5-diphenyloxazol), 0.26 g. of dimethyl POPOP (1,4-bis-2-[4-methyl-5-phenyloxazolyl] benzene), 208 g. of naphthalene, 0.6 l. of methanol, 1 l. of dioxane, and 1 l. of toluene or 10 ml. of scintillation fluid consisting of 4 g. of POP, 0.1 g. of dimethyl POPOP, and 1 l. of toluene. The extent of quenching was determined from a channels ratio analysis utilizing a standard quench correction curve which included the correction factor for counter efficiency. The steroid content for each sample was calculated from the known specific activities and the disintegrations per unit time as obtained from the standard correction curve.

RESULTS

The solubilities of Phase I fluocinolone acetonide (*A*) and Phase I fluocinolide (*B*) at 25° in the various solvents are given in Table I and correspond to the mean value of two determinations. Solvents were chosen so as to give a wide range of f_p values. In the case of *B*, X-ray diffraction powder patterns of the steroid before and after equilibration indicated that no polymorphic conversion had occurred in any of the solvents. In the case of *A*, however, a polymorphic conversion to the clathrate was detected in five solvents (Table I). In these instances the solubilities for Phase I were obtained by extrapolation of a plot of solubility versus time (t) to $t = 0$ where such plots correspond to experiments employing pure

Phase I as the starting material. Consequently, the reported values in these instances are approximations.

The f_p values for the various solvents in Table I were calculated according to the definition ($f_p = F_p/F = F_p/\delta V$). F_p values were calculated from structure alone by summing the F values corresponding to each participating group present in the solvent molecule (esters, ethers, alcohols). Such group F values for many functional groups have been reported by Small (6). It should be pointed out that for diols such as ethylene glycol, propylene glycol, etc., the value of F for a single OH group is 275 as calculated from

Figure 1—Apparent linear relationship between log solubility and log f_p for fluocinolone acetonide (●) and fluocinolide (▲) in various solvents at 25°. * Coordinates for data point (water) which did not fit on axes.

⁹ Chemapec Corp., Hoboken, N. J.

¹⁰ Gelman Instruments Inc., Ann Arbor, Mich.

$F = \delta V$ for the whole molecule and subtracting the reported values for the other groups, while for monofunctional alcohols such as carbitol, cellosolve, etc., the corresponding value is 325 (7). To obtain $F = \delta V$, δ values taken from the technical literature of the supplier or from Reference 2 were used and molar volumes ($V = \rho/\text{mol.wt.}$) were obtained utilizing densities (ρ) at 20° from the technical literature of the supplier or Reference 8. In a few instances where δ values were not available, F was calculated in the same manner as F_p . Fractional molar attraction constants so calculated are included in Table I for each solvent.

The solubility data for both steroids were found to be related to the calculated f_p values of the solvents and an optimum value of f_p was evident. For a log solubility-log f_p correlation the relationship appeared to exhibit linearity separately on each side of a maximum for both steroids. These empirical relationships are shown in Fig. 1 along with the calculated regression lines. Linear equations as determined by the method of least squares which best fit the plots in Fig. 1 are for A

$$\begin{array}{llll} \log S = 3.474 \log f_p + 3.197 & r & n & \\ \log S = -9.773 \log f_p - 1.691 & 0.939 & 9 & \text{(Eq. 6)} \\ & 0.994 & 7 & \text{(Eq. 7)} \end{array}$$

and for B

$$\begin{array}{llll} \log S = 3.554 \log f_p + 2.627 & 0.989 & 10 & \text{(Eq. 8)} \\ \log S = -12.215 \log f_p - 3.139 & 0.990 & 8 & \text{(Eq. 9)} \end{array}$$

where n is the number of data points. The correlation coefficients (r) indicated a high degree of linearity for the apparent relationships cited. Solubilities have been calculated employing Eqs. 6-9 and are included in Table I for comparison with the experimental values. A linear correlation between calculated and experimental values gave $r = 0.916$ at $p = 0.01$ for A and $r = 0.732$ at $p = 0.01$ for B . This result indicated that the relationship is significant but that much of the deviation is masked by the log-log relationship. A relationship between solubility for f_p is apparent, however, from linear plots. Perhaps a more meaningful and practical use of this relationship can be obtained by graphical estimation from linear plots and an empirical log-log relationship need not be forced or assumed.

Fractional molar attraction constants were defined with the intention of placing the solubilizing capability of solvents on a common scale in order hopefully to assess the importance of specific interactions and their relative abundance in various solvents. For strictly nonpolar solvents such as heptane, $F_p = 0$ and $f_p = 0$, while for a strictly polar solvent such as water, $F_p = F$ and $f_p = 1$. It can be shown that F values are additive on a molar basis (6, 9). They are at best only approximately additive on a constitutive and/or

atomic basis but nonetheless the limited additivity of F can be useful in calculating the value of F for solvent molecules if certain limitations and rules are recognized (7). Equations 6-9 indicate the maximum solubility occurs at approximately the same solvent f_p value for A and B (0.428 and 0.431, respectively). Thus, the solvents studied are effective in solubilizing both steroids, the difference being the magnitude of their effect. An optimum in a plot of solubility versus f_p is in agreement with the notion that a proper hydrophobic-hydrophilic balance is required for good solvent properties.

The described techniques and relationships may be useful in estimating the solubilities of test compounds in additional solvents, once limited solubility data have been obtained. It should be pointed out that solubilities obtained utilizing these relationships can give predicted values which are substantially in error. Nonetheless, the relationships can be used to aid in the choice of solvents in appropriate situations and should find application in formulation work. In addition, it is anticipated that these relationships will be applicable to semisolid systems such as creams and ointments where solubility determinations are experimentally impractical or very difficult. Since the solubility of a topical drug in pharmaceutical solvents is necessarily required for the intelligent design of efficacious creams and ointments, additional methods for estimating solubility are an asset to the formulator.

Stabilization of Homatropine Methylbromide–Iodobismuthate Complex in Solution for Quantitative Analysis of Homatropine Methylbromide

S. AHUJA, D. SPIEGEL, and F. R. BROFAZI

Abstract □ The colorimetric reaction between homatropine methylbromide (HMB) and the Dragendorff reagent was investigated as a means of quantitative analysis for HMB. The reaction was found to be unstable under normal laboratory lighting conditions. Stabilization of the colorimetric reaction was achieved by the addition of methanol to an acetone solution of the HMB–iodobismuthate complex in the ratio of 1:1. The stabilization was accompanied by a hypsochromic shift from 474 to 382 $m\mu$. The stabilized colorimetric reaction follows the Beer–Lambert law in the range of concentrations of HMB studied for this investigation. The sensitivity of the method was found to be 0.1 mg. of HMB under the experimental conditions described. However, with slight modifications, this method should be useful for much smaller concentrations of HMB.

Keyphrases □ Homatropine methylbromide analysis—reaction mechanism □ Iodobismuthate complex stabilization—homatropine methylbromide analysis □ Colorimetric reaction—stabilization

For many years, the Dragendorff reagent has been used as a qualitative test reagent for alkaloids. However, it is only recently that the applications of this reagent for quantitative analysis have been reported (1–4). Pfordte (1) used the Dragendorff reagent, as modified by Trabert (5), in the paper chromatographic analysis of atropine, hyoscyamine, and scopolamine. The orange-colored alkaloid spot was eluted from the sprayed paper chromatographic strips with acetone, and the absorbance of this solution was measured at 400 $m\mu$, because the maximum at 475 $m\mu$ faded quickly. Paris and Saint-Firmin (2, 3) employed a thin-layer chromatographic method instead of the paper chromatographic method for quantitative analysis of hyoscyamine and scopolamine bromide with the Dragendorff reagent, as modified by Trabert (5). They used 365 $m\mu$ as the analytical wavelength and noted that the colorimetric solutions were stable in the dark for 30 min. (2) to several days (3).

The present investigation was initiated with the objective of studying the colorimetric reaction of homatropine methylbromide and the Dragendorff reagent as a means of quantitative analysis for homatropine methylbromide (HMB). In the earlier stages of investigation, it was discovered that the colorimetric reaction was unstable, so efforts were made to stabilize the colorimetric reaction in order to achieve a more reliable method of analysis.

EXPERIMENTAL

Reagents—Acetone and methanol, spectroquality, Baker; homatropine methylbromide NF; 5% sulfuric acid; Dragendorff reagent, as modified by Munier and Macheboeuf (6). Ten milliliters of glacial acetic acid and 40 ml. of water are added to 850 mg. of bismuth subnitrate. To 40 ml. of this slurry, 40 ml. of 40% aqueous potassium iodide solution, 125 ml. of glacial acetic acid, and 250 ml. of water are added.

Table I—Stability of HMB–Iodobismuthate Complex in Solution

Solvent Acetone: Methanol	$\lambda_{max.}$ ($m\mu$)	Absorbance at Indicated Time, min.			
		0	15	30	60
100:0	474	0.438	0.453	0.406	0.260
90:10	464	0.448	0.420	0.276	0.199
80:20	459	0.420	0.400	0.350	0.295
70:30	449	0.351	0.329	0.301	0.285
60:40	380	0.497	0.500	0.502	0.634
50:50	382	0.505	0.503	0.502	0.501
40:60	383	0.492	0.488	0.487	0.487
30:70	387	0.460	0.427	0.449	0.756

Method—An accurately weighed amount of homatropine methylbromide was dissolved in distilled water to yield a 0.25-mg./ml. solution. Five milliliters of this solution (equivalent to 1.25 mg. of homatropine methylbromide) was transferred to a 100-ml. beaker, and 2 drops of 5% sulfuric acid and 1 ml. of freshly prepared modified Dragendorff reagent were added. The resulting precipitate was allowed to stand for 1 hr. to facilitate filtration. (The precipitation is quantitative and cannot be readily extracted into any of the common immiscible organic solvents; therefore, filtration is used.) The precipitate was filtered through a fine-porosity sintered-glass funnel with the aid of vacuum. The precipitate was dried by suction and dissolved in acetone directly in the sintered-glass funnel and the solution was collected in a 50-ml. volumetric flask containing a known volume of methanol. The volume was made up with acetone. The resulting solutions were scanned with a recording spectrophotometer¹ in 1-cm. cells.

RESULTS AND DISCUSSION

The Dragendorff reagent, as modified by Munier and Macheboeuf (6), was used for this investigation. This reagent is commonly used in these laboratories as a spray reagent for TLC plates (7) and in that respect, it is similar to that used by previous workers (1–3).

The reaction product of an alkaloid and the Dragendorff reagent has been called alkaloid–iodobismuthate complex (1, 8, 9) and will be so referred to in this paper. The HMB–iodobismuthate complex is obtained as an orange precipitate when HMB is reacted with the Dragendorff reagent, as modified by Munier and Macheboeuf (6). This precipitate, when solubilized in acetone, yields an orange-colored solution with a maximum at 474 $m\mu$. Due to some change in the iodobismuthate complex, the absorbance at 474 $m\mu$ decreases rapidly with a resulting shift of the maximum to 362.5 $m\mu$. From investigations in these laboratories, the stability of the maximum at 362.5 $m\mu$ under regular laboratory lighting conditions, appears to be questionable. [The complex obtained with Dragendorff reagent, as modified by Trabert (5), was also found to be unstable.] Therefore, stabilization of the iodobismuthate complex was considered desirable so that quantitation could be achieved by the use of the complex itself rather than an unknown by-product.

Studies were conducted with several mixtures of solvents to determine a suitable solvent system which would offer greatest stability characteristics for the complex.

Stabilization of the HMB–iodobismuthate complex could be achieved by the addition of methanol to the acetone solution of the complex in the ratio of 1:1. The resulting 50% acetone–methanol

¹ Cary 15 recording spectrophotometer, Cary Instruments, Monrovia, Calif.

Figure 1—Stability of homatropine methylbromide-iodobismuthate complex in 50% acetone-methanol solution (recorded at 15-min. intervals over a period of 1 hr.).

solution was stable for at least 1 hr. in normal laboratory lighting conditions. This time period was considered adequate even if a large number of samples have to be analyzed at the same time; therefore, longer time periods were not checked.

The stabilization was accompanied by a hypsochromic shift from 474 to 382 $m\mu$. Stabilization of the complex could be demonstrated by allowing the acetone-methanol solution to stand for half an hour, evaporating the solvents, dissolving the residue in acetone, and observing the return of the maximum at 474 $m\mu$. This was not the case with solution of the complex in acetone alone, thereby suggesting a definite change in the complex. Table I shows the hypsochromic shifts caused by the addition of various amounts of methanol to the acetone solution of HMB-iodobismuthate complex. The stability of these solutions under normal laboratory lighting conditions, as indicated by change in absorbance readings at λ_{max} , is also shown in Table I. (The reagent blank readings were found to be negligible.)

From these results, it is apparent that stabilization can be achieved when 50 to 60% methanol is present in the acetone-methanol solution with greatest stability being indicated for 50% methanol content. The stability of 50% acetone-methanol solution of the HMB-iodobismuthate complex over a 1-hr. period can be seen in Fig. 1. These data also show that greater sensitivity is obtained with 50% acetone-methanol solution. This was confirmed by studying acetone-methanol solutions of the HMB-iodobismuthate complex containing 55.0, 52.5, 47.5, and 45.0% of methanol. Therefore, it is logical to conclude that of the various acetone-methanol solutions investigated, 50% acetone-methanol solution offers the greatest stability and sensitivity for the quantitation of iodobismuthate complex.

Table II shows that the colorimetric reaction follows the Beer-Lambert law from 0.1 to 1.8-mg. concentrations of HMB. Higher concentrations than 1.8 mg. were not investigated. Lower workable limits were found to be 0.1 mg. under the experimental conditions described. However, with slight modifications such as final dilution volume and the size of the spectrophotometric cell, it should be possible to work with much smaller concentrations of HMB.

These investigations have shown that Dragendorff reagent, as modified by Munier and Macheboeuf (6), can prove to be a useful reagent for quantitative analysis of homatropine methylbromide. The colorimetric reaction is stable and sensitive to small concentra-

Table II—Relationship between Concentration of HMB and Absorbance

Concentration of HMB, mg.	Absorbance at 382 $m\mu$
0.1	0.035
0.2	0.070
0.4	0.152
0.6	0.245
1.0	0.390
1.2	0.480
1.4	0.540
1.6	0.600
1.8	0.680

tions of HMB. Furthermore, the colorimetric reaction should prove useful for quantitative analysis of other alkaloids and compounds reactive with the Dragendorff reagent.

CONCLUSIONS

The Dragendorff reagent, as modified by Munier and Macheboeuf (6), has been found to be a useful reagent for quantitative analysis of homatropine methylbromide. The resulting homatropine methylbromide-iodobismuthate complex in acetone solution has been stabilized by the addition of methanol in the ratio of 1:1. The colorimetric solution obtained has a maximum at 382 $m\mu$ and is stable for at least 1 hr. under normal laboratory lighting conditions. The colorimetric reaction follows the Beer-Lambert law down to a 0.1-mg. concentration of HMB, under the working conditions described in this publication. With small modifications, this reaction could become sensitive for much smaller concentrations of HMB. Furthermore, it may be logically concluded that this method should prove useful for chemical compounds reactive with the Dragendorff reagent.

Effect of Heavy Water on Three High Producing Strains of *Penicillium chrysogenum*

KASHEED MOHAMMED, DANIEL A. NONA, and MARTIN I. BLAKE

Abstract □ Three high antibiotic-producing strains of *Penicillium chrysogenum* (Wisconsin Q176, 51-20F3, and 49-133) were examined for their ability to grow and produce penicillin in nutrient solutions containing pure heavy water. Penicillin titer values and pH changes were observed over the culture study period. Wisconsin Q176 responded most favorably. Continuous feeding of dextrose and potassium phenylacetate gave better antibiotic titers than a single addition of the two components. With either feeding regimen, potassium phenylacetate was more effective as a precursor than *N*-(β -hydroxyethyl)phenylacetamide or α -phenylacetamide. L-Leucine added together with potassium phenylacetate further enhanced penicillin production. The production of the yellow pigment associated with Wisconsin Q176 in protio nutrient cultures was suppressed in deuterium oxide nutrient cultures.

Keyphrases □ Deuterium oxide effect—*Penicillium chrysogenum* penicillin production □ Penicillin production, *P. chrysogenum*—deuterium oxide effect □ Media additives, effect—penicillin production □ Additives, single, multiple feedings—penicillin production, *P. chrysogenum*

Extensive studies have been reported in the literature pertaining to the effects of deuterium oxide on various organisms. In each case, deuterium oxide was substituted for water either partially or *in toto* in the nutrient medium. These investigations have been summarized by Flaumenhaft *et al.* (1) and by Katz (2), who thoroughly surveyed deuterium oxide effects on organisms.

Nona *et al.* (3) studied the effect of deuterium oxide on the culturing of *Penicillium janczewskii* and the antifungal activity of fully deuteriated griseofulvin. In an earlier report, Mohammed *et al.* (4) investigated the effect on the growth and antibiotic production of a number of low producing strains of *Penicillium*. Mycelial dry weights, pH variations, and penicillin potency over a 90-day study period were included in that study.

In the present study three high producing strains of *Penicillium*, the parent strain and two mutants, were cultured in water and deuterium oxide by a continuous feeding technique and by a single addition of dextrose and a precursor.

EXPERIMENTAL

Strains of *Penicillium chrysogenum*—Three high producing strains of *Penicillium* were used in the present study: Wisconsin Q176¹ and two of its mutants, Wisconsin 51-20F3² and Wisconsin 49-133.² Two methods for preserving the stock cultures were utilized: on agar slants (4) at 5° and by lyophilization of healthy spores. The spores were suspended in 1.0 ml. of calf serum and the suspension was freeze-dried. The lyophil cultures were stored at 5°. Propagation of the spores from the lyophil tube was effected

by first suspending the freeze-dried material in Sabouraud liquid medium. Agar slants were then prepared from this enriched medium. Fungal spores obtained from these slants were used for inoculation of the seed inoculum medium.

Preparation of the Seed Inoculum—A standard salt mixture was used throughout this study. The composition of the mixture was (g./100 ml. of solvent): NaNO₃, 0.3; MgSO₄·7H₂O, 0.025; KH₂PO₄, 0.05; ZnSO₄·7H₂O, 0.005; CuSO₄·5H₂O, 0.0003; FeSO₄·7H₂O, 0.005. To prepare the seed inoculum 7.0 g. of dextrose was added to the basic salt mixture. The pH of the solution was adjusted to 6.5 with 25% potassium hydroxide solution. Finally calcium carbonate, 1.2 g., was added. Ninety milliliters of this medium was placed in a 1-l. conical flask; the flask was stoppered with nonabsorbent cotton, capped with aluminum foil, and then sterilized. One loopful of spores obtained from an agar slant prepared as described under *Strains of Penicillium chrysogenum* was used to inoculate the flask. A thick vegetative growth was obtained within 48–54 hr. which was then used for inoculating the fermentation nutrient medium.

Protio and Deuterio Nutrient Media—The protio and the deuterio fermentation media both had the same nutrient composition: the basic salt mixture as indicated under *Preparation of Seed Inoculum*, together with dextrose and a precursor, or a combination of precursors, as listed under *Procedures*. The protio nutrient medium and a deuterio nutrient medium contained distilled water and pure deuterium oxide (99.6%) as the solvents, respectively. However, in preparing the deuterio nutrient medium, the exchangeable hydrogen of the components was replaced with deuterium by dissolving the nutrient mixture in deuterium oxide and lyophilizing. This procedure was repeated to ensure complete exchange. Finally the pH was adjusted to 6.5 with 25% (w/v) potassium hydroxide in deuterium oxide, and 1.0 g. of calcium carbonate/100 ml. of solution was added. After sterilization, 10 ml. of inoculum was added to each flask/100 ml. of nutrient medium. In the case of the deuterio inoculation, the seed inoculum was filtered through a Seitz pressure filter, and the vegetative mycelial growth was washed with deuterium oxide under aseptic conditions prior to inoculation of the sterilized deuterio fermentation nutrient medium.

Procedures—The sterilization techniques, the measurement of pH, and penicillin bioassay determinations have been described in an earlier paper (4). Preparation of the seed inoculum and all fermentations were conducted on an Eberbach rotary shaker at 210 r.p.m. Incubation temperature was kept at 26–28°, and the relative humidity was between 20 and 30%. In all cases, the pH of the fermentation medium was adjusted to 6.5 with 25% potassium hydroxide solution, and 1.0 g. of calcium carbonate was added/100 ml. of medium. One hundred milliliters of nutrient medium was added to a 3-l. conical flask; the flask was plugged with nonabsorbent cotton, capped with aluminum foil, and sterilized.

One series of experiments involved a single addition of dextrose and a precursor or precursors to the basic salt mixture prior to sterilization. The concentration of dextrose was 3.0%. The following precursors were studied (g./100 ml. of nutrient solution): potassium phenylacetate, 0.3; α -phenylacetamide, 0.3; *N*-(β -hydroxyethyl)phenylacetamide, 0.3; and L-leucine, 0.06.

In a second study, dextrose, 2.0 g., and potassium phenylacetate, 0.3 g., or *N*-(β -hydroxyethyl)phenylacetamide, 0.3 g., dissolved in 8.0 ml. of solvent were fed continuously to the basic salt mixture which contained 1.0% dextrose.

In a third experiment, a solution of dextrose containing 2.0 g. in 8.0 ml. of solvent was fed continuously to the basic salt mixture which contained, in addition to 1.0% dextrose, 0.3% α -phenylacetamide.

Following sterilization, the nutrient medium in each flask was inoculated with 10 ml. of seed inoculum. After fermentation had

proceeded for 20–30 hr., the flasks containing 1.0% dextrose in the basic salt formula were fed continuously as indicated in the second and third experiments above. The pH of the continuous feed mixture was adjusted to 6.5 with 25% potassium hydroxide in water or deuterium oxide and sterilized separately in a 250-ml. conical flask. A 240-mm. length of rubber tubing was connected to the tip of a 10-ml. microburet equipped with a Teflon stopcock, and the top was plugged with nonabsorbent cotton. The apparatus was wrapped in aluminum foil and sterilized in a dry heat oven at 180° for 4–6 hr. A sterile transfer chamber was used for transferring the feed mixture to the buret. The rubber tubing from the buret was wrapped with the flask's sterile cotton plug and inserted into the flask in such a way as to have at least 100–120 mm. of the tubing extending inside the flask below the cotton plug. The culture nutrient flask was placed on the shaker with the buret fitted securely with a vinylized three-finger jaws clamp attached to a heavy-based buret stand. The solution was introduced at the rate of 0.08 ml. per hour and required 100 ± 4 hr. for the entire solution to be added. Triplicate flasks were prepared for each single addition and continuous feeding experiment.

RESULTS AND DISCUSSION

Growth Observation—The three strains of *Penicillium* studied grew well in the protio seed nutrient medium. Profuse growth was evident within 24 hr. The culture appeared very thick and gelatinous after 48 hr. Fermentation of the protio or deuterio culture medium which contained all the additives introduced at one time produced greater mycelial growth than the corresponding continuous slow feeding culture. Numerous globular pellets were produced in the protio fermentation cultures that had the nutrients added in a single addition. These pellets were tan in color and varied in size from 1 to 5 mm. in diameter. When deuterium oxide was used as the solvent,

the organisms manifested morphological changes. Small spherical pellets appeared after 60–70 hr. of fermentation. These pellets were white to gray in color and varied in size from 1 to 3 mm. in diameter.

After 24 hr. fermentation, both the protio and deuterio cultures which contained an initial 1.0% dextrose in the basic salt mixture showed sparse pellet formation. These pellets varied in size from 1 to 4 mm. in diameter in the protio culture and 1 to 2 mm. in diameter in the deuterio culture. Continuous slow addition of the feed solution to either the protio or deuterio fermentation medium resulted in an enlargement rather than an increase in the number of pellets. After 150–160 hr., the increase in size of the pellets ranged from 4 to 8 mm. in diameter in the protio culture and 2 to 6 mm. in diameter in the deuterio culture.

A yellow pigment was secreted in all protio cultures fermented by Wisconsin Q176. This phenomenon characteristic of the strain was not observed in any of the deuterio fermentation cultures.

Penicillin Production—The three strains of *Penicillium* under study responded differently in protio and deuterio fermentation culture. Overall, penicillin production and the pH plateau were higher for the protio fermentation culture than for the corresponding deuterio fermentation culture.

Tables I, II, and III show penicillin production, pH plateau, and time for maximum penicillin production for strains Q176, 51-20F3, and 49-133. Continuous feeding of dextrose and potassium phenylacetate gave a higher penicillin assay than single addition. Soltero and Johnson (5) obtained increased penicillin titers by the continuous feeding of glucose or sucrose to the protio fermentation media. These workers used a single addition of lactose in the fermentation media as the control. In the present study, a repressive effect in penicillin yield was noted in all deuterio fermentation cultures. Similar observations were reported in an earlier paper (4). However, at that time, low antibiotic-producing strains of *Penicillium* were examined, and the additives were introduced in a single addi-

tion. Table I shows that continuous feeding of dextrose and potassium phenylacetate to the deuterio fermentation medium gave higher penicillin production than a single addition, 601 u./ml. versus 511 u./ml. In the corresponding deuterio experiments with mutant strains 51-20F3 and 49-133, the penicillin titers were drastically reduced. The two mutants gave higher penicillin titers than the parent strain (Q176) in protio fermentation culture. In deuterio cultures, the parent strain yielded more penicillin than the mutants. Christensen (6) indicated that the virulence of mutants placed in a different environment may equal, exceed, or be less than the parent strain. Changes in the original characteristics of the mutants usually result in altered production of enzymes and organic acids.

L-Leucine significantly stimulated penicillin production in protio fermentation culture (Tables I, II, and III). In deuterio fermentation culture enriched with the amino acid, the stimulating effect in penicillin production did not occur with strains 51-20F3 and 49-133. Strain Q176 produced 742 u./ml. with L-leucine and 511 u./ml. without L-leucine. This represents an increase of 45.2%. Foster (7) explained that leucine served as a precursor for the azolactone moiety of the penicillin molecule.

Continuous feeding or a single addition of dextrose and N-(β-hydroxyethyl)phenylacetamide in protio culture showed relatively high penicillin titers when fermented with either of the three strains of *Penicillium* (Tables I, II, and III). Penicillin production in the related deuterio fermentation culture with strains 51-20F3 and 49-133 (Tables II and III) showed about a twentyfold reduction in antibiotic production and about a twofold reduction with strain Q176 (Table I).

Dextrose administered by either feeding regime to α-phenylacetamide-enriched protio culture did not greatly affect antibiotic production. In deuterio fermentation culture, Wisconsin Q176 (Table I) gave higher penicillin titers than the other two strains.

Tables II and III show that strains 51-20F3 and 49-133 were limited in their capacity to produce antibiotic in a D₂O environment. This severe reduction in antibiotic production in each case is apparently related to a low pH plateau. With these two mutants, it appears higher pH plateaus are necessary to activate the enzyme system required for penicillin biosynthesis. The parent strain Q176 consistently maintained a higher pH plateau and higher penicillin titers in each deuterio fermentation culture studied.

Table I indicates that in deuterio fermentation culture, addition of the precursor potassium phenylacetate gave the highest penicillin titers among the precursors added singly. A combination of L-leucine and potassium phenylacetate further enhanced penicillin production. In deuterio fermentation culture (Tables II and III), severe repression in antibiotic production was evident with each precursor investigated. However, no significant differences were observed in the quantities of penicillin produced. Apparently the amount of penicillin produced in deuterio fermentation culture is not as dependent on the type of precursor used as on the strain of *Penicillium*.

Certain Disubstituted *o*-Aminoacetoxy- and Propoxybenzoic and Cinnamic Acids and their *tert*-Butyl Esters

ALEX GRINGAUZ

Abstract □ Several *o*-aminoacetoxy- and propoxy derivatives of benzoic and cinnamic acids as well as certain of their *tert*-butyl esters have been prepared as potential analgesics and local anesthetics. The syntheses and biological evaluation of representative compounds are presented.

Keyphrases □ Analgesic properties—derivatives of benzoic, cinnamic acids, esters □ Anesthetic properties—derivatives of benzoic, cinnamic acids, esters □ Benzoic acid, esters (derivatives)—synthesis, biological evaluation □ Cinnamic acid, esters (derivatives)—synthesis, biological evaluation □ IR—analysis □ Bradykinin-induced writhing test—biological analgetic screening

The objective of this work was to synthesize several types of compounds structurally related to acetylsalicylic acid in the hope of obtaining a drug which would overcome some of the disadvantages of aspirin. Ideally the desired agent should have analgesic-antipyretic activity equal to or exceeding that of aspirin. It should have a longer duration of action, possibly as a result of greater stability toward hydrolytic degradation both *in vivo* and *in vitro*; this would make liquid dosage forms possible. It should also exhibit good aqueous solubility. It is also desirable that such a compound produce no, or at least greatly reduced, gastric irritation, ulceration, or bleeding.

DISCUSSION

o-Acetoxyphenylpropionic acid (I) was reported (1) to have analgesic-antipyretic properties similar to aspirin. A recent report (2), however, could not verify this potency. Molecular models indicate that the *trans* isomer of II should be incapable of intramolecularly catalyzed hydrolysis and therefore be more stable. Of the two vinyllogs of aspirin (II), only the *cis* isomer showed ac-

tivity (2). For similar reasons the preparation of an acetyl derivative of *o*-hydroxyphenylpropionic acid was attempted. Synthesis of this compound has thus far been unsuccessful. *o*-Acetoxyphenylacetic acid (III), the first homolog of aspirin, was recently prepared (2) and found to lack significant activity.

Compounds of Type IV ($R' = H$) were synthesized (3) but failed to show pharmacological activity of any significance. Their hydrolytic decomposition rate was considerably greater than aspirin

(5–42 times). Since acid functions such as carboxyl groups tend to sharply lower biological potency (4), several esters of IV ($R' = \textit{tert}$ -butyl) were prepared. Two such esters showed relatively good resistance to *in vitro* hydrolysis (3). This factor alone could alter the absorption and distribution picture in the animal body—and thus possibly its pharmacology. The vinyllog principle (5) was the rationale for the preparation of several cinnamates V ($R' = H$ and *tert*-butyl).

p-Methoxyacetylsalicylic acid has good antipyretic activity (6). *o*-Methoxybenzoic acid also exhibits some activity (7). More recently, it was found (8) that 2-(3-carboxy-4-methoxyphenyl)alanine, a precursor to “phenylalanine aspirin,” possessed good analgesic activity. It was therefore deemed of interest to prepare compounds of the *o*-aminopropoxybenzoic acid type (VI) to determine the presence of biological activity. The one member of this series tested for analgesia (XXIV) was, however, devoid of this property.

The synthesis of salicylic acid carbamates of Type VII was unsuccessful (see *Chemistry*). Salicylic acid (VIII) being the main metabolite of both aspirin and salicylic acid appeared to offer interesting possibilities as a structural moiety. Analgesic-antipyretic activity for the 4-nitro derivative has been claimed (9). Attempts to prepare *o*-aminoacetoxy derivatives were undertaken but were unsuccessful.

CHEMISTRY

tert-Butyl aminoacetoxybenzoates (IV) were synthesized by acylation of *tert*-butyl salicylate with bromoacetyl chloride followed by treatment with the appropriate secondary amine. *o*-Coumaric acid was converted to *o*-chloroacetoxybenzoic acid (XVIII) by reaction with chloroacetic anhydride and sodium chloroacetate. Conversion of XVIII to its *tert*-butyl ester (XIX) was accomplished in poor yields by either treatment with isobutylene and H_2SO_4 (9%) or by conversion to the acid chloride with $SOCl_2$ followed by treatment with *tert*-butyl alcohol and pyridine (13%). Reaction of XIX with NaI in acetone followed by the desired amine afforded

V₁(R' = *tert*-butyl) as the free base. Conversion to the hydrochloride salt resulted in cleavage of the *tert*-butyl group in at least one instance (see *Experimental*) yielding the aminoacid hydrochloride V (R' = H). Methyl *o*-(3-bromopropoxy)benzoate (XXIII) was prepared by treatment of methyl salicylate with NaOCH₃ and refluxing the product with 1,3-dibromopropane. Reaction of XXIII with the appropriate amine followed by acid hydrolysis of the methyl ester gave VI as the hydrochloride salt. Alternately, VI could be prepared by reaction of methyl salicylate (as the Na salt) with dialkylaminopropyl chloride followed by hydrolysis of the methyl ester.

Scheme I

The carbamate VII (R = diethyl) was attempted but did not lead to the desired product. Benzyl diethylcarbamoylsalicylate (XXX) was synthesized by treating benzyl salicylate with phosgene and reacting the resulting chloroformate with diethylamine. Alternately XXX was also prepared by direct reaction with diethylcarbamoyl chloride. Reductive debenzoylation of XXX, however, did not afford VII; salicylic acid was the isolable product. A possible mechanism for this unexpected result is proposed (Scheme I).

EXPERIMENTAL

All melting and boiling points are uncorrected; melting points were determined in capillary tubes. Infrared spectra were obtained in KBr pellets on a Perkin-Elmer 337 instrument. Elemental analyses were done by Smith, Kline & French Laboratories and Alfred Bernhardt, Max-Planck Institute, West Germany. Animal testing was carried out by the Pharmacology Department, Menley & James Laboratories.

***tert*-Butyl Dialkyl or Cycloalkylaminoacetoxysalicylate Hydrochlorides**—*tert*-Butyl Salicylate (IX)—This was prepared in 40–50% yield by either treatment of salicyloyl chloride with *tert*-butyl alcohol as described by Cwalina and Gringauz (3) or by H₂SO₄ catalyzed reaction of salicylic acid with excess isobutylene according to McCloskey and Fonken (10).

tert-Butyl Bromoacetoxysalicylate (X)—This was prepared in 68% yield from IX and bromoacetyl chloride according to Cwalina and Gringauz (3).

tert-Butyl Thiamorpholinoacetoxysalicylate Hydrochloride (XI)—To a solution of 8.10 g. (0.0257 mole) of X in 50 ml. absolute ether there was added dropwise and with stirring 5.15 g. (0.0514 mole) of thiamorpholine¹ in 10 ml. of dry ether. The stirred mixture was refluxed for 6 hr. and filtered. Addition of ethereal HCl precipitated 6.0 g. (62.5%) of the desired salt. Repeated recrystallizations from ethyl acetate–ethanol (70:30) gave m.p. 177–178° dec. The free base could also be obtained in 53% yield, m.p. 83–90° (crude). The five additional analogs similarly prepared are listed in Table I.

***o*-Disubstituted Alkylaminoacetoxycinnamic Acid Hydrochloride**—*o*-Coumaric Acid (XVII)—This was prepared in 75–80% yield from coumarin by treatment with aqueous NaOH and yellow HgO according to Seshardi and Rao (11).

¹ A sample of thiamorpholine was supplied by Dr. W. Horrom of Abbott Laboratories, N. Chicago, Ill.

Table II—Disubstituted *o*-3-Aminopropoxybenzoates and Benzoic Acid Hydrochlorides

Compd.	R'	R	Method ^a	M.p. °C. ^b	Anal., %

XXIX	H	Dimethylamino		^d	C, 55.49 H, 6.99	C, 55.62 H, 7.52

^a Methods A and B as described in *Experimental* section. ^b Solvent of recrystallization was ethyl acetate–2-propanol, 80:20 for the methyl esters, 50:50 for the acids. ^c Could not be crystallized. ^d Extremely hygroscopic; no valid m.p. was obtainable.

o-Chloroacetoxycinnamic Acid (XVIII)—A mixture of 50.0 g. (0.302 mole) XVII, 102.5 g. (0.60 mole) of freshly distilled chloroacetic anhydride and 35.6 g. (0.302 mole) of sodium chloroacetate was stirred 15 hr. at 60°. The resultant melt was poured into ice water and stirred until solidification. The crude product obtained was air dried and extracted from unreacted XVII with CH₂Cl₂. Treatment with charcoal and evaporation of solvent afforded 41.0 g. (56.5%) of product which, after recrystallization from benzene–ether melted at 135.0–137.5°.

Anal.—Calcd. for C₁₁H₉ClO₄: C, 54.90; H, 3.77; Cl, 14.74. Found: C, 55.16; H, 3.77; Cl, 14.68.

tert-Butyl *o*-Chloroacetoxycinnamate (XIX)—Direct reaction of XVIII with isobutylene and H₂SO₄ according to McCloskey and Fonken (10) gave a crude yield of 9% with accompanying recovery of XVII and XVIII. A somewhat better yield was obtained by the dropwise addition, at room temperature, of the acid chloride prepared from 34.5 g. (0.143 mole) of XVIII with SOCl₂ in dry benzene to a stirred solution of 10.6 g. (0.143 mole) *tert*-butyl alcohol and 11.3 g. (0.143 mole) pyridine. After 6 hr. the mixture was poured into ice water and extracted with ether. Evaporation of the combined, dried (Na₂SO₄) ether extracts afforded a dark oil. Repeated extractions with boiling petroleum ether (30–60°) yielded, on cooling, 5.6 g. (13.3%) of product. Repeated recrystallization from the above solvent gave a m.p. 55–57°.

Anal.—Calcd. for C₁₅H₁₇ClO₄: C, 60.71; H, 5.78; Cl, 11.95. Found: C, 60.68; H, 5.75; Cl, 12.06.

tert-Butyl *o*-Morpholinoacetoxycinnamate Hydrochloride (XX)—To a solution of 4.4 g. (0.00149 mole) XIX in 50 ml. of N₂-purged acetone there was added 2.22 g. NaI similarly dissolved and the mixture refluxed several hours under N₂. The resulting product was treated with 2.58 g. (0.0298 mole) of morpholine in 100 ml. absolute ether and refluxed an additional 3 hr. After filtering the precipitate the residue was treated with HCl gas to yield, after crystallization from 2-propanol, 3.71 g. (65%) of product. Four recrystallizations gave a m.p. 165–167°.

Anal.—Calcd. for C₁₉H₂₆ClNO₃: C, 59.47; H, 6.83; Cl, 9.24; N, 3.65. Found: C, 59.00; H, 6.87; Cl, 9.12; N, 3.57.

tert-Butyl *o*-3-Azabicyclo-[3.2.2]-nonan-3-ylacetoxycinnamate Hydrochloride (XXI)—This was similarly prepared and recrystallized from ethyl acetate–2-propanol, m.p. 146–147°.

Anal.—Calcd. for C₂₃H₃₂ClNO₄·H₂O: C, 62.85; H, 7.78; N, 3.18. Found: C, 62.70; H, 7.75; N, 3.18.

o-Diethylaminoacetoxycinnamic Acid Hydrochloride (XXII)—This compound was obtained in 67% yield from XIX and diethylamine. Attempted conversion of the *tert*-butyl ester to its hydrochloride apparently cleaved the ester² directly to the free carboxyl group. Repeated recrystallization from 2-propanol gave a m.p. 183–185° dec.

Anal.—Calcd. for C₁₅H₂₀ClNO₄: C, 57.41; H, 6.43; N, 4.47. Found: C, 57.59; H, 6.52; N, 4.49.

***o*-Disubstituted Alkylaminopropoxybenzoic Acid Hydrochlorides**
—Methyl *o*-3-Bromopropoxybenzoate (XXIII)—To 152 g. (1 mole) methyl salicylate there was added a freshly prepared solution of 23.0 g. (1 mole) Na in 400 ml. absolute methanol. After the addition of 487 g. (2.4 moles) of 1,3-dibromopropane, 300 ml. xylene, and 100 ml. dimethylformamide, the methanol was distilled off and the remaining mixture refluxed 14 hr. Following workup with water, the mixture was washed with 5% NaOH, saturated NaCl, and dried (Na₂SO₄). Evaporation of the solvent *in vacuo* gave 118 g. (43%) of an oil, b.p. 135–136° (1.2 mm.), *n*_D²⁵ 1.5381, *d*₄²⁵ 1.363.

Methyl *o*-3-Diethylaminopropoxybenzoate (XXIV)—Method A—To 13.65 g. (0.05 mole) XXIII dissolved in absolute ether there was added 7.31 g. (0.10 mole) diethylamine and the mixture refluxed 18 hr. Filtration of the precipitate, followed by removal of solvent gave 8.3 g. (62.7%) of an oil, b.p. 120–124° (2 mm.), *n*_D²⁵ 1.5094. Treatment with ethereal HCl gave the hydrochloride, m.p. 85–86° (ethyl acetate–2-propanol).

Method B—To a suspension of 0.25 mole of sodium methyl salicylate (prepared as above) in 250 ml. of toluene there was added 37.2 g. (0.25 mole) of 3-diethylaminopropyl chloride and the mixture refluxed 20 hr. Workup as above afforded 14.2 g. (22%) XXIV, b.p. 140–145° (2.5 mm.), *n*_D²⁵ 1.5038. The hydrochloride melted at 86–88°. A mixed melting point with the product obtained by Method A gave no depression. The IR spectra of both salts were identical.

Anal.—Calcd. for C₁₅H₂₄ClNO₃: C, 59.69; H, 8.02. Found: C, 59.79; H, 8.08.

o-3-Diethylaminopropoxybenzoic Acid Hydrochloride (XXV)—Refluxing 10.9 g. (0.0361 mole) XXIV with 5 ml. concentrated HCl and 40 ml. H₂O for 4 hr. gave, after evaporation of the solvent *in vacuo*, an oil. Cooling and repeated scratching with absolute ether afforded 9.1 g. (88%) of product. Three recrystallizations from ethyl acetate–2-propanol (50:50) gave a m.p. 135–137°.

Anal.—Calcd. for C₁₄H₂₂ClNO₃: C, 58.43; H, 7.71. Found: C, 58.19; H, 7.68.

Additional analogs of XXIV and XXV were similarly prepared and are listed in Table II.

PHARMACOLOGY

Analgetic screening was performed using the modified bradykinin induced writhing test in mice (12). The compounds were administered at doses equivalent to the ED₅₀³ of aspirin, on a molecular weight basis, in a volume of 10 ml./kg. Ten mice per group were used for each compound and three groups of controls received the appropriate vehicle. Compounds XI, XV, XVI, XX, XXI, XXII,

² Cwalina and Gringauz (Reference 3) have shown the ease with which similar *tert*-butyl esters are cleaved under analogous conditions.

³ The dose which produces analgesia in 50% of the animals tested.

and XXV were tested. Only XI exhibited any activity. When compared to aspirin this activity was insignificant.

Local anesthetic activity was assayed as the ability of the test agent to inhibit the blink reflex in the rabbit when the cornea was lightly stimulated. Butacaine sulfate (Butyn sulfate) was used as a control local anesthetic. Compounds XI, XV, XVI, XX, and XXI were tested and found to have no local anesthetic activity.

Evaluation of an Improved Heidelberg Telemetry Capsule for the Study of Antacids

Keyphrases ☐ Heidelberg FM-transmitting capsule—evaluation ☐
Gastric function assessment—Heidelberg telemetry capsule, evaluation

Sir:

Development of a telemetry system employing the Heidelberg FM-transmitting capsule has provided a convenient methodological approach to the clinical assessment of normal gastric function, as well as disease- and drug-induced alterations in gastric activity. The Heidelberg capsule, while elegant in concept, has been found lacking in dependability, a defect related possibly to transmitter construction. One factor involved in the lack of reliability may have been the relatively large hydrogen-ion sensor that permitted accumulation of particulate matter (e.g., antacids) and mucous debris, thus interfering with normal operation. Furthermore, a relatively high percentage of the capsules did not exhibit a linear response throughout the functional range of pH 1 to 7 during *in vitro* standardization (1).

A modified Heidelberg probe,¹ having a smaller hydrogen-ion sensitive area, has recently been made available. These redesigned telemetry capsules have demonstrated a high degree of *in vitro* reliability with regard to linearity of response in the workable pH

range of 1 to 7. The purpose of this study was to evaluate the *in vivo* performance of this modified device.

A FM-signal receiving unit,¹ in belt form, was positioned externally over the stomach area of healthy adult human subjects and connected to a recorder for continuous monitoring of transmitted pH values. Throughout the experimental period the subjects sat erect in an arm chair. Each telemetry capsule was activated by saturation of the hydrogen-ion sensitive end-plate with 0.9% sodium chloride solution, and calibrated in Beckman buffer solutions of pH 2 and 7 at 37°. The capsule was swallowed by the fasted subject, and gastric pH was monitored during the subsequent 50-min. period. After recording baseline pH values (3 to 10 min.), a specified dose of one of four commercial antacid preparations (designated A, B, C, and D) was administered with 30 ml. of water at room temperature: antacid A, 22 ml., suspension; B, 22 ml., suspension; C, 5 ml., suspension; D, two tablets. Each antacid preparation contained aluminum and magnesium hydroxides; formulation C also contained magnesium carbonate and methyl polysiloxane.

The apparent onset and duration of gastric acid buffering activity following administration of the three liquid and one solid antacid formulations are reported in Table I.

Although all of the "improved" Heidelberg capsules were apparently operative, as determined by *in vitro* calibration in buffer solutions and recording of pH signal immediately after swallowing the device, in approximately 14% of the trials (5 of 35 experiments) the anticipated elevation of gastric pH after administration of antacid was not perceived. In 86% of the trials the onset of buffering activity (i.e., elevation of gastric pH above 3.0) following administration of antacid was

¹ Medintron Corp. of America, New York, N. Y.

and XXV were tested. Only XI exhibited any activity. When compared to aspirin this activity was insignificant.

Local anesthetic activity was assayed as the ability of the test agent to inhibit the blink reflex in the rabbit when the cornea was lightly stimulated. Butacaine sulfate (Butyn sulfate) was used as a control local anesthetic. Compounds XI, XV, XVI, XX, and XXI were tested and found to have no local anesthetic activity.

Evaluation of an Improved Heidelberg Telemetry Capsule for the Study of Antacids

Keyphrases ☐ Heidelberg FM-transmitting capsule—evaluation ☐
Gastric function assessment—Heidelberg telemetry capsule, evaluation

Sir:

Development of a telemetry system employing the Heidelberg FM-transmitting capsule has provided a convenient methodological approach to the clinical assessment of normal gastric function, as well as disease- and drug-induced alterations in gastric activity. The Heidelberg capsule, while elegant in concept, has been found lacking in dependability, a defect related possibly to transmitter construction. One factor involved in the lack of reliability may have been the relatively large hydrogen-ion sensor that permitted accumulation of particulate matter (e.g., antacids) and mucous debris, thus interfering with normal operation. Furthermore, a relatively high percentage of the capsules did not exhibit a linear response throughout the functional range of pH 1 to 7 during *in vitro* standardization (1).

A modified Heidelberg probe,¹ having a smaller hydrogen-ion sensitive area, has recently been made available. These redesigned telemetry capsules have demonstrated a high degree of *in vitro* reliability with regard to linearity of response in the workable pH

range of 1 to 7. The purpose of this study was to evaluate the *in vivo* performance of this modified device.

A FM-signal receiving unit,¹ in belt form, was positioned externally over the stomach area of healthy adult human subjects and connected to a recorder for continuous monitoring of transmitted pH values. Throughout the experimental period the subjects sat erect in an arm chair. Each telemetry capsule was activated by saturation of the hydrogen-ion sensitive end-plate with 0.9% sodium chloride solution, and calibrated in Beckman buffer solutions of pH 2 and 7 at 37°. The capsule was swallowed by the fasted subject, and gastric pH was monitored during the subsequent 50-min. period. After recording baseline pH values (3 to 10 min.), a specified dose of one of four commercial antacid preparations (designated A, B, C, and D) was administered with 30 ml. of water at room temperature: antacid A, 22 ml., suspension; B, 22 ml., suspension; C, 5 ml., suspension; D, two tablets. Each antacid preparation contained aluminum and magnesium hydroxides; formulation C also contained magnesium carbonate and methyl polysiloxane.

The apparent onset and duration of gastric acid buffering activity following administration of the three liquid and one solid antacid formulations are reported in Table I.

Although all of the "improved" Heidelberg capsules were apparently operative, as determined by *in vitro* calibration in buffer solutions and recording of pH signal immediately after swallowing the device, in approximately 14% of the trials (5 of 35 experiments) the anticipated elevation of gastric pH after administration of antacid was not perceived. In 86% of the trials the onset of buffering activity (i.e., elevation of gastric pH above 3.0) following administration of antacid was

readily detectable. The apparent *in vivo* "failure rate" (14%) encountered in this study was, however, less than the approximately 50% "failure rate" found by other investigators (2) who examined capsules of an earlier design under essentially similar conditions (*i.e.*, unrestrained device in subjects sitting erect).

Considering the amount and composition of the antacid formulations used in this study, an initial rise in gastric pH following ingestion of any of the four preparations may be considered a predictable phenomenon. This applies also to those individuals who may have been subject to gastric hyperacidity at the time of antacid administration. That a pH rise was not detectable in some cases is consistent with the assumption of *in vivo* capsule failure. Transmitter failure in certain cases may have been attributable to location in the stomach, *i.e.*, the device may have lodged in an area of the mucosa whereby contact of the sensor with the gastric contents was prevented or impaired.

Evaluation of the data obtained in those cases where transmission of gastric pH values was confirmed suggests that the duration of the buffering action of antacids cannot be measured reliably by this technique. Approximately 40% of the capsules used in this investigation ceased normal transmission shortly after signaling onset of antacid-induced elevation of gastric pH. In view of the observed rapid increase in the gastric pH of fasted subjects to values which exceeded the capsule range (pH above 7), it is presumed that those capsules were emptied from the stomach together with the gastric contents. Emptying of the stomach is often accelerated by significant elevations in gastric pH (3). The capsule may be retained in the stomach for an arbitrary period by securing one end of a measured length of string to the capsule and the other end to the teeth after swallowing the transmitter. Since attachment of a restraining device would create an artificial situation in which the location of the capsule would be unrelated to retention of antacid in the stomach, it was not employed in this investigation.

The results of this investigation suggest that the *in vivo* performance of the modified Heidelberg telemetric capsule is not completely dependable. It may

be considered a convenient and useful device for monitoring changes in gastric pH in the period immediately following administration of antacids whose buffering activity is qualitatively predictable. Duration of antacid-induced buffering effect could not, under the conditions of this study, be accurately ascertained, due possibly to acceleration of gastric emptying and consequent ejection of transmitter from the stomach.

Formulation of a Morphine Implantation Pellet Suitable for Tolerance-Physical Dependence Studies in Mice

Keyphrases □ Morphine implantation pellet, formulation—tolerance, physical dependence studies □ Dependence studies—morphine pellet formulation □ Cellulose, microcrystalline—implantation pellets

Sir:

There is considerable current interest in the study of morphine addiction, tolerance, and physical dependence. When using laboratory animals (*e.g.*, mice) for such studies, an essential part of the procedure is

administering the morphine in such a way that the animals receive adequate doses of the drug at frequent enough intervals to reach and maintain the desired levels of tolerance and physical dependence. This can be done by repeated daily injections, but this consumes too much time, both in administering the doses and in the time (weeks) it takes for tolerance and dependence to develop. A more convenient alternate procedure is to implant a pellet of morphine subcutaneously, thus allowing a continual gradual release of the drug. Maggiolo and Huidobro (1) have reported such a technique utilizing a pellet of pure morphine base compressed at high pressure. While this pellet proved useful for their studies, it released drug very slowly (25% of the dose in 8 days and 50% in 16 days).

Way *et al.* (2, 3) produced morphine tolerance and dependence in mice by subcutaneously injecting increasing doses of morphine three times a day for 3 consecutive weeks; but from a time-convenience standpoint, they were interested in using the pellet implantation method. However, with the Maggiolo-Huidobro pellet, the mice developed the desired level of tolerance and dependence too slowly. By using a modified formulation developed by these laboratories, Way *et al.* could induce a high degree of tolerance and physical dependence in 2 or 3 days (the modified pellet released 25–50% of the drug in the first 2 days after implantation). Since the publication of the Way articles, we have received a number of requests for manufacturing details. Therefore, the purpose of this Communication is to provide these formulation details pertaining to the experimental products utilized in the previously published paper emanating from these laboratories. For each tablet:

Morphine, purified powder	0.075 g.
Microcrystalline cellulose (Avicel)	0.075 g.
Fumed silicon dioxide (Cab-O-Sil)	0.00075 g.
Calcium stearate	0.0015 g.

Directions: Screen the morphine, microcrystalline cellulose, fumed silicon dioxide, and calcium stearate through 60-mesh screen. Slug using 1.91-cm. (0.75-in.) FFBE punch and die, obtaining thin, firm wafers. Screen, No. 16 mesh, *via* Stokes oscillating granulator. Mix well in a twin shell blender. Compress *via* Colton tablet press model 330:

Tablet weight	0.152 g.
Tablet hardness	15 Strong-Cobb Units
Tablet thickness	3 mm.

Because of the possibility of particle segregation in the hopper of the tablet press, the slugging step was introduced. This is especially important in view of the small batch sizes produced.

The determining factor in selecting microcrystalline cellulose as the diluent was the desire to control pellet density or hardness. Because morphine is soluble in tissue fluids and cellulose is not, it is reasonable to expect that, after some initial rapid release of the drug, the absorption rate would become constant as soon as the material at the surface of the pellet has dissolved. While it is quite possible that other materials could also give the desired effect, the microcrystalline cellulose was chosen because: (a) it is easily compressed to varying

degrees of density while providing a physically stable pellet; (b) it proved a satisfactory vehicle for providing a reasonably constant absorption rate for the drug; and (c) its physical characteristics are such that after 5 days' implantation the pellet remained as a semisolid palpable mass, facilitating easy removal from the animal.

This work suggests that microcrystalline cellulose is a possible vehicle for long-term implantation pellets for human use, provided, of course, it proves to be safe from a toxicity standpoint. Preliminary information suggests that microcrystalline cellulose may be relatively innocuous since implantation of pellets in mice containing no morphine elicited no overt toxic effects. Whether or not the body can adequately eliminate the cellulose from the tissues remains to be seen.

Scheme I

HCl as eluent. TLC using silica plates with an acidic developer indicated that the isolated material was a single entity which could be converted to I by treatment with base (see Scheme I).

Spectral and kinetic evidence suggest that the rearranged material is a cyclic hemi-*ortho* ester (II) of the type postulated as an unstable intermediate in 1-3 acyl migrations (1, 2).

Structural determination was primarily achieved by using NMR. A comparison of the NMR spectra of I with II revealed certain significant differences in the chemical shifts and splitting patterns of several protons (Table I).

The peak positions for the amide nitrogen, the aromatic ring protons, and the CHCl_2 hydrogen were identical in both linear and cyclic form. The peak position of the $\text{C}(1)\text{—H}$ proton in the cyclic compound is 57 c.p.s. downfield from that of the linear form. The deshielding effect produced on esterifying a hydroxyl group on the proton or the protons on the carbon holding the hydroxyl group is well documented (3). Also for the cyclic ester, the splitting of the $\text{C}(2)\text{—H}$ hydrogen by the $\text{C}(1)\text{—H}$ and the two $\text{C}(3)\text{—H}$ protons gives a quartet centered at 4.44 p.p.m. The two hydrogens on

N—H	7.46	7.46
$\text{CCl}_2\text{—H}$	6.35	6.35

Figure 1—The ORD curves of chloramphenicol-3-monosuccinate (I) and the cyclic hemi-*ortho* ester (II). Anhydrous ethanol is the solvent. Dashed portion of lines indicates areas of high absorbance.

$\text{C}(3)$ have shifted upfield to 3.7 p.p.m. as a pair of overlapping doublets, where in the linear form these three protons form a complex multiplet.

The succinate methylene protons in the cyclic *ortho* ester do not give rise to a singlet as is the case in the linear molecule. The signal for these hydrogens in the cyclic compound is an A_2B_2 system which arises from a pair of overlapping triplets. It is thought that different electronic effects associated with sp^2 and sp^3 hybridized carbon atoms adjacent to the succinate methylenes cause splitting of signal.

Additional evidence for the proposed cyclic isomer was obtained from IR and optical rotatory dispersion (ORD) data. Whereas the IR spectrum for I showed three distinct carbonyl absorptions at 1690, 1718, and 1745 cm^{-1} , the spectrum for II showed only two carbonyl peaks at 1690 and 1745 cm^{-1} . This apparent loss of ester carbonyl absorption and a change in absorbance in the C—O—C stretch region in the IR spectrum of II could be explained on the basis of the cyclic isomer (II).

The ORD curve for the cyclic and linear ester is shown in Fig. 1. Due to high absorption of both compounds below a wavelength of 280 $\text{m}\mu$, this region is an approximation based on repeated determinations and several dilutions. Linear chloramphenicol-3-monosuccinate shows a positive Cotton effect, whereas the cyclic ester shows a negative Cotton effect. The ORD curves of *o*-acetylated chloramphenicol-3-monosuccinate and *o*-dichloroacetylchloramphenicol-3-mono-

succinate also shows a negative Cotton effect. Esterification of the secondary hydroxyl group is associated with a change in optical rotation resulting in a negative ORD curve for the *o*¹-ester compound whose ORD curve prior to esterification was positive. Also characteristic of esterification of the *o*¹-hydroxyl group is a paramagnetic shift of the C(1)—H. Both of these phenomena were observed in the rearrangement of chloramphenicol-3-monosuccinate.

Complete migration of the succinyl function was ruled out on the basis of NMR and chemical data. Complete migration would have given a terminal hydroxyl. No peak corresponding to that for the C(3)—OH proton of chloramphenicol was observed. Chemical evidence indicated that the 0 → 0 migration product was incapable of existence in equilibrium with chloramphenicol-3-monosuccinate under experimental conditions.

Attempts to acetylate or methylate the isomeric compound resulted in complex reaction mixtures, presumably due to the breakdown of the cyclic structure by the reacting anion. All spectral and chemical evidence support the proposed structure.

Covalent Addition of *N*-Chlorosaccharin to Cyclohexene

Keyphrases □ *N*-Chlorosaccharin—cyclohexene addition □ Cyclohexene—*N*-chlorosaccharin addition □ *N*-(2-Chlorocyclohexyl)-saccharin—synthesis, structure, formation rate □ IR—identification, structure □ NMR—identification, structure □ UV—rate of formation

Sir:

It has recently been reported (1) that *N*-chloro-*N*-methylethanesulfonamide will add covalently across the >C=C< double bond of 1-hexene under photoirradiation. In similar, but apparently more facile,

Table I—Rate Constants for the Covalent Addition of *N*-Chlorosaccharin to Cyclohexene in Carbon Tetrachloride at 25°

[Cyclohexene] _{added} × 10 <i>M</i>	[<i>N</i> -Chlorosaccharin] _{added} × 10 ⁴ <i>M</i>	10 ² <i>k</i> _{obs.} sec ⁻¹	10 ² <i>k</i> ₁ <i>M</i> ⁻¹ sec. ⁻¹
4.96	6.30	1.69	3.41
3.22	10.00	1.16	3.60

reactions, *N,N*-dichlorobenzenesulfonamide (2) and *N*-aryl-*N*-halosulfonamides (3) will add covalently to cyclohexene. Because *N*-chloro compounds are used as chlorinating and oxidizing agents for a wide variety of compounds, additional reactions of the above type must be expected to occur if the molecules to be chlorinated contain unsaturated groups.

We have recently discussed (4) the possible usefulness of *N*-chlorosaccharin (I) as an organochlorinating agent on the basis of its low chlorine potential in water and its solubility and stability in a variety of organic solvents. However, we now present evidence that I will also covalently add to cyclohexene in a facile reaction at room temperature to yield *N*-(2-chlorocyclohexyl)-saccharin (II).

When I (400 mg.) was added to cyclohexene (15 ml.) at 25°, it gradually dissolved and simultaneously a white powder crystallized out of solution. After recrystallization from acetone–water, this powder had m.p. 171–172.5° and the same elemental analysis as II. (Found: C, 52.07; H, 4.86; Cl, 11.94; N, 4.78; S, 10.97. II, C₁₃H₁₄NCISO₃, requires C, 52.0; H, 4.67; Cl, 11.85; N, 4.67; S, 10.70.) Its structure was confirmed by NMR and IR spectroscopy. Its NMR spectrum showed the presence of 4 benzene protons and 10 cyclohexene protons, but no cyclohexene-ethylene protons were evident. The IR spectrum of the compound was consistent with that of Structure II and contained a strong band at the carbonyl-stretching frequency region. This latter piece of evidence ruled out the possibility that an O—C bond existed between saccharin and cyclohexene. The product did not release iodine from aqueous solutions of potassium iodide, thereby indicating that it was not in equilibrium with *N*-chlorosaccharin and that its chlorine was fixed and no longer “active.”

The rate of formation of the adduct was determined by measuring changes in UV absorbance at 270 *mμ* after carbon tetrachloride solutions of I and cyclohexene (which had been equilibrated at 25.0 ± 0.2°) were mixed in a 1-cm. spectrophotometer cell. The rate of change of absorbance was first order when [cyclohexene]_{added} was much greater than [I]_{added} and pseudo first-order rate constant, *k*_{obs.}, values were calculated. At two different cyclohexene concentrations the value of *k*_{obs.}/[cyclohexene]_{added} = *k*₁ was constant and thus

succinate also shows a negative Cotton effect. Esterification of the secondary hydroxyl group is associated with a change in optical rotation resulting in a negative ORD curve for the *o*¹-ester compound whose ORD curve prior to esterification was positive. Also characteristic of esterification of the *o*¹-hydroxyl group is a paramagnetic shift of the C(1)—H. Both of these phenomena were observed in the rearrangement of chloramphenicol-3-monosuccinate.

REVIEWS

The Molecular Orbital Theory of Organic Chemistry. By MICHAEL J. S. DEWAR. McGraw-Hill Book Company, New York, NY 10036, 1969. vii + 484 pp. 15.5 × 23.5 cm. Price \$16.50.

This book is representative of a general class of books written over the past decade in which quantum chemistry is applied to organic chemistry, with major emphasis on molecular orbital theory. The book is divided into ten chapters, the first four of which develop the concepts of molecular orbital theory useful to the organic chemist. In subsequent chapters, molecules of increasing complexity are treated with considerable emphasis on the conceptualization of the theory. The continual relationship to more classical concepts such as reaction types based upon valence bond mechanisms and the Hammett relationships makes the entrance into molecular orbital theory particularly useful.

There is much emphasis on self-consistent field theory, with very little attention paid to the less exact but simpler Hückel schemes in common use. This is particularly true of Hückel all-valence electron methods which are completely ignored. In places, the level of sophistication of treatment exceeds the needs of the medicinal chemist. There is much written about hydrocarbons but perhaps too little about heteroatom-containing molecules, which, of course, are the tools of the medicinal chemist's trade.

In summary, this book is a useful reference for the organic or medicinal chemist who already has some background in molecular orbital theory.

Principles of Physical, Organic, and Biological Chemistry. By JOHN R. HOLUM. John Wiley and Sons, Inc., New York, NY 10016, 1969. x + 728 pp. 17.2 × 23.5 cm. Price \$10.95.

This book consists essentially of two parts. The first deals with basic physical and chemical principles, including the concepts of energy, atomic structure, thermodynamics, chemical bonds, spontaneity, equilibria, and organic chemistry. The second comprises the application of these principles in developing an understanding of and an appreciation for the molecular basis of life.

The material, which contains appropriate illustrations and examples, is well organized and easily understood. Particularly noteworthy is the author's lucid treatment of the rather difficult subject of thermodynamics. His qualitative discussions of such concepts as internal energy, entropy, enthalpy, and spontaneity are commendable. Indeed, the student of physical chemistry would do well to read his account first and then proceed to the advanced texts.

The latter chapters deal with such topics as, "Biochemical Regulation and Defense," "Important Fluids of the Body," "Energy for Living," "Metabolism of Lipids, Carbohydrates and Proteins," and the "Chemistry of Heredity." These chapters apply the fundamental principles presented in earlier chapters to explain the compositions and functions of living matter. The author's approach in explaining life on a molecular basis should prove to be not only informative to the student but stimulating and fascinating as well.

As stated in the Preface, this book "...is intended for use in a two- or three-term terminal college course in chemistry for students in the humanities, the social sciences, and the paramedical sciences, including nursing, home economics, physical therapy, many areas of biology, and many programs in the agricultural sciences." It is well suited for that purpose.

Small Molecule–Macromolecule Interactions as Studied by Optical Rotatory Dispersion–Circular Dichroism

J. H. PERRIN and P. A. HART

Keyphrases ☐ Small molecule–macromolecule interactions—review
☐ Cotton effect—molecular binding ☐ Metachromasia—molecular binding
☐ Dye effects—optical rotatory dispersion ☐ Optical rotatory dispersion–circular dichroism—molecular binding determination

This review is intended to summarize the study of specific binding of low molecular weight substances to macromolecular systems by the application of optical rotatory dispersion–circular dichroism (ORD–CD). The authors have specifically not included inorganic ions. In addition, solvent and cosolute effects have not been covered because these phenomena are not necessarily related specifically to binding.

The review includes brief discussions of the phenomena of ORD–CD as well as applications to the proteins, nucleic acids, and polysaccharides. Metachromasia, the color-change phenomenon associated with binding, is discussed from the historical viewpoint and in terms of the more recent spectroscopic studies.

Extrinsic (induced) Cotton effects are discussed for dyes, coenzymes, and related ligands when bound to proteins, nucleic acids, polysaccharides, and membranes. The specific structural information (if any) that can be obtained from these studies is presented.

ORD, or the study of the change of optical rotation with wavelength, goes back to the early work of Biot (1) and Fresnel (2), who showed that the rotation of an optically active medium increases with decreasing wavelength of light. Thirty years later came Pasteur's

classical work (3) on the resolution of racemic tartrates. The discovery of the Bunsen burner is frequently considered the major reason that ORD studies did not advance significantly until the 1930's, because measurements were too easily made at the sodium D-line, a wavelength of little significance for most colorless compounds; however, much use was made of these measurements as analytical and characterization tools. In the 1930's, much pioneer work in the field of ORD was done by Lowry (4) and Kuhn (5, 6); they, as well as Mitchell (7), were the first to apply CD to organic chemical problems. Instrumentation still prevented the widespread use of the techniques until the 1950's when commercial ORD instruments became available and, more recently, when CD-measuring devices were introduced. Measurements by both techniques are frequently made down to wavelengths of 185 m μ . For detailed discussions on the theory, instrumentation, and applications of ORD–CD, the reader is referred to books by Crabbé (8), Djerassi (9), and Velluz *et al.* (10), and to reviews by Heller and Fitts (11), Klyne and Parker (12), Moscovitz (13), Tinoco (14), Schellman (15), and Eyring *et al.* (16).

The rotation at any constant wavelength is usually expressed as a specific rotation defined as

$$[\alpha]_{\lambda}^t = \frac{100\alpha_{\lambda}}{lc} \quad (\text{Eq. 1})$$

where $[\alpha]_{\lambda}^t$ is the specific rotation at a temperature t and a wavelength λ , α_{λ} is the observed rotation, l is the pathlength in decimeters, and c is the concentration in grams per 100 ml. of solution; or as a molecular rota-

tion $[M]_\lambda$ defined as

$$[M]_\lambda = \frac{[\alpha]M}{100} \quad (\text{Eq. 2})$$

where M is the molecular weight. The optical rotation of polymeric substances is usually considered a function of individual residues rather than the total molecular weight, and the mean residue rotation is defined as

$$[M]_\lambda = \frac{MRW}{100} [\alpha]_\lambda \quad (\text{Eq. 3})$$

where MRW is the mean residue weight which is around 115 for proteins. Optical rotation is dependent on the refractive index of the solvent; the observed rotation can be approximated to vacuum conditions by the Lorentz correction factor, enabling a reduced mean residue rotation:

$$[M']_\lambda = \frac{3}{n^2 + 2} \frac{MRW}{100} [\alpha]_\lambda \quad (\text{Eq. 4})$$

to be obtained. For more precise work, the dispersion in the refractive index of the solvent must be considered.

More information concerning the primary or secondary structure of a compound is gained by measuring rotations at a series of wavelengths, and the resultant plot of rotation against wavelength is called the rotatory dispersion curve for the solute.

ORIGIN OF OPTICAL ACTIVITY

A beam of plane polarized light can be considered to be made up of a right circularly polarized wave E_R and a left circularly polarized wave E_L . No optical rotation is observed if these two components are transmitted with equal velocity through the medium. However, if the two vectors pass through the medium with unequal velocity, then the plane of their resultant will have rotated through an angle α . If the right circularly polarized component travels faster, then the medium is dextrorotatory; conversely, if the left travels faster, then it is levorotatory. The speed of a lightwave is a function of the refractive index of the medium, and the medium is optically active if it has different indexes of refraction (n_L and n_R) for the left and right circularly polarized light. Fresnel (2) has shown that the rotation in radians per unit length is given by

$$\alpha = \frac{\pi}{\lambda} (n_L - n_R) \quad (\text{Eq. 5})$$

and, using the more familiar specific rotation in degrees per decimeter,

$$[\alpha] = \frac{1800}{\lambda} \left(\frac{n_L - n_R}{c} \right) \quad (\text{Eq. 6})$$

The refractive indexes n_L and n_R vary differently with the wavelength and are approximated by

$$n = 1 + \frac{a\lambda^2}{\lambda^2 - \lambda_v^2} \quad (\text{Eq. 7})$$

where a is a constant function of the strength of the oscillator of characteristic wavelength λ_v . λ_v is a constant and is the same as that in London's equation for

intermolecular attraction (17). This change in refractive index with wavelength means that the specific rotations also are a function of wavelength; in the regions far from optically active absorption bands, they give rise to plain curves, the equations for which have been given by Drude (18):

$$[\alpha] = \sum_i \frac{K_i}{\lambda^2 - \lambda_i^2} \quad (\text{Eq. 8})$$

where λ_i 's are the wavelengths of the optically active electronic transition and K_i 's are constants proportional to the rotatory strength of the i th transition. In the simplest case this modifies to the single-term Drude, giving

$$[\alpha] = \frac{K}{\lambda^2 - \lambda_0^2} \quad (\text{Eq. 9})$$

where λ_0 is the wavelength of the closest absorption maximum. The equation clearly indicates an increase in optical rotation as the wavelength is decreased.

Suppose, however, the medium shows unequal absorption of the incident right and left circularly polarized light; then the emerging light is also elliptically polarized and the phenomenon of unequal absorption is known as circular dichroism. To a good approximation (8), it can be shown that the angle of ellipticity ψ is given by

$$\psi = \frac{\pi}{\lambda} (K_L - K_R) \quad (\text{Eq. 10})$$

where K_L and K_R are the absorption coefficients of the left and right circularly polarized light. A specific ellipticity $[\psi]$ is analogous to the specific rotation, and a molar ellipticity $[\theta]$ is given by (19)

$$[\theta] = \frac{[\psi]M}{100} = 2.303 \frac{4500}{\pi} (\epsilon_L - \epsilon_R) = 3300(\epsilon_L - \epsilon_R) = 3300\Delta\epsilon \quad (\text{Eq. 11})$$

where ϵ_L and ϵ_R are the molar extinction coefficients for the left and right circularly polarized light. The extinction coefficients also vary with wavelength, and the ellipticity of the medium varies with wavelength, enabling a circular dichroism curve to be obtained. A CD curve is only a function of the unequal absorption of the incident light, but the ORD curve is a function of the unequal transmission as well as the unequal absorption of light, the shape of the ORD curve depending on the proximity of any optically active chromophores (8, 9).

The combination of unequal absorption and unequal transmission of the left and right circularly polarized light in the region in which optically active absorption bands occur is known as the "Cotton effect," after the man who first observed these anomalous rotations (7, 20, 21). Whether single or multiple Cotton effects are noticed depends on the number of optically active absorption bands involved; obviously, the wavelength regions of the Cotton effect are of most interest in ORD studies. The molecular amplitude, a , of a Cotton effect is defined as the difference between the molecular rotation at a peak or trough and the molecular rotation of the next extremum of shorter wavelength divided by 100.

This molar amplitude has been shown as a corollary of the Kronig-Kramer theorem (8, 22, 23) to be ap-

proximated to the dichroic absorption ($\Delta\epsilon$) of a CD curve by

$$a = 40.28\Delta\epsilon \quad (\text{Eq. 12})$$

or, using molar ellipticity $[\theta]$,

$$a = 0.0122[\theta] \quad (\text{Eq. 13})$$

This relationship allows at least semiquantitation between ORD and CD, but it is emphasized that the relationships were obtained for the $n\text{-}\pi^*$ transition of a saturated carbonyl group and should be used with caution for other chromophores (8).

To transform CD spectra into ORD spectra, one must use the more general form of the Kronig-Kramer equation (9, 24):

$$[M]_\lambda = \frac{2}{\pi} \int_0^\infty [\theta] \left[\frac{\lambda'}{\lambda^2 - \lambda'^2} \right] d\lambda' \quad (\text{Eq. 14})$$

This integral can be approximated by summation, but the interval must be small, preferably 1 m μ or less.

ORD OF PROTEINS

For a fuller treatment and references, the reader is referred to reviews by Urnes and Doty (25), Yang (26), and Gratzer and Cowburn (27).

Visible and Near UV Region—The $[\alpha]_D$ as an oversimplification can be considered to be made up of two contributions, first a levorotatory one from the amino acid residues and second a dextrorotatory one arising from a secondary and tertiary structure. Typically, a protein shows levorotation $[\alpha_D]$, which is lowered to the range -80 to -120° upon denaturation (28). It was always realized that because the sodium D-line was so far from the absorbing groups and the rotations measured were small and difficult to quantitate, ORD would give better quantitative data.

Early studies were performed on the synthetic poly- γ -benzyl-L-glutamate (29) and poly-L-glutamic acid (30, 31) at wavelengths through the visible region down to 300 m μ . These investigations showed that in helix-promoting solvents the polypeptides had anomalous dispersion which was dextrorotatory at long wavelengths, passing through a maximum and then dropping steeply at shorter wavelengths, whereas in the coil-promoting solvents the ORD curve was simple and levorotatory in the visible region. These observations suggested that ORD would be a powerful tool in elucidating the secondary structure of proteins. The β -forms of polypeptides were also shown to contribute to the optical rotation (29). The oligomers of γ -benzyl-L-glutamate were known to form β -aggregates in a poor solvent such as chloroform, and the ORD of the concentrated solution was dextrorotatory throughout the visible region, in strong contrast to the anomalous dispersion of the α -helix and the levorotation of the coiled forms. The β -aggregates dissociated on dilution, and ORD curves similar to the coiled forms were obtained.

UV Regions—The laboratories of Blout (32, 33) and Doty (34, 35) in the early 1960's reported ORD and CD measurements on polypeptides in the UV region; Doty's group also measured the CD of polypeptides

Figure 1—CD (shaded) and ORD of homopolypeptides in the random coil, α -helical, and β -conformations. Taken from Reference 27 with permission of MacMillans (Journals) Ltd., London, England.

down to 190 m μ , and they calculated the ORD curve using the Kronig-Kramer transform and obtained reasonable agreement with the experimental curve. The use of ORD in protein chemistry is mainly to determine conformations; the currently accepted curves for the various forms, taken from Reference 27, are shown in Fig. 1. Cotton effects may also arise due to aromatic groups such as tyrosine, tryptophane, and phenylalanine, as well as disulfide bonds (26, 36, 37).

Polypeptides containing less than 50% α -helix obey the simple Drude equation, and the constant wavelength term is usually denoted by λ_c ; however, λ_c lacks the physical meaning of the wavelength of the nearest optically active absorption band, and it is the result of a mathematical approximation. For denatured or non-globular proteins, λ_c is near 220 m μ and it is from 230 to 270 m μ for native proteins. λ_c , like $[\alpha_D]$, can be used to estimate the helix content if it is assumed that only the helix and a coil are responsible for the changes. These methods are of only historical interest, and the interested reader is referred to the excellent paper of Yang and Doty (29). In 1956, Moffitt (38) used a quantum mechanical approach to the rotatory dispersion of helices; he, together with Yang (39), published a phenomenological equation to explain the ORD of helical macromolecules to enable an estimate of the percentage of the α -helix to be made:

$$[M']_\lambda = \frac{a_0 \lambda_0^2}{\lambda^2 - \lambda_0^2} + \frac{b_0 \lambda_0^4}{(\lambda^2 - \lambda_0^2)^2} \quad (\text{Eq. 15})$$

The constants, λ_0 and b_0 , are primarily functions of the helical content alone and therefore were regarded as independent of environmental factors such as solvent or side chains; a_0 , however, represents the intrinsic residue rotations and varies with the environment. Using the suggested value of 212 m μ for λ_0 (40, 41), λ_0 has been set at 212 m μ and gives a value for b_0 for the 100% helical conformation of -630 ; assuming that b_0 for the coiled form is close to zero, the fraction in the helical form is given by

$$\frac{-b_0}{630}$$

Numerous modifications of the Moffitt equation have been proposed (see References 25 and 26 for discussion

and further references), but the method gives reliable results if only random coil and α -helical conformations are present. In days when Cotton effects can be directly observed and of readily available CD measurements, the Moffitt equation is really obsolescent. Also, obsolescent are the numerous attempts to use various modification of the multiterm Drude equations to explain the ORD of polypeptides and calculate the percentage α -helix (25, 26). For a critical evaluation of Moffitt's equation, the two-term Drude, and a modified two-term Drude, see the work of Blout's group (40-42).

Wada *et al.* (43) have modified the Moffitt equation to include terms for the β -conformation which had previously been ignored; however, such interpretation is complex, but it appears that the b_0 value is only slightly affected by aggregation. It should be pointed out that Cotton effects due to aromatic residues which appear in many proteins probably invalidate the use of Moffitt's and the various Drude equations for quantitative interpretation.

The advent of equipment capable of measuring ORD spectra down to 185 $m\mu$ enables the Cotton effects to be observed directly, and attempts to calculate the percentage helix can be made by obtaining the curve of a model compound in the fully α -helical form or in the fully random coiled form and finding the conformation of the protein under investigation by simple proportion. Using poly-L-glutamic acid as a model compound, measurements at 233 and 198 $m\mu$ have been recommended (44); again the presence of β -aggregates complicates the picture, particularly as the β -form contribution is variable (45).

CIRCULAR DICHROISM OF PROTEINS

For a general discussion, see the excellent articles by Beychok (37, 46). CD curves for homopolypeptides in the random coil α -helical and β -conformations are shown in Fig. 1. The percentage of any form in a protein can be estimated from the values of the ellipticities at specific wavelengths of reference synthetic materials known to be in the various configurations. This technique is simplified if the β -form is again ignored as is often the case (35, 37, 47). The CD of β -forms has been investigated in detail by Fasman and Potter (45) and Quadrifoglio and Urry (48). Aromatic side chains and disulfides in polypeptides give rise to CD spectra in the 250- $m\mu$ \rightarrow 350- $m\mu$ region (37, 49). It should also be noted that the amino acids, tyrosine, tryptophane, phenylalanine, and cystine, show intense side-chain optical activity near 220 $m\mu$ at all pH's and whether free or as amides and esters (37). This means that estimating the α -helix content and sense for proteins containing a high proportion of these residues is very risky because this side-chain absorption closely overlaps the most important peptide bands. CD has recently been shown to provide a quick criterion of nonidentity between two proteins having similar electrophoretic mobilities and elution profiles (50).

OPTICAL ACTIVITY OF NUCLEIC ACIDS

The origin of optical activity in the monomeric components of the nucleic acids, the purine and pyrimidine

Figure 2—CD (upper) and ORD (lower) of salmon DNA (..) and *E. coli* ribosomal RNA (—). Taken from Reference 54 with permission of Dr. J. T. Yang and Academic Press, New York, N. Y.

ribosides and 2'-deoxyribosides, at the characteristic UV absorption bands of the aglycones is in the asymmetric perturbation of the aglycone chromophore by the glycosidic portion. The rotation varies as a function of substituent changes in the sugar moiety and as a function of changes in the torsion angle (the angle describing the conformation about the glycosidic bond). It has been generally assumed that the torsion angle for most monomeric nucleosides and nucleotides is in the range corresponding to the *anti*-conformation, but recent work (51, 52) demonstrates that for a number of nucleosides (both purine and pyrimidine ribosides) a significant proportion of the conformer equilibrium is composed of the *syn*-form. It is unknown, at present, whether this new information will significantly alter the current status of the nucleic acid conformation problem to be discussed.

When the monomers are joined by the familiar 3',5'-phosphodiester linkage to form nucleic acids, one might expect the polymer rotation to be similar to the monomer rotation, differing perhaps by the small perturbation occasioned by the functional group change at C-3', C-5'. Indeed, that is the observation for unordered polymers (53), but the helical order that can be assumed under appropriate conditions by DNA and some RNA's is characterized by an enhanced optical activity. The complex subject of optical activity of the nucleic acids has been reviewed recently (27, 54) and only the highlights will be discussed here.

Nucleic acid structure can be considered on three different levels, the single-stranded "random" coil, the

single-stranded stacked-base form, and the double-helical form of which there is an A and a B form. The A form of DNA and the double-helical forms of RNA are thought to have similar structural features differing from the B form of DNA in a 15–20° tilt of the base pairs relative to the helix axis compared with virtually no tilt in the B form.

The ORD and CD differences of DNA and RNA may in some cases be rationalized on the basis of the various fundamentally different forms available, but in some cases the observed differences have not been rationalized. Extensive ORD studies of DNA and RNA (55–62) have demonstrated that DNA and RNA from different sources show fairly typical behavior, being characterized by two peaks and a trough in the vicinity of the 260-m μ absorption band (Fig. 2). The relative magnitudes of these characteristic maxima and minima are the distinguishing characteristics that usually allow differentiation between DNA and RNA. The characteristics are best seen in the respective circular dichroism spectra that show a positive ellipticity followed by an intense and a weak negative curve for salmon sperm DNA and a positive effect followed by weak and strong negative effects for double-stranded RNA (63). Extensive prior circular dichroism studies (64–68) recorded similar results.

The first and second ORD peaks of DNA are temperature-dependent as is the first peak of helical RNA. When the variation between rotation at 290 m μ and temperature is studied for DNA, a sharp drop in rotation is seen at the helix-coil transition temperature determined by other means. The same study on helical RNA shows the typical broad melting behavior of that system.

The gross differences in the ORD-CD spectra of DNA and RNA do not arise from double helix-single helix random coil differences, although these forms have typical rotational characteristics. The differences have not been fully rationalized, but some correlations between structure and rotation phenomena do exist. The reader is referred to the review by Yang and Samejima (54) as well as the recent work of Johnson and Tinoco (69 and references therein).

OPTICAL ACTIVITY OF POLYSACCHARIDES

The study of polysaccharide structure *via* the optical rotation method has historically been carried out at the sodium D-line. The current status of the problem has been reviewed (70). Even when ORD and CD were applied, the non-UV absorbance of most sugars and many polysaccharides made interpretation difficult. It is, therefore, not surprising that less is known about the solution conformation of polysaccharides than about proteins and nucleic acids. Recent reports (71–73) show that the mucopolysaccharides, chondroitin sulfate and heparin, have Cotton effects in the region below 220 m μ arising from n - π^* and π - π^* amide transitions.

The mucopolysaccharide ORD spectra are of two different types depending on structure. The 3-1-linked glycosamine sugars show a negative Cotton effect (trough at 217–220 m μ), whereas the 4-1-linked glycosamine sugars (α - or β -glycosidic link) show a dominance of the positive Cotton effect in the π - π^* region (\sim 198

Figure 3—ORD of mucopolysaccharides containing N-acetyl glucosamine. Curve 1, N-acetyl glucosamine; 2, heparin A; 3, chondroitin sulfate-I; 4, S-chondroitin sulfate. Taken from Reference 70 with permission of Marcel Dekker, Inc., New York, N. Y.

m μ) (see Fig. 3). It is thought that the differences may be derived from a preferential association of the 'C-2' nitrogen with the prior C-2 hydroxyl in the first case and of the C-2 nitrogen with the succeeding 2', 3', or 4' hydroxyl in the latter case.

That the mucopolysaccharides appear to have optical properties that depend largely on the way the sugars are linked in the polymer regardless of the configuration of the glycosidic bond indicates that rotatory properties derived from the monomer (74) are probably insufficient indexes of the polymer structure. It is concluded that there is a preferred twisting of the polymer strand imposing unique perturbations on the amide chromophores. The observation of these new amide transitions will no doubt allow more informative studies of polysaccharide secondary structure in solution to be made in the future.

SURVEY OF OTHER METHODS

The reader is referred to the classical review on protein binding by Goldstein (75) for details and references on other experimental methods and to the review by Meyer and Guttman (76) for references concerning specific drugs. These methods, summarized below, can be used for the study of binding of small molecules to macromolecules in general.

Dialysis—The equilibrium method is by far the most widely applied and is capable of giving good quantitative data, provided reasonable experimental precautions, such as a careful pretreatment of the dialysis tub-

ing, are followed. Faster kinetic dialysis techniques have been reported by several workers (77–79).

Ultrafiltration—This is also a widely practiced equilibrium technique which is quicker than equilibrium dialysis but is quantitatively inferior because of the continually changing macromolecule concentration and the accumulation of the macromolecule on the membrane surface.

EMF and Conductivity—Here the incorporation of buffers in the system is an obvious problem and the methods are only useful for studying the binding of ions.

Electrophoresis—This method is qualitatively useful in that it can be possible to find to which macromolecule fraction the small molecule is bound. Precise quantitation is difficult.

Spectroscopy—The method can be useful if the spectra of either the small molecule or the macromolecule is modified in the presence of the other, but in many the interactions cause little or no spectral changes.

NMR and ESR—The use of NMR to study biological interactions has been pioneered by Burgen (80) and Jardetzky (81). The differential changes of the relaxation rates in the high-resolution NMR spectra of both small and large molecules can be used to identify the area of the molecule directly involved in the formation of complexes. Other references can be found in the reviews (82, 83). Electron spin resonance spectroscopy has been applied by studying the ESR spectra of bound free radicals (84). The nature of the ESR spectra is sensitive to the environment, and rapid molecular motion can be detected.

Other methods which have been used include polarography, gel filtration, fluorescence quenching, adsorption, diffusion, the measurement of partition coefficients, and Kerr constant dispersion.

METACHROMASIA

A recurrent phenomenon that arises in the study of binding processes by ORD–CD is metachromasia (metachromasy). Metachromatic complexes are characterized by a shift to lower wavelength of the absorption maximum of the bound species as well as a decrease in its absorbance (hypochromism). The substance that can induce metachromasia in a dye is called a chromotrope. The usual chromotropic substances of biological origin are high-molecular weight polyanions. Heparin, chondroitin sulfate, hyaluronate, nucleic acids, agar, and alginate are such substances. Some inorganic and synthetic chromotropes are silicates, polyphosphates, chitin sulfate, carboxymethylcellulose, alginate sulfate, pectin sulfate, and polyacrylates. Some relatively low-molecular weight substances are chromotropic such as soaps and anionic detergents, *e.g.*, myristate, surface-active agents (Duponol), and phospholipids (85, 86).

Dyes that stain metachromatically are ordinarily metachromatic by themselves and do not obey Beer's law; it is concluded that metachromasia, whether in the presence or absence of macromolecules, is a function of intermolecular dye–dye association. When chromotropes are present, the initial binding of either the dye aggregate or the dye monomer followed by aggregation at the appropriate concentration is thought to be the

sequence of events (87, 88). In fact, when a normally metachromatic dye (methylene blue, toluidine blue) is mixed at low concentration with a substance that normally stains orthochromatically (fibrin, gelatin, and most tissue and cellular structures), the orthochromatic color is seen. Orthochromicity refers to the lack of absorbance maximum shift on binding. Only if the dye concentration is increased does one eventually see metachromasia (89). In addition, ligands that do not ordinarily aggregate in the absence of binding agents (acranil, atebirin, neomonacrin, proflavin, 9-aminoacridine, and some other aminoacridines) show a shift to higher wavelength when bound to nucleic acids, and this bathochromic shift is thought to involve dye–polymer interactions (85, 90, 91). The same observation has recently been made in a study of the binding of proflavin to poly(styrene sulfonic acid) (92).

Elegant studies of the binding of DBTC (4,5,4', 5'-dibenzo-3,3'-diethyl-9-methylthiacarbocyanine) to a large variety of polyanions (93–95) revealed that the dye molecule reacts to form at least five distinct complexes depending on the macromolecule, the polymer–dye ratio, and the pH. Four of the complexes are characterized by a shift of the dye absorbance to higher wavelengths and only one is metachromatic. The complexes are thought to involve dye–polymer interactions, resulting in conformational distortion of the dye, dye–counter ion interactions on the polymer, and perhaps in some cases dye–dye interactions, although these are thought to be of minor importance. Dye–counter ion interactions have been invoked as an alternative rationalization for metachromasia by other workers (96).

PROTEIN INTERACTIONS

Detergents—Putnam and Neurath (97–99) pioneered the investigations into the denaturation of proteins by detergents using techniques such as viscosity, electrophoresis, and precipitation. In these investigations of the binding of dodecyl sulfate to horse serum albumin, they concluded that two distinct complexes were formed, the first occurring without detectable changes in the shape of the albumin but the second only occurring with considerable change in asymmetry of the protein. The complexes were said to be due to the binding of detergent anions to cationic protein groups, this erroneous conclusion coming from the similarity between the number of detergent ions bound and the number of binding sites available. Equilibrium dialysis (100–102) was later used to determine accurately the number of detergent anions bound to serum albumin.

Foster (103), among others, suggested that correlation between the number of anions bound and the number of cationic sites was fortuitous, suggesting that the hydrophobic nature of the anion plays an important role in the binding to the proteins. The application of optical rotatory dispersion to the detergent-binding problem has been made mainly by Bruno Jirgensons at the University of Texas. Using a sodium lamp in his earlier work (104, 105), he noticed that detergents produced a negative shift in the specific rotation and this shift was accompanied by an increase in viscosity. Using the same technique (106) to investigate the $[\alpha]_D$ of the plant pro-

teins, tuburin and pea legumin, denatured with sodium dodecyl benzene sulfonate, he again observed an increased negative rotation, and the effect of the detergent became more marked as the pH increased. In this paper he states that optical rotatory power seems to be one of the surest methods of measuring denaturation, a strong statement when one considers he was measuring at a single wavelength far from the absorbing groups in the proteins; one is not surprised at his immediate interest in obtaining dispersion curves when instrumentation became available.

Using the Rudolf instrument (107), he found that all the proteins he investigated obeyed the single-term Drude equation and that on denaturing a metal-binding β -globulin with AOT and heating to 50°, the dispersion constant of the denatured material was shifted from 243 to 220–230 $m\mu$, whereas the constants for the Bence-Jones protein and γ -globulin increased under the same conditions from 200–215 to 220 $m\mu$. Realizing the work of Foster (103), Kauzmann (108), and Tanford (109), emphasizing the importance of hydrophobic bonds in the folding of proteins, he proceeded to investigate the possibility that the extreme efficiency of the unfolding of globular proteins by surface-active agents (greater than urea, guanidine salts, and alcohol on a molar basis) might be due to the hydrophobic nature of the tail of the detergent molecule (110). Using the Yang and Doty (29) method of obtaining λ_c from the single-term Drude, and suggesting that an increase in λ_c above 220 $m\mu$ reflects an α -helix formation, he found that detergent-treated γ -globulins, pepsin, and soybean trypsin inhibitor showed a limited formation of α -helices. b_0 values from the equation of Moffitt and Yang (39) rose to values close to -80 , indicating α -helix formation.

In the treatment of α - and β -caseins with AOT, the λ_c of α -casein was enhanced considerably while the value for the β -form was not affected. It was also observed that the detergents were more active the longer their hydrophobic chain; for example, the 10-carbon chain of sodium caprate caused λ_c of γ -equine to shift to 234 $m\mu$ from the native value of 210, whereas the same concentration of the 6-carbon chain of sodium caproate caused little or no change in λ_c . He concluded that the hydrocarbon chain of the detergent penetrates into the interior of the proteins, partially unfolding them, these conformational changes being greater the longer the hydrophobic tail of the detergent. Heating the systems to 50° always caused an increased denaturation, presumably due to the fact that at the elevated temperature the micelle-monomer equilibrium of the detergent is shifted toward the free molecules, facilitating the intervention between the protein and the detergent. In an earlier inconclusive paper (111), Jirgensons had found that a bovine albumin, a human albumin, and mercapto albumin had not been denatured by several long-chain sulfosuccinates at 50 or 70°, using no change in λ_c as the criterion. Low reduced viscosities seemed to confirm these observations. Similar observations had been made regarding the effect of detergents on taka-amylase (112), another helical protein. Using improved instrumentation capable of observing the trough of the Cotton effect at 225–240 $m\mu$ due to the α -helical conformation, Jirgensons (113) again turned his attention to effects of

detergents on the nonhelical proteins. He found that the proteins, reduced and carboxymethylated serum albumin, normal serum γ -globulin, myeloma globulin, pepsin, trypsin, trypsinogen, α -chymotrypsin, chymotrypsinogen, and soybean trypsin inhibitor did not show the Cotton effect, but that the Cotton effect was observed with troughs at 225 to 240 $m\mu$ if the hydrophobic chain of the added detergent was long enough. Sodium dodecyl, sodium decyl, and sodium octyl sulfates, as well as sodium dioctyl sulfosuccinate, were used in the investigations. These observations supported the view that the chains of the detergent disturbed the hydrophobic forces essential for the conformation of the nonhelical proteins.

A paper, again involving the nonhelical proteins and anionic detergents, also published in 1962 (114), contained similar observations. Instrumentation allowing the α -helical trough around 230 $m\mu$ to be investigated led Jirgensons (115) to look now at the α -helical proteins such as serum albumin, insulin, growth hormone, lysozyme, bacterial α -amylase, lactic dehydrogenase, and glutamic dehydrogenase. All these proteins showed a definite Cotton effect at 225–235 $m\mu$, and dodecyl sulfate diminished the levorotation of these helical proteins to a greater or lesser extent. The effects were greater with dodecyl than with decyl sulfate. These effects are opposite to those observed earlier for the nonhelical proteins and suggest that the detergent can promote disorganization of helical proteins. The disulfide-linked macromolecules seemed more resistant to this disorganization than did the cystine-free bacterial amylase. This supported the hypothesis that the conformation of the helical proteins also depends upon hydrophobic bonds. In this paper Jirgensons mentions the existence of the β -conformation (25) for the first time. Again turning to the nonhelical proteins, human serum γ -globulin, and myeloma protein (116), treating them with sodium decyl sulfate in alkaline conditions of pH 10.2–11.0 at an elevated temperature of 50°, he found that the b_0 values were initially close to zero but became negative on denaturation and fragmentation by the detergent. The levorotation was also increased; although b_0 returned almost to zero on removing the detergent by dialysis, the levorotation stayed enhanced. He concluded structural changes in the following steps: native ordered \rightarrow strongly disorganized and fragmented \rightarrow partially organized \rightarrow strong disorganized and aggregated fragments. The γ -globulin is split into fragments of molecular weight 56,000 to 75,000 by detergent; however, the observations are complicated by the fact that disulfide and ester bonds are sensitive to alkali.

In another paper (117), again looking at detergents and nonhelical proteins, including the plant proteins, α -conarachin and edestin, he found b_0 to be near zero for the native proteins and negative on treatment with detergent. The specific rotation also became more negative, but he agreed with the statement by Tanford *et al.* (109) that no reliable conclusions concerning conformation can be drawn from the changes of $[\alpha]_D$, especially in the instances when the properties of the solvent are drastically changed. In the same paper it was found that the nonionic surfactant (Brij 35) was less effective than the anionic detergent with the same chain length,

and that lysozyme and pituitary growth hormone are only slightly affected by detergents even on heating. He concluded that the native globular proteins having a b_0 value of near zero are not α -helical yet possess some order in the folding of the polypeptide chains. So at this time there was a possibility that the structure of these proteins in aqueous solution included the β -form. Wada *et al.* (43) had expanded the Moffitt equation in 1961 to take into account the β -configuration; Troitski (118), a Russian worker using a manual spectropolarimeter and a lowest wavelength of 365 $m\mu$, used it to interpret his investigations into the effect of sodium decyl sulfate on γ -globulin, egg albumin, and serum albumin. He concluded that γ -globulin loses its β -structure and retains its α -structure on treatment with detergent. On the other hand, egg albumin lost 35 % of its β -form, but the α -helix content did not change and there was no change at all in the conformation of serum albumin. The author concluded that the detergent degrades the β -structure but not the α -helix, and he suggested that detergents may be specific reagents for the β -configuration in the correct conditions. These observations regarding the α -helix were contrary to those of Jirgensons, and this, together with the claims for the β -structure in aqueous solutions of specially treated poly- α -L-lysine (119, 120) and silk (121), stimulated Jirgensons (122, 123) to further investigations. The proteins having high α -helix content are slightly disorganized, as shown by changes in the amplitudes of the Cotton effect and b_0 values. The disordered proteins such as histones are partially disorganized by the detergents, whereas those with considerable β -conformation like desoxyribonuclease and β -lactoglobulin seem to lose their β -form and acquire some α -helical form. Several other proteins having some β -structure as well as the α -helical form were also investigated, but no clear interpretation is presented; however, the possibility of a somewhat different β -structure is mentioned. In other publications concerning the histone F1 (124, 125), he again reported that decyl and dodecyl sulfate convert the disordered histone partially into the α -helical form. Decker and Foster (126), investigating the interaction of bovine plasma albumin with alkyl benzenesulfonates at pH 6.5, found an initial binding involving 11 ± 1 sites and two other complexes involving 38 and 76 detergent molecules. This is in agreement with the complexes of Putnam and Neurath (98) who used dialysis and moving-boundary electrophoresis experiments. The formation of the higher complexes was found by ORD experiments to be accompanied by some loss of α -helix content of the protein.

Again looking at the nonhelical proteins in 1967 (127), Jirgensons found that tetradecyl sulfate was more effective than dodecyl sulfate in promoting helical formation, again confirming that the hydrocarbon chain plays a decisive role in protein conformation. In their classical paper on the β -form of poly-L-lysine in aqueous solution, Sarkar and Doty (119) found that disordered poly-L-lysine in alkaline solution went to the β -configuration on heating; whereas treatment with sodium dodecyl sulfate in neutral solution seemed to produce a β -form, forming a peak at 205 $m\mu$ and a trough at 230 $m\mu$. However, the magnitude of the trough was greatly

reduced. Supporting evidence for the β -form was obtained from IR, UV, and CD. These observations stimulated further work on synthetic polypeptides, and Grouke and Gibbs (128) found that sodium dodecyl sulfate shifted the random-coiled form of poly-L-ornithine in neutral solution of the α -helical form using ORD and CD methods. This α -helix formation is accompanied by the shift of the ORD minimum to 235 $m\mu$. The α -helical form of poly-L-ornithine was unchanged on heating; a similar treatment on poly-L-lysine had caused the formation of a β -structure (119).

Velluz and Legrand (129), using entirely CD techniques, found that treatment of human serum albumin (HSA) with dodecyl sulfate decreases the helical content to 40 %. Treatment of HSA with detergent and 2-mercaptoethanol (reducing the S—S bonds) causes disappearance of the dichroism in the 250–300- $m\mu$ region (due to loss of S—S bonds) whereas the dichroism in 200–250 $m\mu$ remains constant, suggesting no change in α -helix content. The S—S bonds act as protectors of the rigid structures before denaturation, probably by maintaining a conformation which isolates the sensitive groups from the medium; the detergent seems to prevent the collapse of the rigid structures when the S—S bonds are broken. This is not so on denaturation with urea. The effect of delipidization of lipoproteins has been investigated by ORD and CD (130), but the results are confusing. CD, ORD, and IR show that β -lipoprotein is disordered and probably has some helical structure; the β -apoprotein retains its β -structure, but on treatment with dodecyl sulfate the proteins become more disordered and some α -helix formation may be induced. The conformational changes which had been reported earlier on delipidization (131, 132) are probably caused by the presence of dodecyl sulfate. Dodecyl sulfate has no effect on the configuration of β -lactoglobulin polymorphs A, B, and C as measured by CD (133).

The Cotton effect at near 280 $m\mu$ due to tryptophane residues in egg white lysozyme disappears on exposure to sodium dodecyl sulfate (134) at concentrations which do not affect the α -helix content but do completely inhibit the enzyme activity. This suggests that tryptophane is involved in the formation of the enzyme substrate complex. Similarly, dimethyl benzylmyristylammonium chloride did not affect the secondary structure of lysozyme (135) or acetyl lysozyme (136) but did reduce the enzyme activity. The binding of various sulfates and sulfonates to bovine serum albumin has been investigated (137), and it was found that $[\alpha]_{233}$ changes in a linear manner up until 10 moles of detergent are bound per protein molecule; the rotation remains constant as more detergent is added until a large configuration change takes place when between 45 and 60 moles are bound. This may again be due to the alteration of conformation of the tryptophane residues.

As can be seen from this, the interpretation of the ORD and CD spectra of detergent-protein complexes is difficult and is complicated by the fact that detergents may increase α -helical content (30), convert helical to β -structure (27), abolish β but not helical structure (26), or act as a denaturing agent (19) with various proteins.

Dyes—In 1958, Markus and Karush (138) studied the effect of anionic dyes on the rotatory dispersion of HSA at pH 7.4 from 725 $m\mu$ to 550 $m\mu$ and found that strongly anomalous dispersion curves were obtained. Using a manual polarimeter, it was found that the $[\alpha]_D$ depended on the substituent in the *p*-position of the *p*-benzene-azo-benzoylamino acetic acid dyes. On removing the dyes, all changes were completely reversible. Correlation with viscosity and dialysis experiments suggested to the authors that the changes in the observed $[\alpha]_D$ were due either to structural changes in the serum albumin involving interaction with the end groups of the dyes or the stabilization of resonance forms of the dyes. However, in a later paper, having obtained improved instrumentation, Winkler and Markus (139) showed that the earlier reported anomalous rotation was due to an artifact (stray light) and that the sudden changes in rotation between 500 and 600 $m\mu$ were no longer observed. The curves obtained still showed very strong deviations from the dispersion of HSA in the absence of dye. The earlier conclusions obtained from the sodium D-line measurements were, of course, not affected by these observations.

Blout and Stryer (140) were the first to report a Cotton effect from a polypeptide-dye complex at wavelengths near those of the absorption bands of the dyes. This indicated that the chromophoric group of the dye had acquired asymmetry. L-Polyglutamic acid (141, 142) was used with acriflavine and neutral rhodamine 6G, and it was found that complexing, and the resulting Cotton effects at wavelengths greater than 400 $m\mu$, only resulted when the peptide was in the helical form (below pH 6.0); above pH 6.0 the peptide is in a random configuration, and no anomalous dispersion is observed. The magnitude of the Cotton effect of acriflavine-L-PGA complex as a function of pH showed good agreement with the helix content as determined from $[\alpha]_{546}$. In further investigations with a wider range of dyes, Stryer and Blout (143) again found complexing only in the pH region of high helical content and found molar rotations up to a million for the induced Cotton effects. The signs of the Cotton effects were opposite for the L- and D-polyglutamic acids, leading to the conclusion that helices of opposite screw sense show Cotton effects of opposite sign. Three models were suggested (Fig. 4) for the interaction between the peptide and dye; the first involved an unaggregated dye interacting with the asymmetric α -carbon atom of the peptide residue; the second involved dye end-to-end aggregation giving rise to a super helix around the peptide helix. In the third, the asymmetric polypeptide acts as a sterically determined "seeding center" to favor one of the screw senses of a dye helix which forms tangential to the polypeptide α -helix. None of the models satisfied all the observations (143, 144), although the latter two seem more feasible.

Blout (144) reported that covalent binding of a single dye molecule to a helical macromolecule results in an extrinsic Cotton effect; this does not prove, however, that all dye-polypeptide Cotton effects are the result of a single dye molecule bound to an asymmetric site in the macromolecule. Using the streaming dichroism technique (145), Ballard *et al.* (146) investigated the binding of acridine orange with the α -helical form of poly- α -L-

Figure 4—Three suggested modes of interaction between dye and polypeptide. Model I, unaggregated dye interacts near the asymmetric α -carbon atom of the peptide residue; model II, dye end-to-end aggregate giving rise to dye superhelix; model III, tangential dye helix. Taken from Reference 144 with permission of the editors and Interscience Publishers, New York, N. Y.

glutamic acid. They found three circular dichroism bands associated with the long wavelength absorption band of AO at 495 $m\mu$ and further CD bands associated with the 270- $m\mu$ absorption band of the dye but none associated with the 295- $m\mu$ absorption band. The induced activity was relatively insensitive to the glutamate residue-to-dye ratio but was dependent on the ionic strength of the solution. It was concluded that the dye aggregate in the L-PGA complex has the form of a left-handed super helix bound to the core of a right-handed α -helix of L-PGA. AO binds strongly to PGA over the pH region of the transition from a random coil to α -helix, and Myhr and Foss (147) decided to re-investigate the random coil region of binding. They stress that the method of preparing the complex influences the ORD properties; complexes prepared by changing the PGA conformation in the presence of AO are not the same as those prepared by first changing the PGA conformation and then adding the dye. Their observations suggest that the dye prevents conformational changes in the random coil pH region, and they state that this probably prevented Stryer and Blout from observing optical activity of the random coil complex. Preparing complexes by titrating the L-PGA to the desired pH before adding the dye, they found large Cotton effects in the region of the AO absorption bands for both the helical and random coil pH regions. The curve for the helical form was very similar to that of Stryer and Blout. Yamaoka and Resnik (148) re-investigated the interaction between helical α -PGA and

acridine orange at several dye-to-polymer ratios (D/P) using ORD. Even at a D/P of 0.0001, a broad positive peak was located at 525 m μ , a steep negative trough with a shoulder around 480 m μ , and a second peak at 450 m μ was also found. The curves were in good agreement with those of Stryer and Blout; however, the complexing at very low D/P ratios agreed with the observations of Mason's group (146), which reported binding of approximately two AO molecules per three polymer molecules. This led to support for Blout's first model, *i.e.*, binding of unaggregated dye near the asymmetric α -carbon atom of the peptide residue. The resultant CD curves from the Kronig-Kramer transform, when compared with the measurements of Mason's group (146), show good agreement with the positions and signs of all three extrema, but there is not good agreement on the magnitude of the rotations. Yamaoka and Resnik (149) also investigated the interaction of helical L-PGA and proflavine and found extrinsic optical activity throughout the absorption bands of the dye, but no new peaks or shoulders were found. The induced Cotton effects were shown to be multiple by the Kronig-Kramer transform. This analysis also shows a weak background rotation which may suggest a slight alteration in the polypeptide conformation when the dye is bound.

Eyring *et al.* (150), reinvestigating the PGA-acridine orange system, found significant differences in the ORD curves depending on whether the pH was adjusted before or after mixing. Heating had little or no effect on the curves except in the case of the helical form above 55°, where a decrease in rotation was observed; this was reversible on cooling. Their complexes with helical PGA are very similar to those of Stryer and Blout (143), and they correctly point out that Stryer and Blout overlooked the Cotton effects of the coiled PGA-AO complex by approximating their data with a smooth curve. Yang's group reported Cotton effects with the coiled PGA, although they were much smaller in magnitude than those found with the helical form. There are considerable differences between their data and that of Myhr and Foss, possibly due to differences in experimental conditions.

Others—The binding of coenzymes, substrates, inhibitors, *etc.*, has been investigated by ORD and CD, and particular interest has been shown in extrinsic Cotton effects generated by a chromophoric molecule interacting with an asymmetric site of the protein as in the case of the dyes. Considerable interest has been shown in the interaction of liver alcohol dehydrogenase and nucleotides where a Cotton effect is seen close to the absorption maximum of the complex (151–153). The stoichiometry of this binding has been shown to be two moles of nucleotide per mole of enzyme.

Heme has a plane of symmetry, but the iron atom constitutes a center of asymmetry for a prosthetic group since different ligands may occupy the fifth and sixth coordination sites of the metal atom and because the protein may be linked both to iron and the porphyrin side chains; thus considerable interest has been shown in the optical dispersion of heme proteins (154–157), particularly concerning the Cotton effect in the Soret band. The extrinsic effects of these and other protein-substrate

bindings were reviewed by Ulmer and Vallee in 1965 (158) and only the more recent developments, particularly the obvious usage of CD, will be discussed here. Myoglobin and hemoglobin exhibit a positive Cotton effect in the Soret band of the visible spectrum, regardless of the state of iron oxidation or nature of the ligand in the sixth coordination position of the Fe atom (156, 159). As heme is directly bound to the histidine residue which is part of a right-hand helix segment (160), Beychok (37) investigated the poly-L-histidine-hemin complex but found little correlation with the myoglobin spectra, the situation being complicated by the fact that heme aggregates and binding occurs with monomers as well as aggregates. Urry (161), in a theoretical paper concerning the heme-protein interactions, predicts that the rotational strengths of the proteins change on the interaction and that the changes in the peak and trough of the ORD of apomyoglobin upon binding of heme (162, 163) should not be interpreted as changes in helical content. He also proposed that a substantial contribution to the rotational strength of the Soret transition in these heme proteins arises from coupling with the protein transitions. Concentrating on the troublesome region below 300 m μ , Beychok's group (164) concluded that the major contribution to the 260-m μ CD band of hemoglobin was from heme rather than aromatic residues. The difference in ellipticity in the 260-m μ region between the α - and β -chains reflected a considerable difference in the heme environment in the two cases, or a difference in tightness of the attachment, or both. Side-chain chromophores, rather than heme, were found to generate the longer wavelength bands near 280 to 290 m μ . In a later paper, Javaherian and Beychok (165) found that binding of one hemin per apohemoglobin dimer derived from horse hemoglobin caused restoration of the helix content, not only of the chain having hemin bound but almost all of the helix content in the other chain as well, even without occupation of the heme binding site of that chain. In the same paper they investigated the CD of hemoglobin Gun-Hill (166) and again found that heme is bound only to α -chains. Others (167), investigating the same UV region of human hemoglobin and its subunits, have shown that binding of oxygen and carbon monoxide causes large changes in optical rotation. The changes at 233 m μ were taken to prove a conformational change in the protein but whether both chains are involved was not clear. Similar observations were not made with myoglobin. Darnall *et al.* (168) have recently investigated the CD spectra of methemerythrin with the iron coordinated to a variety of ligands. They concluded that contributions in the 290-m μ region were from tyrosine residues and from the iron atoms. In the peptide n - π^* and π - π^* region, the CD was similar to that of an α -helical conformation, and this did not change with the nature of the iron bound ligand or upon dissociation of the protein into monomers. The extrinsic spectra above 300 m μ due to the heme binding have been well investigated by CD. Myer (169) found that the different oxidation states of the iron in heme of horse heart cytochrome-C caused differences in the Soret region, as well as in the aromatic dichroic bands, and there was an increase of all transitions in the δ absorption region seen in the lower oxida-

tion states. He said that the change in the valence state induces significant alterations in the dissymmetrical environments of the prosthetic heme group and the aromatic side chains, possibly due to the increased ligand-binding affinity of the ferrous state. Strickland (170) investigated the CD spectra of horseradish peroxidase complexed with its enzyme substrate compounds and found wavelength shifts in the Soret region similar to those observed by UV absorption spectrophotometry. In the 280-m μ region the CD of the complex differed from the native enzyme, indicating that heme may contribute to the ultraviolet CD and that the orientation of an aromatic side chain may change. In the 207–222-m μ region the CD spectrum of the protein is unchanged on complexing and suggests the α -helical conformation.

Recently, Japanese workers (171, 172) found that oxidized cytochrome *cc'* shows three types of reversible CD spectra in the 300–450-m μ region depending on pH: type I (neutral), type II (intermediate), type III (alkaline). In the reduced state it has an abnormal spectrum in the pH regions of types I and II, but it has normal spectrum at more alkaline pH's. Alcohols, phenols, and ketones convert type I and type II spectra to type III at fixed pH values, and the efficiency is parallel to the hydrophobicity of the ligand. At pH 7.4, 25% of 2-propanol converts the oxidized form from the neutral to the alkaline type but causes no change in the far UV region, whereas urea at pH 7.0 causes destruction of the α -helix but only a slight shift to the alkaline type in the extrinsic regions. These observations show that a shift from neutral to the alkaline type is not necessarily accompanied by a change in the gross helical conformation which might protect the special environment of the heme. Similar observations were made by Tsong and Sturtevant (173) using an apoenzyme from cytochrome *b₂* free of flavin mononucleotide (FMN). They found a CD spectrum strongly dependent on the oxidation states of heme, and the CD spectrum below 250 m μ was that of an α -helix and independent of the heme. When the enzyme was treated with FMN and *L*-lactate, 80% of the original enzyme activity was recovered and the CD spectrum of the original enzyme was obtained. Denaturing by aging changed the CD spectra below 250 m μ but not above. The enzyme could be partially reactivated to give the original CD spectra. These results suggest direct heme–FMN interaction is responsible for the catalytic and optical properties of cytochrome *b₂*. Van Holde (174) found that the oxygenated hemocyanin gave two dichroic bands in the visible region; on comparison of this spectrum with some peptide–copper (II) complexes, he saw a similarity between the hemocyanins and histidine-containing peptides, suggesting that perhaps the histidine residues are ligands in hemocyanin. Li and Johnson (175) have recently measured the ORD properties of several fetal and abnormal hemoglobins.

The ORD of rhodopsin, before and after irradiation, has been measured (176) and the α -helical content appeared to be diminished after bleaching, and there was a possibility that unbleached rhodopsin also showed a weak Cotton effect in the visible region. Later CD investigations (177) confirmed the extrinsic Cotton effects for rhodopsin and isorhodopsin near the absorption wavelengths of the retinal chromophore. Crescitelli

Figure 5—CD spectra of free FAD 1 and the bound FAD 2. Curve 3, base line. Vertical bars indicate scales corresponding to $\epsilon_L - \epsilon_R = 1$ for Curves 1 and 2, respectively. Taken from Reference 180 with permission of Academic Press, New York, N. Y.

et al. (178) also observed the extrinsic CD bands with rhodopsin and porphyrodopsin, although they differ in behavior in the near UV region; the extrinsic CD bands disappear upon bleaching. The extrinsic CD spectra of squid and cattle rhodopsin (179) have been found to differ, probably due to the difference in protein conformation around the site of attachment of the retinal chromophore. Upon illumination the helical structure of the proteins was converted to a disordered one, and the retinal chromophore lost its optical activity. This change in protein conformation upon illumination is considered to be an important role in initiating the visual process.

One of the more interesting investigations concerning enzymes and their substrates is the binding of flavin adenine dinucleotide to D-amino acid oxidase (180). There is a conformational change of the dinucleotide as a result of the binding to the apoenzyme; this is shown by the inversion of the dinucleotide CD spectrum as seen in Fig. 5 without any appreciable wavelength shift. Apparently the binding between the two rings is preserved, but the mutual steric orientation is markedly changed when the nucleotide is bound to the apoenzyme. Other polypeptides whose interactions have been investigated by ORD or CD include glutamine synthetase (181), ribonuclease (182), bakers yeast *L*-lactate dehydrogenase (183), horse liver alcohol dehydrogenase (184), aspartate transcarbamylase (185), lypolydehydrogenase (186), glutamate dehydrogenase (187–189), pig heart lactate dehydrogenase (190), avidin (191), immunoglobulin (192), muscle phosphorylase B (193), glutamate-aspartate transaminase (194), and lipoproteins (195, 196).

Sonenberg (197) has found that human growth hormone induces changes in the ellipticity of human erythrocyte membranes at 222 m μ , observing a decrease in the negative band of about 30% in a phosphate buffer but not in water. The necessary presence of phosphate suggests that some organization of the membrane is necessary. Similar effects were not observed with bovine growth hormone, bovine serum albumin, bovine insulin, or cortisol. Lenard and Singer (198) had previously investigated the ORD and CD of red blood cells and found approximately one-third in the helical conformation and the remainder in the random coil; however, Urry and Ji (199) have shown that particulate systems can show CD patterns characteristic of an α -helix and caution must be exercised in interpreting data from particulate systems.

Hansch *et al.* (200) have correlated protein binding of a variety of organic compounds of miscellaneous structure with their octanol–water partition coefficients, so demonstrating the nonspecific nature of the process. In the same paper this partition coefficient is related to the

protein binding and the rotation at the Na_D line; however, whether the change in rotation is due to a change in configuration and/or to any induced optical activity of the organic molecule is not apparent.

Chignell (201–203) has studied the interaction of phenylbutazone and some of its analogs as well as a number of other anti-inflammatory substances with BSA and HSA and has found that many of these substances exhibit extrinsic Cotton effects. When phenylbutazone was mixed with human serum albumin, a positive ellipticity band was generated at $287 \text{ m}\mu$. Similar observations were made for oxyphenbutazone and sulfa-pyrazone, although the rotational strengths of the latter substances were smaller. More polar derivatives gave greatly reduced rotational strengths, and the reduction was positively correlated with a poorer distribution of the polar derivatives into nonpolar media.

Fifteen *N*-arylanthranilates, including flufenamic and meclofenamic acids as complexes with human serum albumin, were studied (203), and extrinsic Cotton effects were observed for all of them. Metachromasia was not observed. The binding of flufenamic acid to human, porcine, equine, bovine, canine, ovine, and rabbit serum albumins induced optical activity in all cases, but there were significant ellipticity differences observed and, in particular, a reversal of the sign of the long wavelength band was seen for the ovine and rabbit proteins.

NUCLEIC ACIDS

Acridines—Acridine binding to nucleic acids has been actively studied almost from the time that selective staining of nuclear material by dyes was observed. Interest stems from the function of some of these dyes as antibacterial agents (204) and mutagens (205, 206). Studies of the nucleic acid-dye complexes have involved most of the methods mentioned previously, and a portion of those studies has been reviewed, including some of the optical rotatory dispersion-circular dichroism work to be described (54, 207). A large proportion of the more recent work has been devoted to a determination of the stoichiometry of binding as well as to the structure determination of the complexes.

The stoichiometry of acridine dye binding to nucleic acids has been studied extensively and can be expressed in terms of the quantity (r) of dye (ligand) bound per mole of nucleic acid phosphorus against the concentration of free aminoacridine. The definition of r is

$$r = \sum_{j=1}^{J=P} \frac{n_j k_{jc}}{1 + k_{jc}} \quad (\text{Eq. 16})$$

where n_j is the number of P classes of binding sites (of intrinsic binding constant k_{jc}) for the ligand on the nucleic acid (207). If there are two classes of binding sites, Eq. 16 simplifies to

$$r = \frac{n_I k_{Ic}}{1 + k_{Ic}} + \frac{n_{II} k_{IIc}}{1 + k_{IIc}} \quad (\text{Eq. 17})$$

and in the case of a single type of binding site, Eq. 17 becomes

$$r = \frac{nk_c}{1 + k_c} \quad (\text{Eq. 18})$$

When two or three binding sites are present, it is sometimes possible to select certain linear portions of the r/c versus r plots and attribute the linear portions of them to specific binding sites, allowing calculation of individual n_j 's and k_{jc} 's. However, if the assumption of Langmuir-type binding (implicit in Eq. 18) does not hold because of cooperative phenomena in which a bound ligand promotes the binding of further ligands, it may not be possible to recognize the contribution of each binding site in the r/c plot.

The binding of acridine orange to nucleic acids apparently involves two processes as shown by the curved r/c versus r plots found by Peacocke (90), a strong binding process (I) involving about 0.2 molecule of dye per nucleic acid monomer and a weaker process (II) with a 1:1 dye-monomer ratio. It has recently been shown (208) that the binding is adenyl or guanyl specific and that the weak complex (II) can be distinguished from the strong (I) by hot dialysis or by fluorescence spectroscopy (209). The weak complex dissociates at room temperature and fluoresces at $620 \text{ m}\mu$, whereas the strong complex is stable as high as the denaturation temperature of DNA and fluoresces at $515 \text{ m}\mu$.

Efforts to define the structure of the various nucleic acid-dye complexes were abetted when an extrinsic Cotton effect between 450 and $540 \text{ m}\mu$ (the wavelength region in which DNA-bound acridine orange absorbs) was observed (210) (see Fig. 6). The observed finite rotation must have been due to asymmetric perturbation of the dye chromophore by the DNA, because, by itself, acridine orange is optically inactive. At the same time (210) the observation was made that heat-denatured DNA induced no Cotton effect in bound acridine orange, but later work (211, 212) using denatured calf thymus DNA disclosed an induced Cotton effect in the bound dye. In addition, it has been shown that acridine orange binds to poly A, poly U, and poly C (213).

It was further shown that proflavin displayed an extrinsic Cotton effect when bound to both DNA and RNA (214), followed by similar observations on 1,2,3,9-tetraaminoacridine (215).

Given the observation of induced Cotton effects, it was natural to exploit the observations further as they held a high potential for allowing one to learn more about the nucleic acid-dye complexes. What follows is an historical account of the attempts to establish the structure of the previously mentioned nucleic acid-dye complexes by considerations of the induced optical activity at the absorption maxima of the dye and the dependence of that rotation on temperature, polymer/dye ratios, pH, and ionic strength.

The originally observed induced optical activity in native DNA-bound acridine orange was quite weak at very high polymer-to-dye ratios of around 56. As the P/D ratio decreased from 13 to 1 (maximum dye binding), a strong anomalous dispersion curve developed at $504 \text{ m}\mu$, then gave way to a weaker Cotton effect at $465 \text{ m}\mu$. The observation corresponds to the metachromatic and hypochromic phenomena that had previously been observed spectroscopically. The observed optical activity was thought, at that time, to arise from neighboring, weakly coupled dyes in the case of the higher P/D ratios and to arise from bound dye-

aggregates (strongly coupled) in the case of the meta-chromatic and hypochromic spectrum at low P/D ratios.

At about the same time, Lerman (216) studied the binding of several dyes (acridine orange among them) in terms of viscosities and sedimentation coefficients. The studies were done in the concentration range that would correspond to the high polymer/dye ratio (strong binding). Because of increased viscosity, a decreased sedimentation coefficient (reduced mass per unit polymer length) and a loss of helicity, the hypothesis was advanced that the complex involved intrusion (intercalation) of the dye between two adjacent base pairs causing an extension of the sugar-phosphate backbone. The intercalation hypothesis was presumably supported by later polarized fluorescence work (217) showing that the dye was oriented perpendicularly to the helix axis and by chemical studies (218) that showed an inhibition of diazotization of the primary amino groups of some acridine dyes (proflavin but not acridine orange). The latter observation was a unique consequence of binding to DNA because other polyanions had no effect on diazotization rate.

Circular dichroism of the DNA-acridine orange complex (one dye molecule per base pair) under static and streaming conditions (145, 219) showed a strong positive band at higher wavelengths (505 m μ) and a weaker negative band at shorter wavelengths (467 m μ). These bands increased and decreased, respectively, on streaming, indicating that the 505-m μ band is polarized perpendicularly to the helix axis and the 467-m μ band is parallel polarized.

Since the 500-m μ band of the dye is a π - π^* transition requiring a component along the long axis of the dye, the conclusion was reached that the molecular planes of the acridine orange molecules are tipped relative to the helix axis. It was further concluded that the sign of the ellipticity required a left-handed helical arrangement of the dyes and the best such arrangement involves binding of the acridine ring nitrogen (conjugate acid) to the sugar-phosphate backbone.

The concentration range at which these streaming circular dichroism studies were run was probably in the intermediate range between monomer binding (strong) and aggregate binding (weak), however, and Blake and Peacocke (220) have suggested that the streaming measurements were made on a mixed complex, making the results appropriately ambiguous.

More extensive work by Gardner and Mason (221) dealt specifically with the ambiguities. By measuring circular dichroism over a range of ionic strength, pH, and P/D ratios, they were able to detect three ellipticity bands. Two negative bands at 465 and 488 m μ and one positive band at 505 m μ were observed, and they had optimum intensities at P/D ratios of 3, 9, and 4, respectively. Only the 505- and 465-m μ bands were observed at P/D ratios of less than 3 at low ionic strength and low pH, and those bands are diminished at large P/D ratios. The 488-m μ band was optimum at high ionic strength, neutral pH, and a larger P/D ratio. The 505- and 465-m μ bands were assigned to bound dimers, bound in the form of a skewed (dissymmetric) sandwich, and the 488-m μ band was thought to arise from the bound monomer. It was

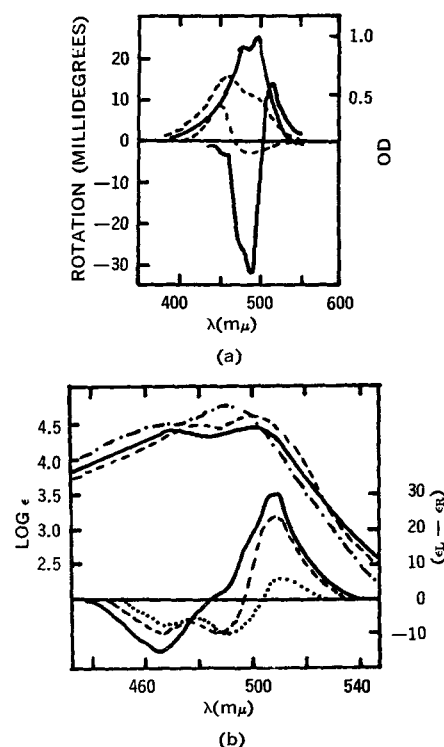

Figure 6—(a) ORD and absorption spectra of acridine orange bound to native DNA at low (---), 28.48 to 15.68 μ M, and high (—), 85.44 to 15.68 μ M, polymer/dye ratios. The upper curve in each pair is the absorption spectrum. (b) CD and absorption spectra of acridine orange bound to native DNA at polymer/dye ratios: (—), 3 and (---), 9 and (· · ·), 15. proposed that the monomer was bound only partly between adjacent base pairs rather than completely occluded (modified intercalation hypothesis) on the basis of the present studies and the previous streaming circular dichroism studies (145).

The binding of proflavin to both DNA and RNA has been studied beginning with observations by Blake and Peacocke (222, 223). These authors studied the optical rotatory dispersion of proflavin bound to DNA and RNA in the 400–500-m μ spectral range. As in the case of acridine orange, no optical activity was observed for the free dye, but a large unsymmetrical Cotton effect (more intense trough than peak) was observed in the presence of DNA and RNA.

The proflavin-DNA complex was studied under conditions of changing ionic strength, DNA denaturation, and P/D ratio. Decreasing the ionic strength increased the extent of binding by a factor of 1.4 but increased the magnitude of the Cotton effect by a factor of 2. At all ionic strengths the magnitude of the Cotton effect increased linearly as the P/D ratio increased (change from type II to type I binding) to a value of about 4, then decreased to noise level with a further increase in the P/D ratio. A statistical treatment of the data indicated that only a small number of proximate dye molecules are required for the observation of optical activity, not an extended helical array as some workers have proposed in polysaccharide studies (224, 225). Denatur-

ation of the DNA did not destroy the optical activity, ruling out the need for long segments of double helix in order to observe optical activity, another requirement that was thought to prevail (140).

Because of the observation of optical activity in the denatured DNA complex, and because RNA is similar in structure to denatured DNA, optical rotation studies were conducted (222) on the RNA-proflavin complex and virtually identical observations were made. However, whereas in the DNA system a reduction of pH to 2.7 obliterated optical activity, which activity returned to higher values when the original pH was restored, the same pH titration in the RNA case was smoothly reversible from pH 7 to pH 2.7 and back to pH 7.

The differences between acridine orange and proflavin probably arise because of the much greater tendency for acridine orange to aggregate (226), and it was concluded that the "monomer" binding of acridine orange is identical with the strong binding of proflavin (type I, high P/D). Because strong binding was observed in denatured systems where double-helical structures are precluded, it was felt that the double-helical structure was not essential for strong binding and that instead a "close contact" between the dye molecules and the nucleic acid bases was the only requirement, leading only incidentally to intercalation in the double-helical structures. A study of the binding of proflavin to poly A and poly U at neutral pH, to poly A at acid pH, and to poly (A + U) led (227) to the conclusion that a relatively rigid conformation of the binding macromolecule is required for the induction of Cotton effects similar to the ones seen in denatured DNA systems. The observations that led to the conclusion were that the homopolymers at neutral pH induced no optical activity in the dye (even though it was bound as shown by other spectroscopic criteria) whereas at lower pH, a Cotton effect was induced. It was further found by a statistical treatment that interaction between as few as two ligands on denatured DNA and RNA was sufficient to generate optical activity.

Further work on the DNA-proflavin complex (149) showed that the unsymmetrical long-wavelength Cotton effect reported by Blake and Peacocke (222) was a composite curve. The latter workers applied the Kronig-Kramers transform to ORD data obtained under conditions similar to those used by Blake and Peacocke, and the calculated CD curves showed the presence of two transitions. The presence of two transitions in the high wavelength region was confirmed by a CD curve of the proflavin-DNA complex determined by Blake and Peacocke (228) which showed an unsymmetrical double-ellipticity curve characteristic of exciton interactions (229-236), confirming the optical activity was a function, in part, of interaction between relatively small numbers of bound chromophores.

Some work has been done (228) on the extent of acridine structure variation tolerated for the induction of Cotton effects by DNA and it has been found that 1,2,3-aminoacridines are optically active at most of the intrinsic ultraviolet absorption bands, but that 9-aminoacridine has optical activity induced only at lower wavelengths and that optical activity is not induced in the 350-500-m μ region.

Additional conclusions outside the scope of this review have been reached regarding the structure of the DNA-dye complexes (237-239).

Other Antibiotics—General studies of the binding of actinomycin D to DNA (240-243) and some related monomeric species have revealed the following characteristics of the complex: (a) binding is guanine specific; (b) binding occurs adjacent to a guanyl-cytidyl pair; (c) binding causes helix distortion; (d) several complexes exist in equilibrium; (e) the peptide side chains conform to the sugar-phosphate backbone so that there is a high energy barrier to conformational change within the complex; and (f) the complexes dissociate slowly. It was concluded that complexation was by intercalation. It has been further shown that actinomycin D is dimeric down to concentrations of 10^{-5} M and that it binds to nucleoside species in the following order of preference: deoxyguanosine, guanosine, adenosine, deoxyadenosine, adenosine monophosphate, adenosine diphosphate, adenosine triphosphate, inosine, and xanthosine.

The circular dichroism of free actinomycin D (211, 244, 245) has been determined in both water (dimer) and ethanol (monomer). The water spectrum shows one strong negative band at 380 m μ and two weaker negative ellipticity bands between 450 and 440 m μ . The ethanol spectrum is composed largely of one negative band. In the presence of DNA (211, 245, 246) the once weak 440-m μ band becomes strongly optically active and is shifted to around 460 m μ . There is a concomitant hypochromic effect that appears in the UV spectrum of the complex, indicating that the changes observed in the inherently optically active ligand are induced as a result of the binding process. The question of the structure of the complex has not been settled although Homer (245) proposes that either the actinomycin D dimer is bound or that the monomer is bound and the metachromatic-hypochromic effect is the result of association between the antibiotic and the purine moieties of the nucleic acid.

The cytotoxic antibiotic kanchanomycin, of unknown structure and possessing inherent optical activity, has been studied with respect to its binding to DNA, RNA, and synthetic polynucleotides by spectrophotometric methods (247) and by optical rotatory dispersion-circular dichroism (248). The binding process requires magnesium ion and, apparently, two different complexes are formed, an initial complex (I) that eventually rearranges to a second complex (II). The initial complex dissociates readily when magnesium ion is removed with EDTA and complex II dissociates more slowly. Circular dichroism spectra of the two forms represent significant departures from the spectrum of the free antibiotic. The latter, in the presence of magnesium ion, is composed of a small positive peak at around 405 m μ and two shallow negative extrema at 365 and 336 m μ . In the presence of magnesium and DNA, two extrema are apparent, a positive one at around 400 m μ and a negative one at 350 m μ . After 20 hr., a complex, more intense negative band at around 375 m μ appears, the spectrum of complex II. Binding of kanchanomycin to poly A gives similar results.

Assorted Ligands—The interaction of DNA with malouetine [5 α -pregnan-3 β ,20 α -ylenebis (trimethylammonium iodide)] and irehdiamine (pregn-5-ene-

3 β ,20 α -diamine) has been thoroughly studied (249) by following changes in the rotatory properties of the nucleic acid. At low ionic strength, two different complexes are formed. The first, requiring a steroid/DNA-P ratio of about 0.2, is characterized by enhanced thermal stability, increased hyperchromicity at 260 m μ , and a shift of the long-wavelength circular dichroic band toward longer wavelengths with an increase in the rotational strength. It is thought that the disordering shown by the hyperchromicity is ligand-induced and may involve a transition of the double helical structure away from the β -form (see under *Optical Activity of Nucleic Acids*). The second complex requires a higher steroid/polymer ratio (greater than 0.2) and the nucleic acid rotatory values of this complex resemble disoriented DNA. The two forms are thought to resemble those assumed by DNA in the presence of planar aromatic rings and copper (II) ions, respectively.

The binding of purines as well as purine and pyrimidine nucleosides has been examined by a number of techniques, including rotation at a single wavelength (250, 251); although the rotation studies do not conform exactly with the subject of this review, the work is important and deserves mention. The interaction of poly U with many of the previously mentioned compounds has been studied. A large positive increase of the rotation at 350 m μ was observed when binding occurred and it was found that 1:1 complexes that were temperature sensitive formed between poly U and adenosine, deoxyadenosine, L-adenosine, 3-isoadenosine, 9-(γ -hydroxypropyl) adenine, and 9-(hydroxypentyl) adenine. No interaction was found for *N*-6-methyladenosine, *N*-1-methyladenosine, and the nucleoside antibiotic tubercidin.

A large number of aryl-substituted diammonium compounds have been observed to display extrinsic Cotton effects when bound to native and synthetic nucleic acids and polynucleotides (252-254) and have been adopted as reporter molecules utilizing CD as the spectroscopic probe.

For nitroanilines of the type Ar(CH₂)_{*n*}N⁺(CH₃)₂·(CH₃)₃N⁺(CH₃)₃·2Br⁻, a red shift and hypochromism are observed for the complexed (DNA and RNA) state. Of further interest is the induction of a positive and a negative Cotton effect in the aromatic chromophore by RNA and DNA, respectively. The evidence seems to indicate a binding of the diammonium group to the anionic phosphate backbone and that the aryl portion lies in the minor groove of the helix. The origin of the oppositely signed Cotton effects is thought to arise from differential conformational preference of the 2,4-dinitroaniline function, depending on the nucleic acid used.

Polysaccharides—The original work of Stone *et al.* (71, 224, 225) on extrinsic Cotton effects in acidic polysaccharide-bound dyes has been reviewed (70). Extrinsic Cotton effects have been observed in dyes bound to λ -carrageenane, heparin, and the chondroitin sulfates (150). The polysaccharide-dye ORD spectra are complex in the region of the dye metachromatic absorption region. Acridine orange, methylene blue, and neutral red all show induced Cotton effects when bound to heparin and the effect disappears at high P/D ratios. At the time, the conclusion was reached that the effect

arose from a helical array of dyes along the polysaccharide chain, but subsequent work in the nucleic acid series showed that a long helical array was not necessary, allowing other rationalizations in the polysaccharide area.

More recent work (150) has shown that chondroitin sulfate and acridine orange form two different complexes (neutral pH) depending on the order of mixing. The induced Cotton effect was more intense when the polysaccharide was added to the dye, the apparent reason being related to dye self-association. This order-of-mixing dependence disappeared at low pH.

The binding of a number of azodyes to α -cyclodextrin has been studied (255) by the ORD technique and only congo red displayed reasonably strong extrinsic Cotton effects that appeared outside the rather strong positive background rotation of α -cyclodextrin.

CONCLUSION

It is apparent from the foregoing that the application of optical rotatory dispersion-circular dichroism to the study of small-molecule binding by macromolecules is able to provide certain specific information and is potentially able to provide much more. It is possible to decide when binding occurs by observing the induction of optical activity in symmetrical chromophores by asymmetrical macromolecules. Of greater interest is the ability to decide whether the chromophore is intimately involved in the binding process and how it is involved. Further, a determination of the effects of binding on the macromolecule is important. Both the latter kinds of information can potentially be obtained from ORD-CD measurements, but greater knowledge of the correlation between macromolecular structure and rotational data is needed as is a more thorough knowledge of the origin of the induced Cotton effect.

A noteworthy recent development that will prove useful in the future, particularly in the study of ligand effects on macromolecular structure, is the difference spectropolarimetric method adopted by Adkins and Yang (256), a method useful in the study of small conformational changes. The method was used to estimate the equilibrium constant for the lysozyme-*N*-acetyl-D-glucosamine interaction.

The interpretation of measurements made on protein systems, if in terms of conformational changes, must take into account recent precautions regarding Cotton effects derived from intrinsic aromatic functional groups as well as recent measurements (257) that reveal how environment alone can change the rotatory properties of cyclic mono- and dipeptides, compounds that are thought to be electronic analogs of polypeptides. The study of membrane-bound small molecules requires that particular attention be paid to the problem of artifacts arising from absorption, flattening, and scattering treated by Urry and Ji (199).

Future studies should concentrate on the careful accumulation of a broader variety of good data and a more rigorous study of the question of optical activity induced by intermolecular interaction. Further, as better correlations between optical activity and conformation in macromolecular systems become available, ligand

effects on that conformation should be studied, perhaps by application of the difference technique mentioned previously.

19-Norsteroids of Unnatural Configuration from Ergosterol

AHMED H. EIMASRY and OLE GISVOLD

Abstract □ A new method for the preparation of a 19-norsteroid of unnatural configuration from ergosterol has been described. This method led to the preparation of $5\alpha,8\alpha,9\alpha,10\alpha$ -19-norpregnan-3,20-dione which possesses unnatural configuration at positions 8 and 10. The following reaction sequence was utilized to prepare this steroid. Ergosterol was photo-oxidized to give bisergostatrienol that was pyrolyzed to yield neoergosterol whose side chain was cleaved by ozonolysis to yield 3β -hydroxy-19-norpregna-5,7,9(10)-20 α -aldehyde. This aldehyde, for the first time obtained in a crystalline state, was degraded *via* ozonolysis of the 3β -hydroxy-20-morpholino-methylene-19-norpregna-5,7,9(10)-triene derivative to give 3β -hydroxy-19-norpregna-5,7,9(10)-triene-20-one. The latter was reduced to the corresponding diol with Ru/carbon, and its Ring B in turn successfully hydrogenated in cyclohexane with Rh/alumina as the catalyst. The diol was oxidized to the diketone with the Jones reagent. Although some of the above transformations previously have been recorded, this report describes marked improvements in the techniques and yields of most of the intermediates.

Keyphrases □ 19-Norsteroids, unnatural configuration—synthesis □ Ergosterol—19-norsteroid synthesis □ IR spectrophotometry—structure □ NMR spectroscopy—identity □ Polarimetry—identity □ Optical rotatory dispersion—identity

It is well established that progesterone (I), the naturally occurring progestin, possesses a wide range of biological activities together with other metabolic effects when administered parenterally (1). *Via* the oral route, however, it is essentially inactive. Ehrenstein's multistep transformation of strophanthidin (II) (2) to yield $14\beta,17\alpha$ -19-norprogesterone (III) gave an opportunity to study the biological activity of a 19-norsteroid (3). It also gave an opportunity to study structure-activity relationships in the progestins that had certain unnatural configurations. In the case of progesterone (I), it has been shown that inversion of configuration at C-17 (from β to α), or at C-14 (from α to β), or at both centers destroys the biological activity, while inverting the configuration at C-8 (from β to α) only reduces it (4). However, activity is retained by inversion of the configuration at C-10 to 10α -progesterone;¹ also, double inversion at both C-9 and C-10 gives retroprogesterone ($9\beta,10\alpha$ -progesterone) whose progestational activities are more potent than progesterone (5).

In the case of 19-norprogesterone (IV), which is orally active, inversion at either C-17, C-14, or C-8 provides progestational agents of high order of activity (2,4,6).

It is evident that progestational activity has been retained in progestins that have an unnatural configura-

tion at C-8 or C-10. Also, loss of the C-19 methyl group exerts a favorable biological effect which is great enough to overcome the unfavorable changes in $14\beta,17\alpha$ -progesterone (inactive). Thus, $14\beta,17\alpha$ -19-norprogesterone (III) is 8 times as active as progesterone (I) (7). Therefore, the preparation and testing of progestins and 19-norprogestins that have other multiple unnatural configurational centers are of considerable interest. One of these is $8\alpha,10\alpha$ -19-norprogesterone (V).

A key intermediate for the preparation of this isomer of 19-norprogesterone is the $5\alpha,8\alpha,9\alpha,10\alpha$ -19-norpregnan-3,20-dione (VI). This article describes the transformation of ergosterol (VII), *via* neoergosterol (IX)—a Ring B aromatic sterol (8), to the key intermediate (VI) possessing the unnatural configuration at C-8 and C-10² (Scheme I).

Ergosterol (VII) was chosen as the most suitable starting sterol because the presence of a double bond in the side chain would permit its degradation by suitable techniques to the C-17 methyl ketone found in the pregnane series. Also the presence of the diene system in Ring B enables one to prepare 19-nor Ring B aromatic steroids *via* a previously known method (8). This route of partial synthesis was preferred over a totally synthetic one because, generally, the former would lead to a pure *d*-enantiomer which is twice as active biologically as the racemic (*dl*-) form expected from the latter (9).

¹ Cited as footnote 5 in *J. Amer. Chem. Soc.*, **88**, 4538(1966) by M. Uskokovic *et al.* that in Belgian Patent 634,693 (1964), Ciba, 10α -progesterone was reported to be a progestational agent.

² The transformation of $5\alpha,8\alpha,9\alpha,10\alpha$ -19-norpregnan-3,20-dione (VI) to $8\alpha,10\alpha$ -19-norprogesterone (V), with the biological results, will be the subject of a forthcoming communication.

Scheme I

DISCUSSION

Preparation of Neorgosterol—Ergosterol (VII) (Scheme I) was photo-oxidized with white light in the presence of eosin Y as a sensitizer by a modification of the method of Mosettig and Scheer (8). The time of exposure to the light was increased from 48 to 72 hr., and also a more diluted solution was used to effect better exposure of ergosterol and eosin to the light. This was necessary because as bisergostatrienol (VIIIa) was formed, it produced a dense white flocculent precipitate. In this way, bisergostatrienol (VIIIa) was obtained in an average yield of 90–96%. Decomposing bisergostatrienol by refluxing in diethylene glycol monoethyl ether (Carbitol) afforded neorgosterol (IX) in 33% yield. Realizing that such a low yield for the second step in the synthesis might mitigate its practical aspects, it was decided to investigate possible variations in this step to increase the yield of neorgosterol. It was reported that pyrolysis of the acetates of these biscompounds affords the Ring B aromatic sterol acetates in 50% yield (8). However, the preparation of the acetate of bisergostatrienol requires large volumes of pyridine (1/180) and a reaction period of 1 week (10), which gave 80% yield. Because protection of the alcohol group had a certain advantage in the pyrolysis step, another method to protect this group, such as the trimethylsilylation method, was sought. Bisergostatrienol (VIIIa) was silylated with bis-(trimethylsilyl)-acetamide (11) by refluxing in benzene under anhydrous conditions. The corresponding bis-(trimethylsilyl)-ether derivative (VIIIb) was obtained in 95% yield. Decomposition of this silyl ether derivative by refluxing in diethylene glycol diethyl ether (Diethyl Carbitol) and by treating the reaction mixture with water and a small amount of *p*-toluenesulfonic acid, to cleave the silyl ether, afforded neorgosterol (IX) in 50% yield.

Degradation of the Side Chain of Neorgosterol—Prior to these studies, neorgosterol (IX) was subjected to ozonolysis conditions in carbon tetrachloride, or to the action of osmium tetroxide followed by periodate cleavage in methanol and acid hydrolysis of the resulting acetal (12). The aldehyde (XIV) obtained in both cases was an oil characterized as the 2,4-dinitrophenylhydrazone. Other investigators (13) ozonized neorgosterol in a mixture of chloroform and acetic acid and purified the crude product by separation of the aldehyde (XIV) with sodium bisulfite. However, no physical data for this aldehyde were reported. Because both ozone and osmium tetroxide cleavage methods did not lead to the separation of a characterizable aldehyde, a different method was sought. Neorgosterol (IX) (Scheme II) was treated with *m*-chloroperbenzoic acid in a mixture of chloroform and benzene at room temperature. The epoxides (X) (mixture of two possible isomers) were obtained by direct crystallization in 90% yield. Opening of the epoxide was accomplished by perchloric acid at the reflux temperature of aqueous acetone. The triols (XI) (two erythro isomers) were obtained in 70% yield. Fieser (14) reacted cholesterol with formic acid and hydrogen peroxide where 3 β ,5 α ,6 β -cholestatriol was obtained in 91% yield. This method was applied on neorgosterol hoping to obtain the triol (XI) in an overall yield higher than in the route *via* epoxide formation and perchloric acid cleavage. However, the epoxide (X) was obtained instead, in about 70% yield. Furthermore, the epoxide (X) proved very resistant to cleavage with hot formic acid. Cleavage of the triol (XI) with periodic acid (15) in methanol afforded the dimethyl acetal (XII) in 95% yield, identical with that previously prepared (12). This indicated that the erythro diol structure underwent the periodate cleavage as readily as the *threo* isomer. Cleavage with periodic acid in aqueous methanol gave the hemiacetal (XIII) as a crystalline compound in high yields. A similar hemiacetal of a C-22 steroidal aldehyde has been reported to be formed under comparable conditions (16). Acetic acid hydrolysis of either the acetal (XII) or the hemiacetal (XIII) in aqueous dioxane gave the aldehyde (XIV) but as a semisolid material. All attempts to induce it to crystallize were unsuccessful; however, it exhibited one spot on TLC using different solvent systems. It showed the characteristic bands for aldehydes in the infrared and gave the reported (12) 2,4-dinitrophenylhydrazone. Cleavage of the triol (XI) with periodic acid in aqueous dioxane gave the aldehyde (XIV), again as an oil possessing the same properties as the one prepared by hydrolysis of the acetals.

These unsuccessful trials in obtaining the aldehyde (XIV) in a pure form prompted a reinvestigation of the ozonolysis of neorgosterol (IX). Slomp (17) has found that methylene chloride is a superior solvent for ozonolysis studies, and that the presence of pyridine, on a mole for mole basis, favors the selective ozonolysis of isolated double bonds over the conjugated ones. It also was reported (18) that a 2% KI solution could be used to determine accurately the cessation of the consumption of ozone by the double bond of isosafrol. A distinct yellow color appears in the KI solution after the reaction of ozone with the double bond has occurred and before ozone attacks the benzene ring. These conditions were applied to the ozonolysis of neorgosterol (IX) which was conducted in methylene chloride at -50° using one equivalent of pyridine. The pure crystalline aldehyde (XIV) was isolated in 92% yield. It was found that both the rate of passing ozone through the reaction and the rate of stirring affect the detection of a correct endpoint in the KI solution. Details are included in the experimental part.

Treatment of the aldehyde (XIV) with morpholine in the presence of a catalytic amount of *p*-toluenesulfonic acid at the reflux temperature of benzene afforded the enamine (XV). Molecular sieve also was used to absorb the water formed during the reaction.

Oxidation of the enamine (XV) with chromic acid in pyridine by the method of Elks (13) afforded, after chromatographic purification and Girard's separation, the C-20 keto compound (XVI) in 20% yield. Such a low yield, together with the successful result of the ozonolysis of neorgosterol (IX), prompted an investigation of the ozonolysis of this enamine. Ozonolysis of the enamine (XV) in methylene chloride at -78° afforded the ketone (XVI), after Girard's separation, in about 40% yield. When pyridine was present, on a mole for mole basis, the ketone (XVI) was obtained in 55% yield. The uptake of ozone was only half of that when pyridine was absent. Greenwood and Rubinstein (19) have found that ether had

Scheme II

some advantages over methylene chloride in increasing the yields of aldehydes and ozonides, while minimizing the formation of other side reactions, during ozonolysis of certain alkenes. Also, raising the temperature of the reaction had a similar effect. Therefore, the enamine (XV) was ozonized in ether at -30° in the presence of 1 mole of pyridine. The ketone (XVI) was obtained in 73% yield after the usual Girard's separation process.

Hydrogenation Studies—For the conversion of the ketone (XVI) to the key intermediate $5\alpha,8\alpha,9\alpha,10\alpha$ -19-norpregnan-3,20-dione (VI), the aromatic Ring B must be reduced by suitable methods. The assignment of the α -configuration at positions 5, 8, 9, and 10 as a result of catalytic reduction methods arises from the fact that the β -side of the molecule of the Ring B aromatic steroids is considerably hindered by the C-18 angular methyl group. This will require that the catalyst approaches the molecule from the less hindered side, the α -side. This is further supported by the report of Farkas and Rapala (20) who found that hydrogenation of equilenin and neoergosterol over ruthenium afforded 40% yield of $5\alpha,8\alpha,9\alpha,10\alpha$ -estrane-3 β ,17 β -diol and 19-nor-24-methyl- $5\alpha,8\alpha,9\alpha,10\alpha$ -cholestan-3 β -ol in 10% yield, respectively. This denotes that such hydrogenations are from the α -side.

Two model compounds (Scheme III), 1,2,3,4,5,6,7,8-octahydrophenanthrene (XVII) and 1,2,3,4-tetrahydro- β -naphthol (XVIII), were selected for catalytic hydrogenation studies. Both are related in structure to the ketone (XVI) in that the former possesses the carbon skeleton of Rings A, B, and C and the latter contains Rings A and B. It is reasonable to assume that conditions needed to hydrogenate these two compounds should be of value in designing experiments to reduce dihydroneoergosterol (XXI) and then the ketone (XVI) with a minimum of undesirable side reactions. Hydro-

genation of the octahydrophenanthrene (XVII) in ethanol containing 1% acetic acid over Rh/alumina at room temperature and 60 p.s.i. proceeded smoothly to provide the *cis-syn-cis*-perhydrophenanthrene (XIX) in excellent yields. The reduction of this compound was previously reported to occur only at 240° and 200 atmospheric pressures over Raney Ni (21). Reduction of 1,2,3,4-tetrahydro- β -naphthol (XVIII) in the same solvent system and under the same conditions afforded *cis,cis*-2-decalol in about 80% yield. Dihydroneoergosterol (XXI) was obtained in 80% yield by hydrogenating neoergosterol (IX) over Adam's catalyst. When dihydroneoergosterol (XXI) was subjected to the hydrogenation conditions used for the octahydrophenanthrene (XVII), the hydrocarbon (XXII) was obtained in about 90% yield, indicating complete hydrogenolysis of the hydroxyl group. Even when a hydrogen pressure of 250 p.s.i. was applied, reduction of this hydrocarbon went very slowly. However, when the amount of catalyst was increased to 10 times that needed to reduce an equimolar amount of octahydrophenanthrene (XVII), reduction went at the usual rate at room temperature and 60 p.s.i. The hydrocarbon (XXIII) was obtained in about 90% yield. The successful hydrogenation of the aromatic B Ring without hydrogenolysis of the hydroxyl group at C-3 is of prime importance to prepare ultimately the key intermediate (VI). Different forms of the oxygen function were prepared in order to prevent hydrogenolysis during the reduction reaction. Hydrogenation of neoergosterol acetate (XXIV) afforded, as a final product, the hydrocarbon (XXIII), with the aromatic compound (XXII) as the intermediate product of hydrogenation.

Dihydroneoergosterol (XXI) was treated with dihydropyran according to the method of Petersen and Gisvold (22) where the tetrahydropyranyl ether (XXV) was obtained. Hydrogenation of

Scheme III

this derivative did not proceed under the previously employed conditions. Even when the amount of catalyst was increased to twice that needed to reduce neoergosteryl acetate and the reaction mixture shaken for 2 days, the tetrahydropyranyl ether derivative (XXV) was recovered unchanged. Because the effectiveness of rhodium in hydrogenating ketones is not conclusive (23), it was thought that hydrogenating dihydroneoergosterone (XXVII) might proceed by reducing the aromatic ring with the preservation of the oxygen function at C-3. To prepare dihydroneoergosterone (XXVII) with a minimum of by-products, preliminary studies were performed on 1,2,3,4-tetrahydro- β -naphthol (XVIII). Oxidation with *t*-butyl hypochlorite (24) afforded the ketone (XXVI) in 90% yield. Oxidation with dimethyl sulfoxide by the method of Pfitzner and Moffatt (25) afforded the ketone (XXVI) in 85% yield. The DMSO method proved more fruitful than *tert*-butyl hypochlorite in oxidizing dihydroneoergosterol, and the ketone (XXVII) was obtained, after purification through Girard's separation, in 75% yield. Hydrogenation of this ketone at room temperature and under ordinary pressures over Rh/alumina proved very difficult, and practically no noticeable absorption of hydrogen occurred during a period of 32 hr. The ketone was recovered from the reaction, *via* the use of Girard's

reagent, in 50% yield. No other substances could be separated from the nonketonic fraction.

In a study of the factors affecting hydrogenation and those favoring hydrogenation over hydrogenolysis, Nishimura (26) reported the usefulness of the catalyst rhodium oxide-platinum oxide (7:3) in hydrogenations where hydrogenolysis is to be avoided. The catalyst consists of rhodium oxide and platinum oxide in a 7:3 ratio by weights of the metals. When this catalyst was employed in the hydrogenation of 1,2,3,4-tetrahydro- β -naphthol (XVIII), dihydroneoergosterol (XXI), neoergosteryl acetate (XXIV), the tetrahydropyranyl ether of dihydroneoergosterol (XXV), and the ketone (XXVII), results similar to those with Rh/alumina reductions were obtained. Nishimura also reported that the hydrogenolysis reaction is acid-catalyzed. Therefore, the amount of acetic acid (1%) used in the hydrogenation of dihydroneoergosterol (XXI) was decreased gradually in an attempt to favor hydrogenation over hydrogenolysis. At a concentration of 0.1%, neither hydrogenation nor hydrogenolysis occurred. With a gradual increase in the amount of acid, very slow absorption of hydrogen occurred which was due chiefly to hydrogenolysis. This was found to be the case with either Rh/alumina or Rh-Pt oxides (7:3) as the catalyst.

These unsuccessful results prompted the investigation of other factors, such as the solvent effect, influencing the extents of hydrogenation and hydrogenolysis reactions. Kindler and Blaas (27) hydrogenated benzoylcarbinyl acetate (XXVIII) over palladium in different solvents. They found that by using an oxygenated solvent such as methanol, dioxane, ethyl acetate, or acetic acid, 2 moles of hydrogen were absorbed and XXIX was obtained in 70–80% yield. However, when a nonoxygenated solvent such as cyclohexane, benzene, or toluene was used, reduction ceased after absorption of 1 mole of hydrogen and XXX was the main product formed. A similar effect was also found in the hydrogenation

tion of 4-chloro- or 4-bromo-2-allylphenol (28). Reduction of the double bond in oxygenated solvents results in appreciable loss of the halogen; while if benzene or cyclohexane is used, elimination of the halogen does not occur. Woodward *et al.*, in their total synthesis of the steroids (29), obtained the glycol (XXXI) as one of the intermediates. Hydrogenation of this glycol, or its acetate or the acetone, over supported Pd in alcohol or ethyl acetate did not cease with the absorption of 1 mole of hydrogen. But, if the reduction was arbitrarily stopped at that point, mixtures of the starting material product of reduction of the disubstituted double bond (XXXIII), and products of reduction of both double bonds (XXXII) were

obtained. When the hydrogenation of XXXI was allowed to proceed to completion, 2 moles of hydrogen were absorbed, giving a complicated mixture of stereoisomeric saturated keto compounds (XXXII). They found that by changing the solvent to benzene, hydrogenation of XXXI, or its diacetate or the acetone, stopped completely after absorption of 1 mole of hydrogen to furnish the corresponding monounsaturated compound (XXXIII) in excellent yields. Therefore, cyclohexane was chosen as the solvent for the reduction of Ring B of the aromatic ketone (XVI).

Hydrogenation of the ketone (XVI) over Rh/alumina in cyclohexane did not proceed even at 1400 p.s.i. hydrogen pressure and the ketone was recovered unchanged (Scheme IV). This ketone was hydrogenated in 65% ethanol at room temperature and 60 p.s.i. over Ru/carbon where 1 mole of hydrogen was absorbed in 2 days. The diols (XXXIV) (mixture of 20 α - and 20 β -) were obtained in 85% yield. When the reduction was conducted in the same way except under 1200 p.s.i., 10 hr. was enough to afford the diols in the same yield. Hydrogenation of this aromatic diol over Rh/alumina in cyclohexane at room temperature and 1400 p.s.i. for 12 hr. afforded the aliphatic diol (XXXV) in 85% yield. The crude reaction product gave a negative tetranitromethane test, indicating the absence of a double bond (30). The IR spectrum of the diol (XXXV) showed the presence of strong OH and C—O stretching vibrations, absence of the phenyl C=C stretching, and the out of plane aromatic C—H bending. NMR spectrum of the crude reaction product showed no aromatic or olefin protons and also the absence of allylic protons at 1.85–2.20 δ . By integration it showed the presence of a multiplet of two protons centering at 3.67 δ corresponding to

Scheme IV

the two protons at C-3 and C-20. By deuterium exchange there was a decrease of two protons in the total value of the integration. This indicates that the hydrogenation of the benzene ring of the aromatic diol (XXXIV) in cyclohexane did not cause hydrogenolysis of the C-3 hydroxyl group.

Oxidation of the diol (XXXV) with Jones reagent (31) in acetone afforded the diketone 5 α ,8 α ,9 α ,10 α -19-norpregnan-3,20-dione (VI) in 90% yield.

Since this compound contains two carbonyl groups not interacting with each other, its rotatory dispersion curve should be the summation of the RD curves of the two separate carbonyl groups (32). However, the specific rotation at the peak (313 m μ) is +2566° (a value of about +3300° was expected). This order of rotation could be accounted for through the contribution of the 17 β -methyl ketone alone, which would indicate that no contribution, or a weak positive Cotton effect, is provided by the 3-keto group. A careful examination of a conformational model of VI in its octant projection would indicate that a positive contribution can be attributed to C-6. Carbon atoms 7 and 8 lying in the horizontal B plane of the octant rule (32) will make no substantial contribution. Carbon atoms 13, 14, 15, 16, 17, and 18 will appear in the lower-left octant and hence will make a negative contribution. These carbon atoms, being more distant from the keto group than C-6 is, will have a smaller influence. Therefore, a resultant weak positive Cotton effect might be obtained for the C-3 keto group, which in turn might explain the RD curve of the diketone (VI).

EXPERIMENTAL

All melting points were determined in capillary tubes in a Thomas-Hoover melting point apparatus and are uncorrected. Optical rotations were obtained using a Perkin-Elmer 114 polarimeter, with a 1-dm. cell at 22° in chloroform. Microanalyses were performed by Schwarzkopf Microanalytical Laboratory, Woodside, N. Y. IR spectra (KBr pellets) were determined on a Perkin-Elmer 237B grating IR spectrophotometer. NMR spectra³ were recorded on a

³ The authors are grateful to Daniel A. Koehler and Thomas N. Riley for preparing the NMR spectra and the ORD curves, respectively.

Varian Associates A-60D spectrometer using concentrations of about 10% and tetramethylsilane as the internal reference standard. ORD curves were determined with a Cary recording spectropolarimeter model 60, using a 1-cm. cell at 25°. Hydrogenations at ordinary pressures were done in a Parr low-pressure hydrogenation apparatus (Parr Instrument Co., Moline, Ill.). Hydrogenations at high pressures were carried out in an autoclave (Autoclave Engineers Inc., Erie, Pa.), and the hydrogenation mixture was stirred magnetically at 500–600 r.p.m. Supported rhodium or ruthenium catalysts (5%) were purchased from Engelhard Industries, Inc., Newark, N. J.

Bisergostatrienol (VIIIa)—The photo-oxidation apparatus consisted of four horizontally fixed, 32-w. white circular fluorescent lamps, with a minimum space between lamps, and enclosed with a reflecting shield of highly polished white interior. The reaction vessel, usually a suitably sized round-bottom flask fitted with a reflux condenser and an efficient stirrer, was placed in the center of the circle of lamps. Fifty grams of Eosin Y⁴ was dissolved in 1500 ml. of ethanol. To this solution, 3.84 ml. of concentrated sulfuric acid (sp. gr. 1.84) was added slowly and with stirring to liberate the free acid. The solution was filtered from the formed sodium sulfate. After bubbling nitrogen through the solution for 30 min., 750 ml. of tetrahydrofuran (THF) (previously passed through activated alumina column to decompose the peroxides) and 50 g. of ergosterol⁵ were added in the dark. The mixture was stirred and irradiated with the white light for 72 hr. under a nitrogen atmosphere. During the reaction time, bisergostatrienol precipitated as dense fine white needles. The mixture was diluted with 4.3 l. of ethanol and the THF was allowed to evaporate spontaneously under the hood overnight. The fine needles were filtered, washed with ethanol and with ether, and dried in a vacuum desiccator. A yield of 45.5 g. (93%) of bisergostatrienol (VIIIa), m.p. 201–203° with decomposition [reported (33) 202–203°], was obtained. The yields of several such reactions averaged 90–96%.

Neoergosterol (IX)—A mixture of bisergostatrienol (VIIIa) (5.0 g.) and diethylene glycol monoethyl ether (Carbitol) (250 ml.) was refluxed for 5 min. in a nitrogen atmosphere. The solution was rapidly cooled to approximately 100° and then added to a mixture of water and crushed ice (250 g.) while stirring. The mixture was kept at –15° for 1 day and filtered while cold; the residue was washed with cold water, dissolved in hot methanol (60 ml.), and allowed to cool slowly. The fine needles of neoergosterol were collected and recrystallized from methanol (60 ml.). The yield was 1.65 g. (33%), m.p. 151–153° [reported (33) 151–152°]; $[\alpha]_D^{20}$ –10° (c 1.0). The IR spectrum showed characteristic peaks at 3330 cm.^{–1} (OH); 3055, 3030 cm.^{–1} (aromatic C–H); 1485, 810 cm.^{–1} (aromatic ring); and 970 cm.^{–1} (*trans* C=C).

Acetylation of Bisergostatrienol—A solution of bisergostatrienol (VIIIa) (1 g.) in pyridine (180 ml.) was mixed with acetic anhydride (15 ml.). After a week the solution was poured into cold water (400 ml.); the separated crystals were collected and washed with dilute acetic acid and with water. After two recrystallizations from benzene–alcohol and drying over P₂O₅ *in vacuo*, colorless fine needles, 830 mg., 80%, m.p. 203–205°, were obtained [reported (10) m.p. 205.5–206°].

Pyrolysis of the Diacetate of the Biscompound; Preparation of Neoergosteryl Acetate (XXIV)—The diacetate of the biscompound (500 mg.) was pyrolyzed by the method described for the biscompound using 40 ml. of diethylene glycol monoethyl ether as the solvent. The yield of neoergosteryl acetate (XXIV) after two recrystallizations from methanol was 250 mg. (50%), m.p. 121–123° [reported (10) 123.5–124°]. The IR spectrum (KBr pellet) showed the absence of the OH group, presence of the ester carbonyl group band (1735 cm.^{–1}), presence of acetate ester characteristic band (1240 cm.^{–1}), and also the bands of the aromatic ring and *trans* double bond were present.

Bis(trimethylsilyl)ether of Bisergostatrienol (VIIIb)—Bisergostatrienol (VIIIa) (2 g.; 0.0025 mole) was suspended in anhydrous benzene (100 ml.), and bis(trimethylsilyl)-acetamide (Aldrich Chem. Co., Milwaukee, Wis.) (11) (1.12 g.; 0.0055 mole) was added. The stirred mixture was refluxed gently for 3 hr. under atmosphere of dry nitrogen. The solution was allowed to cool to

room temperature. The solvent was removed *in vacuo*, and to the residue dry acetone (60 ml.) was added. After cooling at 5° for 1 hr., the material that precipitated was collected and dried *in vacuo* for 24 hr. at room temperature. The yield was 2.2 g. (95%), m.p. 190–192°. The IR spectrum showed the absence of OH absorbance and the presence of the following characteristic bands (34): 1250, 840, 750 cm.^{–1} [Si(CH₃)₃]; 1090–1075 cm.^{–1} (Si–O–C).

Anal.—Calcd. for C₆₉H₁₀₂O₂Si₂: C, 79.58; H, 10.99; Si, 6.00. Found: C, 79.13; H, 10.84; Si, 6.26.

Pyrolysis of the Bis(trimethylsilyl)ether of the Biscompound (VIIIb)—A mixture of bisergostatrienol bis(trimethylsilyl)ether (VIIIb) (1 g.) and diethylene glycol diethyl ether (Diethyl Carbitol) (50 ml.) was refluxed for 5 min. in a nitrogen atmosphere. The solution was cooled rapidly to approximately 100° and added to a stirred mixture of water and crushed ice (50 g.) containing a few crystals of *p*-toluenesulfonic acid. The mixture was worked up in the same way as mentioned under pyrolysis in diethylene glycol monoethyl ether. The yield of neoergosterol (IX) was 490 mg. (50%), m.p. 151–153°.

Neoergosterol-22,23-epoxide (X)—*A. With m-Chloroperbenzoic Acid*—Neoergosterol (IX) (2 g.; 0.0052 mole) was dissolved in dry olefin-free benzene (20 ml.) and chloroform (10 ml.). To this solution was added slowly a cold solution of *m*-chloroperbenzoic acid (FMC Corp., New York, N. Y.) (1 g.; 0.0058 mole) in benzene (15 ml.) and chloroform (10 ml.) and the solution was kept in the dark for 9 hr. at 25°. The solution was diluted with ether (200 ml.), washed with a 10% sodium sulfite solution, sodium bicarbonate solution, and with water until the washings were neutral. The organic solvents were dried over anhydrous sodium sulfate and distilled under reduced pressure. To the solid glassy residue was added 88% methanol (20 ml.) after which a white dense flocculent precipitate was obtained upon trituration. The precipitate was collected, dried *in vacuo* for 48 hr. at 30°. The yield was 1.8 g. (90%), m.p. 105–109° (the wide range is possibly due to the presence of a mixture of the two stereoisomeric epoxides); $[\alpha]_D^{20}$ –13.5° (c 1.0). The IR spectrum showed the absence of the 970 cm.^{–1} band (*trans* C=C) and the presence of a new band at 909 cm.^{–1} (so-called “11-μ band”) characteristic of epoxide rings (35).

Anal.—Calcd. for C₂₇H₄₀O₂: C, 81.76; H, 10.17. Found: C, 81.48; H, 10.30.

B. With Formic Acid and Hydrogen Peroxide—A suspension of neoergosterol (1 g.) in 88% formic acid (20 ml.) was heated at 80° with stirring for 20 min. during which a clear solution was obtained. When the solution came to room temperature, it was treated with 30% hydrogen peroxide solution (3 ml.) and 88% formic acid (10 ml.). The mixture was stirred in the dark at room temperature for 24 hr. The mixture was treated with boiling water (100 ml.), stirred, and kept at 80° for 1 hr., then cooled to room temperature. The oil that separated was collected, dissolved in methanol (50 ml.), and treated with 1 ml. of 25% sodium hydroxide solution and warmed on a steam bath for 15 min. The solution was cooled to room temperature, acidified with dilute HCl, diluted with water (200 ml.), and extracted with ether. The ether extract was washed with water until the washings were neutral, dried, and the ether removed *in vacuo*. The glassy residue was crystallized from 88% methanol. The yield was 710 mg. (70%), m.p. 112–115° (possibly a different ratio of the two isomeric epoxides was obtained). Mixed melting point with the epoxide prepared by the *m*-chloroperbenzoic acid method gave a m.p. of 110–113°. The IR spectrum was identical to that prepared by *m*-chloroperbenzoic acid.

Anal.—Calcd. for C₂₇H₄₀O₂: C, 81.76; H, 10.17. Found: C, 81.95; H, 10.44.

Erythro-22,23-dihydroxy-22,23-dihydroneoergosterol (XI)—To a solution of neoergosterol epoxide (1 g.) in acetone (40 ml.) was added a solution of 2.5 ml. of 70% HClO₄ in 10 ml. water. The solution was refluxed in a nitrogen atmosphere for 3 hr. The solution was diluted with water and extracted with ethyl acetate. The ethyl acetate extract was washed with water until the washings were neutral, dried, and evaporated *in vacuo*. The residue was crystallized from ether when 700 mg. (70%) of colorless crystals were obtained, m.p. 173–175°, that gave a positive periodate–benzidine test (36), indicative of the presence of vicinal diol structure. One of the two erythro isomers was obtained after two recrystallizations from ether–petroleum ether. It was dried *in vacuo* at 70° for 5 hr.; m.p. 206–208°, $[\alpha]_D^{20}$ +29° (c 1.0). The IR spectrum showed the absence of the epoxide band and the presence of strong hydroxyl absorbance at 3375 cm.^{–1}

3 β -Hydroxy-19-norpregna-5,7,9(10)-triene-20 α -aldehyde Dimethyl Acetal (XII)—A solution of the triol (XI) (1 g.) in methanol (40 ml.) was treated with a solution of periodic acid (0.6 g.) in methanol (7 ml.). The solution was stirred in the dark for 18 hr., neutralized with 1*N* NaOH solution, and filtered. The residue on the filter was washed with methanol. The filtrate and washings were concentrated *in vacuo* to a volume of 20 ml., cooled, and 850 mg. (95%) of white crystals of the dimethyl acetal (XII) were obtained; m.p. 177–179°, lit. (12) 178.6–180.9°.

3 β -Hydroxy-19-norpregna-5,7,9(10)-triene-20 α -aldehyde Methyl Hemiacetal (XIII)—A solution of the triol (XI) (1 g.) in methanol (50 ml.) was treated with a solution of periodic acid (0.6 g.) in water (9 ml.). The solution was stirred in the dark for 18 hr. after which time the precipitate that formed was collected and dried *in vacuo*. The yield was 750 mg. (84%); m.p. 142–143°. The IR spectrum showed the absence of a carbonyl absorbance, presence of strong hydroxyl absorbance at 3380 cm^{-1} and at 3430 cm^{-1} . It also showed several sharp peaks at 2820, 1145, 1100, and 1075 cm^{-1} , characteristic of ethers (35).

Anal.—Calcd. for $C_{26}H_{40}O_3$: C, 76.70; H, 9.36. Found: C, 76.47; H, 9.48.

3 β -Hydroxy-19-norpregna-5,7,9(10)-triene-20 α -aldehyde (XIV)—*A. From the Triol (XI)*—A solution of the triol (XI) (1 g.) in peroxide-free dioxane (45 ml.) was treated with a solution of periodic acid (0.6 g.) in water (10 ml.). The solution was stirred in the dark for 24 hr. after which time it was diluted with ethyl acetate (200 ml.) and ether (100 ml.). The solution was washed with water till neutral, dried over anhydrous sodium sulfate, and the organic solvents evaporated *in vacuo* at a temperature less than 40°. The glassy pale yellowish mass that remained was dried *in vacuo* over P_2O_5 for 24 hr. when 620 mg. (82%) was obtained. It was very soluble in the organic solvents and failed to crystallize from most of them. With ether–petroleum ether as solvent for crystallization, an oil was always obtained, $[\alpha]_D -17^\circ$ (c 1.0). The IR spectrum showed the characteristic bands of the aldehyde group at 2700 cm^{-1} (H of CHO) and at 1725 cm^{-1} (C=O).

B. By Hydrolysis of the Acetal (XII) or the Hemiacetal (XIII)—A solution of the acetal (XII) or the hemiacetal (XIII) (500 mg.) in dioxane (20 ml.) was refluxed in a nitrogen atmosphere with a solution of acetic acid (2 ml.) in water (10 ml.) for 5 min. The solution was allowed to cool to room temperature, mixed with ether and ethyl acetate (100 ml. each), and the organic layer washed with water until it was free of acid. The solution was dried over anhydrous sodium sulfate and concentrated to dryness *in vacuo*. The glassy mass that remained was dried *in vacuo* over P_2O_5 for 24 hr. when 420 mg. was obtained. This material was identical to that prepared in Method A in every respect. The 2,4-dinitrophenylhydrazone of this aldehyde melted at 230–231° after one recrystallization from ethyl acetate–methanol, reported (12) 230–232°.

C. By Ozonolysis of Neoergosterol (IX)—A solution of neoergosterol (IX) (5 g.; 0.013 mole) in methylene chloride (400 ml.) and pyridine (1.1 ml.; 0.014 mole) in a tubular reactor equipped with a magnetic stirrer, a gas inlet, and an outlet leading to a $CaSO_4$ drying tube which in turn led to a 2% KI solution, was cooled to -50° in a dry ice–acetone bath. A stream of ozone-rich dry oxygen (5.40% w/w; 7.77 mg. O_3 /100 ml.) (generated by a Welsbach model T-23 ozonator) was passed at a rate of 0.0026 cu. m./min. (0.03 cu. ft./min.) into the stirred solution, and the outcoming gases from the reaction were bubbled through the KI solution. After 15 min. a yellow color was obtained in the KI solution, indicating that about 95% of attack on the double bond had occurred. After an additional 45 sec., the flow of ozone was stopped (1.65 mole equivalents of ozone) and zinc dust (6 g.) and glacial acetic acid (27 ml.) were added. The mixture was allowed to stir at 0–10° for 1 hr. and finally for 5 min. at 35°. The bright-yellow mixture was filtered and washed with two 150 ml. portions of water. It then was cooled by the addition of crushed ice (100 g.) and washed with two 20-ml. portions of cold 10% sodium carbonate, 15 ml. of cold 10% sodium hydroxide, and five 150-ml. portions of cold water, all aqueous washings being back-washed with 20 ml. of methylene chloride. The combined methylene chloride solutions were dried over anhydrous sodium sulfate and the solvent removed under reduced pressure at a temperature less than 40° when a white crystalline residue was obtained. This solid material was dried *in vacuo* over P_2O_5 for 24 hr. when 3.8 g.

(92%), m.p. 132–134°, was obtained; $[\alpha]_D -20^\circ$ (c 1.0). The IR spectrum showed the following characteristic bands: 3515, 3400 cm^{-1} (OH); 3040, 3010 cm^{-1} (aromatic C—H); 2700, 2680 (H of CHO); 1725 cm^{-1} (C=O); 1480, 810 cm^{-1} (aromatic ring), beside the other aliphatic C—H and C—O stretching vibrations. The NMR spectrum showed the following characteristic peaks: singlet at 0.63 δ (C-18 CH_3); doublet centering at 1.20 δ $J = 7$ c.p.s. (C-21 CH_3); singlet at 6.83 δ (2 aromatic protons); and a doublet centering at 9.60 δ $J = 2.9$ c.p.s. (H of CHO). A portion of this material was washed on a funnel with ethyl acetate, anhydrous ether, dried *in vacuo* for 24 hr., m.p. 136–138°; $[\alpha]_D -21^\circ$ (c 1.0).

Anal.—Calcd. for $C_{26}H_{40}O_2$: C, 80.73; H, 9.03. Found: C, 80.54; H, 9.13. The 2,4-dinitrophenylhydrazone of this aldehyde did not depress the melting point when present in a mixture with that prepared from the aldehyde of the periodate reactions. The following observations are significant:

1. During the ozonolysis, if the rate of passing O_3 was increased [0.0035 cu. m./min. (0.04 cu. ft./min.)], an earlier end-point might show in the KI solution and neoergosterol will be separated along with the aldehyde.

2. Also if the rate of stirring is too fast, O_3 will be forced to saturate the solution, and further attack the benzene ring and an incorrect end-point will be obtained. An average rate of stirring of 200–250 r.p.m. with either a magnetic or a mechanical stirrer should be maintained during the ozonolysis.

3. If temperatures colder than -50° are used, the intermediate ozonide will precipitate along with some neoergosterol, causing an incomplete reaction.

3 β -Hydroxy-20-morpholino-methylene-19-norpregna-5,7,9(10)-triene (XV)—A solution of the aldehyde (XIV) (3 g.) in anhydrous benzene (80 ml.) was distilled under nitrogen atmosphere until 20 ml. of distillate was collected (to remove the traces of moisture). To the benzene solution was added 2 ml. of dry morpholine and 12 mg. of *p*-toluenesulfonic acid. This solution was refluxed, while stirred magnetically, under dry nitrogen atmosphere for 4 hr. in the presence of 7 g. of conditioned (by heating at 320° for 5 hr.) Linde 4A molecular sieve 0.160-cm. (0.063-in.) pellets in a continuous-extraction apparatus placed between the condenser and the reaction flask. This assembly permits the condensed vapors of water and benzene to pass through the molecular sieve, so that water will be adsorbed, before it returns to the reaction flask. The solution was cooled, benzene and excess morpholine distilled *in vacuo*, and the pale brown glassy residue dried *in vacuo* over P_2O_5 for 24 hr. The yield was 3.64 g. (99%). The IR spectrum of this enamine showed the absence of carbonyl absorbance and the presence of the enamine double bond absorption frequency at 1645 cm^{-1} (37).

3 β -Hydroxy-19-norpregna-5,7,9(10)-triene-20-one (XVI)—*A. By Oxidizing the Enamine (XV) with $CrO_3 \cdot PY$* —Finely powdered chromic acid (1.65 g.) was added, over a period of 15 min., to stirred anhydrous pyridine (25 ml.) at 0° under nitrogen. A solution of the enamine (XV) (2 g.) in pyridine (25 ml.) was added over 5 min. The mixture was stirred for 4 hr. at 0° and then was allowed to stand overnight at room temperature. Benzene (200 ml.) was added and the mixture was filtered through a column of alumina (25 g.) and the column was eluted with benzene. Evaporation of the eluate *in vacuo* yielded 1 g. of a semisolid material. The ketone (XVI) was separated from this material through the formation of Girard "T" derivative as follows: this semisolid material was dissolved in absolute ethanol (10 ml.), glacial acetic acid (1 ml.), and 1 g. of Girard T reagent was added. The mixture was refluxed under dry nitrogen atmosphere for 1 hr. The solution then was added to sodium bicarbonate (1.26 g.) in water (40 ml.) and the resulting colloidal solution was extracted twice with ether. The clear aqueous layer was acidified to pH 1 with hydrochloric acid and extracted with ether. The ether extract was washed with water until it was free of acid, dried over anhydrous sodium sulfate, and the solvent removed *in vacuo*. The residue was crystallized twice from ether when 0.31 g. (20%) of white rosettes was obtained: m.p. 150–151°, $[\alpha]_D +57^\circ$ (c 1.0 in $CHCl_3$); lit. (13) m.p. 151–152°, $[\alpha]_D +58^\circ$ (c 0.9 in $CHCl_3$). The IR spectrum showed the following characteristic bands: 3340 cm^{-1} (OH); 3040, 3015 cm^{-1} (aromatic C—H); 1700

cm^{-1} (C=O); 1420, 1355 cm^{-1} ($CH_3-C=$); 1480, 810 cm^{-1} (aromatic ring), beside the other aliphatic C—H and C—O stretching vibrations. The NMR spectrum (in CCl_4) showed the following peaks: singlet at 0.51 δ (C-18 CH_3); singlet at 2.11 δ (C-21 CH_3);

multiplet centering at 3.95 δ (H of C-3); and a singlet at 6.73 δ (2 aromatic protons).

B. By Ozonolysis of the Enamine (XV)—Using methylene chloride, a solution of the enamine (XV) (2 g.; 0.0052 mole) in dry methylene chloride (200 ml.) was put in the same tubular reactor with the same outfit used for ozonizing neoergosterol. A stream of ozone-rich dry oxygen (5.40% w/w) was passed at a rate of 0.0026 cu. m./min. (0.03 cu. ft./min.) into the stirred solution at -78° . After 17 min. a yellow color was obtained in the KI solution, indicating about 95% attack on the double bond had occurred. Ozone was stopped after 30 sec. more (4.6 mole equivalents of ozone were absorbed); zinc dust (3 g.) and glacial acetic acid (14 ml.) were added. The solution was worked up and processed for the neutral fraction as previously described under the ozonolysis of neoergosterol. The semisolid material (1.4 g.), that was obtained after distilling the methylene chloride, was purified through Girard T separation procedure as previously described. The residue that remained, after distilling the ether extract of the ketonic fraction, was crystallized twice from ether when 0.62 g. (40%) of white rosettes was obtained; m.p. 151–152°, mixed melting point with the ketone (XVI) prepared by CrO_3 -PY method showed no depression.

Using methylene chloride with pyridine, the above mentioned experiment was conducted in the same way except that pyridine (0.44 ml., 0.0056 mole) was added to the enamine solution before the ozonolysis. A yellow color appeared in the KI solution after passing ozone through the solution for 10 min. The flow of ozone was stopped after 30 sec. more (2.7 mole equivalents of ozone were absorbed). The yield of the ketone (XVI), after Girard T separation and two crystallizations from ether, was 0.85 g. (55%), m.p. 150–151°. The IR spectrum was identical to that prepared by CrO_3 -PY oxidation method and to that prepared by the previously mentioned ozonolysis method.

Using ether, the previous experiment was conducted in the same way except that anhydrous ether (300 ml.) was used as the solvent instead of methylene chloride, and the temperature of the reaction during ozonolysis was adjusted at -30° . The yellow color appeared in the KI solution after 10.8 min. and the flow of ozone was stopped after 30 sec. more (2.9 mole equivalents of ozone were absorbed). The yield of the ketone (XVI), after evaporating the ether extract from Girard T separation under reduced pressure and drying the residue *in vacuo* over P_2O_5 for 24 hr., was 1.28 g., m.p. 142–144°. One recrystallization from ether afforded 1.13 g. (73%), m.p. 151–152°. The IR spectrum was identical to that prepared by the previous methods.

Model Procedure for Hydrogenation—The described amount of catalyst was soaked with a few milliliters of the solvent.⁶ The compound to be hydrogenated was dissolved in the rest of the solvent, mixed with the presoaked catalyst, and the mixture was hydrogenated under the conditions described. After the time used to effect reduction had elapsed, the solution was filtered from the catalyst and diluted with ether (four times the amount of solvent used), washed with 5% sodium bicarbonate solution, water, and then dried over anhydrous sodium sulfate. The organic solvents were distilled under reduced pressure and the products in each case separated as described below.

Perhydrophenanthrene (XIX)—A mixture of 1,2,3,4,5,6,7,8-octahydrophenanthrene (Aldrich Chem. Co., Milwaukee, Wis.) (XVII) (930 mg.; 0.005 mole), ethanol (50 ml.) containing 1% glacial acetic acid, and 5% Rh/alumina (400 mg.) was hydrogenated at room temperature and 60 p.s.i. initial pressure for 9 hr. The hydrogen uptake was 0.016 mole. The crude product was distilled at 87–89°/2 mm. when 870 mg. (91%) of colorless oil, n_D^{20} 1.5010 was obtained; lit. (38) b.p. 109–111°/4 mm. The IR spectrum (liquid film) showed the absence of the aromatic bands (3050, 3025, 3000 cm^{-1} , and 1480, 800 cm^{-1}) and the presence of the aliphatic C—H stretching frequencies at 2890, 2835 cm^{-1} , and C—H bending frequency at 1440 cm^{-1} .

cis,cis-2-Decalol (XX)—A mixture of 1,2,3,4-tetrahydro- β -naphthol (XVIII) (K & K Laboratories, Inc., Plainview, N. Y.) (740 mg.; 0.005 mole), ethanol (50 ml.) containing 1% glacial acetic acid, and 5% Rh/alumina (200 mg.) was hydrogenated at room temperature and 60 p.s.i. initial pressure for 5.5 hr. The hydrogen uptake was 0.015 mole. The crude product was crystallized twice from petroleum ether when 615 mg. (80%), m.p. 102–104°, lit.

(39) m.p. 105°, of XX was obtained. The IR spectrum showed the absence of the aromatic bands (3040, 3000 cm^{-1} and 1485, 735 cm^{-1}) that were present in XVIII and the presence of the following characteristic bands: 3300 cm^{-1} (OH); 1050, 1026 cm^{-1} (C—O), and the other aliphatic C—H bands.

3 β -Hydroxy-19-norergosta-5,7,9(10)-triene; Dihydroneoergosterol (XXI)—A solution of neoergosterol (IX) (5 g.) in ethyl acetate (135 ml.) containing perchloric acid [0.05 ml. of a solution prepared from 70% perchloric acid (10 ml.) and ethyl acetate (90 ml.)] was hydrogenated at room temperature and atmospheric pressure over PtO_2 (100 mg.) for 0.5 hr. The solution was filtered from the catalyst, washed with water till neutral, dried over anhydrous sodium sulfate, and the solvent removed *in vacuo*. The residue was crystallized from methanol when 4.01 g. (80%) of XXI was obtained; m.p. 145–147°, lit. (40) m.p. 146–148°. The IR spectrum showed the absence of the *trans* double bond band at 970 cm^{-1} .

19-Norergosta-5,7,9(10)-triene (XXII)—A mixture of dihydroneoergosterol (XXI) (1.14 g.; 0.003 mole), ethanol (50 ml.) containing 1% glacial acetic acid, and 5% Rh/alumina (500 mg.) was hydrogenated at room temperature and 60 p.s.i. for 7 hr. The crude product was crystallized from methanol when 0.99 g. (90%), m.p. 66–67°, lit. (40) 67–68°, of XXII was obtained. The IR spectrum showed the absence of OH and C—O absorbance and the presence of the aromatic characteristic bands at 3040, 3010, 1485, and 810 cm^{-1} . When the pressure in the above experiment was raised to 250 p.s.i., absorption of H_2 was very slow, and when the reaction was worked up as usual the product (XXII) was isolated in 75% yield (820 mg.).

5 α ,8 α ,9 α ,10 α -19-Norergostane (XXIII)—A mixture of 19-norergosta-5,7,9(10)-triene (XXII) (1.1 g.; 0.003 mole) of dihydroneoergosterol (XXI) (1.14 g.; 0.003 mole), ethanol (50 ml.) containing 1% glacial acetic acid, and 5% Rh/alumina (2.4 g.) was hydrogenated at room temperature and 60 p.s.i. initial pressure for 12 hr. The hydrogen uptake was 0.009 mole, 0.012 mole in case of dihydroneoergosterol. The crude product, 0.99 g. (90%), was a heavy colorless oil that showed no OH bands or aromatic bands in the IR, and it only showed the usual aliphatic C—H absorbances at 2930, 2900, 2840, 1465, 1445, 1380, 1375, and 1365 cm^{-1} . This compound was not investigated further.

Hydrogenation of Neoergosteryl Acetate (XXIV)—A mixture of neoergosteryl acetate (XXIV) (420 mg.; 0.001 mole), ethanol (25 ml.) containing 1% glacial acetic acid, and 5% Rh/alumina (800 mg.) was hydrogenated at room temperature and 60 p.s.i. for 12 hr. The hydrogen uptake was 0.005 mole. The crude product, 330 mg. (90%), was a colorless oil that had an IR spectrum similar to that of XXIII prepared from dihydroneoergosterol (XXI). When the experiment was conducted in the same way except for only 3 hr., 19-norergosta-5,7,9(10)-triene (XXII) was isolated from the crude product by crystallization from methanol in 40% yield (150 mg.), m.p. 65–67°. The IR spectrum was similar to that of the product previously prepared.

3 β -2'-Tetrahydropyranyloxy-19-norergosta-5,7,9(10)-triene (XXV)—Dihydroneoergosterol (XXI) (500 mg.) was dissolved in chloroform (3 ml.) and dihydropyran (200 mg.) (previously dried over KOH, distilled from KOH, and then distilled from sodium). As one drop of a solution containing one drop of phosphorus oxychloride in 5 ml. of ethyl acetate was added, the solution became warm. This solution was warmed to 50° for 20 min., cooled to room temperature, and diluted with ether (100 ml.). The solution was washed with sodium bicarbonate solution, water, dried over sodium sulfate, and solvents removed *in vacuo*. The residue was dried *in vacuo* over P_2O_5 for 24 hr. and then crystallized from methanol. The yield was 540 mg. (90%) of colorless needles, m.p. 125–127°, $[\alpha]_D +13.5^\circ$ (c 1.0). The IR spectrum showed the absence of OH absorbance and the presence of the following characteristic sharp bands: 1195, 1130, 1115, 1070, 1050, and 1025 cm^{-1} (C—O—C—O—C and C—O vibrations) (35). Additional aromatic and aliphatic C—H bands also were present.

Anal.—Calcd. for $\text{C}_{32}\text{H}_{50}\text{O}_2$: C, 82.35; H, 10.80. Found: C, 82.35; H, 10.94.

Attempted Hydrogenation of the Tetrahydropyranyl Derivative of Dihydroneoergosterol (XXV)—A mixture of the tetrahydropyranyl ether derivative (XXV) (200 mg.), absolute ethanol (40 ml.) containing 1% glacial acetic acid, and 5% Rh/alumina (400 mg.; and in another similar experiment 800 mg.) was shaken in a Parr hydrogenator at room temperature and under 60 p.s.i. H_2 pressure

⁶ All the solvents used were boiled for 5 min. to drive off all the dissolved O_2 and then were allowed to cool in an atmosphere of N_2 .

for 2 days. After the usual workup of the reaction, the crude product was crystallized from methanol when 180 mg. of white needles, m.p. 124–126°, that had an IR spectrum similar to that of XXV, were obtained.

3,4-Dihydro-2(1-*H*)-naphthalenone (XXVI)—*A. With tert-Butyl Hypochlorite*—A solution of 1,2,3,4-tetrahydro- β -naphthol (XVIII) (595 mg.; 0.004 mole) in carbon tetrachloride (2 ml.) and pyridine (0.32 ml.; 0.004 mole) was cooled to –5°. From a capillary, *tert*-butyl hypochlorite (0.47 ml.; 0.004 mole) was added and the temperature was allowed to stay at 0° for 15 min. The $\text{PY} \cdot \text{HCl}$ that precipitated was filtered and washed with cold CCl_4 (2 ml.). The filtrate and washings were evaporated at reduced pressure under N_2 . A pale yellow liquid remained, 525 mg. (90%), which yielded a semicarbazone (crystallized from ethanol), m.p. 192–194°, lit. (41) m.p. 193–194°. The IR spectrum (liquid film) showed the absence of OH bands, the presence of strong and sharp carbonyl band at 1720 cm^{-1} together with the other aliphatic and aromatic C—H bands. The NMR spectrum showed the following characteristic peaks: multiplet centering at 2.60 δ (2 protons at C-3), multiplet centering at 3.05 δ (2 protons at C-4), a singlet at 3.61 δ (2 protons at C-1), and a multiplet centering at 7.24 δ (4 aromatic protons).

B. With DMSO—1,2,3,4-Tetrahydro- β -naphthol (XVIII) (595 mg.; 0.004 mole) was dissolved in anhydrous dimethyl sulfoxide (6 ml.) and benzene (6 ml.) containing pyridine (0.32 ml.; 0.004 mole) and trifluoroacetic acid (0.16 ml.; 0.002 mole). After the addition of dicyclohexylcarbodiimide (2.48 g.; 0.012 mole) the reaction mixture was stirred magnetically, under anhydrous conditions, at room temperature for 18 hr. when a fine white precipitate of dicyclohexylurea was being formed throughout the reaction. The mixture was diluted with ether (100 ml.) followed by the dropwise addition of a solution of oxalic acid (1.08 g.; 0.012 mole) in methanol (10 ml.) and the solution was stirred till gas evolution had ceased (0.5 hr.). The solution was cooled, filtered from the urea derivative (m.p. 234°), washed with 5% sodium bicarbonate and twice with water, dried over anhydrous sodium sulfate, and the solvents removed under reduced pressure. The yellow oil that remained was distilled at 117–118°/2 mm. under N_2 . The yield was 495 mg. (85%), its semicarbazone had a m.p. 193–194° which did not depress the melting point of the semicarbazone of the material prepared by *tert*-butyl hypochlorite. The IR and NMR spectra were also identical with the material prepared by *tert*-butyl hypochlorite.

19-Norergosta-5,7,9(10)-triene-3-one (XXVII)—Dihydroneoergosterol (XXI) (1.52 g.; 0.004 mole) was treated as under DMSO oxidation of 1,2,3,4-tetrahydro- β -naphthol (XVIII). The duration, workup of the reaction, was exactly the same as that previously described. The crude residue left after evaporating the solvents under reduced pressure was subjected to Girard's separation procedure as mentioned before under the ketone (XVI) except that a nitrogen atmosphere always was used. The residue that remained after distilling the ether extract of the ketonic fraction was crystallized from methanol. The yield was 1.13 g. (75%) of white needles, m.p. 90–91°, reported (40) m.p. 91–92°. The IR spectrum showed the absence of OH absorbance, presence of carbonyl band at 1720 cm^{-1} and the other aliphatic and aromatic C—H bands.

Attempted Reduction of the Ketone (XXVII)—A mixture of the ketone (XXVII) (380 mg.; 0.001 mole), ethanol (40 ml.) containing 1% glacial acetic acid, and 5% Rh/alumina (750 mg.) was hydrogenated at room temperature and 60 p.s.i. initial pressure for 32 hr. when no noticeable absorption of H_2 occurred. After the usual workup of the reaction mixture, the residue (340 mg.) was subjected to Girard's separation where the ketonic fraction gave 190 mg. (50%) of the ketone (XXVII) identified by its melting point and IR spectrum. Distillation of the ether extract of the nonketonic fraction of Girard's separation did not afford any residue.

Rhodium-Platinum (7:3) Oxides—A mixture of rhodium trichloride trihydrate (769 mg.), chloroplatinic acid (345 mg.), and sodium nitrate (20 g.) was heated slowly until a temperature of 300° was reached in 30 min. The mixture started to melt and the red fumes of the oxides of nitrogen evolved. After the evolution of the gases had subsided (temperature about 400°), the temperature was raised and kept at 460–480° for about 10 min. After cooling, the solid mass was rinsed with distilled water. The solid was collected, washed with 100 ml. of 0.5% aqueous sodium nitrate, and then dried over calcium chloride for 48 hr. The yield was 525 mg. (80%) of fine brown powder.

General Procedure for Reduction over Rh-Pt (7:3) Oxides—The solvent, to be used in the hydrogenation, was boiled for 5 min.

to drive off all the dissolved O_2 , then allowed to cool in an atmosphere of N_2 . The amount of glacial acetic acid was added to make a 1% solution. The catalyst was suspended in few milliliters of this solvent and reduced to the metals by hydrogenation at room temperature and 20 p.s.i. for 0.5 hr. The substance to be reduced was dissolved in the rest of the solvent and then was added to the reduced catalyst and the hydrogenation conducted under the prescribed conditions. The mixture then was filtered, diluted with ether (*ca.* 3 times as the amount of solvent used), washed with sodium bicarbonate solution, water, and dried over anhydrous sodium sulfate. The solvents were removed *in vacuo* and the product was worked up as the conditions warranted.

***cis,cis*-2-Decalol (XX)**—A mixture of 1,2,3,4-tetrahydro- β -naphthol (XVIII) (370 mg.; 0.0025 mole), ethanol (25 ml.), and the catalyst (25 mg.) was hydrogenated at room temperature and 60 p.s.i. The hydrogen uptake was 0.0075 mole in 70 min. The crude product crystallized after the removal of the ether, m.p. 85–89°, one recrystallization from petroleum ether afforded 345 mg. (90%), m.p. 103–104°. The IR spectrum was identical with that of the product prepared from the reduction with Rh/alumina.

Hydrogenation of Dihydroneoergosterol (XXI)—A mixture of dihydroneoergosterol (XXI) (380 mg.; 0.001 mole), ethanol (30 ml.), and the catalyst (50 mg.) was hydrogenated at room temperature and 60 p.s.i. for 24 hr. The crude product was an oil whose IR was similar to that of XXIII. When the above experiment was conducted in the same way and the hydrogenation was stopped after 6 hr., 19-norergosta-5,7,9(10)-triene (XXII) was isolated from the crude product by crystallization from methanol. The yield was 160 mg. (50%), m.p. 65–67°.

Hydrogenation of Neoergosteryl Acetate (XXIV)—The previous two experiments were repeated in the same way except using neoergosteryl acetate (XXIV) (420 mg., 0.001 mole) instead of dihydroneoergosterol. From the first experiment the same oily material was separated, and from the second experiment 19-norergosta-5,7,9(10)-triene (XXII) was obtained in a similar manner.

Attempted Hydrogenation of the Tetrahydropyranyl Derivative of Dihydroneoergosterol (XXV)—A mixture of the tetrahydropyranyl ether derivative (XXV) (200 mg.), absolute ethanol (40 ml.) containing 1% glacial acetic acid (the boiling step was omitted), and the catalyst (40 mg.) was shaken under 60 p.s.i. H_2 pressure and at room temperature for 1 day. Standard manipulation afforded 185 mg. of the ether (XXV) identified by its melting point and IR spectrum.

Attempted Hydrogenation of the Ketone (XXVII)—A mixture of the ketone (XXVII) (250 mg.), ethanol (30 ml.), and the catalyst (40 mg.) was shaken under 60 p.s.i. H_2 and at room temperature for 1 day. Standard manipulation afforded 200 mg. which upon Girard's separation process gave 110 mg. (45%) of the ketone (XXVII), m.p. 89–91°. Nothing could be obtained from the nonketonic fraction after the use of the Girard reagent.

Effect of Acid—A series of experiments was conducted using in each a mixture of dihydroneoergosterol (XXI) (200 mg.), ethanol (30 ml.), and the catalyst (30 mg.) or Rh/alumina (400 mg.). Glacial acetic acid in 0.1, 0.2, 0.3, 0.4, or 0.5% concentration was used. The mixtures were hydrogenated at room temperature and 60 p.s.i. for 8 hr. After the usual workup, the experiments with 0.1% and 0.2% acetic acid concentrations yielded dihydroneoergosterol (XXI). The experiments with higher acid concentrations (they had a slow absorption of H_2) afforded 19-norergosta-5,7,9(10)-triene (XXII) in 40–60% yields, identified by its melting point and IR spectrum.

3 β ,20 β -Dihydroxy - 19 - norpregna - 5,7,9(10) - triene (XXXIV)—A mixture of 3 β -hydroxy-19-norpregna-5,7,9(10)-triene-20-one (XVI) (894 mg.; 0.003 mole), ethanol 65% (80 ml.) (without acetic acid), and 5% Ru/carbon (1.0 g.) was hydrogenated at room temperature at 60 p.s.i. for 2 days. The hydrogen uptake was 0.003 mole. The crude solid (870 mg.) that was obtained after evaporating the organic solvents was crystallized from ether when 760 mg. (85%) of colorless rosettes of the 20 α - and 20 β -diols were obtained, m.p. 169–171°. One hundred milligrams of this mixture was recrystallized twice from methylene chloride to yield 20 mg. (of the 20 β -isomer), m.p. 209–210°, $[\alpha]_D^{25} = -23^\circ$ (c 1.0). The IR spectrum showed the absence of carbonyl band, presence of the following characteristic bands: 3330, 3295 cm^{-1} (OH); 3040, 3000 cm^{-1} (aromatic C—H); 1485, 810 cm^{-1} (aromatic ring); and 1140, 1115, 1080, 1040, and 1020 cm^{-1} (C—O), beside the aliphatic C—H vibrations.

Anal.—Calcd. for $C_{20}H_{28}O_2$: C, 79.96; H, 9.39. Found: C, 79.66; H, 9.45. When this experiment was conducted in the same way, except at 1200 p.s.i. for 10 hr., the same product was separated and the same yield of the diols (XXXIV) was obtained.

3 β -20 β -Dihydroxy-5 α ,8 α ,9 α ,10 α -19-norpregnanediol (XXXV)—3 β -20 β -(& 20 α -)Dihydroxy-19-norpregna-5,7,9(10)-triene (XXXIV), m.p. 169–171° (600 mg.; 0.002 mole), finely powdered, was dissolved in cyclohexane (600 ml.) (previously boiled then cooled under N_2) with the aid of few drops of ethyl acetate. This solution was hydrogenated at room temperature and 1400 p.s.i. over 5% Rh/alumina (1.2 g.) for 12 hr. The catalyst was filtered from the solution which was distilled under reduced pressure and the solid residue (600 mg.) was recrystallized from ether. The yield was 515 mg. (85%), m.p. 185–188°. One hundred milligrams of this mixture was recrystallized twice from methylene chloride when 25 mg. (of the 20 β -isomer) dried for 24 hr. *in vacuo* at 60°, m.p. 230–232°, was obtained, $[\alpha]_D^{25} -6.5^\circ$ (c 0.5). The IR spectrum showed the absence of the aromatic bands and the presence of the following characteristic bands: 3300, 3200 cm^{-1} (OH); 1140, 1095, 1065–1055, 1040, and 1010 cm^{-1} (C—O); and the other aliphatic C—H bands. The NMR spectrum (of the crude reaction product) did not show any peaks in the aromatic, olefinic, or the allylic (1.85–2.20 δ) regions. Also the crude reaction product gave a negative tetranitromethane test (30). Mass spectral molecular ion at m/e 306.

5 α ,8 α ,9 α ,10 α -19-Norpregnan-3,20-dione (VI)—3 β -20 β -(& 20 α -)Dihydroxy-5 α ,8 α ,9 α ,10 α -19-norpregnanediol (XXXV), m.p. 185–188° (306 mg.; 0.001 mole), was dissolved in acetone (40 ml.) previously distilled from potassium permanganate. The solution was cooled to 10° and 0.28 ml. of Jones reagent (31) was added rapidly while stirring the solution under N_2 . After 4 min. the solution was diluted with ether (150 ml.) and washed with water, dried over anhydrous sodium sulfate, and the ether evaporated *in vacuo*. The semisolid residue that remained (298 mg.) was dried *in vacuo* over P_2O_5 for 2 days when colorless fine needles were formed. This residue was recrystallized from ether (10 ml.) when 270 mg. (90%), m.p. 159–161°, was obtained. Another recrystallization afforded 220 mg., dried *in vacuo* at room temperature for 48 hr., m.p. 163–164°, $[\alpha]_D^{25} +32^\circ$ (c 0.5). The IR spectrum showed the absence of OH bands, and the presence of the following characteristic bands: 1710–1700 cm^{-1} (C=O); 1427, 1420 cm^{-1} (CH_2 at C-2 and C-4;

and 1355 cm^{-1} ($CH_3-C=$). The NMR spectrum showed the following peaks: 0.82 δ (C-18 CH_3), 2.15 δ (C-21 CH_3), and a multiplet centering at 2.25 δ (methylene protons at C-2, C-4, and C-17). The ORD (c 0.03 g./100 ml. $CHCl_3$), $t = 27^\circ$, $[\alpha]_{600}^{27} +33^\circ$, $[\alpha]_{589}^{27} +33^\circ$, $[\alpha]_{400}^{27} +226.6^\circ$, $[\alpha]_{360}^{27} +566.6^\circ$, $[\alpha]_{320}^{27} +2162^\circ$, $[\alpha]_{315}^{27} +2450^\circ$, $[\alpha]_{313}^{27} +2566^\circ$ (peak), $[\alpha]_{310}^{27} +2430^\circ$, $[\alpha]_{294}^{27} 0000^\circ$, $[\alpha]_{270}^{27} -3333^\circ$, $[\alpha]_{260}^{27} -3433^\circ$ (trough), and $[\alpha]_{250}^{27} -3433^\circ$. The dispersion curve of this diketone is a "single, positive Cotton-effect curve."

Accepted for publication October 31, 1969.
Presented to the Medicinal Chemistry Section, APHA Academy of Pharmaceutical Sciences, Montreal meeting, May 1969.

Abstracted in part from a dissertation submitted to the Graduate School of the University of Minnesota by Ahmed H. El Masry, in partial fulfillment of the Doctor of Philosophy degree requirements.

This investigation was supported in part by Research Grant HE-06569 from the National Heart Institute, U. S. Public Health Service, Bethesda, Md.

Hydrolysis of Procaine and Its Quaternary Derivatives within Lyotropic Smectic Mesophases

K. S. MURTHY* and E. G. RIPPKE

Abstract □ The effect of solvent anisotropy on ester hydrolysis was studied in lyotropic liquid crystalline phases. Procaine hydrochloride and two of its quaternary derivatives, procaine methyl chloride and procaine ethyl chloride, were employed as substrates, and an aqueous gel consisting of 55% polyoxyethylene tridecyl ether, identified as a neat smectic system, was chosen as the solvent medium. Pseudo-first-order rate constants for the hydrolysis were obtained in the apparent pH range 8.80–11.40, at a temperature of from 30 to 50°, over a surfactant span of 50–65% in the mesophase. Rate measurements were also carried out in aqueous media and in mixed aqueous systems containing polyethylene glycol 300 and 400. The esters were located within the aqueous polyoxyethylene layers as indicated by their UV spectral characteristics. The reaction rates were found to be considerably slower (300- to 1100-fold) in the liquid crystalline phases than in aqueous media. The reactions, as they occur within the smectic phase, are characterized by relatively low apparent activation energies and by large negative entropies of activation.

Keyphrases □ Procaine, quaternary derivatives, hydrolysis—lyotropic smectic mesophases □ Activation energies, entropies—procaine, derivatives, in lyotropic mesophases □ Hydrolysis rate constants—procaine, derivatives, in lyotropic mesophases □ UV spectrophotometry—solubilize location, homogeneous gels

Mesophases, also called mesomorphs or liquid crystals, are states of matter intermediate between crystalline solids and isotropic liquids (1). Molecules in this anisotropic state are orientated with their long axes parallel to one another. The molecules are typically elongated and are generally characterized by the presence of strong dipoles near the centers and weak dipoles near the ends. The parallel orientation of the molecules results both from intermolecular attractions and from the shapes of the molecules. Due to differences in the strengths of the molecular linkages in different directions, for these systems, the transition from the solid to the liquid state takes place in stages, with rising temperature. At lower temperatures the weaker bonds break first, resulting in the formation of mesophases. This is followed at higher temperatures by the loosening of the residual molecular associations when a true liquid state is attained (2).

There are three different types of liquid crystalline phases (3). These are: smectic in which the molecules are arranged in the form of layers with their long axes parallel to each other in the layers and nearly normal to the plane of the layers; nematic where the molecules maintain parallel arrangement along their long axes but are not stratified; and cholesteric where the molecular axes are parallel to the plane of the layers, but the direction of the long axes of the molecules changes continuously in going from one layer to another, resulting in a helical structure. Cholesteric mesomorphism is exhibited by compounds derived from cholesterol, although cholesterol itself is not mesomorphic.

Liquid crystalline structures may be prepared either by heating the crystalline solid (thermotropic meso-

morphism) or by the addition of controlled amounts of polar solvents, generally water, to certain organic compounds (lyotropic mesomorphism). Many amphiphilic compounds, such as soaps and surfactants, having a tendency to form lyotropic mesophases on the addition of water, show the following general sequence of phases (4):

crystalline solid → neat phase → viscous isotropic phase → middle phase → micellar solution → molecular dispersion in water

The term “neat phase” corresponds to the smectic mesophase where the molecules are arranged in the form of lamellar micelles consisting of parallel equidistant sheets of amphiphilic molecules separated by layers of water. In such systems, contact between the polar–polar and nonpolar–nonpolar portions of the molecules is maximized, resulting in a stable configuration. The “middle phase” is composed of long cylindrical micelles arranged in a two-dimensional hexagonal array with the polar groups forming the surface of the cylinders (5).

Several books and reviews dealing with liquid crystals have appeared in recent years indicating the importance of these structures to scientists in different disciplines (6–8). It is generally agreed that lipids exist in biological membranes as mesophases. The structural model for the plasma membrane proposed by Davson and Danielli (9) and Robertson (10) rests on the foundations of a bimolecular lipid leaflet with protein absorbed on both faces. Artificially constituted bimolecular lipid membranes composed of neat smectic structures are currently employed as models for the study of properties of natural membranes (11). In spite of the recognition of the role of mesophases in biological systems, reports of systematic studies of reaction kinetics utilizing these structures as solvent media have been scarce. This is probably related to the fact that nonmesomorphic solutes in relatively low concentrations often tend to destroy or disrupt the parallel orientation of the molecules composing the mesophases.

The only reported kinetic studies employing thermotropic mesophases as solvents were conducted by Svedberg (12, 13) nearly 50 years ago. He studied the unimolecular thermal decomposition of picric acid, pyrogallol, and trinitroresorcinol, at a temperature of 140°, using *p*-azoxyphenetole as the solvent system. Swarbrick and Carless (14) studied the rate of oxidation of benzaldehyde in lyotropic mesophases encountered in ternary systems consisting of betaine–benzaldehyde–water. The reaction rates were found to be significantly lower in the mesophases when compared with the corresponding rates in isotropic systems. Barry and Shotton (15) studied the acid-catalyzed hydrolysis of sodium dodecyl sulfate in the presence of 1-hexadecanol in a solvent medium containing perchloric acid at 60°. They

Figure 1—Equilibrium phase diagram for the system polyoxyethylene (6) tridecyl ether + water showing regions of isotropic liquid (L) and liquid crystalline (LC) phases.

found an increase in the rate of hydrolysis of the substrate in the liquid crystalline phase and attributed this to a decrease in the dielectric constant at the surface of the lamellar micelles constituting the phase.

Because of the ordered arrangement of molecules within mesophases, reaction rates in these systems would be expected to exhibit significant solvent effects in many instances. The aim of this study was to investigate the effect of the anisotropy of the solvent on the kinetics of ester hydrolysis, utilizing lyotropic liquid crystalline phases as the solvent media. Procaine hydrochloride (PHC) was chosen as the ester substrate, and an aqueous gel consisting of 55% polyoxyethylene (6) tridecyl ether was selected as the solvent phase. In order to determine the importance of steric and inductive effects in mesophases, hydrolysis rates of two quaternary derivatives of procaine—procaine methyl chloride (PMC) and procaine ethyl chloride (PEC)—were also studied. For purposes of comparison, hydrolysis rates were also determined in aqueous and polyethylene glycol 300–water solutions.

EXPERIMENTAL

Materials—Polyoxyethylene (6) tridecyl ether.¹ As obtained commercially, this surfactant contained impurities exhibiting absorbance in the UV region. Attempts to eliminate these UV-absorbing materials by treatment with ion-exchange resins and washing with strong alkalis and acids proved to be unsuccessful. Polyethylene glycol 300² (PEG 300) and polyethylene glycol 400² (PEG 400) USP, procaine hydrochloride³ USP. The two quaternary derivatives of procaine, PMC (m.p. 171–173°) and PEC (m.p. 202°), were synthesized according to the procedure of Einhorn and Uhlfelder (16). The compounds were recrystallized from a mixture of ethyl alcohol and ethyl acetate and dried under vacuum at 80° for 12 hr.

^a Conditions: solvents buffered to pH 11.40.

The buffers employed were as follows: for studies at pH 8.80 and 9.70, borate; for pH 10.60 and 11.40, carbonate. *n*-Hexane⁴ spectro-quality reagent. All other chemicals were reagent grade.

Equipment—Polarizing microscope⁵ equipped with Koeffler hot stage, centrifuge,⁶ spectrophotometer,⁷ pH meter.⁸ For kinetic measurements in aqueous buffer solutions at pH 11.40 where the reactions are relatively rapid (half-lives of less than 20 min.), the reactions were conducted directly in silica cells housed within the thermostated compartment of the recording spectrophotometer.⁹

Procedure—*Phase Diagram*—Mixtures containing different concentrations of surfactant were prepared by accurately weighing the surfactant and distilled water in small weighing bottles, melting in a water bath to obtain a homogeneous mass, stirring, and cooling to room temperature. The samples were allowed to equilibrate at room temperature for 48 hr. before being examined for liquid crystalline characteristics.

The identification of the sample as isotropic or liquid crystalline was made by visual and microscopic observations. In this system the mesophase was found to be a viscous, translucent gel. The isotropic liquid was found to be fluid and transparent. Microscopic examination was conducted on a small quantity of the sample placed on a clean glass slide with a coverslip placed lightly on top. The existence of birefringence was verified by observation under crossed polars employing a magnification of 100X. The temperature of phase transition was determined by heating the sample on the hot stage. The rate of heating was at first rapid; but as temperatures came close to the transition temperatures, the rate was maintained at 1° for every 5 min. The temperature at which there was complete disappearance of birefringence, when viewed in the microscope under polarized light, was taken as the temperature of transition. At each surfactant concentration, three such determinations were made and the average value was used. The phase diagram was also determined with the same concentrations of buffer salts as were later used in the kinetic experiments. No significant differences in visual appearance or microscopic features of the mixtures were observed due to the presence of the buffer salts. In all cases there was a slight lowering of transition temperatures of the order of 2° or less.

Assay—The concentrations of the substrates, PHC, PMC, and PEC, in the various solvent systems were followed by measuring the absorbance at 306 m μ . Para-aminobenzoic acid, the degradation product of the substrates, does not absorb appreciably at this wavelength and the observed absorbance change was, therefore, taken as exclusively due to the presence of the substrates. Due to the insolubility of the surfactant in dilute aqueous solutions, the absorbance measurements were made for systems containing the surfactant in 20% ethanol–water solutions. All the kinetic studies were performed at an ionic strength of 0.1 adjusted with potassium chloride.

Systems containing polyoxyethylene chains are generally found to be susceptible to auto-oxidative degradation (17, 18). Such a breakdown of the polyoxyethylene in the systems under study would result

in a significant drop in pH. After some preliminary experimentation, a combination of sodium sulfite and hypophosphorous acid in concentrations of 0.1% each was found to be effective in stabilizing against oxidation. In the course of preliminary experiments, it was also found that reaction rates were extremely low below an apparent pH of 8.00. Studies were, therefore, conducted at higher pH's.

In a typical experiment the following procedure was employed. The theoretically calculated quantities of the buffer salts and the substrates were dissolved in distilled water. A measured volume of this buffer solution was pipeted into a conical flask containing a

previously weighed quantity of the surfactant such that the resultant gel contained the required concentration of the surfactant and was of the desired apparent pH. The ionic strength of the gel was maintained at 0.1 by the addition of potassium chloride to the aqueous solution whenever necessary. In order to obtain a homogeneous gel, the mixture of the surfactant and the aqueous salt solution was melted in a water bath and cooled. The necessary adjustments in the apparent pH of the mesophase were made by the addition of concentrated solutions of sodium hydroxide or hydrochloric acid to the aqueous buffer solution. The gel was then subdivided accurately into 5-g. portions in flasks of 10-ml. capacity. A similar set of flasks containing reference gel was also prepared at the same time in a manner identical to that of the sample gel but without substrate. To suppress any possible oxidation of the surfactants, the gels were degassed with a stream of nitrogen and the flasks were tightly stoppered, sealed, and protected from light. At appropriate intervals, duplicate samples were withdrawn, diluted with 40% ethanol-water solution, and analyzed spectrophotometrically with an appropriately treated blank in the reference compartment of the spectrophotometer.

The apparent pH of the mesophase was determined at a room temperature of about 25° at the start of each kinetic experiment. At subsequent intervals, the pH of the solutions used for the assay were measured to monitor the pH of the gel.

UV Absorption Spectra—The UV absorption spectra of solubilizates have been utilized for determining their location within the different regions of the micelle (19, 20). To prepare the mesophase for UV examination, the homogeneous gel was introduced into the cells with the aid of a syringe. The cells were held in a water bath at 75° until the air bubbles entrapped in the gel were driven off. Because of this procedure, the theoretically added amounts of the substrates could not be retained in the samples. Comparisons

were, therefore, made on the basis of wavelength of maximum absorption.

RESULTS AND DISCUSSION

The regions of temperature and composition for the occurrence of mesophase and isotropic liquid in the surfactant-water mixtures are presented in Fig. 1. The general features of the diagram are similar to that reported in the literature for systems of this type (21). At room temperature, liquid crystalline phases were found to occur in the surfactant concentration range 44–76% w/w. It has not been possible to determine the region where both the phases, isotropic liquid and mesophase, coexist. Typical photomicrographs of the mesophase observed under crossed polars are presented in Fig. 2. The anisotropic spherulites, both positive (extinction arms narrowest at the center of the cross) and negative (extinction arms broadest at the center of the cross), encountered in this system represent one form of focal conic

texture characteristic of smectic structures. Current theories do not consider the middle phase to be smectic (22) since it does not assume any focal conic arrangement. Mixtures containing 50, 55, and 65% surfactant did not show any phase separation when equilibrated at 50° or when centrifuged at room temperature for 7 hr. at 7000 r.p.m. The temperature of transition from the mesophase to the isotropic liquid at 50, 55, and 65% surfactant concentrations are 69, 69, and 64°, respectively. For nonionic surfactant systems, the two-phase region consisting of isotropic liquid and liquid crystalline phases is narrow, and it is reasonable to assume that at 50°, the highest temperature at which the rate studies were carried out, the system is composed of neat smectic phase only.

From the data presented in Table I, it is apparent that the wavelength of maximum absorption for all three substrates in the mesophase are very close to those in the PEG 300-water mixtures but significantly different from those in *n*-hexane and in distilled water. This indicates that the esters are located within the polyoxyethylene layers of the lamellar micelle.

Kinetic Studies—Pseudo-first-order rate constants for the hydrolysis of the substrates were obtained from least-squares calculations of the slopes of the plots of log absorbance versus time. The apparent first-order rate constants for the hydrolysis of the substrates in the mesophase containing 55% surfactant and the corresponding rate constants in simple aqueous buffered solutions at pH 11.40 are presented in Table II. The pH dependence of the pseudo-first-order rate constants in the mesophase is shown in Table III. A typical Arrhenius plot for the hydrolysis reaction in the mesophase is shown in Fig. 3. The value of the heat of ionization of water taken from the literature (23) (12.27 kcal./mole) was subtracted from the observed values to obtain the apparent energies of activation as given in Table IV. The entropy of activation and the frequency factors were calculated from the well-known Eyring equation on absolute reaction rates (24). All data are consistent with the mechanism of hydrolysis (see Scheme I) proposed by Higuchi *et al.* (25) for procaine in strongly alkaline solutions (Fig. 4).

Scheme I

Since the UV absorption data of the esters in the various solvent phases indicated that these substrates were located within the aqueous polyoxyethylene layers of the micelle, the reaction rates were also determined in a medium simulating the environment of the substrates in the mesophase. If the substrates are protected from hydrolytic reaction by the polyoxyethylene chains, then a medium which corresponds in molecular composition to the polyoxyethylene

portion of the surfactant in the mesophase should result in a significant lowering of the observed rates. The results of the rate constants determined in such a medium are given in Table V.

Also, under these conditions, increase in the concentration of ethylene oxide in the solvent system should lower the observed rates. Such an increase in the ethylene oxide concentration can be brought about either by an increase in the PEG concentration or by an increase in the surfactant concentration. Rate constants obtained in both cases are presented in Tables VI and VII. An examination of this data shows that, although polyoxyethylene exerts a shielding action, reducing the rates of decomposition, the observed rates in PEG 300-water systems are higher than in the mesophase. While no definite arguments can be offered to explain the observed differences in the two media, it is probable that these results may reflect differences in the precise orientation of the esters in the two media and their accessibility to hydrolytic attack. This is especially important in view of the results indicating that the reactions are strongly inhibited with an increase in surfactant concentration in the medium.

The degree of protection conferred by polyoxyethylene chains appears to be dependent more on the concentration than on the chain length. The small differences observed in the rates of hydrolysis between the two quaternary compounds, PMC and PEC, both in aqueous and in PEG 300-water mixtures, are within the range of experimental error, and no significance can be attached to them.

SUMMARY

Equilibrium conditions of temperature and composition at which lyotropic mesophases occur were established for the system polyoxyethylene (6) tridecyl ether-water. Employing substrate concentrations of the order of $1 \times 10^{-4} M$, hydrolytic decomposition rates of procaine and two of its quaternary derivatives, PMC and PEC, were determined spectrophotometrically in a medium consisting of 55% surfactant and identified to be of neat smectic type. Apparent energies and entropies of activation were calculated for the reactions in the mesophase from rate measurements in the temperature range 30–50°. The reactions, as they occur in the mesophase, appear to be characterized by low Arrhenius energies of activation and large negative entropies. On the basis of UV spectral characteristics, it was inferred that the substrates are located in the polyoxyethylene region of the lamellar micelles. Kinetic measurements in a 42% PEG 300-water system, which corresponds in composition to the polyoxyethylene portion of the micelle, indicate that the reaction rates are significantly retarded by the polyoxyethylene chains. The degree of retardation appears to be dependent upon the concentration of PEG

in the system. The available data do not appear to indicate any change in the reaction mechanism for the hydrolysis of procaine in the mesophase from that in simple aqueous solutions.

Statistical Techniques in Predicting Thermal Stability

DONALD L. BENTLEY

Abstract □ In developing new pharmaceutical products it is often necessary to predict degradation rates at marketing temperatures from data collected on accelerated degradation taken at elevated temperatures. A technique for predicting degradation rate based on the Arrhenius equation was presented by Garrett in 1956. While his method is characterized by ease of computation involved (necessary due to scarcity of computer facilities at that time), it violates a number of assumptions upon which least-squares analysis is based, and hence inferences made from the results can be misleading. This report presents a method based on weighted least-squares analysis which can easily be adapted for computer analysis. Comparisons are made with the method suggested by Garrett to illustrate differences in technique and the effect the basic assumptions have upon the results obtained by the two methods. A statistical test is presented for determining the applicability of the Arrhenius relation to the data at hand. Finally, the technique is illustrated by application to chloramphenicol.

Keyphrases □ Thermal stability—statistical techniques for prediction, equations derived □ Arrhenius least-squares equations, thermal stability—comparison, evaluation □ Chloramphenicol, thermal stability—statistical determination □ Degradation rates—chloramphenicol

In 1956 Garrett (1) published a paper recognizing the economic benefits of predicting thermal stability of a drug from data collected at elevated temperatures. The method outlined by Garrett was a simple approximation to a method of fitting the Arrhenius relation by weighted least-squares analyses suggested by McBride and Villars (2) in 1954. The approximation suggested by Garrett gained a great deal in ease of computation, yet sacrificed in the extent to which valid inferences could be derived from the results. Until 1960 ease of computation was of primary concern due to scarcity and cost of computer time, but today even the smallest company can easily rent computer time at a reasonable cost. However, the approximate solution suggested by Garrett is the standard method used today (3, 4).

The purposes of this paper are to outline a method for predicting stability as based on the weighted least-squares technique, to illustrate why weighted least squares should be used in lieu of the unweighted approximation, and to present a statistical test for the validity of the Arrhenius assumption which can easily be computed from the results of the weighted method.

Appendix 1 contains the mathematical formulas involved in the weighted least-squares analysis.

THEORETICAL

Arrhenius Relationship—The functional relationship between time and concentration of a drug stored under constant conditions is dependent upon order of reaction and a rate constant which determines speed of reaction. A thorough discussion of methods for picking proper order is outside the scope of this paper and the assumption will be made that correct order can be determined. An example of a typical situation is the first-order reaction given by Eq. 1 where the logarithm of concentration at time t , denoted C_t , is

linearly related to time by

$$\ln C_t = \ln C_0 - k_\tau t \quad (\text{Eq. 1})$$

where τ is the temperature at which storage took place and k_τ is the rate constant.

The Arrhenius relationship:

$$\ln k_\tau = \gamma + \delta/\tau \quad (\text{Eq. 2})$$

states that speed of reaction is dependent upon temperature; that is the logarithm of the reaction rate is a linear function of the reciprocal of absolute temperature. It is this relationship which allows data taken at elevated temperatures to be used to predict the degradation rate at room temperature and hence estimate shelf life of the drug. The rate constants obtained at the elevated temperatures can be used to estimate the parameters in the Arrhenius equation, which in turn can be used to estimate reaction rate at room temperature (or any other desired temperature).

The methods of estimation used in the previous procedure can vary from simple (and quick) eyeball techniques to a thorough statistical analysis based on weighted least squares. The remaining discussion points out the advantages of the latter in comparison to less rigorous techniques.

Simple Linear Regression—Assume a situation in which a variable Y is linearly dependent upon a second variable X . Examples of such a situation include both Eqs. 1 and 2. A general expression for such a relationship is $Y = \alpha + \beta X$. If Y could be measured without error for any value of X , α and β could be determined from two sample points and any further observations would fall on the determined line.

In practice, experimental error enters due to measurement error, biological variation, etc. Hence, an observed Y_i is related to its corresponding X_i by Eq. 3,

$$Y_i = \alpha + \beta X_i + \epsilon_i \quad (\text{Eq. 3})$$

where $\alpha + \beta X_i$ is the underlying relationship and ϵ_i is the error term. This situation is illustrated in Fig. 1 in which the dotted line represents the true but unknown relationship and the error is the vertical distance from the point to the dotted line. The statistician's problem is to estimate α and β . A number of methods are available such as: arbitrarily saying $\alpha = 47$ and $\beta = -10$, fitting the data by eye, and least-squares analysis. The first method is obviously of no value, the second might prove useful if rough guesses are desired; but if a thorough analysis including extrapolation, confidence statements, or tests of hypotheses is desired, a proper least-squares analysis must be performed to make better use of the data.

The conditions of a simple least-squares analysis are as follows: assume a sequence of n observation pairs $(Y_1, X_1), (Y_2, X_2), \dots, (Y_n, X_n)$ represented by the points in Fig. 1. If Eq. 3 holds for all $i = 1, \dots, n$, and if further (a) the additive errors ϵ are independent of one another; (b) the distribution of the error term has mean zero; and (c) the variance of each ϵ_i is σ^2 , a constant not depending upon i or X_i ; then the "best" estimates (5) for α and β are those which will minimize the right-hand side of Eq. 4.

$$\sum_{i=1}^n \epsilon_i^2 = \sum_{i=1}^n (Y_i - \alpha - \beta X_i)^2 \quad (\text{Eq. 4})$$

In Fig. 1 the least-squares line is represented by the solid line and is the one which minimizes the sum of squared distances in the vertical direction from sample points to fitted line.

Note again assumptions (a) that the error ϵ_i is additive, and (c) that the ϵ_i 's have a common variance; that is, dispersion of error is not proportional to X and hence to the expected value of Y .

The results of a least-squares analysis are not restricted to α and $\hat{\beta}$, the estimates of α and β , respectively. Equation 5 gives the variance

Figure 1—Example of regression situation. Broken line represents true unknown relationship; solid line represents least-squares fit to data.

of the estimate of β in which σ^2 is the variance of the ϵ_i 's.

$$\sigma_{\hat{\beta}}^2 = \sigma^2 / \sum_{i=1}^n (x_i - \sum_{i=1}^n x_i/n)^2 \quad (\text{Eq. 5})$$

The smaller the variance of the estimate the greater is the confidence which can be placed in it being close to the true unknown parameter.

One further estimate which can be obtained is given by Eq. 6.

$$S^2 = \sum_{i=1}^n (Y_i - \hat{\alpha} - \hat{\beta}X_i)^2 / (n - 2) \quad (\text{Eq. 6})$$

This is an estimate of σ^2 , the variance of the error term. This estimate is just an average of the squared deviations of the sample points from the fitted line.

Application of Weighted Least-Squares to Stability Studies—Assume an experiment in which a drug has been stored at various temperatures. Assays are made throughout the period of the experiment to estimate concentration as a function of time. According to the Arrhenius relation a faster degradation is expected to occur at higher temperatures; hence, assays for the higher temperature data might be made more frequently but for a shorter period of time.

A simple least-squares analysis is made by fitting Eq. 1 to the data collected at each temperature τ to determine \hat{k}_τ , the estimate of degradation rate for that temperature. The assumptions mentioned previously as required for a valid least-squares analysis will be sufficiently satisfied except for those nonzero-order reactions in which the range over which concentration varies is extremely large.

Along with each estimate of a k_τ is an estimate of the experimental error variance σ^2 as given by Eq. 6 and the coefficient by which σ^2 must be multiplied in order to obtain the variance of \hat{k}_τ , the estimate of k_τ . This coefficient is given by

$$1 / \sum_{i=1}^{n_\tau} (t_i - \bar{t})^2 \quad (\text{Eq. 7})$$

where t_i represents the times at which the assays are made, n_τ represents the number of assays made at temperature τ , and $\bar{t} = \sum_{i=1}^{n_\tau} (t_i/n_\tau)$.

Figure 2 shows the least-square curves for data collected on chloramphenicol at temperatures 32, 34, 42, 58, and 71°. As each analysis yields an estimate of the same experimental error variance σ^2 , these estimates can be combined to form one single estimate of error variance. This estimate will be used later in the analysis and will be referred to as the combined variance estimate denoted S_c^2 .

Figures 3 and 4 illustrate the reason for using weighted least squares for fitting the Arrhenius relationship. Figure 3 is a plot of the various k_τ estimates against reciprocal absolute temperature using a linear scale on both axes. Each vertical line represents a 95% confidence interval for the corresponding k_τ . The horizontal mark indicates the point estimate. The width of each confidence interval depends upon the coefficient given by Eq. 7, that is the times and number of observations taken at each temperature.

Figure 2—Least-squares degradation of chloramphenicol data.

Figure 4 is a plot of the same estimates and same confidence intervals, but drawn on semilogarithm paper. Hence the scale on the vertical axis is $\log_{10} k_\tau$. Note that the length of the confidence intervals for the k_τ at lower temperatures have been lengthened relative to the higher temperatures.

A simple least-squares fit, represented by the broken lines in Fig. 4, was applied to the model:

$$\hat{k}_\tau = e^{\gamma + \delta/\tau + \epsilon} \quad (\text{Eq. 8})$$

that is, $\ln \hat{k}_\tau = \gamma + \delta/\tau + \epsilon$ where \hat{k}_τ is the estimate of k_τ obtained in the previous analyses, and ϵ is an additive error to $\ln k_\tau$ with com-

Figure 3—Arrhenius fit to degradation constants with 71° data included. Vertical lines represent 95% confidence intervals. Solid line is the weighted least-squares line; broken line is the unweighted least-squares line.

Figure 4—Arrhenius fit to degradation constants with 71° data included. Vertical lines represent 95% confidence intervals. Solid line is the weighted least-squares line; broken line is the unweighted least-squares line.

mon variance for all τ . But the true error in \hat{k}_τ is additive to k_τ , not $\ln k_\tau$, because of the method of derivation of \hat{k}_τ ; further, the variances of the errors in the \hat{k}_τ differ according to the coefficient given in Eq. 7. This is illustrated by the extreme difference in the lengths of the lines representing the confidence intervals in Fig. 4. The simple least-squares analysis assumes these lengths to be the same. The effect of the simple least-squares analysis is to force the Arrhenius equation through the low temperature data and essentially ignore the high temperature data. Hence, much more faith is placed in the point estimates of the low temperature \hat{k}_τ than is warranted. Finally, the usual confidence statements on extrapolated

Figure 5—Arrhenius fit to degradation constants with 71° data excluded. Vertical lines represent 95% confidence intervals; solid line is the weighted least-squares line.

degradation rates (such as at room temperature) cannot validly be made.

Appendix 2 outlines justification for applying the method of weighted least squares to the model:

$$\hat{k}_\tau = e^{\gamma + \delta/\tau} + \epsilon_\tau \quad (\text{Eq. 9})$$

where ϵ_τ is now an additive error to k_τ in the estimate \hat{k}_τ and has variance σ_τ^2 . The method of weighted least squares weights each $\ln \hat{k}_\tau$ in inverse proportion to the square of the width of its confidence interval. The weighted least squares fit is represented by the solid lines in Figs. 3 and 4.

Statistical Test of Arrhenius Assumption—The benefits of the weighted least-squares analysis are many. First, the estimates of the parameters of the Arrhenius equation meet the statistician's requirements as the "best" which can be obtained. Second, a confidence interval can easily be constructed around the rate constant for any desired temperature, such as room temperature. Finally, a second estimate of σ^2 , the variance of the original experimental error, can be obtained from the fit of the \hat{k}_τ to the Arrhenius equation. This estimate of variance will be independent of the combined variance estimate S_e^2 based on the original individual temperature analyses, and it will be referred to as the Arrhenius variance estimate and will be denoted S_a^2 . Its formula is included in Appendix 1.

The advantage of the two estimates of error variance is as follows. S_a^2 is dependent upon the validity of the Arrhenius assumption. If the Arrhenius relationship does not hold, S_a^2 will tend to be large relative to the true experimental error variance, and therefore large relative to S_e^2 which does not depend upon the Arrhenius assumption. By dividing the Arrhenius variance estimate S_a^2 by the combined variance estimate S_e^2 , one obtains an F statistic. By comparing the computed F with a tabled F , which can be found in any elementary statistics book (6), the experimenter can determine the validity of the Arrhenius assumption.

A significantly large F ratio would indicate the Arrhenius relationship does not hold. If the Arrhenius assumption is shown to be significantly invalid (that is the dispersion around the Arrhenius line is greater than could be attributed to chance variation in the \hat{k}_τ), then the least-squares line is not valid and should not be used for predictive purposes. Further, no method of fitting a straight line would be valid for predictive purposes.

On the other hand, if the Arrhenius fit does not yield a significant F value, the high as well as low temperature rate constants fit the Arrhenius line within the measurement error involved in the \hat{k}_τ , and hence all rate constants should be weighted according to their error variances.

Example—The above analysis was performed on a chloramphenicol solution. The results of the analysis are given in Table I. The initial analysis was performed at five temperatures: 32, 34, 42, 58, and 71°. Both the weighted and unweighted least-squares analyses were performed in order to make a comparison between the two methods. The two Arrhenius curves are presented in Figs. 3 and 4. Note that the estimate of degradation from the unweighted method for 23° would have been 2.91×10^{-4} and the analysis terminated at this point. This compares with an estimate of 8.01×10^{-4} computed by the weighted method on the same data.

At this point in the weighted analysis the F test was applied. The computed value was 36.95 with 3 degrees of freedom in the numerator and 167 in the denominator. This value is extremely significant ($F = 5.70$ is significant for $\alpha = 0.001$), indicating the Arrhenius assumption invalid. Upon investigation a precipitate was found to have formed in the 71° data soon after termination of collecting data at that temperature. Hence, these data were excluded from the analysis and another weighted least-squares analysis was performed. The F ratio testing the fit of the four remaining temperatures to the Arrhenius relationship yielded a value $F = 0.1110$ with 2 degrees of freedom for the numerator and 136 for the denominator. Such a small value indicates an extremely good fit to the Arrhenius relationship. The weighted least-squares line is plotted in Fig. 5. No analysis was performed by the unweighted method omitting the 71° temperature to emphasize the fact that the unweighted method would not have led to the detection of lack of fit to the Arrhenius relationship.

The new estimate of degradation rate at 23° was 2.12×10^{-4} . Of primary concern is how well this estimate, based on accelerated data collected over an 89-day period, compares with the value observed on production batches. The actual values observed on two separate

APPENDIX 1

Suppose $Y_i = X_{i1}\beta_1 + X_{i2}\beta_2 + \dots + X_{im}\beta_m + \epsilon_i$ for $i = 1, 2, \dots, n$. Define Y to be the $n \times 1$ matrix $[Y_i]$, X the $n \times m$ matrix $[X_{ij}]$, β the $m \times 1$ matrix $[\beta_j]$, and ϵ the $n \times 1$ matrix $[\epsilon_i]$. Then the n observations satisfy $Y = X\beta + \epsilon$. Further, suppose the covariance matrix for ϵ is $\sigma^2 V$ for a known $n \times n$ matrix V and unknown scalar σ^2 . That is the expectation of $[\epsilon\epsilon'] = \sigma^2 V$ where ϵ' is the transpose of ϵ .

The estimate of β is

$$\hat{\beta} = (X'V^{-1}X)^{-1}X'V^{-1}Y \quad (\text{Eq. 10})$$

The estimate of σ^2 is

$$S^2 = (Y'V^{-1}Y - Y'V^{-1}X\hat{\beta})/(n - m) \quad (\text{Eq. 11})$$

The covariance matrix for the $\hat{\beta}$ vector is

$$(X'V^{-1}X)^{-1}\sigma^2 \quad (\text{Eq. 12})$$

which can be estimated by replacing σ^2 by S^2 . To estimate a value on the true line $Y_0 = X_{01}\beta_1 + X_{02}\beta_2 + \dots + X_{0m}\beta_m = X_0\beta$, use the estimate:

$$\hat{Y}_0 = X_0\hat{\beta} \quad (\text{Eq. 13})$$

The variance of the estimate $X_0\hat{\beta}$ is

$$\sigma_{Y_0}^2 = X_0(X'V^{-1}X)^{-1}X_0'\sigma^2 \quad (\text{Eq. 14})$$

which can be estimated by replacing σ^2 by S^2 . A $(1 - \alpha)$ 100% confidence interval on Y_0 can be constructed as

$$X_0\hat{\beta} \pm t_{n-m}^{(1-\alpha/2)}[X_0(X'V^{-1}X)^{-1}X_0'S^2]^{1/2} \quad (\text{Eq. 15})$$

where $t_{n-m}^{(1-\alpha/2)}$ is the point on Student's t distribution with $n - m$ degrees of freedom which is exceeded with probability $\alpha/2$.

To apply the weighted analysis to the degradation problem, first perform an individual analysis on the data at each temperature τ setting $V = I$, the $n \times n$ identity matrix. The matrix X is $n \times 2$ with each element of the first column one (1) and the second column the respective times t_i at which assays were made. Y is the vector of the appropriate function of concentration (for a first-order reaction, Y is the vector of the logarithms of concentration). The second element of the $\hat{\beta}$ vector in Eq. 10 is the estimate \hat{k}_τ of the rate constant.

Call ω_τ the second row, second column element of $(X'V^{-1}X)^{-1}$, $v_\tau = (\hat{k}_\tau)^2/\omega_\tau$ and S_τ^2 the computed value for Eq. 11 at temperature τ based on $n = n_\tau$ and $m = 2$.

The combined variance estimate for the weighted least-squares analysis is

$$S_c^2 = \sum_{\text{all } \tau} (n_\tau - 2)S_\tau^2 / \sum_{\text{all } \tau} (n_\tau - 2) \quad (\text{Eq. 16})$$

The method of fitting the Arrhenius relationship to the \hat{k}_τ is as follows. Set the Y vector to be the logarithms of the \hat{k}_τ 's. The X matrix

has each element of the first column one (1) and the second column the reciprocal absolute temperatures, i.e., $1/\tau$. The matrix V , which is $n \times n$ where n is now the number of temperatures at which data were collected, has the corresponding v_τ on the main diagonal and zeros everywhere else.

The Arrhenius variance estimate S_a^2 is computed at this point by Eq. 11 where n is the number of temperatures and $m = 2$. The F statistic is

$$F = S_a^2/S_c^2 \quad (\text{Eq. 17})$$

having $n - 2$ degrees of freedom in the numerator and $\sum_{\text{all } \tau} (n_\tau - 2)$ degrees of freedom in the denominator. Reject the applicability of the Arrhenius relationship for large F .

Estimates of logarithm of rate constant at absolute temperature τ_0 can be made from the results of the Arrhenius fit by setting $X_0 = (1/\tau_0)$ in Eq. 13. A confidence interval for logarithm rate constant at τ_0 can be established by Eq. 15. Once these have been done the estimate of time for a given drug to degrade from an initial concentration C_0 to a minimal concentration C_m can be estimated and a confidence interval for length of time for such a degradation can be constructed.

APPENDIX 2

Consider a set of n observations $(y_1, x_1), (y_2, x_2), \dots, (y_n, x_n)$ where x_i and y_i are related by

$$y_i = e^{\alpha + \beta x_i} + \epsilon_i \quad (\text{Eq. 18})$$

Denote by \bar{y}_i the true value of y associated with x_i ; that is $\bar{y}_i = e^{\alpha + \beta x_i}$. Then $\bar{y}_i = y_i - \epsilon_i$. Expanding $\ln \bar{y}_i = \ln(y_i - \epsilon_i)$ in a Taylor's series about y_i gives

$$\ln \bar{y}_i = \alpha + \beta x_i = \ln y_i - \epsilon_i \frac{1}{\bar{y}_i} + \text{remainder} \quad (\text{Eq. 19})$$

where the remainder is a term of order $[\epsilon_i/\bar{y}_i]^2$. Provided ϵ_i/\bar{y}_i is much less than 1, the remainder can be ignored. This gives

$$\ln y_i \simeq \alpha + \beta x_i + \epsilon_i/\bar{y}_i \quad (\text{Eq. 20})$$

where the new error term, call it ϵ_i^* , is now ϵ_i/\bar{y}_i . It follows immediately that the mean of ϵ_i^* is zero and the variance of ϵ_i^* is $\sigma_{\epsilon_i}^2/\bar{y}_i^2$. Approximating \bar{y}_i by y_i gives the weighting used in the Arrhenius analysis described in Appendix 1.

Whole Body Measurements of ^{131}I -Tetracycline as an Index of Skeletal Growth

R. G. WOLFANGEL*, S. M. SHAW, and J. E. CHRISTIAN

Abstract ☐ A derivative of tetracycline was tagged with ^{131}I and administered to rats. Whole body retention of the tetracycline was determined by sequential measurements of whole body radioactivity. Statistically significant differences of whole body burdens were found for two age groups of rats (100 g. *versus* 200 g.); the younger animals retaining a greater portion of the administered tetracycline. Subsequent distribution analysis indicated that whole body radioactivity measurements did not precisely assess skeletal burdens of ^{131}I -labeled tetracycline because variable amounts of tetracycline persisted in soft tissue for prolonged intervals after injection, but did provide estimates of skeletal burdens which could be used to recognize differences in skeletal growth rate between groups of young and mature rats. The whole body counting technique may be applicable for the study of metabolic skeletal disorders.

Keyphrases ☐ ^{131}I -Tetracycline—skeletal growth index, whole body measurements ☐ Growth, skeletal—index, radioiodinated tetracycline ☐ Paper chromatography—analysis, identity ☐ UV spectrophotometry—analysis, identity ☐ Scintillation counting, whole body—analysis

Since the initial observations of tetracycline-induced fluorescence of bones by Rall *et al.*, investigators have been examining tetracycline fixation in mineralized tissue (1). The following has been reported concerning the deposition of tetracycline in bones and teeth; deposition occurs after introduction by any route, but is greatest following parenteral administration (2); tetracyclines are actively deposited at all sites of newly mineralizing bone and are relatively permanently fixed in the bone until resorption occurs (3, 4). The quantity of tetracycline deposited in bone is proportional to animal age and the dose administered (5, 6), and the presence of tetracycline in bone or teeth can be readily detected by the appearance of a bright yellow fluorescence under UV irradiation (7, 8).

Tetracycline bone labeling, followed by microscopic measurements of the width, area, or volume of yellow fluorescent zones found in bone sections, is used as an index of skeletal metabolic activity (9–11) such as appositional growth rate, radial rate of osteon closure, and osteon maturation rate. Direct determinations of

the total quantity of tetracycline bound to the skeleton might also provide an index of skeletal metabolic activity; if so, the necessity of skeletal biopsy, sectioning, and tedious fluorescence microscopy currently employed for tetracycline skeletal observations would be alleviated. Thus, ^{131}I -labeled tetracycline was prepared and used to conduct animal studies. Whole body measurements of tetracycline retention, following administration of labeled tetracycline, were investigated for possible value to assess skeletal metabolic activity in young growing rats as compared to older mature rats. The accuracy of whole body counting for the determination of the total quantity of tetracycline bound to the skeleton was established by the direct measurement of labeled tetracycline bound to the entire skeleton of the two age groups of rats, as well as the residual amount of tetracycline remaining in the soft tissue of the animals.

METHODS

Synthesis and Purity—Hlavka *et al.* (12) reported the preparation of 7-iodo-6-demethyl-6-deoxytetracycline (766 tet) by dissolving 6-demethyl-6-deoxytetracycline (66 tet) and *N*-iodosuccinimide (NIS) in concentrated sulfuric acid at 0°. By substitution of ^{131}I for stable iodine, 7-radioiodo-6-demethyl-6-deoxytetracycline (^{131}I -766 tet) was prepared in this laboratory according to Hlavka's directions. The ^{131}I -label was introduced by the preparation of *N*- ^{131}I -iodosuccinimide (N^{131}IS) by modification of the method of Benson *et al.* (13). Aqueous solutions of Na^{131}I (25–75 mc.) were transferred to a test tube containing 2 ml. of carbon tetrachloride, and 1 ml. of NaI carrier (5 mg./ml.) was added. The test tube was fitted with a rubber stopper through which a dropping pipet, filled with concentrated nitric acid, had been inserted. Nitric acid was then added to the water-carbon tetrachloride mixture. The closed tube was left for 18–24 hr., during which time free iodine was formed and dissolved in the organic liquid. The aqueous overlayer was removed with a micropipet allowing the $^{131}\text{I}_2$ in the carbon tetrachloride to remain in the test tube. Stable elemental iodine (1 g.) was placed in an amber 5-dr. vial, the cap lined with Teflon, and 5 ml. of sodium-dried, distilled dioxane added. The solution of carbon tetrachloride, containing $^{131}\text{I}_2$, was transferred to the vial. The test tube was rinsed with 1 ml. additional carbon tetrachloride, and the 1 ml.

rinse added to the reaction vial. Then 1.2 g. of *N*-silver succinimide was added in one portion, the lined cap replaced, and the closed vial agitated continuously for 90 min. The closed vial was immersed in a water bath (50°) for 5 min., removed, and the contents filtered through a sintered-glass filter. The reaction vial and silver iodide precipitate were washed with 2-, 2-, and 1-ml. portions of hot dioxane. The dioxane wash was filtered and added to the filtrate. Carbon tetrachloride (25 ml.) was added to the filtrate, the flask stoppered, covered with aluminum foil, and placed in a freezer for 12–18 hr. The contents of the flask were filtered to obtain $N^{131}IS$ crystals which were washed with 30-, 20-, and 10-ml. portions of carbon tetrachloride. The $N^{131}IS$ crystals were stored in a vacuum desiccator, in the dark, for at least 24 hr. prior to utilization for the preparation of *766. The *766 was prepared with the 66 tet and the $N^{131}IS$ according to the procedures of Hlavka (12).

Analyses of the *766 tet for chemical purity were performed as described by Hlavka *et al.* (12). These analyses included the preparation of spectral absorbance curves and paper chromatographic procedures. Solutions of known concentration (2–15 mcg./ml.) were prepared by dissolving the labeled tetracycline in 0.1 *N* HCl. A Bausch and Lomb Spectronic 505 was used to record a continuous spectral absorbance curve, between the wavelengths of 220 and 370 $m\mu$, for each solution of *766 tet. The absorbance peaks were located and log epsilon values calculated. For the chromatographic procedures, Whatman No. 1 chromatography paper was immersed in a 0.2 *M* phosphate buffer (pH 2) solution and allowed to dry. Labeled tetracycline samples were applied to the buffer-treated chromatography paper as 1–2% solutions (aqueous and/or methanolic). Volumes of 2–25 μ l. of the tetracycline solutions were applied to the paper. The tetracycline-spotted chromatography paper was placed in a standard chromatography jar and developed by the descending movement of *n*-butanol saturated with 0.2 *M* phosphate buffer (pH 2). Developing the paper for 19–20 hr. afforded a solvent movement of approximately 45 cm. The atmosphere of the chromatography jar was saturated with *n*-butanol and water vapor at least 24 hr. before using the jar to develop a chromatogram. Location of the tetracycline on the developed chromatograms was performed by UV light irradiation.

Hlavka *et al.* (12) reported maximum absorbance at 230 and 345 $m\mu$ with log epsilon values of 4.48 and 4.12, respectively, for 766 tet dissolved in 0.1 *N* HCl. UV spectral absorbance curves of the *766 tet prepared in this laboratory showed peaks at 239 and 345 $m\mu$. The log epsilon values calculated for the absorbance peaks of *766 tet were 4.35 and 4.14, respectively. The UV absorbance and log epsilon values were not in exact agreement with the literature. This disagreement is attributed to chemical contamination of the *766 tet with minute quantities of 66 tet. The small amount of chemical contaminant appeared on the developed chromatograms and was identified as 66 tet using R_f values. The degree of chemical contamination was considered insignificant.

To determine the radiochemical purity of the *766, paper chromatographic procedures utilized for the determination of chemical purity were employed. Autoradiography was used to detect the labeled tetracycline. The developed chromatograms were overlaid with No Screen Kodak Medical X-Ray film.² After sufficient exposure time (10^8 d./cm.²), the film was developed in accordance with the recommendations supplied by the Kodak X-ray developer.² The area of the chromatogram bearing the *766 tet (as observed from the autoradiogram) was sectioned. The remaining portion of the chromatogram was considered to contain radiochemical impurities. The sections were counted individually in a 7.6-cm. (3-in.), sodium iodide, thallium-activated well crystal scintillation counting system. Ninety-nine percent of the radioactivity appeared at the R_f of 766 tet.

Whole Body Retention—Two groups of female Sprague-Dawley³ strain albino rats were utilized in this phase of the investigation. The first group of six animals was comprised of young, rapidly growing animals (100 ± 5 g.) and the second group of six rats contained adult rats (200 ± 10 g.). Animals were housed in individual metabolism cages for 24 hr. prior to *766 tet administration and during the remainder of the study. Food and water were allowed *ad libitum*. A dose of 20 mg. of *766 tet (0.25 μ c./mg.) per kilogram of body weight was given to each rat intraperitoneally. Distilled water served as the solvent for the labeled tetracycline.

Figure 1—Whole body retention of labeled tetracycline in rats. Key: ---, 100 g.; and —, 200 g.

Whole body radioactivity counts of each rat were taken using an Armac liquid scintillation counting system.⁴ Just prior to placing the rats in the counter, they were imprisoned in a cylindrical cage which inhibited virtually all motion and allowed for reproducible positioning of the rats within the detector. The initial measurement of whole body radioactivity was made 45–60 min. after the dose of radioiodinated tetracycline was given and was considered as the initial or 100% body burden. Whole body counts were repeated at various time intervals for 480 hr. after drug administration. Subsequent counts were corrected for variation in counter efficiency, background, and radioactive decay to the time of the initial determination. Corrected counts were expressed as a percent of the initial body burden.

During the course of the whole body counting study, urine and feces were collected separately from each rat at 24-hr. intervals. Each intact 24-hr. specimen was counted in the Armac liquid scintillation counting system. The fraction of the administered *766 tet excreted per time interval was calculated in a manner similar to the whole body counts and the data expressed as a percent of the initial body burden.

Distribution—The distribution and retention of *766 tet were determined in young and adult rats at various intervals after intraperitoneal administration of the labeled tetracycline. Sixteen 40-day-old female Sprague-Dawley rats (100 ± 10 g.) were administered a dose of 20 mg. of *766 tet (0.40 μ c./mg.) per kilogram of body weight. Similarly, eighteen 90-day-old female rats (205 ± 10 g.) were each injected with the labeled tetracycline solution. The rats were housed, watered, and fed as in the previous study. Three⁵ animals from each age group were sacrificed 24 hr. after tetracycline injection, and at 72-hr. intervals thereafter, with the final group sacrificed 384 hr. after tetracycline administration. The rats were ether anesthetized and a 1–3-ml. blood sample withdrawn by intracardiac puncture. The rats were then sacrificed by an overdose of ether. Each rat was weighed to the nearest 0.5 g. The following samples were excised for analysis: heart, liver, lung, kidney, spleen, thyroid, humerus, femur, and a 1–3-g. sample of muscle. Each sample, except blood, was rinsed in distilled water and weighed. In most cases, the entire organ was removed and weighed. Each tissue sample was analyzed for tetracycline content by counting in the 7.6-cm. (3-in.), well crystal scintillation counting system. The counting data were expressed as the micrograms of tetracycline in the tissue specimen. Subsequent calculations, using the weight of the tissue specimen and the milligrams of tetracycline initially administered to each rat, were performed to express the data as the percent of

the administered dose of tetracycline retained per gram of tissue or organ, as well as per the entire tissue or organ.

Skeletal Retention—Following the distribution study, six 40-day-old female Sprague-Dawley rats (100 ± 5 g.) and six 90-day-old rats (200 ± 10 g.) received *766 tet in the same manner as described for the distribution study. Three of the rats from each age group were sacrificed at 312 hr. (13 days) and 384 hr. (16 days) after injection of the labeled tetracycline. The entire skeleton was excised from each rat and the total mass of nonskeletal tissue assembled. The skeleton and composited soft tissue from each rat were separately assayed for tetracycline by counting in the Armac liquid scintillation counting system. The quantity of the administered dose of labeled tetracycline retained by the skeletal mass and by the nonskeletal tissue was expressed as a percent of the initial body burden.

Excretion—Examination of excreta obtained from rats dosed with *766 tet was undertaken in order to determine the metabolic fate of the tetracycline. Three 40-day-old female Sprague-Dawley rats (100 ± 10 g.) were injected intraperitoneally with a dose of 20 mg. of *766 tet (2.4 µc./mg.) per kilogram of body weight. Three 90-day-old female rats (200 ± 10 g.) were also given a dose of 20 mg. of *766 tet (2.4 µc./mg.) per kilogram of body weight. A higher specific activity tetracycline was necessary for this phase of the investigation in order to ensure the detection of metabolic products, if any, in the excreta. Following labeled-tetracycline administration, the rats were housed in individual metabolism cages and the excreta collected 48 hr. after injection of the tetracycline. Radioactive products appearing in the 48 hr. excreta were qualitatively analyzed using chromatographic techniques. Thick-layer chromatograms were prepared with an aqueous slurry of MN-Cellulose powder-300.⁸ The cellulose-coated plates were air dried and impregnated with a mixture of 0.2 M phosphate buffer (pH 2.0) and glycerol (19:1). The plates were allowed to air dry before spotting. Untreated urine was applied to the thick-layer chromatograms in amounts ranging from 2.5 to 30 µl. per application. Following thorough homogenization of feces, portions of the fecal homogenates were applied to the thick-layer chromatograms. Each plate was also spotted with a sample of the *766 tet used to dose the rats. After

solvent development,⁷ the chromatograms were autoradiographed for 4 weeks.

RESULTS AND DISCUSSION

Whole body retention of tetracycline for the two different age groups of rats is presented in Fig. 1. Whole body retention of tetracycline was similar during the first 4 days of the experiment, but then the body burden of tetracycline in the younger (100 g.) rats became 1% greater than the mature (200 g.) animals. A Student's *t* difference of means test showed the body burden of tetracycline to be statistically greater (*p* = 0.005) in the younger rats from Day 8 until termination of the study at Day 20. The curves shown in Fig. 1 were fitted by a standard exponential analysis in the sense of least squares. The intercepts and slopes are reported for the long-lived exponentials. The young rats intercept is 1.8% greater and has a half-time 162 hr. faster than the mature rats. The elevated whole body tetracycline retention shown by the young rats was considered to be the result of increased tetracycline fixation to the faster growing skeletal tissue of the younger rats, but this remained to be demonstrated from the distribution and skeletal studies.

The results of the distribution study, expressed in terms of the percent of the administered dose of tetracycline retained by the entire organ or tissue, are presented in Tables I and II and in Fig. 2. In Fig. 2 the curves were fitted by a standard exponential analysis in the sense of least squares. The percent of the administered dose of tetracycline present in the entire skeleton was calculated according to the method of Myers and Jaffe (6). They averaged the micrograms of tetracycline retained per gram of humerus bone and femur bone, then multiplied the value by the total skeletal weight. The values of total skeletal weight were obtained from the body weight of the rats by using data from a quantitative study of skeletal growth in the albino rat performed by Donaldson (14). As may be observed from Tables I and II, the amount of tetracycline decreased to undetectable levels by Day 7 or 10 for the spleen, lung, and heart. The skeleton, liver, thyroid, and kidney persistently contained tetra-

cycline until the termination of the study. For both age groups, bone contained greater amounts of the tetracycline than any of the other tissues studied. After Day 10, the quantity of tetracycline in the skeleton of either age group exceeded the level of all other organs by a factor of 10 or greater.

The intercepts and biological half-times of the whole body retention curves (Fig. 1) and organ distribution curves (Fig. 2) have been summarized and compared in Table III. Both the intercepts, as percent of the dose, and half-times, in hours, are listed for the long-lived exponentials. Differences have been computed by subtracting the value of the mature rats from that of the young rats. Whole body retention curves show an intercept difference of 1.80%. Intercepts of the liver, kidney, and thyroid are very similar for young and adult rats; however, the skeleton shows an intercept difference of 1.92% which is very comparable to the intercept difference seen in whole body retention. Examination of the biological half-time data shows that the long-term whole body retention half-time of the younger rats was 162 hr. shorter than that observed for the older animals. Age differences in the biological half-times of the liver and kidney were not great. Thyroids show a difference in biological half-times between the age groups, but the skeleton, by far, displayed the greatest difference (the younger group 319 hr. faster). Although the intercepts and half-times obtained for whole body retention would not seem to be precise measurements of the tetracycline bone compartment, there is a high correlation between whole body retention intercepts and the skeletal intercepts obtained from the distribution study. This correlation becomes less evident when biological half-times are examined in the same manner.

In addition to the distribution analyses previously described, the levels of tetracycline in entire skeletons were investigated in that time domain where the whole body burdens were statistically greater in the young rats as compared to the mature rats. At Day 13 and Day 16 postinjection, complete skeletons of three females per age group were separated from their respective soft tissue. The skeletons and soft tissues were counted separately for tetracycline content. In Table IV, skeletal and soft tissue retention as a

Table IV—Percent of the Initial Body Burden of Tetracycline Retained by the Skeleton and Nonskeletal Tissue

384	0.901 ± 0.351	0.634 ± 0.153	1.207

^a Mean and standard deviation of three rats per age group. ^b Statistic calculated from the experimental data according to a Student's *t* difference of means test. Any *t*_{obs.} exceeding 4.60 provides statistical proof (4 degrees of freedom, 99.5 percentile point) of greater retention in the younger animals.

percent of the initial body burden is shown for the young and mature rats both at 312 hr. (Day 13) and 384 hr. (Day 16). The younger rats retained more tetracycline in both hard and soft tissue compartments at each time interval. A difference of means test indicated that the skeleton of young rats contained significantly greater amounts of tetracycline than the skeleton of older rats. Skeletal values were also noted to be highly consistent as evidenced by the low standard deviations. Regarding soft tissue retention of tetracycline, considerable variations were present among the members of each group resulting in standard deviations much larger than those obtained for skeletal retention. A difference of means test did not indicate that the observed differences in soft tissue retention between age groups were statistically significant.

The results of this phase of the study indicate that the statistically greater whole body retention of tetracycline previously shown by the young group of rats resulted from localization of increased amounts of tetracycline in the skeletons of the young. This supports the hypothesis that increased skeletal mineralization in young animals can be determined using whole body measurements of radioiodinated tetracycline, but points out that the validity of the test remains dependent upon obtaining either a complete or uniform clearance of tetracycline from the soft tissue compartment prior to making whole body measurements.

Figure 3 graphically represents the percent of the administered tetracycline accumulated in the urine and the feces of rats which were used in the whole body retention study. No significant difference in excretion of the tetracycline was noted between age groups. The data show clearly the importance of fecal excretion as the route of tetracycline elimination.

As described in the methods section, examination of excreta obtained from both age groups was undertaken in order to deter-

mine the metabolic fate of the labeled tetracycline. For both age groups the autoradiograms prepared from chromatograms of urine disclosed the presence of a single labeled compound with an *R_f* value almost identical with that of the *766 tet utilized in the various studies. In feces, the autoradiograms indicated the presence of minute amounts of ¹³¹I-activity other than that identical to the *766 tet standard. Even though the film had been exposed to the chromatogram for 4 weeks the image produced on the film by radioactivity other than that associated with the *766 tet was barely detectable. The *766 tet utilized in these studies was recoverable in the excreta of the animals in essentially unaltered form. This strongly signifies that ¹³¹I-activity remaining in the animal tissue is associated with tetracycline, but does not provide unequivocal proof of this assumption. It would appear that the *766 tet utilized in the various studies was essentially unmetabolized.

Aware that iodination of tetracycline might result in a compound that was not biologically representative of the tetracycline family, attention was devoted to assembling *in vivo* parameters of retention, excretion, and distribution of the iodinated tetracycline. In Table V, biological observations for the iodinated tetracycline are compared to results obtained by other investigators using several commercially available tetracycline antibiotics. There is good correlation between the radioiodinated tetracycline prepared in this laboratory and the other tetracyclines for whole body retention, skeleton and bone uptake, and metabolism. Examination of the percent of the dose eliminated in the feces shows that the radioiodinated tetracycline is excreted in the feces in far greater quantities than the other tetracyclines. Since in most cases the radioiodinated tetracycline compared favorably to the other tetracyclines, the radioiodinated tetracycline is considered to be representative of the tetracycline family of compounds.

SUMMARY AND CONCLUSIONS

Investigators have reported that tetracyclines are rapidly excreted within 7 days of administration and that the majority of tetracycline retained after 7 days remains bound to the skeleton (15, 16). Also, the quantity of tetracycline fixed and retained by the skeleton of animals is proportional to the age of the animal and/or skeletal turnover rate (2, 6, 17). Based upon these reports, an attempt was made to assess skeletal burdens of tetracycline in rats by measurements of whole body radioactivity following administration of radioiodinated tetracycline.

When the whole body retention of labeled tetracycline was studied in young and mature rats, statistically greater body burdens were observed in the younger group. Distribution experiments showed that the higher body burdens of the younger animals were related to their increased skeletal uptake of tetracycline. In subsequent experiments, skeletons of several test rats from each age group were surgically cleansed of soft tissue. Tetracycline skeletal burdens were determined and found to be very uniform within each group, and statistically higher levels of skeletal tetracycline were found in the younger animals when compared to the older. Tetracycline levels within soft tissue were obtained for the same animals. While

skeletal levels were very consistent within each experimental group, the soft tissue values showed relatively large variations among members of each group. The younger rats retained larger amounts of tetracycline in soft tissues, but differences in soft tissue values between age groups could not be statistically verified. The data from the various experiments indicate that age differences in whole body retention of labeled tetracycline did reflect age differences of skeletal tetracycline fixation; however, persistent localization of tetracycline in soft tissue compartments, and the animal-to-animal variation of soft tissue tetracycline residue, reduced the accuracy of predicting skeletal levels by whole body measurements. The proposed technique may be of extreme value in the study of skeletal metabolic disorders provided a rapid, complete, or uniform clearance of tetracycline from soft tissue compartments could be obtained.

In conclusion, the results of this investigation indicate:

1. The labeled tetracycline synthesized in this laboratory was representative of the tetracycline antibiotics.
2. Whole body retention of iodinated tetracycline in young growing rats was greater than in mature rats, and resulted from enhanced skeletal deposition of tetracycline in the young rats as contrasted to the older animals.
3. Residual and variable amounts of tetracycline persisted in soft tissues for prolonged intervals after injection, but the skeleton showed the greatest uptake and consistent binding of the drug.
4. Skeletal fixation of tetracycline can be estimated by whole body measurements of radioiodinated tetracycline, but the accuracy of the estimates obtained is dependent upon a uniform soft tissue clearance and this has been shown to be variable. The technique may be of value for assessment of skeletal metabolic activity, especially when comparing normal to pathological states, providing a uniform clearance of tetracycline from soft tissues can be achieved.

Effect of Probenecid on Renal Clearance of Riboflavin in Man

WILLIAM J. JUSKO, GERHARD LEVY*, SUMNER J. YAFFE, and RAFAEL GORODISCHER

Abstract □ The renal clearance of riboflavin was determined in three human subjects at various serum concentrations of the vitamin with and without prior administration of probenecid. Renal clearances of riboflavin exceeded (up to three times) the endogenous creatinine clearances, which indicates that riboflavin excretion involves renal tubular secretion. The clearance of riboflavin was less at low than at high serum concentrations of the vitamin, characteristic of a saturable tubular reabsorption process. Probenecid decreased the renal clearance of riboflavin, and this effect was directly related to the serum concentration of the inhibitor. The serum protein binding of the vitamin was essentially constant (60%) over the concentration range encountered and was unaffected by the presence of probenecid.

Keyphrases □ Riboflavin, renal clearance, man—probenecid effect
□ Probenecid, effects—riboflavin, renal clearance, plasma protein binding
□ Spectrophotometry—analysis

A pharmacokinetic analysis of literature data by Levy and Jusko (1) yielded renal clearance values for riboflavin in a human subject which were appreciably higher than the normal glomerular filtration rate. Subsequently, it was found that probenecid, an inhibitor of certain specialized renal transport processes (2), decreased the initial rates of urinary excretion of oral and parenteral doses of the vitamin in human subjects (3). These studies suggested that the renal excretion of riboflavin in man involves tubular secretion. The existence of such a mechanism for riboflavin has already been demonstrated in the chicken by Rennick (4) who also noted an inhibitory effect of probenecid on this process.

The purposes of the study to be described were to determine directly the renal clearance of riboflavin in man and to assess quantitatively the effect of probenecid on this process as well as on the plasma protein binding of the vitamin.

EXPERIMENTAL

The studies were carried out in three healthy human subjects: an adult male (Subject J), age 26 years, and two female children (Sub-

jects A and C), ages 8 and 11 years, respectively. The adult subject received a single intravenous dose of riboflavin-5'-phosphate (FMN)¹ equivalent to about 30 mg. of riboflavin (FR) with and without 1 g. probenecid² given orally in suspension 1 hr. prior to FMN injection. Urine was collected at appropriate intervals for a total of 48 hr. Blood samples were drawn from the antecubital vein at -0.5, 0.25, 0.75, 1.25, 2.25, 3.25, 4.5, 6.5, 8.5, 13.0, and 25.0 hr. relative to the time of FMN injection. These times were midpoints of urine collection periods.

The two younger subjects received an initial intramuscular dose of FMN³ equivalent to 16 mg. FR followed by three hourly oral doses of 6 mg. FR as FMN in solution. Urine was collected at hourly intervals and blood was drawn from the antecubital vein at the midpoints of the three urine-collection periods. A 0.5-g. dose of probenecid in tablet form was administered in crossover fashion to the two children 1 hr. prior to the initial dose of FMN. There was an interval of 7 days or more between the control and probenecid studies.

Protein-Binding Determinations—The ultrafiltration technique described in an earlier publication (5) was used to determine the extent of protein binding of the flavins and probenecid in the serum samples.

FMN Stability Study—A series of samples, each containing 1 ml. of FMN in pH 7.4 isotonic Sorensen's buffer and 1 ml. of freshly drawn whole blood from Subject J, were incubated at 37° in the dark. The concentrations of FMN and FR in the samples were determined as a function of time. Control solutions, without blood, were similarly analyzed.

Analytical Method—Riboflavin and FMN were determined fluorometrically by methods previously described (5, 6). Endogenous creatinine levels in urine and serum were determined colorimetrically by the alkaline picrate method (7). Probenecid in serum was assayed by the spectrophotometric method of Dayton *et al.* (8). Initial serum samples were assayed for albumin content as described previously (5).

Data for flavins and probenecid were corrected for blank readings of urine and serum samples obtained prior to administration of the compounds to the test subjects. There was no interference in the assay of any of the compounds due to the presence of the others.

RESULTS

Renal Clearances of Riboflavin and Effect of Probenecid—Riboflavin clearances in Subjects A and C (Table I) were determined

^a Serum samples were obtained at 1.5, 2.5, and 3.5 hr. after initial riboflavin administration and data from each study are listed in that order.

after parenteral administration of the vitamin, with sustaining oral doses given to prevent the usual rapid fall in serum flavin levels. The renal clearances of riboflavin and endogenous creatinine were calculated in the usual way by dividing the urinary excretion rate by the midtime serum concentration. The endogenous creatinine clearance was determined as a measure of glomerular filtration rate (9). For purposes of intersubject comparison, the renal clearance values for the two children were corrected to standard body size of 1.73 m.² by the method of Dubois and Dubois (10).

The riboflavin-creatinine clearance ratios for Subjects A and C ranged from 2.6 to 3.1 in the control periods (Table I). This shows that the vitamin is secreted in the renal tubules. Probenecid caused a decrease in riboflavin clearance and clearance ratios but had no significant effect on the clearance of creatinine. The 0.5-g. dose of probenecid was apparently better absorbed in Subject C than in Subject A as seen by the time course of probenecid serum concentrations in the two children. The relationship between the serum probenecid concentration and riboflavin clearance ratio in the two subjects is shown in Fig. 1.

The experiments in Subject J were designed to determine the renal clearance of riboflavin and the effect of probenecid over a wide range of rapidly changing serum concentrations of the vitamin. The serum concentrations of total riboflavin (FR and FMN) and of FMN alone as a function of time after rapid intravenous injection of FMN with and without prior administration of probenecid are shown in Fig. 2. The corresponding urinary excretion rates as a function of time are shown in Fig. 3. Total riboflavin concentrations in the serum were appreciably higher (Fig. 2) after administration of probenecid while the urinary excretion rates were similar (Fig. 3). Seventy-six percent of the dose was recovered as riboflavin and 14% as FMN in the control experiment. During probenecid administration, 71% was recovered as riboflavin and there was no measurable excretion of FMN.

Figure 1—Effect of probenecid on renal clearances of riboflavin (total flavin) in Subjects A (●) and C (○). The clearance ratio, flavin-creatinine, is plotted as a function of the log serum probenecid concentration, and a least-squares regression line was fitted to the data.

Figure 2—Serum concentrations of flavins as a function of time after rapid i.v. injection of about 30 mg. FR as FMN to Subject J. Total flavin (solid symbols) and FMN (open symbols) concentrations were determined in a control experiment (circles) and following oral administration of 1 g. probenecid (squares). Total flavin curves were obtained by a computer nonlinear least-squares fit to the data.

The curves for total riboflavin concentrations in the serum (Fig. 2) and for urinary excretion rates (Fig. 3) were obtained by nonlinear least-squares computer fit to the experimental data. Preliminary graphical analysis by the method of residuals (11) indicated that these data declined in a triexponential manner. Because the serum and excretion values ranged over more than two orders of magnitude, they were converted to their respective logarithmic values to reduce bias. The "NLIN" digital computer program of Marquardt (12) was then used to fit a triexponential curve of the type:

$$F = A \cdot e^{-\alpha t} + B \cdot e^{-\beta t} + C \cdot e^{-\gamma t} \quad (\text{Eq. 1})$$

to the experimental data where F represents either total riboflavin serum concentrations or urinary excretion rates, t is time, and the remaining symbols are constants. The values of the six constants for each of the four sets of data are listed in Table II. The apparent volume of the central compartment, V_c , was calculated from the serum data using the equation:

$$V_c = \text{dose}/(A + B + C) \quad (\text{Eq. 2})$$

where the denominator represents the computer derived zero-time serum concentration of the flavins (C_p^0). This apparent volume

Figure 3—Urinary excretion rate of flavins as a function of time after rapid i.v. injection of about 30 mg. FR as FMN to Subject J. Lines and symbols are defined as in Fig. 2. No FMN was found in the urine after administration of probenecid.

was 14.0 l. in the control experiment and only 8.3 l. in the presence of probenecid.

FMN concentrations in the serum and urine could be determined only during the early times after injection of the vitamin. Available assay methods are inadequate (5) to detect FMN at low concentrations of the vitamin and in the presence of a large excess of FR. It was thus necessary to determine renal clearance in terms of total riboflavin rather than for FMN and FR separately. However, the clearances of FR and FMN determined separately during the early times in the control experiment were quite similar.

The renal clearances of total riboflavin in the presence and absence of probenecid are plotted in Fig. 4 as a function of the total riboflavin concentration in the serum. The points are experimental values and the curves are the results of clearance calculations based on urinary excretion rate and serum concentration values calculated from the parameters of Eq. 1 listed in Table II. The glomerular filtration rate of Subject J averaged 130 ± 10 ml./min. in the presence and 120 ± 11 ml./min. in the absence of probenecid as measured by the endogenous creatinine clearances. As in Subjects A and C, the riboflavin and creatinine clearance values for Subject J indicate that riboflavin excretion involves tubular secretion. Probenecid has a pronounced inhibitory effect on riboflavin excretion as shown by the appreciable decrease in renal clearance when probenecid was given.

The continuous decline in renal clearance of riboflavin during the course of decreasing serum levels of the vitamin is characteristic of a compound which undergoes saturable tubular reabsorption (9). This mechanism occurs with at least three other water-soluble vitamins: thiamine (13), pantothenic acid (14), and ascorbic acid (9). A multiple-compartment pharmacokinetic model embodying saturable renal tubular reabsorption has been developed and applied to riboflavin clearance data from man and dog (15). The relationship which describes the observed (net) renal clearance (Cl_T) of compounds which undergo apparent first-order excretion (clearance) from serum to urine (Cl_f) and saturable tubular reabsorption is

$$Cl_T = Cl_f - \frac{T_m C_u}{C_p(K_m + C_u)} \quad (\text{Eq. 3})$$

where C_p and C_u are the serum and urine concentrations of the drug, T_m is the tubular reabsorption transport maximum, and K_m is the Michaelis-Menten constant for the saturable tubular reabsorption process (15). Graphical and computer analysis of the experimental renal clearance data obtained in the absence of probenecid has yielded values of 420 ml./min. for Cl_f , 33.3 mcg./min. for T_m , and 16.3 mcg./ml. for K_m (15). It was not possible to determine these parameters when probenecid was administered because the inhibitory effect of this drug was not constant during the experiment.

Figure 4—Renal clearance of total riboflavin plotted as a function of the serum riboflavin concentration in a control experiment (solid symbols) and after oral administration of 1 g. probenecid (open symbols). Curves represent clearances calculated from the least-squares fit of the serum and urinary excretion data. Simultaneously determined endogenous creatinine clearances averaged 124 ± 12 ml./min. and were independent of the serum riboflavin and probenecid concentrations.

Probenecid serum concentrations were determined for Subject J and are shown as a function of time in Fig. 5. These data were used in conjunction with the riboflavin clearance values to construct a drug concentration-response plot which is depicted in Fig. 6. Because of the concentration dependence of riboflavin clearance and the wide concentration range of the data, it was necessary to express the clearances during probenecid administration as a percent of the riboflavin clearance at similar serum concentrations of the vitamin in the control experiment. It should be noted that the pharmacologic effect-serum concentration relationship presented in Fig. 6 (where both riboflavin and probenecid serum concentrations varied markedly) is of a type different from the effect-concentration relationship depicted in Fig. 1 (where the riboflavin concentration was relatively constant). It is of interest, however, that the maximum inhibition of riboflavin clearance⁴ in Subject J occurred at a probenecid serum concentration of about 8 mg. % and that the same maximum inhibitory concentration is obtained upon extrapolating the data from Subjects A and C in Fig. 1 to a clearance ratio of unity. Renal clearance studies in dogs (16) also showed that a similar serum concentration of probenecid (7 mg. %) produced maximum inhibition of renal clearance of riboflavin and PAH.

Figure 5—Concentrations of probenecid in the serum as a function of time after oral administration of 1 g. in aqueous suspension to Subject J. Decline in serum concentration of probenecid represents a half-life of 5 hr.

⁴ This refers to maximum inhibition in terms of actual clearance values (ml./min.) rather than in terms of relative values (percent of control clearance).

Figure 6—Effect of probenecid on renal clearance of flavin in Subject J. The percent of normal clearance was calculated (see text) from the data of Fig. 4 and is plotted as a function of the log serum probenecid concentration.

Protein-Binding Results—The serum samples which were obtained in each of the experiments in Subjects A and C were pooled to obtain adequate volume for a determination of the extent of protein binding of the flavins. In Subject A, the flavins were 64 and 57% bound in the absence and presence of probenecid, respectively. The corresponding values for Subject C were 52 and 54%. These data indicate that probenecid had little or no displacing effect on the protein binding of the flavins. The data show also that if the renal clearance values of riboflavin were corrected for protein binding, the net secretion of the flavins would appear to be even more pronounced than indicated by the data in Table I.

In Subject J, individual serum samples were used to determine the extent of protein binding over an appreciable range of serum concentrations of the vitamin. The results of these determinations are summarized in Table III. Over a 10- to 20-fold range in serum riboflavin concentrations, the fraction of total riboflavin bound remained essentially constant and was similar in the control and probenecid experiments. The albumin concentration of the serum was 4.6 g./100 ml., and it was possible to calculate the theoretical degree of binding of total riboflavin using known values (5) for the albumin-FR and albumin-FMN association constants (1.3×10^3 and 3.2×10^4 liter/mole, respectively, at 30°) and the assayed serum concentrations of FR and FMN (Table 3). The basis for such calculations is given in an earlier report on the plasma protein binding of riboflavin and FMN (5). These calculations show that no change in the degree of protein binding of total riboflavin is to be expected over the concentration range of riboflavin encountered in these experiments. Despite the existence of the two forms of the vitamin in the serum, the extent of binding of total riboflavin remained constant due to the relatively constant concentration ratio of FR and FMN in the serum.

The serum protein binding of probenecid was also determined in the serum samples obtained from Subject J. The extent of protein binding of probenecid remained essentially constant during the course of the experiment and the change in serum concentrations of

Figure 7—Rate of dephosphorylation of riboflavin-5'-phosphate during incubation of 72 mcg. % FMN in fresh whole blood (●) and in pH 7.4 Sorensen's buffer (○). Total riboflavin concentration (FR + FMN) remained constant for the duration of the experiment.

riboflavin did not appear to affect the protein binding of probenecid. Over the serum concentration range of 2 to 8 mg./100 ml., probenecid was $90 \pm 4\%$ protein bound, which is in excellent agreement with the data reported by Dayton *et al.* (8).

FMN Dephosphorylation—The data shown in Figs. 2 and 3 indicate that intravenously administered FMN is rapidly converted to riboflavin until a FR-FMN concentration ratio of about 3:1 is attained. This appears to reflect an equilibrium between the rate of dephosphorylation and the rate of phosphorylation of the vitamin. A similar phenomenon has been observed in the rat by Christensen (17). Phosphatase (18) and flavokinase (19) enzymes in the liver may account for these processes, but enzymes associated with erythrocytes also contribute to the very rapid loss of serum FMN and appearance of FR. Incubation of FMN with fresh whole blood from Subject J and with buffer showed that FMN was rapidly converted to FR in whole blood (Fig. 7), but that there was no dephosphorylation of FMN in the control buffer solution. The concentration of total riboflavin in the blood samples remained constant for the duration of the experiment. Previous experiments have shown (5) that incubation of FMN with human plasma produced no change in the relative protein binding of the vitamin which is indirect evidence that FMN is not dephosphorylated in blood plasma.

DISCUSSION

The results of the present study confirm earlier indications (1, 3) that the renal excretion of riboflavin in man involves tubular secretion. Renal clearances of the vitamin were found to exceed markedly the glomerular filtration rate in three human subjects and it was shown that probenecid has a pronounced inhibitory effect on riboflavin excretion. In Subjects A and C, where the riboflavin serum levels were maintained relatively constant, the effect of probenecid could be characterized by a typical dose-response relationship (Fig. 1). In Subject J, the dose-response relationship (Fig. 6) is complicated by the serum concentration dependence of riboflavin clearances resulting from the saturable tubular reabsorption process. Therefore, the clearances during probenecid administration had to be expressed as a percent of the clearance value obtained in the control experiment at the same riboflavin concentration in the serum.

The riboflavin clearances in Fig. 4 have a constant value of about 100 ml./min. during the time when probenecid serum levels declined from 7.7 to 1.8 mg. % and riboflavin serum concentration ranged from 0.2 to 0.02 mcg./ml. This suggests that probenecid inhibits both the tubular secretion and the specialized reabsorption of the vitamin. With inhibition of both active processes, the clearance of flavin would be expected to remain constant at less than the glomerular filtration rate (124 ml./min.) because the vitamin is bound to some extent to serum proteins. In view of the difference in the probenecid serum concentration-effect relationship during increasing and decreasing probenecid serum levels, respectively, it appears that the time course of probenecid concentration in the serum does not adequately reflect the time course of probenecid concentration at its site of action, particularly in the elimination phase of probenecid. The fact that maximum inhibition of riboflavin clearance was observed while probenecid concentration in the

serum declined from 7.7 to 1.8 mg. % suggests that probenecid is retained at its site of action considerably longer than in the serum.

Probenecid had no serum protein-displacing effect on riboflavin and FMN under the experimental conditions. The protein-binding determinations were also done to determine whether the renal clearance of flavin could change as a result of saturation of protein-binding sites at high serum concentrations of riboflavin. This might result in a greater fraction of unbound riboflavin with concomitant increase in renal clearances at high serum riboflavin levels. The actual measurements and theoretically calculated protein-binding data (Table III) showed that the extent of protein binding of total riboflavin is quite constant over the concentration range used in these studies. The protein-binding data do, however, indicate that correction of the renal clearance values for the extent of riboflavin binding would result in even higher clearance values than shown in Table I and Fig. 4 for the three subjects.

The data in Fig. 2 and Table I show that serum concentrations of riboflavin were substantially higher during probenecid administration than during control experiments. Pharmacokinetic analysis of these data indicates that the apparent volume of the central compartment for the vitamin decreased from 14.0 to 8.3 l. when probenecid was administered. This may be a real effect of probenecid on the distribution of riboflavin or it may reflect the limitations of presently available pharmacokinetic techniques in that an inhibition of renal excretion may modify the apparent distribution constants of the pharmacokinetic model. Studies are now in progress to determine the effect, if any, of probenecid on the distribution of riboflavin in anephric subjects (20). It should be possible in this way to determine if probenecid does in fact modify pharmacokinetic parameters other than those reflecting the renal excretion of riboflavin.

In order to examine the mechanism and kinetics of the renal excretion of riboflavin and the nature of the effect of probenecid on these processes in more detail than is feasible in man, additional studies have been carried out in the dog. The results of these studies, which will be reported in other communications (15, 16), demonstrate that riboflavin excretion in the dog also involves both tubular secretion and saturable tubular reabsorption. After attainment of constant serum levels of riboflavin and PAH, a typical log-linear concentration-response relationship was found for the inhibition of renal clearance of these compounds by probenecid. Interestingly, the maximum inhibitory effect of probenecid on both riboflavin and PAH renal clearance in these dogs was reached at about 7 mg. % serum probenecid concentration, similar to the maximum effective concentration found in the subjects of the present study.

Probenecid inhibits the renal excretion of riboflavin in species other than man and dog. Rennick (4) has demonstrated inhibition of tubular secretion of riboflavin by probenecid in the chicken. Markkanen *et al.* (21) have shown that probenecid decreases the basal excretion of riboflavin in man and rabbits whose riboflavin intake was limited to that derived from the normal diet.

There is evidence (16, 22) that the renal transport mechanism for riboflavin may involve a phosphorylation-dephosphorylation process. Probenecid, besides decreasing the renal clearance of various compounds by competitive inhibition, also inhibits directly those enzymes which require a source of high-energy phosphate bond energy (23). This may be the mechanism of the effect of probenecid on the renal clearance of riboflavin, since no FMN was found in the urine when probenecid was administered in the present study. It is of interest that a similar phosphorylation-dephosphorylation mechanism may be responsible for the specialized intestinal ab-

sorption of riboflavin (24) which also appears to be inhibited by probenecid (3).

Influence of Dimethyl Sulfoxide on the Hemolytic Activity of Antimicrobial Preservatives I

HOWARD C. ANSEL and GARY E. CABRE*

Abstract □ The influence of dimethyl sulfoxide (DMSO) on the hemolytic activity of various chemical types of antimicrobial preservatives has been investigated *in vitro*, using rabbit erythrocytes. Irrespective of the chemical type of preservative, DMSO causes a depression in the hemolytic response of the erythrocytes to the preservative agents. This depression, which is greatest when the DMSO concentration is between 10 and 20%, is dependent upon preservative concentration and time. The degree of the hemolytic depression caused by the presence of DMSO is decreased with an increase in the concentration of the preservative agent or with an increase in the time of exposure. It was concluded that DMSO affects the rate of preservative-induced hemolysis, probably due to a cellular mechanism rather than to an extracellular preservative-DMSO chemical interaction.

Keyphrases □ Antimicrobial preservatives—hemolytic activity □ Dimethyl sulfoxide effect—hemolytic activity, antimicrobial preservatives □ Erythrocyte protection, hemolysis—dimethyl sulfoxide □ UV spectrophotometry—analysis

In a previous communication (1), it was reported that dimethyl sulfoxide (DMSO) in concentrations up to about 20% increasingly depressed the hemolytic response of rabbit erythrocytes *in vitro* to phenol. At greater DMSO concentrations, hemolysis was increased from its depressed level with an increase in the concentration of DMSO, presumably due to the commencement of the hemolytic effects of the DMSO itself.

The present study is an expansion of the previous work, undertaken to ascertain if the curious hemolytic profile obtained for combinations of DMSO and phenol is peculiar to that pair of agents or whether a similar alteration in the hemolytic response of erythrocytes to other chemical types of antimicrobial preservatives occurs in the presence of DMSO. This information would indicate the specificity or lack of specificity of the action of DMSO toward phenol-induced hemolysis and would help set the direction of subsequent studies aimed at the mechanism of the action, since the data obtained would suggest either a cellular-based, general action of DMSO or a specific extracellular drug-drug interaction.

The group of commonly employed antimicrobial preservatives selected for this study includes members representing the various chemical classes of preservatives and for which the individual hemolytic activities could be readily characterized and quantitated (2).

EXPERIMENTAL

Materials—The dimethyl sulfoxide and the antimicrobial preservatives employed in this investigation were reagent grade and were obtained commercially.

Blood Samples—Rabbit blood, obtained by cardiac puncture and defibrinated in the manner previously described (3), was used throughout this investigation. Each blood sample was collected immediately prior to its use and was verified for osmotic normalcy during the course of each experiment (2).

Figure 1—Hemolytic activities of various preservative agents in 0.6% NaCl. Key: A, benzalkonium chloride; B, phenylmercuric nitrate; C, thimerosal; D, chlorhexidine diacetate; E, p-chlorophenol; F, chlorobutanol; G, m-cresol; H, phenylethyl alcohol; I, phenol; and J, benzyl alcohol.

Quantitative Determination of Percent Hemolysis—The colorimetric method employed for the determination of the degree of hemolysis occurring in each test solution has recently been described (2). In brief, it involved the addition of 0.05 ml. of defibrinated blood to duplicate pairs of colorimeter tubes, each containing 5 ml. of test solution. The test mixtures were incubated in a water bath for 45 min. (except where noted) at 37° after which the unhemolyzed cells were settled by centrifugation and the absorbance readings of the hemolysate determined with a Klett-Summerson photoelectric colorimeter. Each absorbance reading was compared with a total hemolysis reading obtained by laking red cells in distilled water. The degree of hemolysis occurring in each test solution was calculated as a percent of total hemolysis. The data reported represent the average of a minimum of two, but usually four, like experiments. During and after the incubation period, each test mixture was macroscopically observed for color changes, precipitation, and other signs of denaturation.

Experimental Solutions—Aqueous solutions were employed throughout the investigation. In determining the hemolytic activity of each of the test solutions, 0.6% sodium chloride was added as an extracellular agent to protect the erythrocytes from simple osmotic hemolysis (1). Thus, any hemolysis occurring in the test solutions could be attributed to the activity of the antimicrobial preservative and/or DMSO. Appropriate control solutions were processed concurrently with the experimental solutions throughout the investigation (1, 2).

In order to assess the influence of DMSO on the hemolytic activity of the various antimicrobial preservatives, it was initially desirable to use concentration levels of the preservatives in the test solutions which would normally exert an intermediate (approximately 50%) degree of hemolysis in the absence of DMSO. Once the upward or downward influence of DMSO on hemolysis was established, the level of antimicrobial agent in the test solution was adjusted accordingly to permit the collection of the widest range of data.

Kinetic Studies—The general experimental design of the research series is such that the degree of hemolysis is determined after a constant 45-min. incubation period. In the current project the hemolytic activities of certain representative test solutions were also determined at incubation intervals of from 5 to 20 min., during periods up to 120 min.

Spectral Studies—Three preservatives which are diverse in chemical structure, benzalkonium chloride, chlorhexidine diacetate, and m-cresol, were subjected to spectral examination

Table I—Molar Concentrations of Preservatives Causing 10%, 50%, and 100% Hemolysis of Rabbit Erythrocytes *In Vitro* in the Presence of 0.6% Sodium Chloride

alone and in combination with DMSO in order to detect evidence of chemical interaction. Such interaction could account for the decrease in hemolytic activity by the preservatives upon the addition of DMSO.

A Perkin-Elmer 212 and a Beckman DU spectrophotometer were employed in this study, and the peak absorbance for each preservative was determined at 282, 256, and 272 mμ, respectively, for benzalkonium chloride, chlorhexidine diacetate, and *m*-cresol. Dimethyl sulfoxide exhibited no absorbance above 250 mμ and thus in combination with the preservatives was noninterfering with the determinations of preservative concentrations. Reference cells were appropriately prepared for each experiment.

RESULTS AND DISCUSSION

Hemolytic Activity of the Antimicrobial Preservatives—The hemolytic activities of the antimicrobial preservatives employed in this study are depicted in Fig. 1 and summarized in Table I. The data were collected for solutions of preservatives in 0.6% sodium chloride and compare well with the hemolytic data obtained previously for certain of the preservatives in 0.9% sodium chloride (2). By reducing the level of sodium chloride in the present study, dissolution of the various preservative agents was enhanced and yet the tonicity of the solution was maintained at a level sufficient to protect the erythrocytes from simple osmotic hemolysis.

The individual hemolysis curves for the preservatives not only indicate the relative hemolytic potency of these agents, but they also provided the means by which the appropriate (intermediate or near-totally hemolytic) concentrations of the preservatives were selected for study in combination with DMSO to determine the influence of the latter agent. Thus, for each preservative, the strength which caused an intermediate degree of hemolysis (approximately 50%) was combined in initial experiments with various amounts of DMSO to determine whether the latter agent promoted a decrease or an

Figure 2—Influence of DMSO on the hemolytic activity of *m*-cresol and *p*-chlorophenol in the presence of 0.6% NaCl. Key: ●, 1.8×10^{-2} M *m*-cresol; and ○, 8.0×10^{-3} M *p*-chlorophenol.

Figure 3—Influence of DMSO on the hemolytic activity of phenylethyl alcohol and benzyl alcohol in the presence of 0.6% NaCl. Key: ●, 5.0×10^{-2} M phenylethyl alcohol; and ○, 7.0×10^{-2} M benzyl alcohol.

increase in the degree of hemolysis compared to the preservative-saline control solution. It was found, in each instance, that the presence of increasing amounts of DMSO to approximately 10–20% caused a progressive decrease in the degree of hemolysis for each preservative agent within the 45-min. period of each experiment. Thus, the studies were continued using an amount of preservative inducing a greater degree of hemolysis (80–100%) so that the influence of DMSO in reducing hemolysis could be followed over a more extensive course.

Influence of DMSO on Preservative-Induced Hemolysis—Figures 2 through 5 depict the influence of DMSO on the hemolytic activities of various preservative agents. It is interesting to note that in each instance hemolysis is dramatically decreased, and indeed almost prevented, as the DMSO level is increased to between 10 and 20%, irrespective of the chemical type of preservative and its effective hemolytic concentration.

Figures 2 through 5 show that as the level of DMSO is increased beyond that amount which induces optimum retardation of hemolysis, hemolysis is increased and may be quantitated until denaturation of the blood occurs at DMSO concentrations of about 30%. It has been previously shown (1) that DMSO in the presence of 0.6% sodium chloride induces a hemolytic response in erythrocytes at DMSO levels of 25% and causes increased hemolysis with increasing concentrations of DMSO until denaturation occurs at approximately 50% DMSO levels. Thus, it would seem as though the portions of the curves in Figs. 2 through 5 beyond the areas of optimum depression reflect the combined cytotoxic activities of DMSO and the preservatives on the red blood cells, with the high concentrations of DMSO being too destructive to lend further any protective influence to the erythrocytes against preservative-induced hemolysis.

The deleterious effects of high levels of DMSO on blood are observed as amber-brown discoloration of the extracellular liquid,

Figure 4—Influence of DMSO on the hemolytic activity of 1.8×10^{-2} M chlorobutanol in the presence of 0.6% NaCl.

Figure 5—Influence of DMSO on the hemolytic activity of phenylmercuric nitrate and thimerosal in the presence of 0.6% NaCl. Key: ●, 3.1×10^{-5} M phenylmercuric nitrate; and ○, 6.1×10^{-5} M thimerosal.

the flocculation of the blood's components, and the precipitation of the hemoglobin from laked erythrocytes. Huggins (4) reported on his observations of the interaction between DMSO and human plasma proteins, noting that true denaturation of plasma protein seems to occur at DMSO concentrations approximating 50%. He stated that precipitation of protein by DMSO occurred with individual plasma fractions—albumin, fibrinogen, gamma globulin—and appears to be a general effect rather than denaturation of a specific plasma component.

At the time it was reported (1) that DMSO interfered with the hemolytic activity of phenol, it was suggested that such an effect might be due to either an extracellular interaction between the two chemical agents, or due to some cellular action of DMSO which retards the ability of phenol to exert its cytotoxic activity.

Since the present work demonstrates that greatly different molar concentrations of the various chemical types of preservative agents are hindered in their effort to destroy the integrity of the erythrocyte by a comparatively large and constant level of DMSO, it would seem to suggest that the mode of this activity is cellular-based rather than by virtue of extracellular chemical interactions between DMSO and the preservative agents. This hypothesis was supported by the spectral analysis of combinations of DMSO with benzalkonium chloride, chlorhexidine diacetate, and *m*-cresol, which failed to indicate any sign of chemical association between DMSO and the preservatives.

Influence of Preservative Concentration—Figure 6 depicts the pattern generally followed as DMSO is added in increasing amounts to various hemolytic concentrations of a preservative agent. It can be seen that the effectiveness of DMSO in causing a reduction in hemolysis is decreased as the concentration of preservative is in-

Figure 6—Influence of DMSO on the hemolytic activity of benzalkonium chloride in the presence of 0.6% NaCl. Key: A, 2.2×10^{-5} M benzalkonium chloride; B, 3.3×10^{-5} M benzalkonium chloride; C, 4.2×10^{-5} M benzalkonium chloride; and D, 6.5×10^{-5} M benzalkonium chloride.

Figure 7—Influence of DMSO on the hemolytic activity of chlorhexidine diacetate. Key: ●, chlorhexidine diacetate in 0.6% NaCl; and ○, chlorhexidine diacetate in 0.6% NaCl and 15% DMSO.

creased. This pattern was found for the other preservatives studied, although in instances in which the range of concentration of preservative used was narrow (because of the slight difference in the quantity required to cause trace, intermediate, and total hemolysis) some of the data collected resulted in overlapping and crossing curves when plotted.

Figure 7 shows the influence of 15% DMSO on the hemolytic activity of various concentrations of chlorhexidine diacetate. In the absence of DMSO, chlorhexidine diacetate induces trace hemolysis at 3.2×10^{-5} M (20 mcg./ml.) concentration and total hemolysis at levels of 1.9×10^{-4} M (120 mcg./ml.). Dimethyl sulfoxide is effective in keeping the level of hemolysis depressed at chlorhexidine diacetate concentrations below about 6.4×10^{-4} M (400 mcg./ml.), but is ineffective at higher preservative levels.

The data of Figs. 6 and 7 convincingly show that although DMSO is effective in depressing the level of hemolysis induced by low hemolytic levels of preservative agents, it is ineffective against preservative concentrations of great hemolytic potency. The difference in the concentration of a preservative required to cause total hemolysis compared to that amount needed to cause trace hemolysis in the presence of DMSO does not seem to contribute to the molar strength sufficiently to suggest that the comparatively massive proportion of DMSO present would be any less able to associate in complexation with the greater amount than with the lower preservative level. Thus, the data would seem to suggest that a cellular-based mechanism for the action of DMSO in preventing preservative-induced hemolysis is more likely than an extracellular drug-drug interaction mechanism.

Kinetic Studies—In order to determine if the effect of DMSO in lowering the level of preservative-induced hemolysis was time-related, experiments were conducted using a constant preservative concentration and several levels of DMSO, with hemolytic activity

Figure 8—Influence of time and DMSO on the hemolytic activity of benzalkonium chloride. Key: A, 3.3×10^{-5} M benzalkonium chloride in 0.6% NaCl; B, 3.3×10^{-5} M benzalkonium chloride in 0.6% NaCl and 5% DMSO; and C, 3.3×10^{-5} M benzalkonium chloride in 0.6% NaCl and 15% DMSO.

determined at intervals of from 5 to 20 min. during periods up to 120 min.

As can be seen in Fig. 8, the addition of DMSO to solutions of $3.3 \times 10^{-5} M$ benzalkonium chloride in saline slows the rate of hemolysis, with 15% concentrations of DMSO being more effective than 5% concentrations in this effort. Thus, whereas earlier data seemed to indicate that 15% DMSO actually had the ability to reduce or even prevent preservative-induced hemolysis, the present results show that it is a time-related phenomenon. The same pattern of data was obtained in experiments using DMSO-phenol and DMSO-chlorhexidine diacetate systems. This would seem to reinforce the premise that DMSO exerts a cellular effect on the erythrocyte which results in a reduction in the rate of preservative-induced hemolysis.

Work soon to be reported from this laboratory shows that erythrocytes take up DMSO from solution and resist attempts to remove it by washing. Gerhards and Gibian (5) found that in human blood about 30% of injected DMSO is bound to plasma protein and 25% to the formed elements of the blood, the remainder remaining free. Thus, it is not unlikely that the attachment of DMSO to the erythrocyte in some manner affects the vulnerability of the cell toward the preservative agents or alters the permeability barriers of the cell affecting the permeation of the preservative agents into the cell or the exit of hemoglobin from the cell.

Spectral Studies—Preliminary studies of the UV absorption spectra of three preservatives, benzalkonium chloride, chlorhexidine diacetate, and *m*-cresol, alone and in combination with DMSO, were performed to indicate whether or not there is a likelihood of a chemical interaction between DMSO and the preservative agents. The preservatives and DMSO were studied at concentration combinations found to be most inhibitory on preservative-induced hemolysis during the present work. Preliminary

data suggest that complexes were not formed. However, more complete studies to rule out complex formation need yet to be made.

In conclusion, the evidence collected more strongly suggests that DMSO interferes with the hemolytic activity of antimicrobial preservatives through a direct action on the erythrocyte or by alteration of its permeability barriers rather than by chemical interaction with the various preservative agents. Further, the degree of this interference is dependent upon the concentrations of both the preservative and DMSO and also upon the length of exposure to these agents.

Interaction of Amine Drugs with a Polycarboxylic Acid Ion-Exchange Resin

SAUL BORODKIN and MARTIN H. YUNKER

Abstract □ The interaction of polacrilin potassium, the salt of a polycarboxylic acid ion-exchange resin, with 11 amine drugs was studied. All drugs showed maximum interaction at pH 4.5–5.5. Tertiary amines exhibited a much greater affinity for the resin than primary, secondary, and quaternary amines. Selectivity coefficients were used to express the degree of interaction, with experiments showing that these values remain constant over wide variations in resin, drug, and alkali metal concentrations. Rate studies demonstrated that both adsorption of drug onto the resin and elution from the resin are very rapid. The rapid elution rates, along with decreasing resin affinity for amine drugs above pH 6.0, indicate that the presence of polacrilin potassium in a dosage form should not affect total drug availability in the gastrointestinal tract.

Keyphrases □ Polacrilin potassium—interaction, amine drugs □ Amine drugs—interaction, polycarboxylic acid ion-exchange resin □ Ion-exchange chromatography—separation □ UV spectrophotometry—analysis

The use of synthetic polycarboxylic ion-exchange resins in pharmacy and medicine has been quite extensive. Their use in congestive heart failure and edema (1), isolation and purification of streptomycin and other drugs (2), and analysis of drugs (3) is well docu-

mented. Adsorbates of amine drugs with carboxylic ion-exchange resins for sustained release (4–7) and taste coverage (8) have been prepared, although to a lesser extent than complexes with sulfonic acid resins.

Because of their unusually large swelling capacities, polymethacrylic carboxylic acid ion-exchange resins have found usage in pharmacy as tablet disintegrants. Van Abbe and Rees (9) reported on the effectiveness of polacrilin potassium¹ as a disintegrating agent, while a later patent (10) describes the use of a similar resin in the acidic form for the same purpose. Being cation exchangers, however, these insoluble polymers have the capability of adsorbing amine drugs, thus possibly interfering with drug availability and assay. This potential incompatibility may have limited the use of these resins as tablet disintegrants to some extent.

The present investigation was undertaken to study the interaction between amine drugs and polacrilin potassium. Eleven commonly used drugs were selected to include primary, secondary, tertiary, and quaternary

Table I—Drugs Used in Study

Drug	pKa ^a	$\lambda_{\max.}$ (0.08 N HCl), m μ
Phenylpropanolamine hydrochloride	9.4	257
Ephedrine base	9.5	257
Pseudoephedrine hydrochloride	9.7	257
Desoxyephedrine hydrochloride	9.5	257
Carbinoxamine maleate	8.1	262
Quinidine sulfate	8.8	280
Methapyrilene hydrochloride	8.8	312
Chromonar hydrochloride	8.3	320
Dextromethorphan hydrobromide	8.3	278
Thiamine mononitrate	— ^b	245
Neostigmine bromide	— ^b	260

^a The pKa's for carbinoxamine and chromonar were determined in this laboratory by potentiometric titration while the others were obtained from the literature. Only the pKa for the most basic amine group in the molecule is listed. ^b Thiamine and neostigmine are quaternary amines.

amines. Although the primary goal of this study was to assess the extent of the potential incompatibility in regard to the use of carboxylic acid resins as disintegrating agents, it was believed that the approach taken and information generated might also be useful for other ion-exchange resin applications.

EXPERIMENTAL

Resin—Polacrilin potassium is the potassium salt of a weakly acidic cation-exchange resin with a polymethacrylic acid-divinylbenzene matrix having a particle size range of 100–500 mesh. A single lot was used in all experiments. Assays showed a potassium content of 5.38 meq./g., a total exchange capacity of 6.97 meq./g.,

Figure 2—Effect of pH on drug distribution ratio. Key: ●, methapyrilene HCl (1 mg./ml.) + polacrilin K (10 mg./ml.); ○, chromonar HCl (1 mg./ml.) + polacrilin K (10 mg./ml.); and □, carbinoxamine maleate (0.25 mg./ml.) + polacrilin K (2.5 mg./ml.).

and a water content of 18.0% (Karl Fischer).

Drugs—Table I lists the drugs used in this study. Other salt forms would be expected to behave similarly. The UV absorbance maxima used in their analysis and the pKa's are included.

Equilibrium Studies—To establish the relationship between interaction of a drug and pH, a series of 12–14 solutions was prepared to contain 200 mg. drug (except for carbinoxamine maleate where 50 mg. was used), 1.8 g. of sodium chloride (isotonic saline concentration), and various predetermined amounts of hydrochloric acid in 200 ml. of solution. Each solution was added to a 300-ml. bottle along with constant amount (0.5–5.0 g. depending on the drug) of polacrilin potassium, and the bottles were rolled at 24–25°. To improve accuracy, the resin–drug ratios in these experiments were much higher than would normally be used in tablets. After 24 hr. the pH was determined, the resin was separated by filtration, and the drug concentration in the filtrate was determined by UV absorbance using a Beckman DU spectrophotometer after the required dilution with 0.08 N HCl. In the case of chromonar, the samples were drawn after 4 hr. as a precaution because of the drug's reported instability. Rate studies with other drugs indicated that adsorption should be close to equilibrium after that time period.

Figure 3—Effect of pH on drug distribution ratio. Key: ●, phenylpropanolamine HCl (1 mg./ml.) + polacrilin K (25 mg./ml.); ○, ephedrine (1 mg./ml.) + polacrilin K (25 mg./ml.); and □, thiamine mononitrate (1 mg./ml.) + polacrilin K (10 mg./ml.).

Figure 4—Effect of pH on drug distribution ratio. Key: ●, desoxyephedrine HCl (1 mg./ml.) + polacrilin K (25 mg./ml.); ○, pseudoephedrine HCl (1 mg./ml.) + polacrilin K (25 mg./ml.); and □, neostigmine bromide (1 mg./ml.) + polacrilin K (10 mg./ml.).

The procedures used to determine the effects of alkali metal, resin, and drug concentrations were identical to the above except for varying concentrations of the component being studied. To ensure the constant pH required in each series, fine adjustments were made with HCl after 4 and 6 hr.

In the temperature study experiments, the equilibrations were run in flasks equipped with mechanical stirrers and submerged in constant-temperature baths.

Relationship between Degree of Resin Dissociation, α , and pH (Fig. 5)—A series of 13 solutions was prepared to contain 1.8 g. of sodium chloride and various predetermined amounts of HCl (for an equilibrium pH range of 2.5–7.5) in 200 ml. of solution. Each solution was added to a 300-ml. bottle along with 2.0 g. of

Figure 5—Relationship between pH and polacrilin K dissociation in 0.154 M NaCl ($n = 2.28$, $pK_a = 6.60$).

polacrilin potassium and the bottles were rolled at 24–25° as in the equilibrium studies. After 24 hr., the pH of each mixture was determined and the resin was separated from the solution phase by filtration. The resin was then reslurried in 200 ml. of 1 N HCl for 2 hr. to elute the cations that had remained in the resin phase. Aliquot samples (20 ml.) were pipetted from both the equilibrium and acid elution solutions and evaporated to constant weight under an IR lamp. Since the solids were a mixture of sodium and potassium chlorides in the molar ratio 154 to 54, the weight concentrations were converted to equivalents per liter by dividing by the weighted average molecular weight (62.63). The concentrations in the equilibrium and elution solutions were equal to $[M]_s$ and $[M]_r$, respectively. Their sum varied from 205–209 meq./l. (theoretical 208) at the 13 different pH's. The fraction of resin in the dissociated form, α , was obtained by dividing $[M]_r$ by the total exchange capacity of the polacrilin (69.7 meq./l.).

Rate Studies—In the adsorption rate studies, 500 ml. of buffer containing 0.154 eq. of sodium was prepared by dissolving 1.94 g. of dibasic sodium phosphate and 19.2 g. of monobasic sodium phosphate in water. Ten grams of polacrilin potassium was added and the pH of the slurry was adjusted to 5.50–5.60 with HCl over a 4-hr. period. One gram of drug was dissolved in 500 ml. of water and the solution was added to initiate adsorption. The slurry was

Table II—Selectivity Coefficients (K_M^D) at Various pH's

Drug	pH			
	4.5	5.0	5.5	6.0
Phenylpropanolamine	2.48	2.67	2.13	1.45
Desoxyephedrine	7.44	5.81	3.80	2.38
Ephedrine	5.37	4.49	2.77	1.72

Neostigmine	6.42	4.22	2.22	1.14

Figure 7—Effect of alkali metal concentration on drug distribution ratio. Key: ●, methapyrilene HCl (1 mg./ml.), polacrilin K (10 mg./ml.), NaCl (0–1.283 meq./ml.), pH 5.3; and ○, dextromethorphan HBr (1 mg./ml.), polacrilin K (10 mg./ml.), NaCl (0–0.616 meq./ml.), pH 5.1.

stirred at 25° for 4 days with methapyrilene and dextromethorphan and for 2 weeks in the case of carbinoxamine and quinidine. Ten-milliliter samples were removed at 2, 5, 10, and 30 min.; at 1, 4, and 24 hr.; and at the end of the run. The solution phase was filtered from the resin and assayed for drug by UV spectroscopy.

In the elution rate studies, 1 g. of methapyrilene hydrochloride, 1.94 g. of dibasic sodium phosphate, and 19.2 g. of monobasic sodium phosphate were dissolved in enough water to make 1 l. Ten grams of polacrilin potassium was added, the pH was adjusted to 5.5 with HCl, and the slurry was stirred for 24 hr. at 25°. The resin, containing approximately 82.0% of the drug, was filtered from the solution and added to 1 l. of fresh buffer solution containing 0.154 meq./ml. of sodium. The pH 6.8 elution-rate run used a buffer containing 18.8 g. of dibasic and 1.86 g. of monobasic sodium phosphate. The buffer in the pH 5.4 study contained 1.94 g. of dibasic and 19.2 g. of monobasic sodium phosphate. Stirring was continued at 25° for 24 hr. with samples being removed after 2, 5, 10, and 30 min. and after 1, 3, and 24 hr. The solution phase was filtered from the resin and assayed for drug by UV spectroscopy.

Figure 9—Effect of polacrilin potassium concentration on drug distribution ratio, methapyrilene HCl (1 mg./ml.), KCl (0.154 meq./ml.), polacrilin K (1.25–30.0 mg./ml.), pH 5.4, $K_M^D = 50.4$.

RESULTS AND DISCUSSION

Effect of pH—Figures 1–4 show the effect of pH on the interaction at equilibrium between polacrilin potassium and the eleven drugs tested. Drug interaction is expressed as a distribution ratio, drug in resin phase, $[D]_r$, divided by drug in solution phase, $[D]_s$, both expressed as meq./ml. of solution. Although the extent of interaction varied considerably with the drug, in all cases the ratio showed a maximum at pH 4.5–5.5. The sharp decrease in complexation below pH 4.5 is apparently caused by the diminishing number of anionic sites on the resin due to its low dissociation constant. The decreasing interaction above pH 5.5, despite the greater ionization of the resin, can be attributed to a decreasing affinity of the polacrilin for amine drugs relative to alkali metal cations. The increasing portion of drug in the unionized form may contribute to this.

Figure 10—Effect of drug concentration on interaction, methapyrilene HCl (0.42–10.08 meq./l.), polacrilin K (10 mg./ml.), NaCl (0.154 meq./ml.), pH = 5.4, $K_M^D = 50.9$.

^a Results of samples at 5, 10, and 30 min. were all intermediate between the 2-min. and 1-hr. percentages. ^b Sampled after 4 days. ^c Sampled after 3 weeks. ^d Sampled at 3 hr.

Although the drug distribution ratio is a convenient term for expressing drug interaction, it will vary with drug, resin, and sodium ion concentrations, as well as with pH. This is demonstrated in Fig. 1 where two different resin concentrations were used with dextromethorphan. Samuelson (3) suggests the use of a selectivity coefficient to express the relative affinities of resins for different cations. In this study the selectivity coefficient, K_M^D , would be defined by the following equation:

$$K_M^D = \frac{[D]_r [M]_s}{[D]_s [M]_r} \quad (\text{Eq. 1})$$

where $[M]_s$ and $[M]_r$ represent the concentrations, in meq./ml., of alkali metal in the solution and resin phases, respectively. The alkali metal concentration includes both the sodium from added sodium chloride and potassium contributed by the polacrilin potassium, with the sodium ion predominating. The selectivity coefficients would be expected to remain constant with variations in drug, resin, and metal concentrations, although it does change with pH.

Calculations of selectivity coefficients from the distribution ratios found in Figs. 1–4 require accurate estimations of $[M]_r$ ($[M]_s$ can be obtained by difference once $[M]_r$ is known). Since the meq. of alkali metal in the resin phase is approximately equal to the meq. of ionized sites on the resin, less those occupied by drug cations, the following equation may be written:

$$[M]_r = \alpha[Re] - [D]_r \quad (\text{Eq. 2})$$

where α is the fraction of total resin equivalents in the dissociated form while $[Re]$ is the resin concentration expressed in meq. total

exchange capacity per ml. of solution. Gustafson (11) has demonstrated that polymethacrylic carboxylic ion-exchange resins follow the empirical relationship:

$$\text{pH} = \text{pKa} + n \log \frac{\alpha}{1-\alpha} \quad (\text{Eq. 3})$$

where pKa is an apparent dissociation constant which changes with ionic strength, while n is a second constant specific for the resin and independent of ionic strength. The linear relationship obtained between pH and $\log \alpha/1-\alpha$ (Fig. 5) shows that polacrilin potassium follows Eq. 3. The values from this experiment allow calculation of selectivity coefficients from the drug distribution ratios shown in Figs. 1–4 using Eqs. 1–3.

The relationship between the selectivity coefficients and hydrogen ion concentration was obtained by plotting $\log K_M^D$ versus pH for each drug. Figure 6 shows some typical results. In all cases the relationship appeared linear between pH 5.5 and 7.5 with slopes of 0.5–1.0. This linearity indicates that the selectivity coefficient is proportional to a power (equal to the slope) of the hydrogen ion concentration. Results below pH 5.5 were inconsistent in that maxima, levelings, and nonlinear increases were observed in the graphs.

Comparison of Drugs—Table II shows the selectivity coefficients obtained for each drug at pH 4.5, 5.0, 5.5, and 6.0. Since all drugs should be essentially in the cationic form at the pH's used, the considerable variations in selectivity coefficients between drugs cannot be attributed to their dissociation constants. The differences are more likely related to steric and resonance effects within the drug cation. Nevertheless the magnitude of the selectivity coefficients can be related to the degree of nitrogen substitution. The five tertiary amine drugs (dextromethorphan, methapyrilene, quinidine, carbinoxamine, and chromonar) showed substantially greater interaction than the other six drugs. At pH 5.0, the average selectivity coefficient for the tertiary amines was approximately 40 times greater than the average for the three secondary amine drugs (ephedrine, pseudoephedrine, and desoxyephedrine). Phenylpropanolamine, the only primary amine studied, showed the smallest interaction. The two quaternary amine drugs varied somewhat in their behavior. Neostigmine gave a selectivity coefficient similar to the secondary amine drugs while the value for thiamine was intermediate between secondary and tertiary amines.

Effects of Alkali Metal, Resin, and Drug Concentrations—The relationship between the drug distribution ratio and the sodium ion concentration is shown in Fig. 7 for methapyrilene and dextromethorphan. Similar curves were obtained with the other drugs tested. To show that these results are consistent with the selectivity coefficient relationship (Eq. 1), the drug distribution ratios were plotted against the calculated alkali metal ratios (Fig. 8). Since Eq. 1 may be rearranged to

$$\frac{[D]_r}{[D]_s} = K_M^D \frac{[M]_r}{[M]_s} \quad (\text{Eq. 4})$$

the linearity obtained demonstrates that the selectivity coefficients remain constant over a wide alkali metal concentration range. $[M]_r$ and $[M]_s$ were calculated from Eqs. 2 and 3, with the variability of pKa with ionic strength being estimated from Gustafson's relationship (11).

Experiments in which the potassium ion concentration was varied gave similar results to those obtained with sodium ion variation. Potassium gave approximately the same selectivity coefficients. The similarity indicates that small changes in the potassium-sodium

Figure 11—Effect of temperature on the drug distribution ratio, methapyrilene HCl (1 mg./ml.), polacrilin K (10 mg./ml.), NaCl (0.154 meq./ml.). Key: ● pH 4.6, and ○, pH 5.3.

ratio within a system should have negligible effect on drug distribution ratios.

Figure 9 shows the effect of polacrilin potassium concentration on the methapyrilene distribution ratio. The distribution ratio was plotted against the calculated $[M]_r/[M]_s$ to attain the linearity predicted by Eq. 4. The results show that the selectivity coefficient also remains constant over a wide range of resin concentration.

In evaluating the effect of drug concentration, a plot of the methapyrilene distribution ratio *versus* $[M]_r/[M]_s$ showed deviation from linearity at low drug concentration. However a straight line was obtained when the concentration of resin-adsorbed drug, $[D]_r$, was plotted against $[D]_r[M]_r/[M]_s$ (Fig. 10). Although the linearity is consistent with Eq. 1, the intercept is not. Apparently the total drug adsorbed is the sum of that adsorbed according to the selectivity coefficient relationship plus a constant:

$$[D]_r = K_M^D \frac{[M]_r}{[M]_s} [D]_s + \text{constant} \quad (\text{Eq. 5})$$

This constant, which becomes significant only at very low drug-resin ratios, can be attributed to a small quantity of drug bound to the resin by forces other than ionic bonding.

Effect of Temperature—The effect of temperature on the methapyrilene distribution ratio at two different pH's is shown in Fig. 11. The decrease in drug-resin interaction with rising temperature is in agreement with Samuelson's generalization (3) that an increase in temperature results in a decrease in ion selectivity.

Rate of Equilibration—Although the large size of the drug cations might be expected to affect exchange kinetics, the rate of equilibration was found to be quite rapid, both for adsorption and elution. Table III summarizes the results of rate studies at 25°. The lack of significant change after 24 hr. in the adsorption runs emphasizes the fact that equilibrium is attained in that time.

The rapid exchange rates are consistent with the results reported by Kunin (12) for carboxylic ion-exchange resins. He noted that, although the exchange rate in going from acid to metal cycle is slow and may require weeks for completion, attainment of equilibrium in going from one metal cycle to another occurs in minutes or hours. Since the latter process most closely resembles both adsorption onto polacrilin potassium (potassium to drug cycle) and elution from the resin (drug to sodium cycle) the rapid rates are not surprising. Further, the fine particle size of polacrilin potassium might contribute significantly to acceleration of the exchange rates.

The rapid exchange rates along with the selectivity coefficient results indicate that the presence of polacrilin potassium in a dosage form should have insignificant effect on the total drug availability. Although appreciable resin adsorption of drug may occur in the gastrointestinal tract during pH 4.5–6.0 exposure, rapid desorption should result as the adsorbate passes into the higher pH of the small intestine. The decreased selectivity coefficients at higher pH along with the rapid elution rates ensure drug availability. Even in the pH 4.5–6.0 range, continuous absorption of drug into the blood would result in elution from the resin. The higher temperatures that would be encountered in the body compared with the 24–25°

data obtained in this study would promote greater drug availability, both through lower selectivity coefficients and faster exchange rates.

SUMMARY AND CONCLUSIONS

1. The interaction between amine drugs and polacrilin potassium follows the selectivity coefficient relationship. It would be expected that other carboxylic acid ion-exchange resins would behave similarly.

2. Tertiary amines show a greater affinity for polacrilin potassium than other amine drugs. In all cases, maximum interaction occurs at pH 4.5–5.5.

3. The rapid elution rates, along with decreasing interaction above pH 6.0, indicate that the presence of polacrilin potassium in a dosage form should not affect total *in vivo* availability. It is questionable whether any significant delay in absorption would occur.

4. The high selectivity coefficients obtained with some drugs indicate that precautions must be taken in assaying for amine drugs in the presence of polacrilin potassium. Buffers above pH 7.0 or below pH 3.0 or solutions with high cation concentrations may be used to effect complete drug elution.

Effect of Age on Intestinal Absorption of Riboflavin in Humans

WILLIAM J. JUSKO, GERHARD LEVY,* and SUMNER J. YAFFE

Abstract □ The development of gastrointestinal absorption function in humans was studied using riboflavin, a vitamin which is absorbed by a site-specific (proximal small intestine) and saturable transport process. Oral doses of 150 mg./m.² body surface area of riboflavin-5'-phosphate were administered in solution to subjects ranging in age from 0.25 to 40 years. The urinary recovery of the vitamin increased significantly (from 6 to 12% of the dose) over this age range. The ratio of maximum excretion rate to dose and the time of occurrence of the maximum excretion rate were independent of age. The kinetics of riboflavin elimination also did not show any appreciable change with age. These observations suggest that, in the age range studied, younger subjects retain the vitamin at intestinal absorption sites for a shorter period of time than do older subjects. This appears to be due to decreased intestinal transit rate with increasing age. Prompt release of drugs from pharmaceutical dosage forms seems therefore even more important in children than in adults in order to assure adequate absorption.

Keyphrases □ Riboflavin absorption—intestinal □ Age effect—riboflavin intestinal absorption □ Kinetic equations—urinary excretion parameters relationship, gastrointestinal absorption □ Elimination half-life, riboflavin—age effect

There is little biopharmaceutical information available to aid in the design of oral dosage forms for infants and children. Of the various physiologic characteristics which might change with age, those related to gastrointestinal absorption are among the least studied. Several recent reviews have pointed to the need for quantitative studies of intestinal absorption function at various ages (1-3).

In the course of investigations of factors affecting the gastrointestinal absorption of riboflavin (4) and riboflavin-5'-phosphate (5) in man, it was found that this vitamin is absorbed in the proximal small intestine by a saturable transport process. The absorption of riboflavin can therefore serve as an index of gastrointestinal transit rate since absorption only occurs while the vitamin is in the proximal small intestine. Since the gastrointestinal absorption of drugs administered in solid dosage forms can be impaired if the solid drug is not dissolved before or during passage through the small intestine (6), the results of absorption studies with riboflavin are applicable in general terms to other drugs inasmuch as their absorption is affected by the rate of gastrointestinal transit. The use of riboflavin is particularly advantageous in this study involving infants and children since the absorption of this vitamin can be assessed from urinary excretion data (4, 5).

THEORETICAL

In order to understand more clearly the relationship of urinary excretion parameters (time course of excretion rates and urinary recovery) to gastrointestinal factors involved in absorption by a specialized transport process (maximum absorptive capacity and intestinal transit rate), it is useful to evolve mathematical

relationships for a simple pharmacokinetic model which is consistent with the proposed mechanism of intestinal absorption.

If a substance is absorbed by a saturable specialized process in the small intestine and the dose administered (X_D) is large enough to saturate the absorption process, then the rate of absorption can be considered to be zero order ($V_{\max.}$). Assuming the body to be a single compartment and the rate of elimination to be first order (k_E), the appropriate pharmacokinetic model is:

where X represents amounts of drug, subscripts refer to amount absorbed (A), amount in the body (B), and amount eliminated *via* urine (U), and by metabolism and/or extrarenal routes (M), and $X_D \gg X_A$. First-order rate constants for the elimination processes are represented by k_e and k_m and:

$$k_E = k_e + k_m \quad (\text{Eq. 1})$$

The differential equations which are applicable are:

$$-dX_A/dt = V_{\max.} \quad (\text{Eq. 2})$$

$$dX_B/dt = V_{\max.} - k_E \cdot X_B \quad (\text{Eq. 3})$$

$$dX_U/dt = k_e \cdot X_B \quad (\text{Eq. 4})$$

While absorption is occurring, solution of these equations for X_B yields:

$$X_B = (V_{\max.}/k_E) \cdot [1 - \exp(-k_E \cdot t)] \quad (\text{Eq. 5})$$

and from Eqs. 4 and 5, it can be seen that:

$$dX_U/dt = (V_{\max.} \cdot k_e/k_E) \cdot [1 - \exp(-k_E \cdot t)] \quad (\text{Eq. 6})$$

The maximum amount of drug in the body, $(X_B)_{\max.}$, occurs when Eq. 3 equals zero or:

$$(X_B)_{\max.} = V_{\max.}/k_E \quad (\text{Eq. 7})$$

and the corresponding maximum urinary excretion rate, $(dX_U/dt)_{\max.}$, from Eqs. 4 and 7 is therefore:

$$(dX_U/dt)_{\max.} = V_{\max.} \cdot k_e/k_E \quad (\text{Eq. 8})$$

The actual peak excretion rate (ER_p) will be proportional to $V_{\max.}$ (Eq. 8) only after absorption at $V_{\max.}$ has proceeded over a period of at least 4 elimination half-lives, i.e., when:

$$\exp(-k_E \cdot t) \rightarrow 0$$

so that Eq. 5 reduces to Eq. 8. If the time of occurrence (t_p) of ER_p is $< 4 \cdot t_{1/2}$, then $V_{\max.}$ can be determined by rearranging Eq. 6 to yield:

$$V_{\max.} = (ER_p \cdot k_E/k_e) / [1 - \exp(-k_E \cdot t_p)] \quad (\text{Eq. 9})$$

The amount of drug absorbed (X_A), from Eq. 2, is:

$$X_A = V_{\max.} \cdot t_p \quad (\text{Eq. 10})$$

where t_p is the time during which drug absorption proceeds. This equation shows that two intestinal factors can modify the amount of drug absorbed under the conditions of the model: (a) the maxi-

Figure 1—Urinary excretion rate as a function of time after oral administration of 150 mg./m.² riboflavin to a human subject.

mum absorption rate (V_{max}), and (b) the residence time of drug at the absorption site (t_g). Since the urinary recovery of drug is proportional to the amount absorbed:

$$X_U^\infty = X_A \cdot k_a/k_E \quad (\text{Eq. 11})$$

it will also be dependent on the contribution of V_{max} and t_g to intestinal absorption of the drug.

Although the kinetics of absorption and excretion of riboflavin are more complex than the theoretical model, the mathematical relationships developed here will facilitate interpretation of the experimental results.

EXPERIMENTAL

Thirteen male and 10 female human subjects in apparent good health served as test subjects. The age of the subjects ranged from 3 months to 40 years. After an overnight fast, each subject received an oral dose of 150-mg. riboflavin, administered as riboflavin-5'-phosphate¹ (FMN), per square meter of body surface area. The surface area was calculated from the weight and height of each subject by the method of Dubois and Dubois (7). The vitamin was given in 15 to 40 ml. of aqueous solution immediately following a standard breakfast consisting of 30 g. cereal and 250 ml. milk or formula per square meter surface area. An equal volume of orange juice was usually mixed with the FMN solution to mask the taste. Urine was usually collected in older children and adults at 0.5-hr. intervals for 4 hr., 1-hr. intervals for the next 4 hr., and then at convenient intervals for a total of 36 hr. The subjects were moderately hydrated with oral fluids during the course of experiments to maintain adequate urine output. Studies on infants and children were carried out at the Children's Hospital of Buffalo under medical supervision. A plastic urine collection device was taped to the genital region of the infants and permitted quantitative collection of samples. The subjects were required not to take any drugs or vitamin preparations for at least 3 days prior to or during the experiments.

Total riboflavin in urine was determined fluorometrically by methods previously described (4, 5). An 18- to 24-hr. blank urine collection was obtained in each subject, and all data were corrected for blank values.

RESULTS

The typical time course of urinary excretion rate of riboflavin after oral administration of FMN is shown in Fig. 1. From such excretion data, the following parameters were determined for each subject: half-lives of elimination, urinary recovery, peak excretion rate, and time of occurrence of the peak excretion rate.

The results shown in Fig. 1 indicate that the decline in urinary excretion rate was biexponential but the initial "rapid" phase with a half-life of about 1.4 hr. accounts for elimination of most of the vitamin. A smaller fraction of the excreted vitamin was recovered in the urine during the terminal "slow" phase. To estimate the rapid and slow half-lives of elimination, semilogarithmic plots of amount of riboflavin remaining unexcreted as a function of time were constructed. Typical results obtained in four of the younger subjects are shown in Fig. 2. After the absorptive phase, which affects the first four hours of elimination, the decline in excretion was resolved into the rapid and slow phases by the method of residuals (8). The data are shown for the younger subjects because these were generally more variable than results obtained in older children and adults. This is partially due to the difficulty in ensuring complete urine voiding at the desired collection times for such subjects.

The relationship of the rapid and slow half-life of elimination to age of the subjects is shown in Fig. 3. In this and subsequent plots and statistical treatments, the logarithm of age was used. The rapid half-life of elimination exhibits a limited range of values, averaging 1.4 hr., and neither the least-squares regression nor the correlation coefficient shows any significant change of this parameter with age. The mean values, least-squares regression slopes and intercepts, correlation coefficients, and statistical calculations for this parameter, as well as others to be considered, are summarized in Table I. The slow half-life of elimination was quite variable but shows a barely statistically significant ($p = 0.05$) tendency to increase with age. Tests were repeated in five of the subjects as shown in Fig. 3. In four of these, where the age of the subject was similar in both tests, an average of the pairs of parameters was used with the mean of the logarithm of age in the statistical calculations.

There was a statistically significant ($p < 0.01$) increase in urinary recovery of riboflavin with age (Fig. 4), from a mean of about 6% at 0.25 years to about 12% at 40 years of age. Since the dose of riboflavin administered (150 mg./m.²) was greatly in excess of that

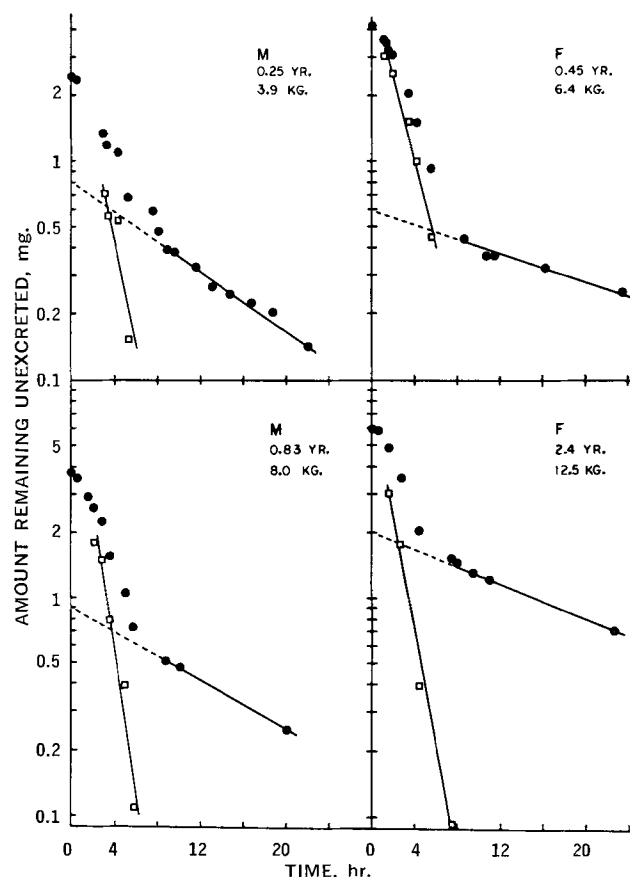

Figure 2—Amount of riboflavin remaining unexcreted (●) as a function of time in four children. The rapid half-life of elimination was determined (□) from the postabsorptive data using the method of residuals by extrapolating (dashed line) the linear slow phase of elimination to the ordinate. Sex, age, and weight of the subjects are shown.

which can be absorbed (4, 5), the percent urinary recovery of the vitamin was correspondingly low.

The relationship of the peak excretion rate of riboflavin to the age of the subjects is shown in Fig. 5. The actual peak excretion rate was divided by the dose of riboflavin administered to permit comparison of the data over the entire age range. This parameter shows a slight and statistically insignificant ($p = 0.2$) tendency to increase with age. The value chosen for the peak excretion rate for the individual subjects is the average of the three highest excretion rates found. This method was chosen to reduce bias caused by occasional high excretion rate values resulting from incomplete voiding of an earlier sample by the younger subjects. The use of only the single highest values yielded a slope of essentially zero and indicated therefore no change with age.

The time of occurrence of the peak excretion rate is plotted as a function of age in Fig. 6 and shows a slight, but insignificant ($p = 0.25$), tendency to decrease with age.²

DISCUSSION

The intestinal absorption of riboflavin was studied as a function of age in normal subjects under conditions where maximum absorption of the vitamin will occur (*i.e.*, with food). The dose is at least five times greater than that needed to saturate the absorption process (4, 5) which accounts for the relatively low urinary recovery of riboflavin (Fig. 4). Because of the large dose employed, an

assumption that riboflavin absorption occurs at a maximum rate (V_{max}) during the early times after administration appears justified.

The urinary recovery of riboflavin shows a definite, though small, increase with age of the subjects (Fig. 4). As shown in the *Theoretical* section, the increase in urinary recovery is a direct measure of the effect of age on intestinal absorption providing that the elimination kinetics of the vitamin are not also altered in the age range studied (Eq. 11). The kinetics of elimination of riboflavin are complex, but the data suggest that the renal excretion of the vitamin does not significantly change with age. A biexponential decline in elimination of riboflavin was found (Fig. 2), but it can also be seen (Fig. 1) that most of the vitamin is excreted during the phase characterized by a rapid half-life. This parameter remained essentially constant over the age range studied (Fig. 3). Although the slow half-life of elimination showed a tendency to increase with age, this phase contributed less than 30% to the overall urinary recovery of riboflavin. Furthermore, since the urinary excretion of the vitamin was only followed for 36 hr., it is probable that the age dependency of the slow half-life would cause the urinary recoveries of riboflavin to be even greater in the older subjects if urine was collected over a longer time period. Also, the length of the slow half-life relative to the duration of urine collections limits considerably the accuracy of this parameter.

Two factors should primarily affect the intestinal absorption of a substance such as riboflavin under the conditions of this study: the maximum absorptive capacity and the intestinal transit rate (Eq. 10). Since the peak excretion rate to dose ratio (Fig. 5), the time of its occurrence (Fig. 6), and the rapid half-life of elimination (Fig. 3) all seem unaffected by age, it may be concluded that the maximum absorptive capacity of riboflavin, when corrected for body surface area, is probably quite constant in the age range studied (Eq. 9). It therefore appears that an age-dependent increase in retention of the vitamin at intestinal absorption sites is responsible for the increased urinary recovery of riboflavin with age. This may be primarily due to decreased intestinal transit rate in older subjects. The possibility that the relative length of intestine capable of absorbing riboflavin increases with age cannot be ruled out although the age independence of V_{max} and t_p do not support this possibility.

Although the vitamin was administered as FMN in the present study, there is extensive evidence showing that FMN is rapidly and almost completely dephosphorylated to free riboflavin in the small intestine (5). The specialized transport process appears to involve subsequent rephosphorylation of riboflavin to FMN in the

Figure 3—Relationship between the rapid and slow half-life of elimination and the age (logarithmic scale) of the subjects. Squares and circles represent male and female subjects, respectively. Dashed lines connect repeated tests in the same subject and the solid line shows the least-squares regression fit of the data (Table I).

² The difference in the number of data points shown in Figs. 3–6 is due to the lack of availability of some of the values, usually because of not frequent enough urine collections, particularly in the younger subjects.

Figure 4—Relationship between the percent urinary recovery of riboflavin and age of the subjects. Symbols are defined as in Fig. 3.

Figure 5—Relationship between the ratio of peak excretion rate to dose and age of the subjects. Symbols are defined as in Fig. 3.

intestinal wall (5, 9). The possibility that conversion of the oral dose of FMN to riboflavin could be rate-limiting in the absorption process appears to be ruled out by identical urinary excretion data obtained after oral administration of either form of the vitamin (4, 5). The lack of change in the peak excretion rate to dose ratio with age and the observation (9) that the activity of intestinal phosphatases decreases rather than increases with age (at least in the rat) further rule out the FMN dephosphorylation rate as a factor causing increased absorption of riboflavin with age.

The dependence of absorption on age and intestinal transit time is not unique for riboflavin. D-Xylose, used commonly in clinical tests of intestinal absorption (10), exhibits absorption characteristics very similar to riboflavin. This sugar appears to be absorbed by a specialized process chiefly in the duodenum and proximal jejunum (10, 11). Lanzkowsky *et al.*, using both urinary excretion (12) and blood level (13) measurements, have shown a significant (twofold) increase in D-xylose absorption over an age range similar to that used in this study. Barreiro *et al.* (14) have further demonstrated a correlation of D-xylose absorption with intestinal transit time using direct measurements of intestinal motility in human subjects.

Many physiologic factors can influence drug absorption from the gastrointestinal tract (15), but little information is available on their role at various ages. A number of intestinal enzymes exhibit age-dependence in activity (1). Bender (16) has described a pronounced decrease in splanchnic blood flow in the elderly. Gastric emptying rate, though dependent on numerous factors and usually quite variable, is considered to be relatively constant throughout the childhood growth period (17). Intestinal secretions, the segmental activity of the bowel, the type of intestinal motility, the degree of vascularity, and the relative length of the intestine could also vary

Figure 6—Relationship between the time of occurrence of the peak excretion and age of the subjects. Symbols are defined as in Fig. 3.

with age (1, 2, 9) and affect drug absorption. The increase in riboflavin absorption with age may, in part, be related to one or more of these factors which may also alter the apparent retention of the vitamin at intestinal absorption sites.

The results of this study should not be extrapolated to ages outside of the age range investigated. Bender (18) has cited possible factors which may account for decreased specialized intestinal absorption of several compounds in the elderly and it is known that many physiologic processes undergo rapid quantitative changes in the neonate (17). The results of the present study do suggest, however, that prompt release of drugs from pharmaceutical dosage forms to assure absorption is even more important in young children than in adults, in view of the apparently shorter residence time of such drugs at intestinal absorption sites.

Synthesis of Potential Antimalarials: Primaquine Analogs

S. M. TALATI, M. R. LATHAM, E. G. MOORE, G. W. HARGREAVES, and
C. DeWITT BLANTON, Jr.*

Abstract □ A series of 8-aminoquinolines, analogous to primaquine and carrying a substituent in position two, have been synthesized by standard methods and tested for activity against *Plasmodium berghei* in mice. The results of preliminary biological tests are reported.

Keyphrases □ 8-Aminoquinolines—synthesis □ Antimalarial activity—8-aminoquinolines □ TLC—separation □ IR spectrophotometry—identity

Quinoline quinones may offer a lead in the search for better antimalarials, since the mechanism of action for the important 6-methoxy-8-aminoquinolines appears to involve their *in vivo* conversion to the quinoline-*o*-quinone (1, 2). Pamaquine-5,6-quinone (I) is apparently identical with a product isolated from the feces of chickens which have been fed the drug (3, 4), and this metabolite has been reported to be 16 times as active as the parent *in vitro* (5, 6). It is likely, therefore, that the antiplasmodial activity (*Plasmodium gallinaceum*) was associated with the metabolic intermediate. Thus, the high *in vitro* antimalarial activities of 6-hydroxypentaquine, pentaquine-5,6-quinone, and pamaquine-5,6-quinone, in contrast to the *in vitro* inactivity of pentaquine (II) and pamaquine (III), lend support to Schonhofer's theory (7-9) that the *in vivo* action of the 8-aminoquinolines upon the erythrocytic or tissue stages of malaria plasmodia is due to the quinonoid products to which these drugs are converted by the host.

Much of the early work directed toward the synthesis of various 5,6-quinones was apparently abandoned because of compound instability. However, a clue to a technique for stabilizing the quinoline-*o*-quinone may be found in a paper by Holmes (10), involving introduction of a 2-hydroxyl function into the quinoline nucleus. Furthermore, the introduction of such a group suggests a modification which might be made in the 8-aminoquinolines in order to lower toxicity. Holmes (10) speculated that the oxidative detoxication of quinine by rabbit liver, far from indicating, as usually assumed, the advantage of blocking the 2-position of the quinoline antimalarials, might equally well be construed as an argument in favor of deliberately introducing an oxygen at this position. Specifically, it appears possible that substances which are structurally related to the 8-aminoquinoline drugs, and which are both quinoline quinones and carbostyrils, might exhibit a desirable combination of low toxicity and high antimalarial activity.

This report describes experiments directed toward the synthesis of substituted 8-aminocarbostyryl-5,6-quinones (IV) with particular attention given to the synthesis of analogs of primaquine (V), as this agent is among the more active 8-aminoquinoline antimalarials. The target compounds (IV) were not obtained, but a series of 2-benzyloxy- or 2-hydroxy-6-alkoxy-8-(amino-

III; R = -CH(CH₃)(CH₂)₃N(C₂H₅)₂
V; R = -CH(CH₃)(CH₂)₃NH₂

alkylamino)quinolines were successfully prepared. These represent a new group of 8-aminoquinolines, which are the immediate precursor of the carbostyryl-*o*-quinones.

To achieve the synthesis of the desired carbostyrils, it was necessary to prepare 2-benzyloxy-6-alkoxy-8-aminoquinoline (VI) (11), followed by incorporation of an appropriate side chain at position-8 (VII, VIII) (11, 12) and cleavage of the ether (IX) (11) or ethers (X) (11, 13) (see Scheme I). Theoretically, oxidation (1, 10) of this latter product (IX or X) should give the carbostyryl-*o*-quinone (XI). Present evidence (IR, elemental analysis, molecular weight, *etc.*) suggests that the quinoline nucleus was destroyed in attempts to prepare the carbostyryl-5,6-quinones.

In addition to the 6-methoxy derivatives, the authors have prepared several 6-ethoxy derivatives, since reports (13) in the literature indicate that ethyl ethers are more readily cleaved to the hydroxyl compound. The nature of the substituent on the 8-amino function was varied by incorporating different homologs of the alkylamino moiety (VIII), as well as some arylalkyl amino moieties (XII) (see Scheme II).

As cleavage of the 2-benzyloxy analogs produced erratic results during attempted hydrogenolysis to the 2-hydroxy analogs (IXa-e) (11),¹ a 2-methoxy analog (VIIId) was prepared in hope of achieving simultaneous acid cleavage of the 2,6-dialkoxy moieties (X). Preliminary experiments for this latter reaction have not been successful.

PHARMACOLOGICAL RESULTS

Test Methods—The compounds were tested against *P. berghei* in mice and *P. gallinaceum* in chicks and *P. gallinaceum* in mosquitoes.²

¹ Only one of the 2-hydroxy-6-alkoxy-8-aminoquinoline derivatives was obtained by this procedure—*viz.*, IXd.

² These test data were supplied by the Walter Reed Army Institute of Research, Washington, D. C.

Mice were infected by two routes: (a) intraperitoneal injection of parasitized blood, and (b) intraperitoneal injection of a sporozoite suspension. The first test was conducted by Dr. L. Rane, University of Miami (14-16) and the other by Dr. Maurice King, Illinois Institute of Technology.³

The testing in chicks was also conducted by Dr. Rane⁴ and the

³ The detailed test method will be published elsewhere. Mice were treated with drug on Days -1, 0, and 1 days of infection. Blood smears for parasite determination are made on Days 6, 10, 14, and 21 after infection. Drug effectiveness was evaluated by comparing the mean parasitemia of the drug-treated group to that of the nondrug-treated controls at slide Day 14. A value of less than 0.25 of the control value was considered for activity. Primaquine was active under these conditions.

⁴ Chicks (9-12 days old) were infected with a uniform disease fatal to 100% of untreated controls within 3-4 days. Compounds under test were dissolved or suspended in peanut oil and administered subcutaneously or *per os* immediately after infection of the chicks. An increase of 100% in survival time was considered to be the minimum effective response to the antimalarial activity of a drug. Chicks that survived for 30 days were recorded as cured.

mosquito test by Dr. E. J. Gerberg, Insect Control and Research, Inc., Baltimore, Md. (17).

Testing Results—Table I summarizes the results of the Compounds VIIIa-e. Chloroquine, quinine, and primaquine are included for comparison. The other compounds discussed in this paper are not included because they were found inactive in these test systems.

Compound VIIIa was also tested as a prophylactic agent by Dr. King. It was found inactive at 480 mg./kg. while primaquine demonstrated activity at 90 mg./kg.

None of the compounds was active in the mosquito test.

EXPERIMENTAL

All melting points were taken on a Mel-Temp capillary melting point apparatus and are uncorrected. The microanalyses and molecular weight determinations were by Galbraith Laboratories, Inc., Knoxville, Tennessee. IR spectra were determined with a Perkin-Elmer model 137 Infracord. TLC was performed on plates coated with silica gel G and Eastman chromatogram sheets, type 6060.

6-Methoxy-8-nitroquinoline and 6-Ethoxy-8-nitroquinoline (XIII)—These quinolines were prepared from 4-methoxy-2-nitroaniline and 4-ethoxy-2-nitroaniline by the procedure of Mosher *et al.* (18) or by the procedure of Yale *et al.* (19). (6-Methoxy-8-nitroquinoline was also purchased from Winthrop Laboratories, N. Y.)

Table I—Increase in Mean Survival Time (Days)

Compound	Dosage, mg./kg.			<i>P. gallinaceum</i> in Chicks ^b 120
	<i>P. berghei</i> in Mice ^a			
	40	160	640	
VIIIa	1.7	3.5	15.7 ^c	6.4
VIIIb	1.7	3.3	10.2 ^d	
VIIIc	—		Inactive	6.8
VIIId	—		Inactive	6.4 ^e
VIIIe	0.5	3.9 (2/5) ^f	(5/5) ^f	9.5 (3/5) ^f
Chloroquine	0.5	4.1	8.6 ^d	7.6
Quinine	4.6	10.0	(5/5) ^f	
Primaquine	1.2	3.4	6.5	
phosphate	4.5	8.8 (2/5) ^f	(5/5) ^f	

^a A compound is considered to be active if the mean survival time of the treated group is more than double the mean survival time of the control group (5 animals were used in a group). Controls normally live 6-7 days. ^b Controls normally live 3-3.5 days. ^c Curative for one animal. ^d Curative for two animals. ^e At 140 mg./kg. ^f Drug toxicity is considered the cause of death when treated animals die before controls; fractions in parentheses represent toxicity death over total animals in treated group.

6-Methoxy-8-nitroquinoline and 6-Ethoxy-8-nitroquinoline Methiodides (XIV)—The quaternization procedure of Mislow and Koepfli (11) was utilized. The yield of the 6-methoxy derivative (XIVa) was 90–98% of theory, melting at 143–144° (lit. m.p. 149°). 6-Ethoxy-8-nitroquinoline methiodide (XIVb) was prepared in a crude yield of 98% and, after recrystallization from butanol, melted at 143–145°.

6-Methoxy-1-methyl-8-nitro-2-quinolone and 6-Ethoxy-1-methyl-8-nitro-2-quinolone (XV)—The crude methiodides (XIV) were oxidized by the procedure of Mislow and Koepfli (11). 6-Methoxy-1-methyl-8-nitro-2-quinolone (XVa), prepared in a 61.5% yield, melted at 190–191° (lit. m.p. 186–187°). 6-Ethoxy-1-methyl-8-nitro-2-quinolone (XVb) was recrystallized from methanol to give a 50% yield, m.p. 154–155°. (If pure methiodide was used, the yield could be raised to 87%.)

2-Chloro-6-methoxy-8-nitroquinoline and 2-Chloro-6-ethoxy-8-nitroquinoline (XVI)—Chlorination of the quinolone (XV) was carried out by the procedure of Mislow and Koepfli (11). The 2-chloro-6-methoxy derivative (XVIa) was obtained in a 71% yield, m.p. 224–226° (lit. m.p. 225–226°). 2-Chloro-6-ethoxy-8-nitroquinoline (XVIb) was prepared in a 77% yield, m.p. 162–162.5°.

Anal.—Calcd. for C₁₁H₉ClN₂O₃: C, 52.28; H, 3.56; N, 11.09. Found: C, 52.30; H, 3.60; N, 10.92.

6-Methoxy-8-nitrocarbostyryl and 6-Ethoxy-8-nitrocarbostyryl (XVII)—Hydrolysis of the chloro compounds (XVI) was accomplished using the procedure of Mislow and Koepfli (11). The 6-methoxy derivative (XVIIa) melted at 209–211° (lit. m.p. 210–211°). The ethoxy derivative (XVIIb) was obtained in a yield of 76% and melted at 162–164°.

Anal.—Calcd. for C₁₁H₁₀N₂O₄: C, 56.39; H, 4.30; N, 11.87. Found: C, 56.18; H, 4.33; N, 11.90.

2-Benzoyloxy-6-methoxy-8-nitroquinoline and 2-Benzoyloxy-6-ethoxy-8-nitroquinoline (XVIII)—The carbostyryls (XVII) were benzylated by standard procedures (11). The 6-methoxy derivatives (XVIIIa; 65–76% yield) melted at 137–139° (lit. m.p. 139–140°).

2-Benzoyloxy-6-ethoxy-8-nitroquinoline (XVIIIb), obtained in a 52% yield, melted at 125–126°.

Anal.—Calcd. for C₁₈H₁₆N₂O₄: C, 66.66; H, 4.93; N, 8.64. Found: C, 66.82; H, 4.83; N, 8.62.

2-Benzoyloxy-6-methoxy-8-aminoquinoline and 2-Benzoyloxy-6-ethoxy-8-aminoquinoline (VI)—Reduction of the nitro compound (XVIII) was accomplished by the procedure of Mislow and Koepfli (11). Yields of 40–60% were obtained for the 6-methoxy derivative (VIa), which melted at 84–85° (lit. m.p. 86–87°). 2-Benzoyloxy-6-ethoxy-8-aminoquinoline, obtained as a gray powder (74%), melted at 120–122°.

Anal.—Calcd. for C₁₈H₁₈N₂O₂: C, 72.98; H, 6.08; N, 9.46. Found: C, 73.54; H, 6.37; N, 9.27.

Sample revealed only one spot on TLC (silica gel G plate eluted with chloroform–ethanol, 15:1).

Preparation of 2-Methoxy-6-ethoxy-8-nitroquinoline (XIX)—To a solution of 23.85 g. of 6-ethoxy-8-nitrocarbostyryl (XVIIb) in 500 ml. of hot 2.5 N sodium hydroxide was added 200 ml. of dimethyl-sulfate in 25-ml. portions, the solution being basified after each addition. On cooling, light-yellow needles crystallized out. Recrystallization from ethanol gave a product which had three spots on TLC. The material was placed on an alumina column and eluted with benzene–chloroform, chloroform–ethanol, and ethanol. Fraction I (benzene–chloroform) gave 12.8 g. of shining yellow plates, m.p. 128–129°. Fraction II (chloroform–ethanol) gave 4.4 g. of yellow needles, m.p. 155–156°. The melting point and IR spectrum revealed that the product from Fraction II was identical to 1-methyl-6-ethoxy-8-nitro-2-quinolone (XVb). The last fraction gave a small amount of starting material, m.p. 164–165°. The product from Fraction I was recrystallized as the 2-methoxy-6-ethoxy-8-nitroquinoline. This product was homogeneous on TLC (benzene–chloroform, 15:3).

Anal.—Calcd. for C₁₂H₁₂N₂O₄: C, 58.06; H, 4.83; N, 11.29. Found: C, 57.95; H, 4.92; N, 11.15.

Table III—Substituted 8-(Aminoalkylamino)quinolines (VIII)

Structure (VIII)	R	R'	R''	n	M.p.	Yield	Anal., %	
							Calcd.	Found
a C ₂₂ H ₂₉ I ₂ N ₃ O ₂	CH ₃	C ₆ H ₅ CH ₂ -	CH ₃	3	125 dec.	74–92	C, 42.35 H, 4.67 N, 6.76	C, 42.51 H, 4.71 N, 6.66

^a This compound (VIIIb) was also prepared as the monohydrated diphosphate salt. Calcd. for C₂₁H₃₁N₃O₁₁P₂: C, 44.62; H, 5.84; N, 7.43. Found: C, 44.59; H, 6.29; N, 7.43. ^b Percent iodine: calcd., 41.68; found, 41.68.

If care was taken to ensure complete solution of the 6-ethoxy-8-nitrocarbostyryl before addition of the dimethylsulfate, it was possible to raise the yield of desired product. In one case, tetrahydrofuran was employed to facilitate solution in the hot alkali solution (65–70°). With this modification, the procedure gave 86.6% 2-methoxy-6-ethoxy-8-nitroquinoline, m.p. 125–126°.

2-Methoxy-6-ethoxy-8-aminoquinoline (VIc)—A suspension of 2-methoxy-6-ethoxy-8-nitroquinoline was reduced on the Parr apparatus with platinum oxide. The product, which melted at 140–143° (72%), was used in the next step without elemental analysis (preparation of VIIIId).

Preparation of *N*-(Bromoalkyl)phthalimides (XX)—The procedure of Elderfield *et al.* (20) was employed. [*N*-(3-Bromopropyl)-phthalimide was obtained commercially.]

Preparation of 2-Benzylxy(or methoxy)-6-methoxy(or ethoxy)-8-(phthalimidoalkylamino)quinolines (VIIa–e, Table II)—The procedure of Elderfield (20) was slightly modified for this condensation. A solution of 0.08 mole of 2-benzylxy(or methoxy)-6-methoxy(or ethoxy)-8-aminoquinoline, 0.4 mole of sodium acetate, and 0.08 mole of the appropriate *N*-(bromoalkyl)phthalimide in 300 ml. of 66% ethanol was refluxed for 3 days. An additional quantity of the phthalimide (0.08 mole) was added on the second day and 0.4 mole of sodium acetate was added each day. The pH was maintained near 7–8. A dark-brown oil separated from the reaction. The reaction mixture was cooled, diluted with 600 ml. of water, saturated with potassium carbonate, and extracted with ether. (Any solid, which appeared, was collected with the ether fraction.) The ether extract was concentrated to one-half its original volume and chilled to give a yellow precipitate. [In some cases, it was necessary to dry the ether extract (MgSO₄), evaporate to dryness, and add anhydrous ether to achieve a precipitate.] The product which dissolved in the ether was found to be a mixture of starting materials. This procedure generally yielded a product of sufficient purity for the next step—TLC showed the product to be homogeneous. Analytical samples were prepared by recrystallization from 95% ethanol or aqueous DMF (see Table II for physical data).

Preparation of 2-Benzylxy(or methoxy)-6-methoxy(or ethoxy)-8-(aminoalkylamino)quinoline Dihydriodides (VIIIa–e, Table III)—The procedure of Mosher (12) was utilized. In some cases, the phthalimido product was not readily soluble in ethanol, and solution was achieved by the addition of chloroform. TLC showed the product to be homogeneous (methanol–diethylamine, 19:1) (see Table III for physical data).

Preparation of 6-Ethoxy-8-(3-aminopropylamino)carbostyryl Monoacetate (IXb)—A solution of 2-benzylxy-6-ethoxy-8-(3-aminopropylamino)quinoline was reduced on the Parr apparatus with palladium oxide. The product was isolated as the monoacetate and recrystallized from absolute ethanol to give light-yellow needles (47.7%), m.p. 183–184° (IR 3450, 1670, 1610, and 1550 cm.⁻¹).

Anal.—Calcd. for C₁₆H₂₃N₃O₄: C, 58.22; H, 7.16; N, 13.08. Found: C, 58.00; H, 7.33; N, 12.87.

2-Benzylxy-6-methoxy-8-(4-amino-1-methylbutylamino)quinoline (VIIId) and 2-benzylxy-6-methoxy-8-(4-aminobutylamino)quinoline (VIIc) were subjected to similar reaction conditions, but the analytical data were inconclusive and structural assignments have not been made at this time.

(VIIId to IXa) *Anal.*—Calcd. for C₁₈H₂₁N₃O₂·CH₃COOH (IXa): C, 61.07; H, 7.18; N, 12.57; mol. wt. 334. Found: C, 57.29; H, 6.89; N, 13.35; mol. wt. 210 (CH₃OH).

(VIIc to IXc) *Anal.*—Calcd. for C₁₄H₁₉N₃O₂·CH₃COOH (IXc): C, 60.00; H, 6.87; N, 13.12. Found: C, 55.06; H, 6.70; N, 13.49.

In one experiment, attempts were made to isolate the carbostyryl as the hydriodide salt. It was not possible to obtain a product that was homogeneous on TLC.

Anal.—Calcd. for C₁₅H₂₁N₃O₂·2HI: C, 33.96; H, 4.15; I, 48.21; N, 7.92. Found: C, 36.44; H, 4.54; I, 46.22; N, 7.10.

Attempted Preparation of 2,6-Dihydroxy-8-(3-aminopropylamino)quinoline (X)—A solution of 8 g. (0.022 mole) of 2-benzylxy-6-ethoxy-8-(3-aminopropylamino)quinoline in 50 ml. of methyl cellosolve was heated and stirred with 80 ml. of 48% hydrobromic acid at 120–130° for 4 hr. The solvent was evaporated, *in vacuo*, to give the hydrobromide which was suspended in water and neutralized with sodium bicarbonate to give a product of unknown structure. This substance was recrystallized from pyridine–water to give yellow platelets, m.p. 202–203°. IR spectrum indicated ether cleavage, showing a band at 1680 cm.⁻¹, characteristic for carbonyl

absorption. However, molecular weight and elemental analysis did not correlate with calculated values. TLC showed the product to be homogeneous (methanol–diethylamine, 15:2).

Anal.—Calcd. for C₁₂H₁₃N₃O₂: C, 61.80; H, 6.43; N, 18.02; mol. wt., 233. Found: C, 70.90; H, 7.33; N, 11.83; mol. wt. (DMF), 480.

2-Benzylxy-6-methoxy-8-(4-aminobenzylamino)quinoline Dihydrochloride (XII)—This procedure was adapted after that of Tipson and Clapp (21). Two grams (0.007 mole) of 2-benzylxy-6-methoxy-8-aminoquinoline was mixed with 1.5 g. of *p*-nitrobenzaldehyde in 25 ml. of DMF and 5 drops of piperidine. This mixture was allowed to stand for 1 hr. with stirring after heating just briefly on a water bath. The solution was then shaken on the Parr apparatus, under hydrogen, with platinum oxide until 3 p.s.i. of pressure had been lost. Filtration of the catalyst and dilution of the filtrate with water gave a greenish-yellow product. This substance was dissolved in ether, dried, and treated with charcoal before removal of the drying agent. Hydrogen chloride was passed through the ethereal solution to give a product melting at 225–227° (78% yield). TLC revealed only one spot (methanol–diethylamine, 19:1) (IR 3400, 2850, 1610, and 1580 cm.⁻¹). Analytical sample recrystallized from ethanol–ether.

Anal.—Calcd. for C₂₄H₂₁N₃O₂·2HCl: C, 62.88; H, 5.46; N, 9.17. Found: C, 62.76; H, 5.61; N, 9.20.

It was possible to isolate and characterize the intermediate, 2-benzylxy-6-methoxy-8-(*p*-nitrobenzylideneamino)quinoline, m.p. 118–122° (XIIc).

Anal.—Calcd. for C₂₄H₁₉N₃O₄: C, 69.73; H, 4.60; N, 10.16. Found: C, 69.65; H, 4.73; N, 9.92.

2-Benzylxy-6-methoxy-8-(3-aminobenzylamino)quinoline dihydrochloride (XIIb), m.p. 149–152°, was prepared by a similar procedure.

Anal.—Calcd. for C₂₄H₂₁N₃O₂·2HCl (XIIb): C, 62.88; H, 5.46; N, 9.17. Found: C, 62.68; H, 5.32; N, 9.09.

Odor Threshold and Gas-Chromatographic Assays of Vaginal Odors: Changes with Nitrofurazone Treatment

A. DRAVNIKS, B. K. KROTOSZYNSKI, L. KEITH*, and I. M. BUSH*

Abstract □ Although vaginal disorders are frequently accompanied by malodors, the efficiency of drugs to reduce the malodors by reducing the infection has been difficult to estimate. Recently, techniques have become available for combining sensory and gas-chromatographic approaches to compare odor intensities of complex vapor mixtures. These techniques were applied to vaginal odors. An apparatus was devised to collect vaginal vapors in a form suitable for odor-relevant gas-chromatographic analyses, as well as for odor-threshold determinations. Odor changes in vaginal vapors upon treatment with nitrofurazone vaginal suppositories were studied on five patients with several types of disorders (hematuria, endometritis, and stress incontinence). The distribution of odorous components in the gas chromatograms reflected, through disappearance of many malodorous peaks, a significant reduction in the content of the malodorous volatile compounds in the vaginal vapors. Odor-threshold measurements were conducted in an apparatus where nonodorous methane tracer and a hydrogen-flame ionization detector were used to measure the degree of vapor dilution needed to reach the threshold, using the ASTM odor-threshold test design combined with ED₅₀ statistics. These measurements similarly indicated that odors were reduced by the drug.

Keyphrases □ Vaginal odor threshold, intensity—analysis □ Odors, vaginal—threshold, intensity determination □ Nitrofurazone effect—vaginal odors □ GLC—analysis

It is usually noted that a reduction in bacterial population in suitable media is accompanied by a reduction in the odors. Odor reduction is often subjectively observed when the antibacterial agent nitrofurazone¹ is used in the treatment of vaginal disorders accompanied by malodor. In the absence of a satisfactory method for quantitative or precise qualitative assay of odors, such observations have remained in the form of testimonials.

Recently, techniques have become available for more detailed studies of the odors in complex mixtures. These techniques are based on combinations of psychophysical (sensory) and gas-chromatographic methods, the latter providing means for collecting and separating the components of odorous vapors. In the present work these techniques were adapted to assay the vaginal odors and their changes upon treatment with an antibacterial

preparation. Odor thresholds of vaginal vapors were also determined.

PRINCIPLES OF ODOR MEASUREMENT

The odor results from interaction of vapors with the observer's chemoreceptors (primarily olfactory and to some extent trigeminal). Substances differ in odor thresholds, *i.e.*, in the lowest concentrations in air at which the odors of their vapors can be detected. Observers also differ in sensitivity (olfactory acuity), so that odor thresholds are represented not by sharp concentration levels but rather by concentration zones, within which the thresholds for different observers can vary severalfold. To a lesser extent, thresholds as estimated by the same observer may vary from time to time.

Above threshold levels, odor intensity increases in proportion to a fractional power (0.2–0.7) of the odorant concentration in air. These relations are expressed in Stevens' law (1, 2):

$$I = k (C - C_{thr})^x \quad (\text{Eq. 1})$$

where I is psychophysical odor intensity, k is a coefficient (small for weak odors, large for strong odors), C is concentration of the odorant in air, C_{thr} is threshold concentration of the odorant, and x is an exponent. The values of k , C_{thr} , and x are not necessarily related. Corollaries of this expression are: (a) odor intensity experienced by an observer does less than double when the odorant's concentration is doubled; *e.g.*, for $x = 0.5$, the concentration must increase by a factor of 4 to increase the intensity by a factor of 2; (b) if an odorant A has smaller values of k and x than another odorant B, an undiluted A can smell weaker than undiluted B, while diluted A can smell stronger than similarly diluted B; (c) since the highest possible concentration of an odorant is at its saturation pressure, odorants with low x , or high threshold and an average x , may never reach very high odor intensity.

Odor-threshold values, therefore, do not necessarily indicate the undiluted odor intensity; rather, the odor of a lower threshold odorant will be noticed farther from the source than will that of a higher threshold odorant. In addition, above the threshold, the character of the odor can be objectionable, as with the malodors, or acceptable, as with fragrances.

The composition of odorous vapors of biochemical origin is complex, with many odorants participating. Odorants present at sub-threshold concentrations can summate (sometimes even synergistically) to reach threshold and can modify the character of odors of other substances which are present at suprathreshold levels. In odor assay, therefore, all those substances that are present at levels exceeding reasonable fractions, *e.g.*, one-tenth of their threshold concentrations, must be considered. Gas-chromatographic techniques permit the delivery of separated components for sensory

Odor Threshold and Gas-Chromatographic Assays of Vaginal Odors: Changes with Nitrofurazone Treatment

A. DRAVNIKS, B. K. KROTOSZYNSKI, L. KEITH*, and I. M. BUSH*

Abstract □ Although vaginal disorders are frequently accompanied by malodors, the efficiency of drugs to reduce the malodors by reducing the infection has been difficult to estimate. Recently, techniques have become available for combining sensory and gas-chromatographic approaches to compare odor intensities of complex vapor mixtures. These techniques were applied to vaginal odors. An apparatus was devised to collect vaginal vapors in a form suitable for odor-relevant gas-chromatographic analyses, as well as for odor-threshold determinations. Odor changes in vaginal vapors upon treatment with nitrofurazone vaginal suppositories were studied on five patients with several types of disorders (hematuria, endometritis, and stress incontinence). The distribution of odorous components in the gas chromatograms reflected, through disappearance of many malodorous peaks, a significant reduction in the content of the malodorous volatile compounds in the vaginal vapors. Odor-threshold measurements were conducted in an apparatus where nonodorous methane tracer and a hydrogen-flame ionization detector were used to measure the degree of vapor dilution needed to reach the threshold, using the ASTM odor-threshold test design combined with ED₅₀ statistics. These measurements similarly indicated that odors were reduced by the drug.

Keyphrases □ Vaginal odor threshold, intensity—analysis □ Odors, vaginal—threshold, intensity determination □ Nitrofurazone effect—vaginal odors □ GLC—analysis

It is usually noted that a reduction in bacterial population in suitable media is accompanied by a reduction in the odors. Odor reduction is often subjectively observed when the antibacterial agent nitrofurazone¹ is used in the treatment of vaginal disorders accompanied by malodor. In the absence of a satisfactory method for quantitative or precise qualitative assay of odors, such observations have remained in the form of testimonials.

Recently, techniques have become available for more detailed studies of the odors in complex mixtures. These techniques are based on combinations of psychophysical (sensory) and gas-chromatographic methods, the latter providing means for collecting and separating the components of odorous vapors. In the present work these techniques were adapted to assay the vaginal odors and their changes upon treatment with an antibacterial

preparation. Odor thresholds of vaginal vapors were also determined.

PRINCIPLES OF ODOR MEASUREMENT

The odor results from interaction of vapors with the observer's chemoreceptors (primarily olfactory and to some extent trigeminal). Substances differ in odor thresholds, *i.e.*, in the lowest concentrations in air at which the odors of their vapors can be detected. Observers also differ in sensitivity (olfactory acuity), so that odor thresholds are represented not by sharp concentration levels but rather by concentration zones, within which the thresholds for different observers can vary severalfold. To a lesser extent, thresholds as estimated by the same observer may vary from time to time.

Above threshold levels, odor intensity increases in proportion to a fractional power (0.2–0.7) of the odorant concentration in air. These relations are expressed in Stevens' law (1, 2):

$$I = k (C - C_{thr})^x \quad (\text{Eq. 1})$$

where I is psychophysical odor intensity, k is a coefficient (small for weak odors, large for strong odors), C is concentration of the odorant in air, C_{thr} is threshold concentration of the odorant, and x is an exponent. The values of k , C_{thr} , and x are not necessarily related. Corollaries of this expression are: (a) odor intensity experienced by an observer does less than double when the odorant's concentration is doubled; *e.g.*, for $x = 0.5$, the concentration must increase by a factor of 4 to increase the intensity by a factor of 2; (b) if an odorant A has smaller values of k and x than another odorant B, an undiluted A can smell weaker than undiluted B, while diluted A can smell stronger than similarly diluted B; (c) since the highest possible concentration of an odorant is at its saturation pressure, odorants with low x , or high threshold and an average x , may never reach very high odor intensity.

Odor-threshold values, therefore, do not necessarily indicate the undiluted odor intensity; rather, the odor of a lower threshold odorant will be noticed farther from the source than will that of a higher threshold odorant. In addition, above the threshold, the character of the odor can be objectionable, as with the malodors, or acceptable, as with fragrances.

The composition of odorous vapors of biochemical origin is complex, with many odorants participating. Odorants present at sub-threshold concentrations can summate (sometimes even synergistically) to reach threshold and can modify the character of odors of other substances which are present at suprathreshold levels. In odor assay, therefore, all those substances that are present at levels exceeding reasonable fractions, *e.g.*, one-tenth of their threshold concentrations, must be considered. Gas-chromatographic techniques permit the delivery of separated components for sensory

assay at concentrations 10–20 times higher than those in the original odorous air mixtures. In this way, mixtures can be studied for predominance and intensities of certain odor notes (*e.g.*, obviously objectionable, fragrant, *etc.*).

METHODS

Vaginal Vapor Collection—Figure 1 shows the arrangement for vaginal vapor collection. A perforated Teflon tube 1.91-cm. (0.75-in.) i.d. and 9.52 cm. (3.75 in.) long (with the disklike collar) was provided with two openings at the outer end. One of these was connected to a vapor collector by Teflon tubing heated along its entire length by low-voltage Teflon-insulated resistance wire. The collector was made of stainless-steel tubing 0.97-cm. (0.38-in.) i.d. and 25.4 cm. (10 in.) long, packed with Teflon powder coated with 10% hydrocarbon grease, mol. wt. about 1000 (Apiezon L). Prior to use, the organic vapors were removed from the collector by heating it in a stream of highly purified helium until a satisfactory base line gas chromatogram was obtained. During the sample collection from the vagina, the collector was kept in an aluminum block at 38° to prevent the condensation of water from vapors. Vaginal vapors were made to flow into the collector by allowing silicone oil to flow from the upper to the lower of the two flasks shown. A dry ice-propanol trap between the collector and the oil prevented atmospheric or oil vapors from reaching the collector. Organic vapors from the vagina dissolved in the hydrocarbon grease coating of the collector, while water vapor passed through.

The other Teflon tube leading to the vaginal insert allowed air to replace that which was removed into the collector. To block room vapors from entering the collector *via* this Teflon tube, room air was first passed through an activated carbon adsorber cooled to -80° by a dry ice-propanol mixture. Usually 2 l. of air was sampled during a

Figure 2—Example of ED_{50} odor-threshold determination of vaginal vapors.

collection period of 20 min. In addition to the collected vapors, the Teflon insert with its vaginal debris was used for odor-threshold studies. Immediately after removal from the patient, the insert was placed into an odorless glass vessel provided with inlet and outlet tubing. If odor study on the insert was postponed, the vessel and contained insert were stored in a freezer and brought back to room temperature shortly before study.

Odor-Threshold Measurements—The statistical design followed a combination of triangle test (3) and quantal response (4) methods. The vapor from the insert with vaginal debris, in known dilutions with nitrogen, was led in a special olfactometer to one of three sniffing ports. In this olfactometer, nonodorous methane carries the vapor into a nitrogen stream. The amount of subsequent dilution by cryogenically deodorized nitrogen is monitored continuously by a hydrogen-flame ionization detector. The detector indicated the methane content by a proportional increase in the ionization current. The measurements permitted calculations of the degree of dilution of odorous vapors in the sniffing port.

The panel of observers sniffed at each of the three sniffing ports by using the statistical design of the ASTM method (5). A negative response was recorded if no odor was reported at any of the ports, or if the observer reported odor at a wrong port. A positive response was recorded if an odor was reported at a correct port (ports were changed randomly). Concentrations of odorous vapors were increased threefold for the next observations, and so on. At each of the concentrations, several observers reported their judgments independently.

Data were tabulated, ranked, and plotted as shown in Table I and Fig. 2. This approach is the same as that used in the study of responses to poisons or other drugs, except that here the response is a positive observation of odor. The concentration level at probability = 0.50 is the odor ED_{50} , the lowest level at which half of the observers would sense an odor. The detector units of the olfactometer were converted to p.p.m. of headspace, using the methane calibration factor.

Gas-Chromatographic Sensory Assay—The vapors in the collector (Fig. 1) were transferred by a special injection needle to a gas chromatograph, using procedures described elsewhere (6). The transfer was effected in a device in which high-purity helium was passed through the collector and injection needle, connected in series with a short length of Teflon tubing. The needle was cooled with liquid nitrogen while a heated copper block traveled along the collector at the velocity of 2.54 cm. (1 in.)/min. in the direction of He flow. The motion was provided by means of a motor-actuated string device (7). Vapors from the collector were eluted in the direction opposite to that which was followed during collection. This method minimized the contamination of the sample by impurities generated by decomposition of the collector's hydrocarbon-grease phase, since each portion of the collector was heated for only a short time.

In the gas chromatograph the carrier gas was He at a flow rate of 10 ml./min. An open tubular column 15.24 m. (50 ft.) long, coated with polyethylene glycol (Carbowax 20 M), was used, and temperature was programmed from 60 to 180° at 4° /min. A hydrogen-flame ionization detector was used, with a sensitivity of approximately 4000

pg./cm.² of the gas-chromatographic peak area² at 0.1 × 1 electro-meter setting (the highest sensitivity setting available). A series of *n*-alkanes was run as standard for conversion of retention times to approximate Kovats Indices (8) using a fifth-order polynomial curve and a computer to interpolate values.

At the exit from the gas-chromatographic column 110 ml./min. of He was added to the column effluent and the combined effluent of 120 ml./min. was split 1:1 so that 60 ml./min. was delivered, respectively, to the detector and to a sniffing port. A chemist experienced in this technique observed and recorded the odor of the gas chromatographically separated components (9, 10).

By this technique the components of the vapors are delivered at their respective concentrations at the ports in a sequence which depends on vapor pressures and polarities (in a gas chromatographic sense) of the components. The following concentration relations apply. For example,³ let the original concentration of a component in the air = *n*-g./ml. At perfect efficiency the collection and transfer from 2000 ml. will deliver 2000 *n*-g. into the gas chromatograph. Of this, 1000 *n*-g. goes to the sniffing port, diluted in He carrier and subsequently, on leaving the port, to some extent also diluted by room air. A typical peak was carried out in 20–40 ml. He, and if the substance was evenly distributed (in mixing with air before reaching the nose), the actual concentration reaching the nose was 10 *n*-20 *n*-g./ml. This was higher, by an order of magnitude than that in the original vaginal air sample. Due to losses in collection and transfer, however, the actual concentration factor was somewhat less.

Potent odorants with low-odor thresholds can exhibit odor at concentrations in the range 0.1–10 pg./ml. of air. Calculations indicate that by collecting organic vapors from 2 l. of air and using a detector with sensitivity on the order of 1000 pg./cm.² of chart area, most odor-relevant compounds will be adequately represented in the gas chromatograms. A few, however, still can be odorous without exhibiting visible peaks.

The odor characters of the various components are tabulated in broad categories. The most convenient categorization is a hedonic one; it is based on a scale of "obviously fragrant" and "pleasant" at one end to "objectionable" and "highly objectionable" (repulsive or nauseating) at the other. Between these extremes there is a category of odors of slight, mild, or moderate character. These do not impress observers as being significantly fragrant or objectionable. This intermediate category consists of odors, some of which do not immediately resemble a familiar odor and others which do have an obviously distinct recognizable character ("musty," "sour," "mushroomlike," "burnt," "medicinal," etc.).

Because of differences in the character and intensity of odors of the components, the number of distinguishable peaks and their prominence are not the best guides for the comparison of odors of different samples. In addition, some peaks may represent more than

one component, each with different sensory characteristics. Most organic materials are odorous at sufficient concentrations. However, some substances, such as hydrocarbons, have high thresholds and can produce large peaks in chromatograms but are not odorous on elution from the sniffing port, and, therefore, contribute little to the initial (mixed) odor. Also, a rich pattern with many larger peaks can indicate strength of an odor but not its objectionability.

Although overall richness can be a guide to the comparison of samples which are similar in composition, much more odor-relevant information is obtained by tabulating peaks by their odor categories and comparing the number of peaks in different categories. As unpleasant odors come under control during treatment, the number of objectionably odorous peaks decreases. Such effects occur even in those chart locations where no pleasantly odorous peaks emerge.⁴ In locations where both objectionable and nonobjectionable and/or

Figure 4—Changes in number of odorous peaks in vaginal-vapor chromatograms upon nitrofurazone treatment.

pleasant peaks coexist, and may be only partially resolved, malodor control leads to a decrease of malodorous components. As a result overall odor at that zone of the chromatogram changes from malodorous toward the neutral or fragrant. Also, odorous peaks can become smaller and nondetectable at the sniffing port whenever the odorant there falls below its odor threshold. In essence the process serves as a "spectrograph" for the odorants, with magnification and focussing to aid the odor observations.

Figure 3 illustrates gas chromatograms obtained in a case in which overall odor intensity of vaginal vapors decreased sharply upon treatment with nitrofurazone. The number of components observed in the gas chromatogram also decreased. In this case, the most significant change occurred in the odor character of the peaks:

Chromatogram No.	Number of Peaks			
	Objectionable	No Odor	Neutral	Fragrant
1	14	13	2	0
2	—	4	9	1

Schedule of Tests—Table II shows the diagnoses and the arrangement of test samplings. All subjects were selected from hospitalized patients.

The suppositories (Rx) contained nitrofurazone, 0.3%, in a base of glyceryl monolaurate and polyoxyethylene (4) sorbitan monostearate. They melt at body temperature and are self-emulsifying in vaginal fluids. It is assumed that the 2-g. suppository was spread fairly evenly over the vaginal mucosa. The suppository did not exhibit fragrant or objectionable odor.

RESULTS AND DISCUSSION

Odor Thresholds—Measurements of odor thresholds are summarized in Table III. In all cases the threshold increased upon treatment with nitrofurazone. To make the odor unnoticeable, less nitrogen was needed to dilute the vapors after treatment than before. For the six subjects this difference reaches the 95% confidence level (error probability of 0.05 or less by the Wilcoxon test).

There was a tendency for this effect to diminish as thresholds increased, with a rank-correlation coefficient of +0.74, somewhat short of the +0.83 value required for the 95% confidence level.

Since during odor-threshold studies the insert was at room rather than at body temperature, the absolute threshold values are lower; differences between them, however, are valid for comparisons. Also, the character (quality) of an odor is not considered in measurement of threshold.

Reciprocals of odor thresholds cannot, *per se*, uniquely describe odor intensities. Even in the absence of fragrant components, vapors with lower thresholds do not necessarily have higher odor intensities when not so diluted. The odor threshold data were instructive and indicated that odor was controlled by treatment. However, a better insight can be gained into what occurs with the odor complex during treatment from inspection of the odorograms.

Gas-Chromatographic Assays—Data from odor assays combined with gas-chromatographic separation of vapor components are

compiled in Tables IV and V. The Kovats Index coordinates' numerical increase indicates that the vapor pressures of the corresponding odorants were decreasing, or their solubilities in the polar stationary phase (polyethylene glycols)⁶ were increasing. No calibration was available toward the end of the scale, where values are listed simply as seconds of retention time and therefore are valid only relatively. Coding of odor characters is indicated in the legends to Tables IV and V.

These odorograms indicate clearly changes in vapor composition associated with use of nitrofurazone suppositories.

Case 1 was that of a normal subject. Vapor-component odors were distributed widely over the range from objectionable (only two peaks were in the most objectionable category) through many neutral to some pleasant components.

In the other five cases investigated, pretreatment odorograms were dominated by components of varying objectionability. After nitrofurazone treatment few, if any, objectionable odorants were observed. Some fragrant notes occurred after treatment, and many components were represented by small peaks unassociated with odor; these components were present at levels far below their odor thresholds. Regions where malodors were present before treatment were not populated by odorous peaks after treatment, or showed peaks with lower odor intensities. These may correspond either to the same substances as were present before treatment, now at lower concentrations, or to new (*e.g.*, fragrant) substances, or to a mixture of the two with objectionable components in part reduced.

As is evident from inspection of Tables IV and V, the effect of treatment cannot be explained by mere masking of unpleasant peaks by fragrant components. In several gas-chromatographic positions where highly objectionable peaks were observed before treatment, no fragrant or other odorous peaks appeared after treatment.

Figure 4 shows the frequency of occurrence of various categories of odors in the vaginal vapors studied, regardless of positions of the gas-chromatographic peaks of these odorants.

The chemical identification of the malodorous components would be significant and should represent a natural extension of this work. However, because of the very low concentrations of the odorants, this is a formidable task and was not undertaken at the present time. For an orientation (see Tables IV and V), the components with Kovats Index of 1000–1100 correspond to the substances boiling in the range of 100–180° and having molecular weight of 80–150. Substances with larger indexes boil higher and have larger molecular weights.

The corresponding relative areas are not useful for comparison of odor relevance since substances vary so greatly in thresholds and intensities of odors. A small peak may be associated with a strong odor and a large peak may be odorless. Even comparison of what appears to be the same peak in two gas chromatograms can be misleading. For example, a peak may correspond to an unresolved mixture of two substances, one contributing most of the area but no odor, the other being responsible for the odor but for only a small fraction of the peak's area. If no odor is observed in the presence of a peak from the sniffing port, this can indicate the presence of components which might still be odorous at a higher concentration.

In odor assays by the technique outlined previously, the method should be considered as a help in separating various odor notes so that they can be surveyed more accurately. The gas chromatograms indicate approximate chromatographic locations of component odorants, convenient for systematization and display.

SUMMARY AND CONCLUSIONS

A technique for gas-chromatographic separation and assay of the components of complex vaginal odors, assumed to be due in large part to bacterial action, was applied to the study of vaginal odors before and after treatment with nitrofurazone antibacterial vaginal suppositories. Odor thresholds changed under treatment in a direction which indicated reductions in the noticeability of odors at a distance. The assays indicated that major changes occurred in the composition of the complex odors, with significant reduction in the occurrences of objectionably odorous components at odor-threshold

⁶ *n*-Alkanes are designated by their number of carbon atoms times 100; thus the number for *n*-decane is 1000. Polar compounds' numbers are higher, relative to the number of C atoms (*e.g.*, *n*-butanol's number of 1113).

and suprathreshold concentrations. Under treatment of the vagina with the suppository, the respective odorograms became populated by nonobjectionably odorous components and some fragrant ones which may have been derived from the suppository preparation (although its composition and odor qualities provide no support for this statement). In some gas-chromatographic positions which were populated by malodors before treatment, no odorants were found after treatment; the effect of treatment therefore is not a simple masking but rather the result of simultaneous reduction in malodorous components and increased dominance of milder odors and fragrances.

Spectral Studies of Trimethylsilyl Ether of Chloramphenicol

MICHEL MARGOSIS

Abstract □ The trimethylsilyl ether of chloramphenicol used in GLC analysis has been characterized by UV, near IR, IR, NMR, and mass spectroscopy, confirming the structure of the *O,O*-ditrimethyl siloxy derivative. Pyridine and acetonitrile, used as solvents in the silylation reaction, promote formation of diastereomers. Addition of hydroxylic solvents promotes the inversion of configuration and causes partial solvolysis. To verify this, two fractions were collected from a GLC column and analyzed by IR and mass spectroscopy. The experimental evidence presented establishes the two fractions as diastereomers.

Keyphrases □ *O,O*-Ditrimethyl siloxy chloramphenicol diastereomers—structure confirmation, effect of pyridine, acetonitrile □ Trimethylsilyl ether—chloramphenicol derivative, effect of pyridine, acetonitrile □ IR—structure, identification □ UV—structure, identification □ NMR—structure, identification □ Mass spectrometry—structure, identification □ GLC—analysis, separation

Chloramphenicol, D(−)-*threo-p*-nitrophenyl-2-dichloroacetamido-1,3-propanediol, is a certifiable antibiotic for which neither of the current official assay methods (microbiological and UV procedures) (1) is specific. Gas-liquid chromatographic (GLC) procedures were investigated for chloramphenicol assay; however, when chloramphenicol was chromatographed on a QF-1 column above 200°, poorly resolved peaks were obtained, which were probably due to thermal breakdown products (Fig. 1). When it was chromatographed on a DC-200 or SE-30 column, no peaks of any kind were obtained.

Several workers (2–4) have successfully applied the silylation method of Bentley *et al.* (5) to this determination. However, several problems arose when the method was tried in this laboratory. The principal difficulties

included contamination of the anode of the flame-ionization detector and solvent tailing, similar to that previously observed in the GLC of lincomycin (6). To overcome these difficulties, the technique was modified as follows: a previously developed extraction procedure (6) was used; methanol or other hydroxylic solvent was added to the sample immediately before injection into the gas chromatograph; different solvent systems were used; and the reaction mixture was evaporated to dryness and reconstituted in an inert solvent.

The TMS derivative prepared by the procedure of Bentley *et al.* (5) exhibited a single symmetrical chromatographic peak at 5.7 min. (Fig. 2) on each of the three columns (7), and recovery was quantitative. Freshly prepared solutions of the derivative gave no other significant peaks when injected directly. After standing (at least overnight), these solutions began to exhibit secondary peaks at 9.2 min., which reached limiting values of 2–3.5% of the area in the case of ethyl acetate or methylene chloride solutions but increased to about 50% in pyridine or acetonitrile. The addition of small amounts of methanol or other hydroxylic solvents tended to accelerate this reaction. With increasing amounts of methanol, additional peaks at 4.3 min. were noted on the QF-1 column (Fig. 3) but not on the DC-200 or SE-30 columns. When the methanol solution of the derivative was partitioned between water and carbon tetrachloride, the chromatogram of the nonpolar fraction showed two peaks (at 5.7 and 9.2 min.; Fig. 4) attributed to the TMS ether of chloramphenicol and its *erythro* isomer, while the chromatogram of the polar fraction was similar to that of the

and suprathreshold concentrations. Under treatment of the vagina with the suppository, the respective odorograms became populated by nonobjectionably odorous components and some fragrant ones which may have been derived from the suppository preparation (although its composition and odor qualities provide no support for this statement). In some gas-chromatographic positions which were populated by malodors before treatment, no odorants were found after treatment; the effect of treatment therefore is not a simple masking but rather the result of simultaneous reduction in malodorous components and increased dominance of milder odors and fragrances.

Chloramphenicol, D(−)-*threo-p*-nitrophenyl-2-dichloroacetamido-1,3-propanediol, is a certifiable antibiotic for which neither of the current official assay methods (microbiological and UV procedures) (1) is specific. Gas-liquid chromatographic (GLC) procedures were investigated for chloramphenicol assay; however, when chloramphenicol was chromatographed on a QF-1 column above 200°, poorly resolved peaks were obtained, which were probably due to thermal breakdown products (Fig. 1). When it was chromatographed on a DC-200 or SE-30 column, no peaks of any kind were obtained.

Several workers (2–4) have successfully applied the silylation method of Bentley *et al.* (5) to this determination. However, several problems arose when the method was tried in this laboratory. The principal difficulties

included contamination of the anode of the flame-ionization detector and solvent tailing, similar to that previously observed in the GLC of lincomycin (6). To overcome these difficulties, the technique was modified as follows: a previously developed extraction procedure (6) was used; methanol or other hydroxylic solvent was added to the sample immediately before injection into the gas chromatograph; different solvent systems were used; and the reaction mixture was evaporated to dryness and reconstituted in an inert solvent.

The TMS derivative prepared by the procedure of Bentley *et al.* (5) exhibited a single symmetrical chromatographic peak at 5.7 min. (Fig. 2) on each of the three columns (7), and recovery was quantitative. Freshly prepared solutions of the derivative gave no other significant peaks when injected directly. After standing (at least overnight), these solutions began to exhibit secondary peaks at 9.2 min., which reached limiting values of 2–3.5% of the area in the case of ethyl acetate or methylene chloride solutions but increased to about 50% in pyridine or acetonitrile. The addition of small amounts of methanol or other hydroxylic solvents tended to accelerate this reaction. With increasing amounts of methanol, additional peaks at 4.3 min. were noted on the QF-1 column (Fig. 3) but not on the DC-200 or SE-30 columns. When the methanol solution of the derivative was partitioned between water and carbon tetrachloride, the chromatogram of the nonpolar fraction showed two peaks (at 5.7 and 9.2 min.; Fig. 4) attributed to the TMS ether of chloramphenicol and its *erythro* isomer, while the chromatogram of the polar fraction was similar to that of the

Figure 1—Chloramphenicol on QF-1 column at 238°.

parent compound, with its major fragment peak at 4.3 min., reverted by solvolysis.

By chromatographing chloramphenicol in the three different columns, it has also been determined that the same TMS derivative is obtained using either the procedure of Bentley *et al.* (5) (see *Experimental*) or *N,O*-bis(trimethylsilyl) acetamide.

In the first phase of this study, the TMS derivative, as originally prepared for GLC analysis, was characterized and identified by UV, IR, NMR, and mass spectroscopy. In the second phase, the two nonpolar chromatographic effluents were trapped with a simple collection system and identified by IR and mass spectroscopy.

EXPERIMENTAL

Instrumental Analysis—Gas Chromatography—A Barber-Colman model 5000 was used with a flame-ionization detector and a 1.83-m. (6-ft.) \times 3-mm. U-shaped glass column packed with 5% QF-1 on 80–100-mesh Gas Chrom Q. The carrier gas was nitrogen at 23 p.s.i., 58 ml./min., and the column temperature was 238°. For fraction collection, a 23:1 splitter was connected to the exit of the column, with the column temperature at 250° and the collector tube temperature at 240°.

Gas Chromatography–Mass Spectroscopy—An LKB model 9000 combination gas chromatograph–mass spectrometer equipped with a 1.83-m. (6-ft.) \times 0.635-cm. (0.25-in.) stainless steel column packed with 3% OV-17 on Gas Chrom Q was used. The temperatures were: flash heater, 270°; column, programmed from 200°; and the separator and source, 300°. The carrier gas was helium and the ionization potential was set at 70 ev.

Mass Spectrometry—The mass spectrometer was an Atlas CH4 equipped with a probe inlet system permitting the sample temperature to be maintained independently from the ion source. The conditions were as follows: ion source regulated at 250°; the ionization potential, 70 ev.; magnetic scanning; accelerating voltage, 3 kv.; and sample temperature, 60–80°.

Nuclear Magnetic Resonance—Varian A-60 spectrometers were used.

Spectrophotometry—UV and near IR spectra were obtained with a Cary 14 spectrophotometer with 1-cm. and 10-cm. cells, respectively. The IR spectra were obtained with Beckman IR-12 and Perkin-Elmer 457 spectrophotometers.

Sample Preparation—Sample 1 (S1)—Deuterated chloramphenicol was obtained by treating chloramphenicol with D₂O and freeze-drying.

Figure 2—TMS ether of chloramphenicol (S2) on QF-1 column at 238°.

Figure 3—TMS ether of chloramphenicol with methanol added (S3 before extraction) on QF-1 column at 238°.

Sample 2 (S2)—The derivative “standard” used for this qualitative analysis was prepared by the Bentley *et al.* (2) procedure which consists of dissolving an appropriate amount of chloramphenicol in pyridine, adding an excess mixture of hexamethyldisilazane and trimethylchlorosilane (9:1), and allowing the mixture to stand 30–60 min. About 75% of the mixture was evaporated with heat and air to dryness; the residue was dissolved in carbon tetrachloride, filtered, and reevaporated to dryness. Solutions were made from this stock sample in appropriate solvents for GLC and spectral analyses.

Sample 3 (S3)—The sample for effluent analysis was prepared as described for S2, but after standing for 30 min., methanol was added to about 5% of original volume, and the solution was allowed to stand overnight. An equal amount of CCl₄ was added and the mixture was shaken. Water was then added and the CCl₄ was extracted. The extract was washed twice with water and passed through a CCl₄-saturated wad of glass wool. About 50 μ l. of this CCl₄ solution was injected into the chromatograph. Fraction collection was started as soon as the first peak began to appear by connecting an open-end glass capillary tube to the split end of the

column exit with a sleeve of Teflon “spaghetti” tubing and leaving it connected until near the end of the peak. Another glass capillary was similarly connected to collect the second fraction. The separations and collections were repeated until enough material was collected for the various analyses.

The effluent samples were prepared for mass spectrometry by rinsing each capillary tube with 10 μ l. of CCl₄ into a gold microcup which was placed in the instrument inlet probe after air evaporation. Samples for IR analyses were prepared by rinsing each capillary tube with 10 μ l. of CCl₄ onto a small amount of KBr. The KBr was then ground in a boron carbide mortar until dry, pressed into a 1-mm. disk, and scanned on an IR spectrophotometer equipped with a beam condenser.

RESULTS AND DISCUSSION

Characterization of the TMS Derivative—There are four possible isomers of *p*-nitrophenyl-2-dichloroacetamido-1,3-propanediol: two enantiomers each of the *threo* and of the *erythro* configuration. However, only the D (—)-*threo* conformer (chloramphenicol) possesses therapeutic antibiotic activity.

Figure 4—Carbon tetrachloride extract of mixture in Fig. 3 (S3) on QF-1 column at 238°.

Figure 5—IR spectrum of chloramphenicol KBr disk.

The silylation reaction that produces a derivative sufficiently volatile and stable for use in GLC analysis yields the *O,O*-ditrimethylsilyl ether as represented in Structure I. Substantiation of this structure forms the main part of this study.

Morphology—The trimethylsilyl ether of chloramphenicol (S2) is a colorless, amorphous solid that crystallizes slowly over a period of weeks and melts below 55°. In contrast, chloramphenicol

is a white crystalline solid melting at around 152°.

Ultraviolet Analyses—The UV spectrum of S2 in cyclohexane exhibited a single absorption band with a maximum at 264 $m\mu$ and an absorptivity of 10,900 l./mole cm. A methanolic solution showed a maximum at 273 $m\mu$ whereas chloramphenicol itself showed a maximum at 278 $m\mu$ in water with absorptivity of 9630 l./mole cm.

The UV spectrophotometric method has been demonstrated to be rather nonspecific (8), since the single absorption band near 280 $m\mu$ ascribed to the $n\text{-}\pi$ transition of the nitrophenyl nucleus is also exhibited by many structurally related compounds (9, 10). Yamamoto *et al.* (4) reported that chloramphenicol, *p*-nitrophenylserinol (1-phenyl-2-amino-1,3-propanediol), and *N*-acetyl-*p*-nitrophenylserinol were separated on a SE-52 column above 200°. These workers collected the effluents and decided that they were not degradation products on the basis of UV spectrophotometry. This seems to contradict the fact that chloramphenicol was previously shown by thermogravimetry to decompose rapidly at about 160° (11) as well as the author's findings of thermolysis of chloramphenicol on the QF-1 column.

Infrared Analyses—A near IR spectrum of S2 in CCl_4 showed the presence of an amide proton at 6702 and 4926 cm^{-1} , aro-

Figure 6—IR spectrum of TMS ether of chloramphenicol (S2).

matic protons at 6050, 5907, and 4615 cm^{-1} , and methyl protons at 4355 cm^{-1} .

IR spectra of chloramphenicol and S2 were obtained as KBr disks (Figs. 5 and 6). Significant absorption bands common to both spectra were those of the amide proton stretching mode at about 3400 cm^{-1} , the amide carbonyl fundamental at about 1695 cm^{-1} , the aromatic nucleus at 1610 cm^{-1} , the nitro group at 1527 and 1351 cm^{-1} , and the aromatic substitution pattern at 2000–1667 and 758 cm^{-1} .

The spectrum of S2 showed additional new intense bands at 2967 and 2882 cm^{-1} attributed to the symmetric and asymmetric stretching mode of the six methyl groups; at 1259 cm^{-1} due to the rocking deformation mode of the methyl groups; at 1135 and 1120 cm^{-1} due to the Si—O—C stretching; at 850 and 755 cm^{-1} due to the Si—C bond. The position, shape, and intensity of the absorption bands at 1259, 850, and 755 cm^{-1} are particularly characteristic of Si—(CH₃)₃ groups. The absorption bands due to the hydroxyl functions near 3330 cm^{-1} have disappeared.

Nuclear Magnetic Resonance—The NMR spectra of S2 in CCl₄ and in deuterated acetone were obtained and compared to that of deuterated chloramphenicol (S1) in deuterated acetone. Replacing the three readily exchangeable protons with deuterium clarified the spectrum to some extent by eliminating three peaks and reducing the splitting pattern and peak overlap. A typical spectrum obtained from a CCl₄ solution is shown in Fig. 7 and assignments of peaks are given in Table I.

A comparison of spectra obtained from deuterated acetone solutions shows that the spectrum of S2 was, as expected, similar to that of S1 except for the NH proton at 7.45 p.p.m., and the two trimethylsilyl groups of 0.10 and 0.15 p.p.m.

The C₃ proton peaks were found at 3.63 and 3.75 p.p.m. compared with 3.75 and 3.85 p.p.m. in the deuterated compound. Similarly, the C₂ proton peak appeared at 4.07 versus 4.25 p.p.m., the C₁ proton peak at 5.35 versus 5.33 p.p.m., the CHCl₂ proton peak at 6.25 versus 6.35 p.p.m., and the aromatic proton peaks at 7.95 p.p.m. for both compounds. Thus, the silylation of chloramphenicol results in a variable upfield shift of the peaks, believed to be most likely due to the shielding effects of the silyl function.

The NH proton coupling with the C₂ proton ($J = 9$ c.p.s.) shows up as a doublet. The aromatic proton splitting is typical of *p*-nitro substitution. The CHCl₂ and the methyl protons of the siloxy groups at C₁ and C₃ gave rise to singlets. The C₁ proton doublet peak is indicative of a coupling with the C₂ proton. The latter, in turn, exhibited a more complex multiplet because it couples with the amide proton as well as with one at C₁ and two at C₃. The two C₃ protons may also be expected to be nonequivalent because of their adjacent position to an asymmetric carbon.

The two singlet peaks observed for the trimethylsilyl groups are clear evidence of the nonequivalence of the two groups. This nonequivalence may be due partly to the diamagnetic anisotropy of the benzene nucleus. Similarly, the two doublets centered at 4.16 p.p.m. indicate that the two C₃ protons are nonequivalent. The relative values of the integrated peaks are also consistent with the proposed structure.

Mass Spectroscopy—In the electron-impact mass spectrum of chloramphenicol (Fig. 8) and S2 (Fig. 9), some fragmentation may be common to both compounds or may be associated solely with silyl ethers (12–15).

One mode of scission common to both compounds occurs between C₁ and C₂, resulting in two major fragments (I and II), where R is H in chloramphenicol and Si(CH₃)₃ in S2.

(a) R = H, m/e 153

(b) R = Si(CH₃)₃, m/e 225

II

(a) R = H, m/e 170

(b) R = Si(CH₃)₃, m/e 242

In chloramphenicol, the two fragments appear as the base peak at m/e 153 (RI = 100%; Σ_{35} , the calculated percentage of total ionization over the range m/e 35 to M^+ , = 6.16%) and at m/e 170 (RI = 56%; Σ_{35} = 3.42%). High resolution has shown the m/e 153 peak to be a doublet due to the loss of HO from Fragment II as the main fraction, whereas the other is ascribed to protonated Fragment Ia (16). S2 is ruptured at the same site with protonated Fragment Ib at m/e 225 (RI = 58%; Σ_{35} = 14.94%), and Fragment IIB at m/e 242 (RI = 4.9%; Σ_{35} = 1.27%).

Fragmentations generally ascribed to trimethylsilyl ethers are expectedly found in the spectrum of S2. The molecular ion is barely perceptible at m/e 466 (RI = 0.012%; Σ_{35} = 0.003%) at

Figure 7—NMR spectrum of TMS ether of chloramphenicol (S2) in CCl₄.

Figure 8—Mass spectrum of chloramphenicol.

Figure 9—Mass spectrum of TMS ether of chloramphenicol (S2).

Figure 10—IR spectra of microsamples: (a) Standard TMS ether of chloramphenicol (S2). (b) Chromatographic Fraction I from S3. (c) Chromatographic Fraction II from S3.

a high instrument sensitivity. The loss of one methyl group to yield the (M-15)⁺ peak at m/e 451 (RI = 1.8%; $\Sigma_{35} = 0.45\%$) and the subsequent elimination of trimethylsilanol to yield a (M-15-90)⁺ peak at m/e 361 (RI = 2.0%; $\Sigma_{35} = 0.52\%$) are particularly useful in establishing the proper location of the molecular ion. A broad metastable peak at m/e 290 (calculated $361^{3/4}/451 = 288.96$ and $363^{3/4}/453 = 290.88$ for the +2 peak), probably due to the coalescence of two metastable peaks from each of the two chlorine isotopes, was observed corresponding to this sequence.

Fragment Ib (m/e 225) seems to undergo losses typical of *O*-silyl ethers, M-15, -73, or -90, in addition to the loss of atomic oxygen from the nitro group to show peaks at m/e 194 (RI = 3.3%; $\Sigma_{35} = 0.84\%$), m/e 136 (RI = 2.2%; $\Sigma_{35} = 0.58\%$), and m/e 119 (RI = 0.86%; $\Sigma_{35} = 0.22\%$), respectively.

Fragment IIb (m/e 242) shows a similar pattern of an *O*-silyl ether with the loss of 15, 30, or 73, simultaneous with the elimination of COCHCl₂, to give peaks at m/e 116 (RI = 4.3%; $\Sigma_{35} =$

1.11%), m/e 101 (RI = 0.93%; $\Sigma_{35} = 0.24\%$), and m/e 58 (RI = 2.4; $\Sigma_{35} = 0.61\%$).

Characterization of Gas Chromatographic Effluents—A preliminary melting point of an evaporated nonpolar mixture of S3 taken before chromatography was about 71–72°, in contrast to about 55° for the standard S2.

An IR spectrum of chloramphenicol obtained with a Beckman IR-12 spectrophotometer matched that reported by Sensi (17) and by Suzuki (18) but differed somewhat from that reported by Suzuki and Shindo (19). However, the latter authors did indicate spectral differences between the *threo* and *erythro* conformers in the crystalline state in the 5.93–5.97, 6.40–6.54, and 10.00–11.10- μ regions. Although these differences were expected to appear in the silyl ethers, none was detected in the KBr spectra of the collected fractions (Figs. 10a, b, c). In fact, both fractions from S3 appeared to be identical to the standard S2.

i,j	455	7.58	4	Quartet

^a Chemical shift (ν) measured in c.p.s. from tetramethylsilane used as internal standard in CCl₄ and in p.p.m. (δ).

Standard S2, a fresh derivative solution, and S3 were injected into the LKB 9000 and the Barber-Colman 5000 gas chromatographs. The resultant chromatograms showed identical retention times for standard S2, the fresh derivative solution, and the first fraction from S3. The mass spectra of S2 and of the fresh derivative solution obtained after injection into the LKB 9000 were identical to S2 placed directly into the inlet probe, indicating that the three samples were identical.

The mass spectrum of each collected fraction was compared to that of the S2 and the same fragmentation pattern was obtained peak for peak (Fig. 11), confirming the identity of each as the *O,O*-ditrimethylsilyl ether of *p*-nitrophenyl-2-dichloroacetamido-1,3-propanediol. However, S2, although essentially identical to Fraction I, differed from Fraction II in the relative intensity of several fragment peaks and clusters (Fig. 12).

The conclusion that Fraction II is the diastereomer of chloramphenicol silyl ether is substantiated by the available data as follows: the methanol-treated silyl solution (S3) yielded two GLC peaks and enantiomers are not known to be separable under these conditions; IR spectra showed that both effluent fractions were identical to S2; and mass spectra showed that Fraction I was identical with the S2 but differed from Fraction II only in the relative abundance of some peaks.

Petersson *et al.* (12) and Capella and Zorzut (14) have shown that mass spectra of diastereomers have the same fragmentation pattern but differ in the relative intensities of some fragment peaks. They report that the *m/e* 147 disiloxonium ion exhibits a very high abundance, particularly when the sample material contains more than one trimethylsilyl group. The *m/e* 147 peak was also reported to be more intense in the *erythro* than in the *threo* conformer in the case of oleic and elaidic acid derivatives. With regard to chloramphenicol silyl ether, the *m/e* 147 peak was found to be relatively weak but significant at about RI = 5% and $\Sigma_{35} = 1\%$ for both fractions of S3 as well as for S2. Walden inversions of structures related to chloramphenicol have been reported to occur with phosphorus halides (20), in esterification reactions (21), with heat (22), with hydrolysis (23), and with other nucleophilic attack by solvolysis (24).

ACKNOWLEDGMENTS AND ADDRESSES

Received July 29, 1969, from the National Center for Antibiotics and Insulin Analysis, Division of Pharmaceutical Sciences, Food and Drug Administration, Department of Health, Education, and Welfare, Washington, DC 20204

Accepted for publication November 6, 1969.

The author wishes to express his appreciation to Dr. J. Y. T. Chen, Mr. J. N. Damico, and Mrs. B. S. Fisher of the Food and Drug Administration, for obtaining some of the spectra and for most helpful discussions, and to Mr. R. Pittman of the National Institutes of Health, for the determinations with the LKB 9000.

This study was initiated at the National Center for Antibiotics and Insulin Analysis and pursued at the FDA Institute for Advanced Analytical Chemistry at Georgetown University under the supervision of Dr. Charles F. Hammer, Director.

Release Study of Sulfaethylthiadiazole (SETD) from a Tablet Dosage Form Prepared from Spray-Congeaed Formulations of SETD and Wax

IMTIAZ S. HAMID and CHARLES H. BECKER*

Abstract □ *In vitro* dissolution patterns of some spray-congealed products of sulfaethylthiadiazole-wax made into compressed tablets are reported. The tablets were made with a Carver laboratory press, employing a single force of compression and being approximately the same weight. The rate of release of sulfaethylthiadiazole (SETD) from the tablets was evaluated in acid pepsin medium and alkaline pancreatin medium using a rotating-bottle method. There was a gradual decrease in the amount of SETD released from the tablets as the concentration of sorbitan monooleate increased in the formulation, using acid pepsin medium. In alkaline pancreatin medium, an increase in the percentage of SETD released was noted as the concentration of surfactant increased. The mechanism of release of SETD appeared to be due to erosion, solubilization, and leaching of the drug from the tablet. The Higuchi model for drug release from inert matrices could describe the release pattern only for the initial few hours when apparently the variables other than the amount of drug released and time were essentially constant.

Keyphrases □ Sulfaethylthiadiazole-wax tablets—drug release □ Spray-congealed formulations—SETD-wax compressed tablets □ Dissolution, *in vitro*—SETD-wax compressed tablets □ Surfactant effect—SETD release, tablets □ Wax matrix effect—SETD release, tablets

The purpose of this investigation was to study *in vitro* the dissolution patterns of some spray-congealed sulfaethylthiadiazole-wax products made into compressed tablets. The spray-congealed products, in powder form, were prepared in this laboratory by John and Becker (1), and the dissolution patterns of the various powdered products were reported. Other workers (2-4) studied release patterns of tablet formulations which were simply made by mixing the active drug with inert matrices and compressing the materials into tablets.

Inasmuch as the release patterns of sulfaethylthiadiazole (SETD) from the spray-congealed drug-wax products, in powder form, were known in this study, with and without surfactant, it would be of value to know the release pattern of the drug from the same products when compressed into tablet form. Such factors as force of compression, possible fusion of the material on compression, and degree of disintegration or erosion (or both) of the tablets during dissolution should have decided effects on the release pattern of the drug. Other investigators (2-4) have reported dissolution patterns of drug from inert matrices in tablet form, but they did not report the release patterns of the drug imbedded in the matrices in the powder form.

EXPERIMENTAL

Materials—The spray-congealed SETD-wax products, in powder form, used to make the tablets in this study were prepared and reported by John and Becker (1). All other materials employed conformed to USP or NF specifications or were of analytical reagent quality.

White wax, a synthetic waxlike ester,¹ and a combination of equal parts of these waxes were employed in the formulations of John and Becker (1) as matrices, and these are designated as W_1 , W_2 , and W_3 , respectively. The surfactant, sorbitan monooleate,² was used in some of the formulations in concentrations of 0, 1, 4, and 10%, and these are designated as S_0 , S_1 , S_4 , and S_{10} , respectively. The tablets were made from three finenesses of spray-congealed powders, since these were atomized with three different nozzle sizes, namely, 0.05, 0.10, and 0.15 cm., and these are designated as N_2 , N_4 , and N_6 , respectively.

Manufacture of Tablets—There were no additives incorporated in the tablets which were made with a Carver laboratory press. Accurately weighed, 0.5000 g. of the spray-congealed powder was put into the die. The die and the punches, 1.27 cm. in diameter, were previously lubricated with a small amount of talc to avoid sticking of the tablet to the punches. The 4000-p.s.i. gauge pressure was maintained for 1 min. All tablets were accurately weighed after compression, and they did not vary by more than 10 mg. It could be assumed that the surface area was essentially the same for a particular wax product made into tablets.

Assay Method—The SETD released was assayed by the Bratton-Marshall (5) procedure using a Klett-Summerson photoelectric colorimeter with a No. 54 filter.

***In Vitro* Dissolution Studies**—The rotating-bottle apparatus (6) was used to determine the dissolution behavior of the SETD from the tablets. Tablets weighing approximately 0.5000 g., accurately weighed, were put in 90-ml. screw-capped bottles, and to each bottle 60 ml. of acid pepsin medium (simulated gastric fluid USP, pH 1.1) was added. Duplicate samples were allowed to rotate end-over-end at a speed of 40 to 45 r.p.m. in a water bath maintained at $37 \pm 1^\circ$. Samples were removed at specific time intervals, *i.e.*, at 0.25, 0.5, 1, 1.5, 2, 4, and 8 hr. Dissolution studies were also conducted in an alkaline pancreatin medium, test fluid B, pH 8.3, of Robinson and Swintosky (7), in a similar manner. Samples were removed for assay at 0.5, 1, 1.5, 2, 4, 8, and 12 hr.

Samples were also run for extended periods of time, *i.e.*, 24 and 48 hr., although equilibrium was not attained in acid pepsin medium or alkaline pancreatin medium.

RESULTS AND DISCUSSION

Spray-congealed products with white wax as the matrix were very tacky powders. The tackiness increased as the concentration of sorbitan monooleate in the formulations was increased, causing difficulty in transferring these powders into the die. The punches and the die had to be polished with a lubricant, talc, in order to obtain smooth and uniform tablets.

Spray-congealed products containing a combination of white wax and the synthetic waxlike ester in a 1 to 1 ratio were free flowing powders, but the ones with a higher concentration of the surfactant, sorbitan monooleate, were not free flowing. However, the tablets were easier to make from these products than those containing white wax alone as the matrix. In all of these instances, the punches and die had to be polished with talc to obtain smooth tablets.

All of the spray-congealed products containing the synthetic waxlike ester alone as the matrix, including the product having as high as 10% sorbitan monooleate, were free-flowing powders. However, the ones without surfactant could not be compressed into tablets at 4000-p.s.i. gauge pressure. This appeared to be due

to the friability of the finished tablet, as well as adherence or sticking of the tablet to the punch surface. The products with surfactant, on the other hand, could be compressed into tablets easily.

Tables I, II, and III give the dissolution data in acid pepsin medium and alkaline pancreatin medium from tablets with matrices of white wax (W_1), synthetic waxlike ester (W_2), and a combination of equal parts of these waxes (W_3) and varying concentrations of sorbitan monooleate. The tables also include dissolution data from the powder forms of the same formulations, reported earlier (1), for comparison.

Effect of Sorbitan Monooleate—There was an increase in the amount of SETD released with time from all tablets, with and without surfactant, in acid pepsin medium. However, there was a decrease in the rate of release of SETD from the tablets in acid pepsin medium as the concentration of surfactant in the tablets increased, particularly over the early dissolution testing periods, that is, from 0.25 to 4 hr. In most cases of powder forms of the same products (1) and for the same time period, there was an increase in the rate of release of SETD as the concentration level of sorbitan monooleate increased from 0 to 4%, but the rate of release decreased with the level of surfactant concentration at 10%. The magnitude of release of SETD was anywhere from 25 to 100 times

less in tablet dosage form than in powder form. The decrease in the percent release of SETD from the tablets, as the concentration of sorbitan monooleate was increased, could be due to more cohesiveness of the products which increased as the concentration of surfactant was increased in the formulations. This can cause agglomeration of particles, which in turn can result in less surface area exposed to the dissolution medium. In addition, there could have been some fusion of particles under the compressional force used in tableting which could result in less porosity and more compactness of particles, thereby decreasing the release of SETD. Although sorbitan monooleate lowers surface tension and should theoretically increase the release of drug from a tablet, the surfactant apparently is not effective in an acid medium of low pH such as acid pepsin medium, nor is it as effective with tablets which are excessively compact.

An increase in the percentage of SETD released from tablets with time was noted in alkaline pancreatin medium, as the concentration of surfactant was increased in all the formulations of different waxes. This was also true for the same products in the powder form, except the percentage of release was of a larger magnitude (1). The release of SETD from white wax was anywhere from 35 to 60 times greater in powder form than that in tablet dosage form. The

increase in percent of SETD release in both tablet and powder forms may be due, partially, to surface tension lowering effect of sorbitan monooleate on the dissolution medium. Sorbitan monooleate probably enhances the action of alkaline pancreatin medium to accelerate softening and erosion of the wax-matrix tablets which did occur. It should be pointed out, also, that alkaline pancreatin medium contains ox bile extract which is a surfactant due to the presence of bile salts; this, combined with sorbitan monooleate, could have been more effective than either surfactant used alone.

Effect of Wax Matrix—Those tablets which could be made from formulations of spray-congealed SETD–synthetic waxlike ester powders gave the highest drug release of the three matrices investigated in an 8-hr. dissolution study in acid pepsin medium. Tablets with white wax alone as the matrix gave the lowest drug release. A combination of synthetic waxlike ester and white wax in a 1 to 1 proportion as the matrix ranged between the two above matrices in regard to release of SETD. This was true with and without surfactant. This effect may be due to the chemical composition of the two waxes. The synthetic waxlike ester contains a high percentage of glyceryl tristearate but no free fatty acids. The ester might have been hydrolyzed sufficiently in the acid pepsin medium to account for the highest percentage of SETD released of the three matrices studied. On the other hand, white wax, not a glyceryl ester and not as easily hydrolyzed by acids, contains free fatty acids which are practically insoluble in the acid pepsin medium, hence showing the lowest drug release from this matrix. The products in powder form were also observed to possess similar characteristics (1).

As compared to the acid pepsin medium dissolution study, the percent of SETD released from tablets was found to be the highest from the white wax matrix in alkaline pancreatin medium over a 12-hr. period. Tablets with the synthetic waxlike ester alone as the matrix gave the lowest drug release. A combination of the synthetic waxlike ester and white wax in a 1 to 1 proportion was intermediate in release of SETD. Similar results were obtained when these products were studied in powder form by John and Becker (1). The high release of SETD from tablets containing the white wax matrix alone can most likely be attributed to the presence of free fatty acids in the wax which react with the alkalinity of the dissolution medium to form soaps that act as surfactants. The synthetic waxlike ester is apparently not as easily eroded and dispersed in alkaline pancreatin medium as white wax due to the lack of free fatty acids.

The percent of drug released from tablets of all the waxes, after any comparable time interval in alkaline pancreatin medium, was greater than in acid pepsin medium. One explanation is that the drug SETD is more soluble in an alkaline medium than in an acid medium. Secondly, the constituents of the waxes, both free fatty acids and the esters, are apparently more soluble and dispersible in an alkaline medium.

Effect of Nozzle Size—No definite conclusions could be drawn as to effect of nozzle size used in the pneumatic atomization of the various spray-congealed SETD–wax products and the influence of their particle sizes when made into tablets on the release of the drug in acid pepsin medium as well as in alkaline pancreatin medium. As reported earlier (1), the average particle size of SETD–white wax powders spray congealed with different nozzle sizes, namely, 0.05, 0.10, and 0.15 cm., was 9.2, 13.4, and 14.8 μ , respectively; for the SETD–synthetic waxlike ester powders, the average particle size was 7.8, 12.2, and 14.6 μ ; and for the SETD–synthetic waxlike ester–white wax powders in a 1 to 1 proportion, the average particle size was 8.9, 13.1, and 18.8 μ , respectively. Apparently the difference in ranges of particle sizes was not sufficient to show any significant pattern in release of SETD from the respective tablets. It appears likely that the force of compression employed in making the tablets, resulting in some fusion of the waxy materials, removed any possible effects of particle size if such exist in this instance.

***In Vitro* Dissolution Pattern of SETD from Tablets Made from Inert Wax Matrices**—Higuchi (8) derived the following equation for drug release from granular inert matrices:

$$Q = A \left[\frac{DK}{r} (2 - KC_s) C_s t \right]^{1/2} \quad (\text{Eq. 1})$$

where Q is the amount of drug released after time t per unit exposed area, D is the diffusivity of drug in the homogeneous matrix media, A is the total amount of drug present in the matrix per unit volume, C_s is the solubility of the drug in the matrix system, r is the tortuosity factor of the capillary system, and K equals the specific

Figure 1—Plot of percent SETD released as a function of time for dissolution from SETD–synthetic waxlike ester–white wax (1:1) tablets and powder in acid pepsin medium. Key: ∇ , $W_3N_6S_{10}$; \bullet , $W_3N_6S_4$. Solid line: powder; dashed line: tablets.

volume of the drug. Under the conditions where shape, size, weight, degree of compression, and surface area remain essentially unchanged, the above equation reduces to:

$$Q = kt^{1/2} \quad (\text{Eq. 2})$$

where k is a constant taking account of all the factors held constant in Eq. 1.

The percent of SETD released from the tablets after dissolution in the acid pepsin medium from all three matrices evaluated in this investigation was plotted as a function of square root of time. The linear relationship according to Eq. 2 was observed to be valid for a few hours where the release was less than 2%. After that the dissolution data did not follow this pattern, apparently due to considerable change in the effective surface area of the tablets. Similarly, the percent of SETD released from the tablets after dissolution in alkaline pancreatin medium from all three matrices was plotted as a function of square root of time. Likewise, in this instance, a deviation from linearity was observed after a few hours due to change in effective surface area of the tablets as erosion and some dispersion of the tablets occurred. Tablets compressed from spray-congealed products containing white wax alone as the matrix were observed to be more soluble than the other wax matrices employed and, hence, showed more deviation. After 6 hr. of exposure in the alkaline pancreatin medium, the SETD-white wax tablets were about half of the original size.

Dissolution of SETD from Spray-Congealed SETD-Wax Powders versus Dissolution of SETD from Tablets—It would be of interest to compare the dissolution of SETD from spray-congealed SETD-wax powders to the dissolution of SETD from tablets prepared from the same products. Figure 1 shows the percent of SETD-released against time from SETD-synthetic waxlike ester-white wax, in a 1 to 1 proportion, powder and tablets. It is apparent that the magnitude of release of SETD from the powdered forms is much greater than that in the tablet dosage form. The compressional force required in tableting resulted in some fusion, less porosity, and more compactness of the particles which seems to be

responsible for the small amount of SETD release from the tablets.

Further work on tablets employing spray-congealed products of drug in wax matrices with modifier, which are free flowing, suitable for direct compression, and which release the active ingredient more completely, is presently under investigation. The results of this study will be reported separately in a later paper.

Fitting a Double-Exponential Curve to Observed Salicylate Concentrations in Blood

F. W. MUELLER and S. V. LIEBERMAN

Abstract ☐ For interpretation of the results of blood concentration data to be meaningful, a very careful evaluation of the basic aspects of data collection, data description, and analysis is essential. The importance of these considerations is illustrated by the magnitude of observed differences in rate constants obtained under a variety of possible data-handling methods. The method of curve fitting presented, which minimizes squared logarithmic deviations, offers a different approach by utilizing relative error rather than absolute error. If truly equal weights are desired for data points, it is felt that this is the more appropriate definition of best fit. In any case, no mathematical technique for fitting a model to the data can compensate for an inadequate description of drug activity.

Keyphrases ☐ Blood concentration data—evaluation, basic aspects ☐ Rate constants—double-exponential curve fitting ☐ Salicylate concentration levels—rate constants, curve fitting, example

A desire to determine rate constants for drug absorption and elimination has resulted in the development of numerous analytical and mathematical tech-

niques for pharmacokinetic analysis. In recent years, the applications of pharmacokinetic analysis have progressed rapidly from graphical solutions of concentration *versus* time plots to computer programs applied to increasingly sophisticated mathematical models. The latter yield apparent first-order rate constants for various processes of distribution and elimination [e.g., Levy *et al.* (1) and Wagner (2)]. In many publications, the estimated values obtained for the parameters of the models have been presented without any indication that other values are possible. Where a number of apparent first-order rate constants are derived by a series of arithmetic manipulations from these estimated parameters, any inaccuracy in these estimates will be magnified in the subsequent computations. For a given set of observations, there are several important statistical considerations which merit careful attention before beginning the process of fitting a specific model to observed data.

Fitting a Double-Exponential Curve to Observed Salicylate Concentrations in Blood

F. W. MUELLER and S. V. LIEBERMAN

Abstract □ For interpretation of the results of blood concentration data to be meaningful, a very careful evaluation of the basic aspects of data collection, data description, and analysis is essential. The importance of these considerations is illustrated by the magnitude of observed differences in rate constants obtained under a variety of possible data-handling methods. The method of curve fitting presented, which minimizes squared logarithmic deviations, offers a different approach by utilizing relative error rather than absolute error. If truly equal weights are desired for data points, it is felt that this is the more appropriate definition of best fit. In any case, no mathematical technique for fitting a model to the data can compensate for an inadequate description of drug activity.

Keyphrases □ Blood concentration data—evaluation, basic aspects □ Rate constants—double-exponential curve fitting □ Salicylate concentration levels—rate constants, curve fitting, example

A desire to determine rate constants for drug absorption and elimination has resulted in the development of numerous analytical and mathematical tech-

niques for pharmacokinetic analysis. In recent years, the applications of pharmacokinetic analysis have progressed rapidly from graphical solutions of concentration *versus* time plots to computer programs applied to increasingly sophisticated mathematical models. The latter yield apparent first-order rate constants for various processes of distribution and elimination [e.g., Levy *et al.* (1) and Wagner (2)]. In many publications, the estimated values obtained for the parameters of the models have been presented without any indication that other values are possible. Where a number of apparent first-order rate constants are derived by a series of arithmetic manipulations from these estimated parameters, any inaccuracy in these estimates will be magnified in the subsequent computations. For a given set of observations, there are several important statistical considerations which merit careful attention before beginning the process of fitting a specific model to observed data.

STATISTICAL CONSIDERATIONS

An equation, describing the biological system, is used as a model, and an iterative curve-fitting procedure is necessary to obtain the estimated rate constants. This requires: (a) a selection of a descriptive statistic for the data, (b) a definition of best fit, and (c) a choice of the method of deriving the best fit. All three affect the estimated equation and, as a result, the conclusions drawn from an evaluation of the results. The average is the statistic most frequently used to describe concentration levels for a group of individuals. The best fit is commonly defined as the curve which minimizes the sum of the squared deviations between observed and computed concentrations. Under certain conditions, however, other alternatives are equally rational.

The selection of a statistic should obviously be based upon its descriptive quality. Physiological characteristics of individuals are such that, many times, salicylate concentration levels at a given time are not normally distributed. Consequently, the median of a group may be a better choice than the mean. If drug concentrations at observed time periods follow the normal or any other symmetric distribution, results with mean or median will be very similar. As for best fit, either the sum of the squared differences between observed and computed concentrations or the sum of the squared differences between the logarithms of these concentrations can be minimized. Comparisons of these latter differences are equivalent to relative percent deviations. Usually, accuracy of analytical methods is in terms of percentage error rather than absolute error, and a definition of best fit using differences in logarithms may be more appropriate. As basic as all these considerations seem, very little attention has been given to how they affect results.

In order to estimate the kinetic rate constants for orally administered drugs in tablet form, a biexponential curve-fitting procedure was developed for Teorell's equation 25 (3) for two consecutive monomolecular reactions giving the relationship of drug concentration in blood with time. Both averages and medians were used in fitting, and results based on each of the previously mentioned definitions of best fit were compared. The purposes of this paper are: to present this fitting procedure; to discuss briefly other available methods; and to illustrate the effect of data point selection, the definition of best fit, and the descriptive statistic chosen on the estimated rate constants.

METHODS AND DISCUSSION

The Model—Teorell's equation 25, describing the kinetics of drug appearance in the blood and disappearance from the blood when administered other than intravenously, was used:

$$C = \frac{a_0 K_a}{Vd(K_a - K_d)} (e^{-K_d t} - e^{-K_a t}) = \frac{\gamma K_a}{\delta} (e^{-K_d t} - e^{-K_a t}) \quad (\text{Eq. 1})$$

where: C = blood drug concentration in mcg./ml.; a_0 = dose in mg./kg.; Vd = the specific apparent volume of distribution (l./kg.); K_a = apparent drug appearance rate constant in hr^{-1} ; K_d = apparent drug disappearance rate constant in hr^{-1} ; t = time after ingestion in hours; γ = proportionality constant (a_0/Vd); and $\delta = K_a - K_d$.

In the manner of Lowenthal and Vitsky (4), rearranging Eq. 1 gives Eq. 2,

$$C = \frac{\gamma K_a}{\delta} e^{-K_d t} (e^{\delta t} - 1) \quad (\text{Eq. 2})$$

and taking natural logs of Eq. 2 gives the linear Eq. 3:

$$\ln \frac{C}{e^{\delta t} - 1} = \ln \frac{\gamma K_a}{\delta} - K_d t \quad (\text{Eq. 3})$$

The Delta Search—A least-squares best fit for Eq. 3 is derived by a search of delta (δ) values from an initially estimated δ in steps of 0.1. For each delta, a residual sum of squares about the fitted line is obtained. Once the direction of delta, from the initial estimate is determined, the 0.1 increment or decrement is repetitively applied for as long as a decrease in variability is observed. When an increase occurs, the search step is reduced to 0.005 and the value of the delta which gives the best fit is obtained. The absolute

Figure 1—Typical salicylate concentration curve for aspirin, 650 mg. (10 gr.).

value of the slope of the best fit line is the estimated K_a . Subtracting δ from K_a yields K_d , and by substituting the K_a and K_d values the intercept ($\ln \gamma K_a / \delta$) can be solved for gamma (γ).

Time Axis Intercept—When the dose is administered as tablets, a form which does not provide immediate availability of the complete dose, early moments are not characterized by the first-order biexponential model. Instead, a time gap exists between the time of administration (time zero) and an extrapolated "kinetic time zero," the time at which the best fitting curve crosses the time axis. Termination of the fitting process at time zero assumes that the model is immediately applicable upon administration of the drug, and that the extrapolated curve should pass through the origin. As illustrated by Fig. 1, this is not true. The best fit to the observed data is based on a curve passing through the time axis at a point greater than zero.

The next phase of the search is directed toward finding the time axis intercept which gives the overall best fit. This is accomplished by subtracting a time increment, in this case 1 min., from each of the observed time periods, and once again searching for a delta to obtain the best fit to the data. The squared deviations for this fit and the previous fit are compared. If the current fit is superior, an additional time increment is subtracted and the delta search is repeated. This is continued until the sum of squared deviations for the current fit shows an increase. At this point, 0.5-min. time increments are applied, and the estimate of the time axis intercept is determined to the nearest half minute (Fig. 2). The search is now complete and an optimum K_a , K_d , γ , and time axis intercept (Δt) are available.¹

Best Fit—The procedure just described was designed to obtain a best fit by minimizing the sum of squared logarithmic deviations between observed and computed concentrations. Three papers, Lowenthal and Vitsky (4), Wagner (5), and Wiegand and Sanders (6), have presented other mathematical techniques for fitting the double-exponential model. All of these published methods are designed to obtain a set of constants minimizing the sum of squares for deviations between observed and computed concentrations.

Figure 2—Illustration of delta search for time axis intercept (Δt). Data points are from average salicylate concentration following 650-mg. (10-gr.) dose of aspirin. Best fit results are $\delta = 2.490$, $K_a = 2.617$, $K_d = 0.127$, $\gamma = 27.3$, and $\Delta t = 6.5$.

300	17.01	16.64	16.99
	$K_a = 5.61$		$K_a = 4.91$
	$K_d = 0.108$		$K_d = 0.111$
	$\gamma = 28.3$		$\gamma = 28.6$
	$\Delta t = 7.5$		$\Delta t = 6.0$

Selections of a definition of best fit, of observation times for data points, and of a descriptive statistics are, to a degree, a matter of choice and certainly subject to more than one opinion. The evaluation of which method provides the best fit is much more objective. For a given definition of best fit, the method can be considered correct only if it generates a set of constants meeting the least-squares criterion, *i.e.*, minimal residual sum of squares.

A valid comparison of these methods would require the application of each program to a common set of data. Although this has not been done, a general review of these procedures suggests that the results would differ. The Lowenthal and Vitsky method uses both definitions of best fit during the search for the constants. A two-dimensional grid search for K_a and K_d is performed. For each K_a and K_d , a gamma to complete the set is computed from the intercept of the best fit to the linearized Eq. 3 previously shown. The best set of constants is selected on the basis of minimal sum of squares of differences in observed and computed concentrations. Obtaining gamma by one definition of best fit and the best set by the other definition gives a different result than one from a three-dimensional search.

Wagner submits too little detail to evaluate the iterative routine for estimating the parameters. Essentially, his procedure yields a set of constants, K_a , K_d , A , and B which are used to determine γ and Δt by subsequent computations. The third procedure, proposed by Wiegand and Sanders, a modification of an iterative least squares by Deming (7), also simultaneously searches for a set of constants and should lead to a best fit. Although the time axis intercept can be computed by the Wiegand and Sanders procedures, their published data are for drug administered in solution with immediate application of first-order processes assumed. If, instead of this zero-time assumption, an intercept is computed by the delta search program, an 8-min. value is obtained with a substantially larger K_a providing the best fit. The suitability of assuming a zero-time intercept and essentially forcing a curve through the origin leads to other areas of importance: selection of data time points, limitations of curve extrapolation, and interpretation of computed rate constants.

Data Point Selection—Curve fitting is undertaken to obtain estimated rate constants which offer an adequate description of drug activity. It is, therefore, vital that the period of activity be sufficiently defined if the resulting constants are to be meaningful.

Figure 3—Computed biexponential curves with minimized $\Sigma(\ln C' - \ln C)^2$ for 650-mg. (10-gr.) dose of aspirin. Solid line for fit to averages: $K_a = 2.62$, $K_d = 0.107$, $\gamma = 25.3$, and $\Delta t = 8.0$. Broken line for fit to medians: $K_a = 1.68$, $K_d = 0.160$, $\gamma = 29.4$, and $\Delta t = 8.5$.

Selection of time periods, obviously, depends upon the characteristic curve for the drug. At least two or three time periods on the ascending and descending portion of the curve and one point near the peak should be selected. To establish the ascending portion accurately, the first observation should be taken as early as possible. Likewise, the descending portion should be clearly determined by later time points. Early observations are extremely critical for rapidly absorbed drugs characterized by a sharp early rise in concentration. Failure to obtain an early observation often leads to an inaccurate computed value for K_a . Under these circumstances, K_a will not be representative, and extrapolation of the curve at early moments will be misleading. Because of the mutual dependence of the constants, inadequate description of any portion of the curve can impair the accuracy of all constants.

Table I provides an example of the effect of inadequately defining the early portion of the curve. A best fit was determined for average salicylate levels from 650 mg. (10 gr.) of a buffered aspirin measured at 10, 20, 40, 120, 240, and 300 min. A best fit for the same data without the 10-min. observed average reduced the computed K_a from 5.61 to 4.91; in this case K_d and γ were not appreciably changed. The observed 10-min. concentration was 5.88 mcg./ml., and the computed 10-min. level for the fit to all points was 5.87 mcg./ml. Removing the 10-min. reading and extrapolating the computed curve result in a 10-min. estimated value of 7.95 mcg./ml., a 35% deviation from the observed value.

The descriptive quality of computed constants cannot be separated from the careful selection of data points. Drug description by pharmacokinetic rate constants is applicable only over the period observed. Therefore, the activity period of interest must be adequately covered by the observed data.

Medians and Means—To evaluate differences between fitting the model to medians and to means, a set of constants was determined for each. Salicylate levels for 18 subjects on a 650-mg. (10-gr.) dose of buffered aspirin and two separate trials of a 650-mg. (10-gr.) dose of commercial aspirin were used.

The choice of averages or medians is highly dependent upon the data. Averages are more stable and, when symmetrical distributions of concentrations are observed, deserve preference. Frequently, however, physiological characteristics of individuals are such that salicylate concentrations at early time periods fall in nonsymmetrical distributions. A few rapid drug absorbers produce averages considerably higher than the medians. Figure 3 illustrates this situation using salicylate concentrations for a 650-mg. (10-gr.) dose of aspirin. The best fit was obtained using the delta search. The fit to medians produced a lower K_a and a higher K_d than the fit to averages. Because of the skewness of the concentration distributions at early time periods, choice of the medians in this case might be desirable, since it, by definition, represents the middle value.

Table II gives the calculated constants and residual sum of squares for the best fit for the three sets of data. A comparison of sums of squares indicates that two of these three fits to averages were better than the corresponding fits to medians. This obviously does not imply that averages should be chosen inasmuch as the most representative statistic will not necessarily provide the lowest residual sum of squares.

Weighting of Data Points—Weighting of data points is often suggested in pharmacokinetic publications, but weighting factors are rarely proposed. Actually, the two definitions of best fit mentioned earlier represent forms of weighting. The best fit definition minimizing the sum of squared deviations appears to give equal weight to all points, but, to a degree, it is really giving more weight to the larger data values. It assumes that the reliability of all points, on the basis of absolute error, is the same. Since from an analytical point of view it is probably more accurate to assume that the reliability of all points is the same with respect to percentage error, minimizing the total squared deviations would give more weight to the larger observed values (*i.e.*, the middle portion of the curve). In contrast, minimizing the sum of squared differences in logarithms, under the assumption of equal absolute error, would give more weight to the lower observed values (*i.e.*, the ends of the curve). The choice of definition of best fit depends upon which viewpoint is more appropriate. Fitting to minimize sum of squares of differences gives a curve with greater percentage deviations of observed and computed concentrations for the low values. Minimizing squared differences in logarithms, on the other hand, presents a curve with a more uniform allocation of percent differ-

					3.26	0.237	7.30	8.0 (Best fit)

ences of observed and computed values. Table III shows the results of fitting for each definition of best fit using data from each of the previously mentioned publications.

When choosing a definition of best fit or weighting factors, variation in the physiological characteristics among individuals should not be confused with the reliability of analytical determinations. Greater variation at early time periods of the concentration curve does not necessarily mean that the analytical accuracy is poorer at these time periods. The inaccuracy of K_a estimates may be partially a result of fitting for minimal sum of squared deviations or the lack of an early observation, since giving less weight to the lower observations or the lack of an early point could create greater error in estimating this portion of the curve. Minimizing sum of squared differences in logarithms should give more validity to the fit at the early and late time periods.

Other Alternatives—Using individuals or the geometric mean can present a problem for the delta search method if any observations at the early time period give a zero concentration level. If no zero levels are observed, fitting to the geometric means is equivalent to fitting data groups for individuals when minimizing the sum of squares of differences in natural logs. Obtaining a set of constants for each subject also presents fitting problems when all individual curves do not adequately fit the model. Due to the mutual dependency of a set of constants, the appropriateness of separately obtaining an average or median K_a , K_d , γ , and Δt from the group of individual sets must also be considered.

Physical Stability of Sulfaguanidine Suspensions

R. D. C. JONES*, B. A. MATTHEWS†, and C. T. RHODES‡

Abstract □ The effects of several variables—electrolyte, type, and concentration of surfactant and nature of vehicle—upon the physical properties of sulfaguanidine suspensions have been investigated. It is shown that the concept of controlled flocculation may usefully be applied to the formulation of pharmaceutically acceptable suspensions of this drug.

Keyphrases □ Sulfaguanidine suspension—physical stability □ Stability, sulfaguanidine suspension—electrolyte, surfactant, vehicle effects □ Sedimentation volume—sulfaguanidine suspension □ Redispersibility—sulfaguanidine suspension

Sulfaguanidine is an extremely useful antibacterial drug which is virtually nonabsorbed from the gastrointestinal tract. It is therefore particularly effective in the treatment of localized gastrointestinal infections. Because the drug does not enter the blood stream, it may be given in quite large doses, even to very young children. In the treatment of dysentery, doses of 3 g. three times daily are common and doses of 5 g. are sometimes used for severe cases.

The choice of a suspension rather than a tablet or capsule is often controlled by patient acceptability. While solid dosage forms are often supplied to adults, the treatment of children, particularly the very young, is easier with a suitably flavored suspension. There are a number of proprietary suspensions containing sulfaguanidine available for both pediatric and adult use.

In order to ensure uniformity of dosage, it is the aim of the pharmaceutical formulator to produce a preparation for which the minimum of shaking will cause homogeneous distribution of drug. It has been shown that the concept of controlled flocculation may be usefully applied to pharmaceutical suspensions (1–4). In the present paper the authors report studies which show how controlled flocculation may be applied to the formulation of sulfaguanidine suspensions.

EXPERIMENTAL

Materials—Sulfaguanidine BPC,¹ cetyltrimethylammonium bromide,² polysorbate 80,² aluminum chloride reagent grade, glycerol BP, glass-distilled water.

Particle Size—The particle size of the sulfaguanidine used in this investigation was determined using a model B Coulter counter in the manner previously described by Matthews and Rhodes (5) and Short *et al.* (6). Raw Coulter data were converted to percentage weight and percentage number oversize by a computer program. The results shown in Fig. 1 represent the mean of three determinations.

Sedimentation Volume—The sedimentation volumes of test suspensions were determined at intervals during storage by the method previously described (3).

Sedimentation volume is defined as the ratio of the ultimate settled height, H_u , to the original height, H_o .

Figure 1—Particle size spectrum of sulfaguanidine BPC. Key: ●, number; and ○, weight.

Redispersibility—To standardize evaluation of redispersibility, the machine described by Matthews and Rhodes (3) was used. This rotates the measuring cylinders in which the suspensions were stored through 360° at a constant speed of 20 r.p.m.

Preparation of Suspensions—Preliminary tests were performed to determine the type and concentration of surfactant to wet the drug. Of the surfactants screened, cetyltrimethylammonium bromide (CETAB) and polysorbate 80 were shown to have satisfactory wetting properties at $1 \times 10^{-2} M$ and were compatible with the aluminum chloride used as the flocculating agent.

Suspensions were prepared by dispersing 5 g. of drug in 50 ml. of double strength surfactant solution ($2 \times 10^{-2} M$) by means of a Silverson mixer (Silverson Ltd., London, England); 40 ml. of water and 10 ml. of electrolyte solution (10 times the required concentration) were then added. The measuring cylinders containing the suspensions were then stoppered and shaken well before storage at laboratory temperature (about 18°). Suspensions containing glycerol were prepared as before, being made to volume with a suitable glycerol–water mixture.

RESULTS AND DISCUSSION

The particle size spectrum of the sulfaguanidine BPC used in this project is shown in Fig. 1. Although official, this material is of a comparatively large particle size, larger than many formulators would choose to use in suspensions. This further demonstrates the need for more official standards on particle size (5–7). However, the studies of controlled flocculation reported in this paper are substantially independent of particle size. Of course, with a different concentration of drug or with a drug of different particle size, minor modification in electrolyte or surfactant concentration might be required.

Results of the study of suspensions of sulfaguanidine wetted by $10^{-2} M$ polysorbate 80 in the presence of different concentrations of aluminum chloride as flocculating agent are shown in Fig. 2.

¹ Supplied by British Drug Houses, Poole, England.

² Tween 80, supplied by Honeywell Atlas Ltd., London, England.

Figure 2—Flocculation of sulfaguanidine, wetted by polysorbate 80, by aluminum chloride. Key: ○, sedimentation volume; and ●, redispersion value.

It can be seen that there was a steady increase in sedimentation volume from about 5×10^{-5} M aluminum chloride until a maximum value of about 16% at 5×10^{-3} M. Increase in concentration of aluminum chloride above this concentration produced no corresponding increase in sedimentation volume. The progressive rise in sedimentation volume was accompanied by an increase in the ease of redispersibility, as is evidenced by the number of revolutions of the redispersing apparatus required to return the system to a homogeneous state. These results may readily be interpreted in terms of

the changes in energies of interaction between the suspended particles caused by adsorption of ions from solution. It has recently been shown that calculated energies of interaction for griseofulvin are in qualitative agreement with experimental stability results (8, 9). The general theory relating such values as zeta potential sedimentation volume and redispersibility has been previously discussed in some detail (1, 3). The sedimentation volumes of the flocculated systems are high because the floccules form rapidly and insufficient time is available for the formation of a tight, impacted cake. Thus, the ease of redispersibility increases with electrolyte concentration since relatively small forces can accomplish destruction of the nonimpacted floc, whereas the reverse situation obtains in the deflocculated system. The results shown in Fig. 3 for suspensions wetted by CETAB are similar. However, it is noteworthy that with this surfactant an increase in the concentration of flocculating agent above 5×10^{-2} M produced a reduction in sedimentation volume.

Having determined the optimum aluminum chloride concentration for the two surfactants, some studies were made of the effect of glycerol upon the sulfaguanidine suspensions. Four series of suspensions were prepared for this study, two sets for both surfactants, with and without aluminum chloride. The results are shown in Tables I–IV.

In the series of suspensions wetted by CETAB, in the presence of aluminum chloride, there was a small but significant increase of sedimentation volume as the glycerol concentration is increased until at 50% glycerol the products are quite inelegant. There was, however, a substantial increase in the redispersion value. A possible factor to be taken into account in considering this finding is that with the increase in viscosity of the medium the speed at which the redispersing machine operated was not great enough to redisperse the floccules. It is suggested that when redispersibility tests are used on suspensions in which the vehicle is other than aqueous, considerable care should be taken in the theoretical interpretation of such data since the effective shear at the particle-particle junctions in the floccules will vary with the viscosity and density of the continuous phase. In detailed studies of such systems, it might be useful to vary the redispersing force by modifications in apparatus design or speed of operation.

35	17.2	15	16
40	17.2	16	17

The change in sedimentation volume recorded in Table I is considerably less than had been expected. It is possible that this finding could be due to interaction between the aluminum ion and glycerol which would affect the availability of flocculant electrolyte, reducing the degree of flocculation of these systems. However, the authors have not been able to find literature substantiation of this hypothesis. This possible explanation is supported by the difference in effect which the glycerol had upon the redispersion values of the flocculated and unflocculated systems. Values increased for the systems with electrolyte but decreased for the deflocculated systems.

From the results shown in Table II, it can be seen that in the absence of flocculating agent, there was a marked increase in the sedimentation volume with increase in glycerol concentration. There was also a substantial increase in the ease of redispersibility as the glycerol concentration was increased. In the absence of electrolyte the sedimentation volume is controlled by such factors as viscosity and density of vehicle and the degree of heterogeneity of the dispersed phase. For any given system there is a critical particle size at which sedimentation will occur. Comparison of the redispersion values shown in Tables I and II shows that while the electrolyte-flocculated systems show no change in redispersion value over a 5-week period, the other systems show a marked decrease in the ease of redispersibility. This finding further points up the advantage of controlled flocculation.

Tables III and IV show the results obtained when polysorbate 80 was used as the wetting agent. The results are broadly similar to those obtained with the CETAB systems. Again, the change in sedimentation value with increasing glycerol concentration is very much greater in the absence of electrolyte, indicating the possibility of interaction between the flocculant and glycerol. Also, the effect of glycerol upon the redispersion value differs for the two systems in the same way as in the CETAB study.

The results reported in this paper further demonstrate the utility of the controlled flocculation technique in suspension formulation. Sulfaguanidine, wetted by a suitable surfactant, may be flocculated by aluminum chloride to give a pharmaceutically elegant preparation. Such suspensions may be readily redispersed, and tests have shown that even after prolonged storage such products retain satis-

factory physical properties; whereas in the absence of electrolyte, impaction becomes increasingly evident. The addition of glycerol to the flocculated systems did not produce the added effect which was expected. Reasons for this behavior are the subject of further investigation.

Use of the Derjaguin, Landau, Verwey, and Overbeek Theory to Interpret Pharmaceutical Suspension Stability

B. A. MATTHEWS* and C. T. RHODES†

Abstract □ Earlier work on the coagulation of drug suspensions is extended to other types of drugs and electrolytes. The coagulation mechanism is interpreted using the Derjaguin, Landau, Verwey, and Overbeek theory to predict energy of interaction curves. It is suggested that coagulation occurs at the primary minimum but that the depth of this is restricted due to steric stabilization by the surfactant film. A quantitative estimation of this stabilization is made using a recently published technique. The practical implications of these findings for the pharmaceutical formulator are discussed.

Keyphrases □ Suspensions, pharmaceutical—stability □ Coagulation—suspensions □ Interaction energies—computer prediction □ Stability, suspension—theory, experimental findings

The formulation of a solid-in-liquid drug suspension, which will remain free from impaction on storage, presents a challenging problem to the development pharmacist. One method which has been suggested for approaching this problem has been to use the principle of controlled flocculation (1). Although some workers (2) have questioned whether this procedure can be applied to macroscopic particles, the present authors have shown (3) that both flocculation, probably involving chemical bridging, and coagulation, resulting from zeta potential reduction, can be used to prevent impaction. It has also been shown (4) that comparisons may be made between coagulation in model monodisperse systems and in heterodisperse drug suspensions.

It has been demonstrated previously (3) that Brownian motion and differential sedimentation rates can cause particle collisions and, in the present paper, the coagulation mechanism is investigated further in terms of energy of interaction curves. Earlier work on flocculation and coagulation in suspensions of griseofulvin by aluminum chloride is extended to a sulfonamide (sulfamerazine) and a corticosteroid (hydrocortisone). Coagulation by mono- and divalent electrolytes is also examined to determine the extent of applicability of the Schulze-Hardy rule to supracolloidal suspensions.

THEORY

The theory which describes quantitatively the stability of lyophobic colloids and which enjoys almost universal acceptance is that propounded by Derjaguin and Landau (5) and, independently, by Verwey and Overbeek (6). This theory, known as the D.L.V.O. theory, involves a comparison of the forces of electrostatic repulsion and of van der Waals attraction. The theory ignores the effect on stability of materials such as polymers but, within this restricted framework, it provides an extremely useful basis for understanding stability phenomena.

Potential Energy of Electrostatic Repulsion—The potential energy of repulsion V_R may be expressed in D.L.V.O. theory by the following equation:

$$V_R = \epsilon a \psi \delta^2 \exp(-Kh) / [(h/a) + 2] \quad (\text{Eq. 1})$$

where $\psi \delta$ = the potential at the Stern layer which is usually identified with the experimentally determined zeta potential; a = the particle radius; K = the Debye-Hückel thickness; h = the interparticular distance; and ϵ = dielectric constant. Equation 1 holds for small Ka values and small potentials. For large Ka values and $\psi \delta < 50$ mv., a condition which may be expected in many pharmaceutical suspensions, Krut (7) has given the following approximate expression:

$$V_R = \frac{\epsilon a \psi \delta^2}{2} \ln [1 + \exp(-Kh)] \quad (\text{Eq. 2})$$

van der Waals Attraction—It was suggested by Kallman and Willstätter (8) that the attractive forces between colloidal particles could be quantized by integrating the van der Waals attraction between their constituent atoms or molecules. Although the attractive potential energy between two atoms is low and decays with the inverse sixth power of the distance, it was shown by de Boer (9) and Hamaker (10) that the total interaction energy between two colloidal particles was sufficient to compete with double-layer repulsion.

The expression derived for the attraction energy, V_A , is

$$V_A = -\frac{Aa}{12h} \quad (\text{Eq. 3})$$

where A is the Hamaker constant describing the attraction between two similar particles in a given medium and h is the distance between the particles. This simple equation is not valid when the London forces operate over distances comparable with or larger than 0.1λ where λ is the wavelength of intrinsic oscillations of the atoms. This is due to the "retardation effect" which is caused by the finite time necessary for electromagnetic waves to travel from one atom to the other atom in which it is inducing a dipole.

Schenkel and Kitchener (11) have analyzed the retardation effect and have derived empirical equations which enable attractive energies to be calculated allowing for this effect. These may be applied to coarse suspensions and aerosols. The equations are:

$$V_A \text{ (fully retarded)} \approx -(2.45Aa)/(120\pi h^2) \quad (\text{Eq. 4})$$

$$V_A \text{ (partially retarded)} = -\frac{Aa}{\pi} \frac{2.45\lambda}{120h^2} - \frac{\lambda^2}{1045h^3} + \frac{\lambda^3}{5.62 \times 10^4 h^4} \quad (\text{Eq. 5})$$

Equation 4 may be usefully applied for particle separations greater than 150 Å and Eq. 5 for shorter distances.

Total Energy of Interaction—Since the repulsive and attractive energies are in the same units, they may be summated to produce total energy of interaction curves:

$$V_{\text{total}} = V_A + V_R \quad (\text{Eq. 6})$$

These may be of three general types and are illustrated in Fig. 1.

Curve *A* pertains when $V_R \gg V_A$, i.e., where there is a large repulsive potential at the double layer. In such cases the dispersion will be indefinitely stable provided that the particles are not sufficiently large to sediment under gravity. Curve *B* shows a high potential barrier which must be surmounted if particles are to approach sufficiently closely to enter the deep primary energy minimum *P*. If the height of this barrier V_M greatly exceeds the mean thermal energy of the particles, they will not be able to enter *P*. The value of V_M necessary to prevent this is considered to be approximately 10–20 kT [Napper (12)], corresponding to a zeta potential of approximately 50 mv. The curve reaches a minimum at *P*, a very small interparticular distance, because of the Born repulsion between adjoining electron clouds.

Figure 1—Total energy of interaction between two particles, V_T as a function of interparticulate distance h .

Curve B also has a secondary minimum, S, at greater distances; if this is deep enough, approximately 5 kT or greater, loose coagulation is possible. Aggregates formed by particles in the secondary minimum would be readily broken up by dilution or shaking. Schenkel and Kitchener (11) showed that 10- μ polystyrene particles were able to undergo secondary minimum coagulation.

When Curve C pertains, the London attraction completely overwhelms electrostatic repulsion and rapid coagulation occurs.

Other Stabilizing Mechanisms—It has been known for many years that substances such as nonionic surfactants may, if adsorbed at the particle surface, stabilize a dispersion in the absence of a significant zeta potential. The structure of various types of adsorbed layers has been considered by Ottewill (13). Early attempts to quantize the steric stabilization due to an adsorbed film have been summarized by Lyklema (14). A more recent approach is that of Ottewill and Walker (15) whose method has been used in the present paper.

The shape of the potential energy of steric stabilization curve V_s is shown also on Fig. 7 (15). It possesses a sharp cutoff at an interparticulate distance of $2d$, where d is the thickness of the adsorbed layers and is approximately equal to the fully extended surfactant chain length at nearly monolayer coverage. These authors have studied the effect of a film of the nonionic surfactant $C_{12}H_{25}(\text{OC}_2\text{H}_4)_6\text{OH}$ on the stability of polystyrene latex. It was realized that there are distinct similarities between this surfactant and the anionic alkyl ether sulfates used by the present authors. It is reasonable to suppose that if the repulsion due to the anionic grouping is neutralized by a polyvalent cation, the surfactant will behave similarly to a nonionic. Ottewill (20) has suggested that the same treatment could be applied quantitatively to the system used above with modifications for the shorter chain length of $C_{12}H_{25}(\text{OC}_2\text{H}_4)_2\text{SO}_4$. The repulsive force V_s due to the adsorbed film is expressed in the equation:

$$V_s = \frac{4\pi C^2}{3V_1\rho_2^2} \left(\psi_1 - \chi_1 \right) \left(d - \frac{h}{2} \right)^2 \left(3a + 2d + \frac{h}{2} \right) \quad (\text{Eq. 7})$$

where C is the concentration of surface-active agent in the adsorbed layer, V_1 is the molecular volume of the solvent molecules,¹ ρ_2 is the density of the adsorbed film, ψ_1 is an entropy parameter, χ_1 is a dimensionless quantity characterizing the interaction energy of the surface-active agent, d is the length of the surfactant molecule, h is the distance between the particles, and a is the particle radius.

EXPERIMENTAL

Materials—Griseofulvin, fine and coarse particles, ammonium dioxyethylated dodecyl sulfate (ADDS), sodium dioxyethylated dodecyl sulfate (SDDS), and aluminum chloride were those described earlier (3, 4, 16). Sulfamerazine BPC 1954 (Ferryman & Co. Ltd.), m.p. 236° (BPC 1954, 235–239°), specific gravity 1.393, specific surface area 0.60 m.²/g., determined on the Fisher subsieve sizer (16). Hydrocortisone BP (micromilled, Merck Sharp

and Dohme Ltd.), m.p. 213.5° (BP 1968, 214°), specific gravity 1.277 ("Merck Index" gives 1.289 for the acetate), specific surface area 5.53 m.²/g. (16). Sodium chloride, calcium chloride (British Drug Houses, Ltd.) Analar. Distilled water was freshly redistilled from an all-glass still immediately prior to use.

Methods—Suspensions were prepared as described previously (4). They were stored in 100-ml. measuring cylinders at laboratory temperatures. Sedimentation volumes were measured as before (4); they are expressed as percentages. Sedimentation volume is defined as the ratio of the ultimate settled height, H_u , to the original height, H_o . Zeta potentials were measured also as before (4).

RESULTS AND DISCUSSION

Effect of Electrolyte Valency on Coagulation—Moderately acidic pH values were necessary (3, 4) for aluminum chloride to induce coagulation because of precipitation of aluminum hydroxide above pH 4.0. This indicated that the coagulation principle might not be applicable to pharmaceutical suspensions, even if problems of taste and toxicity could be overcome. It was decided, therefore, to see whether a divalent or monovalent electrolyte could produce the same effect. Since the earlier experiments had indicated that the mechanism involved was probably similar to that in colloids, it was realized that greater concentration of lower valency electrolytes would be necessary.

To determine whether pH would significantly affect coagulation with these electrolytes, the experiments were performed at pH 3.0 and at natural pH (5–6). Sodium chloride and calcium chloride were chosen as electrolytes and the technique used was as described before (4). The results are shown in Fig. 2, together with the results on aluminum chloride at pH 3.0 for comparison. The results indicate that pH has little effect on the coagulation produced by these salts. The minimum concentration of electrolyte required to produce maximum coagulation was molar for the monovalent salt, $5 \times 10^{-2} M$ for the divalent, and $5 \times 10^{-4} M$ for the trivalent. These are in the ratio of 100:5:0.05 which is in reasonable agreement with the Schulze-Hardy rule values of 100:1.6:0.13. It was noticed that the results obtained with calcium chloride were similar to those obtained with the other electrolytes, i.e., that concentrations of electrolyte greater than the critical value produced little further increase in sedimentation volume. However, with the maximum concentration of calcium chloride employed, 2 M, a sudden further increase in sedimentation volume occurred. Since no compatibility tests had been performed with ADDS and mono- and divalent electrolytes, the suspensions experiment was repeated leaving out the griseofulvin.

It was noticed that this large concentration of calcium chloride, 2 M, produced a distinct opalescence whereas all of the other solutions remained clear. This precipitation of the surfactant was evidently the cause of the increase in sedimentation height, and this point on the curve can be considered as the point of transition between a coagulation and a flocculation reaction (3).

Reversibility of Coagulation in Suspensions—If coagulation in the system investigated above is dependent primarily on the effect of the cations on the repulsive potential caused by the surfactant, and

Figure 2—Coagulation of fine-particle griseofulvin in $10^{-3} M$ ammonium dioxyethylated dodecyl sulfate by aluminum, calcium and sodium chloride. Key: solid symbols, pH 3.0; open symbols, natural pH.

¹ This is given as v_1 in the paper which would be the volume fraction of the solvent, but this is a misprint (20).

Figure 3—Coagulation of several drugs in 10^{-3} M ammonium dioxyethylated dodecyl sulfate by aluminum chloride at pH 2.0.

if no precipitation reaction occurs, the phenomenon should be reversible. This was investigated by preparing a 2.5% suspension of fine-particle griseofulvin in 10^{-3} M SDDS and adding 10^{-3} M aluminum chloride. The suspension became coagulated and sedimented to leave a clear supernatant. After storage overnight the suspension had a sedimentation volume of 18%. The supernatant (80 ml.) was decanted and replaced by 80 ml. of 10^{-3} M SDDS solution at the same pH (4.3). The suspension was redispersed and allowed to sediment again. The suspension was observed to be a typical uncoagulated dispersion and sedimented slowly leaving an opalescent supernatant. After 2 weeks the sedimentation volume was 5.0% and the griseofulvin had impacted on the base of the cylinder. This was considered good evidence that coagulation is reversible and that no irreversible reaction occurs between the surfactant and the electrolyte.

Coagulation in Suspensions of Other Drugs—Since Haines and Martin (1, 17) and Wilson and Ecanow (2) have studied sulfamerazine suspensions, it was decided to extend these investigations to this drug also. Hydrocortisone was also selected as a representative of another important class of drug, which is formulated as suspensions. It was found that ADDS wetted both of these materials at the previously used concentration, 10^{-3} M, so suspensions were prepared as before at pH 2.0. The results are shown in Fig. 3, together with results on coarse and fine griseofulvin taken from Reference 4 for comparison.

The shape of the sedimentation volume–electrolyte concentration graph is identical in each case, the only real difference being the heights of the plateaus. These were, in order of increasing height, griseofulvin coarse particle, sulfamerazine, griseofulvin fine particle, and hydrocortisone. It was considered that this difference between drugs was probably a reflection of their particle sizes and, since the specific surface area was considered to be the most appropriate parameter for comparison, this was determined for each on the Fisher sub-sieve sizer. The results are shown in Table I.

The results confirm that the height of the sedimentation curve plateau is a function of the particle size, although other properties such as the contact angle between the drug and the surfactant may have some influence. This same phenomenon has also been reported in suspensions of inorganic salts by Wolf and Kurtz (18). These results suggest that coagulation can be applied to a wide range of insoluble drugs as a formulation technique.

Interpretation of Coagulation in Pharmaceutical Suspensions by Means of the D.L.V.O. Theory—A number of attempts have been made in the literature to relate the stability of monodisperse latex suspensions to the D.L.V.O. theory, *e.g.*, Schenkel and Kitchener

3	10^{-3}	Coagulated	17.0	3.565×10^6	-17.0
4	10^{-2}	Coagulated	17.5	9.046×10^6	-4.5

(11) and Ho and Higuchi (19). As far as is known, however, no published attempts have been made to compare coagulation in pharmaceutical suspensions with this theory.

Equation 6 can be combined with Eq. 7 to give an expression for the total energy of interaction:

$$V_{\text{total}} = V_A + V_R + V_S \quad (\text{Eq. 8})$$

A computer program was written to evaluate V_{total} from these equations using the following data.

V_A —The Hamaker constant A —Two values of this have been taken, 10^{-13} and 5×10^{-13} , which are stated to be reasonable values for an organic substance in water (11, 19). The Hamaker constant for the surfactant film has been assumed to be the same as for the solvent.

The characteristic wavelength λ of intrinsic oscillations of the atoms was assumed to be 10^{-8} cm. (19).

The particle radius a —Three values were studied, 0.5, 1.0, and 2.5 μ . The results are expressed for particle diameters.

The interparticulate distance h —Values from 10 to 800 \AA were studied.

V_R —The dielectric constant was taken as 78.54. Since ψ_0 is difficult to determine experimentally, it was approximated to the zeta potential. Watillon and Joseph-Petit (21) have listed papers where this approximation is made.

Four suspensions were prepared containing 2.5% w/v fine particle griseofulvin and 10^{-3} M SDDS. The concentrations of aluminum chloride were 10^{-5} , 10^{-4} , 10^{-3} , and 10^{-2} M, and suspensions were left at their natural pH values. Zeta potentials and sedimentation volumes were measured as before and the results are shown in Table II.

V_S —The chain length d of the surfactant was calculated from molecular models. It was found to be about 25 \AA . All other data were taken from Ottewill and Walker (15): $C = 0.26$ g./ml., $p_2 = 1.0$ g./ml., $\psi_1 = 0.5$, and $\chi_1 = 0.25$.

The curves obtained for 1- μ particles are shown in Figs. 4 and 5, and the complete results showing the position and depth of the various minima are given in Table III.

The results indicate that, regardless of which value of the Hamaker constant is used, Suspensions 1 and 2 should be highly uncoagulated. This is found in practice. If the higher value of A is taken, a secondary minimum should occur between particles in Suspension 2. Verwey and Overbeek (6) give an example of a suspension of 1- μ

Figure 4—Total energy of interaction curves for particles of 1- μ diameter in Suspensions 1-4. Hamaker constant: $A = 10^{-13}$.

particles in a solution of $10^{-3} M$ 1:1 electrolyte where there was a secondary minimum of 6 kT and where loose coagulation could occur. The secondary minimum found above reached a depth of 9 kT for 5- μ radius particles, and this might be an explanation of the slight increase in sedimentation volume that occurred in this suspension (see Table II).

Suspensions 3 and 4 were found in practice to be coagulated to practically the same extent; *i.e.*, they had similar sedimentation volumes and similar redispersibility characteristics. The energy of interaction curves should therefore be very similar in shape. This is only possible if the higher value of the Hamaker constant is taken. If the lower value is taken, Suspension 3 still has a very high maximum and a secondary minimum of similar depth to Suspension 2 described above.

With the value of A of 5×10^{-13} , Suspensions 3 and 4 both show coagulation in the primary minimum but the depth of this is restricted due to the contribution of V_s , which is zero at 50 Å but rises rapidly at lower interparticle distances. The primary minimum would otherwise plunge to many hundreds of kT at interparticle distances of about 10 Å. Coagulation in the primary minimum in colloidal suspensions is usually accepted to be irreversible. It was pointed out by Hamaker (22) that the frictional and inertial forces exerted by shaking increase much more rapidly

with particle size than forces of adhesion. He gave an example of a suspension of 1- μ particles where the depth of the minimum was about 25 kT or 10^{-12} ergs. Hamaker calculated that a force of 10^{-6} dyne or 10^{-9} g. would be necessary to supply this energy over a distance of 10^{-6} cm. This, he pointed out, was equivalent to 300 times the particle weight. He stated: "Whether it is actually possible to supply forces of this order of magnitude by shaking is, in itself, open to question, though it is not excluded."

The situation would appear to be very similar in the suspensions described above. It should be stressed, however, that because of the irregular shape of the particles and the very open structure of the coagulated cake, the number of points of contact will be very small. In addition to this, surface irregularities, impurities, or sorption of the surfactant in the micellar form may prevent particles from approaching even to a distance of 50 Å and, if this situation pertains, the depth of the minimum will be restricted even further.

These results may also explain why the sedimentation volume-electrolyte concentration graph exhibited a rapid change with fine-particle griseofulvin and a more progressive change with the coarse-particle material. Examination of the two drugs under a microscope showed that the particles in the fine sample were very smooth, whereas in the coarse drug they were much rougher. This might enable the particles in the fine material to approach each other to within the surfactant-restricted primary minimum at a lower concentration of electrolyte than in the case of the coarse particles.

Rheological Examination of the Coagulated Suspensions—It was considered that examination of these suspensions in a viscometer, with a means of applying a variable shear rate, would provide evidence of the interparticle forces occurring in them. Although a Haake Rotovisco apparatus was available, there was no suitable attachment for handling these suspensions.² Samples were therefore sent to Baird and Tatlock Ltd. Suspensions 1–4 were prepared as before but the concentration of fine-particle griseofulvin was increased to 25% w/v to give a suitable reading on the instrument. Four readings were taken at different shear rates and commencing with the largest shear rate. The results are shown in Table IV.

Although these results are not conclusive, they do agree with the earlier data. Suspensions 1 and 2 are both basically Newtonian and show the same viscosity at all shear settings. Suspensions 3 and 4 both exhibit pseudoplasticity or plasticity, and there is very little difference between the readings obtained from each. The results on Suspensions 3 and 4 tend to confirm that there are attractive forces holding the particles together but that these forces can be overcome by the application of shear and the suspension can become more fluid. The absence of a complete set of results for increasing and decreasing rates or shear means that it is impossible to tell if the systems are thixotropic. There is clearly scope for further work on the rheology of coagulated suspensions.

Figure 5—Total energy of interaction curves for particles of 1- μ diameter in Suspensions 1–4. Hamaker constant: $A = 5 \times 10^{-13}$.

² The authors thank J. K. Watkins of Baird and Tatlock Ltd., London, for the rheological measurements on the Haake Rotovisco apparatus.

CONCLUSIONS

It is considered that these results provide a good semiquantitative explanation of the coagulation phenomena found, if allowance is made for all the nonideal factors which occur in these suspensions and for the likely errors in ascribing values to some of the parameters.

The following guidelines may be set out for the formulation of a suspension by the coagulation technique.

1. Select a nontoxic anionic surfactant which will wet the drug or drugs and determine the minimum concentration needed. It is desirable to choose a surfactant of an appropriate chain length to ensure that the depth of the energy of interaction curve minimum is of the right order in comparison with the size of the particles. Test the electrolyte for compatibility with the surfactant.

2. Select a suspending agent, if necessary, which will not interact with the surfactant or coagulating electrolyte.

3. Add just sufficient of the electrolyte to produce coagulation in the surfactant-restricted primary minimum.

4. Ensure that the balance between the attractive and repulsive forces is not altered by any additional excipients such as color or preservatives.

5. The state of the coagulated suspension after a comparatively short interval may be considered as a good guide to the long-term storage results of such a suspension. The type of quality control standards applicable to such a suspension are:

- (a) Control of the particle size of the suspended material by a Coulter counter, Fisher sub-sieve sizer, or other techniques.

- (b) Measurement of the zeta potential of the final suspension. The standard should probably be a maximum value since the work described above has suggested that further lowering of the parameter has little effect on the nature of the system.

- (c) Determination of the ratio between the H_u/H_o values of a coagulated and uncoagulated suspension.

- (d) Evaluation of the rheological properties of the suspension.

- (e) Measurement of redispersibility after storage.

It is believed that the work in this paper has shown that an adequate comprehension of the interfacial properties of suspensions enables their formulation to be approached from truly rational prin-

ciples rather than by empirical techniques. As Elworthy (23) has remarked: "The principal point is to understand the interparticulate forces in order to be able to control them." It is the hope of the authors that this paper has contributed, in some measure, to an increase in the understanding of these forces as they affect the interfacial properties of pharmaceutical suspensions.

Substituted Tetralins II: Preparation of 2-Amino-4-carbamyl-6-methoxy-4-methyltetralin

DONALD E. GREEN*, ARNOLD R. MARTIN, and ALLEN I. WHITE†

Abstract □ The synthesis of 2-amino-4-carbamyl-6-methoxy-4-methyltetralin was accomplished by isonitrosation of the correspondingly substituted precursor 1-tetralone and subsequent catalytic reduction. This structural analog of meperidine exhibited only very slight analgesic activity.

Keyphrases □ 2-Amino-4-carbamyl-6-methoxy-4-methyltetralin—synthesis □ Analgesic activity—2-amino-4-carbamyl-6-methoxy-4-methyltetralin □ IR spectrophotometry—structure

Recently the preparation and analgesic potency of some 2-aminotetralin derivatives of general structure, Ia, were reported (1). As part of a continuing study of structure activity relationships in the series, it was decided to prepare compounds having a carbonyl function ($R_2 = C-R$) in the 4-position. These derivatives are of

interest because of their relationship to the meperidine and ketobemidone series of analgesics (IIIa and IIIb, respectively). The title compound (II) represents the first 4-carbonyl-containing derivative prepared in the authors' laboratory. It is anticipated that II can be converted to either Ib or Ic ($X = H$; $Y = OCH_3$) by conventional procedures and that separation of stereoisomers can be effected (see structures).

Attention had been focused since the early stages of the work in the authors' laboratory on the utility of 1-tetralones as useful intermediates for the introduction of 2-amino substituents into the tetralin moiety. A five-step sequence, beginning with a glyoxylation and ending with a Curtius reaction (26% overall yield), has been described previously (1). A more direct route, the isonitrosation of 1-tetralones followed by a catalytic reduction using the methods of Kindler and Peschke (2) and Rosenmund and Karg (3), appeared to be more suitable for the preparation of 4-carbonyl-2-aminotetralins.

PROCEDURE

A number of routes may be employed for the synthesis of 1-tetralones. The most common procedures are the cyclodehydration of γ -arylcarboxylic acids and the oxidation of the corresponding tetralins. Since a 6-methoxy substituent on the tetralin nucleus was also desired for the authors' purposes,¹ any direct cyclization to a 1-tetralone must, of necessity, proceed from less readily available *meta*-substituted phenyl intermediates. Moreover, the additional structural requirement imposed by the desire for a quaternary carbon atom to become C₄ in the tetralin system required the inclusion of an alkyl group on this carbon as well as the carbonyl moiety. A common general method for the preparation of a γ -quaternary carboxyl compound is a Michael condensation using acrylonitrile or methylacrylate on a tertiary carbon bearing a labile hydrogen atom. Thus, the starting material chosen for the sequence was *m*-methoxy-

hydratropenitrile (IV), which was prepared by the procedure of Kugita and Oine (4).

The synthesis of II is outlined in Scheme I. Compound V was prepared directly by carbomethoxyethylation of IV. The best results were obtained when IV was treated with methylacrylate and *N*-benzyltrimethylammonium hydroxide (5) without a solvent and by heating the mixture to reflux briefly after allowing it to stand overnight. In this manner, yields of up to 63% of V were obtained. The saponification of the ester (V), employing the procedure of Fuson and Miller (6), gave nearly quantitative yields of the cyano acid (VI) without affecting the nitrile group.

Cyclization of VI to a 1-tetralone was accomplished using several conventional cyclizing agents (stannic chloride, anhydrous hydrogen fluoride, and polyphosphoric acid). Aluminum chloride was not investigated because of its propensity to cause cleavage of ethers. The initial reagent employed was polyphosphoric acid, which has found extensive use in similar cyclizations (7-9). Although nearly a quantitative yield of crude ketonic material was obtained, the removal of a low-melting contaminant afforded only about a 75% yield of a pure tetralone, which was subsequently shown to be the amidotetralone (VIII) rather than the cyanotetralone (VII). Cyclodehydration by hydrogen fluoride (9-11) likewise gave about 75% yields of the same amidotetralone. This unexpected result had been obtained also by Price and Kaplan (11) in the cyclization of β -cyano- γ -(*p*-methoxyphenyl)-butyric acid. No doubt, entry of moisture into both the polyphosphoric acid and hydrogen fluoride-catalyzed reactions caused hydrolysis of the nitrile group. By far the most commonly employed reagent for cyclizations to tetralones is stannic chloride, either on the free acid (10, 11) or on the derived acid chloride (7, 8, 11-13). Moreover, from γ -cyano- γ -arylbutyric acids, Horning and Schock (8, 13) obtained good yields of 1-cyano-4-oxotetralins (hereafter designated 4-cyano-1-tetralones for simplicity and uniformity of nomenclature). By utilizing their procedure, yields well in excess of 90% of a quite pure product were obtained routinely.²

Although one of the ultimate goals of this investigation is to introduce an ester group at C₄ of a 2-aminotetralin system, no attempt was made in this synthetic scheme to convert either the amidotetralone (VIII) or the cyanotetralone (VII) to the corresponding ester because of the possibility of intramolecular aminolysis of the ester at C₄ by the primary amino group at C₂. Because the amide group does not react with primary amines and is resistant to catalytic reduction, it was decided to convert the cyanotetralone (VII) to the amidotetralone (VIII). The hindered nature of the nitrile group of VII became apparent when it was subjected to vigorous acid-catalyzed hydrolysis conditions without alteration. The nitrile (VII) was converted to the amide (VIII) in yields of 85-90% using alkaline hydrogen peroxide in a Radziszewski reaction (7, 15).

Nitrosations of aliphatic ketones have been reported using nitrous acid, nitrosyl chloride, nitrosyl sulfuric acid, nitrous fumes, and esters of nitrous acid (16). Acid or base is usually required as a catalyst with the last two reagents named. For the nitrosation of a carbon atom attached to a single activating group, such as a carbonyl, base catalysis is ordinarily not effective and acid must be used. However, cyclic ketones and phenones can be nitrosated in good yields using basic catalysts. 1-Tetralones and 1-indanones, being both cyclic and aromatic, are especially reactive toward nitrosation. Tetralones, however, seem to be quite susceptible to side reactions. Basic conditions promote oxidation of the products (dihydronaphthoquinone monoximes) to the quinoneimine tau-

² The cyclization of γ -*m*-methoxyphenylbutyric acids or their chlorides can give rise to both 6- and 8-methoxy-1-tetralones. Although there have been occasional reports (12, 14) of the formation of small amounts of the 8-methoxy analogs by cyclization into the *ortho*-position with reference to the methoxyl group, it has been shown (9, 12) that excellent yields of the 6-methoxy analogs formed by cyclization into the *para*-position only are the usual result.

¹ Substitution of an oxygen function in the 6-position of the tetralin system corresponds to a 3-oxygen function in the morphine series.

tomers of 2-nitroso-1-naphthols. Acid reagents often cause rearrangements of substituents on the alicyclic ring.

The tetralones synthesized in this laboratory are resistant to aromatization because of the presence of a quaternary carbon at C₄. Therefore, the early attempts at the nitrosation of these compounds were conducted using concentrated hydrochloric acid and amyl nitrite in methanol according to the procedure of Perkin and Robinson (17). However, these initial experiments were uniformly unsuccessful as had been those of Horning and Schock (8) on a similar tetralone. Reports of successful nitrosations of variously substituted tetralones by the use of base (7, 18) prompted a trial of this catalyst. Using the procedure of Kornfeld *et al.* (7) a yield of about 30% of the desired isonitrosoamidotetralone (IX) was obtained in the initial trial run. Subsequent nitrosation experiments employing both acid- and base-catalyzed reactions on a number of tetralones revealed several beneficial modifications in both procedures³ and led to good yields of IX by both methods.

The last step in the reaction sequence, leading to the substituted 2-aminotetralin (II), consists of the reduction of the enol-nitroso (or keto-isonitroso) moiety. Nitrosation of aryl ketones followed by reduction of the resulting product has long been used as a standard method for the preparation of various derivatives of β -phenethylamine (19). However, catalytic reductions often lead to aryl α -amino ketones, aryl α -aminoalkylcarbinols, or diarylpiperazines (20). Lithium aluminum hydride reductions give aryl α -aminoalkylcarbinols (21).

The synthesis of nonoxygenated amines by hydrogenations using palladium catalysts was studied extensively by Rosenmund and Karg (3). It was found that strong Lewis acids such as sulfuric acid, boron trifluoride, zinc chloride, hydrochloric acid, and (most especially) perchloric acid promoted the hydrogenolysis to the benzyl group. The use of nonaqueous fatty acid solutions and elevated temperatures also was found to be beneficial. However, the fact that these conditions were not always necessary is demonstrated by the reduction of 3-carboxamido-7-methoxy-1-tetralone to 2-carboxamido-6-methoxytetralin by the use of palladium on carbon in absolute alcohol without the use of either an acid catalyst or solvent (11).

The reduction of IX to the corresponding 2-aminotetralin (II) was accomplished using essentially the original procedure of Rosenmund and Karg (3). The use of 10% palladium on carbon and anhydrous perchloric acid (22) caused the reduction to proceed with much greater ease. The first 2 moles of hydrogen (reduction of the oxime) were taken up in 2–3 min. and the uptake of the third mole

(reduction of the carbonyl) required only another 15 min. at room temperature. Gentle heating was required to cause the hydrogenolysis to occur, the stoichiometric quantity being taken up in about 2 hr. at 45° but requiring less time if the temperature is raised slightly more. Rosenmund and Karg required a temperature of 80–90°; but a report (19) of reduction of the aromatic ring at about 100°, using essentially the same other reaction conditions, prompted a search for means to accomplish the desired reduction at a lower temperature. The aminotetralin (II) was isolated by the same procedure as used by Rosenmund and Karg. However, it was discovered that a large quantity of organic material (as the perchlorate salt?) remained adsorbed to the catalyst. A methanol extraction of the catalyst, using a continuous extraction apparatus, recovered 0.48 g. of material from reduction in which 1.05 g. of nitrosated tetralone had been used. The IR spectrum of the hydrochloride salt of reduction product was consistent with that of a primary amine salt. No evidence of OH absorption was observed.

When examined by the method of Eddy and Leimbach (23), Compound II (as the hydrochloride) exhibited only very slight analgesic activity at a dose of 0.34 mmole/kg. This order of activity is roughly equivalent to that previously reported (1) for primary amines of the tetralin series.

EXPERIMENTAL⁴

Methyl- γ -cyano- γ -(*m*-methoxyphenyl)valerate (V)—When the dropwise addition, with vigorous stirring, of 35.8 g. (0.417 mole) of freshly distilled methyl acrylate into 56.4 g. (0.350 mole) of *m*-methoxyhydratropionitrile (IV) and 1 ml. of a 35% *N*-benzyltrimethylammonium hydroxide in methanol solution was started, the temperature immediately rose to about 60°. After cooling the mixture to 45°, further additions of methyl acrylate did not produce a rise in temperature, but the addition of another 0.5 ml. of *N*-benzyltrimethylammonium hydroxide solution again caused the temperature to rise sharply. Subsequently, 1 drop of *N*-benzyltrimethylammonium hydroxide solution was added occasionally while the remaining methyl acrylate was being added, the temperature being held at 45–50° by external cooling. After the addition was completed, the mixture was stirred at 55° for 1 hr. and then allowed to stand overnight at room temperature. The solution was then refluxed (110°) for 15 min., cooled, diluted with ether, washed with water, and dried with sodium sulfate. Flash distillation of the ether followed by vacuum distillation of the residual oil gave 15.8 g. of a colorless oil, b.p. 95–97° (1.0 mm.); 54.4 g. (62.8%) of cyanoester (V), b.p. 133–136° (0.3 mm.) and 122° (0.15 mm.); and a high-boiling residue which solidified upon cooling.

The combined product from several runs was fractionally distilled through a 0.91-m. (3-ft.) Podbielniak column to obtain the analytical sample, b.p. 158.1° (corrected) (1.5 mm.); n_D^{20} , 1.5129; d_4^{20} , 1.117; $\lambda_{\text{max}}^{\text{C}14}$, 2232 cm.⁻¹ (C \equiv N) and 1733 cm.⁻¹ (ester C=O).

Anal.—Calcd. for C₁₄H₁₇NO₃: C, 68.00; H, 6.93; N, 5.66; saponification equiv., 247. Found: C, 67.65; H, 7.08; N, 5.66; saponification equiv., 250.

γ -Cyano- γ -(*m*-methoxyphenyl)valeric Acid (VI)—A mixture of 30.9 g. (0.125 mole) of V, 12 g. of potassium hydroxide, 12 ml. of water, and 60 ml. of methanol was warmed and then allowed to stand overnight at room temperature. After removing most of the methanol, the solution was diluted with water and washed with ether. The aqueous phase was acidified with 6 *N* hydrochloric acid, the oil which separated was removed, and the aqueous layer was extracted three times with ether. The organic phases were combined and washed with a saturated solution of sodium chloride. Concentration of the ethereal solution gave 28.9 g. (99.3%) of the cyanoacid as white prisms, m.p. 101.5–102.0° (ethanol–water), continuous submaxima between $\lambda_{\text{max}}^{\text{CHCl}_3}$ 2440 and 3330 cm.⁻¹ (COOH), 2232 cm.⁻¹ (C \equiv N), and 1716 cm.⁻¹ (C=O).

Anal.—Calcd. for C₁₃H₁₅NO₃: C, 66.94; H, 6.48; N, 6.00; neut. equiv., 233. Found: C, 66.70; H, 6.43; N, 5.91; neut. equiv., 230.

1,2,3,4-Tetrahydro-7-methoxy-1-methyl-4-oxonaphthonitrile (VII)—To a solution of 34.9 g. (0.150 mole) of cyanoacid (VI), in

³ A more complete discussion of the acid- and base-catalyzed isonitrosation of 1-tetralones, plus an attempt to interpret the structure of the oxamino ketones formed on the basis of their spectral properties, will be the subject of a future publication from the authors' laboratory.

⁴ Melting points were determined on a calibrated Fisher-Johns melting point block and are corrected unless otherwise specified. The IR spectra were obtained with a Beckman IR-5 spectrophotometer; all spectra of solutions were determined in a cell with a 0.1-mm. pathlength. The analyses were performed by the Weiler and Strauss Microanalytical Laboratory, Oxford, England, or by the Galbraith Laboratories, Inc., Oxford, Tenn.

Scheme 1

150 ml. of anhydrous ether and 10 drops of pyridine, was added 19.5 g. (0.165 mole) of thionyl chloride. The mixture was allowed to stand overnight and then the ether and excess thionyl chloride were removed *in vacuo* (aspirator) from a 40° water bath. Forty milliliters of anhydrous benzene was added and removed *in vacuo* as above; then another 40 ml. of benzene was added and removed similarly, removing the last traces *in vacuo*. The residual yellow oil was dissolved in 20 ml. of anhydrous benzene and chilled, with stirring, in an ice-brine bath until about half the benzene had frozen to the wall of the flask. A solution of 35 ml. of stannic chloride in 35 ml. of anhydrous benzene was added rapidly, producing a sticky red complex which was not stirrable. After standing for 30 min., the complex was decomposed with 100 ml. of concentrated hydrochloric acid, 100 g. of ice, and 100 ml. of ether. The aqueous layer was separated and extracted with ether and then with benzene. The combined organic phases were washed with 5% hydrochloric acid, with 5% sodium hydroxide solution, and finally with a saturated solution of sodium chloride. Evaporation of the volatile solvents deposited 31.1 g. (96.2%) of VII as long white needles, tinged with yellow, m.p. 95°. (The yellow color could be washed off with cold ethanol without significant loss of cyanotetralone.) Two recrystallizations from methanol afforded the analytical sample, m.p. 101.5–102.0°, $\lambda_{\text{max}}^{\text{CHCl}_3}$ 2235 cm^{-1} ($\text{C}\equiv\text{N}$) and 1689 cm^{-1} ($\text{C}=\text{O}$).

Anal.—Calcd. for $\text{C}_{13}\text{H}_{13}\text{NO}_2$: C, 72.54; H, 6.09; N, 6.51. Found: C, 72.95; H, 6.52; N, 6.44.

1,2,3,4-Tetrahydro-7-methoxy-1-methyl-4-oxo-1-naphthamide (VIII)—By Cyclization of VI with Polyphosphoric Acid—A mixture of 3.0 g. (13 mmoles) of VI with 25 ml. of polyphosphoric acid was stirred at 90–100° for 1 hr. When the orange-brown reaction mixture was poured into 250 ml. of water and 250 ml. of chloroform, stirred by a magnetic stirrer, the viscous mass quickly dissolved. The

phases were separated and the greenish-yellow fluorescent aqueous layer was extracted twice with chloroform; then the combined extracts were washed twice with 5% sodium hydroxide and twice with water. After drying with sodium sulfate, evaporation of the chloroform extracts afforded 2.9 g. (97%) of yellowish amidotetralone (VIII). Two recrystallizations from water with the use of decolorizing carbon afforded white crystals, m.p. 179.0–179.5°; $\lambda_{\text{max}}^{\text{CHCl}_3}$ 3484 cm^{-1} (free NH), 3378 cm^{-1} (bonded NH), and 1675 cm^{-1} (amide $\text{C}=\text{O}$).

Anal.—Calcd. for $\text{C}_{13}\text{H}_{15}\text{NO}_3$: C, 66.94; H, 6.48; N, 6.00. Found: C, 67.16; H, 6.39; N, 5.98.

By Cyclization of VI with Hydrogen Fluoride—About 75 ml. of anhydrous hydrogen fluoride was added to 5.0 g. (21 mmoles) of cyanotetralone (VI) in a polyethylene bottle. When all of the hydrogen fluoride had evaporated, the residue was poured onto ice, the solution was made alkaline, and the solid was removed by filtration and washed with ice water. The dried solid, 4 g. (75%), m.p. 178–180°, did not depress the melting point of the amidotetralone obtained from the polyphosphoric acid cyclization, and the IR spectra of the two samples were identical.

By the Radziszewski Reaction on VII—A suspension of 21.5 g. (0.100 mole) of cyanotetralone (VII) in 41 ml. of 30% hydrogen peroxide and 200 ml. of 95% ethanol was warmed to 60° with stirring. The addition of 2 ml. of 7.5 *N* sodium hydroxide caused the solution to reflux, accompanied by a rapid evolution of oxygen. The clear, colorless solution was refluxed a total of 45 min. with the addition of more sodium hydroxide solution, as was necessary, to maintain the pH at about 9.5. After neutralizing the mixture, the ethanol was removed *in vacuo*, water was added, and the mixture was heated to boiling and filtered before chilling to crystallize the product. The white crystals of crude amidotetralone amounted to 20.4 g. (88%). Its identity was established by comparison of its IR spectrum with an authentic sample prepared as previously described and by mixed melting point (no depression).

1,2,3,4-Tetrahydro-3-isonitroso-7-methoxy-1-methyl-4-oxo-1-naphthamide (IX)—By Acid Catalysis—A chilled mixture of 1.8 ml. (22 mmoles) of precooled concentrated hydrochloric acid and 2.8 ml. (2.6 g., 25 mmoles) of cold, dry *n*-butyl nitrite (24) was added rapidly, with vigorous stirring, to a suspension of 4.7 g. (20 mmoles) of amidotetralone (VIII) in 30 ml. of reagent methanol chilled in ice. The ice bath was removed and the white suspension was allowed to warm spontaneously. When the temperature reached 15° the mixture took on a green tint and a mild exothermic reaction set in. At 25°, evolution of a colorless gas began and the exothermic reaction became more vigorous; the temperature rose to 42° and then fell to 35° while most of the solid dissolved. Warming the yellowish-green suspension at 40° for 2 hr. produced a copious white precipitate which was removed by filtration and washed with ice-cold methanol. After drying, the white microcrystalline oxime (IX) weighed 3.1 g. (59%), m.p. 210–218° (dec.).

The filtrate from the reaction mixture and the methanol washings of the crystals were returned to the flask and warmed at 40–45° for another hour. Adding 0.5 ml. of *n*-butyl nitrite to the dark-green solution and raising the bath temperature slightly caused the color of the solution to change to yellow and caused more solid to separate. After another 45 min. at 50°, 0.1 g. (2%) of IX, m.p. 217–222° (dec.), was filtered off. The product was soluble in aqueous alkali and sodium carbonate, giving a deep-yellow solution, but was almost insoluble in water and all common organic solvents except methanol, acetic acid, pyridine, dimethylformamide, and methyl cellosolve. Recrystallization from methanol-methylene chloride (1:1) gave stubby, very pale needles which darkened at about 205°, sintered at about 215°, and melted (in an evacuated capillary) at 220.1–224.1° (corrected) with evolution of a gas. The oximinotetralone (IX) gave an immediate strong orange color with ferric chloride in ethanol which faded upon warming or acidification. It dissolved in concentrated sulfuric acid to give a deep-yellow color rather than the intense red color which is typical of oximes of α -diketones (17). A yellow solution of its sodium or potassium salt gave the characteristic intense blue color with ferrous sulfate (25).

Anal.—Calcd. for $\text{C}_{13}\text{H}_{14}\text{N}_2\text{O}_4$: C, 59.53; H, 5.38; N, 10.68. Found: C, 60.06; H, 5.68; N, 10.49.

The solubility and melting behavior of the crude product suggested the presence of a less-polar, lower-melting isomer. Attempts to separate the suspected mixture on anionotropic alumina (Woelm) were unsuccessful.

By Alkaline Catalysis—A solution prepared by dissolving 0.86 g.

(0.022 g. atoms) of potassium in 4 ml. of absolute ethanol and 8 ml. of anhydrous toluene was added to a suspension of 4.7 g. (20 mmoles) of VIII in 75 ml. of anhydrous toluene with vigorous stirring in a nitrogen atmosphere. The clear, dark solution was chilled to 5° in an ice bath, and 2.8 ml. (2.6 g., 25 mmoles) of cold *n*-butyl nitrite was added slowly. When the exothermic reaction ceased, the ice bath was removed and the suspension was allowed to warm spontaneously to room temperature. The brown mixture was stirred at 45° for 1.5 hr., cooled, diluted with an equal volume of anhydrous ether, allowed to stand overnight, and dried in a vacuum oven.

The brown salt (5.9 g., 97% yield) was dissolved in 20 ml. of water containing 1 ml. of 10% sodium hydroxide solution and filtered to remove a few milligrams of dark-green solid. (An ether extraction of the filtrate removed more of the green compound.) Chilling the aqueous phase and acidifying to pH 4 with glacial acetic acid caused 3.9 g. (74%) of light-brown, gummy solid, m.p. 161–179°, to separate. Triturating the solid with ice-cold methanol in a chilled mortar afforded 1.8 g. of buff-colored powder which softened at 200° and melted from 208–219°. Recrystallization from methyl cellosolve–water (1:1) gave yellow needles, m.p. 216–220°, which did not depress the melting point of IX prepared by acid catalysis and which had an identical IR spectrum. Its sodium salt gave the characteristic deep-blue color with Fe⁺⁺ (24).

Evaporation of the methanol filtrate from the trituration of the gummy solid left a dark-brown gum which was dissolved in chloroform and from which a buff-colored solid was precipitated by petroleum ether. Recrystallization of the material from dilute ethanol gave a yellow solid, m.p. 156–165°; $\lambda_{\text{max}}^{\text{mineral oil}}$ 3185 and 1692 cm.⁻¹; $\lambda_{\text{max}}^{\text{CHCl}_3}$ 3663, 3344, 3205, and 1692 cm.⁻¹. This material has not yet been identified.

3-Amino-1,2,3,4-tetrahydro-7-methoxy-1-naphthamide Hydrochloride (II)—A mixture of 1.050 g. (4.00 mmoles) of IX, 1.05 g. of 10% palladium on carbon, 4.4 ml. of a 2 *N* solution of anhydrous perchloric acid in glacial acetic acid (8.8 mmoles), and 45 ml. of glacial acetic acid were placed in a Parr hydrogenator at an initial pressure of 3.5 atm. When shaking was started, the first 2 moles of hydrogen were taken up in 3–4 min., the next 0.5 mole in about 10 min., and the next 0.5 mole in about 30 min., by which time the uptake of hydrogen had practically ceased. Warming the mixture to 40–45° caused the uptake of hydrogen to recommence. After 2 more hours the slow, steady uptake ceased with a total consumption of 108% of the theoretical amount of hydrogen. (Increasing the temperature causes the reduction to become complete in a shorter time.) The catalyst was removed by centrifugation and the solution was concentrated to dryness at the water pump. The residue, which was dissolved in water, was rendered distinctly alkaline and extracted first with ether and then with chloroform. The organic extracts were dried separately with potassium carbonate followed by potassium hydroxide pellets and then treated with anhydrous hydrogen chloride. Only 7 mg. of amine hydrochloride was obtained from the ether extract, and only 27 mg. was obtained from the chloroform extract. Therefore, the alkaline aqueous phase was placed in a liquid–liquid continuous extractor and extracted overnight with ether. After drying the ether phase as above, 315 mg. of the amine hydrochloride was precipitated with hydrogen chloride. The total recovery was 349 mg. (32.2%). (From the methanol extraction of the catalyst in a continuous extraction apparatus, 0.48 g. of crystalline material was obtained. Assuming that the material was the perchlorate salt of II, that weight represents another 37% of product.)

The amine hydrochloride was dissolved in 12–15 ml. of absolute

alcohol, a small amount of insoluble material was filtered off, and the solution was diluted with about two to three volumes of anhydrous ether. The product separated as shiny white microcrystalline plates. A second recrystallization afforded the analytical sample, which darkened at 255°, softened at 263°, and melted (in an evacuated capillary) at 267.5–270.0°; $\lambda_{\text{max}}^{\text{mineral oil}}$ 3390 and 3279 cm.⁻¹ (NH), 2012 cm.⁻¹ (NH₃⁺), and 1647 cm.⁻¹ (amide C=O).

Anal.—Calcd. for C₁₃H₁₈N₂O₂·HCl: C, 57.67; H, 7.07; N, 10.35; Cl, 13.10. Found: C, 57.23; H, 7.12; N, 10.21; Cl, 12.94.

Testing for Uniformity: Sampling Plans in Pharmacopeias for Weight, Volume, and Content Uniformity

VALERIA PIETRA and IVO SETNIKAR

Abstract □ A procedure for analyzing the unit-to-unit uniformity specifications given by several pharmacopeias and for translating them into coefficients of variation is presented. Since the pharmacopeias fail to give the probability level of the compliance with the specifications, two largely adopted probability levels were considered: the 95% level which is important to the producer and the 10% level which is important to the consumer. The coefficients of variation implied by official uniformity specifications for the weights of tablets, capsules, miscellaneous oral forms, and sterile solids; for injection volume; and for content were calculated. The examined pharmacopeias show remarkable differences, both with regard to the sampling strategy and to the allowed variability of the considered dosage forms.

Keyphrases □ Pharmacopeias, dosage form uniformity testing—comparison □ Uniformity specifications—coefficient of variation calculations □ Coefficient of variation, dosage forms—equations □ Variability determination—dosage form units

The USP and NF introduced their first uniformity test, for unit-to-unit weight variability of tablets, in the 1950 editions. Since then uniformity specifications have been extended to the weight of other dosage forms (capsules and sterile solids) and, in other pharmacopeias, to the volume of injectable solutions (1–3). Finally, a uniformity specification for the content of the active ingredient of some tablets was introduced by USP XVII and NF XII (4).

As a general rule the official uniformity tests state the sample size and limit the number of specimens which may be outside certain limits. The allowed variability is difficult to evaluate since it depends on two factors: on the sampling plan and on the limits which discriminate the “inside” from the “outside” specimens. The pharmacopeias do not inform either on the maximum variability that a product complying with the specification may have (important information for the consumer) or on the maximum variability compatible with the compliance of the product (important information for the producer).

The uniformity specifications given by several pharmacopeias were therefore analyzed, translated into coefficients of variation, compared, and their efficacy and weaknesses commented upon.

THEORY

Although concerned with measurements of continuous variables, uniformity specifications of pharmacopeias involve sampling plans worked out for attributes, i.e., for the restriction of “defectives.” However, since in the context defectives are the specimens which

have a weight, volume, content, etc., outside some established limits, there is nothing intrinsically wrong with these specimens, provided that their incidence in the product does not exceed a certain percentage. Defectives in the context is therefore a misnomer and is properly substituted by the word “outsiders.”

When the acceptance of a lot is based on a sampling plan defined by the sample size n and the acceptance number c , the probability of acceptance P_a depends on the percentage of outsiders in the submitted lot and is shown by the operating characteristic curve (OC curve) which may be calculated by the binomial expansion. The OC curve does not, of itself, give information about the percentage of outsiders which is considered critical for accepting a lot, but rather gives a general picture of the performance of the sampling plan on which it is based. In order to define, through the OC curve, the maximum percentage of outsiders allowed, the P_a must be agreed on and specified. Conventionally, two P_a values are considered as particularly important in sampling-inspection procedures (5): the P_a of 95%, representative of the “producer’s risk” (R_p), and the P_a of 10%, used for defining the “consumer’s risk” (R_c). A possible alternative value for defining the R_c may be the 5% acceptance probability.

In Table I the percentages of outsiders in the population corresponding to these three levels are given for the most common sample sizes asked by official specifications or used in pharmaceutical inspections.

The values of Table I were calculated using the central F distribution (6) for sample sizes $n \leq 30$, owing to the fact that in the expansion of the binomial:

$$\frac{1}{2} (n_1 + n_2 - 2) \\ [p + (1 - p)]$$

P_a is the sum of the first $n_1/2$ terms and $(1 - P_a)$ is the sum of the remaining $n_2/2$ terms when:

$$\frac{p}{1 - p} = \frac{n_1}{n_2} \cdot F_{P_a}; n_1, n_2 \quad (\text{Eq. 1})$$

For sample sizes $n = 50, 60$, and 100 , the percentages of outsiders were calculated with the aid of the tables of Cameron (7), i.e., using Poisson’s approximation (6).

Table I shows the capability of a plan to detect and to limit the outsiders in a lot. But this is only one step toward the assessment of variability, which depends also on the limits used for discriminating the insiders from the outsiders. These limits are symmetrically set about the mean and are expressed as fractions of the mean. The official uniformity specifications can be converted into an appropriate measure of variability (coefficient of variation, CV) by means of the factors given in Table II, the entries of which are the reciprocals of the abscissas of the normal curve, corresponding to the fractions of outsiders, multiplied by 100. A numerical example of this conversion is shown in the section *Specifications for Uniformity of Tablet Weights*.

In fact, for the evaluation of the variability through the percentage of outsiders and the amplitude of limits, the distribution pattern of the variable must be recognized. Unfortunately the sample sizes prescribed by official codexes are inadequate for the identification of the distribution type and larger samples may not be available in field inspections, in inspections performed by the

Table I—Percentage of Outsiders which Will Be Accepted with the Stated Probabilities^a for Samples of Stated Sample Size and Rejection Number^b

^a Accept. prob. ^b *O*_{tol.}

average consumer, or in outgoing quality inspection of the producer. This obstacle may be overcome assuming a normal distribution. But the variables involved do not always conform to the normal distribution, since sometimes they are truncated normal, skew, leptokurtic or platykurtic, or bimodal, etc. (8–10). Nevertheless, a normal distribution is very frequent, and therefore it is still meaningful to assume it for analyzing uniformity specifications and for comparing those of different official codexes. Obviously this assumption must be kept in mind in critical situations and in borderline conditions. In these cases the distribution type ought to be checked with large samples before drawing final conclusions.

Table II—Factors (*u*) for Calculating *CV*^a in Relation to the Percentage of Outsiders

Outsiders, % ^b	0	1	2	3	4	5	6	7	8	9
0	^c	39	43	46	49	51	53	55	57	59
10	61	63	64	66	68	69	71	73	75	76
20	78	80	81	83	85	87	89	91	93	95
30	97	99	101	103	105	107	109	112	114	116
40	119	121	124	127	130	132	135	138	142	145

^a *CV* = *u* · *L*; *L* is the limit about the mean and expressed as fraction of the mean. ^b E.g., for 22% outsiders, *u* = 81. ^c Factors for percentages between 0.05 and 0.90:

Percent Outsiders, %	0.05	0.10	0.20	0.25	0.30	0.40
	29	30	32	33	34	35
Percent Outsiders, %	0.50	0.60	0.70	0.80	0.90	
	36	36	37	38	38	

ANALYSIS OF THE UNIFORMITY SPECIFICATIONS OF PHARMACOPEIAS

With the exception of the "Pharmacopée Française" (11), the most important recent pharmacopeias demand the compliance with uniformity tests for several dosage forms. In the present study the pharmacopeias listed in Table III were examined, their uniformity tests analyzed, and the percentages of outsiders calculated with the aid of Table I at the acceptance probability levels of *R*_p = 95% and of *R*_c = 10% and then converted into *CV* values using Table II.

^a Same specifications for granules, dragee-cores, and pastilles. ^b Weigh 100 tablets and calculate the average weight M . $L = 0.10 M$ for tablets weighing less than 80 mg.; $L = 4$ mg. + 0.05 M for tablets weighing 80 mg. or more; values of L from 0.058 to 0.10 M were considered for calculating CV .

Some specifications set their limits about the sample mean m and some about the true mean μ . In the first case the same specimen may be sometimes an outsider and sometimes an insider, according to the value of the mean of the sample which includes it. As a consequence the probability of acceptance depends also on the random difference between the sample mean and the true mean, as shown in a previous paper (12). No correction was made, however, for this situation or for the influence of double-sampling plans on the OC curve, since these corrections require propositions not given in the examined pharmacopoeias.

Specifications for Uniformity of Tablet Weights—Table IV summarizes the uniformity specifications and the acceptance conditions given for tablets.

Most pharmacopoeias set two interlinked conditions shown in Table IV under the headings I and II. These conditions may be analyzed even by the trinomial expansion (13).

^a The actual values of L are given in Table VII. ^b The ranges shown reflect the ranges of L values for different capsule weights. ^c Cf. Note (a) in Table VII. ^d Cf. Note (b) in Table VII. ^e Cf. Note (c) in Table VII. ^f Cf. Note (d) in Table VII. ^g Cf. Note (e) in Table VII.

Table VII—Notes for Capsules

(a) Type A specification for contents of hard capsules. Limits: $L = 0.10 m$ for contents of 120 mg. or less; $L = 0.075 m$ for contents of more than 120 mg. Type B specification for contents of soft capsules (chlorthianisene, ethchlorvynol, ethosuximide, halibut liver oil, paramethadion, phytonadione, tetrachloroethylene).

(b) For hard and for soft capsules.

Content, mg.	>300	151-300	51-150	≤50
L	0.05 m	0.075 m	0.10 m	0.15 m

If the weight of content is labeled, m is the label weight. If the weight of content is not labeled, m is the sample average weight.

(c) $L = 0.05 m + 10$ mg. Values from 100 to 1000 mg. were considered for calculating CV .

(d) Type A specification for the weights of whole capsules. In the event of noncompliance, type B specification is applied to contents. The definition of specification B is obscure.

(e) Type A specification for the weights of whole capsules. In the event of noncompliance, type B specification is applied to the contents. If the contents fail to comply with test B1, test B2 is allowed, provided that not more than 6/20 contents fall outside the limits $m \pm 0.10 m$. These conditions correspond to a producer's $CV \leq 7.5$ and a consumer's $CV \leq 13.5$.

The implied maximum percentages of outsiders are given in the O_P column (for a $P_a = 95\%$, i.e., the producer's risk) and in the O_C column (for a $P_a = 10\%$, i.e., the consumer's risk). The limits which discriminate the outsiders are set by most pharmacopoeias symmetrically about the sample mean. Usually different limits are given according to the average tablet weight. The "Pharmacopoea Nordica" makes an exception since it relates the weight limits to the mean obtained on a larger sample than that used for measuring variability and considers a sliding variation instead of a step-by-step one. From Tables IV and V it may be noted that both the limits and the tablet weights which define them are quite different in the examined codexes.

The actually allowed unit-to-unit variabilities are given as CV values in Table IV, the ranges of which reflect the ranges of the

L values given in Table V for weights of different tablets. Remarkable differences may be noted between the uniformity levels required by the different codexes.

The following example, based on the BP uniformity specifications for tablets greater than 250 mg., shows how the CV values were obtained. The sampling plan is defined by $n = 20$ and $c = 2$ (Table IV). According to Table I there is a 95% probability of accepting the submitted lot if 4.5% (O_P) of the items of the lot are outside the limits, which are $m \pm 0.05 m$ (Table V). From the table of the normal distribution, it is found that 4.5% outsiders (O_P), namely, 2.25% at each end, lie beyond the limits $m \pm 2 SD$. Therefore, $2 SD = 0.05 m$, so that $CV = 100 SD/m = 2.5$.

The CV values may be obtained using the factors of Table II:

$$CV = u \cdot L = 50 \cdot 0.05 = 2.5 \quad (\text{Eq. 2})$$

Specification for Uniformity of Capsule Weights, for Weights of Miscellaneous Oral Forms, and for Suppository Weights—Tables VI

and VII show the weight uniformity specification for capsule weights, Table VIII shows those for miscellaneous oral dosage forms, and Table IX shows those for suppositories.

These tables were prepared following the same criteria adopted for tablets and, as for tablets, there is little similarity between the different sampling plan strategies and procedures.

Specifications for Uniformity of Injectables—Tables X and XI summarize the specifications for weight uniformity of sterile solids. There are large differences with regard to the allowed CV values and still more with regard to the weight classes for which the sizes of limits change (Table XI).

The specifications for uniformity of volume of injectables are more regular (Table XII). These specifications are given in four of the examined pharmacopeias.

Content Uniformity—USP-NF are the first pharmacopeias to introduce a specification on content uniformity. The prescribed two-step procedure is summarized in Table XII and the operating characteristic curve is given in Fig. 1.

For the values of L cf. Table XI.

^a μ is the labeled weight. ^b The pooled mass of the 10 units must be within $\pm 10\%$ of the labeled mass, if this is smaller than 2000 mg., and within $\pm 15\%$ of the labeled mass if this is larger than 2000 mg. ^c The specification concerns the implants. ^d The sample average must be within $\mu \pm 0.5 L$ (cf. Table XI). ^e μ is the labeled weight. ^f Step 2 is allowed when the sample does not comply with Step 1 and when less than 7/20 weights are outside $m \pm 0.10 m$. The producer's CV may therefore reach a value of 7.5 and the consumer's CV a value of 13.5. The sample average m must be between $\mu \pm 0.07 \mu$, where μ is the labeled weight. The USP-NF do not state if the last rule applies to the sample of 20, or of 60, or to both.

DISCUSSION

The specifications for uniformity tests prescribed in several important pharmacopeias are remarkably different, even in the same codex for different dosage forms, and lack essential information for establishing the variability actually allowed. If the specifications are analyzed with constant criteria, their comparison becomes possible and reveals discrepancies as *CV* at the consumer's risk level from 8.0 to 15.7 for tablets, from 6.8 to 15.7 for capsules, from 8.0 to 12.0 for miscellaneous oral forms, from 4.3 to 8.6 for suppositories, from 8.6 to 27.1 for sterile solids, and from 8.0 to 15.8 for injection volume.

For some dosage forms, different variabilities are allowed, depending on the average weight. The criteria adopted for establishing these weight classes differ markedly in the examined pharmacopeias as shown by Table V for tablets, Table VII for capsules, and Table XI for sterile solids. The differences are difficult to understand since they are not related to technical reasons because most dosage forms are produced with a narrower weight variability than that necessary for the compliance with the official specifications. The differences are even not justified by some needs of the consumer, who may be prepared to accept differences in uniformity according to the safety margin or to the therapeutic efficacy of a drug, but not according to the dosage form or to the size of the dosage form by which the drug is administered.

Uniformity specifications with two interlinked compliance conditions (I Condition and II Condition in the tables) imply a larger *CV* for the second condition than for the first, both for the producer and for the consumer. Probably the second condition aims to establish absolute limits to variability or to protect from abnormal variability. Compliance with absolute limits, however, cannot be assured by sample inspections, and abnormal variability can be investigated only with much larger sample sizes than those considered by the official specifications.

Most specifications consist of a one-step sampling plan. There are some exceptions, *e.g.*, USP–NF describe a two-step sampling plan for capsules, for sterile solids, and for content of active ingredient. These double plans are difficult to comment on since the second step in the three plans has different effects, both on the variability allowed to the producer and on the protection for the consumer.

Figure 1—Characteristics of two-step sampling plan for content uniformity of USP–NF. Key: AI, operating characteristic (OC) curve for acceptance after the first sampling {10,0}; RI, OC curve for rejection after the first sampling {10,2}; AII, OC curve for acceptance after the second sampling {10,1;20,0}; ASN, average sample number related to percent outsiders; R_p , producer's risk level ($P_a = 0.95$); R_c , consumer's risk level ($P_a = 0.10$).

Perhaps the most critical uniformity specification is the two-step sampling plan for content, required by USP–NF for some drugs dosed in tablets. The operating characteristic (OC) curves, given in Fig. 1, show that the second step adds a very small amount of tolerated outsiders at the level of the R_p and that there is practically no difference of tolerated outsiders at the level of the R_c . The advantage of the second step, therefore, is not clear.

The specification for content uniformity apparently restricts variability to the same order of magnitude as that allowed for tablet weights. The *CV* allowed for content, however, is comprehensive both for variability of actual content and for the apparent variability, *i.e.*, that linked to the analytical error, which may reach values of 3% and more and is different for each analytical method. Therefore, the allowances for content variability are actually different for each drug, depending on the precision of the analytical method.

In conclusion, the official uniformity specifications may be analyzed in order to obtain useful information on the variabilities actually allowed. The relevant *CV* values may be calculated and used for production-control charts and for acceptance inspections performed with other sample sizes. They inform also the consumer about the variability which may inhere in accepted products.

The approach presented in this paper complements that of Roberts (14) who studied the relationship between *CV* of the lot and the probability that a sample fails the USP–NF uniformity tests for weight of tablets, capsules, or sterile solids.

SYMBOLS AND DEFINITIONS

- P_a = acceptance probability
 n = sample size
 c = acceptance number
 p = fraction of defectives (or outsiders) in the population

Table XII—Official Specifications for Uniformity of Injection Volume and for Content Uniformity

Codex	Sample Size	Plan	Acceptance Conditions			<i>CV</i>	
			Limits	O_p	O_c	Producer	Consumer
BP	10	0/10	$\mu \pm L^a$	0.5	21.0	1.8–3.6	4.0–8.0
PB	10	1/10	$\mu^b \pm 0.15 \mu$	3.5	34.0	7.2	15.8
PJ	10	1/10	$\mu^b \pm 0.15 \mu$	3.5	34.0	7.2	15.8
WHO	10	1/10	$\mu^b \pm 0.15 \mu$	3.5	34.0	7.2	15.8
USP–NF	10	0/10	$\mu^c \pm 0.15 \mu$	0.5	21	5.4	12
	30	1/30	$\mu^c \pm 0.15 \mu$	1.5	21.5	6.2	12

^a For labeled volumes ≤ 2.0 ml., $L = 0.10 \mu$ (μ = prescribed volume) and the sample average volume within $\mu \pm 0.05 \mu$. For labeled volumes > 2.0 ml., L must be within the labeled volume and $+0.05 \mu$. The prescribed volume μ is given in a table. ^b μ is the prescribed volume given in a table of the codex. Directions are given for the limits of the average sample volume. ^c Specification for content uniformity. The second step, with additional 20 contents, is allowed when not more than one value in Step 1 exceeds $\mu \pm 0.15 \mu$. This implies a producer's *CV* of 7.2 and a consumer's *CV* of 15.7. μ is the labeled content. The specification applies to tablets of hydrocortisone, prednisolone, prednisone, chlorpromazine, prochlorperazine, digitoxin, ergonovine, and phenobarbital.

OC = operating characteristic curve
 R_c = consumer's risk (set at a 10% level)
 R_p = producer's risk (set at a 95% level)
 CV = coefficient of variation [$CV = (s/m) \cdot 100$]
 s = sample standard deviation
 m = sample mean
 μ = population or true mean
 T = prescribed value
 L = limit symmetrically set about the mean
 k = fraction of the mean by which limits are expressed ($L = km$)
 u = factor for calculating CV from k when a normal distribution is assumed ($CV = uk$)

Outsiders = specimens outside mean $\pm L$

Insiders = specimens inside mean $\pm L$

Quantitative Gas-Liquid Chromatographic Determination of Estrone in Dermatological Products

PRAMOD P. KARKHANIS and JON R. ANFENSEN

Abstract □ A gas-liquid chromatographic procedure employing an internal-external standard ratioing technique is described for the analyses of estrone in dermatological preparations. The analysis of a cream or lotion is performed by the addition of an internal standard, extraction of sample with 10% sodium hydroxide, filtration, adjustment of the filtrate pH to 9–9.5, and chromatography on a 3% OV-1 column.

Keyphrases □ Estrone dermatological products—analysis □ Extraction procedure, estrone—internal—external standard ratioing technique □ GLC—analysis □ Equilenin solution—internal standard

Estrone has been incorporated in creams primarily for the treatment of senile vaginitis, pruritus vulvae, leukoplakia vulvae, and in emollients for the relief of local antikeratotic and trophic therapy in skin of the climacteric. In addition to the base, these preparations frequently contain vitamin A, hydrocortisone, and pyrilamine maleate for local antihistaminic and analgesic effect.

Several chemical methods for the estrone are found in the literature (1–5). However, due to the small amount of the steroid and the interference from the other ingredients in these pharmaceutical preparations, the results obtained with some of these methods were unreliable. The biological assay of estrone (6), based on the cellular change in the vagina of the spayed mouse or rat, gave erratic results.

Kroman *et al.* have quantitatively determined the concentration of estrone in the human plasma using a combination of chemical extraction and gas chromatography (7) and Wotiz and Chatteraj have described a method to determine estrone in low- and high-titer urine employing TLC and gas chromatography (8).

A GLC procedure has been described for ethinyl estradiol in both sesame oil solutions and solid dosage forms, using estrone as an internal standard, by Talmage *et al.* (9); Boughton *et al.* have determined ethinyl estradiol in tablets and granulations by gas chromatography using estrone as an internal standard (10). The proposed method, with a simple clean-up procedure, allows the separation and determination of estrone by gas chromatography while eliminating interferences from excipients commonly present in the creams and lotions.

EXPERIMENTAL

The proposed method, with a simple clean-up procedure, allows the separation and determination of estrone by gas chromatography while eliminating interferences from excipients commonly present in the creams and lotions.

EXPERIMENTAL

Instrument—Hewlett-Packard 5754A research chromatograph equipped with Hewlett-Packard 3370A electronic integrator and Honeywell Electronic 16 recorder.

Column—A 1.22-m. (4-ft.) helical glass column, 4 mm. i.d.

Liquid Phase—Three percent OV-1 on diatomite aggregate¹ (HP), 80–100 mesh (Supelco, Inc., Bellefonte, Pa.). The column is conditioned overnight at 300° with a helium flow rate of 45 ml./min.

¹ Chromosorb G, Johns-Manville Products Corp., New York, N. Y.

Figure 1—A typical chromatograph.

Operating Conditions—Hydrogen pressure 14 p.s.i.; air pressure, 30 p.s.i.; helium flow rate, 70 ml./min.; column oven temperature, 245°; detector temperature, 290°; injection port temperature, 290°; detector, flame ionization.

Reagents and Solutions—Estrone NF²; equilenin (K and K Laboratories, Inc.); chloroform NF; sodium hydroxide 10% aqueous solution; 6 N sulfuric acid.

Standard Estrone Solution—Weigh accurately 50.0 mg. of estrone NF into a 25-ml. volumetric flask. Dissolve in and make to volume with methanol-methylene chloride (1:1).

Internal Standard Equilenin Solution—Weigh accurately 50.0 mg. of equilenin into a 50-ml. volumetric flask. Dissolve in and make to volume with methanol.

Working Standard Solution—Pipet 1 ml. each of standard and internal standard solutions into a small stoppered flask. Evaporate the solvent to dryness on a steam bath. To the residue add 0.5 ml. of chloroform. Mix well.

Preparation of Sample Solution—Into a glass or polypropylene stoppered tube, weigh accurately an amount of sample containing approximately 1.0 mg. of estrone. With a pipet add 1 ml. of internal standard solution followed by 20 ml. of 10% sodium hydroxide solution. Heat on a steam bath for about 5 min. and then shake the tube on a mechanical shaker for about 10–15 min. or until the sample is well dispersed. Cool to room temperature. Filter the solution under vacuum through a 0.64-cm. (0.25-in.) layer of diatomaceous earth³ spread over glass-fiber filter paper (2.1 cm.)

in a Gooch crucible. Rinse the tube with 10 ml. of water and filter the rinsing.

Transfer the filtrate to a 100-ml. beaker; rinse the vacuum flask with 10 ml. of water and transfer it to the beaker. Adjust the pH of the solution to 9–9.5 with 6 N sulfuric acid while mechanically stirring. Transfer this solution to a 125-ml. separator and extract three times with 25 ml. chloroform. Collect the chloroform layer and discard the aqueous layer after the third extraction. Filter the chloroform extract through about 5–6 g. of anhydrous sodium sulfate over a glass-fiber filter paper into a 125-ml. flask. Wash with 10 ml. chloroform. Evaporate the solvent to about 10 ml. on a Rinco evaporator. Transfer the solution to a small tube, rinse the flask with 5 ml. of chloroform, and transfer it to the tube. Then evaporate the solvent to about 1 ml. by heating in a stream of nitrogen. This is the working sample solution.

Chromatography—Balance the instrument after it has reached the operating temperatures and then set the range at 10² and attenuator to 8. Inject approximately 3–4 μl. of working standard solution and working sample solution, using a 10-μl. Hamilton syringe. The estrone peak has a retention time of about 3.0 min., whereas the equilenin peak has a retention time of about 4.0 min. The area under each peak is determined with an electronic integrator or by employing a manual technique (11).

Calculations— E_s = estrone peak area, E_q = equilenin peak area, A = micrograms of estrone in the working standard solution, and W = sample weight in grams:

$$\frac{A}{W} \times \frac{E_s/E_q \text{ for sample}}{E_s/E_q \text{ for std.}} = \text{mcg. estrone/g.} \quad (\text{Eq. 1})$$

Figure 2—A chromatograph obtained from the extract of dermatological preparation.

Table I—Determination of Estrone in Commercial Preparations

Product	Label Claim, mcg. Estrone	Estrone Found, mcg./g.
Cream I	200.0	205.4
Cream II	200.0	202.9
Emollient	200.0	204.8

RESULTS AND DISCUSSION

The calibration curve for concentration of estrone *versus* integrated area of estrone/integrated area for equilenin gave a straight line. A typical chromatograph is shown in Fig. 1, and a chromatograph obtained from the extract of the dermatological preparation is shown in Fig. 2. Liquid phases such as SE-30, OV-1, and XE-60 were investigated. OV-1 [methyl silicone (Supelco, Inc.)] was found to be most satisfactory because of its stability at high temperatures.

The accuracy of a gas chromatographic procedure is dependent upon the ability to compensate for errors resulting from extraction, filtration, and injection. The internal-external ratioing technique makes it possible to minimize these errors when an internal standard with chemical properties similar to the compound being quantitated can be identified. The most important chemical similarity to achieve is that of partition coefficient since large errors are introduced by extraction losses. Equilenin was selected as an internal standard due to its very close structural relationship with estrone (Structures I and II) so that the losses incurred during the entire operation were compensated. The value of *R*, the response factor as described by Celeste and Turczan (12), was found constant; however, it should be noted that

when employing the internal-external ratioing procedure, the determination of gas chromatographic response factor is not necessary.

The sample cream base formulated was composed of cetyl alcohol, stearyl alcohol, spermaceti, beeswax, white petrolatum, mineral oil, glycerin sodium lauryl sulfate, ascorbyl palmitate, BHT, BHA, and methyl- and propylparabens. Vitamin A palmitate and hydrocortisone alcohol were also present. To this cream base a fixed amount of internal standard of equilenin and known amounts of estrone at different levels were added. For 18 replicate samples, average recovery and coefficients of variation were found to be 98.9% and 1.1%, respectively. Three commercial preparations⁴ were assayed for their estrone content. The results obtained are shown in Table I.

Simultaneous Determination of Nonderivatized Phenylpropanolamine, Glyceryl Guaiacolate, Chlorpheniramine, and Dextromethorphan by Gas Chromatography

ERNEST MARIO and LAWRENCE G. MEEHAN

Abstract □ A gas chromatographic procedure is described for the rapid and quantitative determination of phenylpropanolamine, glyceryl guaiacolate, chlorpheniramine, and dextromethorphan in a commercially available cough-cold preparation. Pramoxine is used as the internal standard. The active ingredients are extracted in chloroform and injected without further treatment. A single chromatogram, obtained isothermally, quantitatively resolves all four ingredients.

Keyphrases □ Phenylpropanolamine, glyceryl guaiacolate, chlorpheniramine, dextromethorphan—simultaneous determination □ GLC—analysis □ Pramoxine—GLC internal standard

In recent years, the introduction of cough-cold preparations containing several active ingredients has increased sharply. The combining of antitussive, antipyretic, and antihistaminic drugs has distinct commercial advantages in that several cough-cold symptoms can be treated simultaneously with a single preparation. However, these combination-dose forms present serious difficulties to the quality control analyst who is concerned with identification and independent quantitation of each active ingredient. Classical wet methods are time consuming, expensive, and frequently of little use when the physical-chemical properties of two or more ingredients are relatively similar. The applicability of gas chromatography to pharmaceutical analysis is well documented in the literature (1-10), and the resolution of many types of mixtures has been published. Serious difficulties are often encountered when relatively polar compounds of high molecular weight are chromatographed (11). These materials often exhibit excessive tailing, and the selection of the liquid phase becomes very critical if resolution is to be obtained. The problem is compounded when active ingredients of widely divergent polarities are present in a given mixture. In a recent article, Hishta and Laubach (12) analyzed a mixture of phenylpropanolamine, phenylephrine, phenyltoloxamine, and chlorpheniramine by gas chromatography after forming the bistrimethylsilylacetamide (BSA) derivative.

This investigation was undertaken to study the advisability of using a low liquid load of nonpolar silicon rubber SE-30 in a modified all-glass system for the resolution of a multicomponent drug mixture containing ingredients of widely divergent polarities without the use of derivatives. In initial studies utilizing metal columns, it was found that the results were often inconsistent, showing incomplete recovery and excessive peak tailing. Apparently the active ingredients, when present in the free base form, interact in some way with metal surfaces. On modification to an all-glass, on-

column injection system, these problems were eliminated.

EXPERIMENTAL

Equipment—A Varian Aerograph model 1200-1 with flame ionization detector was used for the experimental work. The column used was a 2.44-m. (8-ft.) coiled Pyrex glass, 0.32-cm. (0.125-in.) o.d., packed with 2% SE-30 on 80/100-mesh diatomite [Chromosorb W (HP), acid washed and silanized]. Gas flow rates of 30 ml./min. for hydrogen, 30 ml./min. for helium, and 300 ml./min. for air were used. The instrument was modified by replacing the 0.64-cm. (0.25-in.) injection port containing 0.32-cm. (0.125 in.) metal inserts with an 0.32-cm. (0.125-in.) injection port, and the column was extended through the port to the septum. Injection was on-column, and therefore the sample did not come in contact with any metal surface except for the brief instant it passed through the syringe needle during injection. The detector oven and injection port were maintained at 270°. The column oven temperature was held isothermal at 180° through the analysis.

Reagents—The pramoxine internal standard was prepared by weighing approximately 1 g. of pramoxine hydrochloride of known purity into a 250-ml. separator containing 25 ml. of deionized water. After solution was effected, 25 ml. of 50% sodium hydroxide solution was added cautiously to the aqueous phase in the separator while cooling under cold tap water. This solution was then extracted with four 20-ml. portions of chloroform. The chloroform extracts were filtered through cotton and pooled in a 100-ml. volumetric flask. The total volume was adjusted to 100 ml. with chloroform. The solution, when refrigerated, was stable for approximately 6 weeks.

Sample Preparation—A commercially available cough-cold preparation was analyzed in this study.¹ The sample was prepared by pipeting 25.0 ml. of the "cough syrup" into a 250-ml. separator. Five milliliters of concentrated hydrochloric acid was added and the sample extracted with three 30-ml. portions of carbon tetrachloride. The carbon tetrachloride extracts were pooled and back-washed once with 30 ml. of deionized water. The aqueous extracts were pooled in a 250-ml. separator and the carbon tetrachloride phase discarded. Twenty-five milliliters of 50% sodium hydroxide was then added cautiously to the aqueous phase and cooled periodically under cold tap water. The sample was then extracted with seven 30-ml. portions of chloroform, adding 5 g. of sodium chloride to the combined phases during each of the first four extracts. The chloroform extracts were filtered through cotton and pooled in a 250-ml. wide-mouth beaker. The extracts were evaporated continuously (*but never to dryness*) on a steam bath with a stream of forced air. Evaporation was continued until approximately 25 ml. of the combined chloroform extracts remained. This volume was transferred quantitatively to a 50-ml. volumetric flask to which 5.0 ml. of the pramoxine internal standard reagent had been added. The total volume was adjusted to 50 ml. with chloroform.

Standard Preparation—A standard was prepared by weighing to the nearest tenth of a milligram approximately 55 mg. of phenylpropanolamine hydrochloride, 75 mg. of glyceryl guaiacolate, 5 mg. of chlorpheniramine maleate (prepared by weighing and dissolving 100 mg. of chlorpheniramine maleate into 100.0 ml. of deionized water and pipeting 5 ml. of this stock solution), and 37.5 mg. of dextro-

Figure 1—Typical chromatogram. Key: A, phenylpropanolamine; B, glyceryl guaiacolate; C, chlorpheniramine; D, dextromethorphan; and E, promoxine.

methorphan hydrobromide into a 250-ml. separator containing approximately 25 ml. of deionized water. After solution was effected, this standard solution was treated exactly as described for the sample solution, including the addition of 5.0 ml. of promoxine.

Procedure and Analysis—A 10- μ l. Hamilton syringe equipped with a Chaney adapter was used to inject 2.0 μ l. of the sample and standard solutions alternately. Values were calculated by peak height measurement. Since a completely synthetic standard was prepared in a manner identical to the procedure used to obtain the sample, and the detector response was linear within concentrations of $\pm 25\%$ of theory (see *Results and Discussion*), the ratio of the peak heights in the internal standard to each unknown could be stated in constant proportion to the ratio of their amounts, that is

$$\left[\frac{H_x}{H_s} \right]_{\alpha} = \left[\frac{C_x}{C_s} \right]_{\alpha} \quad (\text{Eq. 1})$$

and

$$\left[\frac{H_x}{H_s} \right]_{\beta} = \left[\frac{C_x}{C_s} \right]_{\beta} \quad (\text{Eq. 2})$$

where H_x is the peak height of the individual component to be analyzed, H_s is the peak height of the promoxine internal standard, C_x is the concentration of the component in mg./ml., C_s is the concentration of the promoxine internal standard in mg./ml., α is the ratio within the standard solution, and β is the ratio within the sample solution. Combining Eqs. 1 and 2,

$$\left[\frac{H_x}{H_s} \right]_{\alpha} \left[\frac{C_x}{C_s} \right]_{\beta} = \left[\frac{H_x}{H_s} \right]_{\beta} \left[\frac{C_x}{C_s} \right]_{\alpha} \quad (\text{Eq. 3})$$

Rearranging Eq. 3,

$$\left[\frac{C_x}{C_s} \right]_{\beta} = \frac{\left[\frac{H_x}{H_s} \right]_{\beta} \left[\frac{C_x}{C_s} \right]_{\alpha}}{\left[\frac{H_x}{H_s} \right]_{\alpha}} \quad (\text{Eq. 4})$$

But the concentration of the internal standard is held constant in both the sample (β) and the standard (α) solutions. Therefore, Eq. 4 simplifies to

$$[C_x]_{\beta} = \frac{\left[\frac{H_x}{H_s} \right]_{\beta} [C_x]_{\alpha}}{\left[\frac{H_x}{H_s} \right]_{\alpha}} \quad (\text{Eq. 5})$$

Since the term $[C_x]_{\alpha}$ is known, and $[H_x/H_s]_{\alpha}$ and $[H_x/H_s]_{\beta}$ are measured experimentally, Eq. 5 can be solved for $[C_x]_{\beta}$ (the mg./ml. of unknown in sample). The values obtained from Eq. 5 were compared to

	9.38	9.33	99.47

the theoretical amounts of each component and the percent recovered calculated.

RESULTS AND DISCUSSION

A typical chromatogram is shown in Fig. 1. All the peaks are symmetrical and well resolved. Table I contains data of the detector response in a concentration range of $\pm 25\%$ of the theoretical drug quantities contained in the sample preparation. Table II contains the recovery data for the four active ingredients in duplicate samples of 10 different lots of the cough preparation calculated from peak height values. Precision and accuracy data are also presented and indicate excellent reproducibility.

The initial preextraction of the cough preparation with carbon tetrachloride was necessary to remove the organic soluble flavor and coloring additives which interfere with the chromatogram.

A simplified single-injection, gas chromatographic method for determining phenylpropanolamine, glyceryl guaiacolate, chlorpheniramine, and dextromethorphan in a commercially available cough preparation has been presented. The use of an isothermal method results in excellent resolution of all four components not withstanding their widely divergent polarities and boiling points. The modification of the chromatograph to an all-glass, on-column injection system yields quantitative, reproducible results. The pro-

Utilization of the Solids Processor for Preparation of Tablet Granulations

FRANK W. GOODHART, J. RONALD DRAPER, and FRED C. NINGER

Abstract □ Various factors relating to the use of vacuum tumble dryers for the preparation of tablet granulations were studied. A dryer was employed (the 1-cu. ft. solids processor) which has a working capacity of 15–18 kg. for most pharmaceutical granulations. A typical process involves the wetting of the substrate with a drug solution and then drying at a predetermined temperature and vacuum. It was found that uniform drug distribution for low-dose tablet formulations could be obtained. Drying rates were determined for spray-dried lactose and dicalcium phosphate dihydrate at two temperatures and three tumbling speeds. Drying times varied from 35 to 60 min. A series of modified direct compression formulations was studied in which microcrystalline cellulose was used at two levels; two lubricants, calcium stearate and stearic acid, were employed; and lubricant addition was carried out by two methods, internal and external. The effects of these factors on tableting characteristics were monitored by an instrumented tablet machine (Stokes BB-2), and the final physical properties of the tablets were determined. A series of antacid granulations was prepared in which the influence of mixing time and the amount of granulating fluid was varied. The resulting granulations and tablets were characterized as described above.

Keyphrases □ Solids processor—preparation, tablet granulations □ Tablet granulations, preparation—solids processor □ Vacuum tumble dryers—data, mixing, drying, formulation, processing factors

New technology for the formulation of solid dosage forms has been developed over the past 5–10 years. The availability of new materials *per se*, new forms of old materials, and the invention and utilization of new machinery have allowed the formulation and manufacture of many products by simplified methods. Thus, the use of direct compression of medicinals, especially

those in the low- and medium-dose range, has overtaken older traditional methods of wet granulation and slugging. Emphasis on faster dissolution rate and providing the drug in a readily available form are other reasons for updating tablet formulation and technology.

Some methods for simplified processing of tablet granulations have been described. A spray-drying process was reported by Raff *et al.* (1). A placebo granulation was prepared by spray drying and the drug, colorant, and tablet lubricant were added to the granulation and blended. A one-step spray-drying process could conceivably be feasible if the high inlet temperature would not physically or chemically affect the drug. Later, Kornblum described a spray-drying process for the preparation of a granulation for the formulation of sustained-action tablets (2).

The Littleford-Lodge mixer has been shown to be of value in mixing small quantities of active ingredients with inert diluents (3). In experiments using 250 mcg. of micronized salicylamide per 100 mg. of terra alba, coefficients of variation for drug content were from about 1 to 4% over a 0.5–10-min. interval of mixing. Mixing unmiconized salicylamide gave a significantly higher coefficient of variation.

An air-suspension technique for the preparation of tablet granulations was described by Wurster (4). These granulations were 16–20% active by weight, and deviation of content from theory was about –1 to +6%. The amount of solids lost was 1–8%.

Some of these methods might be satisfactory for active products in the low-dose range, arbitrarily in the

Keyphrases □ Solids processor—preparation, tablet granulations □ Tablet granulations, preparation—solids processor □ Vacuum tumble dryers—data, mixing, drying, formulation, processing factors

New technology for the formulation of solid dosage forms has been developed over the past 5–10 years. The availability of new materials *per se*, new forms of old materials, and the invention and utilization of new machinery have allowed the formulation and manufacture of many products by simplified methods. Thus, the use of direct compression of medicinals, especially

those in the low- and medium-dose range, has overtaken older traditional methods of wet granulation and slugging. Emphasis on faster dissolution rate and providing the drug in a readily available form are other reasons for updating tablet formulation and technology.

Some methods for simplified processing of tablet granulations have been described. A spray-drying process was reported by Raff *et al.* (1). A placebo granulation was prepared by spray drying and the drug, colorant, and tablet lubricant were added to the granulation and blended. A one-step spray-drying process could conceivably be feasible if the high inlet temperature would not physically or chemically affect the drug. Later, Kornblum described a spray-drying process for the preparation of a granulation for the formulation of sustained-action tablets (2).

The Littleford-Lodge mixer has been shown to be of value in mixing small quantities of active ingredients with inert diluents (3). In experiments using 250 mcg. of micronized salicylamide per 100 mg. of terra alba, coefficients of variation for drug content were from about 1 to 4% over a 0.5–10-min. interval of mixing. Mixing unmiconized salicylamide gave a significantly higher coefficient of variation.

An air-suspension technique for the preparation of tablet granulations was described by Wurster (4). These granulations were 16–20% active by weight, and deviation of content from theory was about –1 to +6%. The amount of solids lost was 1–8%.

Some of these methods might be satisfactory for active products in the low-dose range, arbitrarily in the

Figure 1—*Photograph of the 1-cu. ft. vacuum tumble dryer used throughout the study.*

area of 0.5–5 mg. per tablet. Ordinarily, tablet weights for these drug potencies would be 100–200 mg. When low microgram (10–100) quantities of drug are to be incorporated into a tablet, it is the generally accepted procedure to dissolve the drug in an appropriate solvent and apply the solution to the tablet substrate. The reasoning for this procedure is that drug particles often vary substantially in physical characteristics from the tablet substrate. Adequate dry blending of low-dose drugs would be dependent on a number of factors. Among these are the relative size distribution of the substrate compared to the drug, the ratio of drug to the substrate, the degree of affinity of the substrate for the drug, and the degree of static charge. The type of mixer used and mixing time are additional practical considerations. In one report, the mixing technology for 0.1-mg. reserpine tablets weighing 100 mg. (5) was studied. It was found that 100 mg. of the ultimate dry mix obtained had a coefficient of variation of 3.5%. However, on wetting this mix and granulating with water, the resulting granules had a coefficient of variation of 4.3%. The explanation for the slight segregation in the mix was the fact that the various components had different affinities for the water.

From these considerations, it was believed that vacuum tumble dryers (VTD) would provide advantages to the total processing of pharmaceutical granulations. Formerly, two reports on the use of twin-cone vacuum dryers for pharmaceutical material had ap-

peared (6, 7), but no data on the total processing of tablet granulations were reported. VTD provides a method for addition of drug from solution, thus eliminating the various problems encountered in dry mixing procedures; among these are colorant blending and static charge. Since the material is agitated during drying, the tendency for the drugs to migrate, a factor which might produce nonuniformity within the powder bed, is minimized. Other advantages which are readily apparent are: (a) drying in vacuum can be carried out at lower temperatures, thus heat-labile drugs may be processed more favorably; (b) installations are compact; (c) solvent can be recovered; (d) complete enclosure of the mixing chamber virtually eliminates the possibility of contaminating adjacent areas with potent drug; (e) tumble dryers are easy to clean; (f) discharging of material from the VTD is easy and this results in high yields of finished product. One-step processing of some formulations might be feasible and this alone greatly simplifies manufacturing procedures. It was also believed that overall processing time might be shorter than could be achieved with other equipment. In opposition to these advantages are the relatively high cost of vacuum dryers and the fact that this equipment is not available in many pharmaceutical processing plants.

A general study of the technology for using VTD was undertaken in order to better understand its overall applicability to the processing of pharmaceutical

granulations. Experiments on mixing, drying, formulation factors, and processing factors were carried out and are reported here.

EXPERIMENTAL

General Description of Equipment—The equipment employed was a 1-cu. ft. vacuum tumble dryer¹ which is shown in Fig. 1. A schematic representation is illustrated in Fig. 2. The shell, 1, is fabricated of 304 stainless steel, and all pipes and fittings are 304 stainless steel. It has a working capacity of about 15–18 kg. for most pharmaceutical materials and is driven by a $\frac{3}{4}$ -hp. Reeves Vari-Speed Motodrive which can turn the shell at speeds to 47 r.p.m. The shell is jacketed, thus providing a method of heating or cooling the material being processed. Access covers are provided on both sides and a butterfly valve and additional cover are used for discharging the material. The intensifier bar is operated by a separate 3-hp. motor. The bar functions as a disperser for added liquid material. A liquid feed tube is used in conjunction with the intensifier bar for the addition of liquids. Liquids are dispersed between two sets of disks on the intensifier bar. Spacings between the disks may be varied from 0.013 to 0.051 cm. (0.005 to 0.020 in.). The prongs on the dispersing disks are used for more vigorous mixing or for the reduction of agglomerates.

The jacket is heated by means of chromalox immersion heater and a liquid circulating pump. Heated liquid may be chilled by shunting the circulation through a heat exchanger which is connected to the same chiller that is used for the condensing system.

The vacuum and condensing system consists of a felt ring-type filter in the vessel, a vapor temperature thermometer, an absolute mercury manometer, a solids separator, two slanted condensers leading to a receiver, a Kinney KC-8 vacuum pump, and a Carrier model 30EA005 liquid chilling package. An ethylene glycol–water mixture was used in the chilling unit and the temperature of the

Table I—Composition of Tablet Granulation for the Determination of Uniformity of Mixing

	One Tablet	110,000 Tablets
Methylparaben USP	0.20 mg.	0.0220 kg.
Isopropyl alcohol NF		1.500 l.

Calcium stearate NF	1.50 mg.	0.165 kg.
	150.00 mg.	16.500 kg.

circulating liquid was generally -2 to -5° . A solenoid valve between the vacuum pump and the condensers closed when the vacuum pump was turned off, thus preventing the condensers from being fouled with oil. The vacuum pump was vented to the atmosphere for removal of vapors which collect in the oil.

General Operation—Material is placed in the shell and the access covers are fitted and sealed against the recessed O-rings. Care must be taken to obtain a good seal because small amounts of material between the lid and O-ring may cause a leak which interferes with the operation of the processor. The material may be mixed by tumbling, and if lumps are present the intensifier bar may be turned on. Dispersion blades on the intensifier bar effectively break up agglomerates and give additional agitation for better mixing. Liquids are then added via the liquid feed tube. For the preparation of low-dose tablets, typically 1000–1500 ml. of drug solution is added to 15–18 kg. of substrate. Usually the time period of addition is 5 min., but shorter intervals are also satisfactory. Part of the solvent containing no drug is retained for flushing the liquid feed tube and dispersing disks. Heat and vacuum are then applied to the shell. The degree of vacuum that may be used is determined by the inspection of the vapor pressure–temperature curve for the solvent being used and the temperature of the condensate. For isopropanol the condensed liquid had a temperature of about 23° ; thus, a vacuum of 40 mm. of Hg could be applied without causing the isopropanol to boil. Upon reaching a vacuum of 40 mm. of Hg, the vacuum pump is shut off. Evaporation and condensation of the solvent continue at about this level of vacuum until most of the solvent is collected. The receiver is emptied at this point and full vacuum is applied to the system to remove the last traces of solvent. Generally, this process using isopropanol takes about 30–50 min. and solvent recoveries are 90–95%. Ordinary materials used for producing low-dose tablet formulations are easily emptied from the shell, giving very high yields of finished product. No problems with the sticking of materials to the shell were encountered in this work.

Materials—Spray-dried lactose USP XVII, dibasic calcium phosphate dihydrate USP XVII, isopropyl alcohol NF XII, stearic acid USP XVII, calcium stearate NF XII, starch USP XVII, microcrystalline cellulose NF XII (Avicel PH 101), methyl *p*-hydroxybenzoate, an estrogenic steroid, and an antacid powder containing magnesium trisilicate, aluminum hydroxide, and magnesium hydroxide.

Equipment—Stokes BB-2 27 station tablet machine instrumented to detect and measure compression force (CF), ejection force (EF), and lower punch pulldown force (LPPF); an air-actuated pressure-regulated hardness tester; a friabilator (8); and a USP XVII tablet disintegration tester.

Evaluation of VTD for the Distribution of Low-Dose Ingredients—Preliminary experimentation on the preparation of drug concentrates, which were to be diluted for the production of tablets by the direct compression method, indicated that homogeneous blends could be obtained. The drug concentrates varied in composition from about 0.20 to 0.75% w/w. An experiment was designed for checking typical drug distribution in a 150-mg. tablet containing 200 mcg. of active ingredient. A model drug, methylparaben, was chosen for this work in order to minimize any assay difficulties which might occur. Tablets were prepared according to the formula shown in Table I.

Microcrystalline cellulose, starch, and spray-dried lactose were placed in the VTD and mixed well by tumbling. Methylparaben was dissolved in 1 l. of isopropyl alcohol and added to the powder mix.

An additional 500 ml. of isopropyl alcohol was used for rinsing the liquid feed tube and intensifier bar. The general procedure previously given was used to dry the granulation. Jacket temperature was set at 66° and the entire process was completed in 40 min. At the end of the run, three 100-g. samples of granulation were withdrawn from the two sides and bottom of the processor. Samples of granulation weighing approximately 150 mg. each were assayed in duplicate in order to determine uniformity of mixing. A spectrophotometric procedure was utilized for assay of methylparaben. This involved treating the sample with 0.05 *N* sodium hydroxide, filtering, and reading at 295 m μ . A blank was similarly prepared from the active granulation, but the solution was neutralized with 0.05 *N* HCl to quench the absorbance of methylparaben at 295 m μ . The precision of the method was estimated by assaying six samples of the bulk 100-g. sample from the bottom position.

Factors Affecting the Drying Rate of Spray-Dried Lactose and Dicalcium Phosphate Dihydrate—Preliminary work on drying 16.5–18-kg. charges of these materials indicated that two machine factors might affect drying rate. Temperature, of course, was one factor and speed of tumbling the second factor. Two temperatures, 42 and 66°, and three tumbling speeds, 7, 17, and 31 r.p.m., were studied.

Isopropyl alcohol (1500 ml.) was added to 16.5 kg. of spray-dried lactose or 18.0 kg. of dicalcium phosphate dihydrate over a 5-min. period. The choice of the material to be run, the temperature, and tumbling speeds were randomly selected. After liquid addition via the liquid feed tube, a vacuum of 60 mm. Hg was applied and the jacket temperature was turned on. At the end of an additional 5 min., the vacuum was reduced to about 40 mm. Hg and the processing continued until 1400–1450 ml. of isopropanol had been collected. Measurements of the condensate collected were made every 5 min. by means of measuring the height of the liquid in the receiver which had been previously calibrated. The condensate was drained from the receiver and full vacuum was applied. Usually an additional 10–40 ml. of isopropanol was collected.

Preparation of Low-Dose Tablet Granulations—The problem of mixing very small quantities of drugs with diluent is usually overcome by adding a solution of the drug to the diluent. VTD seemed ideal for such granulations since the drug could be added through the liquid feed tube and the mixture could then be conveniently dried in a closed system. Furthermore, it also seemed reasonable to add colorants and tablet lubricant by means of solution or suspension, thus allowing a one-step processing method.

Figure 3—Evaluation of mixing for methylparaben, 200 mcg./150 mg., prepared in the vacuum tumble dryer. Key: T, top; M, middle; and B, bottom.

A factorial experiment was designed in order to test a number of formulation variables. These were the level of microcrystalline cellulose, 20 and 35%; kind of lubricant, stearic acid and calcium stearate; and method of lubricant addition, internal or external. Other excipients common to all formulas were spray-dried lactose and starch; the overall formulas are given in Table II with the method of lubricant addition.

A steroid drug was used at 10- and 25-mcg. levels during initial investigation. It was decided to carry out formulation screening without drug since excessive quantities were required and the formulations not containing drug had the same physical and compression characteristics as active granulations.

The general procedure for preparing these granulations was to blend the lactose, starch, and microcrystalline cellulose in the VTD. In the case of internally lubricated formulations, a suspension of the lubricant and the colorant was made in isopropanol and added to the powder blend by means of the liquid feed tube and rotating intensifier bar. In formulations where the lubricant was added externally, only the colorants were added from suspension in isopropanol. The same procedure was used for drying as described previously under drying rate experimentation, but a temperature of 66° and a speed of 7 r.p.m. were used for all runs. Lubricants, when added externally, were passed through a No. 60 screen onto a portion of the dried granulation, preblended, and then added to the bulk of the granulation and drum rolled for 20 min.

Finished granulations were characterized by determining flow rate through a standard Stokes BB-2 hopper, by compression on an instrumented Stokes BB-2 tablet machine, and by measuring finished tablet characteristics. Tablets were prepared using 0.71-cm. (9/32-in.) flat-faced beveled-edge punches at a weight of 150 mg. and a speed of 1400 tablets per minute.

Preparation of an Antacid Granulation by the Standard Wet Granulation Technique—The components of this granulation were

^a Material: spray-dried lactose, 16.5 kg. Date: June 4, 1968. Liquid: isopropanol, 1500 ml. Tumbling speed: 31 r.p.m. Jacket temperature: 66°.

mixed in the VTD by means of the impeller bar while tumbling. Batch size was 15 kg. Varying amounts of water from 2100 to 2800 ml. were added, and agitation time with the intensifier bar was varied to determine whether these were important factors in the actual processing of the granulation. The water was added over a 5-min. period *via* the liquid feed tube and rotating intensifier bar. Drying temperature was at a jacket setting of 60° and tumbling speed was 25 r.p.m. Mesh sizes, bulk density, and flow rates were measured on all samples. Tablets were compressed on the Stokes BB-2 instrumented tablet machine using 1.58-cm. (0.63-in.) flat-faced beveled-edge punches at a theoretical weight of 1.33 g.

RESULTS AND DISCUSSION

Evaluation of Mixing—Replicate assays of a well-mixed granulation from the bottom position resulted in a mean content of 202.2 mcg. and a standard deviation of 1.40. Results from duplicate positional assays are plotted in Fig. 3 along with 95% confidence limits derived from the standard deviation obtained from the replicate measurements. There is a lack of any significant difference in the content of the three positional samples. In view of the turbulent condition of the powder bed during liquid addition, uniform mixing was expected. The VTD was fitted with lucite lids rather than the standard steel access covers. This allowed a viewing of the condition of the contents under the various processing conditions. Liquid addition at the rate of 200–300 ml. per

minute was observed, and it was noted that the high degree of turbulence produced by the intensifier bar in conjunction with tumbling of the VTD effectively wetted only the powder. It seemed unlikely that localized wetted areas could be produced under these processing conditions. On drying, the mixture was free flowing, and localized sticking was not experienced.

Drying Rates—Little information has been published on drying pharmaceutical materials and particularly complete tablet granulations in VTD. Swartz and Suydam (7) described the drying of calcium sulfate dihydrate, lactose, and mannitol in the Rovac twin-shell processor after addition of 1000 ml. of water to 10 kg. of substrate. Under the conditions of heat and vacuum employed in the Rovac drying, a rising rate, constant rate, and falling rate drying cycle was observed. Heat transfer coefficients for the system were calculated and reported.

40	3.37
50	3.70

Isopropyl alcohol is often the solvent of choice for addition of drugs to a tablet substrate; therefore, this solvent was chosen for experimentation. A typical processing sheet for these experiments is shown in Table III. Liquid was added over the first 5-min. period and the jacket temperature was turned on. After about 15 min. the jacket circulating fluid reached the setting of 66°. Batch temperature was 46° after 10 min. of operation and eventually reached 66° by the end of the run. Condensate begins to flow well after 10 min. and is rapidly collected over the next 25 min. of processing. The increased vapor temperature through the run indicated that isopropyl alcohol vapors were being collected in a somewhat superheated condition. During some processes it is advisable to back-flush the felt filter by means of quickly opening the ball valve (item 18 in Fig. 1). Inrushing air forces dry powdered material off the filter, thus allowing better vapor flow from the vessel.

Comparative condensate volumes collected as a function of time are shown in Fig. 4 for dicalcium phosphate dihydrate at 42°. These data clearly point out the advantage of drying at a high tumbling speed over slow tumbling. The process is completed in 45 min. at a tumbling speed of 31 r.p.m., but 60 min. is required for drying at 7 r.p.m. Similar data were obtained for drying spray-dried lactose, Fig. 5. When drying was carried out at 66° the effect of tumbling speed was much diminished and the drying time becomes almost entirely temperature dependent.

Drying rates were calculated and are shown in Figs. 6 and 7 for spray-dried lactose and dicalcium phosphate dihydrate. At 66° the drying rate reached a maximum of about 100 ml./min. for lactose and between 67 and 87 ml./min. for dicalcium phosphate. At this higher temperature setting, a sharply rising drying rate occurs followed by a very sharp drop in rate. Drying at 42° gives a somewhat lower drying rate and a subsequent increase in overall processing time of about 10–15 min. A nearly constant drying rate was noted for dicalcium phosphate at the two lower speeds and for lactose only at the lowest speed. The effect of tumbling speed on drying rates is probably due to the greater surface area exposed at the higher speeds. At these higher speeds the effect of centrifugal force on holding the material to the walls might be considered a factor which would retard drying rate. However, the materials employed in this study were in motion even at high speed, and this factor would then contribute to the somewhat increased drying rates.

Larger VTD requires longer drying periods, but drying time does not increase proportionately with size. The manufacturer was asked for information on drying time in larger processors, and the factors for various sizes are listed in Table IV (9).

Predicted drying time for a process in a 30-cu. ft. VTD would be three times the time in a 1-cu. ft. VTD. Thus, a process requiring 35 min. in the 1-cu. ft. VTD would require 105 min. in a 30-cu. ft. VTD or 135 min. for a process requiring 45 min. in the smaller

Figure 7—Drying rates for dicalcium phosphate dihydrate using 1500 ml. of isopropyl alcohol and a 18.0-kg. load. Key: S₁, 7 r.p.m.; S₂, 17 r.p.m.; and S₃, 31 r.p.m.

unit. These drying times are quite reasonable in view of drying times and extra handling needed by alternate methods.

Low-Dose Tablet Granulations—Granulations were processed in a routine manner similar to those carried out for spray-dried lactose in the drying rate experiments. Overall processing time was 45 min. and about 93–97% of the added isopropanol was recovered. All materials were free flowing when dried and no sticking to the lids or vessel itself occurred. Yields were very high.

Flow rates were determined by loading 4.0 kg. of granulation into the standard hopper used for the BB-2 machine and noting the weight delivery onto a balance at 15- or 30-sec. intervals. Distance from the bottom of the hopper to the balance platform was 15.24 cm. (6 in.). This type of experiment gives an indication of the glidant activity of the granulation and also whether or not flow is sluggish. Sluggish or nonlinear flow rates have been shown to increase variability of tablet weights under some conditions of tableting (10). All eight of the granulations prepared exhibited linear flow rates as calculated by regression analysis. Flow rates for the various granulations are given in Table V in g./sec.

The highest flow rates are for granulations containing stearic acid added from alcoholic solution. Lubricant added internally generally gives higher flow rates except for calcium stearate at the high level of microcrystalline cellulose. These data might be indicative of a lubricant coating around the substrate particles.

An attempt was made to compress tablets at hardnesses of about 6 and to measure the resulting compression properties and physical

^a Determined using the Numinco bulk density tester.

properties. These data are summarized in Table V. Tablets were compressed from all eight granulations, but two of these, 3 and 4, demonstrated very high friability of 10–11%. A considerable amount of capping occurred during the friability test. While a relatively high compressive force was used to tablet these formulations, average hardnesses of only 4.6 and 3.2 were attained. Each of these formulations contained calcium stearate and a lower level of microcrystalline cellulose.

Formulation factors were quite significant in the amount of compressive force needed to make a tablet and to a lesser extent on the magnitude of ejection force. In Fig. 8, average compressive force is shown as a function of the formulation factors. All three factors were very significant statistically. The most significant factor was the level of microcrystalline cellulose. Low level (20%) formulations required compression at an average of 1906 lb. but the higher level (35%) formulations were compressed at an average of 1055 lb. Formulations with the higher microcrystalline cellulose levels had hardnesses of 5.6–6.8 and were virtually nonfriable. Granulations containing internally added lubricant (I) required higher compressive force than externally added lubricant (E), Fig. 8. The higher force for the internally lubricated substrate is related to crystal fracture and realignment in order to obtain a particle bonding. The calcium stearate formulations were compressed on the average at higher compressive force levels than stearic acid formulations.

The effect of formulation factors on the resultant ejection force is shown in Fig. 9. The type of lubricant is seen to have no significant effect on ejection force, but both method of lubricant addition and microcrystalline cellulose level were highly significant. The degree of difference between externally and internally lubricated granulations is small from the practical viewpoint. It appears that internally added lubricant may be satisfactory over a long run and that the final mix step, so common for all tablet granulations, could be omitted. Since microcrystalline cellulose itself does not adhere to die walls when directly compressed, it seems reasonable that in-

creasing its level in tablet formulations reduces ejection force. It is conceivable that savings in both tool and machine wear are possible by working at lower compressive forces. Whether or not this factor is worth considering over the use of more expensive raw materials has not been determined.

Disintegration times on all formulations were good. Formulas 5 and 6 indicate a tendency toward longer disintegration times on these internally lubricated granulations. Drug dissolution studies would be required to determine further the extent of drug availability as a function of lubricant addition method.

The coefficient of weight variation for all formulas seemed to be reasonable but Formulation 1 was somewhat higher than the others. During the flow rate studies, it was noted that this formula tended to plug the hopper on several occasions. On other runs, uniform flow was observed. The somewhat sluggish nature of this granulation probably accounts for the higher weight variability.

Preparation of Antacid Tablets—Granulations were produced using various levels of water and two mixing times as noted in Table VI. Increments of water were increased by 200 ml. in successive experiments. Preliminary experiments indicated that at least 2000 ml. of water was required to produce a granulation that could be tableted and that 2800 ml. produced an overwetted granulation which balled up in the processor. Tablets were compressed at hardnesses of about 10 kg./sq. in. and the resultant compressive force was measured.

Statistical comparison of flow rates of the granulations showed a significant difference in slopes between experiments. A trend towards higher flow was noted as the amount of water used to granulate increased. The mesh sizes of all granulations were about the same with the exception of Formula 8 which was coarser. In Formula 8 the highest level of water and the longest mixing time were used. This coarser mesh pattern could account for higher flow rate. Formula 3 exhibited the lowest flow rate and also the highest

Figure 8—Average compressive force as a function of formulation factors for direct compression granulations. Key: AL, microcrystalline cellulose 20%; AH, microcrystalline cellulose 35%; I, internal lubrication; E, external lubrication; CS, calcium stearate; and SA, stearic acid.

Figure 9—Effect of formulation factors on ejection force. Key: CS, calcium stearate; SA, stearic acid; I, internal lubrication; E, external lubrication; AL, microcrystalline cellulose 20%; and AH, microcrystalline cellulose 35%.

coefficient of variation of compressive force. However, weight variation of Formula 3 was comparable to other experiments.

Comparing experiments, hardness was not directly proportional to compressive force, indicating that these formulations require a somewhat different compression force for preparing tablets of an average hardness of 10. It is believed the variability in required compression force between different granulations of the same formula might be large enough to preclude using compressive force as a possible specification in this type of product. The reasons for shifts in required compression force have not been reported at this time nor their importance described.

All formulations were satisfactory with respect to chew and mouthfeel characteristics, and no substantial difference could be found between formulations when tasted by a small taste panel.

Moisture recovery on drying was 98–99%, and processing times varied from 105 min. for the lowest amount of added water to 120 min. for the highest amount of added water. Whether these relatively long processing times, compared with an isopropanol process, are acceptable depends to a large degree on the kind of product being made and the required rate of production.

SUMMARY AND CONCLUSIONS

Various data on the operation of a 1-cu. ft. VTD as related to general tableting technology have been reported. The results indicate that vacuum tumble drying is a satisfactory process for some particularly common types of tablet formulations. It was found that adequate mixing could be obtained and that the short processing time coupled with good yields were other advantages. Obviously the use of such equipment on a larger scale requires the usual considerations of loading, unloading, cleaning, etc. While

the authors' experience in working with the VTD on a pilot scale was highly satisfactory, other alternate methods are available. However, the convenience factor as well as other advantages listed earlier seems to indicate the VTD may often be the process of choice.

Encapsulation of Clomacran Phosphate {2-Chloro-9-[3-(dimethylamino)propyl]acridan Phosphate} I: Effect of Flowability of Powder Blends, Lot-to-Lot Variability, and Concentration of Active Ingredient on Weight Variation of Capsules Filled on an Automatic Capsule-Filling Machine

GEORGE M. IRWIN*, GERALD J. DODSON, and LOUIS J. RAVIN

Abstract □ A correlation has been shown to exist between the flow properties of clomacran phosphate powder blends and capsule fill weight variation when an automatic capsule-filling machine is used. A correlation of 0.96 was obtained for the capsule mixes tested. Weight variation of the finished capsules is also affected by lot-to-lot variability and concentration of clomacran phosphate. Granulation of the active ingredient overcomes most of the problems normally encountered and provides finished capsules of uniform weight.

Keyphrases □ Clomacran PO₄—encapsulation □ Weight variation—clomacran PO₄ □ Powder blends flowability, lot variability effects—capsule weight variation □ Concentration effect, clomacran PO₄—capsule weight variation

Automatic capsule-filling machines are a recent addition to the equipment available to the industrial pharmacist for the encapsulation of powders. A detailed description of the operation of one of these machines (the

Zanasi capsule-filling machine) was reported by Stoye (1). He pointed out that, with a well-formulated product, capsules can be filled with a high degree of filling accuracy. Recently Reier *et al.* (2) evaluated the factors affecting the encapsulation of powders using a semi-automatic filling machine, but the literature has little information on the development of formulations to be used with an automatic capsule-filling machine. The purpose of this paper is to report data related to some of the problems encountered during the development of a capsule mix containing clomacran phosphate for use with the Zanasi capsule-filling machine.

In these studies, an attempt has been made to correlate the flowability of powder mixes, as measured with the flowometer described by Gold *et al.* (3), with the weight variation of capsules observed during encapsulation with the Zanasi. In addition, the way in which lot-to-lot variability, the concentration of clomacran

phosphate in the powder mixes, and different strength granulations affected the weight variation of the capsules were also evaluated.

EXPERIMENTAL

Materials—Clomacran phosphate, SK & F; lactose USP; magnesium stearate USP; sodium lauryl sulfate USP; free-flowing starch¹; lactose, spray-dried²; terra alba, English³; calcium phosphate, dibasic⁴; polyvinylpyrrolidone⁵; fumed silica.⁶

Apparatus—Zanasi automatic capsule-filling machine was used.⁷ The recording powder flowmeter described by Gold *et al.* (3) was used throughout these studies for the flowability measurements. Since the apparatus was designed to measure flow rates of granulated materials, it was necessary to use a Vibrolator⁸ to facilitate the flow of the powder blends from the hopper.

Preparation of Powder Blends—Six powder blends containing a constant concentration of drug, lubricant, and excipient were prepared; different excipients were used in each formula. A formulation without active ingredient was also prepared. The formulas for the various powder blends are listed in Table I.

Each powder blend was prepared in the same manner prior to flow-rate measurements. Several additional powder blends were prepared in order to determine the effect of lot-to-lot variability and concentration of the active ingredient on the weight variation of finished capsules. The formulas for these blends are listed in Tables II and III. Flow-rate measurements were not obtained for powder blends listed in Tables II and III.

⁶ Cab-O-Sil, Cabot Corp., Boston, Mass.

⁷ Model LZ 164, United Shoe Machinery Corp., Boston, Mass.

⁸ Model UCV-6, Martin Engineering Co., Neponset, Ill.

Clomacran phosphate granulations were prepared with different lots of chemical at several concentrations of active ingredient to determine what effect granulating would have on the weight variation of finished capsules. The formulas for the granulations are listed in Table IV.

Flow-Rate Measurements—Flow rates expressed in g./sec. were determined with the flowmeter for the seven powder blends. Each value represents an average of four determinations. Samples were run on 2 different days to minimize variations due to ambient conditions.

Preparation of Capsules—The powder blends evaluated for their flow properties were filled into No. 4 capsules. Any necessary adjustments were made for the first formulation and kept constant throughout the study.

Twenty groups of 10 capsules each were collected from each of the seven formulations encapsulated. These capsules were in turn divided into groups of five according to the dosator from which they had been obtained. All capsules were weighed on a torsion balance to establish the control weight during the filling operation, and one of the five capsules from each group was randomly selected and weighed on an analytical balance. Accurate weights were obtained for 20 capsules from each dosator for the seven powder blends.

Similar procedures were employed during the encapsulation of the formulations prepared to evaluate the effect of lot-to-lot variability and concentration of active ingredient. The granulation was treated in a similar manner. Nos. 1, 3, and 4 capsules were used to encapsulate the 100-, 50-, and 25-mg. strengths, respectively.

RESULTS AND DISCUSSION

Rate of Flow Measurements—Stoyle (1) has outlined the essential characteristics for powder blends which are to be encapsulated with the Zanasi capsule-filling machine. During the authors' preliminary investigation it was observed that whenever capsules prepared from a particular powder blend had a high coefficient of weight variation, a cavity was left in the powder bed in the hopper which was not completely refilled after the dosator removed the charge. This observation prompted these flow-rate measurement studies. The flow-rate measurements served as a screen to select a combination of

Table V—Rate of Flow Measurements for Various Powder Blends

Blend	Rate of Flow, g./sec.
1	4.08
2	1.01
3	0.95
4	0.75
5	0.58
6	0.52
7	Did not flow

ingredients having the best flow properties. Flow-rate data obtained for seven capsule blends are shown in Table V.

It is evident from these data that the flow-rate varies with the different blends. Figure 1 illustrates the relative order of flow rate for three of the powder blends evaluated. The actual rates were determined by dividing the total weight flowing through the hopper by the total elapsed time.

Capsule Weight Variation—The weight variation for the seven capsule blends was calculated as a percent of capsule fill, since the density of the mixes differed, depending upon the excipients used in each case. For the lot of empty capsules used to encapsulate the powder blends, the mean and standard deviation were determined to be 37.1 and 1.3 mg., respectively. Utilizing these values and the standard deviation for the finished capsules, it was possible to calculate the standard deviation for the capsule fill alone. The values for the mean and standard deviation and the coefficient of variation for the seven powder blends are listed in Table VI.

Figure 2 illustrates a plot of rate of flow *versus* coefficient of variation for five blends.⁹ A linear response was obtained and a correlation coefficient of 0.96 was calculated which indicates a good fit of the data. It is evident from this correlation that the flowability of the powder blends is related to the weight variation of the clomacran phosphate capsules filled on the Zanasi capsule-filling machine.

On the basis of flowability and weight variability data, powder blend No. 2 appeared to have the essential characteristics for encapsulation using the Zanasi. Subsequent powder blends containing varying concentrations of ingredients similar to those of powder blend No. 2 were evaluated on the basis of coefficient of weight variation of finished capsules. Since a correlation of 0.96 had been obtained between flowability and coefficient of variation for several capsule blends, it was felt that weight variation of finished capsules could be used to evaluate future powder blends. A coefficient of weight variation of 3% was arbitrarily set as a maximum. Any formulation that exceeded this limit was considered unsatisfactory.

Effect of Different Lots of Clomacran Phosphate Chemical—Table VII illustrates what effect various lots of clomacran phosphate chemical had on the capsule weight variation of finished capsules. A variation was noted when different lots of chemical were used, and further examination of the chemical indicated a difference in particle size. Figure 3 shows photomicrographs of several lots of clomacran phosphate chemical. The data suggest that a difference in particle size is responsible in part for the observed weight variation. The chemical of larger particle size shows less variation. Formula No. 10 prepared with chemical Lot C had a coefficient of weight variation outside the 3% limit.

Effect of Concentration of Clomacran Phosphate—The data in Table VIII indicate that the concentration of clomacran phosphate

Table VI—Capsule Weight Variation Data for Seven Clomacran Phosphate Blends

Blends	\bar{X} , mg.	σ , mg.	CV
1	175	1.8	1.0
2	168	2.8	1.7
3	164	3.9	2.4
4	136	5.0	3.7

Formula	Lot of Chemical	\bar{X} , mg.	σ , mg.	CV
8	A	281	1.6	0.6
9	B	229	4.9	2.1
10	C	219	7.3	3.3

Table VIII—Capsule Weight Variation for Powder Blends Containing Different Concentrations of Clomacran Phosphate

Formula	Dosage Strength, mg.	\bar{X} , mg.	σ , mg.	CV
11	25	258	3.9	1.5
12	50	235	10.8	4.6
13	100	153	12.4	8.1

in the powder blend has an effect on the weight variation of finished capsules. The greater the concentration of active ingredient in the blend, the greater the weight variation. The differences in fill weight are due to the change in density of the capsule blends as the concentration of active ingredient is increased. The formulas for these blends are listed in Table III. A coefficient of variation greater than 3% was observed for Formulas No. 12 and No. 13; therefore they were considered unsatisfactory for encapsulation.

Effect of Granulating Clomacran Phosphate—When granulations of different strengths of clomacran phosphate were prepared using different lots of chemical as shown in Table IV and the resulting

**Figure 2**—A plot of rate of flow versus coefficient of variation for five powder blends.

⁹ Data for powder blends Nos. 1 and 7 were not included in this figure. Blend No. 1 had no active ingredient and Blend No. 7 did not flow.

Figure 3—Photomicrographs for several lots of clomacran phosphate chemical. Each scale division is equivalent to 6 μ .

Table IX—Capsule Weight Variation for Clomacran Phosphate Granulations

Formula	Dosage Strength, mg.	\bar{X} , mg.	σ , mg.	CV
14	25	187	2.4	1.3
15	50	228	2.0	0.9
16	100	443	3.8	0.9
17	25	213	2.0	1.0
18	50	263	2.8	1.1
19	100	452	4.0	0.9

powder was filled into capsules, there was no appreciable difference in the weight variation of the finished capsules. These data are shown in Table IX.

The granulation process essentially eliminated the effect of lot-to-lot variability and concentration of the active ingredient. In every instance the granulated formulas showed a coefficient of variation of less than 1.5%, regardless of the lot of chemical or the concentration of active ingredient in the powder blend.

SUMMARY

1. The flowmeter is a useful device for evaluating the flow properties of powder blends intended for encapsulation with an automatic capsule-filling machine.

2. A correlation of 0.96 was obtained between the rate of flow for five powder blends prepared for encapsulation and the coefficient of variation of the finished capsule fill weight.

3. Capsule weight variation was affected when different lots of clomacran phosphate were used. The particle size of the chemical contributed in part to the weight variation of the finished capsule.

4. The concentration of active ingredient in the capsule mix affected the weight variation. When formulating capsule blends of different strengths for encapsulation with an automatic capsule-filling machine, it may be necessary to reformulate to maintain satisfactory weight control.

5. The use of a granulated powder overcomes most of the problems normally encountered and provides finished capsules of uniform weight.

Some Coumarin Constituents of *Prunus mahaleb* L. Fruit Kernels V

M. EL-DAKHAKHNY

Abstract □ It was possible to isolate 2-glucosyloxy-4-methoxyethyl *trans*-cinnamate from the alcoholic extract of the defatted *Prunus mahaleb* L. fruit kernels. The structure of this compound was confirmed by IR, NMR, and mass spectra. Further evidence was sought through its de-ethylation into 2-glucosyloxy-4-methoxy *trans*-cinnamic acid which was identical in every respect with authentic material prepared synthetically. Through acetylation it afforded a tetraacetate, the structure of which was also confirmed by NMR and mass spectra. The identity of the sugar as glucose was ascertained by enzymatic and acid hydrolysis and subsequent paper chromatography in three different solvent systems.

Keyphrases □ Coumarins—*Prunus mahaleb* fruit kernels □ Paper chromatography—separation, identification □ Optical rotation—identity □ IR spectrophotometry—structure □ NMR spectroscopy—structure □ Mass spectroscopy—structure

In a previous communication (1), it was reported that *Prunus mahaleb* L. kernels contain herniarin (7-methoxycoumarin) both in a free form and as a glucoside. The present author, during examination of the alkaloidal fraction of the kernels, was able to isolate a crystalline compound which appears not to have been reported before. Although this compound was isolated from the alkaloidal fraction, it was found to be free of nitrogen and gave negative color reactions for alkaloids. The aim of this work was to study the structure of this compound. Pharmacological studies on this compound have been carried out and will appear shortly.

EXPERIMENTAL

Melting points were determined on a Kofler block and are uncorrected. IR spectra were determined in KBr using a Leitz Unicam S.P. 200 G. NMR spectra were determined in DMSO using a 60-Mc. instrument. Mass spectra were determined with CH₄, instrument at 70°, using an electron energy of 70 eV. Optical rotations were determined with a Perkin-Elmer 141 polarimeter.

Isolation of 2-Glucosyloxy-4-methoxyethyl *trans*-Cinnamate (I)—Five hundred grams dried and defatted mahaleb kernels was extracted with 95% ethanol to exhaustion. After concentration of the alcoholic extract, ether was added to precipitate choline and other glycosides. After decantation of ether, the precipitate was dissolved once more in alcohol and ether was added once again. The combined ethereal extracts were concentrated and extracted with diluted HCl to remove the alkaloids. The aqueous acidic solution was then made alkaline with ammonia and extracted with chloroform. The chloroform was dried over anhydrous sodium sulfate and then concentrated. After evaporation of chloroform, a yellow semisolid residue with a strong characteristic odor was left. Repeated crystallization from chloroform-methanol gave colorless needles, m.p. 180–182°, $[\alpha]_D^{25} = -58.8^\circ$ (in pyridine, yield 90 mg. about 0.2% of alcoholic extract, C = 56.22%; H = 6.30%; C₁₈H₂₄O₉ requires C = 56.24% and H = 6.29%). It gave a single spot on silica gel G developed with chloroform-methanol (85:15; *R_f*, 0.267) which could be seen as a dark blue fluorescent spot in UV light. It gave a positive reaction for Molisch test and negative reactions for alkaloids and flavonoids.

The UV spectrum in ethanol showed maxima at λ 239, λ 296, and λ 322 m μ ($\epsilon = 8.83 \times 10^3$, 1.23×10^4 , and 1.55×10^4 , respec-

2-glucosyloxy-4-methoxyethyl *trans*-cinnamate(acetate)
I

tively). The IR spectrum showed bands characteristic for hydroxy groups (3380 cm⁻¹), carbonyl in conjugation with a double bond (1680 and 1615 cm⁻¹), 1,2,4-trisubstituted aromatic structure (1570, 772, 766, and 760 cm⁻¹) (2). This compound was identified as 2-glucosyloxy-4-methoxyethyl *trans*-cinnamate (Structure I).

The mass spectrum of this compound (Fig. 1) showed a molecular ion peak at *m/e* 384 (46.7%) from which the expulsion of methanol gave a peak at *m/e* 352 (8.5%). The important fragmentation behavior of the molecule includes the following features (Scheme I); expulsion of 162 mass units by loss of C₆H₁₀O₅ for the glucose moiety leads to an ion at *m/e* 222 (22.3%) formulated as "A." Subsequent expulsion of ethanol by the possible mechanism indicated by the arrows leads to the highly conjugated ion "B" which appears as the strongest ion in the spectrum (base peak). The latter ion loses carbon monoxide presumably from the cyclohexadienone system with the formation of ion "C" which appears at *m/e* 148 (81.5%). Further degradation of the latter ion happens by expulsion of methyl radical giving the stabilized ozonium ion "D" at *m/e* 133 (58.7%). Subsequent expulsion of carbon monoxide gives a C₇H₅O⁺ ion at *m/e* 105 (11.7%) which may be represented by the constituent "E."

Enzymatic Hydrolysis of the Glucoside—Twenty milligrams of Compound I was dissolved in about 20 ml. of water, about 20 mg. of B-glucosidase in 20 ml. water was added, one drop of toluene for preservation, and the mixture was kept for about 10 hr. at 37° with occasional shaking. The mixture was then extracted with ether. The ethereal layer was dried over anhydrous sodium sulfate and then examined chromatographically on paper (Whatman No. 1) using the upper phase of *n*-butanol-acetic acid-water (4:1:5) for developing. Spots were located under UV light. The liberated aglycone gave one spot (*R_f*, 0.863) and was different from the original compound (*R_f*, 0.79) and from herniarin (*R_f*, 0.905).

Figure 1—Mass spectrum of glucoside.

Scheme I—Fragmentation pattern of glucoside.

The aqueous layer after filtration and concentration under reduced pressure was tested chromatographically on paper (Whatman No. 1) against reference sugars using the following solvent systems: (a) *n*-butanol-acetic acid-water, 4:1:5 (3); (b) ethyl acetate-pyridine-water, 5:2:5 (4); and (c) collidine saturated with water (5).

The chromatograms were developed for about 24 hr. (descending). After drying at room temperature, they were sprayed with *p*-anisidine-phosphoric acid reagent (6). In the three solvent systems, the aqueous phase gave a brown spot which was identical to that of glucose run as a reference material.

Acid Hydrolysis of the Glucoside—To the alcoholic solution (20 ml.) of about 20 mg. of the glucoside, about 20 ml. 2 *N* sulfuric acid was added and the mixture was refluxed for about 1 hr. The reaction mixture was then diluted with water and extracted with ether. The ethereal layer was tested chromatographically on paper (Whatman No. 1, solvent: upper phase of *n*-butanol-acetic acid-water, 4:1:5) and on silica gel G (solvent: benzene-3% methanol). It gave one spot identical to herniarin.

The aqueous layer, after being neutralized with barium carbonate, was passed through a column of ion-exchange resin (Dowex 50WX, 50-100 mesh, hydrogen form) to remove any barium ions and then concentrated under reduced pressure and tested chromatographically on paper using the same solvents mentioned previously. The only brown spot was identical to reference glucose.

Acetylation of the Glucoside—One hundred milligrams of the crystalline compound was dissolved in 1 ml. of anhydrous pyridine, then 1 ml. of acetic anhydride was added and the mixture was

heated at 100° for about 2 hr. The pyridine and acetic anhydride were evaporated under reduced pressure leaving a colorless crystalline mass. Recrystallization from aqueous methanol gave colorless needles, m.p. 160-162°, $[\alpha]_D^{25} = -56.5^\circ$ (in chloroform). Tested chromatographically on silica gel G, it gave one fluorescent spot (solvent: chloroform-methanol, 85:15; *R_f*, 0.35). The IR spectrum in KBr showed the disappearance of the hydroxyl band. The NMR spectrum showed three acetyl groups at $\delta = 2.17$ and another one at $\delta = 2.14$ accounting for the acetyl group attached to C₆ of the sugar moiety (Structure I), one methoxy group at $\delta = 4$. There were bands indicating the presence of an ethyl group at $\delta = 1.42$ (triplet, *J* = 7 c.p.s.) and $\delta = 4.3$. It showed also three aromatic protons: H(₃') at $\delta = 6.98$ (singlet), H(₅') at $\delta = 6.9$ (doublet, *J* = 9 c.p.s.), and H(₆') at $\delta = 7.9$ (doublet, *J* = 9 c.p.s.). Two *trans*-ethylenic protons appeared: H(₁') at $\delta = 7.91$ (doublet, *J* = 16 c.p.s.) and H(₂') at $\delta = 6.55$ (doublet, *J* = 16 c.p.s.). The sugar moiety appeared as a complex multiplet ($\delta = 5-6$).

The mass spectrum showed the presence of a molecular ion at *m/e* 552. Further fragmentation showed the loss of four molecules of acetic acid successively and then behaved like the mother compound.

Deethylation of the Glucoside—Twenty-five milligrams of the crystalline glucoside was dissolved in about 25 ml. aqueous alcohol (20%), then 25 ml. of 1% KOH in aqueous alcohol was added and the mixture was left overnight at room temperature. The next day the solution was passed through a column of ion-exchange resin (Dowex 50WX, 50-100 mesh, hydrogen form) to neutralize the potassium hydroxide. The effluent neutral solution was evaporated under reduced pressure. The colorless mass left, when crystallized from water, gave plates m.p. 196-198°, $[\alpha]_D^{25} = -50.7^\circ$ (in pyridine) (12 mg. yield); reported for 2-glucosyloxy-4-methoxy *trans*-cinnamic acid (III), 194-196° (7). When tested chromatographically on paper (Whatman No. 1, solvent: *n*-butanol-acetic acid-water, 4:1:5), it gave one spot (*R_f*, 0.635) which was identical with authentic 2-glucosyl-4-methoxy *trans*-cinnamic acid prepared synthetically (7). IR spectra of both products were also identical.

DISCUSSION

2-Glucosyl-4-methoxyethyl *trans*-cinnamate (I, Scheme II) was isolated from the alkaloidal fraction of the alcoholic extract of *Prunus mahaleb* L. kernels. NMR spectra of the compound and its tetraacetate showed signals for an ethyl group. These signals were found to be persistent even after thorough drying or using solvents other than ethanol or methanol for crystallization. The presence of the ethyl group as a part of the molecule and not as impurity was proved by mass spectra of both the compound and its acetate. That the compound occurs in the *trans*-form was shown by the IR spectrum [985 cm.⁻¹ (2)] and by the NMR spectra showing the presence of two *trans*-ethylenic protons, H(₁') at $\delta = 7.91$ (doublet, *J* = 16 c.p.s.) and H(₂') at $\delta = 6.55$ (doublet, *J* = 16 c.p.s.).

Scheme II—Reactions of the glucoside.

Nevertheless, on acid hydrolysis the compound gave herniarin. The formation of herniarin may be accounted for by the transformation of the liberated 2-hydroxy-4-methoxy-*trans*-cinnamic acid (IV, Scheme II) to the *cis*-form in presence of hydrogen ions. However, enzymatic hydrolysis did not give herniarin but gave 2-hydroxy-4-methoxyethyl *trans*-cinnamate (IV) which was found to be less mobile on paper than herniarin. The structure of the glucoside (I) was also ascertained through its de-ethylation to the free-acid glucoside (III) which was identical in every respect with authentic material prepared synthetically (7).

SUMMARY

2-Glucosyloxy-4-methoxyethyl *trans*-cinnamate was isolated in a crystalline form from the alcoholic extract of *Prunus mahaleb* L. fruit kernels. The structure of this compound was proved by IR, NMR, and mass spectra. It was further ascertained by de-ethylation of the compound to the free-acid glucoside which was identical with authentic material. On acetylation, it afforded a tetraacetate, the spectral studies of which (IR, NMR, and mass spectra) assured the suggested structure. On acid and enzymatic hydrolysis, it afforded glucose which was identified by chromatographic techniques.

Tablet-to-Tablet Variation of Drug Content of Sugar-Coated Tablets Containing Drug in the Sugar Coat

J. THURUP CARSTENSEN*, ARNOLD KOFF, J. B. JOHNSON, and S. H. RUBIN

Abstract In dosage forms where active drug is added to a sugar coat, it may be shown that the distribution of assays should be normal and the standard deviation should be proportional to the square root of the number of coats. Although, in a series of batches, the standard deviation was found linearly related to the square root of the number of coats, the plot failed to intersect at the origin and did not have the required slope, presumably due to secondary contributions to the variation such as pan build-up.

Keyphrases Drug content variation—sugar coating, tablets □ Tablet coatings—drug content variation □ Core size, tablets—coating drug content variation □ Coatings, tablet—drug content relationship

In recent years, several publications have dealt with tablet-to-tablet variation of uncoated tablets or compression coated tablets. Garrett (1) and Garrett and Olson (2) have studied the problem from the point of view of content of drug; Brochmann-Hanssen and Medina (3), Smith *et al.* (4), Lazarus and Lachman (5), and Airth *et al.* (6) analyzed the situation from the point of view of weight variation. Some publications, *e.g.*, those of Lachman *et al.* (7) and Kaplan (8), conclude that statistical variation may be used as a means of evaluating processes; whereas others, *e.g.*, those by Grundman and Ecanow (9) and French *et al.* (10), have been concerned with the problem of statistical sampling.

The inherent variations in sugar-coated tablets have been touched upon by Bhatia (11), but this paper aims not at the statistical variation to be expected but rather

Table I—Tablet-to-Tablet Variation of Sugar-Coated Tablets, Showing Standard Deviation as a Function of Number of Coats, *n*

Number of Coats (<i>n</i>)	\sqrt{n}	$10^2 \times SD (\Sigma), \text{mg.}$	Average Drug Content per Tablet ($n\mu$), mg.	$\sqrt{n\mu}$
1	1.00	1.6	0.120	0.347
2	1.41	3.0	0.244	0.494
6	2.45	12.5	0.693	0.835

13	3.61	23.6	1.456	1.208
16	4.00	22.5	1.790	1.340

on the effect of incompatibilities. Anderson and Sakr (12), in a comprehensive treatment of the statistics of sugar coating, studied the mean line average as a parameter, since smoothness of the tablet was their main point of discussion. Since some coated tablets contain the active component in the sugar coat, it would appear important to know whether expected statistical variations might apply in such a situation. Mattocks (13) has pointed out the problem associated with uniformity of coating, and Butensky (14) has found that, weight-wise, the coefficient of variation rises to a maximum of 7% at a stage prior to the final subcoating. The work by Anderson and Sakr (12) also implies that the coefficient of variation of the mean line average appears to level off at a certain stage of the coating operation,

Nevertheless, on acid hydrolysis the compound gave herniarin. The formation of herniarin may be accounted for by the transformation of the liberated 2-hydroxy-4-methoxy-*trans*-cinnamic acid (IV, Scheme II) to the *cis*-form in presence of hydrogen ions. However, enzymatic hydrolysis did not give herniarin but gave 2-hydroxy-4-methoxyethyl *trans*-cinnamate (IV) which was found to be less mobile on paper than herniarin. The structure of the glucoside (I) was also ascertained through its de-ethylation to the free-acid glucoside (III) which was identical in every respect with authentic material prepared synthetically (7).

SUMMARY

2-Glucosyloxy-4-methoxyethyl *trans*-cinnamate was isolated in a crystalline form from the alcoholic extract of *Prunus mahaleb* L. fruit kernels. on the effect of incompatibilities. Anderson and Sakr (12), in a comprehensive treatment of the statistics of sugar coating, studied the mean line average as a parameter, since smoothness of the tablet was their main point of discussion. Since some coated tablets contain the active component in the sugar coat, it would appear important to know whether expected statistical variations might apply in such a situation. Mattocks (13) has pointed out the problem associated with uniformity of coating, and Butensky (14) has found that, weight-wise, the coefficient of variation rises to a maximum of 7% at a stage prior to the final subcoating. The work by Anderson and Sakr (12) also implies that the coefficient of variation of the mean line average appears to level off at a certain stage of the coating operation,

and, thereafter, the coefficient of variation remains fairly constant with increasing weight.

In studying the drug content uniformity in the coating of tablets, it has been the experience of the authors that the size of the tablet affects the final tablet-to-tablet variation. The aim of the investigation reported here is an analysis of this point and of the statistical assumptions which can and cannot be made.

EXPERIMENTAL

Deep concave placebo tablet cores were enteric coated, and sub-coats were added in conventional fashion in an 81.31-cm. (32-in.) tablet-coating pan. The drug, which had an exceedingly low water solubility, was micronized and then added in form of a suspension

in a gelatin-acacia syrup. Sixteen applications of equal weight were used to accomplish a total addition of 1.79 mg. of drug per tablet.

Twenty tablets were removed and assayed individually after the first and 16th applications, and 10 tablets were removed and assayed after the 2nd, 6th, 11th, and 13th applications. The average drug content and the standard deviations were calculated for each sample. The standard deviations obtained after the various coats are listed in Table I. The results are shown graphically in Fig. 1. The individual results from the sample taken after the first coat are listed in Table II.

Four additional batches were made, using the same coating procedure and tablet core (120 mg.), but assays were only performed on the final tablet (20 individual tablets). One batch was made with a 100-mg. core, two batches were made with a 160-mg. core, and three batches were made with a 175-mg. core, again employing the same manufacturing procedure but only assaying 20 individual tablets of the final product. Seven batches of tablets of four other active compounds were produced and assayed in a similar fashion, using different core sizes (120, 175, 300, and 390 mg.). The tablet-to-tablet variation of the final tablets appeared normally distributed; the results from all 18 batches are shown in Figs. 2 and 3.

RESULTS AND DISCUSSION

The data in Table II and Fig. 4 imply a normal distribution of the assays of the first coat; the variance associated with this will be denoted as σ^2 in the following. The test for normality is not rigorous, but suffices to justify the assumption of normality as a starting point. As shall be shown, this assumption implies a normal distribution of the final tablet assays as well. Other conceivable distributions would be binomial (fraction p coated, $[1-p]$ not coated). This for a large number of applications would lead to a Poisson distribution and eventually, for a very large number of coatings, would approximate a normal distribution. In this light, 16 applications is not a large number. If one assumes that the distribution of the first coat can be described by the normal deviate x_1 , the second coat by x_2 , and the n^{th} coat by x_n , each with an average μ , and if one assumes x_1, x_2, \dots, x_{16} to be independent variables, then (as shown in the Appendix) it is straightforward to show that the variance after n coats (Σ^2) should be given by $n\sigma^2$, where σ is assumed to be identical for each coat, i.e., equal to that of the first coat. A plot of the standard deviation as a function of the square root of the number of coats should, therefore, produce a straight line through the origin with a slope identical to the standard deviation of the first coat: $\Sigma = \sigma \cdot \sqrt{n}$. The coefficient of variation will decrease with increasing number of coats since

$$\frac{\sqrt{n}\sigma^2}{\mu n} = \frac{\sigma}{\mu\sqrt{n}} \quad (\text{Eq. 1})$$

It is seen from Fig. 2 that the standard deviation of individual tablet assays from all 18 batches (of varying tablet size) exhibited great scatter. The trend, however, is unmistakably that the standard deviation decreases with increasing tablet size. Although it is difficult to draw conclusions from such data, some speculation may be offered. Figure 3 represents the data of Fig. 2 in logarithmic form, and a line of slope 1 is more compatible with the data than a line of slope $\frac{2}{3}$, so that the standard deviation might be related to the volume (or weight) of the tablet rather than to the surface. If this

Figure 1—The standard deviation of assayed drug content of tablets as a function of the square root of the number of coats (upper scale) and the square root of the amount of drug found per tablet (lower scale).

Figure 2—Sugar-coated tablets with drug in sugar coat: $2 \times$ standard deviation as a function of tablet size.

Figure 3—Variation of drug content as a function of tablet size on a natural logarithmic scale. The standard deviation is on a percentage basis, the tablet weight is in milligrams.

indeed is the case, then the assumption that σ is the same for all 16 applications may not be true.

The volume increase during the 16 coats is small; however, it would appear from Fig. 1 that the size increase during the application of the active coat does not play an important role, since linearity seems to prevail. On the other hand, it is obvious that the line neither passes through the origin nor has a slope equal to the standard deviation of the first application. It is possible, since there is always build-up on the pan, that in the earlier stages some drug is deposited on the build-up on the pan and that in later coats some drug is applied back to the tablets by attrition, and thus a second contribution to the standard deviation occurs.

The findings have significance in the sense that the tablet-to-tablet variation will be smaller the larger the number of coats, i.e., the application of a given amount of drug is best accomplished with a larger number of coatings of more dilute coating mixture than with a smaller number of coatings with a more concentrated mixture. The data also imply that a large tablet core yields a better drug distribution in the active coat than a small core. It is obvious that other factors (e.g., viscosity and surface activity of the syrup-suspension containing the active ingredient, as well as core shape) are of significance. These have not been a subject of this study and have been kept constant in order to evaluate the statistical, rather than the physicochemical, aspect of sugar coating.

APPENDIX

Suppose n coats of active material are applied to a payload of tablets. Let the distribution of the first coat be designated by the normal deviate x_1 , the second x_2 , and the n^{th} x_n , and, assuming x_1, x_2, \dots, x_n to be independent variables with identical variances, then the moment-generating function for the distribution of $x_1 + x_2 + \dots + x_n$ is (15)

$$M_{x_1+x_2+\dots+x_n}(\theta) = M_{(x_1)}M_{(x_2)}\dots M_{(x_n)} = \prod_{i=1}^n \frac{1}{\sigma\sqrt{2\pi}} \int_{-\infty}^{\infty} \exp[x_i\theta] \cdot \exp\left[-\frac{[x_i - \mu]^2}{2\sigma^2}\right] dx_i = e^{\theta n\mu} \cdot e^{n\sigma^2\theta^2/2} \quad (\text{Eq. 2})$$

where μ is the amount of drug applied. The first moment about $\theta = 0$ is the mean $n\mu$ and is given by:

$$\left[\frac{\partial M}{\partial \theta}\right]_{\theta=0} = n \cdot \mu \quad (\text{Eq. 3})$$

The second moment is

$$\left[\frac{\partial^2 M}{\partial \theta^2}\right]_{\theta=0} = [n\mu]^2 + n \cdot \sigma^2 \quad (\text{Eq. 4})$$

The variance is the second moment minus the square of the first moment, both at $\theta = 0$, i.e.:

$$\Sigma^2 = [n\mu]^2 + n\sigma^2 - [n\mu]^2 = n\sigma^2 \quad (\text{Eq. 5})$$

Figure 4—Results from the last two columns of Table II. The ordinate is the cumulative fraction larger than a certain figure, and the abscissa is the fraction expected if the distribution were normal with average content 0.119 mg. and SD 0.016 mg.

If one takes the square root:

$$\Sigma = \sigma \cdot \sqrt{n} \quad (\text{Eq. 6})$$

i.e., the standard deviation after n coats (Σ) is proportional to the square root of the number of coats with σ , the standard deviation of the first coat, as the proportionality factor. Furthermore the distribution after n coats will be normal if it was normal originally. For large n , this may be expected for any type distribution (central limit theorem).

Action of Antibiotics on Respiratory Tract I: Ampicillin

G. BENZI, E. BERMUDEZ, and E. ARRIGONI

Abstract □ *In vitro* ampicillin antagonizes the barium chloride-, histamine-, and acetylcholine-induced spasm on the dog bronchial chains. Ampicillin is more effective in preventing a histamine than an acetylcholine bronchospasm, while isoprenaline and adrenaline are similarly potent against the effects of the two agonists. *In situ* the antibiotic induces at first a prompt but short increase in ventilation; subsequently, a lesser but persistent activity remains for 2 or 3 hr.

Keyphrases □ Ampicillin effect—respiratory tract □ Histamine-, barium chloride-, acetylcholine-induced bronchospasm—ampicillin effect □ Respiratory ventilation—ampicillin effect

In previous research, the action of some antibiotics *in vitro* and *in situ* upon the motility and tone of the extrahepatic biliary tract (rifamycin SV, erythromycin, tetracyclines, ampicillin, aminosidin, spiramycin, and dicloxacillin) and the ureter (ampicillin and dicloxacillin) was studied. It was particularly observed that ampicillin relaxed the above-mentioned musculatures, normal or hypertonized by barium chloride, histamine, serotonin, carbachol, or cholecystokinin (1, 2). This behavior points out the problem of the action of the antibiotics on various tissues, including the respiratory tract.

The purpose of the present paper is to report the ampicillin action on the airways *in vitro* and *in situ*. In this field, the *in vitro* pharmacological preparation consisting of a chain of tracheal or bronchial rings has been used (3, 4). Human, guinea pig, and dog preparations are equally sensitive to contracting agents, such as histamine and acetylcholine (5), and the activity of the drugs on isolated human bronchial chains agrees closely with that found by other workers using preparations from animals, including the dog (6). *In situ* the changes in airway smooth muscle tone may be measured: (a) by recording the dynamic pressure-volume relationship of the lungs (7), the resistance to airflow in the trachea isolated *in situ* or in the respiratory tract (8, 9); and (b) by the radiography of the airways (10).

The direct record of the ventilation by a rubber balloon inserted into a primary or secondary bronchus was used. For the experiments *in vitro* and *in situ*, the dog was chosen because of its size and availability.

METHOD

The experiments were performed in the dog both *in vitro* and *in situ*. Ampicillin sodium salt, of which amounts are expressed in terms of D(-)-6-(α -amino- α -phenylacetamido)-penicillanic acid, was used.

Experiments *In Vitro*—Bronchi of 32 mongrel dogs of either sex (weighing 7.4 to 10.9 kg.) were removed immediately after death. All tissues were dissected and cut in rings which were tied together in chains with loops of cotton. The mucosa was removed to allow greater freedom of movement of the muscle. Four to six rings were suspended in a 50-ml. organ bath containing Tyrode solution gassed with 95% oxygen and 5% carbon dioxide; the temperature

was 36.5–37.5°. The tonus level of preparations was continuously recorded by a strain-gauge lever, giving a magnification of $\times 15$ to 20, tension 200 mg., writing on a kymograph drum. The preparations were left 2 hr. before any drugs were given. Three submaximal doses of acetylcholine were given until regular responses were obtained, before any doses of acetylcholine itself or other agonists were tested.

The action of ampicillin (62.5–2000 mcg./ml.) was evaluated against the stimulation by barium chloride (100–400 mcg./ml.); for the construction of the dose-response curve, ampicillin activity was taken as the percent inhibition of the recorded response area by barium chloride stimulation during a 20-min. period of contact.

For comparative assay with other well-known bronchodilators, the activity of ampicillin (2048–16,384 mcg./ml.), *l*-adrenaline (0.5–4 mcg./ml.), and *dl*-isoprenaline (0.125–2.0 mcg./ml.) was evaluated against the stimulation by acetylcholine chloride (0.2–2 mcg./ml.) and histamine acid phosphate (1.0–10 mcg./ml.). Two-dose levels of agonist and antagonist were usually used; the agonists were left in contact with the preparation for 0.5–1 min. Ampicillin was introduced into the bath 10 min., and adrenaline or isoprenaline 30 sec. before the acetylcholine or histamine doses. The ED₅₀, the slope of the curve, the potency ratio, and their 95% confidence limits were calculated (11).

Experiments *In Situ*—The experiments were carried out on 28 beagle dogs of either sex (weighing 10.7–16.8 kg.) preanesthetized with urethane (0.4 g./kg. i.p.). Anesthesia was induced and maintained by chloralose (80 mg./kg. i.v.); the arterial blood pressure was measured from a cannula inserted into a femoral artery; the intestinal movement and tone were recorded by a rubber balloon inserted into the jejunum.

During the succinylcholine chloride (1 mg./kg. i.v.) action, an intratracheal Warne tube was set in place. Through this tube a little rubber balloon was pushed into a primary or, if possible, secondary bronchus under X-ray examination.

Arterial blood pressure and intestinal and bronchial activities were recorded by a polygraph Physioscript EE12 Schwarzer.

Ampicillin (1.25–80 mg./kg.) was administered intravenously by a polystan tube inserted into the femoral vein. Two submaximal doses of *dl*-isoprenaline or *l*-adrenaline were given i.v. until regular responses were obtained before any doses of ampicillin sodium salt were tested. To analyze the mechanism of action, ampicillin was tested after: (a) cutting the vagi, and (b) treatment with the following drugs: morphine hydrochloride (4–8 mg./kg. i.v.), atropine sulfate (2–3 mg./kg. s.c.), dibenamine hydrochloride (2–5 mg./kg. i.v.), D(-)-INPEA (4–8 mg./kg. i.v.), chlorpheniramine maleate (2–3 mg./kg. s.c.), cyproheptadine hydrochloride (300–600 mcg./kg. i.v.), hexamethonium bromide (300–600 mcg./kg. i.v.).

Figure 1—Action of ampicillin on dog bronchial chain stimulated by barium chloride. The barium chloride (250 mcg./ml.) was added to the bath at the marks (○). The antibiotic (Δ) was present in the bath at the following concentrations: 1 = 0 mcg./ml.; 2 = 250 mcg./ml.; 3 = 500 mcg./ml.; 4 = 1000 mcg./ml. At Δ the recording apparatus was stopped for the first 8 min. of contact with ampicillin.

Table I—Dog Bronchial Chain *In Vitro*: ED₅₀, Slope Function of the Line (*S*), and Estimated Relative Potency (ERP), with 95 % Confidence Limits, of *dl*-Isoprenaline, *l*-Adrenaline, and Ampicillin against the Stimulation by Acetylcholine Chloride (0.2–2 mcg./ml.) and Histamine Acid Phosphate (1.0–10 mcg./ml.)

RESULTS AND DISCUSSION

On the dog bronchial chains *in vitro*, ampicillin (62.5–2000 mcg./ml.) reduces or inhibits the stimulation by barium chloride (Fig. 1); the log dose–response curve is indicated in Fig. 2.

The comparative assay of ampicillin, isoprenaline, and adrenaline action against the stimulation by acetylcholine or histamine is summarized in Table I and shows that isoprenaline is more active than adrenaline and ampicillin in reducing the agonist-induced spasm. It is possible to observe that against acetylcholine-induced contraction, ampicillin is about 1/8600 as active as *l*-adrenaline and about 1/28,000 as active as *dl*-isoprenaline. According to Mc Dougal and West (5), on dog tracheal rings aminophylline possesses about 1/10,000 the activity of adrenaline and about 1/40,000 the activity of isoprenaline. On the other hand, ampicillin, as is aminophylline (5), is more effective in preventing a histamine than an acetylcholine bronchospasm, while adrenaline and isoprenaline are similarly potent against the effects of the two agonists.

Obviously the *in vitro* technique employed provides information concerning potency ratio or mechanisms operant in the airway wall; nevertheless it is unphysiological, the studies being limited to denervated portions of the airways. However, it is impossible to correlate directly the present results with clinical conditions. In fact it is well known that many bronchoconstrictive stimuli act, at least in part, *via* reflex mechanisms, and these effects are absent in the *in vitro* preparation. Nevertheless, the results *in vitro* related to isoprenaline and adrenaline agree with the findings of previous workers (12) using *in vivo* the test of the antagonism of the effects of a histamine aerosol in guinea pigs.

The observations *in situ* indicate that, after intravenous injection of 1.25–80 mg./kg., ampicillin induces a biphasic action. At first the antibiotic induces a prompt, high, but short (5–20 min.) increase in ventilation, and subsequently a lesser but persistent activity remains for 2 or 3 hr., as summarized in Table II and exemplified in Fig. 3. No change in systemic blood pressure occurs during the ampicillin action on the airways.

The increase in ventilation induced by ampicillin during its first phase of action is similar to those caused by the i.v. injection of isoprenaline (0.125–2 mcg./kg.) and adrenaline (0.5–5 mcg./kg.). Nevertheless, related to the very different biotransformation, the total time of activity of the sympathomimetic amines is much shorter

(2–8 min.) than that of ampicillin, and furthermore the well-known changes in systemic blood pressure occur.

The *in situ* preparation utilized by the authors does not provide any information on drug effects on peripheral airways which are vitally concerned with the gas-exchange process. The pressures recorded by the bronchial balloon must have been changes in the depth of respiration, and it is completely possible that the results

Figure 2—Log dose–response curve of ampicillin action against the stimulation by barium chloride. The ordinate shows the inhibition percent of the contracting action by barium. The concentrations of the antibiotic (mcg./ml.) are plotted on the abscissa in logarithmic scale. The vertical lines indicate standard errors of the means. Eight preparations at each dose level.

Figure 3—Action of ampicillin i.v. on the ventilation of a dog in situ. From top to bottom: tracing recorded by a balloon inserted into the bronchus; blood pressure (mm. Hg); 1 = control condition; 2 = 2 min. after injection i.v. of 10 mg./kg. of ampicillin; 3 = 30 min. later; 4 = 1 hr. later; 5 = 2 hr. later.

are only in part associated with changes in bronchial tone. In fact, it should be noted that: (a) the baseline of bronchial balloon pressure did not change appreciably in response to ampicillin, indicating that the resting tone of bronchial muscle was slightly or not affected by the drug; (b) the ampicillin action was antagonized by the high respiratory depression by morphine; and (c) the antibiotic action was unaffected after treatment with atropine, dibenamine, INPEA, chlorpheniramine, cyproheptadine, and hexamethonium.

In conclusion, only *in vitro* is it possible to postulate the ability of ampicillin to relax directly the bronchial musculature. *In vivo* the pressure fluctuations noted with each breath were probably not caused by rapid breath-to-breath changes in bronchial tone. It is more likely that ampicillin increased the activity of the respiratory center, causing an increase in ventilation and a subsequent increase in anatomic deadspace.

Determination of Epitetraacycline and Chlortetraacycline in Tetraacycline by Quantitative Thin-Layer Chromatography

IDO C. DIJKHUIS and MARTHA R. BROMMET

Abstract □ Small amounts of epitetracycline and chlortetracycline in tetracycline were determined by quantitative thin-layer chromatography on kieselguhr layers, impregnated with a citrate-phosphate solution, pH 5.5, containing 10% glycerin. The method involves chromatography under sharply defined conditions (relative humidity, temperature, and rapidity of spotting) in order to obtain a good separation of the different zones and to prevent rapid epimerization during development. After elution with 0.1 N HCl, epitetracycline was measured at 356 mμ, while for chlortetracycline the fluorimetric method of Chicarelli was used. The possible identities of three other impurities—with R_f values between epitetracycline and tetracycline—are discussed; their percentages were calculated as epitetracycline.

Keyphrases □ Epitetraacycline—analysis, separation in tetraacycline □ Chlortetraacycline—analysis, separation in tetraacycline □ TLC—analysis □ Spectrophotometry—analysis

In 1963, Remmers *et al.* (1) described a spectrophotometric determination of 4-epitetraacycline (epi-TC) in tetracycline (TC), based on the absorbance-ratio difference at 254 and 267 mμ. However, this method is not suitable for measuring small amounts of epi-TC

in commercial samples; accurate measurements at those wavelengths are disadvantageously affected by the presence of anhydrotetracyclines (ATC, epi-ATC). The paper chromatographic method, reported by Addison and Clark (2), gives better information about the percentage of epi-TC.

When small amounts of chlortetracycline (CTC) are to be determined, the spectrophotometric procedure, given by Woolford *et al.* (3), is not preferable. It is also not possible to apply the fluorimetric procedure [Chicarelli (4)] because the fluorescence of the CTC is quenched by the TC solution.

In 1964, Sonanini and Anker (5) described the identification of three tetracyclines on kieselguhr layers, impregnated with a solution (pH 3.7) containing 5% glycerin. In 1968, Ascione *et al.* (6) reported the separation of some tetracyclines on the same support, impregnated with a EDTA-PEG 400-glycerin solution, pH 7.0.

The present authors used the idea of Sonanini and Anker as a starting point for a quantitative determination of epi-TC and CTC present in commercial samples of TC.

Figure 3—Action of ampicillin i.v. on the ventilation of a dog in situ. From top to bottom: tracing recorded by a balloon inserted into the bronchus; blood pressure (mm. Hg); 1 = control condition; 2 = 2 min. after injection i.v. of 10 mg./kg. of ampicillin; 3 = 30 min. later; 4 = 1 hr. later; 5 = 2 hr. later.

are only in part associated with changes in bronchial tone. In fact, it should be noted that: (a) the baseline of bronchial balloon pressure did not change appreciably in response to ampicillin, indicating that the resting tone of bronchial muscle was slightly or not affected by the drug; (b) the ampicillin action was antagonized by the high respiratory depression by morphine; and (c) the antibiotic action was unaffected after treatment with atropine, dibenamine, INPEA, chlorpheniramine, cyproheptadine, and hexamethonium.

In conclusion, only *in vitro* is it possible to postulate the ability of ampicillin to relax directly the bronchial musculature. *In vivo* the pressure fluctuations noted with each breath were probably not caused by rapid breath-to-breath changes in bronchial tone. It is more likely that ampicillin increased the activity of the respiratory center, causing an increase in ventilation and a subsequent increase in anatomic deadspace.

Determination of Epitetraacycline and Chlortetraacycline in Tetraacycline by Quantitative Thin-Layer Chromatography

IDO C. DIJKHUIS and MARTHA R. BROMMET

Abstract □ Small amounts of epitetracycline and chlortetracycline in tetracycline were determined by quantitative thin-layer chromatography on kieselguhr layers, impregnated with a citrate-phosphate solution, pH 5.5, containing 10% glycerin. The method involves chromatography under sharply defined conditions (relative humidity, temperature, and rapidity of spotting) in order to obtain a good separation of the different zones and to prevent rapid epimerization during development. After elution with 0.1 N HCl, epitetracycline was measured at 356 mμ, while for chlortetracycline the fluorimetric method of Chicarelli was used. The possible identities of three other impurities—with R_f values between epitetracycline and tetracycline—are discussed; their percentages were calculated as epitetracycline.

Keyphrases □ Epitetraacycline—analysis, separation in tetraacycline □ Chlortetraacycline—analysis, separation in tetraacycline □ TLC—analysis □ Spectrophotometry—analysis

In 1963, Remmers *et al.* (1) described a spectrophotometric determination of 4-epitetraacycline (epi-TC) in tetracycline (TC), based on the absorbance-ratio difference at 254 and 267 mμ. However, this method is not suitable for measuring small amounts of epi-TC

in commercial samples; accurate measurements at those wavelengths are disadvantageously affected by the presence of anhydrotetracyclines (ATC, epi-ATC). The paper chromatographic method, reported by Addison and Clark (2), gives better information about the percentage of epi-TC.

When small amounts of chlortetracycline (CTC) are to be determined, the spectrophotometric procedure, given by Woolford *et al.* (3), is not preferable. It is also not possible to apply the fluorimetric procedure [Chicarelli (4)] because the fluorescence of the CTC is quenched by the TC solution.

In 1964, Sonanini and Anker (5) described the identification of three tetracyclines on kieselguhr layers, impregnated with a solution (pH 3.7) containing 5% glycerin. In 1968, Ascione *et al.* (6) reported the separation of some tetracyclines on the same support, impregnated with a EDTA-PEG 400-glycerin solution, pH 7.0.

The present authors used the idea of Sonanini and Anker as a starting point for a quantitative determination of epi-TC and CTC present in commercial samples of TC.

Table I—Percentages of epi-TC and CTC and Compounds A, B, and C in Three Commercial Samples of TC

Sample No.	epi-TC, %	CTC, %	A, %	B, %	C, %
I	2.4	0	0.3	0.6	0.6
	2.4	0	0.3	0.7	0.7
	2.5	0	0.2	0.9	0.7
II	1.1	3.4	0.3	0.5	0.5
	1.2	3.4	0.2	0.5	0.5
	1.4	3.5	0.3	0.6	0.5
III	5.8	0.1	0.4	0.5	0.4
	5.6	0.1	0.4	0.4	0.5
	5.5	0.1	0.4	0.5	0.6

EXPERIMENTAL

Materials—*Kieselguhr, Purified*—One-hundred grams of Kieselguhr-G (Merck) is suspended in 500 ml. of 4 *N* HCl, boiled, and filtered; this procedure is done three times to remove the binder (CaSO₄) and most of the iron. After washing with distilled water, the product is suspended in 500 ml. of a 1% aqueous EDTA solution, pH 3, and boiled again to eliminate traces of Fe⁺⁺⁺ and Ca⁺⁺ ions. The purified kieselguhr is finally washed with distilled water and methanol and dried at 100°. As a control for purity, 500 mg. is suspended in 5 ml. of 0.1 *N* HCl and centrifuged; the absorbance of the clear solution at 356 mμ is <0.005.

Solution pH 5.5—Forty-three milliliters of citric acid (0.1 *M*), 57.0 ml. of Na₂HPO₄·2H₂O (0.2 *M*), and 10 ml. of glycerin (sp. gr. 1.23) were used.

Tetracycline Hydrochloride (USP Reference Standard, Packaged July 1968)—Dried over P₂O₅ at 60° in *vacuo*. Absorbance of a 1% solution in 0.1 *N* HCl in a 1-cm. cell at 356 mμ is 308. Impurities: ATC, 0.1% [spectrophotometric (7)]; CTC, 0.3%; epi-TC, 0.5%; Compound A, 0.1%; Compound B, 0.2%; Compound C, 0.2%.

Epitetracycline Ammonium Salt¹—Absorbance of a 1% solution in 0.1 *N* HCl in a 1-cm. cell at 356 mμ is 316. Impurities: epi-ATC, 0.3% [spectrophotometric (7)]; TC, 0.5%. Because of its instability, epi-TC was only used in calculating the recoveries of epi-TC and TC after spotting and elution.

Chlortetracycline Hydrochloride—From capsules (Aureomycin), dried over P₂O₅ at 60° in *vacuo*. Absorbance of a 1% solution in 0.1 *N* HCl in a 1-cm. cell at 269 mμ is 194; this value has been corrected for the absorbance of TC present in CTC (0.6%, determined by quantitative TLC).

Oxytetracycline (OTC), 2-acetyl-2-decarboxamido-tetracycline (ADTC),¹ methacycline (MTC), anhydrotetracycline (ATC),¹ and epi-anhydrotetracycline (epi-ATC)¹ were used for the thin-layer chromatographic identification of other impurities in tetracycline.

Kieselguhr Layers—Layers (0.25 mm.) were prepared with the Desaga apparatus by application of a slurry of 4 g. purified kieselguhr in 8 ml. of the solution, pH 5.5, per 20 × 20-cm. glass plate. The plates were stored at 15° and a relative humidity of 65–75% during 2 days before use.

All chemicals used were of analytical grade.

Microliter pipets, 5-μl., 55-mm. length (microcaps, Drummond Scientific), were used.

Apparatus—Beckman DU spectrophotometer. Filter-fluorimeter, primary filter 364 mμ, secondary filter 414 mμ. TLC-tank, 20 × 20 × 8 cm., saturated with dichloromethane-ethanol 95% (9:1) at 15°.

PROCEDURES

Chromatography—The sample of TC is dissolved in methanol at 0° in a concentration of 20 mg. per ml. Approximately 1 mg. of the sample (= *p* mg. dried substance) is spotted rapidly over 15 cm. and the plate is placed immediately in the developing solvent [dichloromethane-ethanol 95% (9:1) at 15°]. The time between spotting and developing must not exceed 3 min. The fluorescing zones are marked under longwave UV light.

R_f values are: epi-TC, 0.1; Compound A, 0.17; Compound B, 0.30; Compound C, 0.38; TC, 0.55–0.65; CTC, 0.80; epi-ATC, 0.85; ATC, 1.

If necessary, the fluorescence of CTC can be activated by spraying a few milliliters of 0.01 *N* NaOH on the plate. Activation of the fluorescence of epi-TC, by spraying with NaOH or by holding the plate above ammonia vapor, is not recommended because of rapid decomposition of this compound.

Assay of Epitetracycline (Hydrochloride)—The epi-TC zone is scratched off, transferred into a stoppered centrifuge tube, and extracted with 5.00 ml. of 0.1 *N* HCl. After centrifuging, the absorbance (*A*) of the clear solution is determined at 356 mμ. To eliminate inaccuracies in spotting and elution, 50 mcg. of the TC standard (concentration 1 mg. per ml.) is spotted over 15 cm.; after elution with 5.00 ml. of 0.1 *N* HCl, the absorbance at 356 mμ is determined (= *A*_{stand.}).

$$\% \text{ epi-TC} = \frac{A \times 5}{A_{\text{stand.}} \times p} \quad (\text{Eq. 1})$$

In this laboratory the *A*_{stand.} for TC was 0.277 ± 0.003 (recovery 90%), while for epi-TC with the same procedure a recovery of 91% was obtained. The absorbance of the blank—250 mg. of developed kieselguhr per 5.00 ml. of 0.1 *N* HCl—was negligible; also the background absorbance between epi-TC and Compound A was very small (about 0.005), and therefore no correction had to be made. This background absorbance, due to epimerization during development, increased at higher *R_f* values; the values of the percentages of Compounds A, B, and C in Table I were corrected with 0.1, 0.2, and 0.2, respectively.

Assay of Chlortetracycline (Hydrochloride)—The CTC zone is scratched off, transferred into a stoppered centrifuge tube, and extracted with 5.00 ml. of 0.2 *N* NaOH. After centrifuging, the fluorescence of the clear solution is determined about 15 min. after NaOH addition, adjusting the reading of the galvanometer at a suitable value. The percentage of CTC (hydrochloride) is calculated from the standard curve.

CTC Standard Curve—To eliminate inaccuracies in spotting and elution, 5, 10, 15, and 20 mcg. of the CTC standard (concentration 0.5 mg. per ml.) are spotted over 15 cm. After elution with 5.00 ml. of 0.2 *N* NaOH the fluorescence is measured. In this laboratory the recovery of the CTC standard was 97 ± 3%, while Beer's law was obeyed. The fluorescence of the blank was nil.

DISCUSSION

Before good results could be obtained in the determination of epi-TC and CTC in TC, many problems had to be solved. While the qualitative examination of these substances was easy—because only 1–5 mcg. of a sample of TC can be spotted on the plate—it was rather difficult to separate them when 1–1.5 mg. had to be examined. (These great quantities were necessary for spectrophotometric measurements.) Moreover, epi-TC and CTC also had to be separated from five other impurities present in most commercial samples of TC: ATC, epi-ATC, and the Compounds A, B, and C. Finally, chromatography on one plate and with one developing sol-

Figure 1—The quantitative TLC separation of the impurities in commercial tetracycline hydrochloride.

¹ The authors are grateful to Dr. J. Keiner (Jena, D.D.R.) for his gift of ADTC and to Mr. J. Ribbers (Organon, Holland) for the preparation of highly purified epi-TC, ATC, and epi-ATC.

Figure 2—Chromatogram of five possible impurities in commercial tetracycline (OTC, ADTC, MTC, CTC, and ATC are standard substances).

vent was tried. After rejecting ethyl acetate and chloroform-acetone (1:1) and kieselguhr layers pH 3.7 (5), dichloromethane-ethanol 95% (9:1) was selected, in combination with kieselguhr impregnated with a buffer solution pH 5.5, containing 10% glycerin. In order to obtain reproducible values in the determination of epi-TC, the influence of the chemicals used and the influence of small variations in the technique were studied. It was found that the separation of the zones depended greatly on the amount of purification of the kieselguhr and on the condition of the layer before and during development (relation of relative humidity to temperature). Further, it was observed that the partial conversion of TC into epi-TC during the determination was strongly influenced by the amount of time between spotting and development and by the temperature of the methanolic TC solution. Working under the conditions described under *Procedures*, the epimerization is negligible and the chromatogram shows sharply defined zones of about 0.5 cm. width. Because the recoveries of epi-TC and TC are practically equal, TC is preferred as a standard substance for epi-TC determinations, being more stable than epi-TC.

As to CTC, the fluorimetric procedure is preferable because of its high sensitivity. Only very high percentages of epi-ATC (R_f 0.85) might quench the fluorescence.

In nearly all samples of TC, three yellow fluorescing zones between epi-TC and TC were observed (Fig. 1). After elution with 0.1 *N* HCl, maximum absorbances were found at about 355 $m\mu$. Two-dimensional TLC using methyl ethyl ketone saturated with the buffer solution, pH 5.5, as second phase suggests that their identities might be oxytetracycline (R_f 0.17), 2-acetyl-2-decarbox-amido-tetracycline (R_f 0.30), and methacycline (R_f 0.38) (Fig. 2). Keiner *et al.* (8) used this developing solvent, pH 4.7, to separate ADTC from epi-TC and TC. However, the authors did not succeed in a definite identification by IR, mainly due to the large quantity of eluted glycerin and to the decomposition of these three compounds during the isolation. They were determined quantitatively—calculated as epi-TC—to give an idea of the possible errors in epi-TC determination if no sharply defined zones can be obtained.

The methods for the determination of epi-TC and CTC are not limited to tetracycline substances but can also be performed in some TC formulations. For aqueous solutions and suspensions of TC, it is recommended in most cases to freeze-dry the preparation and to spot after dissolving in methanol.

Finally, this quantitative TLC method can also be applied to determine impurities in other tetracyclines like chlortetracycline, demethylchlortetracycline, and methacycline. In oxytetracycline studies, however, the solvent system used in development should be replaced by another one.

Gas-Liquid Chromatographic Determination of Melphalan

J. T. GORAS*, J. B. KNIGHT†, R. H. IWAMOTO†, and P. LIM†

Abstract □ The gas-liquid chromatography of melphalan and its decomposition products, determined as trimethylsilyl derivatives, is reported. The application of this procedure to the quantification of intact melphalan in a pharmaceutical preparation is described.

Keyphrases Melphalan and dosage forms—analysis □ GLC—analysis □ Chrysene—internal standard □ Mass spectroscopy—identification

The compound *p*-di(2-chloroethyl)amino-*L*-phenylalanine,¹ NSC 8806 (melphalan, *L*-sarcolysin, *L*-phenylalanine mustard), is a chemotherapeutic agent used in the treatment of various tumors (1–7). Because the drug is susceptible to hydrolytic degradation, an assay procedure that quantitatively measures intact melphalan in the presence of its hydrolysis products was desired. The hydrolytic degradation of melphalan (I) (8, 9) and related nitrogen mustards (10–12) has been reported as a replacement of one or both chlorine atoms by hydroxyl groups to give Forms II and III (see Scheme I).

Quantitative procedures that have been applied to melphalan include direct UV spectrophotometry, ionic and total chlorine determination, spectrophotofluorimetry (8), and a colorimetric assay utilizing γ -(4-nitrobenzyl)pyridine (NBP) (12, 13). The first three procedures are inherently nonspecific in this application. The NBP assay has been employed by Friedman *et al.* (12) to study the hydrolysis of two simpler nitrogen mustards. However, it has been recently demonstrated that the NBP reagent is reactive with both Forms I and II of a mustard similar to melphalan and cannot be considered specific for the intact molecule (14).

Klebe *et al.* (15) have shown that, in the absence of moisture, many amino acids form stable and volatile *N*- and *O*-bonded trimethylsilyl derivatives with bis(trimethylsilyl) acetamide (BSA) and may be assayed by GLC. Other silylating reagents have been used for quantitative preparations of trimethylsilyl derivatives of

amino acids (16), but BSA was preferred for these experiments because of its higher reactivity as a silyl donor.

Quantitative conversion of amino acids to trimethylsilyl derivatives is accomplished simply by dissolving either the free amino acids or their hydrochlorides in an excess of BSA reagent. Degradation products II and III are capable of further reaction with BSA to form Compounds V and VI, respectively (see Scheme II).

Melphalan bulk, which served as a reference standard, was silylated with BSA and chromatographed as the trimethylsilyl derivative of the intact compound. A mixture of hydrolytic decomposition products was prepared, silylated, and chromatographed under the same conditions. Peaks having retention times of 1.1 and 1.3 relative to the intact melphalan derivative (IV) were recorded and identified as trimethylsilyl derivatives V and VI, respectively. The separation permitted the quantitative determination of intact melphalan in a freeze-dried dosage formulation containing mannitol. With the use of an internal standard, the assay is accurate as well as rapid and specific.

EXPERIMENTAL

Reagents and Materials—Melphalan bulk used in this study was provided by the Drug Distribution Unit of Cancer Chemotherapy National Service Center, National Institutes of Health. A sterile, freeze-dried intravenous dosage formulation of melphalan dihydrochloride was prepared from bulk material by this laboratory. Each vial contained 50 mg. of melphalan and 100 mg. of mannitol. A purified grade of BSA² in septum-stoppered vials was obtained for the experiment. A solution of chrysene³ in chloroform (2.5 mg./ml.) was prepared fresh daily for use as an internal standard. The column packing employed for GLC was a laboratory preparation consisting of 2.5% (w/w) of a silicone polymer⁴ on acid-washed,

silanized, 80/100 mesh diatomaceous earth.⁵ All solvents were reagent grade quality and used as supplied.

Instrumentation—A gas chromatograph⁶ equipped with a flame-ionization detector and an all-glass column (1.8 m. long, 3 mm. i.d.) was employed for quantitative work. Prepurified nitrogen was used as the carrier gas at a flow rate of 30 ml./min. The column oven was operated isothermally at 210°, the injector at 250°, and the detector at 215°. A similar gas chromatography system⁷ was used to obtain fractions for mass spectrometry analysis. The mass spectral data were obtained from a modified mass spectrometer⁸ with an upper limit of *m/e* 500 and with resolution capabilities of 1/1000.

Procedures—Derivatives were prepared for qualitative GLC analysis by reacting approximately 10 mg. of dry sample with 0.5 ml. of BSA. The reactions were carried out in 1-ml. septum-stoppered vials, and BSA was introduced with a hypodermic syringe to exclude atmospheric moisture. The reactions were complete in 15 min. at room temperature, and 3- μ l. portions of the solutions were injected onto the column with a microliter syringe.⁹ This procedure was followed using samples of melphalan bulk, melphalan freeze-dried dosage formulation, and hydrolytically degraded melphalan. The latter material was obtained by heating an aqueous solution of bulk melphalan at 40° and carefully monitoring the extent of the hydrolysis by measuring the amount of ionic chlorine liberated. When the concentration of ionic chlorine represented one-half of the total chlorine, the solution was cooled and lyophilized.

The quantification of intact melphalan in the freeze-dried dosage formulation was accomplished with the aid of an internal standard. Exactly 10.0 ml. of internal standard solution was added to the contents of each vial. The vials were fitted with septum-stoppered caps and 2.5 ml. of BSA was introduced with a hypodermic syringe. The vials were shaken and allowed to stand at room temperature for 1 hr. A syringe was used to withdraw 4- μ l. portions of the solutions for injection onto the column. A standard solution was prepared for each series of samples by following the same procedure with an accurately weighed quantity of melphalan bulk approximately equivalent to that in the samples. The initial injection was used only to condition the column and the associated chromatogram was disregarded. Samples and standard solution were alternately chromatographed.

Calculations—Peak heights were measured from adjusted base-lines and the peak height ratios of intact melphalan to chrysene were determined. The quantity of intact melphalan in the samples was determined by direct comparison of peak height ratios between samples and standard solution.

Identification of Derivatives—Samples of the trimethylsilyl derivatives were collected at the exit port of the gas chromatograph for identification. The collected fractions were protected from atmo-

Figure 1—Chromatogram of an assay preparation from freeze-dried dosage formulation: A = solvent, B = mannitol-TMS, C = impurity in chrysene, D = chrysene, E = melphalan-TMS (IV), F = decomposition product-TMS (V).

spheric moisture and immediately analyzed by mass spectrometry. The mass spectral data are summarized in Table I. In the case of the fraction representing the derivative of melphalan reference material, sufficient sample was isolated to allow recovery of the parent compound by hydrolysis of the trimethylsilyl groups. The resulting product, melphalan, was identified by IR spectroscopy and paper chromatography.

RESULTS AND DISCUSSION

Qualitative Determinations—The silylated melphalan reference sample chromatographed as a single component. Three components, the first of which corresponded to the reference sample, were obtained when partially hydrolyzed material was silylated and chromatographed. Fragments common to *N,O*-bis(trimethylsilyl) derivatives of amino acids (17) and aryl amino acids (18) were prominent in the mass spectrum of each fraction. Molecular weights determined from the mass spectral data were in agreement with those calculated for IV, V, and VI. In addition, paper chromatographic and IR spectroscopic analyses established that the parent compound of the reference sample derivative was intact melphalan.

GLC analysis of silylated dosage formulation revealed the presence of V. Mannitol in the formulation eluted early as a silylated product and posed no problem. Relative retention times are given in Table II.

The same elution order was found when the derivatives were chromatographed using a relatively less polar liquid phase;¹⁰ however, the order was reversed when a relatively more polar phase¹¹ was employed.

Quantification of Intact Melphalan in Dosage Formulation—A typical chromatogram for the assay of a freeze-dried dosage formulation preparation is shown in Fig. 1 (in this particular assay, Compound VI is not present). Chrysene was selected for the internal standard because it is nonreactive with BSA and no decomposition products elute at or near its retention time (0.66 relative to intact melphalan).

The average of five replicate determinations for percent intact melphalan in a single vial of dosage formulation was 88.7% with a standard deviation of 1 (range = 2.5%).

Variations of less than 3% were found in the assay of several vials from the same production lot. The samples and reference solutions may be used for quantitative work up to 24 hr. after preparation.

Synthesis of 4-{p-[(2-Chloroethyl)-(2-hydroxyethyl)amino]phenyl}butyric Acid and Its Behavior in the 4-(4-Nitrobenzyl)pyridine Assay Procedure

M. K. BALAZS*, C. A. ANDERSON, R. H. IWAMOTO, and P. LIM†

Abstract □ The synthesis of 4-{p-[(2-chloroethyl)-(2-hydroxyethyl)amino]phenyl}butyric acid is reported. Investigation of the behavior of this compound in the NBP assay procedure showed that it alkylates NBP in a manner similar to chlorambucil. Therefore the results obtained from the assay of chlorambucil and similar aryl nitrogen mustards by the NBP method must be interpreted with due caution.

Keyphrases □ 4-{p-[(2-Chloroethyl)-(2-hydroxyethyl)amino]phenyl}butyric acid—synthesis □ 4-(4-Nitrobenzyl)pyridine alkylation—4-{p-[(2-chloroethyl)-(2-hydroxyethyl)amino]phenyl}butyric acid □ Chlorambucil analysis—4-{p-[(2-chloroethyl)-(2-hydroxyethyl)amino]phenyl}butyric acid interference □ Colorimetric analysis—spectrophotometer □ TLC—separation, identification □ IR spectrophotometry—structure □ NMR spectroscopy—structure

The compound 4-(4-nitrobenzyl)pyridine (NBP) has been used as an analytical reagent for alkylating agents, among which are the nitrogen mustards such as melphalan,¹ chlorambucil,² and uracil mustard.³ The

general method involves the alkylation of NBP; subsequent basification results in the formation of a chromophore whose intensity can be measured photometrically.

The following reaction sequence has been suggested by Petering and Van Giessen (1) (Scheme I).

Holtzman (2) reportedly was able to isolate the product obtained from the reaction of mustard gas with NBP; he identified it as the mono-NBP product.

The NBP procedure has been considered in the authors' laboratories for the assay of chlorambucil. One

¹ 4-{p-[Bis(2-chloroethyl)amino]phenyl}-L-alanine.
² 4-{p-[Bis(2-chloroethyl)amino]phenyl}butyric acid was furnished by Cancer Chemotherapy National Service Center.
³ 5-[Bis(2-chloroethyl)amino]uracil.

The average of five replicate determinations for percent intact melphalan in a single vial of dosage formulation was 88.7% with a standard deviation of 1 (range = 2.5%).

Variations of less than 3% were found in the assay of several vials from the same production lot. The samples and reference solutions may be used for quantitative work up to 24 hr. after preparation.

Synthesis of 4-{p-[(2-Chloroethyl)-(2-hydroxyethyl)amino]phenyl}butyric Acid and Its Behavior in the 4-(4-Nitrobenzyl)pyridine Assay Procedure

M. K. BALAZS*, C. A. ANDERSON, R. H. IWAMOTO, and P. LIM†

Abstract □ The synthesis of 4-{p-[(2-chloroethyl)-(2-hydroxyethyl)amino]phenyl}butyric acid is reported. Investigation of the behavior of this compound in the NBP assay procedure showed that it alkylates NBP in a manner similar to chlorambucil. Therefore the results obtained from the assay of chlorambucil and similar aryl nitrogen mustards by the NBP method must be interpreted with due caution.

Keyphrases □ 4-{p-[(2-Chloroethyl)-(2-hydroxyethyl)amino]phenyl}butyric acid—synthesis □ 4-(4-Nitrobenzyl)pyridine alkylation—4-{p-[(2-chloroethyl)-(2-hydroxyethyl)amino]phenyl}butyric acid □ Chlorambucil analysis—4-{p-[(2-chloroethyl)-(2-hydroxyethyl)amino]phenyl}butyric acid interference □ Colorimetric analysis—spectrophotometer □ TLC—separation, identification □ IR spectrophotometry—structure □ NMR spectroscopy—structure

The compound 4-(4-nitrobenzyl)pyridine (NBP) has been used as an analytical reagent for alkylating agents, among which are the nitrogen mustards such as melphalan,¹ chlorambucil,² and uracil mustard.³ The

general method involves the alkylation of NBP; subsequent basification results in the formation of a chromophore whose intensity can be measured photometrically.

The following reaction sequence has been suggested by Petering and Van Giessen (1) (Scheme I).

Holtzman (2) reportedly was able to isolate the product obtained from the reaction of mustard gas with NBP; he identified it as the mono-NBP product.

The NBP procedure has been considered in the authors' laboratories for the assay of chlorambucil. One

¹ 4-{p-[Bis(2-chloroethyl)amino]phenyl}-L-alanine.

³ 5-[Bis(2-chloroethyl)amino]uracil.

possible contaminant is 4- $\{p-[(2\text{-chloroethyl})-(2\text{-hydroxyethyl})\text{amino}]\text{phenyl}\}$ butyric acid, the chlorambucil hemimustard, VIII. This can result from hydrolysis of chlorambucil or from incomplete chlorination during the preparation of the mustard. Since VIII is still an alkylating agent, it may react with NBP to yield a chromophore characteristically similar to that resulting from the reaction between NBP and chlorambucil. If this happens, the usefulness of the NBP assay of aryl bis-mustards may be questionable. To clarify this situation, the authors have prepared the chlorambucil hemimustard and studied its behavior in the NBP procedure.

RESULTS AND DISCUSSION

The synthesis of VIII was carried out as described in Scheme II; the details are given in the *Experimental* section.

Scheme II

Chlorambucil and its hemimustard were treated with NBP under identical, optimal conditions, which were experimentally determined by varying the substrate-NBP ratio and the period of heating. The results, expressed in molar absorptivities, are given in Tables I and II.

The data show that the hemimustard, VIII, does react with NBP to yield a product whose visible absorption characteristics are similar to those of the chlorambucil-NBP chromophore. Therefore, it is felt that the data obtained from the NBP assay procedure of aryl nitrogen mustards must be interpreted with due caution.

A comparison of the respective molar absorptivities indicates that the intensity of the hemimustard NBP product is only 0.8 that of the chlorambucil-NBP value. The hemimustard appears to reach its maximum color faster than does chlorambucil. At this time, no

attempt has been made to seek an explanation for either of these observations because such information is beyond the scope of this communication.

EXPERIMENTAL⁴

NBP Assay Procedure—Chlorambucil (1.2 mg.) or VIII (1.1 mg.) was dissolved in 25.0 ml. of 95% EtOH. A 1.0-ml. aliquot of this solution was placed in a 5.0-ml. volumetric flask together with 1.0 ml. of an NBP solution (3.55 g./50 ml. of acetone) and 1.0 ml. of buffer solution (1.0 g. of potassium hydrogen phthalate/100 ml. of H_2O).

The flask was kept at 85° in a water bath for 30 min. The solution was cooled immediately for 2–3 min. in an ice bath, and 0.1 ml. of a KOH solution (1.4 g./25 ml. of 95% EtOH) was added.⁵ The solution was diluted to 5.0 ml. with 95% EtOH and shaken. After 2 min. the absorbance from 560–570 $m\mu$ was recorded. This procedure was used by varying the heating time to obtain the data tabulated in Table II. The molar ratios were varied by changing the concentration of NBP solutions so that the data in Table I could be obtained.

Materials—4-Nitrobenzylpyridine (NBP) (Aldrich Chemical Co.) was used without further purification.

The chlorambucil used was chromatographically homogeneous on Whatman No. 1 paper, solvent system $n\text{-BuOH-HOAc-H}_2\text{O}$, 5:2:3, and by GLC as its silyl derivative on a 1.52-m. (5-ft.) 5% SE-54-diatomaceous earth (Gas Chrom W, Applied Science Laboratories, Inc.) column at 210° . Elemental analysis for the chlorambucil sample was satisfactory.

Anal.—Calcd. for $\text{C}_{14}\text{H}_{19}\text{Cl}_2\text{NO}_2$: C, 55.27; H, 6.30; Cl, 23.31; N, 4.60. Found: C, 55.57; H, 6.25; Cl, 23.05; N, 4.60. The IR spectrum of this material was identical to that of an authentic sample. The NMR spectrum is consistent with that expected for the compound; 1.90 δ (m, 2H, $\text{CH}_2\text{-CO}_2\text{H}$), 2.40 δ (m, 4H, $\phi\text{-CH}_2\text{-CH}_2\text{-}$), 3.65 δ [s (broad), 8H, $\text{ClCH}_2\text{CH}_2\text{-}$], 6.80 δ (q, 4H, aromatic), and 11.0 δ [s (broad), 1H, CO_2H].

Methyl 4-[(*p*-Benzylideneamino)phenyl]butyrate (I)—A mixture of 6.15 g. (0.03 mole) of methyl 4-(*p*-aminophenyl)butyrate, 0.50 g. of fused potassium acetate, and 3.71 g. of benzaldehyde was refluxed in 50 ml. of absolute EtOH for 4 hr. The cooled solution was diluted with 75 ml. of H_2O and extracted with ether. The ether extracts were combined, dried (MgSO_4), filtered, and evaporated at reduced pressure (first at 20 mm. and then at 0.6 mm.) for 7 hr. The product, 8.45 g. (94%), was characterized by spectral and chromatographic evidence. The IR spectrum showed the expected absorption at 6.24μ , indicative of a benzal imino system. The NMR spectrum, showing expected increase in aryl protons, was consistent with the proposed structure. TLC on silica gel in Solvent System 1 showed only a minor contaminant in addition to a main spot.

Methyl 4-[(*N*-Benzylamino)phenyl]butyrate (II)—A solution of 8.45 g. (0.03 mole) of crude benzylidene compound in 90 ml. of 95% EtOH was stirred in an atmosphere of hydrogen gas in the presence of 1.0 g. of 5% Pd-C catalyst for 85 min., during which time the theoretical amount of hydrogen was consumed. The catalyst was removed by filtration; the reaction mixture was concentrated to a tan oil, 7.56 g. (89%), which was of sufficient purity to use in the

⁴ The IR spectra were recorded as neat liquid films, as mineral oil mulls, or as CHCl_3 solutions. The NMR spectra were taken as CDCl_3 solutions with internal TMS ($\delta = 0.0$) using a Varian A60-A spectrometer. Where multiplets are involved the chemical shift is measured from TMS to the center of the multiplet. In TLC, Solvent System 1 is benzene-ether, 1:1, and System 2 is $\text{CHCl}_3\text{-MeOH}$, 2:1.

⁵ The quantity of added base has been found to be quite critical, since the addition of insufficient or excess base in this experiment causes a decrease of the absorbance at 560–570 $m\mu$.

next step. The IR spectrum showed an absorption at 2.90 μ attributed to N—H. The NMR spectrum exhibited a two-proton singlet at 4.3 δ and a five-proton singlet at 7.3 δ that were assigned to the benzyl group.

SiO₂ TLC (Solvent System 1) of the reaction mixture shows two major spots. One of these is the desired *N*-benzyl compound, II, while the slower moving spot travels identically as methyl 4-*p*-(aminophenyl)butyrate. In smaller scale preparation, column chromatography on SiO₂ (Solvent System 1) was employed to remove the primary amine. In the subsequent hydroxyethylation reaction, it was found that the bis-hydroxyethylated compound, methyl 4-*p*-[bis-hydroxyethylamino]phenyl]butyrate could be easily separated from the desired compound, III, by chromatography so that extensive purification at this reduction step is not necessary.

Methyl 4-*p*-(*N*-Benzyl)-(2-hydroxyethylamino)phenyl]butyrate (III)—A 100-ml. round-bottom flask containing 7.6 g. (0.028 mole) of the *N*-benzyl compound, II, 40 ml. of 50% HOAc, and 7.7 ml. of ethylene oxide at 0° was stoppered and kept at room temperature for 16 hr. The reaction mixture was then poured into 75 ml. of H₂O and neutralized with solid NaHCO₃. This solution was extracted with several portions of EtOAc. The combined EtOAc extracts were washed thoroughly with H₂O, dried (MgSO₄), filtered, and evaporated to a brown oil (7.89 g.).

The crude hydroxyethyl compound was purified by chromatography on a 40 × 2.2-cm. SiO₂ column. The column was developed first with ϕ H—Et₂O, 9:1, followed by ϕ H—Et₂O, 4:1, which eluted 5.22 g. (66%) of Compound III as an oil. The IR spectrum exhibited the expected —OH bands at 2.9 and 9.55 μ . The NMR spectrum exhibited, in addition to those resonances observed for Compound II, a four-proton multiplet centered at 3.65 δ which was assigned to the methylene groups of the newly added 2-hydroxyethyl moiety.

Methyl 4-*p*-(*N*-Benzyl)-(2-acetoxyethylamino)phenyl]butyrate (IV)—A solution of 5.22 g. (0.016 mole) of the hydroxyethyl Compound III, 15 ml. of dry pyridine, and 15 ml. of acetic anhydride was kept overnight in a 100-ml. round-bottom flask. The reaction mixture was poured into 100 ml. of H₂O, neutralized with NaHCO₃, and extracted with EtOAc. The combined EtOAc extracts were washed with *N* HCl (until the aqueous wash remained at pH 1), H₂O, saturated NaHCO₃, and again with H₂O. The EtOAc solution was dried (MgSO₄), filtered, and evaporated to an oil, 4.97 g. (84%). The material was homogeneous on SiO₂ TLC (Solvent System 1) and its IR showed the typical acetoxy band at 8.10 μ . The NMR spectrum exhibited a three-proton singlet at 1.99 δ which was assigned to the acyl methyl group. In addition, there was a two-proton triplet at 4.25 δ (J = 6 c.p.s.) that was assigned to the AcO—CH₂— protons.

Methyl 4-*p*-(2-Acetoxyethylamino)phenyl]butyrate (V)—A solution of 4.95 g. (0.013 mole) of the *N*-benzyl-acetoxyethylamino Compound IV in 35 ml. of 95% EtOH was stirred with 0.56 g. of 5% Pd—C catalyst in the presence of hydrogen gas at atmospheric pressure until slightly more than the theoretical amount of gas was taken up (16 hr.). The catalyst was removed by filtration and the ethanol was evaporated under reduced pressure to yield 3.49 g. (93%) of an oil which was homogeneous on SiO₂ TLC (Solvent System 1). The NMR spectrum showed that the benzyl group was removed since the two singlets attributed to the protons of the benzyl group were absent in the spectrum. The IR spectrum showed the expected N—H band at 2.90 μ .

Methyl 4-*p*-(2-Hydroxyethyl)-(2-acetoxyethylamino)phenyl]butyrate (VI)—Hydroxyethylation of V with ethylene oxide was carried out in a manner similar to that used for the preparation of III. A 2.69-g. (0.009-mole) portion of V gave 2.18 g. (70%) of an oil whose NMR spectrum was consistent with that expected for the desired compound. The additional methylene groups of the hydroxy-

ethyl group were observed as a nine-proton multiplet at 3.6 δ (the integration includes the three protons of the O—CH₃ singlet). At 4.2 δ a two-proton triplet was assigned to the methylene group adjacent to the acetoxy moiety. The IR spectrum showed absorptions at 5.70 and 5.80 μ , the former being assigned to the acetate, and at 2.90 and 9.55 μ , both of which were assigned to the OH.

On SiO₂ TLC (Solvent System 1) the compound was nearly homogeneous and showed three minor contaminants in addition to a large major spot.

Methyl 4-*p*-(2-Chloroethyl)-(2-acetoxyethylamino)phenyl]butyrate (VII)—Freshly distilled POCl₃ (20 ml.) and 2.61 g. (8.0 mmoles) of the hydroxyethyl compound, (VI), were heated at reflux for 1 hr. and then poured into 200 ml. of crushed ice. The mixture was stirred for 20 min., with ice being added periodically, and then extracted with several portions of chloroform. The combined CHCl₃ extracts were dried (MgSO₄), filtered, and evaporated to give 2.45 g. (88%) of a yellow oil. The oil was essentially homogeneous on silica gel TLC in Solvent System 1. The NMR spectrum exhibited the fol-

lowing resonances: 2.00 δ (s, 3H, CCH₃); 3.62 δ (m, 6H, —CH₂—CH₂— and —CH₂—CH₂ of *N* substituents); 3.67 δ (s, 3H, O—CH₃); 4.21 δ (t, J = 6 c.p.s., assigned to CH₂ adjacent to Cl or OAc); and 6.85 δ (q, 4H, J = 8.5 c.p.s., aromatic). The IR spectrum (neat) showed no absorption at 2.90 μ and an absorption at 13.3 μ which was assigned to C—Cl. The crude material was purified by preparative silica gel plates (Solvent System 1) to yield 1.29 g. (68%) of an analytically pure oil.

Anal.—Calcd. for C₁₇H₂₄ClNO₄: C, 59.73; H, 7.08; N, 4.10. Found: C, 59.76; H, 7.23; N, 4.15.

A smaller scale reaction, carried out prior to the above experiment, gave material that had identical IR, NMR, and TLC to the material prepared above. A satisfactory chlorine analysis was obtained.

Anal.—Calcd.: 10.37. Found: 10.3 for this material.

4-*p*-(2-Chloroethyl)-(hydroxyethylamino)phenyl]butyric Acid "Hemimustard" (VIII)—The hydrolysis of the blocking groups was performed in refluxing HCl. A solution of 1.405 g. (4.1 mmoles) of Compound VII and 3.0 ml. of concentrated HCl was heated at reflux for 4 hr. The reaction mixture was cooled, diluted with H₂O, buffered at pH 5 by the addition of NaOAc, and extracted with several portions of CH₂Cl₂. The CH₂Cl₂ extracts were combined, dried (MgSO₄), filtered, and concentrated to a colorless oil, 1.20 g. (84%).

A portion of the crude material was dissolved in Et₂O—petroleum ether (b. p. 30–60°). After 3 days in the cold, there was deposited crystalline VIII; recrystallization from the same solvent yielded an analytically pure product, m.p. 51–53° (uncorrected). The material was homogeneous on silica gel TLC (Solvent System 2).

Anal.—Calcd. for C₁₄H₂₀ClNO₃: C, 58.84; H, 7.05; Cl, 12.40; Cl[−], 0.0; N, 4.90. Found: C, 58.72; H, 6.93; Cl, 12.54; Cl[−], 0.0, N, 4.86.

Riboflavin Distribution and Elimination in Two Functionally Anephric Human Patients

WILLIAM J. JUSKO*, JACK R. LEONARDS†, and GERHARD LEVY*‡

Abstract □ Pharmacokinetic studies in normal human subjects have suggested that probenecid modifies appreciably the distribution in the body of riboflavin and certain drugs. To exclude the effects of probenecid on renal excretion, the distribution and elimination of riboflavin with and without probenecid were studied in two functionally anephric patients during hemodialysis. A pharmacokinetic analysis of the time course of plasma levels of the vitamin, based on a two-compartment open model, indicates no appreciable effect of probenecid on the distribution and transfer rate constants of riboflavin. Riboflavin was eliminated more slowly by hemodialysis of the patients than by renal excretion in normal subjects. The rate of removal of riboflavin by hemodialysis appears to be primarily a function of the rate of blood flow through the dialyzer.

Keyphrases □ Riboflavin distribution, elimination—anephric patients □ Anephric condition—riboflavin distribution, elimination □ Probenecid effect—riboflavin distribution, elimination □ Hemodialysis—riboflavin elimination

The possible effect of probenecid on the distribution of various compounds in the body has been of recent interest. Gibaldi *et al.* (1, 2) have shown in studies with penicillins that, in addition to the well-known inhibitory effect on the renal excretion of this antibiotic, probenecid also seems to increase significantly the fraction of drug in the apparent body compartment from which elimination occurs. The results of recent studies in this laboratory suggest that probenecid affects also the distribution of riboflavin in the body (3). Since riboflavin is eliminated primarily by renal excretion, it was of interest to pursue further studies in functionally anephric patients in order to exclude the primary renal effect of probenecid. These studies were carried out during the course of hemodialysis of the anephric patients and may also be of nutritional interest since it has been suggested that vitamin deficiencies could develop due to the removal of water-soluble vitamins by dialysis (4).

EXPERIMENTAL

Two functionally anephric¹ male human patients, who were undergoing hemodialysis, served as test subjects. Subject S, age 30, with chronic membranous glomerulonephritis, and Subject K, age 34, with collagen disease, were maintained on a Kiil and a Skeggs-Leonards dialyzer, respectively. Both systems involved dialysate flow of approximately 580 ml./min. and blood flow of about 270 ml./min. Hematocrit values of each subject ranged from 0.22 to 0.24, and the plasma albumin concentration was about 3.2 g. % in each subject.

An intravenous dose of 38.9 mg. riboflavin as riboflavin-5'-phosphate² was administered 3 to 5 hr. after the start of hemodialysis. One gram of probenecid³ in aqueous suspension was given orally, in crossover fashion, 1.5 to 2.0 hr. prior to riboflavin. Blood samples were collected proximal to the arterial shunt 0.5 hr. before and at 0.25, 0.5, 1.0, 2.0, 3.0, 4.0, and 6.0 hr. after injection of riboflavin. Studies in each patient were separated by a 7-day interval.

¹ Less than 3% of normal renal function.

² Hyrye Injection, S.F. Durst Co., Philadelphia, Pa.

³ Benemid, Merck Sharp and Dohme, West Point, Pa.

Figure 1—Time course of total riboflavin (●) plasma concentrations in an anephric subject (S) after intravenous injection of 38.9 mg. riboflavin as riboflavin-5'-phosphate (FMN). Also shown for comparative purposes are riboflavin serum levels in a normal subject (○), 85 kg., who received an i.v. dose of 31 mg. riboflavin as FMN; and (□), probenecid plasma concentrations in the anephric patient after oral administration of 1 g. probenecid at -2 hr.

Total riboflavin (5) and probenecid (6) concentrations in plasma were determined by methods described previously. No mutual interference in the analyses of the two compounds was found (3). Plasma concentrations were corrected for blank values of samples obtained prior to the administration of either drug.

RESULTS

The time course of total riboflavin and probenecid plasma concentrations in Subject S are shown in Fig. 1. Also depicted for purposes of comparison are riboflavin plasma concentrations obtained in a normal subject. The plasma concentrations of riboflavin (C_p) as a function of time (t) in the anephric subjects were fitted to a biexponential equation:

$$C_p = A \cdot \exp(-\alpha t) + B \cdot \exp(-\beta t) \quad (\text{Eq. 1})$$

using the "NLIN" digital computer program of Marquardt (7). The distribution (k_{12} , k_{21}) and elimination (k_d) rate constants of the typical two-compartment open model (elimination occurring from the central compartment) were obtained from the parameters A , α , B , and β as described by Rescigno and Segre (8). The apparent volume of the central compartment (V_c) was calculated from:

$$V_c = \text{dose}/(A + B) \quad (\text{Eq. 2})$$

and an additional "volume" parameter, (V_d) β , was determined from:

$$(V_d)\beta = V_c \cdot k_d/\beta \quad (\text{Eq. 3})$$

as described by Gibaldi *et al.* (9). The body clearance (Cl_b) of the vitamin was calculated from:

$$Cl_b = k_d \cdot V_c \quad (\text{Eq. 4})$$

All of the parameters and rate constants described, which were obtained from riboflavin plasma levels in the presence and

^a Symbols are defined in the text. ^b Body weights: S, 56 kg.; K, 73 kg. ^c Plasma concentration range of probenecid: Subject S: 2.47 to 0.95 mg. %; Subject K: 3.96 to 1.22 mg. %. ^d Coefficient of determination: $(\Sigma \text{obs.}^2 - \Sigma \text{dev.}^2) / \Sigma \text{obs.}^2$

absence of probenecid, are listed in Table I. The coefficient of determination (CD) for each of the four sets of data is close to unity, indicative of the excellent fit of the experimental data to the curve calculated from Eq. 1.

It was also of interest to determine if blood flow through the dialyzer or diffusion of riboflavin across the dialysis membrane may be rate limiting in the elimination of the vitamin by hemodialysis. The effective plasma flow rate (Q_E) through the dialyzer can be calculated from the relationship:

$$Q_E = Q \cdot (1 - \text{HCT}) \cdot F_f \quad (\text{Eq. 5})$$

where Q is the actual blood flow rate (about 270 ml./min.), HCT is the hematocrit (0.23), and F_f is the fraction of nonprotein-bound vitamin in the plasma. The value of the latter was calculated to be about 0.5 based on the actual albumin concentration in the plasma (3.2 g. %) and the previously determined (10) association constants of the vitamin with human albumin. The effective plasma flow rate thus estimated from Eq. 5 is about 110 ml./min., which is quite similar to the body clearance values observed in three of the four studies in the anephric patients (Table I). It was not possible to determine dialysance directly due to the very rapid rate of flow of the dialysis fluid (580 ml./min.) which resulted in such extensive dilution of riboflavin, making its determination in the dialysis fluid impossible.

DISCUSSION

The distribution parameters V_c and $(V_{d-\beta})$ are very similar in all four tests when expressed as a percent of body weight (Table I). Probenecid, therefore, had no apparent effect on the distribution of riboflavin in the body under the experimental conditions. The rate constants k_{12} and k_{21} were somewhat more variable but also showed no consistent differences as a function of probenecid administration. It may be concluded, therefore, that the apparent effect of probenecid on riboflavin distribution in a normal subject (3) is probably an indirect result of its effect on the renal excretion of the vitamin.

The distribution parameter V_c ranged from 24.2 to 26.7% of body weight in the present study which is appreciably larger than the 16% value reported previously for a normal subject (3). This difference is consistent with the low hematocrit and low plasma albumin concentration in the anephric patients.

The similarity of three of the four body clearance (Cl_b) values to the calculated effective plasma flow rate through the dialysis system suggests that blood flow through the dialyzer is either the

rate-limiting step or at least one of the rate-determining processes in the elimination of riboflavin by hemodialysis. This assumes that metabolism and extrarenal excretion (other than hemodialysis) contribute little to the elimination of the vitamin in anephric patients as is the case in normal subjects (1, 3).

Renal clearance of riboflavin in normal subjects involves glomerular filtration, renal tubular secretion, and renal tubular reabsorption by a specialized saturable process (11). Clearance is, therefore, concentration dependent, ranging from as high as 400 ml./min. at high plasma concentrations of riboflavin to 150 ml./min. or less at low plasma concentrations in normal adults (11). On the other hand, body clearance of riboflavin is not concentration dependent in functionally anephric patients due to the absence of a renal reabsorption process. A direct comparison of renal clearance in normal subjects with body clearance in hemodialyzed patients is therefore impossible.

The pharmacokinetics of riboflavin elimination in anephric patients and normal subjects differ also in that the time course of riboflavin concentration decline in the plasma of the patients is describable by a biexponential expression while a triexponential expression is required for normal subjects (11). This appears to be due to the absence of the renal reabsorption capability in the patients. A similar effect has been found in newborn infants whose renal mechanisms are immature (12).

It is of interest that probenecid, which is eliminated in normal subjects almost exclusively by biotransformation and which because of its high affinity to plasma proteins (6) is not likely to be removed effectively by hemodialysis, was as rapidly eliminated in the two patients (half-life of 2 to 4 hr.) as in normal subjects at a comparable dosage level (3, 6). On the other hand, drugs that are eliminated solely or primarily by renal excretion have a much longer half-life in anephric patients than in normal subjects (13, 14).

Improved Procedure for Determination of Microamounts of Sulfamethazine and Procaine Penicillin Admixed with Chlortetracycline and *p*-Arsanilic Acid in Medicated Feeds

MURUGAN MALAIYANDI and JEAN P. BARRETTE

Abstract □ An improved technique is presented for the separation and determination of both sulfamethazine and procaine penicillin in medicated feeds. This method utilizes diazotization of the free amino compounds with nitrite and coupling with the Bratton-Marshall reagent to produce a soluble red dye. The absorbance of this dye at 545 m μ is measured. Results on six laboratory-mixed medicated feeds are reported.

Keyphrases □ Sulfamethazine—analysis, medicated feeds □ Procaine penicillin—analysis, medicated feeds □ TLC—separation □ Bratton-Marshall reaction—colorimetric analysis □ UV spectrophotometry—analysis

Sulfamethazine and procaine penicillin in combination with other drugs, such as chlortetracycline, tylosine, and *p*-arsanilic acid, are admixed in swine and cattle feeds for the prevention of infection associated with

hemorrhagic septicemia, swine dysentery, bacterial scours in calves (1) and coccidiosis in chickens (2). Gerriets (3) observed that chickens fed with sulfamethazine-incorporated, riboflavin-deficient fodder developed typical clinical riboflavin avitaminosis, and he concluded that in sulfamethazine therapy both riboflavin and vitamin K₃ should be supplemented in the feed. It has been shown that the excretion of sulfamethazine is not complete and the concentration of the sulfa drug in bovine milk (4, 5) and plasma proteins (6) can be relatively high. Borsnk (7) noted that injection of sulfamethazine in hen eggs affected embryonic development, resulting in poor hatchability, several growth disturbances, and prenatal malformations. Because of these and other harmful side effects recorded in the literature, it has become necessary for the regulatory agencies to develop reliable analytical methods for estimating these drugs in feeds.

Several reports have appeared in the literature concerning the separation and determination of sulfamethazine and procaine penicillin in combination with other drugs, and these methods have been summarized in a previous communication (8). The present paper describes an improvement over the procedure outlined in the earlier method (8) for the estimation of sulfamethazine and procaine penicillin, and their extraction from the adsorbent alumina is accomplished with considerable saving of time. By this procedure, six laboratory-prepared samples containing varying amounts of *p*-arsanilic acid, chlortetracycline, sulfamethazine, and procaine penicillin have been extracted and the components separated cleanly from one another on thin-layer alumina plates and estimated spectrophotometrically.

EXPERIMENTAL

Apparatus—The extraction apparatus for eluting the drugs from thin-layer alumina is illustrated in Fig. 1. The alumina chromatoplates were prepared as previously described (9).

Reagents—An analytical sample of sulfamethazine (m.p. 198–198.5°) was obtained by crystallizing a technical sample¹ twice from a mixture of methanol-petroleum ether (b.p. 66–68°) followed by a final recrystallization from benzene-petroleum ether (b.p. 66–68°) mixture. The sample was shown to be identical to an authentic sample by determination of mixed melting point, elemental analysis, *R_f* values, and IR and NMR spectra. From the UV absorption spectrum, the sample was found to be 99.8% pure.

Procaine Penicillin²—Analytical standard was used without further purification. All organic solvents were glass-distilled. The alumina³ for thin-layer chromatography was processed according to the method of Malaiyandi *et al.* (9) with plates activated at 120°

Figure 1—Extraction apparatus.

instead of 145°. Aqueous hydrochloric acid, 6 *N*; aqueous sodium nitrite solution, 1.0%; aqueous ammonium sulfamate solution, 5.0%; Bratton-Marshall reagent (aqueous *N*-(1-naphthyl)ethylenediamine dihydrochloride), 0.1%. The last three reagents were all freshly prepared each week and stored in a refrigerator (5°).

PROCEDURE

Standard and Recovery Curves for Procaine Penicillin and Sulfamethazine—*Standard Curve*—Ten aliquots (in duplicate) containing known amounts of different concentrations of procaine penicillin and sulfamethazine in ethanol were transferred to separate 50-ml. volumetric flasks. To these flasks was added 3.0 ml. of 6 *N* HCl followed by 15 ml. of distilled water. The flasks were heated on a water bath at 70–80° for 15 min. and the ethanol was evaporated off with a gentle stream of nitrogen (about 45 min.). The solutions were diluted with 10 ml. water and estimated by the procedure described for the preparation of standard curve for *p*-arsanilic acid (9).

Recovery Curve—A concentrated ethanolic solution containing known amounts of a mixture of procaine penicillin and sulfamethazine was prepared. Eight aliquots (in duplicate) containing amounts varying from 10 to 200 mcg. of drugs were applied to thin-layer alumina plates (0.25–0.30 mm. thick) along with a clearly visible reference spot at one side of the plate. The plates were developed as described in the earlier method (8).⁴

The areas⁵ containing the drugs were separately scraped off the plate, and the adhering alumina was swept with a camel hair brush onto glazed paper. The alumina was transferred to the hot water-circulated extraction apparatus over a bed of prewashed methanol-moistened diatomaceous earth (Celite 545, about 1.5–2.0 cm. high). The drug was eluted with 175 ml. of hot 2.0% methanolic hydrochloric acid. The eluate was evaporated using a rotary vacuum evaporator (bath temperature below 37°) to a volume of about 15 ml. The concentrate was quantitatively transferred to a 50-ml. volumetric flask with three rinsings of about 5-ml. portions of aqueous methanol. The flask was heated on a water bath at 70–80° and the methanol evaporated with a gentle stream of nitrogen. When the evaporation of methanol was complete, the contents of the flask were cooled, diazotized, and coupled with the Bratton-Marshall reagent as described previously. After 30 min. the solutions were diluted to volume, shaken thoroughly, and centrifuged. The absorbance was then measured and plotted to obtain the recovery curve.

Preparation of Laboratory Premixes—Six laboratory-blended samples of medicated feed containing *p*-arsanilic acid, chlortetracycline, procaine penicillin, and sulfamethazine at levels ranging from 120 to 1250 mcg./g. of feed were prepared by grinding 50-g. portions of unmedicated feed with varying amounts of the four drugs in a Sorvall-Omni mixer. After mixing for about 5 min., the mixture was tumbled on a Fisher-Kendall mixer for about 15 min. These operations were repeated twice and the sample was carefully transferred to a container which was then tumbled for 1 hr. to achieve thorough mixing.

Extraction of Drugs and Their Estimation—Two 1.0-g. portions (a_1 and a_1') and one 5.0-g. portion (a_5) of the medicated feed were extracted with 50–55 ml. of a solvent mixture containing ammonium hydroxide–dimethylformamide–chloroform–ethanol (5:5:20:20). (In the case of a_5 , 200 ml. of the same solvent mixture was used.) After refluxing for about 8 hr. the warm extracts were filtered through a bed of diatomaceous earth and concentrated under reduced pressure to about 5 ml. (20 ml. in the case of a_5). The concentrates were then quantitatively transferred to 10-ml. (50 ml. in the case of a_5) volumetric flasks with several rinsings with absolute ethanol and made to volume. Aliquots ($4 \times 250 \mu\text{l.}$) of this extract were applied to a thin-layer alumina plate and developed, and the drugs were extracted and estimated as described in the previous section.

⁴ If the humidity of the laboratory is very high, use of a 60:30:8:2 solvent mixture is recommended. When fresh dimethylamine solution is available, a 60:30:5:5 solvent composition is used.

⁵ Along with the solvent front, a fluorescent lipid band moved. This lipid band should be excluded to avoid intractable turbidity during centrifugation.

Figure 2—Standard and recovery curves for procaine penicillin. Key: ○, standard curve; □, recovery curve by previous method; and ▲, recovery curve by present method.

RESULTS AND DISCUSSION

The need for processed alumina and the choice of range of pH (7.2–7.4) of the adsorbent and the solvent systems to effect a clean separation of procaine penicillin and sulfamethazine from other drugs have been discussed in the earlier report (8). To avoid the laborious procedure of extraction of the drugs from the adsorbent alumina, a convenient technique was developed using a hot water-jacketed filtering funnel. By this expedient the alumina powder containing the drug was directly transferred over the bed of diatomaceous earth in the filtering funnel. The drug was eluted with 2% hot methanolic hydrochloric acid which, by circulating hot water in the jacket, was maintained above 50° during filtration.

It had been previously observed that neither procaine penicillin nor sulfamethazine was completely recovered (88–91%) (8) from adsorbent alumina. Being highly polar compounds, it is not surprising that some of the drugs were firmly adsorbed on the substrate. To evaluate the extent of elution by the current method and compare it with the method described earlier (8), eight aliquots (in duplicate) of a standard mixture containing varying amounts ranging from 10 to 200 mcg. of each drug were applied to thin-

Figure 3—Standard and recovery curves for sulfamethazine. Key: ○, standard curve; □, recovery curve by previous method; and ▲, recovery curve by present method.

f_5		1145	11.2		733	8.3

layer plates, developed, extracted, and estimated. Also, 10 aliquots (in duplicate) of separate standard solutions of procaine penicillin and sulfamethazine were directly determined to obtain the standard curves.

It can be seen from Fig. 2 that by the previous technique, extraction of procaine penicillin at low levels was almost in agreement with the amounts obtained with the standards; whereas at levels above 40 mcg., the recoveries were considerably poorer. This seems to indicate that with the former procedure the alumina was firmly retaining some of the drug. By the current technique, however, it is apparent that the recovery of the drug is very consistent, and better than 93% recoveries are obtained in the range 10–200 mcg.

Examination of Figs. 2 and 3 reveals that the recovery of sulfamethazine by the previous procedure (91%) was better than that of procaine penicillin. It is evident from Fig. 3 that more than 95% recovery of the sulfa drug was obtained by the current technique. By employing the present procedure, two 1-g. and one 5-g. portions of Sample *a* were analyzed and found to be homogeneous.

To test the validity of the method, six laboratory-blended samples were analyzed and the averages of the results of two duplicate analyses of each sample are given in Table I. A close examination

of the data reveals that the estimated contents of procaine penicillin are slightly higher than the amount actually added. The standard deviation^a varies from ± 3.0 to 20.0 for the six samples, indicating that although the variation is large it is still acceptable. On the other hand, in the case of sulfamethazine the results are highly reproducible with exceedingly small standard deviations (within ± 10.0) and are in close agreement with the amounts actually added.

A comparison of results of the two 1-g. and the 5-g. portions of each sample shows that there is complete agreement between these analyses. For routine work, a 5-g. sample extraction is recommended for the convenience in extraction and makeup of solutions. This extraction procedure can be profitably extended to many other estimations involving thin-layer chromatography.

Factors Affecting a Fluorometric Assay of Folic Acid

JOHN R. HAZLETT and DANE O. KILDSIG

Abstract □ A fluorometric method of assaying folic acid, based on the oxidation of folic acid by potassium permanganate, has been investigated. Various factors were found to affect the relative fluorescence obtained in the assay. These include the concentration of potassium permanganate, the length of oxidation time, and the pH and temperature of the solution.

Keyphrases □ Folic acid—analysis □ Potassium permanganate effect—folic acid fluorescence □ pH effect—oxidized folic acid fluorescence □ Temperature effect—oxidized folic acid fluorescence □ Fluorometry—analysis

The oxidative degradation of folic acid by potassium permanganate yields a fluorescent pterine (1). As a result, this oxidation has been used in analytical procedures for the quantitative determination of folic acid

Table I—Final Fluorescent Intensity

Concentration of $KMnO_4$ (moles/l. $\times 10^{-5}$)	Fluorescent Intensity (F_∞)
4.43	80.5
6.33	78.0
9.49	75.0
31.6	80.5

(2, 3). The formation of the free pterine derivative provides an approximately 20-fold increase in fluorescent intensity over that of native folic acid fluorescence.

In a comprehensive study, Allfrey *et al.* (2) measured directly the fluorescence of the oxidized mixture as well as that of the chromatographically isolated oxidation

Factors Affecting a Fluorometric Assay of Folic Acid

JOHN R. HAZLETT and DANE O. KILDSIG

Abstract □ A fluorometric method of assaying folic acid, based on the oxidation of folic acid by potassium permanganate, has been investigated. Various factors were found to affect the relative fluorescence obtained in the assay. These include the concentration of potassium permanganate, the length of oxidation time, and the pH and temperature of the solution.

Keyphrases □ Folic acid—analysis □ Potassium permanganate effect—folic acid fluorescence □ pH effect—oxidized folic acid fluorescence □ Temperature effect—oxidized folic acid fluorescence □ Fluorometry—analysis

The oxidative degradation of folic acid by potassium permanganate yields a fluorescent pterine (1). As a result, this oxidation has been used in analytical procedures for the quantitative determination of folic acid

Table I—Final Fluorescent Intensity

Concentration of $KMnO_4$ (moles/l. $\times 10^{-5}$)	Fluorescent Intensity (F_∞)
4.43	80.5
6.33	78.0
9.49	75.0
31.6	80.5

(2, 3). The formation of the free pterine derivative provides an approximately 20-fold increase in fluorescent intensity over that of native folic acid fluorescence.

In a comprehensive study, Allfrey *et al.* (2) measured directly the fluorescence of the oxidized mixture as well as that of the chromatographically isolated oxidation

Figure 1—Effect of KMnO_4 concentration on the fluorescent intensity of folic acid solutions. Key: \circ , 2.54×10^{-5} moles/l.; \bullet , 4.43×10^{-5} moles/l.; \ominus , 9.49×10^{-5} moles/l.; and \odot , 3.16×10^{-4} moles/l.

Figure 2—Decrease in maximum fluorescence with increasing KMnO_4 concentration.

product. Their simplest direct procedure was valid only over the narrow pH range of 3.9 to 4.4, and there was no evidence of fluorescence dependence on potassium permanganate concentration. In the present investigation, this direct method is more thoroughly investigated with respect to the influence of the potassium permanganate concentration on fluorescent intensity.

EXPERIMENTAL

The fluorescence measurements were made on an Aminco-Bowman spectrophotofluorometer. Excitation maxima were found at 275 and 375 $m\mu$ with maximum fluorescence observed at 445 $m\mu$.

Figure 3—First-order plots of the oxidation of folic acid with varying concentration of KMnO_4 . Key: \circ , 2.54×10^{-5} moles/l.; \bullet , 6.33×10^{-5} moles/l.; and \ominus , 9.49×10^{-5} moles/l.

Figure 4—Log-log plot of the initial rate of the oxidation reaction as affected by the concentration of KMnO_4 .

To determine the effect of KMnO_4 concentration on the fluorescent intensity of folic acid solutions, the concentration of KMnO_4 was varied from 2.54×10^{-5} to 4.43×10^{-4} moles/l. All solutions contained 4.53×10^{-6} moles/l. of folic acid and were buffered at pH 8.12 with a borate buffer. The spectrophotofluorometer was standardized and the fluorescence measured at 25°. The standard solution was obtained by filtering the oxidized folic acid solution to remove the residual manganese dioxide, resulting in a clear colorless solution. If necessary, 1.0 ml. of 3% hydrogen peroxide was added to reduce the remaining KMnO_4 .

RESULTS AND DISCUSSION

Oxidation of Folic Acid—The oxidation of folic acid may be followed by determining the increase in fluorescence of the solution due to the formation of a pterine.¹ The increase in fluorescent intensity as related to the concentration of KMnO_4 is shown in Fig. 1. The rate of fluorophor formation is seen to increase with increasing concentration of KMnO_4 . However, as the concentration is increased above 4.43×10^{-5} moles/l., the total magnitude of the fluorescence decreases. The decrease in maximum fluorescence with increasing KMnO_4 concentration is shown in Fig. 2. This decrease in

Figure 5—Effect of pH on the fluorescent intensity of the folic acid oxidation product. Key: ---, excitation 375 $m\mu$; and —, excitation 275 $m\mu$.

¹ 2-Amino-4-hydroxy-6-carboxypteridine (Reference 1).

Figure 6—Effect of temperature on the fluorescent intensity of the folic acid oxidation product.

fluorescence is probably due to quenching by the MnO_2 formed during the reaction. This effect of KMnO_4 concentration probably was not observed by Allfrey *et al.* (2) because of the magnitude of the KMnO_4 concentration used (1.23×10^{-3} moles/l.).

A plot of the logarithm of the difference $F_\infty - F_t$, where F_∞ is the final fluorescence and F_t is the fluorescence at time t , is shown in Fig. 3. The linearity of the plot indicates the reaction is first order with respect to folic acid. The value of F_∞ used in this plot was obtained by allowing the solutions to equilibrate for 48 hr. and filtering the solutions to remove the MnO_2 . In some cases, 1.0 ml. of 3% hydrogen peroxide was added to reduce any remaining KMnO_4 . The resulting divalent manganese ions do not appear to quench the fluorescence of the oxidation product. The values obtained for F_∞ are shown in Table I. The close agreement of the final values, essentially independent of KMnO_4 concentration, justifies the use of the expression $F_\infty - F_t$ in the logarithmic plot.

The order of the reaction with respect to KMnO_4 can be determined from the slope of a plot of log initial rate of reaction *versus* log KMnO_4 concentration as shown in Fig. 4. The slope of this line, 0.986, indicates a first-order reaction with respect to KMnO_4 . The effect of quenching is seen at the highest concentration. The

mechanism of this oxidation reaction, which is apparently second order, is being investigated.

Fluorescence *versus* pH—The effect of pH on the fluorescence of the oxidized folic acid is shown in Fig. 5. The existence of a plateau between pH 7 and 9 differs from the narrow plateau between pH 3.9 and 4.4 previously reported (2). This again could be due to the greater concentration of KMnO_4 used in the earlier investigation, 1.23×10^{-3} moles/l., which as seen in Fig. 2 would have resulted in a considerable decrease in the fluorescent intensity. The increase in fluorescence near pH 11 may be due to the ionization of the lactim hydrogen of the pterine.

Fluorescence *versus* Temperature—As discussed by Udenfriend (4), fluorescence can be very sensitive to temperature. The effect of temperature on the fluorescence of the oxidation product is shown in Fig. 6. The greatest temperature dependence occurs between 20 and 28° and represents an error of approximately 2% per degree.

CONCLUSIONS

The oxidation of folic acid with KMnO_4 has been found to produce a fluorescence whose magnitude is dependent on the concentration of KMnO_4 . An optimum concentration of KMnO_4 was found, above which a decrease in fluorescence occurred due to quenching. The time required for maximum fluorescence also varied with the concentration of KMnO_4 . As expected, both pH and temperature markedly influenced the fluorescence obtained, the optimum pH being between 6 and 9.

Hydroxyindole-*o*-methyltransferase IV: Inhibitory Activities of Some *N*-Acrylyltryptamines and *N*-Crotonyltryptamines

BENG T. HO, MICHAEL B. NOEL, and WILLIAM M. McISAAC

Abstract □ Several *N*-acrylyltryptamines and *N*-crotonyltryptamines were synthesized to explore the mode of binding of the double bond in *N*-(1-cyclohexenecarbonyl)tryptamine to hydroxyindole-*o*-methyltransferase. Chlorine substitution at the β -position of the acrylyl or crotonyl group increased inhibition of the enzyme.

Keyphrases □ *N*-Acrylyltryptamines and *N*-crotonyltryptamines—synthesis □ *N*-(1-Cyclohexenecarbonyl)tryptamine double-bond binding—hydroxyindole-*o*-methyltransferase □ Chlorine substitution, *N*-acrylyltryptamines and *N*-crotonyltryptamines—hydroxyindole-*o*-methyltransferase inhibition □ IR spectrophotometry—structure □ NMR spectroscopy—structure

In previous works from this laboratory (1, 2), *N*-(1-cyclohexenecarbonyl)tryptamine (I) and *N*-benzoyltryptamine (II) were found to be, respectively, 3.4 and 2.3 times better inhibitors of hydroxyindole-*o*-methyltransferase (HIOMT) than *N*-cyclohexanecarbonyltryptamine (III). To explore the mode of binding of the carbon-carbon double bond in I, *N*-acrylyltryptamine (IV) and *N*-crotonyltryptamine (V) were synthesized. Since chlorine substitution on the *ortho* position of the phenyl group of II resulted in a sixfold increase in inhibitory activity (2), this study also includes Compounds VII–IX for investigating the possible enhancement of

binding of the acrylyl ($\text{CH}_2=\text{CH}-\overset{\text{O}}{\parallel}{\text{C}}-$) and crotonyl ($\text{CH}_3-\text{CH}=\text{CH}-\overset{\text{O}}{\parallel}{\text{C}}-$) groups by a chlorine atom at the beta position.

Results showed that IV and V were inhibitors of equal activity (Table I). The terminal CH_3 of the crotonyl moiety of V did not appear to contribute to the binding of this inhibitor to the enzyme. Substitution of the "methylene" hydrogen of the acrylyl group of IV by a chlorine atom slightly increased the activity (see VII). A greater increase in inhibition resulted when the chlorine atom was introduced to the "methine" carbon of the crotonyl moiety of V; VIII and IX were about twice as active as V.

The relative weakness in activities of those acrylyl and crotonyl derivatives compared to I could be attributed to the absence of several saturated methylene carbons which are capable of binding to the enzyme *via* hydrophobic interaction. The finding that *ortho*-chlorophenyl derivative (VI) is a much better inhibitor than the phenyl derivative (II), whereas the chlorocrotonyl derivatives (VII and VIII) are only slightly more active than the crotonyl derivative (V), can be visualized as a difference in the effect of a chlorine atom on the two series. A chlorine atom would be expected to exert stronger effect on the binding of an aromatic phenyl ring, as in the case of VI, than on an isolated double bond, as in VII or VIII. The

observation that I was a better inhibitor than III would indicate that the $\text{C}=\text{C}$ of the cyclohexenyl moiety of I provided additional binding to the enzyme. This type of unsaturated linkage is capable of complexing with the enzyme *via* a mixture of donor-acceptor, hydrogen-bonding, and even hydrophobic interactions (3).

PROCEDURES

N-Acyltryptamines IV, V, VII, VIII, and IX were prepared by the treatment of tryptamine with the appropriate acid chlorides obtained commercially or prepared from the corresponding acids. Attempts to prepare VIII from tryptamine and *trans*-3-chlorocrotonic acid in the presence of dicyclohexylcarbodiimide (DCC) were unsuccessful. Tryptamine and chlorocrotonic acid formed a salt which was insoluble in most organic solvents except aqueous tetrahydrofuran and aqueous acetonitrile. In the latter two cases, the only compound isolated from the reaction was the acylurea XI (m.p. 163–164°, MeOH ν_{max} (KBr): 1700, 1645 ($\text{C}=\text{O}$); 1615 cm^{-1} ($\text{C}=\text{C}$).

Anal.—Calcd. for $\text{C}_{17}\text{H}_{27}\text{ClN}_2\text{O}_2$: C, 62.5; H, 8.33. Found: C, 62.4; H, 8.35.

In the preparation of V, a second, higher melting crystalline compound was isolated. Dissimilarities in the IR spectra of the two products led to the initial assumption that one of them was disubstituted amide, *N,N*-dicrotonyltryptamine. However, elemental analyses indicated that they were isomeric, whereupon the melting points of both analytical samples were retaken. The compound, which originally had a m.p. of 83–84°, now melted over a range of 96–110°. When subjected to IR analysis, the spectrum of this substance changed to that of the higher melting compound in 2 hr. Further investigation was hampered by the unsuccessful attempts to isolate the lower melting product in later preparations.

EXPERIMENTAL

Melting points are corrected and were taken on a melting-point apparatus.¹ IR spectra were obtained with a spectrophotometer.²

***N*-Acrylyltryptamine (IV)**—To a solution of 1.46 g. (10 mmoles) of tryptamine and 1.5 ml. (10.8 mmoles) of triethylamine in 75 ml. of chloroform was added, at 0°, 0.73 ml. (10.2 mmoles) of acrylyl chloride. The mixture was stirred at ambient temperature for 4 hr.; then 400 mg. (28%) of tryptamine hydrochloride was filtered off. The filtrate was extracted successively with 25-ml. portions of water, 2 *N* HCl, 2 *N* NaOH, and again water. The organic layer was dried (Na_2SO_4) and evaporated *in vacuo* to a yellow oil. Water was added to a solution of the oil in MeOH until turbidity occurred. The oily layer, which deposited upon standing, was separated by decantation and dissolved in 100 ml. of boiling water. After treating with char-

Table I—Inhibition of HIOMT by

Compound	R	I ₅₀ ^a mM
I	1-Cyclohexenyl	0.25 ^b
III	C ₆ H ₁₁ —	0.85 ^c
II	C ₆ H ₅ —	0.37 ^c
VI	<i>o</i> -ClC ₆ H ₄ —	0.055 ^b
IV	CH ₂ =CH—	0.90
V	CH ₃ —CH=CH—	0.95
VII	Cl—CH=CH—(<i>trans</i>)	0.75
VIII	Cl, CH ₃ —C=CH—(<i>trans</i>) ^d	0.50
IX	Cl, CH ₃ —C=CH—(<i>cis</i>)	0.45

^a Concentration of an inhibitor giving 50% inhibition of the enzyme.

^b Data from Reference 2. ^c Data from Reference 1. ^d *Trans* refers to the configuration in which the methyl and carbonyl groups are opposite one another.

coal (Norit) and filtering through diatomaceous earth (Celite), the solution was allowed to evaporate on bench top, yielding 650 mg. (31% after correction for recovery of tryptamine) of white, lustrous plates, m.p. 77–79°. Several recrystallizations from water gave an analytical sample, m.p. 79–80°; ν_{\max} (KBr): 1620 (C=O); 745 cm⁻¹ (indole CH).

Anal.—Calcd. for C₁₃H₁₄N₂O: C, 72.9; H, 6.59; N, 13.1. Found: C, 72.6; H, 6.45; N, 13.0.

***N*-Crotonyltryptamine (V)**—In a similar manner as described in the preparation of IV, 10 mmoles of tryptamine was treated with crotonyl chloride in chloroform in the presence of triethylamine. After stirring at ambient temperature for 17 hr., the mixture was washed successively with water, 2 *N* HCl, 2 *N* NaOH, and water. The organic layer, after drying (Na₂SO₄), was evaporated *in vacuo*, leaving a yellow oil which did not crystallize. Distillation of this oil under reduced pressure yielded a pale-yellow, viscous oil which became semisolid upon setting, m.p. 76–78°. Extraction of the oily distillate with boiling water and subsequent evaporation of the extracts led to the formation of 660 mg. (30%) of small, lustrous plates, m.p. 78–80°. Several recrystallizations from water gave an analytical sample, m.p. 83–84°; ν_{\max} (KBr): 1620 (C=O); 745 cm⁻¹ (indole CH).

Anal.—Calcd. for C₁₄H₁₆N₂O: C, 73.6; H, 7.06; N, 12.3. Found: C, 73.7; H, 7.10; N, 12.2.

Continuous extraction of this residual oil with boiling water yielded additional crops of crystals. The combined crops were recrystallized from water to give a higher melting V, m.p. 116–120°. An analytical sample was obtained upon further recrystallization of this product from water to a constant m.p. 129–130°; ν_{\max} (KBr): 1630 (C=O); 745 cm⁻¹ (indole CH).

Anal.—Calcd. for C₁₄H₁₆N₂O: C, 73.6; H, 7.06; N, 12.3. Found: C, 73.9; H, 7.16; N, 12.3.

***N-trans*-(3-Chloroacryl)tryptamine (VII)**—A solution of 2.13 g. (20 mmoles) of *trans*-3-chloroacrylic acid and 3.0 ml. (23.5 mmoles) of benzenesulfonyl chloride in 15 ml. of xylene was heated at 90° for 30 min. and then distilled at 115–128°. This fraction of distillate, containing the acid chloride and xylene, was diluted with 15 ml. of chloroform and added at 0° to a solution of 3.2 g. (20 mmoles) of tryptamine and 4 ml. (29 mmoles) of triethylamine in 40 ml. of chloroform. The mixture was stirred at ambient temperature for 17 hr.; filtered to remove the tryptamine hydrochloride; and treated with water, 2 *N* HCl, 2 *N* NaOH, and water as described in the preparation of IV. The chloroform layer was dried (Na₂SO₄), treated with charcoal, filtered, and then evaporated *in vacuo*, leaving a pale-yellow semisolid. This product was dissolved in ether and treated with petroleum ether (b.p. 30–60°) to cloudiness. Upon chilling, 1.25 g. (25% after correction for recovery of tryptamine) of pale-yellow needles, m.p. 108–111°, was yielded. Subsequent recrystallization from ether–petroleum ether (b.p. 30–60°) gave an analytical sample as clumps of white needles, m.p. 109–110.5°; ν_{\max} (KBr): 1640 (C=O); 740 (indole CH).

Anal.—Calcd. for C₁₃H₁₃ClN₂O: C, 62.8; H, 5.27; Cl, 14.3; N, 11.3. Found: C, 62.7; H, 5.13; Cl, 14.0; N, 11.1.

***N-trans*-(3-Chlorocrotonyl)tryptamine (VIII)**—A mixture of 1.0 g. (8.3 mmoles) of *trans*-3-chlorocrotonic acid, 0.75 ml. (10.4

mmoles) of SOCl₂, and 6 ml. of CHCl₃ was refluxed for 45 min. After cooling, the solution was added to a chilled solution of 2.4 g. (15 mmoles) of tryptamine and 2.0 ml. (14.4 mmoles) of triethylamine in 25 ml. of CHCl₃. The mixture was stirred at ambient temperature for 4 hr., filtered to remove tryptamine hydrochloride, and concentrated to about 5 ml. Addition of 20 ml. acetone to this CHCl₃ solution precipitated a mixture of triethylamine hydrochloride and tryptamine hydrochloride which was removed by filtration. The acetone filtrate was evaporated *in vacuo* leaving an oil. A solution of this oil in chloroform was treated with water, 1 *N* HCl, 1 *N* NaOH, and water as described in the preparation of IV; dried (Na₂SO₄); treated with charcoal; and again evaporated *in vacuo*. The residual pale-yellow oil was extracted repeatedly with hot ether. When the combined ethereal extract was concentrated to about 20 ml., it turned cloudy and thick, shiny needles deposited upon standing on the bench top. Addition of petroleum ether (b.p. 30–60°) to this ethereal mixture caused the precipitation of more product; total first crop was 800 mg. (38%), m.p. 73–75.5°. Subsequent extractions of the original oil with ether afforded an additional crop of 390 mg. (18%). Thus, the total yield was 56%. Recrystallization of the first crop several times from ether–petroleum ether gave an analytical sample as shiny platelets, m.p. 77–78.5°; ν_{\max} (KBr): 1620 (C=O); 745 cm⁻¹ (indole CH). NMR (CDCl₃): δ 2.18 (doublet, CH₃); 5.91 (doublet, olefinic H). Assignment of *trans* configuration was based on 3-chlorocrotonic acid (4).

Anal.—Calcd. for C₁₄H₁₅ClN₂O: C, 64.0; H, 5.75; N, 10.7. Found: C, 64.1; H, 5.86; N, 10.8.

***N-cis*-(3-Chlorocrotonyl)tryptamine (IX)**—The procedure was similar to that used for VII, except that the *cis*-3-chlorocrotonyl chloride was prepared by refluxing the corresponding acid with PCl₅ in xylene and distilled at 135–140°. The yellow oily product from the reaction was dried thoroughly *in vacuo* and then dissolved in 15 ml. of anhydrous ether. Concentration of the ethereal solution to about 5 ml. caused the deposition of a 44% yield (after correction for recovery of tryptamine hydrochloride) of yellow crystals, m.p. 98–101°. Addition of petroleum ether (b.p. 30–60°) to the filtrate of the first crop gave another 44% yield of less pure material, m.p. 89–93°. Recrystallization of the first crop several times from ether–petroleum ether afforded an analytical sample as transparent prisms, m.p. 102.5–103.5°; ν_{\max} (KBr): 1630 (C=O); 740 cm⁻¹ (indole CH). NMR (CDCl₃): δ 2.85 (doublet, CH₃); 5.83 (doublet, olefinic H). Assignment of *cis* configuration was based on 3-chloroisocrotonic acid (4).

Anal.—Calcd. for C₁₄H₁₅ClN₂O: C, 64.0; H, 5.75; N, 10.7. Found: C, 63.9; H, 5.67; N, 10.6.

Assay—Hydroxyindole-*o*-methyltransferase was isolated from beef pineal gland and purified according to the method of Axelrod and Weissbach (5).

The stock solutions of all the inhibitors were prepared in 50% aqueous propylene glycol. Incubation was carried out with *N*-acetylserotonin and *S*-adenosyl-L-methionine-methyl-¹⁴C according to the previously described procedure (6).

Enhancement of Steroid Absorption by Dialkylamides

Keyphrases □ Steroids—absorption □ Absorption, steroids—*N,N*-dialkylalkylamide effect □ Prednisone absorption enhancement—*N,N*-di-*n*-propylpropionamide

Sir:

Amides having two alkyl substituents on the nitrogen atom can interact in nonaqueous solvents with a number of organic nonelectrolytes to form molecular complexes (1). This suggests that the lipid phase of biologic membranes might provide an environment conducive to complex formation between nitrogen-substituted amides and certain drugs. Pronounced drug–amide complex formation in the lipid phase of biologic membranes might be expected to influence the rate of drug transfer across such membranes. The direction and magnitude of this effect would presumably depend on the partition coefficient and diffusion characteristics of the drug relative to those of the drug–amide complex in the membrane and on the extent of the drug–amide interaction.

The influence of nitrogen-substituted amides on drug absorption has not been investigated extensively. There is evidence, however, that *N,N*-dialkylalkylamides can influence the percutaneous absorption rate of certain drugs. Munro and Stoughton, for example, reported *N,N*-dimethylacetamide (DMA) and *N,N*-dimethylformamide to be superior to ethanol, benzene, and a cream base in promoting the penetration of hydrocortisone and griseofulvin into human skin (2). Reid and Brookes found that the percutaneous absorption of three corticosteroids was more rapid from an ointment base containing 25% DMA than from three other ointment bases (3). These observations are explainable on the basis of drug–amide complex formation, although a physical alteration of the cutaneous barrier may have occurred since amide concentrations of 25–100% were used.

We have studied the effect of relatively low *N,N*-dialkylalkylamide concentrations on steroid absorption from the rat small intestine. This preliminary communication describes one representative system: prednisone and *N,N*-di-*n*-propylpropionamide (DPP). Male Sprague-Dawley rats, starved 14–22 hr., were prepared as described by Doluisio *et al.* for studying drug absorption from solution by the *in situ* rat small intestine (4). Seven milliliters of drug solution was placed in the intestine, and 0.2-ml. samples were removed at 10-min. intervals for 1 hr. The volume of the luminal prednisone solution was maintained constant by adding solvent (isotonic saline) immediately prior to sample removal. About 4 ml. additional solvent was required for this purpose. The concentration of prednisone in the sample

^a The effect of DPP was statistically significant ($p < 0.001$) at all times.

was determined by the colorimetric procedure of Porter and Silber (5). The initial prednisone and DPP concentrations in the luminal solution were 5×10^{-4} *M* and 2.8×10^{-2} *M* (0.5% v/v), respectively. Prednisone concentrations determined in the serial samples were corrected for previously removed drug.

The results of the absorption experiments are summarized in Table I. The presence of amide enhanced significantly ($p < 0.001$) the absorption of the steroid. A detailed kinetic analysis of the entire data will be presented in a subsequent report. The nature of the prednisone–DPP interaction was studied in both water and isopropyl myristate (IPM) by equilibrium solubility and equilibrium partition methods. The results indicate that a molecular complex of stoichiometry other than 1:1 formed between prednisone and DPP. The interaction was more extensive in a nonpolar than in a polar medium. For example, 2% v/v DPP increased the solubility of prednisone in IPM by 137%, compared to a 27% increase obtained under similar conditions in water. In addition, the IPM–water partition coefficient was increased 110% when the IPM phase contained 2% v/v DPP. The IPM–water partition coefficient of DPP is about 4.

The integrity of the intestinal membranes did not appear to be affected by DPP in the concentration used in this study. The gross appearance of the gut did not change; the absorption rate of caffeine, a drug that does not appear to interact with DPP in a nonaqueous solvent (IPM), was the same in the presence and absence of the amide. (Caffeine and DPP may interact slightly in water; the aqueous solubility of caffeine is increased 15% by 2% v/v DPP.)

Additional data, to be presented in a future report, indicate a relationship between the alkyl chain length of the nitrogen substituent and the absorption-enhancing effect of the dialkylpropionamides. These findings are significant because they may lead to a better understanding of intestinal absorption processes, particularly with respect to enhancing the absorption rate of certain poorly absorbed drugs.

Synthesis and Antibacterial Activity of 1-Styryl-3,4-dihydroisoquinolines

Keyphrases ☐ 1-Styryl-3,4-dihydroisoquinolines—synthesis ☐
Antibacterial activity—1-styryl-3,4-dihydroisoquinolines

Sir:

So far, the synthesis of 1-styrylisoquinolines has been achieved either by the cyclization of the Schiff bases derived from cinnamaldehyde (1, 2) or by the condensation of 1-methylisoquinoline with aromatic aldehydes (3). In this communication, we wish to report a new procedure for the synthesis of 1-styryl-3,4-dihydroisoquinolines which were isolated as methiodide salts. The procedure involves the cyclodehydration of substituted β -phenethylamides to 3,4-dihydroisoquinolines through the Bischler-Napieralski reaction (4).

Details about the synthesis and characterization of 1-styryl-3,4-dihydroisoquinoline methiodides (Compounds 1–7) will be published (5).

The methiodide salts (Compounds 1–7) were subjected to *in vitro* screening for antimetabolites by a new method (6). In this method, the detection system utilizes the gram-positive *Bacillus subtilis* and gram-negative *Escherichia coli*. Both organisms were grown in two types of agar: nutrient agar and a completely synthetic medium with glucose as the only source of carbon.

Table I—Inhibition of *B. subtilis* Grown in Two Different Media^a

Compound	R ₁	R ₂	Nutrient Agar	Synthetic Agar
1	Ph	Ph	24	35
2	Ph	<i>p</i> -Methylphenyl	25	36
3	<i>p</i> -Methylphenyl	<i>p</i> -Methylphenyl	29	35
4	<i>p</i> -Ethylphenyl	<i>p</i> -Ethylphenyl	36	39
5	<i>p</i> -Chlorophenyl	<i>p</i> -Chlorophenyl	28	35
6	Me	Ph	16	22
7	Me	Me	0	0

^a The numbers in the body of the table are zones of growth inhibition in mm. around a 13-mm. paper disk.

These seven compounds were tested at concentrations of 1 mg./ml., and the results are presented in Table I.

The inhibition of test organism by Compounds 1–6 was stronger on synthetic agar than on nutrient agar. However, the difference was not large enough to suggest an antimetabolite-like mode of action (5). Compound 7 was essentially inactive against *B. subtilis*. None of the compounds inhibited the growth of *E. coli*. These results indicate that 1-styryl-3,4-dihydroisoquinoline methiodides possess some antibacterial activity.

A more extensive testing will be required before any structure-activity correlation can be drawn.

REVIEWS

Methodenlehre der therapeutisch-klinischen Forschung. By P. MARTINI, G. OBERHOFFER, and E. WELTE. 4th ed. Springer-Verlag, New York, N. Y., 1968. viii + 495 pp. Price \$37.00. (In German)

The 4th, new, and completely revised edition of the original book of the late P. Martini is the legacy of this pioneer of exact clinical-therapeutic research. The three basic requirements for meaningful research are reliable clinical standards, the exclusion of secondary complicating factors, and the use of mathematical comparisons for the objective evaluation of clinical results. The discussion of these aspects is the thematic center of the book of Martini, Oberhoffer, and Welte. The large amount of scientific information is very well organized and clearly written.

After an interesting historical review the fundamentals of clinical therapeutic research in the experimental phase and the unity of clinical and experimental research are discussed in Chapters 2 and 3. In particular the causality and expediency of medical research and especially the common necessary suppositions in experiments are treated. In a special, very instructive chapter, important co-factors ("Mitursachen") in therapeutic problems are described. In particular the exclusion of these disturbing factors and the role of side effects in clinical research are characterized. A large part of the book deals with the problems of statistics, data processing, and documentation. It is up-to-date and presented in such a way that it is easily understandable even for nonspecialized readers. The fundamental principles of statistics, the influence of variables on the mean value and deviation, data processing, and programming as applied in clinical research are presented. The largest part of the book is concerned with the special methodology of clinical-therapeutic research in selected diseases such as scarlet fever, diphtheria, malaria, hepatic and lung diseases, high blood pressure, heart insufficiency, kidney and gastric diseases, and many others. These discussions are particularly oriented toward the selection of reliable clinical standards and the application of mathematical comparisons. The influence of individual, collective, and psychological factors in some special organ diseases are also discussed.

The appendix contains instructive statistical tables, computer programs, and a detailed literature index and also a separate author register. This arrangement appears to be effective and useful. The copiously equipped book is recommended to everyone working in the field of medical research and data processing.

Aromatic Nucleophilic Substitution. By JOSEPH MILLER, in *Reaction Mechanisms in Organic Chemistry*, monograph 8. Edited by C. EABORN and N. B. CHAPMAN, Elsevier Publishing Co., 335 Jarvan Galenstraat, P.O. Box 211, Amsterdam, The Netherlands, 1968. xi + 408 pp. 14.5 × 22 cm. Price \$23.50.

This monograph represents a comprehensive review and interpretation, both quantitative and qualitative, of a multiplicity of aromatic nucleophilic substitution reactions including S_N^1 , activated S_N^2 and benzyne mechanisms, charge-transfer and covalent complexes. These mechanisms as well as a brief summary of side reactions, kinetic evidence, and energetics of substitution reactions are introduced in Chapter 1 (26 pp.). Chapter 2 (11 pp.) considers the S_N^1 mechanism in greater detail; Chapter 3 (18 pp.) similarly discusses the benzyne or elimination-addition mechanism. The last Chapter 9 (23 pp.) considers less common aromatic S_N reactions while Chapter 7 (73 pp.) summarizes and interprets results obtained when studying nucleophilic substitution in nonbenzenoid aromatic systems. Comparison is made between homo- and heterocyclic organic systems; heterocyclic systems are desirably categorized as π -excessive and π -deficient. Considerations of inorganic and other nonbenzenoid aromatic systems (tropylium ions, quinones, etc.) conclude Chapter 7.

While the entire monograph is well written, this reviewer found Chapter 4 (72 pp.) concerning substituent effects in aromatic S_N reactions to be presented in a particularly interesting and informative manner. Pan-activating substituents, which is a term introduced by the author to "denote a substituent which is able to activate electrophilic, nucleophilic and radical substitution in an aromatic ring to which it is attached," are discussed along with a consideration of the effects of most functional groups on S_N versus S_E reactions. Hammett and related treatments, Dewar's proposal concerning the mode by which a substituent may affect a distant reaction center, the effect of *o*, *p*, *m* and two or more substituents on aromatic S_N reactions are topics discussed in a complete and concise manner. Substituents are classified into eight groups dependent upon their chemical nature; the influence of each group of functions is comparatively discussed when they are bonded *p*, *o*, and *m* to the leaving group.

Chapter 5 (40 pp.) dealing with the leaving group, Chapter 6 (30 pp.) concerning the nucleophile, and Chapter 8 (47 pp.), which considers the medium (solvent), catalytic and steric effects, are very informative and are of interest to synthetic as well as theoretical chemists. Subjects discussed in these chapters are treated quantitatively and qualitatively in terms of aromatic S_N^1 and S_N^2 reactions. Chapter 8 also considers photo and metal ion catalysis. Experimental results, along with their interpretation, are presented in all chapters. The monograph is well referenced into 1967 and is not only of value to the practicing chemist, but to the student who is presently studying theoretical organic chemistry on a graduate level.

The Chemistry and Physics of High Energy Reactions. By ERNEST J. HENLEY and EVERETT R. JOHNSON. University Press, 6411 Chillum Place, N.W., Washington, D.C., 1969. vi + 475 pp. 15 × 23 cm. Price \$18.50.

This volume is intended to provide a coherent textbook as an easy entry for the novice in the field of radiation chemistry. The material is presented in thirteen chapters in a high level, mathematical manner. Material is presented on units, radiation, radioactivity, and general nomenclature; interaction of radiation with matter; radiation sources; and radiation dosimetry. Other topics include radiation chemistry of gases, solids, water, and aqueous systems, as well as the effects of radiation on liquid hydrocarbons, polymers, and radiation-induced polymerizations.

Throughout the book the authors insert numerous example problems which are very useful for the comprehension of concepts. Also included are a multitude of tables and figures containing significant data. The text is broad in scope, rather cursory on certain topics, but provides excellent in-depth information on many areas of radiation chemistry. Although it is the stated intent of the authors to limit references, additional citations in areas discussed briefly would be helpful to the reader.

In summary, this book is a complete, well-prepared text which is most valuable as a reference or textbook for the radiation chemist and as a reference for the radiobiologist.

REVIEWS

Methodenlehre der therapeutisch-klinischen Forschung. By P. MARTINI, G. OBERHOFFER, and E. WELTE. 4th ed. Springer-Verlag, New York, N. Y., 1968. viii + 495 pp. Price \$37.00. (In German)

The 4th, new, and completely revised edition of the original book of the late P. Martini is the legacy of this pioneer of exact clinical-therapeutic research. The three basic requirements for meaningful research are reliable clinical standards, the exclusion of secondary complicating factors, and the use of mathematical comparisons for the objective evaluation of clinical results. The discussion of these aspects is the thematic center of the book of Martini, Oberhoffer, and Welte. The large amount of scientific information is very well organized and clearly written.

After an interesting historical review the fundamentals of clinical therapeutic research in the experimental phase and the unity of clinical and experimental research are discussed in Chapters 2 and 3. In particular the causality and expediency of medical research and especially the common necessary suppositions in experiments are treated. In a special, very instructive chapter, important co-factors ("Mitursachen") in therapeutic problems are described. In particular the exclusion of these disturbing factors and the role of side effects in clinical research are characterized. A large part of the book deals with the problems of statistics, data processing, and documentation. It is up-to-date and presented in such a way that it is easily understandable even for nonspecialized readers. The fundamental principles of statistics, the influence of variables on the mean value and deviation, data processing, and programming as applied in clinical research are presented. The largest part of the book is concerned with the special methodology of clinical-therapeutic research in selected diseases such as scarlet fever, diphtheria, malaria, hepatic and lung diseases, high blood pressure, heart insufficiency, kidney and gastric diseases, and many others. These discussions are particularly oriented toward the selection of reliable clinical standards and the application of mathematical comparisons. The influence of individual, collective, and psychological factors in some special organ diseases are also discussed.

The appendix contains instructive statistical tables, computer programs, and a detailed literature index and also a separate author register. This arrangement appears to be effective and useful. The copiously equipped book is recommended to everyone working in the field of medical research and data processing.

Aromatic Nucleophilic Substitution. By JOSEPH MILLER, in *Reaction Mechanisms in Organic Chemistry*, monograph 8. Edited by C. EABORN and N. B. CHAPMAN, Elsevier Publishing Co., 335 Jarvan Galenstraat, P.O. Box 211, Amsterdam, The Netherlands, 1968. xi + 408 pp. 14.5 × 22 cm. Price \$23.50.

This monograph represents a comprehensive review and interpretation, both quantitative and qualitative, of a multiplicity of aromatic nucleophilic substitution reactions including S_N^1 , activated S_N^2 and benzyne mechanisms, charge-transfer and covalent complexes. These mechanisms as well as a brief summary of side reactions, kinetic evidence, and energetics of substitution reactions are introduced in Chapter 1 (26 pp.). Chapter 2 (11 pp.) considers the S_N^1 mechanism in greater detail; Chapter 3 (18 pp.) similarly discusses the benzyne or elimination-addition mechanism. The last Chapter 9 (23 pp.) considers less common aromatic S_N reactions while Chapter 7 (73 pp.) summarizes and interprets results obtained when studying nucleophilic substitution in nonbenzenoid aromatic systems. Comparison is made between homo- and heterocyclic organic systems; heterocyclic systems are desirably categorized as π -excessive and π -deficient. Considerations of inorganic and other nonbenzenoid aromatic systems (tropylium ions, quinones, etc.) conclude Chapter 7.

While the entire monograph is well written, this reviewer found Chapter 4 (72 pp.) concerning substituent effects in aromatic S_N reactions to be presented in a particularly interesting and informative manner. Pan-activating substituents, which is a term introduced by the author to "denote a substituent which is able to activate electrophilic, nucleophilic and radical substitution in an aromatic ring to which it is attached," are discussed along with a consideration of the effects of most functional groups on S_N versus S_E reactions. Hammett and related treatments, Dewar's proposal concerning the mode by which a substituent may affect a distant reaction center, the effect of *o*, *p*, *m* and two or more substituents on aromatic S_N reactions are topics discussed in a complete and concise manner. Substituents are classified into eight groups dependent upon their chemical nature; the influence of each group of functions is comparatively discussed when they are bonded *p*, *o*, and *m* to the leaving group.

Chapter 5 (40 pp.) dealing with the leaving group, Chapter 6 (30 pp.) concerning the nucleophile, and Chapter 8 (47 pp.), which considers the medium (solvent), catalytic and steric effects, are very informative and are of interest to synthetic as well as theoretical chemists. Subjects discussed in these chapters are treated quantitatively and qualitatively in terms of aromatic S_N^1 and S_N^2 reactions. Chapter 8 also considers photo and metal ion catalysis. Experimental results, along with their interpretation, are presented in all chapters. The monograph is well referenced into 1967 and is not only of value to the practicing chemist, but to the student who is presently studying theoretical organic chemistry on a graduate level.

The Chemistry and Physics of High Energy Reactions. By ERNEST J. HENLEY and EVERETT R. JOHNSON. University Press, 6411 Chillum Place, N.W., Washington, D.C., 1969. vi + 475 pp. 15 × 23 cm. Price \$18.50.

This volume is intended to provide a coherent textbook as an easy entry for the novice in the field of radiation chemistry. The material is presented in thirteen chapters in a high level, mathematical manner. Material is presented on units, radiation, radioactivity, and general nomenclature; interaction of radiation with matter; radiation sources; and radiation dosimetry. Other topics include radiation chemistry of gases, solids, water, and aqueous systems, as well as the effects of radiation on liquid hydrocarbons, polymers, and radiation-induced polymerizations.

Throughout the book the authors insert numerous example problems which are very useful for the comprehension of concepts. Also included are a multitude of tables and figures containing significant data. The text is broad in scope, rather cursory on certain topics, but provides excellent in-depth information on many areas of radiation chemistry. Although it is the stated intent of the authors to limit references, additional citations in areas discussed briefly would be helpful to the reader.

In summary, this book is a complete, well-prepared text which is most valuable as a reference or textbook for the radiation chemist and as a reference for the radiobiologist.

Pharmaceutics—Galenical Pharmacy. By ERIK SANDELL, translated from Swedish by R. PAMELA ZACHARIAS. 364 pp. 16 × 23 cm. May be obtained by payment through international money order addressed to E. Sandell, postal giro account number 15 84 49, Postgirokontoret, Stockholm 1, Sweden.

Professor Sandell intends to present a "basic course in Pharmaceutics and Galenical Pharmacy and . . . to direct more specialized

studies through reference to monographs, other texts and journal publications."

His text touches on many areas of pharmaceuticals: small scale manufacturing, preparation of medicinals official in the Scandinavian countries and, in certain instances, rationale of dosage form.

Professor Sandell has had various levels of success in covering a wide range of topics; some, in a manner not usual, but in a way which would be welcomed, in the typical "American" text. However, the treatment of theory and certain topics is somewhat abbreviated and the approach to some of the topics is at an intermediate rather than at a basic level. It seems that the author, in his attempt to cover a wide range of topics, has included, for example, areas such as *Honeys* and *Lamillae* and has given only a cursory treatment of *Isotonicity* and *Hydrogen Ion Concentration*. On the other hand there is a short, but welcomed, discussion of *Jet Injection*.

Almost every section has some references which may as intended, direct the reader to a more specialized study of the topic being considered. However, students in the United States would find it difficult to abstract the many foreign language publications that are cited.

Generally speaking, the choice of topics and their sequence of presentation is logical. What is disturbing in a basic text is to find different levels of treatment of the material. It may be, as Professor Sandell states that, "this text-book is . . . typically Scandinavian . . .," i.e., geared to their educational systems.

Although this reviewer cannot recommend *Pharmaceutics—Galenical Pharmacy* as a text for undergraduates in this country, there is merit in the author's approach to several topics.

An Introduction to Chromatography on Impregnated Glass Fiber. By FREDERICK C. HAER. Ann Arbor Science Publishers, Inc., Box 1425, Ann Arbor, MI 48106, 1969. xiv + 173 pp. 15 × 23 cm. Price \$2.50.

The author describes the nature and application of a variation of thin-layer chromatography known commercially as "instant TLC." This rapid method has attracted minor usage, but is growing due to the present availability of several forms of impregnated adsorbents.

The information is set out in eleven short chapters. Theory, general techniques, equipment, and history are described in the first four chapters. Individual chapters are devoted to major chemical groupings of lipids, amino acids, steroids, sugars, and nucleic acids. A separate chapter treats toxicological problems. Each chapter includes complete procedures for sample handling, isolation, and purification prior to chromatography. General and theoretical aspects are handled clearly and are supported by illustrations that are well chosen and executed. Drugs are not treated extensively, and pharmaceuticals not at all. The reference value of this book is limited largely to biochemistry, although other applications have been published.

This book is a handy laboratory manual and should be available in any laboratory using instant TLC. It supplements the well-known texts on TLC and paper chromatography. It is written clearly and illustrated well, and it has adequate indexing and referencing.

The hospital pharmacist, as a drug information specialist, confronts the problem of locating sources of good clinical information on drugs and then interpreting and evaluating this information.

As stated in the Preface, the American Society of Hospital Pharmacists conducted the Institute on Drug Literature Evaluation in

March 1968, to offer presentations and a forum for discussion of topics designed to assist interested hospital pharmacists in becoming more proficient in the evaluation, understanding, and use of the clinical drug literature.

Seventeen presentations of the Institute are given in this book, covering various topics of clinical pharmacy and literature evaluation.

Mechanisms of Surfactant Effects on Drug Absorption

MILO GIBALDI and STUART FELDMAN

Keyphrases ☐ Absorption, drug—surfactant effect ☐ Surfactant effect, drug absorption—mechanism ☐ Solubility, drug—surfactant effect ☐ Dissolution rate—surfactant effect ☐ Gastric emptying—surfactant effect ☐ Membrane permeation—surfactant effect ☐ Physiologic surfactants—gastrointestinal drug absorption

Surface-active agents are one of the most important groups of adjuvants in pharmaceutical preparations. One or another of these agents has been used, for diverse reasons, in almost every type of dosage form. The widespread use of surfactants as well as their unique physical-chemical properties has prompted considerable interest in the possible influence of these agents on drug absorption. Attention has been focused to inadvertent effects on drug absorption which may result from the inclusion of a surface-active agent in a given formulation as well as to the use of surfactants in a deliberate attempt to modify drug absorption.

The drug literature contains a number of reports which clearly demonstrate that surface-active agents can influence the rate and extent of absorption of certain drugs. However, enhancement as well as inhibition of the absorption and pharmacologic activity of drugs has been observed in the presence of surfactants. Many of these reports have been reviewed by Blanpin (1). A more recent compilation has been provided by Swisher (2) in a review primarily concerned with the environmental exposure levels and toxicity of surfactants. As noted by Levy (3), much of the difficulty in interpreting some of these studies has been due to the different types of effects which surface-active agents can exert.

These effects include interaction with biologic membranes and modification of membrane permeability, interaction with the drug, interaction with the dosage form, and interaction with the organism itself resulting in a pharmacologic effect which may in turn influence drug absorption. These effects may be operative at the same time, some tending to enhance drug absorption, others tending to retard it, and the net effect dependent on the relative magnitude of each.

This article is intended as a selective, rather than exhaustive, review of the drug literature which illustrates the major mechanisms of surfactant activity affecting drug absorption. Several critical determinants of the rate and extent of drug absorption—*viz.*, drug solubility and dissolution rate, gastric emptying, and membrane permeation, are considered with respect to the influence of surface-active agents. Finally, attention is given to the role of physiologic surfactants in the gastrointestinal absorption of drugs.

ROLE OF DRUG SOLUBILITY AND DISSOLUTION RATE IN GASTROINTESTINAL ABSORPTION

When a drug is administered orally in solid form (tablet, capsule, or suspension) or intramuscularly as a pellet or suspension, one frequently finds that the rate of absorption is controlled by the slowest step in the following sequence:

solid drug $\xrightarrow{\text{dissolution}}$ drug in solution $\xrightarrow{\text{absorption}}$ absorbed drug

In many instances the slowest or rate-limiting step is found to be dissolution of drug in the fluids at the ab-

sorption site. When dissolution is the controlling step in the overall process, absorption is said to be dissolution rate limited. Since the rate-limiting step in the absorption process is the dissolution step, any factor influencing the rate of solution must influence also the rate of absorption. According to dissolution theory (4-6), two important parameters determining the dissolution rate of a solid in a given solvent are the solubility of the drug in the dissolution medium and the surface area of the drug exposed to the medium.

The molecules of many surface-active agents tend to aggregate in aqueous solutions when some bulk concentration, termed the critical micelle concentration (CMC), is exceeded. These aggregates, known as micelles, frequently demonstrate a marked tendency to associate with and solubilize organic and inorganic solutes. The phenomenon of micellar solubilization has been reviewed by Swarbrick (7) and is the subject of a recent text (8). In view of the relationship between solubility and dissolution rate as formulated in the Noyes-Whitney equation (4), the enhanced solubility of a drug in a micellar solution of surfactant should result in a proportional increase in the dissolution rate. While this proportionality is never realized in practice (because of the failure of the Noyes-Whitney relationship to account for changes in the effective diffusion coefficient of the drug), the increase in apparent solubility will usually result in an increase in dissolution rate.

The dissolution rate of a drug, regardless of dissolution mechanism, is always directly proportional to the effective surface area of the drug, *i.e.*, the surface area of drug available to the dissolution fluids. The relationship between surface area, dissolution rates, and gastrointestinal absorption rates has been reviewed by Levy (9) and, more recently, by Fincher (10).

The effective surface area of a drug is usually much smaller than the specific surface area which is an idealized *in vitro* measurement. Many drugs whose dissolution characteristics could be improved by particle size reduction are extremely hydrophobic and may resist wetting by gastrointestinal fluids. Therefore, the gastrointestinal fluids may come in intimate contact with only a fraction of the potentially available surface area. The effective surface area of hydrophobic drug particles can often be increased by the addition of a surface-active agent to the formulation, which functions to reduce the contact angle between the solid and the gastrointestinal fluids. Reduction in contact angle permits more intimate contact of drug and fluids, thereby increasing effective surface area and dissolution rate.

In 1948, Kellner *et al.* (11) studied the effect of polysorbate 80 (polyoxyethylene sorbitan monooleate) on the *in vivo* absorption of cholesterol. These workers reported that rabbits fed polysorbate 80 and cholesterol developed blood cholesterol levels that were two to three times as high as those obtained by feeding cholesterol alone. The reason suggested for this marked increase in cholesterol absorption in the presence of the surfactant was an improved emulsification of cholesterol in the intestinal tract and more efficient absorption. However, solubilization of cholesterol by polysorbate 80 and increased dissolution rate of the water-insoluble compound could also account for the observed effects.

Another example of a possible surfactant effect on drug absorption involving solubilization and increased dissolution rate is found in the work of Fuchs and Ingelfinger (12). These workers observed that sodium lauryl sulfate "hastened the appearance and increased the levels of vitamin A in the blood of human subjects." Krause (13) reported that incorporation of sodium lauryl sulfate in G-strophanthin pills resulted in an increase in absorption of the drug in dogs, guinea pigs, rabbits, and cats. The author postulated that an increase in solubility and a higher rate of dissolution of the drug in the presence of the surfactant were responsible for the increase in pharmacologic effect noted with the formulation.

In a study concerned with the oral absorption of spironolactone, Gantt *et al.* (14) found that when polysorbate 80 was administered with the steroid, gastrointestinal absorption was markedly improved. One explanation for the observed effects is an increase in the dissolution rate of the drug due to solubilization and/or wetting effects by the surfactant. However, changes in the formulation and manufacture of the dosage form upon incorporation of the surfactant may have also played a role in the enhanced absorption (15).

Kakemi *et al.* (16) studied the rectal absorption of sulfonamides in the presence of several nonionic surface-active agents. In experiments where sulfoxazole was administered in the form of suspensions containing varying concentrations of polysorbate 80, it was found that the blood level after 1 hr. increased with increasing concentrations of surface-active agent up to a maximum polysorbate 80 concentration of 20%, the concentration of surfactant which completely solubilized the excess drug. Comparison of relative drug solubility in surfactant solutions and relative blood levels indicates that an 18-fold increase in sulfoxazole solubility in the presence of 20% polysorbate 80 results in a threefold increase in initial blood level compared to the level following the administration of the control suspension.

A number of studies have attempted to quantitate the relationship between drug solubility in micellar solutions and dissolution rate. Bates *et al.* (17) reported substantial increases in the dissolution rates of griseofulvin and hexestrol in micellar solutions of bile salts. Bates *et al.* (18) have also shown that physiologic concentrations of lysolecithin, a phospholipid, produce marked increases in the solubility and dissolution rate of hexestrol, dienestrol, and griseofulvin. The results of these studies are in general agreement with the Noyes-Whitney relationship (4). However, in each case, because of the extremely low solubilities of the drugs, dissolution was followed over a concentration range which was above the saturation solubility of the drug in water.

Dissolution studies conducted under "sink conditions" (*i.e.*, drug concentration in solution does not exceed 10 to 20% of saturation solubility in buffer) in micellar solutions clearly show that dissolution rate is not proportional to the apparent solubility of the drug. This was first demonstrated by Higuchi (5), who found that the ratio of dissolution rate of benzocaine in polysorbate 80 solution to that without the surfactant was substantially lower than the ratio predicted by the Noyes-Whitney theory. These results have been sup-

ported by the findings of Parrott and Sharma (19), Gibaldi *et al.* (20), and Elworthy and Lipscomb (21).

In 1964, Higuchi (22) presented a theoretical analysis pertinent to the influence of interacting colloids, such as micelles, on mass transport. Higuchi concluded that dissolution rate (d.r.) in micellar solution under sink conditions could be described by

$$\text{d.r.} = \frac{DC_s}{h} + \frac{D_m C_m}{h} \quad (\text{Eq. 1})$$

where D and D_m are the diffusion coefficients for the free drug and micelle-solubilized drug species, respectively, C_s is the solubility of the drug, C_m is the solubility increase due to solubilization, and h is the effective diffusion layer thickness. The influence of solubilization is determined by calculating the ratio (R) of dissolution rate in surfactant solution to that in pure solvent and by assuming that certain constants, such as h , have essentially the same value under each experimental condition. It follows that

$$R = \frac{DC_s + D_m C_m}{DC_s} \quad (\text{Eq. 2})$$

Rewriting Eq. 2 according to Singh *et al.* (23):

$$R = \frac{D_{\text{eff.}} C_t}{DC_s} \quad (\text{Eq. 3})$$

where C_t is the total solubility of the drug in the surfactant solution $D_{\text{eff.}} = (DC_s + D_m C_m)/C_t$. According to Eq. 3, at any degree of micellar solubilization the larger the molecular size of the micelle-drug species formed upon interaction, the smaller will be the influence of solubilization on the dissolution rate. Hence the potential influence of enhanced solubility on dissolution rate in a micellar solution is offset by the expected small diffusion coefficient of the micelle-drug species. In fact, it is plausible to consider that in some cases $D_{\text{eff.}} \cong DC_s/C_t$ and that the surfactant would have virtually no effect on dissolution rate. Higuchi (22) further predicted that the magnitude of effects of interacting colloids on dissolution rate will approach that on solubility only when the drug concentration in solution approaches or exceeds the solubility in pure solvent. The larger effects on dissolution rate predicted above saturation solubility are evident in the reports of Bates *et al.* (17, 18) and Wurster and Polli (24).

Gibaldi *et al.* (20) studied the effect of micellar solutions of a nonionic surfactant on the dissolution rate of benzoic acid using the rotating-disk and static-disk methods. Their results suggested that Eq. 3 was not applicable to all dissolution systems since the influence of the surfactant on dissolution rate was substantially greater in the static-disk method studies than in the rotating-disk method studies. The role of hydrodynamics in assessing the influence of colloidal solubilizers on dissolution rate was subsequently quantified by Singh *et al.* (23). These workers found that the influence of surfactants on dissolution rate using the stirred and static-disk methods could be described by Eqs. 4 and 5, respectively:

$$R = \frac{(D_{\text{eff.}})^{2/3} C_t}{D^{2/3} C_s} \quad (\text{Eq. 4})$$

$$R = \frac{(D_{\text{eff.}})^{1/2} C_t}{D^{1/2} C_s} \quad (\text{Eq. 5})$$

Equation 3 described the situation reasonably well only when dissolution occurred under conditions of apparent laminar flow provided by a propeller-driven stirrer apparatus.

These findings were confirmed by Gibaldi *et al.* (25) in their studies on the dissolution of benzoic and salicylic acids in micellar solutions of polyoxyethylene lauryl ether. Their results also suggest that the influence of micellar solubilization on the dissolution rate of drugs from conventional dosage forms will be significantly greater than that predicted by diffusion layer theory (Eq. 3).

While the influence of micellar solubilization on dissolution rate has been studied rather extensively, the effect of low concentrations (below the CMC) of surface-active agent on the dissolution of drugs from powders and other solid dosage forms has been given limited attention. Finholt and Solvang (26) studied the dissolution of phenacetin powder dusted on the surface of 0.1 *N* HCl containing low concentrations of polysorbate 80. An increase in the polysorbate 80 concentration from 0 to 0.01 % causes a significant increase in the dissolution rate. A linear relationship was observed when the time required to dissolve 10 % of the powder was plotted as a function of the surface tension of the test solution. The effect of polysorbate 80 on the dissolution rate of phenacetin is caused mainly by its ability to reduce the contact angle between the powder and the dissolution medium.

More recently, Weintraub and Gibaldi (27) studied the influence of pre-micellar concentrations of a non-ionic surfactant and certain physiologic surfactants on the dissolution rate of drugs from powders and from commercial dosage forms. Polyoxyethylene lauryl ether and lysolecithin enhanced the dissolution rate of powdered salicylic acid in 0.1 *N* HCl, and sodium glycocholate increased the dissolution rate of powdered salicylamide in pH 6.0 buffer. In each case the effect principally involved a "wetting" phenomenon rather than solubilization. Both the nonionic ether surfactant and lysolecithin enhanced the dissolution rate of aspirin from a tablet dosage form but were without effect on the dissolution rate of the drug from a capsule dosage form. Good correlation was found between surface tension lowering and the dissolution rate of aspirin from the tablet.

ROLE OF GASTRIC EMPTYING AND INTESTINAL TRANSIT IN DRUG ABSORPTION

The rate at which a drug leaves the stomach may have a profound influence on the overall rate and extent of drug absorption. For example, a weak base such as quinine will be absorbed primarily from the small intestine rather than from the stomach. Slow gastric emptying can also affect the biological availability of drugs that are unstable in gastric fluids.

An example of the effect of gastric emptying on drug absorption can be found in the work of Levy and Jusko (28). These workers studied the absorption of riboflavin in human subjects and found that administration of the vitamin after a test meal increased the urinary recovery

Table I—Influence of Bile Salts on Gastric Emptying of Phenol Red in the Rat

10 mM	1	56
26 mM	4	17 \pm 5

^a Results expressed as percent of dose emptied 0.5 hr. after gastric intubation.

of the vitamin. Riboflavin is apparently absorbed by a specialized process high in the jejunum (28). Since the absorption process for riboflavin is capacity limited, the rate at which the vitamin passes the absorption site may have an influence on the overall extent of absorption. The authors postulate that a meal reduces the rate of gastric emptying and in turn the rate at which riboflavin reaches the site of specialized transport. This in turn results in an increase in the gastrointestinal absorption of the vitamin.

Varga (29) studied the effect of route of administration on the LD₅₀ of chloroquine in rats. He found that there was a marked difference between the LD₅₀ of chloroquine after gastric intubation (1080 mg./kg.) and intestinal intubation (210 mg./kg.). The difference in LD₅₀ was attributed to the delayed gastric emptying resulting from a pharmacologic effect of chloroquine since little absorption of the drug occurs from the stomach.

Surface-active agents, particularly polyoxyethylene derivatives, may influence gastric emptying rate and intestinal transit by physically altering the viscosity of the gastrointestinal fluids. Levy and Jusko (30) have shown that an increase in the viscosity of the gastrointestinal fluids can decrease the absorption rate of certain drugs by retarding the diffusion of drug molecules to the absorbing membranes and by reducing gastrointestinal transit. Okuda *et al.* (31) studied the effects of nonionic surfactants on the intestinal absorption of vitamin B₁₂. These workers found that three of the surfactants studied enhanced the gastrointestinal absorption of the vitamin when the surfactant was administered undiluted in high doses. The enhancing effect of polysorbate 80, polysorbate 85 (polyoxyethylene sorbitan trioleate), and G-1096 (polyoxyethylene sorbitan hexaoleate) was postulated to be due to the formation of a highly viscous mass in the gastric and intestinal lumen which resulted in a delay in gastric emptying and an enhancement in the gastrointestinal absorption of vitamin B₁₂.

A surfactant may also exert a specific pharmacologic effect on the gastrointestinal tract which may influence drug absorption. For example, Lish (32) reported that dioctyl sodium sulfosuccinate, an anionic agent, inhibits the rate of propulsion of a test meal through the gastrointestinal tract of the rat. The effect was ascribed to a slowing of gastric emptying by the surfactant. The mechanism of action was thought to be mediated by a substance (or substances) formed after contact of the

intestinal mucosa with the surface-active agent. In a recent study, Necheles and Sporn (33) found that there was an inhibition of gastric motility in the dog following introduction of certain detergents into the gastric pouch.

The influence of bile salts on gastrointestinal motility and transit has been the subject of several reports. Pan-nett and Wilson (34) first reported in 1921 that the addition of a small quantity of sodium taurocholate to a test meal is followed by an abnormally rapid evacuation of the stomach contents. They also found an increase in the secretion of acid in the presence of the bile salt. In a detailed study, Sasaki (35, 36) reported the effects of orally administered bile salts on the motility of the rabbit gastrointestinal tract. Sasaki (35) found that the effects of bile salts on gastric motility were extremely variable, with a slight increase in motility noted at low doses of bile salts and a small decrease in motility at higher dose levels. The effect of bile salts on intestinal motility (36) also was of a small order of magnitude. The bile salts usually produced a small increase in motility.

Recently, Feldman and Gibaldi (37) reported on the effect of orally administered bile salts on gastric emptying in the rat. Using phenol red as a marker substance, these workers found that both sodium deoxycholate and its taurine conjugate, sodium taurodeoxycholate, significantly decreased gastric emptying of the phenol red test solution (Table I). A significant difference was observed, however, in the relative influence of the bile salts on gastric emptying. The unconjugated bile salt produced results comparable to the conjugated derivative at about 0.1 to 0.2 the dose of the latter. Further studies (38) as to the influence of sodium deoxycholate on gastric emptying as a function of time after administration indicate that the bile salt markedly alters the pattern of gastric emptying. Gastric emptying of intubated phenol red in control rats proceeds in an apparent first-order manner with a half-life of about 13 min. In rats given sodium deoxycholate, an initially rapid gastric emptying phase, followed by a transition region where little emptying occurs, is noted over the 1st hour. The 2nd hour after intubation is characterized by an exponential decline in phenol red in the stomach, with a half-life of 36 min.

Intubation of sodium deoxycholate and sodium taurodeoxycholate also results in a large net secretion of fluids into the gastric pouch for at least 1 hr. after administration. The increase in gastric secretion and volume in the presence of bile salts offers an explanation for the observed decrease in gastric emptying. Hunt and MacDonald (39) have shown that as the volume of a test meal increases, the percentage of the gastric contents leaving the stomach per unit time becomes smaller. In addition, these workers noted that distension of the intestine reduces the coordinated propulsive activity of the gastric antrum as well as the duodenum. Thus, it appears likely that the reduced gastric emptying and transit rate through the proximal intestine induced by the administration of bile salts are related to the increase in the volume of fluid secreted into the gastric pouch.

The possibility exists that oral administration of bile salts may influence the absorption of drugs admin-

istered concurrently by modifying the pattern of gastric emptying. For example, the data of Mayersohn *et al.* (40) suggest that the increased absorption of riboflavin in man observed upon coadministration of sodium deoxycholate may be due, in part, to a decrease in gastric emptying. Administration of riboflavin with sodium deoxycholate results in both a pronounced increase in the peak urinary excretion rate of flavins as well as a marked delay in the occurrence of the peak rate compared to control studies (Fig. 1). A reduced rate of gastric emptying would result in prolonged and more complete absorption of the vitamin since absorption is limited to the proximal intestine and occurs *via* a "saturable" process (28, 41).

FACTORS INFLUENCING DRUG PERMEATION OF BIOLOGIC MEMBRANES

Two possible ways come to mind by which the rate of drug transfer from solution across biologic membranes may be altered. First, a change in the physical-chemical properties of the drug due to the presence of an additive could reduce or enhance the rate of transport and, second, an alteration in the permeability of the membrane could also influence transfer rate. Each of these possibilities is developed further in the subsequent paragraphs.

1. Drug-Adjuvant Interactions—A significant change in the ability of a drug to permeate a biologic membrane may result from an interaction with another molecule. A molecular complex consists of constituents held together by weak forces such as hydrogen bonds. This type of interaction is usually reversible, provided that the complex is sufficiently soluble in the biologic fluids. The properties of drug complexes, including solubility, molecular size, diffusiveness, and lipid-water partition coefficient, can differ significantly from the properties of the respective free drugs. These differences are responsible for the fact that many drug complexes cannot penetrate biologic membranes and, therefore, have no biologic activity (42). In such cases, the fraction of drug in the complex, which is in equilibrium with the noncomplexed drug, will be in an essentially nonabsorbable form and the effective concentration of drug will be less than the total concentration.

Surfactants may also interact with drug molecules and affect the gastrointestinal absorption of these compounds. Riegelman and Crowell (43-45) studied the effects of surfactants on the rectal absorption of iodoform, triiodophenol, and iodide in rats. Polysorbate 80 and sodium lauryl sulfate were found to decrease the rectal absorption rate of iodoform and triiodophenol, but to increase the absorption rate of iodide. The decrease in rectal absorption rate of iodoform and triiodophenol was attributed to micellar complexation of the drugs, while the increase in iodide absorption rate was postulated to be due to a cleansing action of the surfactant on the intestinal mucosa surface. Since iodide ion is lipid insoluble, it would not be expected to be incorporated into the surfactant micelles. Retardation of iodoform and triiodophenol absorption in the presence of micellar concentrations of the surfactants is in accord with the following model: (a) a micellar solution con-

sists of two phases; (b) the partition ratio of drug between the micellar phase and the aqueous phase is constant, independent of drug concentration; and (c) absorption of the drug incorporated in the micelle is negligible. Since the drug in the micellar phase is unavailable for absorption, the effective concentration of the drug is less than the apparent concentration, and a decreased absorption rate is observed.

Levy and Reuning (46) studied the effect of micellar solutions of polysorbate 60 (polyoxyethylene sorbitan monostearate) on the absorption of ethanol and salicylic acid from the rat gastric pouch. These workers found that in the presence of 2% polysorbate 60 the absorption of salicylic acid was decreased from 50% in 1 hr. to 33% in 1 hr., while ethanol absorption remained unchanged. The observed effect was due to a decrease in activity of salicylic acid as a result of micellar complexation. The absorption of ethanol (which would not be incorporated into the surfactant micelles) was unaffected by the presence of the surfactant.

Kakemi *et al.* (16) studied the effect of various non-ionic surface-active agents on the rectal absorption of sulfonamides from solution in the rat. At concentrations of the surfactant above the CMC, a reduction in the absorption rate of the sulfonamides was observed due to "entrapment" of drug in micelles. The experimental results were in agreement with the limiting case of the following theoretical equation, assuming that the solubilized drug was not absorbed to any appreciable extent.

$$A_T = \frac{A_f}{1 + K_m S} + \frac{A_m K_m S}{1 + K_m S} \quad (\text{Eq. 6})$$

where A_T , A_f , and A_m represent the absorption rates of both free and micelle-solubilized drug, free drug, and solubilized drug, respectively; S is the surfactant concentration (g./100 ml.); and K_m is a distribution constant equal to [drug-micelle]/[free drug] · [S].

Yamada and Yamamoto (47) found similar effects of micellar solutions of polysorbate 80 on the intestinal absorption of salicylamide in the perfused rat small intestine. Also, they observed no apparent effect of polysorbate 80 on the mucosal membrane, as determined by permeability experiments with salicylamide before and after a prolonged perfusion of the intestine with a

Figure 1—Urinary excretion rate of apparent riboflavin after oral administration of 30 mg. riboflavin (Subject W. J.). Key: ○, control, and ●, 600 mg. sodium deoxycholate.

polysorbate 80 solution. This technique, however, can only detect irreversible effects on membrane permeability. Matsumoto (48) offered essentially the same mechanism of micellar solubilization and a corresponding decrease in free drug concentration to explain the effect of polysorbate 80 on the intestinal absorption of sulfisoxazole in the rat. Saski (49) studied the effect of micellar solutions of tyloxapol, a nonionic surface-active polymer, on the transfer of hydrocortisone across the everted rat intestine. Drug transfer rate was inversely proportional to the surfactant concentration and the viscosity of the solution tested. The data suggest that the membrane is impermeable to the drug-micelle species.

2. Membrane Permeability—A number of substances have been found to “interact” with biologic membranes and thereby alter permeability or transport characteristics. For example, Schanker and Johnson (50) and Windsor and Cronheim (51) have shown that the chelating agent, ethylenediaminetetraacetic acid, can increase the *in vivo* intestinal absorption of a number of lipid-insoluble compounds in the rat. The depletion of calcium from the intestinal membranes by the chelating agent was suggested as the reason for these results.

Surfactants may also be capable of modifying the properties of biologic membranes. Alexander and Trim (52) reported that the penetration of hexylresorcinol into *Ascaris lumbricoides* can be affected by ionic surfactants in two different ways. Surfactant concentrations below the CMC increased the penetration of hexylresorcinol into the worm. These workers suggested that a complex between hexylresorcinol and surfactant monomer was responsible for the increase in concentration of the drug at the membrane surface. They did not consider the possibility that the site of action of the surfactant could be the membrane itself and that the increased penetration of the drug in the presence of the surfactant could be due to alteration of membrane permeability. At concentrations of surfactant above the CMC, the absorption of hexylresorcinol was reduced due to the formation of an unabsorbable micelle-drug complex.

Levy *et al.* (53) studied the effect of a nonionic surfactant, polysorbate 80, on the absorption of a number of barbiturates across the goldfish membranes. The absorption rate of the barbiturates was found to increase significantly in the presence of low concentrations (below the CMC) of surfactant and to decrease at higher concentrations of the surfactant. Scheme I was proposed to explain the results. Further studies by Levy and Anello (54) showed that the increase in absorption rate of secobarbital at concentrations of

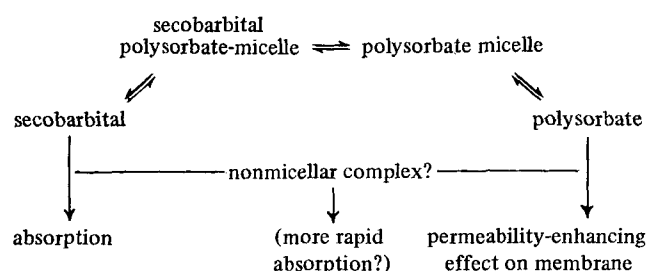

polysorbate 80 below the CMC was due to an increase in the permeability of the biologic membranes rather than to formation of a more rapidly absorbed nonmicellar polysorbate–secobarbital complex. Anello and Levy (55) have also shown that premicellar concentrations of polysorbate 80 enhance the absorption and exsorption of 4-aminoantipyrine across the goldfish membranes. Gibaldi and Nightingale (56) studied the influence of sodium taurodeoxycholate on pharmacologic effect (time required to produce overturn) of pentobarbital and ethanol in goldfish. These workers found that the bile salt significantly potentiated the pharmacologic effect, presumably by modifying membrane permeability. Further studies (57) indicated that the bile salt exerts an all-or-none effect on the uptake of 4-aminoantipyrine in goldfish; an alteration in membrane permeability is observed above a certain bulk concentration but below the CMC of the surfactant. Whitworth and Yantis (58) found an increase in the absorption of salicylic acid across the external membranes of the frog in the presence of 0.1 % polysorbate 80.

In a study of the percutaneous absorption of ionic surfactants, Scala *et al.* (59) found that the salt of a long-chain fatty acid, an alkylbenzene sulfonate, and dodecyltrimethyl ammonium chloride alter skin permeability as they diffuse into and through the skin. When nicotine and thiourea were placed in the surfactant solution, the rate of diffusion of these compounds was found to increase with time, similar to the diffusion characteristics of the surfactants themselves. In the absence of surfactant, nicotine and thiourea showed linear diffusion which remained constant over the time period studied. In a study of the effects of polysorbate 80 on the *in vitro* metabolism of Ehrlich-Lette ascites carcinoma cells, Kay (60) found that the permeability of the cells was increased greatly in the presence of the surfactant as shown by the uptake of a dye, Lissamine green.

Appel *et al.* (61) found that simultaneous feeding of sodium lauryl sulfonate and inulin to rats results in up to a 10-fold increase in urinary inulin excretion over control values. The enhanced urinary excretion of inulin may be the result of an increase in intestinal permeability to inulin in the presence of the surface-active agent.

Mori *et al.* (62) reported that rats and hamsters fed polysorbate 20 (polyoxyethylene sorbitan monolaurate) showed increased gastrointestinal absorption of iron. However, Brise (63) in a later study reported that there was no effect of polysorbate 20 on iron absorption in man. He further postulated that the increase in absorption of iron in hamsters in the presence of polysorbate 20 observed by Mori *et al.* may have been due to some “toxic” action of the surfactant.

Suzuki *et al.* (64) found increased capillary permeability, as measured by a circulating dye, at the site of an intracutaneous injection of various nonionic surfactants. The authors concluded that this increase was mainly due to the wetting and solubilizing effects of the surfactants on the lipid structure of the capillary wall. Penzotti and Mattocks (65) found an increase in the rate of peritoneal dialysis of urea and creatinine in rabbits in the presence of surface-active agents. It was found that the order of magnitude of effects decreased in the following manner: cationic > anionic >> nonionic.

Scheme I

The possible mechanisms of action were not discussed, but it appears likely that the mechanism may involve a permeability alteration of the peritoneal membrane.

Nissim (66) studied the effect of feeding cationic, anionic, and nonionic surface-active agents on the histology of the mouse gastrointestinal tract. He found marked pathological changes when the ionic surfactants (cationic and anionic) were fed to mice but no effects when nonionic surfactants were tested. Taylor (67) studied the effects of cetyltrimethylammonium bromide on transport and metabolism in the small intestine of the rat. The surfactant was found to produce no histological damage to everted rat intestine sacs at concentrations of 10^{-4} M, but caused considerable injury to the mucosa at concentrations of 5×10^{-4} M and 10^{-3} M. Concomitant with the mucosal damage by the higher concentrations of the surfactant was an inhibition of the everted intestinal transport of glucose, methionine, and water.

Lish and Weikel (68) studied the effects of surface-active agents on the absorption of an anionic dye, phenol red, from the colon of the anesthetized rat. Anionic surfactants were found to enhance greatly absorption of the dye while a nonionic surfactant had no effect. None of the surfactants studied influenced the absorption of a cationic dye, methyl violet.

Matsuzawa *et al.* (69) found that the addition of nonionic surfactants (polysorbate 80 and a series of polyoxyethylene derivatives of hydrogenated castor oil) to solutions of the antibiotic, enduracidin hydrochloride, resulted in an increase in absorption of the antibiotic from the femoral muscles of the rat. The mechanism of action was not elucidated, but there is a strong possibility that the surfactant may have altered the permeability of the muscle to the antibiotic.

Engel and Riggi (70, 71) studied the effect of surfactants on the intestinal absorption of heparin in the rat. They found that intraduodenal administration of heparin with either sodium lauryl sulfate, dioctyl sodium sulfosuccinate, or G-3300 (an alkyl aryl sulfonate) resulted in an increase in heparin absorption over that observed when heparin was administered alone. These workers also reported enhanced heparin absorption in the presence of 0.4% sodium taurocholate. The authors postulate that the increase in heparin absorption is due to an effect of the surfactant on the intestinal mucosa.

Davenport (72) has reported that bile salts are capable of increasing the permeability of the gastric mucosa as judged by hydrogen-ion flux. The influence of an unconjugated bile salt, sodium deoxycholate, on the absorption of phenol red in the rat was recently studied by Feldman *et al.* (73) using three different techniques to assess absorption—*viz.*, urinary excretion after oral administration to intact animals, loss of drug from *in situ* intestinal loops, and transfer of drug across the isolated everted intestine. Each method showed that the bile salt markedly enhances the absorption or transfer rate of phenol red across the gastrointestinal membranes. The studies in intact animals indicated that the effect of sodium deoxycholate on gastrointestinal permeability was reversible.

Few studies of surfactant effects on drug absorption in man have been reported. Mayersohn *et al.* (40) found

that when 600 mg. sodium deoxycholate is administered 30 min. prior to a 30-mg. dose of riboflavin, there is a 50 to 80% increase in total urinary recovery of apparent riboflavin. A similar but less marked enhancement was observed when the same dose of flavin mononucleotide was given with the bile salt. It is likely that change in the permeability of the gastrointestinal membranes is the principal mechanism of these effects, although in the case of riboflavin a reduction in gastric emptying may also play a role.

PHYSIOLOGIC SURFACTANTS AND DRUG ABSORPTION

Interest in the possible existence of a surfactant(s) in gastric fluid has been stimulated by the recent work of Finholt and Solvang (26). Samples of gastric juice obtained from patients under examination for diseases of the stomach showed low surface-tension values (38 to 47 dynes/cm.) and marked wetting activity as judged by powder dissolution studies. The rates of dissolution of powdered phenacetin in diluted gastric juice and in diluted HCl at the same pH and adjusted to the same surface tension with polysorbate 80 were similar but markedly faster than the rates observed in diluted HCl alone. Hence, the dissolution of hydrophobic drugs in the stomach may be facilitated by the presence of physiologic wetting agents.

The source of this surface activity in gastric fluids is not known, nor is it known whether or not gastric secretions themselves manifest surface activity. The presence of surface-active compounds in the gastric juice of some *Crustacea* was established by Vonk (74). Van den Oord *et al.* (75) reported that no bile salts could be detected in extracts of crab gastric juice. However, material with emulsifying properties was isolated; later, these compounds were shown to be fatty acylsarcosyltaurines (76). Further work by Van den Oord (77) suggested that the emulsifiers occurring in the gastric juice of the crab are of endogenous origin. Unfortunately, similar studies with human gastric juice are not available.

A possible source of the surface activity observed in human gastric fluid may be contamination from the duodenum. Reflux of duodenal contents would result in the presence of conjugated bile salts and lysolecithin, both highly surface active, in the gastric fluid. This possibility is strengthened by a recent report of Rhodes *et al.* (78) on the concentration of bile acids in the human stomach upon fasting and after a test meal.

Gastric fluid from normal fasting subjects contained a mean bile acid concentration of 0.08 ± 0.03 (SE) mM. The levels observed after a test meal were essentially the same. On the other hand, gastric fluids from fasting subjects with gastric ulcers contained a mean bile acid concentration of 0.65 ± 0.34 (SE) mM. For gastric ulcer patients, in contrast to normal subjects, the concentration of bile acids after food was always greater than the immediate preprandial value. These findings indicate that a small amount of reflux of intestinal contents into the stomach occurs normally and that the reflux of bile is increased considerably in patients with gastric ulcers. Since Finholt and Solvang (26) obtained gastric juice from patients under examination for diseases

Table II—Influence of Bile on Sulfadiazine Absorption from Intestinal Loops in the Rat

Experimental Condition	No. of Animals	% Absorbed in 3 hr. ± 1 SD
Controls	6	43 ± 8
Sham bile duct ligation	6	44 ± 7
Bile duct ligation	10	26 ± 17
Choleresis	6	63 ± 8

of the stomach, the extrapolation of their results to normal gastric fluid requires further investigation.

One of the most important groups of surfactants present in man is the bile salts. Bile is chiefly composed of conjugated bile salts, cholesterol, calcium, and lecithin, a phospholipid (79). There are six bile salts present in man—*viz.*, the taurine and glycine conjugates of deoxycholic acid, chenodeoxycholic acid, and cholic acid, present as the sodium salts. Endogenous bile salts represent the end products of cholesterol metabolism in the liver and are stored in the gall bladder after conjugation in the liver until required for digestion. The conjugation of bile salts by the liver with glycine and taurine is an essential physiologic process, since unconjugated bile salts are insoluble at the relatively low pH (6.3–6.6) present in the upper portion of the small intestine. Although the bile salts secreted into the intestinal lumen are, for the most part, conjugated, free acids may be present in the feces due to cleavage of the conjugated bile salts by microorganisms present in the large intestine. The concentrations of conjugated bile salts in the upper jejunum of the fasting human are above the critical micelle concentration and range between 5 and 10 mM (80). During fat digestion, concentrations of conjugated bile salts in the order of 40 mM are commonly found in the jejunum (81).

Bile salts have long been implicated in the absorption of fat from the small intestine. They are known to have an important role in the emulsification of water-insoluble, long-chain triglycerides and in stimulating the hydrolytic action of pancreatic lipase, resulting in a mixture consisting of fatty acids, monoglycerides, diglycerides, and triglycerides (82). A powerful emulsifying agent is also formed by removal of a fatty acid moiety from a molecule of lecithin by a pancreatic phospholipase to give lysolecithin (83).

The ability of bile salts to solubilize lipid material has also been known for many years. The two lipids that are appreciably solubilized by the bile salt micelles are the lipolysis products—*viz.*, monoglycerides and fatty acids (82). Hofmann and Borgstrom (84) have shown that the presence of monoolein in a bile salt micelle greatly increases its ability to solubilize saturated fatty acids. Feldman and Borgstrom (85) have recently shown that small amounts of diglyceride and triglyceride can also enter such micelles. Fatty acids and monoglycerides contained in the micelles are delivered to the brush border of the mucosal cells of the proximal small intestine, where they are absorbed by a process which is not understood at present. The bile salts, however, are not appreciably absorbed from the proximal intestine and become available for further solubilization of fat

digestion products. Intestinal motility eventually carries the bile salts to the ileum where they are absorbed by an active transport process (86).

Bile salts have also been shown to be involved in the absorption of materials other than fats. Bernhard *et al.* (87) showed that in the biliary fistula rat less than 1% of a dose of vitamin A was absorbed. However, if a solution of sodium cholate or taurocholate was introduced into the duodenum, the absorption of vitamin A was increased significantly. Greaves (88) has also reported that bile salts are essential for the intestinal absorption of vitamin K in the rat. Adequate absorption of vitamin D by the rat was shown by Greaves and Schmidt (89) to require bile. When the bile duct was implanted into the colon, the animals absorbed little or none of the vitamin. Oral administration of deoxycholic acid greatly improved absorption of the vitamin in these rats. Taylor (90) confirmed the need for bile for adequate vitamin D absorption in dogs. Heymann (91) also found that dogs did not absorb crystalline vitamin D₂ when bile was not present in the small intestine.

Several reports have appeared in the literature (92–94) as to the importance of bile salts in the intestinal absorption of cholesterol. These studies also showed that the addition of exogenous bile salts enhances the absorption of this sterol.

Lengemann and Dobbins (95) found that intraperitoneal injections and large oral doses of sodium taurocholate enhanced the absorption of calcium by the rat, provided that bile was allowed to flow freely into the small intestine. Seyfried and Lutz (96) reported that the intestinal absorption of tetraiodophenolphthalein is greatly diminished in the absence of bile. Simultaneous administration of bile or bile salts increases the absorption of this substance. Pekanmaki and Salmi (97) found that the absence of bile from the intestine of cats reduced the absorption of free phenolphthalein but had no influence on the amount of absorbed phenolphthalein glucuronide, a water-soluble conjugate. The effect of the endogenous bile on free phenolphthalein absorption was attributed to the solubilizing effect of bile salts on the free drug.

Recently, Meli *et al.* (98) reported that endogenous bile influences the rate of intestinal absorption of ethynylestradiol-6,7-³H-3-cyclopentyl ether in rats. The rate of absorption of the estrogen was considerably lower in biliary-cannulated rats than in control animals. Since the steroid is relatively water insoluble, it is reasonable to consider that the presence of bile salts increased the solubility of the drug in the intestinal lumen and thereby enhanced the dissolution and absorption rate.

Nightingale *et al.* (99) studied the absorption of sulfadiazine in aqueous suspension from proximal intestinal loops in the rat under four experimental conditions—*viz.*, in control animals with intact bile flow, in bile duct-ligated animals, in sham-ligated animals, and in animals where bile flow was stimulated by intraperitoneal administration of sodium dehydrocholate. The results are shown in Table II and clearly indicate that bile flow is an important factor in sulfadiazine absorption from intestinal loops. The mechanism by which bile enhanced sulfadiazine absorption is probably due to micellar solubilization, resulting in an increase in the

dissolution rate of the drug. This possibility is supported by *in vitro* solubility studies.

As noted, conjugation of free bile acids with glycine and taurine results in a considerable lowering of the pKa. Consequently, the conjugated bile acids exist in the intestinal lumen almost entirely as negatively charged ions. In the presence of amphipathic cations, bile salts behave as typical amphipathic anions and an insoluble molecular complex is the frequent result.

Neomycin, a tetrasaccharide with two positively charged amine groups, precipitates glycine and taurine conjugates of dihydroxy and trihydroxy bile salts from aqueous solution (100). Addition of kanamycin, a cationic disaccharide antibiotic, to human bile also results in precipitation (101). Formation of an insoluble complex between a drug and a component of the luminal contents will probably result in decreased absorption of the drug. The poor oral availability of certain drugs such as streptomycin may well be due to bile salt interaction.

Although the detergent properties of bile salts are well recognized, their potential for altering or regulating membrane permeability in the intestine has been given little attention. It is perhaps significant that the ileum, which is the site of active transport of conjugated bile salts, is the region of the small intestine in which the mucosal cells have the shortest life span (102).

Levels of conjugated bile salts in the order of 10^{-2} M, comparable to the levels normally found in the proximal intestine, alter the permeability of the everted rat intestine to salicylate (103), salicylamide (104), riboflavin (40), and several other drugs. The salicylate data are shown in Table III. There is a greater than twofold increase in the steady-state transfer rate of salicylate when micellar concentrations (>5 mM) of taurodeoxycholate are initially present in the mucosal solution. There are no significant differences between the transfer rates observed at different sodium taurodeoxycholate concentrations above the CMC. Mucosal solutions containing 1 and 5 mM taurodeoxycholate produced considerably smaller changes in membrane permeability, an increase of 20–40% over control steady-state transfer rates. Incubation of the intestinal segments in drug-free mucosal solution containing 10 mM bile salt followed by the determination of salicylate transfer from bile salt-free drug solution yielded transfer rates essentially equivalent to those observed when 10 mM taurodeoxycholate was initially present with the drug.

The data in Table III suggest that the bile salt effect is mediated *via* two different mechanisms. One mechanism appears to be operative at concentrations of sodium taurodeoxycholate below or about the CMC and results in small increases in salicylate transfer rates. A second mechanism, which results in large increases in the permeability of the intestinal membrane, appears to be operative at sodium taurodeoxycholate concentrations above the CMC.

The possibility that monomeric and micellar species of bile salt affect the biologic membrane in a significantly different manner is supported by recent studies on bile salt transfer in isolated jejunal loops of the rat. Dietschy (105) reports that at concentrations below the CMC the rate of passive transfer of sodium taurocholate increased

Table III—Effect of Sodium Taurodeoxycholate (STDC) on Mucosal-to-Serosal Steady-State Transfer of Salicylate^a Across the Everted Rat Small Intestine at pH 6.0

	No. of Intestinal Segments	Transfer Rate \pm SD, mcg./min.
Control	19	40 \pm 5
STDC		
100 mM	2	90 (87, 93)
50 mM	4	89 \pm 10
10 mM	11	87 \pm 10
5 mM	6	57 \pm 9
1 mM	7	48 \pm 7
Incubation		
Control	4	40 \pm 4
STDC, 10 mM	4	85 \pm 7

^a Mucosal salicylate concentration maintained essentially constant, 2 mg./ml. Serosal salicylate concentration never exceeded 0.25 mg./ml.

linearly with increasing mucosal concentrations of bile salt. According to Dietschy (105), “since the concentration of monomer becomes almost constant as the total concentration of bile acid is raised to and beyond the CMC, the rate of passive diffusion similarly should reach a limiting value at this same point if bile acid monomer were the only species diffusing passively across the bowel wall.” In fact, the permeability coefficient of the membrane actually increased at taurocholate concentrations above the CMC. “Micellar” taurocholate appears to move across the intestinal membrane twice as fast as the monomeric form. Based on the authors’ findings, one need not conclude that micellar transport of taurocholate proceeds at a faster rate than monomer transport or indeed that it occurs at all. It is possible that micellar concentrations of bile salt in contact with the mucosa significantly enhance the permeability of the membrane toward the monomeric species.

The latter possibility is further supported by Nogami *et al.* (106) who studied the sorption of surface-active agents by isolated rat intestine. The sorption of sodium lauryl sulfate and cetyltrimethylammonium bromide, with time, followed first-order kinetics at bulk concentrations below the CMC and zero-order kinetics at concentrations exceeding the CMC. This change in order is consistent with a mechanism involving penetration of

Figure 2—Segments of everted rat small intestine after 1-hr. incubation. Key: A, physiologic buffer; B, buffer with 10 mM sodium taurodeoxycholate and 5 mM egg lecithin; and C, buffer with 10 mM sodium taurodeoxycholate.

Table IV—Influence of Egg Lecithin, Oleic Acid, and Glycerol Monooleate (GMO) in Modifying the Effect of 10 mM Sodium Taurodeoxycholate (STDC) on the Transfer Rate of Salicylate Across the Everted Rat Small Intestine at pH 6.0

Incubation Media	No. of Intestinal Segments	Mean Transfer Rate \pm SD, mcg./min.
Control	6	30 \pm 3
STDC	15	78 \pm 8
STDC + 5 mM lecithin	4	55 \pm 9 ^a
STDC + 10 mM lecithin	4	51 \pm 3 ^a
STDC + 3 mM oleic acid	4	72 \pm 5 ^a
+ 1 mM GMO		
STDC + 6 mM oleic acid	2	64 (63, 66)
+ 4 mM GMO		

^a Results significantly different from STDC alone ($p < 0.05$, Student's t test, method of paired comparisons).

the monomer but not the micellar species. However, in each case the observed zero-order rate constant was larger than the zero-order rate constant calculated from the results of experiments using pre-micellar concentrations. Hence, the micellar species appear to alter the permeability of the tissues for the monomeric species.

When the intestinal tissue is incubated in solutions exceeding 5 mM bile salt concentration, the changes in permeability are invariably accompanied by pronounced changes in the gross appearance of the mucosal surface (Fig. 2). These observations suggest the possibility that micellar concentrations of sodium taurodeoxycholate produce pronounced changes in membrane structure, conceivably by solubilizing lipid components of the membrane such as phospholipids. These observations also raise an intriguing question as to why such toxic effects are not observed in the intact animal where the intestinal concentration of conjugated bile salts is comparable to that used in the *in vitro* studies.

The micellar species in the proximal intestine normally contains a significant amount of lecithin in addition to the conjugated bile salts. During digestion the micelle will also contain considerable amounts of fat digestion products. Feldman and Gibaldi (107) compared the effect of micellar solutions of pure bile salt and bile salt with lecithin or fat digestion products on the permeability of the everted rat intestine to salicylate. Their results are shown in Table IV. Addition of either phospholipid (egg lecithin) or fat digestion products (oleic acid and glycerol monooleate) to 10 mM solutions of sodium taurodeoxycholate resulted in a protective effect on the everted intestinal membrane. There was a significant decrease in the transfer rate of salicylate after exposure of the everted intestine segment to 10 mM sodium taurodeoxycholate containing either phospholipid or fat digestion products when compared to the transfer rates in 10 mM sodium taurodeoxycholate alone. As shown in Fig. 2, egg lecithin also protected the intestinal mucosa from the gross histological effects of the bile salt. Similar protective effects were observed with the fat digestion products. The results of this study may explain why conjugated bile salts are highly "toxic" to intestinal tissue *in vitro* but are apparently innocuous *in vivo*.

Apparent Directional Permeability Coefficients for Drug Ions: *In Vitro* Intestinal Perfusion Studies

ROBERT H. TURNER^{*†+}, CHANDRAKANT S. MEHTA^{*‡}, and LESLIE Z. BENET⁺

Abstract □ The *in vitro* absorption kinetics for nine drugs were followed using a perfusion apparatus. Identical perfusion runs were made on everted and noneverted segments of the same rat intestine so that the ratio of directional permeability constants (reported as everted rate to noneverted rate) could be calculated. Both negatively and positively charged drug ions (including the quaternary ammonium compound pralidoxime chloride) exhibited permeability coefficient ratios around 1.3, while completely unionized drugs showed the expected ratio of 1.0. In light of the similarity in the ratio of permeability constants for drug ions and sodium ions, salicylate was tested in a sodium-free buffer resulting in a ratio of 1.08. It appears that the difference in directional permeability constants observed with ionized drugs in the intestine may be explained in relation to sodium transport. It is pointed out that *in vitro* intestinal transport studies could lead to erroneous conclusions concerning the degree of absorption of ionizable drugs *in vivo*.

Keyphrases □ Absorption kinetics—*in vitro* intestinal perfusion □ Perfused intestine—drug transport □ Everted, noneverted intestine—directional permeability constants □ Permeability constants, directional—ratios □ Ionization effect—drug permeability coefficient ratios

Considerable work is being and has been carried out on the transport of various drugs across intestinal membranes. This work has been adequately reviewed by Wilson (1) and more recently by Benson and Rampone (2). The forces causing movement across the intestinal membrane can be divided into five classes: cellular metabolic energy, activity gradients, electrical gradients, hydrogen-ion gradients, and solvent drag. One of the first areas studied extensively was that of hydrogen-ion gradients from which a theory evolved to explain the absorption of ionized and unionized drugs. This theory, called the "pH partition hypothesis," was developed by Brodie *et al.* (3–7). These authors concluded from their investigations that most drugs are absorbed from the gastrointestinal tract by a process of passive diffusion of the unionized drug species across a lipoidal membrane. Thus, in line with this hypothesis, Hogben *et al.* (4) suggested that the unequal distribution of weak organic acids or bases across the gut wall is due to: (a) much greater permeability of the gut wall to the unionized form of the compound than to its ionized form, and (b) a difference in pH on the two sides of the intestinal wall. They further postulated that the distribution of weak acid or base is dependent on the "virtual" pH of the mucosal solution (the pH of a narrow microclimate adjacent to the mucosal intestinal surface) rather than the pH of the bulk mucosal

solution. They pointed out that such a microclimate of fluid with a low pH calculated to be 5.3 would lead to a relatively high concentration of unionized acid next to the mucosa (as compared to the concentration of unionized acid in the bulk mucosal solution at a higher pH, normally 6.6) and consequently lead to increased mucosal to serosal movement of the acid by means of nonionic diffusion. By this mechanism, values greater than one for the steady-state concentration ratio, $C_{\text{plasma}}/C_{\text{gut}}$, of a weak acid could be explained without postulating a specific active-transport mechanism.

This hypothesis seems to be consistent with the *in vivo* data of Schanker *et al.* (5) who found that the lowest pKa of an acidic drug showing rapid absorption was about 3, while the corresponding highest pKa for a basic drug was 8. However, there seems to be a great discrepancy between the results obtained *in vitro* and those obtained *in vivo*. It would appear that ionized drug species are much more easily absorbed when membrane permeability is measured using one of the three commonly employed *in vitro* techniques: the everted sac method of Wilson and Wiseman (8), the Crane and Wilson method (9), and use of a perfusion apparatus (10, 11). In 1966, Benson and Rampone (2) stated: "This is the era of the everted sac, developed by Wilson and Wiseman, and much of the investigation reported in this review was based upon this *in vitro* technique." Most intestinal absorption studies in the pharmaceutical sciences (see Reference 12 for review) are still run using the *in vitro* techniques already mentioned. Therefore, this paper is directed toward identifying the discrepancy between *in vivo* and *in vitro* results and to point out the possible unapplicability of *in vitro* intestinal studies, especially when the transport of ionized drugs is observed.

There are a number of studies in the literature which show large differences between *in vitro* results and those expected on the basis of the *in vivo* hypotheses. For example, Hogben *et al.* (4) calculated the ratio of permeability coefficients for unionized and ionized (P_u/P_i) salicylic acid to be 4500; but Nogami and Matsuzawa (13), using absorption kinetics with *in vitro* perfused segments, found this ratio to be 6. Likewise for the drug aminopyrine, Hogben *et al.* (4) calculated a permeability coefficient ratio approaching infinity, but Nogami and Matsuzawa (14) found P_u/P_i equal to 11 in their *in vitro* studies. Nogami *et al.* (15) also found that the *in vitro* permeability coefficients for sulfathia-

zole in ionized forms exceeded the permeability coefficient for the unionized drug.

More recently, Kakemi *et al.* (16) studied the absorption of barbituric acid derivatives through the *in vitro* rat small intestine. Here they found that the pH partition hypothesis was only partially operative, in that absorption rate constants increased in the pH range 6.5 to 7.5 over those rate constants determined at pH 5.5 where barbituric acid derivatives are almost completely unionized. These authors also found that plots of percent barbiturate bound to intestinal mucosa against initial pH of the perfusate, all had maxima in the pH 6.5 to 7.5 region. They speculated that the complexation of barbituric acid derivatives to proteins of the mucosal surface raised the concentration of drug at the membrane surface, which in turn favored absorption in the serosal direction. This proposal is similar to that suggested by Singh *et al.* (17) and Levy and Matsuzawa (18) where drugs complexed to inert ingredients still show measurable absorption rates.

It became apparent to the present investigators that in these *in vitro* studies, the assumption was made that drugs were transported through the intestine by an identical process in each direction. Permeability constants for mucosal (gut) to serosal (plasma) transport were assumed to be the same as for serosal to mucosal transport. However, there were some interesting aspects of the reported data which might lead to the assumption that there was a difference in directional permeability constants. For instance, Nogami and Matsuzawa (13) found that the permeability coefficients for ionized salicylate and unionized salicylic acid increased with the lapse of time. They attributed this increase to the fact that salicylic acid is a toxic substance for living cells and might cause a physiological change in the intestinal tissue. However, this increase in calculated permeability coefficients could also be explained by the fact that the permeability coefficients for mucosal to serosal transport are greater than those for serosal to mucosal transport. The Nogami and Matsuzawa *in vitro* data for aminopyrine (14) would also be consistent with a difference in directional permeability coefficients; and the hypothesis of Kakemi *et al.* (16) implies that in a certain pH range, mucosal to serosal transport of barbituric acid derivatives is favored. Therefore, in this study, the authors have undertaken to determine experimentally whether there is a basis for assuming a difference in directional permeability coefficients and, if such a difference exists, to identify its mode of action.

EXPERIMENTAL

Materials—The following reagent, USP, or NF grade drugs and chemicals were tested: salicylic acid, salicylamide, aminopyrine, aniline, antipyrine, acetanilide, quinine sulfate, pralidoxime chloride (2-PAM chloride), and 5-nitrosalicylic acid. Monobasic sodium phosphate with one water of hydration, dibasic sodium phosphate anhydrous, monobasic potassium phosphate anhydrous, and dibasic potassium phosphate anhydrous were used in preparing the isotonic buffers.

Buffer Solutions—Three considerations entered into the selection of the buffer solutions to be used in these experiments. First, the authors wished to prepare an isotonic buffer solution having the greatest possible buffer capacity, since it is known that the jejunal

Table I—Isotonic Buffer Formulas per Liter

	NaH ₂ PO ₄ · H ₂ O, g.	Na ₂ - HPO ₄ , g.	KH ₂ PO ₄ , g.	K ₂ HPO ₄ , g.
Sodium phosphate buffer, pH 6.6	11.44	8.73		
Sodium phosphate buffer, pH 7.4	3.06	14.70		
Potassium phosphate buffer, pH 6.6			11.03	10.46
Potassium phosphate buffer, pH 7.4			3.07	18.36

epithelium of the rat maintains a slightly acidic pH within its lumen by hydrogen-ion secretion (4) and since there is the possibility of an acidic zone adjacent to the mucosal surface as was proposed by Hogben *et al.* (4). A buffer with a very high buffering capacity should eliminate the possibility of this acidic layer influencing drug absorption since Hogben *et al.* (4) have shown *in vivo* that strong buffers decrease the effect of the virtual pH. Second, the authors wanted to use only buffers having pH values which corresponded to the physiological values found either within the intestine or in its intact blood supply. Therefore, the buffers utilized were only those at pH 6.6 and pH 7.4. In light of the unusual results described in the Kakemi *et al.* (16) study of barbituric acid derivatives, it was felt that working at pH's other than 6.6 and 7.4 could possibly introduce effects not normally seen in the intestine. Third, since the authors wish to identify a possible cause for the difference in directional permeability coefficients, they wanted to use buffer solutions containing a minimum number of compounds. Therefore, they chose to make the isotonic buffers using dibasic and monobasic sodium phosphate exclusively.

Figure 1—Diagrammatic representation of the *in vitro* perfusion apparatus. Key: A, inside compartment, 15 ml.; B, outside compartment, approximately 140 ml.; C, intestinal segment, 10-cm. length available for absorption; D, capillary bubble pump; E, difference between heights of inside and outside compartments, 2 cm.; and F, 100% oxygen.

Figure 2—Sample data plot for the absorption of salicylate through the rat intestine. Outside solution, 1000 mcg./ml. drug in isotonic pH 7.4 sodium phosphate buffer. Inside solution, isotonic pH 7.4 sodium phosphate buffer. Initial absorption rate through: everted segment (●) = 1.76 mcg./ml./min.; noneverted segment (■) = 1.39 mcg./ml./min. Permeability coefficient ratio $P_E/P_{NE} = 1.27$.

Using the proper sodium chloride equivalents, a reasonable activity coefficient value for hydrogen ions in an isotonic solution, and the Henderson-Hasselbalch equation, it is possible to calculate (19) the required amount of sodium phosphates in each buffer, as presented in Table I. Using the Van Slyke equation, the pH 6.6 sodium buffer was found to have a buffer capacity of 0.078 and the pH 7.4 buffer had a capacity of 0.048. The buffer capacities of these solutions are approximately twice those for the isotonic buffer solutions at similar pH's listed by Martin (19). During the

course of a 40–60-min. perfusion run, the buffering solutions were found to vary by no more than 0.03 pH units, a value well within the accuracy expected in making pH measurements (20). In addition, some perfusion studies were run in a sodium-free buffer, where monobasic potassium phosphate and dibasic potassium phosphate were utilized in preparing the buffers. The formulas for these isotonic buffers, pH 7.4 and 6.6, are presented in Table I.

Perfusion Studies—Male Sprague-Dawley rats weighing about 250 g. were starved 24 hr. prior to the experiment but allowed free access to water. The rats were sacrificed with a sharp blow; the intestines (jejunum and ileum) were immediately removed and flushed with 40 ml. of the buffer solution to be used in the absorption run. The upper portion of the intestine was cut into two segments of 12 cm. each, and one of the two segments was everted. (In a series of experiments, the first segment of the intestine was everted alternatively.) The *in vitro* absorption kinetics for various drugs were followed using a perfusion apparatus (see Fig. 1) modified slightly from that described by Dietschy *et al.* (21). Each of the two intestinal segments (one everted and one noneverted) was tied securely onto a perfusion apparatus, being certain to maintain the same relative tautness in the stretched segments. The perfusion apparatuses were so designed that only a 10-cm. segment of the intestine was available for absorption. The inside compartment of each apparatus was then filled with 15 ml. of the appropriate isotonic phosphate buffer solution. The inside compartments were placed in large test tube shaped vessels that were suspended in a controlled-temperature water bath, which was maintained at $37.0 \pm 0.5^\circ$. The outside compartment was filled initially with 130 ml. of a solution containing 1000 mcg./ml. of the drug dissolved in the same isotonic buffer as was used in the inside compartment. Additional drug solution was then added to the outside compartment until a 2-cm. difference in height resulted between the solution in the inside compartment and that in the outside compartment (see Fig. 1). Oxygen was bubbled through the drug solution by means of a capillary tube, and through the solution in the inside compartment by means of a built-in capillary bubble pump which circulated the buffer through the intestinal segment. The rates of bubbling in the two separate apparatuses were adjusted to approximately the same rate, one bubble/second. At regular intervals, 0.1-ml. samples were removed from the inside solution of each apparatus. For each drug, the time intervals were adjusted so that the sixth and final sample was removed from the inside compartment before the concentration in that compartment reached 100 mcg./ml. (i.e., less than 10% of the outside concentration).

Assay Procedures—The 0.1-ml. samples taken from the inside compartments were diluted and assayed by either a UV measurement on the Cary 15 spectrophotometer or by a spectrofluorometric procedure on the Aminco-Bowman spectrofluorometer. Table II lists the various drugs studied, the pH of the buffer in which they were run, the diluent used in the analytical procedure, the amount of diluent added to the 0.1-ml. sample, and the apparatus and wavelengths at which the drug was measured. Standard plots for each drug were made using five known concentrations of the drug in the appropriate diluent.

RESULTS

After assaying each of the drug samples, plots were made of concentration of the inside solution *versus* time for both absorption through the everted and through the noneverted intestinal segments. Figure 2 contains a sample plot of data for the absorption of salicylate ions through two adjacent segments of rat intestine.

Riggs (22) has shown that the transfer of substances by simple diffusion across thin membranes may be described by a useful simplification of Fick's law as presented in Eq. 1:

$$\frac{dQ_i}{dt} = D_m A_m R_{m/s} (C_o - C_i) / \Delta x_m \quad (\text{Eq. 1})$$

When this equation is specifically applied to this experiment:

Q_i = the amount of drug in the inside compartment at any time, t

D_m = the effective diffusivity of the drug in the intestinal membrane

A_m = the area of the membrane available for free diffusion

$R_{m/s}$ = partition coefficient between membrane and solvent

Table II—Analytical Procedures

Drug	pH of Perfusion Study	Diluent	Dilution, ml. ^a	Apparatus and Wavelengths ^b
Acetanilide	6.6	pH 6.6 buffer	1.0	UV at 237
Aminopyrine	7.4	pH 7.4 buffer	1.0	UV at 260
Aniline	7.4	pH 7.4 buffer	3.0	SPF: Ex 285, Em 354
Antipyrine	6.6	pH 6.6 buffer	1.0	UV at 255
5-Nitrosalicylic acid	7.4	0.1 N HCl	2.0	UV at 308
Quinine sulfate	6.6	0.1 N H ₂ SO ₄	3.0	SPF: Ex 352, Em 454
2-PAM chloride	7.4	0.1 N NaOH	1.0	UV at 335
Salicylic acid	7.4	0.1 N NaOH	5.0	SPF: Ex 300, Em 408

	Potassium phosphate buffer					

^a Not significant.

Δx_m = the thickness of the membrane

C_o = concentration of drug in the outside compartment at any time, t

C_i = concentration of drug in the inside compartment at any time, t

For the experiments run in this work, the last sample of the inside compartment of the perfusion apparatus was always taken at a time when the concentration of that compartment could be considered negligible compared to the concentration of the outside compartment. For example, in Fig. 2 the highest concentration reached in the inside compartment was 57.6 mcg./ml. as compared to an outside concentration of 1000 mcg./ml. Therefore, it may safely be assumed that the backward flow of drug from the inside compartment to the outside compartment is negligible during the time of the experiment and, therefore, C_i can be eliminated from the equation. In addition, since the outside solutions were of such a high concentration and of such a large volume (approximately 140 ml.), it is safe to assume that C_o is a constant throughout the absorption run. Therefore, for these experiments, Eq. 1 may be written as Eq. 2 when absorption is studied through the everted gut and as Eq. 3 when absorption is studied through the noneverted gut:

$$V_i \frac{dC_{iE}}{dt} = P_E C_o \quad (\text{Eq. 2})$$

$$V_i \frac{dC_{iNE}}{dt} = P_{NE} C_o \quad (\text{Eq. 3})$$

where P_E is defined as the permeability coefficient for absorption through the everted gut—this permeability coefficient contains the diffusion constant, D , the area of the membrane, A , the partition coefficient, $R_{m/s}$, and the thickness of the membrane Δx . The left-hand sides of Eqs. 2 and 3 have been converted into concentration units to correspond with the method of assay where C_{iE} refers to the concentration of the inside compartment when absorption is studied through the everted gut, and NE refers to measurements taken when the gut is not everted. Thus, it may be seen from Eq. 2 that as per the design of the experiment, the absorption rates through the everted and noneverted gut should appear to follow zero-order kinetics as is shown by the straight-line relationships in Fig. 2. Since the concentrations of drug in the outside solutions were always the same (1000 mcg./ml.), and since the volumes of the inside compartments (V_i) were always the same, dividing Eq. 2 by Eq. 3 shows that the ratio of the absorption rates will equal the ratio of apparent permeability coefficients. Table III contains the absorption rates and permeability coefficient ratios for the nine drugs followed in this study. The table contains the pKa of each drug, the pH of the buffer solutions used in the tests, the number of paired trials (each trial refers to one everted and one noneverted absorption run through intestinal segments of the same rat), the average everted and noneverted absorption rates plus or minus the standard deviations for these average rates, and the average of the ratios of permeability coefficients for individual paired runs, plus or minus the standard deviation. As will be noted from the data in

Table III, the standard deviations for the average rates of absorption are relatively much higher than the standard deviations for the averages of the permeability coefficient ratios. This would be expected since the absorption rates are a function of the biological variability of the absorption of a drug through the intestine of a number of different rats. However, each of the ratios of permeability coefficients was determined from absorption studies through intestinal segments from the same rat. Therefore, the biological variability of differences in absorption rates due to the individual physiological characteristics of the intestine should be cancelled out to a large extent in the permeability coefficient ratios. Table III also compares the level of significance between the average ratio of permeability coefficients for each drug and the value 1.00 (the value expected if drug passage through the intestinal membrane was identical in each direction). Student's t test was used and 0.05 was taken as the minimum level of significance.

Table IV presents the data for the individual paired runs for salicylic acid in pH 7.4 sodium phosphate buffer. The regression coefficient for each set of data points is also presented in parentheses after the rate determined from the slope of the line drawn through these points. Figure 2 is the plot for the data listed as Run 6 in Table IV.

At the end of the perfusion runs, the difference in heights between the solution in the inside compartment and that in the outside tube was measured and found to have decreased by 0.5 cm. Measurements show that this decrease corresponds to a loss of approximately 1.4 ml. from the inside compartment. Since six 0.1-ml. samples were taken out of the inside compartment during the course of the experiment, there was an overall diffusional loss of 0.8 ml. from the inside compartment to the outside during the course of an absorption run. Since solvent movement was always against the drug flux, it may safely be assumed that solvent drag was not a significant factor in the permeability coefficient ratio.

DISCUSSION

The resulting permeability ratios presented in Table III may be classified into three areas: those very close to a ratio of 1.0, those close to a ratio of 1.3, and an indeterminate group with a ratio midway between 1 and 1.3. The two compounds with ratios very close to 1.0, acetanilide and antipyrine, can be considered to be completely unionized at the pH of the perfusion study. However, a compound such as 2-PAM chloride, which must be completely ionized because it is a quaternary ammonium compound, exhibits a permeability ratio that significantly differs from 1.0. The two other compounds in the study, which may be assumed to be completely ionized at the pH of the perfusion run, salicylic acid and 5-nitrosalicylic acid, also show permeability coefficient ratios very close to 1.3. Quinine sulfate, which is also ionized to a large extent (at least 97%, the majority of which will be the singly positively charged species) exhibits a ratio closer to those of the other ionized drugs than to the ratios around 1.0 for the unionized drugs. Aniline and salicylamide, two compounds which would be expected

Av.	1.780		1.331		1.352

to be at least 97% unionized, give permeability ratios intermediate between those values expected for unionized drugs and those ratios expected for ionized drugs. The aminopyrine (pKa 5.0) run at pH 7.4 appeared to be an exception, since although the drug would be only slightly ionized at this pH, a ratio of 1.31 was found. Excluding the data for aminopyrine and realizing that, as yet, not enough drugs have been run to substantiate a general theory, the data would suggest the following: drugs that are known to be incapable of ionization show the typical uniform path of distribution of drug molecules through the intestine. That is, the mucosal to serosal transfer was equal to the serosal to mucosal transfer, giving a permeability coefficient ratio of 1. If, however, the drug was capable of ionizing to some degree (salicylamide and aniline), the permeability coefficient ratios increased slightly. However, if the drug was completely ionized, whether positively or negatively charged, the permeability coefficient ratio was found to be very close to 1.3. From the data in Table III, it may be concluded that the passage of ionized drugs through the *in vitro* intestine is not a completely passive process.

In looking for an explanation for the 1.3 value for the permeability ratio of ionized drugs, the authors were struck by the similarity of this ratio to the permeability ratio observed by Curran and Solomon for sodium flux in the rat intestine (23). Recently, there have been a number of studies describing sodium ion dependent transport in the intestine as reviewed by Crane (24) and Curran (25). Therefore, an attempt was made to run a similar absorption rate study for salicylic acid in potassium phosphate buffer where sodium ions were completely excluded. This study (as presented at the bottom of Table III) gave a ratio of 1.08, a value very close to the ratios determined for unionized drugs. Although this result must be considered preliminary, there seems to be good evidence that sodium ion transport may be involved in the difference in apparent directional permeability coefficients which have been found in the *in vitro* rat intestine. Further work in this area is now being carried out.

Another interesting result which is obvious from Table III is that the absorption rates for ionized drugs through the intestine are very similar for all of the compounds studied, whether they are positively or negatively charged drug ions. The rate of 2-PAM chloride is especially significant since this compound obviously exists as an ionized species while it is being transported through the *in vitro* intestine. Previously, on the basis of the virtual pH theory of Hogben *et al.* (4), it might have been assumed that ionized drugs apparently pass through the intestine because a sufficient number of the ionized species become unionized at the virtual pH of the acidic microlayer adjacent to the mucosal surface. However, the similarity in rates between 2-PAM chloride, salicylate ions, and quinine ions seems to indicate that ionized drugs do pass through the *in vitro* intestine.

Another interesting similarity may be seen between the absorption rate of salicylate ion and 5-nitrosalicylate ion. Schanker *et al.* (5) found that there was a wide difference between the absorption of these two acids from the rat intestine *in vivo*. Over a given time interval, 60% of the salicylic acid was absorbed, while only 9% of the 5-nitrosalicylic acid was absorbed. The difference in the absorption of these two compounds was used in the explanation of the virtual pH hypothesis. Hogben *et al.* (4) state: "An absorbing surface with a pH of 5.3 would explain why the lowest pKa of an acidic drug compatible with rapid absorption is about 3, while

the highest pKa for bases is about 7.8. In each case, the ratio of unionized to ionized drug is 1:200. This appears to be the minimal proportion of unionized drug necessary to insure rapid absorption under the conditions of our experiments."

Although the validity of these data cannot be questioned with respect to *in vivo* absorption, it would appear that this 1:200 ratio is not significant when considering passage through the *in vitro* rat intestine. Furthermore, it leads the authors to believe that the virtual pH hypothesis should not be applied to passage through the *in vitro* intestine.

It is obvious from the data in Table III that drugs which are assumed to be absorbed as unionized species show absorption rates which are significantly higher than those for ionized drugs. This is especially pertinent when considering the permeability ratios for aniline and salicylamide. It is believed that it is safe to assume that these drugs are being absorbed as unionized species and, therefore, the indeterminate ratios (1.12 and 1.13) are assigned as being related to the experimental error inherent in the methods utilized when the absorption rates become large. It is interesting to note that aniline, the compound absorbed at the highest rate in this study, was only found to have an absorption rate about 9 times higher than that for ionized drugs. This difference in rate between unionized and ionized drugs in the *in vitro* intestine is very similar to that reported by Nogami and Matsuzawa (10, 13), but it is quite different from the relative rates of absorption predicted by Hogben *et al.* in the *in vivo* intestine.

Because of the unusual nature of the permeability coefficient ratio for aminopyrine, a drug which would be expected to be unionized and therefore to have a ratio close to 1, preliminary paired runs of aminopyrine in a potassium phosphate buffer have been run. These runs give an average ratio of 1.10. Although work is continuing on this compound, it would appear that aminopyrine is being transported by a process which is different than the other compounds in this study. The authors believe that this result might be significant with respect to *in vivo* transport as well as to *in vitro* transport, since aminopyrine was one of the two drugs studied by Hogben *et al.* (4) which yielded results consistent with a calculated virtual pH of 5.3 at the intestinal wall.

Since the permeability coefficient ratios for the completely unionized drugs, acetanilide and antipyrine, are so close to 1.0, it would appear that the difference in surface area between the mucosal and serosal membranes is not important. This leads the authors to believe that the rate-limiting step in intestinal transport is passage through the membrane rather than passage into or out of the membrane. Under these conditions the surface area of the membrane exposed to the drug solution does not affect the rate of passage. This, in fact, is an implicit assumption in Rigg's simplification of Fick's law as was presented in Eq. 1.

CONCLUSIONS AND SUMMARY

The initial absorption rates for nine drugs were determined *in vitro* through both the everted and noneverted rat intestine using a perfusion apparatus. Two of these drugs, acetanilide and antipyrine, may be considered to be completely in the unionized form at the pH of the buffers used in this work, 6.6 and 7.4. Two other compounds, an acid, salicylamide, and a base, aniline, should be at least 97% unionized in the buffers in which they were studied. The other five drugs studied, including a quaternary ammonium compound—pralidoxime chloride—may be considered to be completely ionized in these studies. On the basis of the nine drugs observed in this work, the authors feel that the following conclusions can be made (with full realization that more extensive studies in different buffer solutions must be undertaken to confirm these results):

1. Drug ions do pass through the *in vitro* rat intestine.
2. These ions pass through the *in vitro* rat intestine at a rate which is much faster than that predicted on the basis of *in vivo* results.
3. Drug ions show a difference in directional permeability coefficients in the *in vitro* rat intestine, with mucosal to serosal transfer occurring about 1.3 times faster than serosal to mucosal transfer. This difference is not observed for the completely unionized drugs.
4. It appears that this difference in directional permeability coefficients might be related to a sodium ion coupled transport.

since when sodium was completely replaced by potassium in the bathing buffer solutions, only a 1.08 value was obtained for the ratio of permeability coefficients for salicylate ion.

5. It would appear that the virtual pH hypothesis of Hogben *et al.* (4) is inoperative when considering *in vitro* intestinal transport.

6. If the presently accepted hypotheses concerning the *in vivo* intestinal absorption of ionizable drugs are valid, it would appear that *in vitro* intestinal transport studies could lead to erroneous conclusions concerning the degree of absorption of ionizable drugs *in vivo*.

Parameters Affecting Absorption of Griseofulvin in a Human Subject Using Urinary Metabolite Excretion Data

PETER KABASAKALIAN, MICAELA KATZ, BERNARD ROSENKRANTZ, and EDWARD TOWNLEY

Abstract □ Using the urinary excretion of 6-demethylgriseofulvin as the index of absorption, the effects of three previously studied parameters (high-fat breakfast, particle size, and dissolution rate) on the absorption of griseofulvin in a single subject are compared with published blood level data derived from many subjects. The results of the effects of three new parameters (time of dose administration, low-dose level, and gastrointestinal transit time) are also reported.

Keyphrases □ Physiological availability—griseofulvin, man □ Griseofulvin absorption parameters—urinary excretion data, man □ 6-Demethylgriseofulvin metabolite—griseofulvin absorption parameters, man □ Trimethylsilyl ether derivative—6-demethylgriseofulvin, griseofulvin metabolite □ GLC—analysis

The factors (1–12) affecting the absorption of orally administered griseofulvin in man have been studied by measuring (using a fluorometric chemical analytical

procedure) the level of griseofulvin in blood at various times after drug administration. The calculation of the degree of absorption is based on the assumption that the physiological availability of the drug is proportional to the area (usually determined by the trapezoidal rule) under the blood level–time curve (3, 5, 13–15).

The factors affecting absorption were found to be a function of the diet (high-fat meal) (1, 2), the dosage formulation [particle size (3–7), dissolution rate (8, 9), solubility (7, 10), and presence of surfactants (4, 7)], and the dosage regimen [dosage level (3, 11, 12) and repetitive dosage schedule (6, 7, 9, 11)].

The nonlinear (logarithmic) relationship (3, 11, 12) between the dose ingested and the area under the blood level–time curve has raised questions concerning the validity of the model on which this method of calculating absorption is based. Atkinson *et al.* (11) suggested

since when sodium was completely replaced by potassium in the bathing buffer solutions, only a 1.08 value was obtained for the ratio of permeability coefficients for salicylate ion.

5. It would appear that the virtual pH hypothesis of Hogben *et al.* (4) is inoperative when considering *in vitro* intestinal transport.

6. If the presently accepted hypotheses concerning the *in vivo* intestinal absorption of ionizable drugs are valid, it would appear that *in vitro* intestinal transport studies could lead to erroneous conclusions concerning the degree of absorption of ionizable drugs *in vivo*.

Parameters Affecting Absorption of Griseofulvin in a Human Subject Using Urinary Metabolite Excretion Data

PETER KABASAKALIAN, MICAELA KATZ, BERNARD ROSENKRANTZ, and EDWARD TOWNLEY

Abstract □ Using the urinary excretion of 6-demethylgriseofulvin as the index of absorption, the effects of three previously studied parameters (high-fat breakfast, particle size, and dissolution rate) on the absorption of griseofulvin in a single subject are compared with published blood level data derived from many subjects. The results of the effects of three new parameters (time of dose administration, low-dose level, and gastrointestinal transit time) are also reported.

Keyphrases □ Physiological availability—griseofulvin, man □ Griseofulvin absorption parameters—urinary excretion data, man □ 6-Demethylgriseofulvin metabolite—griseofulvin absorption parameters, man □ Trimethylsilyl ether derivative—6-demethylgriseofulvin, griseofulvin metabolite □ GLC—analysis

The factors (1–12) affecting the absorption of orally administered griseofulvin in man have been studied by measuring (using a fluorometric chemical analytical

procedure) the level of griseofulvin in blood at various times after drug administration. The calculation of the degree of absorption is based on the assumption that the physiological availability of the drug is proportional to the area (usually determined by the trapezoidal rule) under the blood level–time curve (3, 5, 13–15).

The factors affecting absorption were found to be a function of the diet (high-fat meal) (1, 2), the dosage formulation [particle size (3–7), dissolution rate (8, 9), solubility (7, 10), and presence of surfactants (4, 7)], and the dosage regimen [dosage level (3, 11, 12) and repetitive dosage schedule (6, 7, 9, 11)].

The nonlinear (logarithmic) relationship (3, 11, 12) between the dose ingested and the area under the blood level–time curve has raised questions concerning the validity of the model on which this method of calculating absorption is based. Atkinson *et al.* (11) suggested

the existence of a linear relationship between the half-life and logarithm of the ingested dose. This dependence of half-life on the amount of drug in the blood is unusual if elimination was following a simple model containing first-order rate constants. Riegelman has shown that one basic assumption of the model, the constancy of the apparent volume of distribution, is invalid for griseofulvin in the rabbit (16). He has also questioned the single-compartment basis of the model in man (17). However, Riegelman has recently shown that, although a multicompartment model is necessary for calculating absorption, the plasma level-time curve for man (18) was proportional to the dose administered.

A further complication relating to the use of blood data has been the fact that most investigations have used a single-dosage regimen. Marvel *et al.* (7) have shown that in the case of griseofulvin, a factor (surfactant in formulation) which enhanced absorption of griseofulvin under a single-dosage regimen did not do so under a multiple-dosage regimen for which this drug is intended.

Besides the use of blood level data, physiological availability can be estimated from urinary excretion data (19, 20). A significant amount of drug must be excreted unchanged in the urine if questions of valid use of this method are not to be raised (21). Unfortunately, the amount of free griseofulvin excreted in the urine is only about 0.1% of the ingested dose (22). Fortunately, the urinary excretion of the reported metabolite (23) (6-demethylgriseofulvin) of griseofulvin can be used for this purpose. Absorbed griseofulvin is reported to be completely excreted as 6-demethylgriseofulvin (10).

This investigation was undertaken to determine whether urinary metabolite excretion data as first used

by Riegelman (10) can be used to study the parameters that affect the absorption of griseofulvin in man, but which may not conveniently be studied by the blood level method.

EXPERIMENTAL¹

Material—Commercially available 250-mg. regular size and microsize griseofulvin formulations of three manufacturers, together with one 500-mg. regular size and one 250-mg. and seven 125-mg. microsize experimental griseofulvin formulations, were used in this study.

In Vitro Dissolution Test—Katchen's (8, 24) modified oscillatory tube method was used with simulated intestinal fluid.

Subject—A single healthy ambulatory subject was used in this study. During the experimental period, there were no dietary restrictions except for fat intake during the time of dosage administration and high-fat meal experiments. The normal diet was bland. During the gastrointestinal transit time study, the diet was altered as noted in Table V.

Dosage Regimen—A single-dosage regimen was used. The dose was administered at 7:30 a.m., 12:00 noon, 6:00 p.m., or 12:00 midnight as noted in the time of dose administration study immediately prior to the three regular daily meals; no meals were skipped. After this study, 12:00 noon was chosen as a fixed parameter for the rest of the studies.

Urine Collection—The urine was collected normally for 3 days subsequent to drug administration and combined into 24-hr. samples. The urine volume and pH were noted. The urine was analyzed right after collection. No change in metabolite concentration was observed over several months on repeated assays.

Analytical Method—The urine was analyzed for 6-demethylgriseofulvin² by gas-liquid chromatography. Twenty-five milliliters of urine was acidified to pH 1 and extracted with 25 ml. of chloroform.

Figure 1—Plot of metabolite yield after the subject has taken a single dose of 250-mg. microsize griseofulvin experimental Product A at various times during the day: ●, with a nonfat meal; and ×, with a fat meal.

¹ All gas chromatograms were obtained on a F and M model 400 gas chromatograph with a flame-ionization detector and a Minneapolis Honeywell recorder.

² β -Glucuronidase and sulfatase hydrolysis did not indicate the presence of any conjugated metabolite.

^a By subject receiving at 12:00 noon a single dose or fractions of 500 mg. of regular size griseofulvin Product B.

A 10-ml. aliquot of the chloroform extract was evaporated to a residue on a steam bath under a nitrogen atmosphere. The residue was dried in a draft oven at 60° for 10 min. The trimethylsilyl ether derivative was formed according to the procedure of Horning *et al.* (25), using 100 μ l. of B.S.A. reagent,³ mixing, and heating for 10 min. at 60°. After the addition of 100 μ l. of pyridine, a 5- μ l. sample was injected into a diatomaceous earth⁴ column containing 1% OV-17⁴ (a phenylmethyl siloxane polymer) as liquid phase. A 1.22-m. (4.0-ft.) column exhibited at 225° a retention time of 12.4 min. and 1300 theoretical plates for 6-demethylgriseofulvin.

RESULTS AND DISCUSSION

Time of Dosage Administration—The amount of metabolite excreted in the urine in a 3-day period after the administration of an experimental 250-mg. microsize griseofulvin product, A, is recorded in Table I. While the subject's diet was kept low in fats, the time of dosage administration was varied. The results of these experiments are also displayed in the form of a graph in Fig. 1.

The absorption as indicated by the amount of metabolite yield is a function of the time of drug administration. The absorption is lowest early in the morning after a night of fasting. In all the previous (1–12) studies of absorption of griseofulvin in man, the drug was administered early in the morning, *i.e.*, at breakfast time. The absorption reached a maximum when the drug was administered at noon. Griseofulvin administered at supper time or at midnight yielded intermediate absorption values.

The effect of time of griseofulvin administration has not previously been reported. It is not evident why there should be a maximum and minimum absorption when the drug is administered at noon and breakfast time, respectively. That this is not a spurious response but very real was revealed by the fact that the amount of metabolite excreted when the drug was again administered at noon and breakfast time after a lapse of a month was nearly identical to the initial values as shown in Table I.

Perhaps a circadian rhythm (26) involved in the drug absorption [such as intestinal motility or the 24-hr. bile cycle (27)] is responsible for this phenomenon.

High-Fat Meal—Using the experimental Product A, the effect of a high-fat meal at breakfast and supper time just prior to drug

administration yielded the results shown in Table I. It should be noted that the high-fat meal followed by drug administration at breakfast increased drug absorption. There was no similar effect when the high-fat meal before drug administration was at supper time.

The previous (1, 2) reported effects of a high-fat meal were determined at breakfast time.

Gastric-emptying time (28) is affected by the fat content of the meal. Since griseofulvin is reported to be absorbed (29) mainly in the intestines, the effect of the high-fat meal would be equivalent to taking the drug at a later time.

Using the graph in Fig. 1, the metabolite yield when a high-fat breakfast was consumed by the subject, and assuming a linear relationship to be in existence between the maximum and minimum absorption points, one can calculate a delay of about 2.5 hr. A similar equivalent delay at supper time would cause no increase in absorption (Fig. 1).

Dose Level—A single dose or fractions of the regular size 500-mg. griseofulvin Product B was administered at noon. The metabolite yields are listed in Table II. The results of these experiments are also displayed in the form of a graph in Fig. 2 using the metabolite-to-griseofulvin dose ratio as an indicator. The urine pH and volumes are also presented and show no effect.

As the dose level of the griseofulvin increased 100-fold, the amount of metabolite excreted increased proportionately, as indicated by the constancy of the metabolite-to-griseofulvin ratio. It is apparent that the percentage of the drug absorbed is independent of the dose level. The constancy of this metabolite yield-to-dose ratio served as an internal calibration of absorption, even though the metabolite yield was low in this individual. In previous (3, 11, 12) studies in man, the logarithm of the dose and blood level have been linearly correlated. Atkinson *et al.* (3, 11) have used dose levels of 250 mg. to 1.0 g., while Grin and Denic (12) have used dose levels of approximately 250 mg. to 8.0 g. A plot of logarithm of dose administered and amount of metabolite excreted is shown in Fig. 3. There appears to be no linear relationship as with the blood level data.

These results cannot be compared with blood level data since no experimental data with low griseofulvin levels have been previously reported.

The absorption of drugs from the gastrointestinal tract are generally assumed to undergo two steps as shown in Eq. 1:

The first is the dissolution of the solid dosage and the second is the transport of the drug in solution in the gastrointestinal lumen through a lipoidal permeable membrane into the blood.

Although the extremely low water solubility of griseofulvin probably makes the dissolution step the rate-limiting step in the absorption process, one might have expected that the water solubility would not be self-limiting any longer at the lower doses and that at least the regular size griseofulvin would approach the microsize griseofulvin in its yield of metabolite (a metabolite-to-griseofulvin dose ratio of 0.10 *vs.* 0.21 from the time of dose administration study). Instead, the regular size griseofulvin acted as if it obeyed the cube root law of dissolution of Hixson and Crowell (30).

Hixson and Crowell derived an equation for the dissolution of a single particle in which the surface area was allowed to change with time while its shape factor (ratio of dimensions) remained constant. Niebergall and Goyan (31) extended the equation for use

Figure 2—Plot of metabolite-dose ratio vs. logarithm of dose for subject receiving at 12:00 noon a single dose or fraction of 500-mg. regular size griseofulvin Product B.

Figure 3—Plot of metabolite yield vs. logarithm of dose for subject receiving at 12:00 noon a single dose or fraction of 500-mg. regular size griseofulvin Product B.

in multiparticulate systems by assuming N equal-size particles. When the amount of solute needed to saturate a given volume of solvent is much greater than the concentration of material in solution, the integrated form becomes

$$N^{1/3}(w_0^{1/3} - w^{1/3}) = N^{1/3}(Kt) \quad (\text{Eq. 2})$$

where N is the number of particles, w_0 is the initial weight of each particle, w is the weight of the particle at time t , and K is the product of the intrinsic dissolution rate constant, solubility, density, and shape factor for the solute.

Therefore, no matter what the total number of particles is, the cube-root law indicates that all particles of identical size obey the fundamental relationship. A graphic presentation of this law using the fraction dissolved, $(w_0 - w)/w_0$, is shown in Fig. 4. A consequence of this relationship is that if the gastrointestinal transit time is constant, the percentage absorption of the drug will be independent of the amount of drug administered.

Particle Size—Table III contains the results of six commercially available 250-mg. griseofulvin products. Three products, C, D, and E, were manufactured with microsize griseofulvin; three products, F, G, and H, were produced with regular size griseofulvin. These drugs were administered at noon time.

The microsize griseofulvin products yielded about twice as much metabolite as the regular size griseofulvin products.

Although the results within each group appeared to differ from each other, these differences are not considered significant since they include formulation content and analytical variations. The mean amount of metabolite obtained from the use of the microsize griseofulvin products was found to be 50.7 mg., while the corresponding value from the regular size griseofulvin products was found to be 26.6 mg. This indicates that the regular size griseofulvin is equivalent to about one-half the microsize griseofulvin.

This equivalency was difficult to determine when blood level data were used because of the nonlinear response of blood level to dose administered. However, blood level data (3–7) did yield this

information when dosages of microsize and regular size griseofulvin were compared at identical blood levels.

Although the *Federal Register* (32) classifies griseofulvin into large particles (regular size) and microsize material, there isn't as large a difference between the material as their names imply. The specification of the specific surface area for the large particle griseofulvin is that it should not be less than 0.35 and not more than 0.65 m.²/g., while that for the microsize griseofulvin is that it should not be less than 1.3 and not more than 1.7 m.²/g. The ratio of the average of these limits is 1:3 with respect to surface area.

^a By subject receiving at 12:00 noon a single dose of 125 mg. of microsize griseofulvin products having different dissolution rates.

Matthews and Rhodes (33) reported surface area of 0.38 m.²/g. of regular size griseofulvin and 1.32 m.²/g. of microsize griseofulvin. The ratio of surface area of regular size to microsize griseofulvin in this case is 1:3.5.

An inspection of Fig. 4 indicates that the rate of dissolution is essentially constant up to the time when about 40% of the solute has dissolved. Therefore, the ratio of percentage absorptions of microsize and regular size griseofulvin can be calculated by the use of a form of the Noyes-Whitney (34) equation, Eq. 3 (where S is the surface area, V the volume of solvent, K_1 the rate constant, and w_s the weight of solute needed to saturate the solution), when the total absorption is below 40% and the amount of solute in solution is very much less than that required to saturate the solution.

$$V(dw/dt) = -K_1S(w_s) \quad (\text{Eq. 3})$$

$$\frac{[N_1(dw_1/dt)]}{[N_2(dw_2/dt)]} = \frac{N_1S_1}{N_2S_2} \quad (\text{Eq. 4})$$

Substituting the reported (33) surface areas of 1.32 and 0.38 m.²/g. of microsize and regular size griseofulvin, respectively, yields the following ratio:

$$(N_1S_1)/(N_2S_2) = 1.32/0.38 = 3.5 \quad (\text{Eq. 5})$$

The ratio of metabolite yield actually found was 2. This may be due to the fact that the griseofulvin has a hydrophobic surface which has not been completely converted to a hydrophilic surface by granulation (35, 36), and/or that there is significant absorption of air on its surface (37), and/or the particles do not regain their surface area on disintegration of the dosage formulation due to particle aggregation.

Of course, the model used may be incorrect because of the non-uniformity of particle size and/or departure from the concept of retention of constant shape factor during the course of the dissolution process.

Dissolution Rate—Comparison of the amount of metabolite excreted after the ingestion of six experimental microsize griseofulvin formulations, having different dissolution rates (Table IV), did not reveal any relationship between the logarithm of the dissolution rate (Fig. 5) and absorption (except for the slowest dissolving Product N). These observations appear to differ from those of Katchen and Symchowicz (8, 9). They reported a positive correlation between the logarithm of dissolution rate (amount dissolved in 30 min.) in simulated intestinal fluid and the 24-hr. mean griseofulvin plasma level. However, a closer scrutiny of Katchen and Symchowicz's papers indicates that under the single-dosage regimen there is a large intersubject variation in the effect of dissolution rates. In fact, two (Subjects 4 and 8) out of their 18 subjects show

Figure 5—Plot of metabolite yield vs. logarithm of dissolution rate (mg. dissolved/30 min.) for subject receiving at 12:00 noon a single dose of 125 mg. of microsize griseofulvin experimental products having different dissolution rates.

no correlation between dissolution rate and drug absorption. The subject used in this investigation evidently falls into this minority group.

Recently there has been a flurry of investigations to increase the dissolution rate of griseofulvin and thus supposedly of increasing gastrointestinal absorption. Goldberg *et al.* (38) have reported a eutectic mixture with considerable solid solubility of griseofulvin in succinic acid having dissolution rates about seven times faster than the pure material. Mayersohn and Gibaldi (39) have published a new method of solid-state dispersion of griseofulvin in polyvinylpyrrolidone. The resultant product is reported as having greatly increased dissolution rates over micronized griseofulvin. A recent patent (40) reports that higher griseofulvin blood levels in the rat can be obtained by the use of an intimate mixture of griseofulvin and isogriseofulvin. The success of all these approaches has yet to be proven in man.

There are basically two types of drugs (41), those in which the sequence of drug concentration in the body and pharmacologic activity coincides and those in which there is a considerable delay. In the former case, rapid onset of pharmacological activity is desired; therefore, a dosage form which permits the drug to be

^a By subject receiving at 12:00 noon a single dose of 125 mg. of microsize griseofulvin Product O followed by alterations in diet.

absorbed rapidly is required. These drugs are usually taken in a single-dosage regimen and may be considered to belong to the fast-action "aspirin" type drugs.

In the second case, where there is considerable delay in pharmacologic response, there is little advantage in rapid drug release from the dosage form as long as release is not delayed to the point of reducing drug absorption. The drugs in this category are usually taken in a multiple-dosage regimen. Griseofulvin fits into this category. The usually recommended treatment with griseofulvin is a multiple-dosage regimen lasting from 4 to 6 weeks.

Gastrointestinal Transit Time—The results of the attempt to vary the gastrointestinal transit time by the use of alterations in diet (red peppers, excess milk, pepperoncini, greasy fried foods, nuts, and alcohol) for the noon meal immediately after ingestion of 125-mg. microsize griseofulvin experimental Product O are shown in Table V. These variant components of the diet were used independently. Red peppers, excess milk, and pepperoni had a diarrhetic effect; excess nuts had a constipating effect; the greasy fried food had a nauseating and a sense-of-fullness effect; and the alcohol had a relaxing effect on the subject.

Product O had a dissolution rate which was slightly faster than that for Product N whose absorption appeared to be impaired by its low-dissolution rate. The percentages dissolved in 30, 60, and 120 min. were 3, 6, and 13%, respectively.

Although these diets may have varied the transit time through the whole gastrointestinal tract, there is little evidence that the transit time through the absorption site was affected much (except in the cases of greasy fried food and nuts), as evidenced by the relatively constant metabolite yield which was comparable to that obtained when the subject had his normal meal. The absorption increased significantly when the irritating diet components were greasy fried foods and nuts.

SUMMARY AND CONCLUSIONS

The effects of six parameters on the physiological availability of orally administered griseofulvin formulations were studied by the use of urinary metabolite excretion data from a single subject. The first parameter, time of dosage administration, had an effect on griseofulvin absorption in the manner of a circadian rhythm, the absorption being least in the morning and the most at noon time. The second parameter, high-fat meal, appeared to be equivalent to a delay in time of dosage administration and subsequently had its effect dependent on the previous factor. The third parameter, dose level, indicated that the percentage absorption of drug was independent of the amount of drug administered. The fourth parameter, particle size, showed that microsize griseofulvin was absorbed about twice as much as regular size griseofulvin. The fifth parameter, dissolution rate of the griseofulvin formulation, had little effect on absorption of griseofulvin as long as the dissolution rate was above that for Product N. The sixth parameter, gastrointestinal transit time, could not be varied enough by dietary means (except in the cases of greasy fried foods and nuts) to affect significantly the residence time of the griseofulvin at the absorption sites.

Obviously, these effects cannot be considered representative of the general population. The urinary metabolite excretion data were in agreement with published blood level data estimation of physiological availability of griseofulvin in formulations for the effect of particle size, high-fat breakfast, and dissolution rate (minority subjects). No published blood level data exist for the time of dosage administration, gastrointestinal transit time, and low-level dose factors. It is inconvenient or impracticable to study these parameters by the blood level method.

Microelectrophoresis and Adsorption Studies of Cholesterol Particles in Bile Salt and Alkyl Surfactant Systems

DANIEL MUFSON* and WILLIAM I. HIGUCHI

Abstract □ As part of a continuing program to understand better the behavior of cholesterol particles in physiological situations, an investigation of the interactions of the cholesterol surface with bile salts and alkyl surfactants was undertaken. Microelectrophoretic techniques and adsorption experiments were employed to characterize the adsorption behavior of these agents. In contrast to the alkyl surfactants, the adsorption of bile salts on the cholesterol particle surfaces was much less than expected in the concentration ranges investigated. These results were initially surprising in light of earlier studies where bile salts were found to inhibit greatly the growth of cholesterol crystals. However, the present data are consistent with the idea that the relatively rigid bile salt molecules can adsorb only onto specific sites on the cholesterol surfaces while the more flexible alkyl surfactants can more readily interact.

Keyphrases □ Cholesterol surface, interaction—bile salts, alkyl surfactants □ Electrophoretic mobility—cholesterol particles □ pH-mobility profiles—cholesterol dispersions □ Microelectrophoresis—cholesterol—bile salts, surfactant interactions □ Adsorption studies—cholesterol—bile salts, surfactant interactions

Cholesterol¹ has been implicated as the cause of many diseases, from atherosclerosis to xanthomatoses. While intensive research has been directed toward the understanding of the role cholesterol plays in these disease states, most of it is of a biological or clinical nature. There is surprisingly little reported work on the quantitative physical chemistry of these systems. For example, even the water solubility of cholesterol was an unknown quantity until recently (1). It, therefore, seems that *in vitro* physical-chemical investigations could be used to advantage to solve some of the very pressing problems of cholesterol deposition, namely, gallstone formation and atherosclerosis.

Cholesterol levels in the body are the results of absorption and synthesis on the one hand and excretion on the other. Removal occurs almost exclusively in the feces *via* the gallbladder. The cholesterol being virtually insoluble in water must be rendered soluble for removal. This function is normally performed by the bile. However, the pathological condition in which cholesterol deposits in the gallbladder, cholelithiasis, is widespread; surgical removal of gallstones is one of the most common operations performed today (2). Gallstone operations today outnumber appendectomies (3). A recent study showed that 59.6% of the women and 41.5% of the men (aged 60 to 100) exhibited gallstones at autopsy (4). "As more people live to develop biliary disease at an older age, surgeons can expect to see and treat an increasing number of patients with difficult

biliary problems, complicated by all the other medical problems common to older patients." (5)

The mechanisms leading to the formation of gallstones are imperfectly understood. This is due in part to the many conflicting reports which are to be found in the literature. Bile is a supersaturated solution of cholesterol. Factors responsible for increasing cholesterol's concentration in the gallbladder bile may lead to its precipitation as stones (6). Stones will show almost infinite variation in their composition, appearance, and physical properties, dependent upon the factors involved in their formation (7). Stasis of the bile, pH changes, irritation, coagulation, infection, and the bile salt-phospholipid-cholesterol ratio are some of the factors intimated in the cholesterol deposition process. These factors often interact to produce stone formation. For example, infection can produce a change in pH and irritation of the gallbladder wall. This may allow the absorption of a significant amount of bile salt through the gallbladder wall, seriously affecting the bile salt-cholesterol ratio. The high energy of the supersaturated system is then relieved by the precipitation of cholesterol.

Stones have been found during surgery (8) which suggested that they were formed by the aggregation of smaller spherical particles of cholesterol. Frey *et al.* (9) have observed clusters of cholesterol crystals in the gallbladders of mice fed a lithogenic diet. Thus it appears that in the later stages of stone formation, aggregation of cholesterol particles plays an important role.

There have been physical-chemical studies concerned with the interactions of bile salts and cholesterol in micellar solutions (10–12), at interfaces (13), and at crystalline surfaces (14, 15).

Saad and Higuchi approached the problem from the point of view of cholesterol crystal growth. The influence of cholate, taurocholate, and glycocholate on the precipitation behavior of cholesterol in aqueous media was investigated as a function of pH (14). The Coulter counter was utilized to follow the particle-size distribution changes with time in the supersaturated and undersaturated cholesterol suspension systems. With increasing pH, the rates of growth and dissolution became progressively retarded, with complete inhibition of these processes at pH 8 and higher. The bile salts seemed to exhibit specificity of action which suggested strong binding to specific sites on the cholesterol crystal surface. Conventional long-chain surfactants, sodium dodecyl sulfate and myristyl- γ -picolinium chloride, at 1% concentration had no effect on the crystal growth rate.

Although surgical observations have suggested aggregation of cholesterol crystals as a mechanism for gallstone growth, this aspect has not been pursued from a colloidal-chemical point of view. It would seem that

¹ Systematic nomenclature for compounds given trivial names in the text includes: cholest-5-en-3 β -ol, cholesterol; 3 α ,7 α ,12 α -trihydroxy-5 β -cholanoyl glycine, glycocholic acid; 3 α ,12 α -dihydroxy-5 β -cholanoyl glycine, glycodeoxycholic acid; 3 α ,7 α ,12 α -trihydroxy-5 β -cholanoyl taurine, taurocholic acid; 3 α ,7 α ,12 α -trihydroxy-5 β -cholanoyl acid, cholic acid.

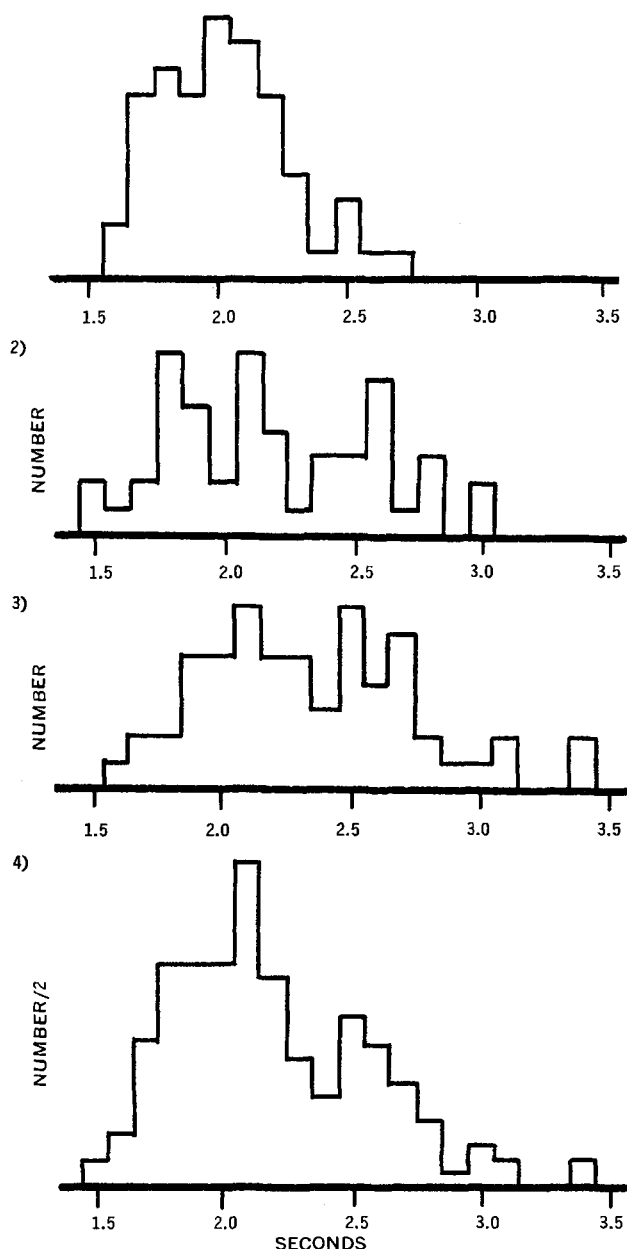

Figure 1—Histograms of the velocity distribution of cholesterol particles in 10^{-2} M NaCl (time required to travel 0.5 division of Zeta-Meter eyepiece): (1), Experimenter I; (2), Experimenter II; (3), Experimenter II (4-day-old sample); and (4), summation of A, B, and C.

such a study of the interfacial chemistry of the crystalline cholesterol-bile salt system should be helpful. An investigation of this nature might yield information concerning the etiology and prophylaxis of cholelithiasis.

Microelectrophoresis can be used as a valuable tool to measure interactions at the liquid-solid interface (16-18). Investigations of cholesterol dispersions by microelectrophoretic techniques have been performed. In 1930, Remezov published a voluminous work on the physical-chemical properties of the colloidal state of cholesterol, cholesterol esters, and lecithin (19-23). It is difficult to interpret and correlate his procedures and data. Moyer (24) found Remezov's directions for sol preparation to be too general to reproduce. Douglas and Shaw (25) studied the effect of pH on the electrophoretic mobility

of cholesterol, finding a substantial increase in mobility as the pH was raised. Seaman investigated the effects of pH and salts on the mobility of cholesterol particles (26).

In the present studies, the effects of both bile salts and alkyl surfactants on the electrophoretic mobility of cholesterol particles have been determined. Adsorption studies on the same systems were used to complement this data and to allow explanation of some of the phenomena observed.

EXPERIMENTAL

General Considerations—Because the goal of this study was to monitor and interpret the surface properties of cholesterol particles in aqueous media, the presence of minute impurities and the manner of preparation of the dispersant were expected to be important. Cholesterol is known to be unstable towards light, heat, and other radiation in the presence of air. Until the advent of thin-layer chromatography, the widespread nature of cholesterol's autoxidation was not realized (27). Many products are produced during autoxidation, almost all of which are more polar than cholesterol. Oxidation of cholesterol in the presence of UV light has been reported to produce acids of unknown structure (28, 29).

The purity of experimental materials is always of importance in studies of surface properties (30-32). The cholesterol dispersions of some earlier investigations had shown a pH-mobility dependency. This is surprising in light of the nonionogenic nature of cholesterol. The effect of pH on the mobility of cholesterol dispersions of varying purity was therefore initiated prior to the studies of the cholesterol-surfactant systems.

Materials—Purified cholesterol was prepared by subjecting commercial cholesterol (Fisher Scientific Co. and Eastman Organic Chemicals) to the dibromination purification procedure of Fieser (33). Upon the termination of this method, the sample was further recrystallized from ether-methanol, ether-ethanol, and ethanol-water. The purified crystalline sample (m.p. 150°) was stored in a refrigerator under nitrogen. It was found by TLC to be homogeneous. The carbon-hydrogen analysis of this material agreed well with theory: theoretical C, 83.37; H, 12.03; observed C, 84.04; H, 11.99.

The IR spectra² of this sample, run in CHCl_3 , agreed with those in the literature (34-36).

Distilled water of $<2 \mu\text{mho}$ specific conductance was employed in all studies.

All inorganic salts were of analytical reagent quality. Most of the organic additives were used as received unless otherwise noted; *n*-octanol (Fisher Scientific Co.), sodium taurocholate (Mann Research Laboratories, Inc., New York, N. Y., and Calbiochem, Los Angeles, Calif.), sodium cholate (Mann special enzyme grade), cholic acid (Eastman), sodium glycocholate [Calbiochem (A grade)], sodium glycodeoxycholate [Calbiochem (A grade)], sodium dodecyl sulfate-³⁵S (Nuclear-Chicago Corp., Des Plaines, Ill.), sodium dodecyl sulfate (supplied by Dr. K. J. Mysels), cholic-carboxyl-¹⁴C acid (Tracerlab, Waltham, Mass.), naphthalene A.R. (J. T. Baker Chemical Co., Phillipsburg, N. J.), 2,5-diphenyloxazole (PPO) (Packard Instrument Co., Inc., Downers Grove, Ill.), octanol-¹⁴C (ICN, City of Industry, Calif.).

Buffers used were prepared by titration of the appropriate components in a beaker. The pH was monitored with a Corning model 7 pH meter.³ Buffers were stored under refrigeration to retard mold growth. Sodium acetate, 1.0 *N*, was added to 10^{-3} M acetic acid to produce pH 5 buffer. A pH 6.8 stock buffer was made by dissolving 0.340 g. of potassium phosphate (KH_2PO_4) and 0.254 g. of sodium phosphate dibasic anhydrous (Na_2HPO_4) in enough water to make 100 ml. One milliliter of this stock buffer was used for each 100 ml. of dispersion. Sodium hydroxide (0.1 *N*) was added to 10^{-2} M boric acid to produce the pH 9 buffer and to 10^{-4} M sodium borate to produce the pH 11 buffer.

Preparation of Dispersions for Microelectrophoresis—Dispersions of cholesterol for microelectrophoretic evaluation were prepared

² Perkin-Elmer model 337, Norwalk, Conn.

³ Corning Glass Works, Corning, N. Y.

Figure 2—The pH-mobility profile of cholesterol (bars represent $\pm 1.96 \sigma$ of the population).

by dilution of concentrated stock dispersions or by precipitation *in situ*.

Stock Dispersion—To prepare 100 ml. of 0.5% w/v dispersion, 500 mg. of the purified cholesterol was first dissolved in 10 ml. of hot ethanol. This solution was subjected to ultrasonic irradiation as 10 ml. of water was quickly added. Irradiation was continued for 30 sec. The resultant dispersion was then added to 80 ml. of water, ultrasonified for 30 sec., treated with nitrogen, and stored in the dark. Twenty-four hours was allowed to elapse before this material was used. Two milliliters of this stock was used to prepare 100 ml. of dispersion containing 0.01% cholesterol. The system was ultrasonified prior to use to disperse any aggregates which may have formed.

In Situ Precipitation—Enough purified cholesterol was dissolved in ethanol so that 1 ml. of this solution yielded a 0.01% dispersion when properly reacted; 1 ml. of water was added to an equal quantity of the alcoholic solution. Ultrasonic energy was supplied during mixing. To this dispersion were added the other components of the study, *i.e.*, sodium chloride, buffer, and test additive.

Electrophoretic Mobility Measurements—The electrophoretic mobility of individual particles was measured by the use of a commercial microelectrophoresis apparatus, the Zeta-Meter.⁴ Descrip-

Figure 3—Concentration-mobility profile of the dodecyl pyridinium chloride-cholesterol (□) and the sodium dodecyl sulfate-cholesterol (■) systems.

⁴ The units of electrophoretic mobility are micron/sec. per volt/cm. Since it is awkward to constantly restate these units, the use of the electrophoretic mobility unit, e.m.u., is proposed; 1 e.m.u. = 1 (micron-cm.)/(volt-sec).

Figure 4—Concentration-mobility profile of cholesterol-bile salt systems: cholate (○), taurocholate (□), glycocholate (Δ), glycodeoxycholate (◊), at pH 6.8.

tions of the apparatus appeared recently (37, 38) and will not be repeated here.

The mobility is determined by measuring the time required for a particle to move over a given distance under a known potential gradient. Twenty particles were observed per experiment. Riddick (39) has stated that: "In tracking colloids to determine average EM or zeta potential, one should select *only* particles which appear to be migrating at very close to average velocity—scrupulously avoiding those which approach maxima or minima. However, some systems will show such extreme variation that selection of *average* velocity is difficult to impossible."

During the course of preliminary work, it was found that the mobility was dependent on location within the cell. As current is passed through the cell, oxidation and reduction take place at the appropriate electrodes. It is then possible for these products to migrate in the cell. The concentration of these materials will be highest in the region of the cell closest to the ends. It is for this reason that all electrophoretic mobility readings were made in the center of the cell. Furthermore, that portion of a sample under investigation that had been used for a mobility measurement was discarded after use. The cell was then thoroughly cleaned and wiped.

All mobility measurements were made at $25 \pm 2^\circ$ unless otherwise stated. Mobility readings were conducted within 72 hr. of sample preparation. Twenty-four hours was allowed for equilibration between cholesterol and the test additives. Electrophoresis systems containing organic liquids, *i.e.*, *n*-octanol, were examined in the glass electrophoresis cell. Earlier tests had shown the glass and plastic cells to yield similar data.

Adsorption Studies—The protocol for adsorption studies was as follows: buffer, sodium chloride, and adsorbate were added to 1.0 g. of cholesterol. The complete adsorption system was shaken on a Burrell shaker at $25 \pm 2^\circ$. One-milliliter aliquots were withdrawn after the suspensions had been filtered through silver membrane filters⁵ (1.2 μ). The 1.0-ml. aliquot was placed into glass scintillation vials containing a dioxane "cocktail" (naphthalene and PPO). The number of counts per minute (c.p.m.) was determined in a Beckman liquid scintillation system.⁶

The cholesterol used for all adsorption studies was prepared by the recrystallization of commercial cholesterol, twice from ethanol and once from ethanol-water. The suspensions used for the adsorption studies were prepared by the following method. The recrystallized cholesterol which had been dried under vacuum was ground in a porcelain mortar. One-gram samples were placed in flasks. The other components of the adsorption system were then added. Grinding was shown not to affect the adsorption properties of the cholesterol.

Throughout all experiments, electrophoretic and adsorption, unless specifically noted otherwise, the ionic strength was maintained at a constant level with $10^{-2} M$ NaCl.

RESULTS AND DISCUSSION

Baseline pH-Mobility Profiles—The distributions of particle velocities in a typical cholesterol dispersion are given in Fig. 1.

⁵ Selas Flotronics, Spring House, Pa.

⁶ Beckman Instruments, Inc., Fullerton, Calif.

Figure 5—The adsorption isotherm of sodium dodecyl sulfate (●) and sodium cholate (□) on cholesterol.

Note that the average velocities are quite similar, yet the distributions are broad, and in agreement with the observations of Seaman (26) who found the mobilities of alcohol-precipitated cholesterol particles in a given batch to exhibit considerable scatter. Electrophoretic data reported in the literature usually signify the average mobility of 20 particles in a single experiment. Due to the broad distributions encountered in the cholesterol system, it was decided to repeat each experiment several times and record the mean of the mean mobilities. (The standard deviation was generally ≤ 0.5 .)

Figure 2 shows the influence of pH on the electrophoretic mobility. As can be seen, there appeared to be little or no influence of buffer concentration upon the mobility at constant pH. It is of interest to compare these results with those of Seaman (26), Moyer (24), and Douglas and Shaw (25). At high pH's, Douglas and Shaw found e.m.u. values as high as -5 . These are contradictory to the authors' results and to those of Seaman. The large mobility observed by Douglas and Shaw may have been related to the presence of oxidation products of cholesterol. Aging and heating of cholesterol were found to increase the pH-mobility dependence of cholesterol (40).

Effects of Bile Salts and of Alkyl Surfactants on the Electrophoretic Mobility of Cholesterol Particles—Figure 3 shows the concentration-mobility profiles for cholesterol particles in the sodium dodecyl sulfate-cholesterol and the dodecyl pyridinium chloride⁷-cholesterol systems for which substantial mobility dependencies upon concentration were noted. Similar experiments with hexadecyl pyridinium chloride and dodecyltrimethylammonium bromide showed that the

⁷ Purified by extraction and recrystallization (41).

Figure 7—The effect of octanol (●), 10^{-3} M sodium cholate (□), and octanol-sodium cholate (△) on the pH-mobility profile of cholesterol (○).

large concentration dependencies are typical of the alkyl surfactants.

Figure 4 gives the concentration mobility profiles of cholesterol particles in bile salt systems. It is of interest to note that although these salts have different side chains and varying numbers of hydroxyl groups on the four-ring nucleus, they all have similar concentration effects on electrophoretic mobility. This similarity might be related to the fact that although the hydrophilic portions are different, the hydrophobic "backs" of all these bile salts are nearly the same (42).

It was, however, surprising that the electrophoretic mobility produced by all the bile salts remained rather small even at the highest bile salt concentrations. These results initially appeared contradictory to the earlier findings based upon the studies of cholesterol crystal growth inhibition by cholates which suggested strong interaction of bile salt anions with the cholesterol surface. However, as will be seen, these data are consistent with the idea that cholates may exhibit limited adsorption on cholesterol surfaces while conventional long-chain alkyl surfactants are able to adsorb more generally.

Adsorption Studies—Figure 5 represents the data on the adsorption of sodium dodecyl sulfate and of sodium cholate from aqueous solutions onto cholesterol. Experiments at 1×10^{-3} M cholate were not meaningful because of the large uncertainties in the calculated amounts adsorbed at high concentration.

These results show that cholate reaches an adsorption plateau at around 10^{-5} M. This plateau is reached at the same concentration levels used previously in the Coulter counter studies of crystal growth inhibition. These results are also consistent with the micro-

Figure 8—The effect of octanol concentration on the adsorption of 10^{-5} M sodium cholate on cholesterol (80% saturated octanol solution signifies that 80 ml. of saturated solution has been added to an electrophoretic or adsorption system which contains a total of 100 ml.).

Table I—Effect of Octanol on the Mobility of the Sodium Taurocholate–Cholesterol and Sodium Dodecyl Sulfate–Cholesterol Systems at pH 6.8

	— e.m.u.
Taurocholate (10^{-3} M)	1.92
Taurocholate (10^{-3} M) + octanol	4.44
Sodium dodecyl sulfate (10^{-3} M)	6.86
Sodium dodecyl sulfate (10^{-3} M) + octanol	7.22
Sodium dodecyl sulfate (10^{-4} M)	2.35
Sodium dodecyl sulfate (10^{-4} M) + octanol	2.65

electrophoretic data in which the bile salts showed very little change in effect on mobility over the range of concentrations studied.

For sodium dodecyl sulfate, adsorption increased sharply between 10^{-6} and 10^{-4} M, and reference to Fig. 3 indicates that adsorption should continue to increase up to about 10^{-3} M. Thus it appears that the adsorption plateau of sodium cholate occurs at a relatively low surface coverage and is consistent with the microelectrophoretic data present in Fig. 4.

Influence of Octanol and Other Additives on the Adsorption Behavior of Cholates—The low electrophoretic mobility of cholesterol particles in cholate solutions (Fig. 4) and the low extent of adsorption of cholates onto cholesterol (Fig. 5), in contrast to the behavior of the alkyl surfactants, suggested that cholates, probably because of their rigid nuclear structures, cannot be accommodated conveniently by all sites on cholesterol particle surfaces. This idea suggested that an investigation of the influence of additives upon the adsorption behavior of the cholates might be worthwhile, particularly in light of the observation that an unpurified sample of sodium taurocholate gave much higher limiting electrophoretic values than the purified sample (Fig. 6).

Thus the influence of a large number of compounds upon the electrophoretic mobility of cholesterol particles in cholate solutions was investigated (40). It was found that only octanol substantially altered the electrophoretic behavior at 10^{-3} M cholate. As can be seen in Fig. 7, octanol did not increase the electrophoretic mobility of the cholesterol particles. However, in combination with millimolar cholate, electrophoretic mobility values as large as those obtained with the alkyl surfactants were observed. It is noteworthy that the influence of octanol upon the electrophoretic mobility was negligible at 10^{-4} M cholate.

Experiments were also carried out to determine the influence of octanol on the adsorption of cholate. However, due to large uncertainties, meaningful data were obtained only for cholate concentrations up to 10^{-4} M cholate. Figure 8 shows that at 10^{-5} M cholate, octanol actually reduced the adsorption of cholate upon the surface of cholesterol. Similar results were obtained at 10^{-4} M cholate.

These findings suggest strongly that octanol is an inhibitor for cholate adsorption at low concentrations, but at high cholate concentrations it is able to assist in the adsorption of cholate. At low cholate concentrations, octanol may compete with cholate for those sites that would normally accommodate cholate; at high cholate concentrations ($> 10^{-3}$ M), octanol may act as a mediator.

The extent of the mediation which occurs at the higher cholate concentration might be expected to be greatest in a system where both the adsorbent and the adsorbate are rigid molecules as in the case here. Indeed it was found (Table I) that octanol had relatively little effect upon the electrophoretic mobility of cholesterol particles in sodium dodecyl sulfate solutions. It is worthwhile to recognize that many biological situations can involve such "three body" interplay, e.g., cholesterol–protein interactions might be enhanced by the presence of flexible lipid molecules.

Dissolution of Poorly Water-Soluble Drugs I: Some Physical Parameters Related to Method of Micronization and Tablet Manufacture of a Quinazolinone Compound

SAUL S. KORNBLUM and JEFFREY O. HIRSCHORN

Abstract □ An investigation was conducted to analyze the dissolution behavior of a poorly water-soluble drug. Two specific methods of micronization were employed which provided drug forms of different physical characteristics, specific surface area, and particle-size range. The drug, a quinazolinone compound, was micronized by employing spray drying and air attrition. The micronized drugs, pelletized pure drugs, and tablets prepared from same by direct compaction were subjected to dissolution-rate studies at pH 1.2 and 3. *In vitro* dissolution data obtained have demonstrated a significant variation for the pure spray-dried and air-attritioned drugs at pH 1.2, although physical specifications had suggested the contrary of that reported. The pure drug forms, when pelletized, resulted in elimination of the difference observed for dissolution rates with the pure drug powders. Dilution of the pure drugs with tablet excipients and subsequent direct compaction into tablets resulted in an improvement of dissolution behavior compared to that obtained with the pure drug forms.

Keyphrases □ Dissolution behavior—poorly water-soluble drugs □ 1 - Isopropyl - 7 - methyl - 4 - phenylquinazolin - 2(1H) - one—dissolution □ Micronization effect—poorly water-soluble drug □ Spray-drying effect—poorly water-soluble drug □ Pellets, poorly water-soluble drug—dissolution

During the past decade, numerous publications have related biological availability data with the particle size of various drugs which are orally administered. The importance of the technological understanding and improvement of the dissolution rate for poorly water-soluble drugs has been well documented (1). *In vitro* dissolution-rate information has readily permitted distinction between different dosage forms containing the same drug with relationship to their gastrointestinal absorption characteristics. Solubility rate of a substance has been quantified directly to surface area for nearly a century (2). Reduction to a smaller workable particle-size range for poorly water-soluble drugs has been the general practice during the past decade. The research pharmacist, when formulating a solid or liquid dosage form of an insoluble drug, has relied upon a variety of processes, *i.e.*, grinding, air attrition, ball milling, and controlled precipitation, to obtain the ultimate in particle-size reduction. Air attrition has gained the most widespread acceptance, which has led to the availability of a variety of fluid energy mills (3).

A review article (1) was recently published which dealt in depth with particle size of drugs and its relationship to absorption and activity. Sulfadiazine, griseofulvin, and sulfaethidole (4–6) are a few of those compounds studied in an effort to establish the clinical effect of reduced particle size.

The twofold purpose of the present research was to study the dissolution behavior for a pure water-insoluble drug, which was micronized by spray-drying and air-attrition processes, with a compressed dosage form of the same, and to investigate the acceptability of spray

drying as an alternative method for the preparation of micron-sized particles. Dissolution behavior has been compared for both physical forms with relationship to two different physical parameters: particle-size range and specific surface area.

EXPERIMENTAL

Spray-drying and air-attrition processes were selected for the manufacture of micron-sized particles of a poorly water-soluble drug. Spray drying appeared interesting to study in this instance, since it was thought that the process would impart certain desirable physical characteristics not typical of air-attritioned material such as unrestricted particle flow and ease of uniform dispersion of hydrophobic particles in an aqueous system as well as the possible presence of small holes in the spherical particles which would provide additional surface area.

Materials—1-Isopropyl-7-methyl-4-phenylquinazolin-2(1H)-one was synthesized in accordance with quality control standards for a pure drug.¹ The drug chosen for this study is indicative of a heterocyclic nitrogen base which does not readily form salts except at extremely low pH. The saturation concentration of the spray-dried and air-attritioned drugs in distilled water with a pH 6.0 and after 6-hr. exposure was found to be 2.7×10^{-4} moles/l. at 37° employing a rotational dissolution apparatus. Initially, the drug was twice passed through a laboratory hammer mill² which utilized a plate with 1-mm. perforations. The drug was then micronized by air attrition, employing a conventional fluid energy mill.³ The micronized drug exhibited large particle aggregates which resulted from the high degree of surface energy developed by particle friction during processing. Additional drug from the same batch was used for preparing material by a spray-drying process which is described in the next section.

Spray-Drying Process—A 50-g. quantity of the quinazolinone compound was dissolved in 50 ml. chloroform, reagent grade, employing mechanical stirring. Special denatured alcohol (90% ethyl alcohol–10% methyl alcohol) was added to bring the solution to 125 ml.

A portable laboratory spray dryer⁴ equipped with a centrifugal atomizing wheel, which functioned from air-turbine drive with a velocity of about 40,000 r.p.m., was employed in this study. The heated chamber of the spray dryer was maintained at 100–120° and the outlet temperature at 75–85°. The drug solution was introduced to the atomizing wheel by employing a Sigmamotor pump⁵ which was adjusted to a flow rate of 15 ml./min. A cyclone collector separated the spray-dried drug from the solvent system. The solvent was not recovered; however, if scale-up was considered, a solvent-recovery method could be designed. The micron-sized drugs were both stored in tightly closed glass containers.

Physical Form and Particle-Size Range of the Pure Drug Forms—The particle-size range for the spray-dried and air-attritioned quinazolinone compounds was determined by a photomicroscopic method utilizing a grid graduated in microns. Observation of the photographs of the spray-dried drug depicted sphere-shaped amorphous particles which ranged in diameter from 1 to 15 μ . The irregular crystalline fragments of the air-attritioned drug measured from 1 to 5 μ .

⁵ Sigmamotor, Inc., Middleport, N. Y.

Specific Surface Area of the Pure Drug Forms—The spray-dried and air-atritioned quinazolinone compounds were subjected to the classical low-temperature adsorption Brunauer, Emmett, and Teller (B.E.T.) technique⁶ for specific surface area measurement. Krypton gas was used as the adsorbate. The method permitted sample outgassing to less than 1 μ of pressure. One-gram samples of the spray-dried and air-atritioned materials were heated to 50° and outgassed for 8 hr. to evacuate gasses and vapors acquired from exposure to the atmosphere. The surface area analysis involved incremental gas volume adsorption measurements which were made by accurately determining the equilibrium pressure following the introduction of gas quantities into the system. The specific surface area was found to be 1.37 m.²/g. for the spray-dried drug and 2.78 m.²/g. for the air-atritioned drug.

Pellets of the Pure Drug Forms—A comparative study was designed to determine the effect on dissolution when the two pure drug forms were compressed into pellets. Fifty milligrams of the drug was compressed using a single station tablet press,⁷ employing 6-mm. shallow-concavity punches. Each pellet was formed with a thickness that was maintained at 1.80 mm., which assured equivalent surface area for both materials tested. Although the hardness was measured as 3 kg. with an air-operated Strong-Cobb tester, the pellets did not fracture during the dissolution runs but remained intact with slow dissolution.

Tablet Manufacture Employing Spray-Dried and Air-Atritioned Quinazolinone Compounds by Direct Compaction—The composition for tablets manufactured by direct compaction (D.C.) utilizing spray-dried and air-atritioned drugs are given in Table I.

Direct Compaction Manufacturing Procedure—The ingredients listed in Table I were accurately weighed and passed through a No. 20-mesh screen. The materials were transferred to a glass mortar and gently blended so that the drug's particle structure would not be altered. Then 160 mg. of the blended powders was placed into the die cavity of the single station tablet press and compressed, using 8-mm. flat, beveled-edge punches. The tablet hardness was maintained at 6.5 ± 0.5 kg. which was monitored by using a compressed air-operated Strong-Cobb tester. The tablet thickness was measured using a micrometer; each tablet employed in this study had to adhere to a measurement of 2.75 ± 0.01 mm. This physical measurement assured compliance of each tablet to the hardness range established for this study. The direct compacted tablets were subjected to the USP disintegration test and were found to disintegrate within 25 ± 5 sec. These tablets were formulated to give fast disintegration in an attempt to observe uninhibited drug dissolution. Tablet disintegration occurred with the rapid formation of discrete particles of drug-diluent which resulted from rupture of the tablet matrix.

Dissolution Rate Analysis of the Pure Drugs, Pellets, and Tablets—The dissolution apparatus that was initially employed in this study was the beaker-stirrer method. The poor wetting property exhibited by the pure drug forms required selection of another method that would permit a more uniform contact of solvent and powders. The rotating-bottle method was found most suitable for attaining reasonably precise data for consecutive experiments, whereas with the beaker-stirrer method it was not possible. Preliminary experiments revealed that 20 r.p.m. was a suitable speed for demonstrating definite differences in dissolution behavior for the pure materials investigated. Rotational rates less than 20 r.p.m. did cause a substantial decrease in the dissolution rate from that reported in this paper. Each sample bottle was immersed in a water bath maintained at $37 \pm 0.5^\circ$. The powder, pellet, or tablet was placed in a 75-ml. capacity, amber glass bottle containing 50 ml. of aqueous solvent which had been previously adjusted to a pH of 1.2 or 3 with hydrochloric acid. The solvent had been preheated to 37° prior to the addition of the sample. At the moment of sample addition, the time was recorded as $t = 0$. The vessel was tightly closed with a bakelite cap lined with a polyethylene sealer. Dissolution of the drug and tablets was studied over a 30-min. interval, and each sample was carried through a 60-min. period to establish whether total availability of the drug in solution was reached. Preliminary studies indicated that a 60-min. test period was sufficient, since two half-lives were encompassed which permitted valid comparison of the $t_{25\%}$, $t_{50\%}$, and $t_{75\%}$.

Table I—Tablet Composition for D.C. Tablets Prepared from Spray-Dried and Air-Atritioned Quinazolinone Compounds

Materials	Quantity per 160-mg. Tablet
Isopropylmethylphenylquinazolinone, spray-dried or air-atritioned	50.0 mg.
Microcrystalline cellulose ^a	25.0 mg.
Colloidal silica ^b	0.5 mg.
Corn starch USP	12.0 mg.
Lactose, spray-dried USP	69.5 mg.
Stearic acid powder USP	3.0 mg.

^a Avicel, FMC Corp., Marcus Hook, Pa. ^b Cab-o-Sil, Cabot Corp., Boston, Mass.

The dissolution studies for the pelletized substances were carried out for 6 hr. at pH 1.2 in the same manner employed for the tablets. A quantity of 50 mg. of the quinazolinone compound was chosen since it represented a concentration below the aqueous saturation point of 60.5 mg./50 ml. at pH 1.2. The closer the quantity of drug in solution is to the saturation equilibrium the slower the approach to total solubility. The present investigation included the following test samples: 50 mg. spray-dried and air-atritioned drugs. In addition, pellets and tablets were studied which contained 50 mg. of spray-dried and air-atritioned drugs. These materials were all subjected to the outlined dissolution rate analysis at pH 1.2 and, in most cases, pH 3.

Nonsink conditions were employed in these experiments to observe the dependence upon limited hydrogen-ion concentration as related to dissolution. An unusual situation was observed: the pH's of the systems at the termination of the dissolution runs did not vary more than ± 0.1 unit from the starting value for both pH 1.2 and 3. This was explained by the particular pK_a of the drug, which was determined by spectrophotometric and solubility-pH data to be 2.51.

The analytical details of the dissolution experiments involved the withdrawal of a 1-ml. sample at the specified time interval using a pipet with filter-tip. The aliquot was diluted with the specified acid solution, utilized in the dissolution study, to 100 ml. The adsorption of the diluted solution was measured in a Cary recording spectrophotometer over the UV spectra, and the maximum absorbance at 232 m μ was used to calculate the drug concentration per 50 ml. of test solution. A correction factor was calculated for each sequential sampling as a result of the volume change that occurred because the test solution withdrawn for the pellet and tablet runs was not replaced after each sampling.

Individual sample containers were employed for the pure drug forms for each time segment; otherwise, some of the drug would have adhered to the filter-tip of the pipet with each withdrawal, which would have introduced a recurring error.

RESULTS AND DISCUSSION

The quinazolinone compound utilized in this study may be classified as a heterocyclic nitrogen base which exhibited poor aqueous solubility that was shown to be a function of hydrogen-ion concentration and method of micronization. The drug undergoes solubilization by interaction with hydronium ion to form a salt.

The concentration of the compound (mol. wt. 278) at 50 mg./50 ml. was calculated to be 3.6×10^{-3} moles/l. The unprotonated form of the compound formed a saturated solution in distilled water with a concentration of 2.7×10^{-4} moles/l. The hydrochloric acid solution at pH 1.2 contained about 6.3×10^{-2} moles/l. hydrogen ion, which provided about an 18 times greater hydrogen ion than the concentration of the compound. Therefore, complete solution of the 50 mg. at this pH was obtained. At pH 3 the hydrogen-ion concentration was about 1×10^{-3} moles/l., which limited the solubility of the compound since there was a fourfold excess of drug over hydrogen ion. Henceforth, one would expect only about 13 mg. of the compound to go into solution in the protonated form at pH 3. This approximates the values recorded in Table II, which were obtained experimentally.

The dissolution data obtained for the spray-dried and air-atritioned drugs at pH 1.2 and 3 can be compared by observing Table II. The spray-dried and air-atritioned drugs possessed dissimilar particle-size distributions in the low micron range. These

data indicate that at pH 1.2 an increase in dissolution rate was observed for the drug when micronized by spray drying as compared with the air-attritioned form. The results were unexpected since the specific surface area of the air-attritioned drug was determined to be twofold that found for the spray-dried drug. The apparent surface area of a poorly water-soluble material in contact with the aqueous medium appears to be unrelated to its specific surface area. Based on this factor, correlation of specific surface area with dissolution behavior without experimental verification could be quite deceptive. It was thought possible that the smaller air-attritioned particles were not subjected to the same intensity of agitation as were the large spray-dried particles; however, by physical observation it was quite apparent this was not the case. In fact, the air-attritioned drug had a definite tendency to form large particle aggregates which diminished the surface area, thereby resulting in a dissolution rate that was less than expected. Furthermore, it was also possible that surface hydration and solubility characteristics varied for both physical forms as a result of their different physical characteristics.

Pellets prepared from the spray-dried and air-attritioned materials, possessing equal surface area, were evaluated with regard to their respective dissolution rates, and Fig. 1 indicates the results obtained. The intended incorporation of the drugs, at a later stage, into a tablet matrix required an interpretation of the interparticle bonding forces that existed for each of the physical drug forms. If the specific particle structure of the drug resulted in dissimilar interparticle adhesion, subsequent inclusion into a tablet could possibly influence the dissolution behavior. The interparticle adhesion that occurs in a solid system may result from either partial fusion or partial dissolution at the surface of the particles induced by energy added during the compression (7).

From Fig. 1 it appears evident that pellets from the two physical drug forms have no significant difference in their dissolution rates.

Figure 1—Apparent zero-order dissolution rates of pelletized spray-dried and air-attritioned drugs were performed in 50 ml. aqueous solution at pH 1.2. 60	46.4	13.0	50.4	12.9

^a Represents the average of three experiments with standard deviation of not more than 1.1 for all data recorded.

An apparent zero-order equation for the dissolution data for both pellets was adhered to, which is in accord with the experimental conditions of constant dissolution surface area. By pelletizing the drug forms, the variation of surface wetting observed with the pure drug powders was eliminated. This phenomenon resulted in a need for clarification of the effect on dissolution when the pure drug form was diluted with common tablet excipients and then compressed into tablets.

The experiments designed to study the effect on dissolution with the drug forms in directly compressed tablets revealed certain definite departures from the results obtained with the pure drugs. The direct compaction method was utilized to prepare the tablets, since it permitted dilution of the drug without significant alteration of their physical forms. For this reason, the wet granulation method data were not included in this paper since it was shown to manifest additional complexities in following dissolution of the drug. A retarding effect on dissolution was experienced as a result of materials utilized in wet granulation, *i.e.*, granulating liquid and water-insoluble excipients, which tend to form a barrier layer on the surface of the drug particles during the granulating process.

The physical parameters, *i.e.*, tablet disintegration and thickness, were strictly controlled for the tablets prepared by direct compac-

^a Each time interval was determined from the plotted data in Fig. 2.

tion. The tablets were formulated to give rapid disintegration, 25 ± 5 sec., in an attempt to observe uninhibited drug dissolution.

Dissolution data obtained for both sets of direct compacted tablets manufactured from the two drug forms have been tabulated in Table III for pH 1.2 and 3.

The dissolution rate obtained for the tablets prepared from air-attritioned and spray-dried drug proved to be quite similar in dissolution behavior (Fig. 2). These results indicate a substantial change from the comparative dissolution rates obtained with the pure air-attritioned drug under the same experimental conditions. The incorporation of the air-attritioned drug into a tablet matrix resulted in omission of the particle aggregates experienced with the pure drug. In addition, the improved dissolution rates for the tablets were probably a result of the hydrophilic property of the solid system and the increased surface area of the drug due to the force of compression.

Dissolution data obtained with the spray-dried drug and tablets of the same at pH 1.2 appear to have parallel dissolution patterns. The dissolution behavior experienced with both tablets compares more closely with the particle size and specific surface area data obtained for the pure drugs.

Table IV provides a tabulation of the time required for the dissolution of 25, 50, and 75% of the drug from both the powders and tablets, which is a convenient method for comparing dissolution data. The solid systems studied in this research were too complex for the application of reaction-order equations and, if utilized, would have possibly led to their misuse.

SUMMARY AND CONCLUSIONS

The results of dissolution studies at low pH provided information that rationalized the practical application of spray drying for the micronization of poorly water-soluble drugs. The air-attritioned drug had a tendency to form large particle aggregates which hindered its apparent dissolution rate in the pure form. In addition, the air-attritioned particles differed from the spray-dried inasmuch as they possessed a high degree of surface energy which gave rise to their sticking to each other and the sides of the storage container. Difficulty existed in handling and formulating the drug into the various forms.

The significantly greater dissolution rate that was observed for the pure spray-dried drug at pH 1.2 despite the smaller particle-size range of the air-attritioned drug would lead one to criticize the selection of a particular physical form of a poorly water-soluble drug by analyzing only physical dimension data. Particle-size range and specific surface area measurements for different physical forms of the drug studied were misleading and quite unrelated to their dissolution behavior. More pertinent is the apparent surface area of the drug available for solvent wetting for a poorly water-soluble material. The apparent surface area was not directly measured in these studies; however, dissolution is an indirect approach to the matter. The large particle aggregates, such as those observed with the air-attritioned drug, interfered with the apparent dissolution rate and gave data that would not normally be expected.

With this hydrophobic drug, it was found that the rotating-bottle method permitted acceptable reproducibility of the dissolution results. On the other hand, the beaker-stirrer method failed in this aspect as a result of discontinuous wetting of the powder by the

acidic medium. With the appearance of a variety of dissolution systems in the literature (8), the authors would like to emphasize that the ability to repeat an experiment and obtain valid reproducibility should be the prime objective. A base line for dissolution behavior should always be established with the pure drug powder by employing an *in vitro* dissolution technique, and this should be done prior to fabrication of the dosage form. In this manner, the necessary properties of the tablet or capsule matrix can be more accurately determined.

The quinazolinone compound studied was insoluble in distilled water; however, by reducing the pH, limited solution did occur. The heterocyclic nitrogen in the quinazolinone structure was protonated in solution and the lower the pH of the aqueous system, the greater was its total solubility under nonsink conditions.

The dissolution data obtained for the two pure drug forms could have resulted in selection of the spray-dried drug for use in a solid dosage form; however, with additional experimentation employing a compressed tablet formulation, greater insight was obtained. Incorporation of the drug powders into a compressed tablet was helpful in clarifying possible false conclusions that could have been drawn from the dissolution data for the pure drugs. The dilution factor which resulted when the air-attritioned drug was combined with tablet excipients decreased the interparticle aggregation effect experienced with the pure form. When the tablet was placed in the aqueous medium, it released discrete particles, composed of drug and diluent, upon disintegration. This phenomenon greatly improved the dissolution behavior for the air-attritioned drug in the tablet form, since the discrete particles eliminated the particle aggregation observed with the pure drug powder. The dissolution rates for the pure spray-dried drug and tablets (Fig. 2) were not greatly different, since particle aggregation was not operative during the powder's dissolution experiments. The tablet diluents employed for the compressed tablets were selected where possible for their water-soluble or hydrophilic properties. This particular consideration can assist the diffusion-dissolution-diffusion processes required for dissolution of a drug from the discrete particles resulting from tablet disintegration. Water-insoluble components in the tablet matrix would tend to retard the overall dissolution process of a poorly water-soluble drug. This aspect has been utilized in the design of sustained-release dosage forms by employing a water-insoluble material to reduce dissolution rate. When a tablet disintegrates, the discrete particles formed should be as hydrophilic in property as possible in order to assist the dissolution process.

The variation of dissolution behavior shown in this paper for the pure drug, and tablets of same, underline the fallacy of performing dissolution rate analysis with various physical forms of the pure drug without inclusion of a proposed solid dosage form in such studies. The early initiation of preformulation kinetic studies for new drugs quite often incorrectly forces one to select the supposed best physical form of a drug prior to the consideration of dosage form research. The physical form and its dissolution behavior must be considered by the research pharmacist in organizing the development protocol for new drugs which fall into the category of poorly water soluble.

Controlled Drug Release through Polymeric Films

A. L. FITES, G. S. BANKER, and V. F. SMOLEN

Abstract □ The drug-permeability properties of several water-insoluble films were studied with respect to their potential application for the control of drug release from solid pharmaceutical dosage forms. Films composed of poly(methylvinylether)-maleic anhydride copolymer, crosslinked with polysorbate 20 (Tween 20), appeared as the most promising of the systems studied for the film-controlled drug-release applications. The permeability of the films can be controlled by appropriate adjustment of their polysorbate 20 content, molecular weight of the polymer, and humidity pretreatment. The permeability of the films was, however, found to be affected also by the pH of the diffusion medium.

Keyphrases □ Drug release, controlled—through polymeric films □ Polysorbate 20 effect—polymeric film formation □ Polymeric films—drug permeability □ Permeability coefficients—polymeric films □ Diagram—permeation cell □ UV spectrophotometry—analysis

The importance and pharmaceutical applicability of polymer films are well established in providing protective coatings and controlling drug release from oral dosage forms. In general, two basic factors may be involved in the film-controlled release of medicaments; *i.e.*, the dissolution of the film in the gastrointestinal fluids and its permeability (1, 2). With insoluble films, which maintain their integrity in traversing the gastrointestinal tract, only the latter need be considered. Therefore, the application of an insoluble film coat of desired permeability characteristics to an ordinary compressed tablet could conceivably be utilized to control drug release. This method would be advantageous in its economy and simplicity, provided predictable and controllable release rates are attainable.

In the present study, several synthetic polymeric films were investigated with respect to their drug-permeability properties for the purpose of determining their feasibility for controlled drug-release applications. One film which appeared promising was further investigated with respect to the factors influencing its permeability.

MATERIALS AND METHODS

Polymers, Drugs, and Diffusion Media—Table I describes the polymer systems used in this study. These systems were selected primarily on the basis of the insolubility of the resulting films in gastric and intestinal fluids. The cellulose acid phthalate (CAP) film system contains the maximum amount of plasticizer, PEG 400, consistent with insolubility of the film and absence of tackiness. The proportion of ethylcellulose (EC) to the methylcellulose (MC) was chosen, on the basis of preliminary studies, to produce a maximum permeability and insolubility. The observation in this laboratory that the addition of polysorbate 20 (Tween 20) renders the otherwise soluble poly(methylvinylether)-maleic anhydride (PVM-MA) films insoluble was the basis for its inclusion in this study.

Caffeine was chosen for these studies due to its relatively non-ionogenic nature, stability, and ease of assay. Nicotinic acid was also used as a model drug in some of the preliminary experiments.

Figure 1—Permeation apparatus employed in the study of drug permeation through free films. Key: 1, adjustable cell clamp; 2, 120-ml. amber bottle; 3, 600-ml. beaker; 4, polyethylene gaskets; 5, screw cap; and 6, film sample.

The media in which the drugs were allowed to diffuse consisted of distilled water and buffer solutions of the following composition:

pH	Composition (mmole/l.)	
1.30	HCl, 1.4	NaCl, 34.2
5.83	KH ₂ PO ₄ , 25	NaOH, 1.8
7.20	KH ₂ PO ₄ , 25	NaOH, 17.4

The pH values of the solutions approximate that of gastric and intestinal fluids.

Permeation Cells—Figures 1 and 2 illustrate the permeation cells and the experimental arrangement. The cells consisted of approximately 120-ml. glass screw-capped chambers. The polymer films were placed between two polyethylene gaskets and were held in place by the plastic screw caps which were drilled to contain a 1.91-cm. (0.75-in.) diameter opening. These cells were inverted into their respective 600-ml. beakers, which contained the receiving medium for the diffusing drugs, where they were held by lucite clamps which allowed adjustment of their depth in the beakers. The medium in each beaker was maintained at 37° and was agitated with a magnetic stirrer employing the setup described in Fig. 2. The magnetic stirrers were connected to a central control; each was synchronized to 325 r.p.m. with a strobe timing light and was rechecked periodically. Fluctuation was minimized during operation by use of a voltage stabilizer and by allowing a warm-up period before proceeding with an experiment.

Preparation and Treatment of the Film—The films of composition listed in Table I were prepared by a casting technique employing a glass substrate. A fixed area on the smooth glass surface was marked off with masking tape. In each case the polymer was evenly spread into the area with a brass film-casting knife as described by Munden (3). The resulting film possessed a uniform thickness, which was controlled by adjustment of the blade level in the film-casting knife and by the number of tape layers. The average thickness of completed films was determined with a micrometer.¹

Prior to testing, all films were stored over anhydrous calcium sulfate² under vacuum at 25° for a minimum of 48 hr. In addition, the PVM-MA films were stored for precisely 48 hr. at a humidity of 52.4%, maintained by a saturated solution of sodium bromide at 41°.

Procedures—The pretreated polymer film was secured in the cell which was immersed into the beaker containing 400–500 ml. of the receiving medium, either distilled water or buffer solution, previously equilibrated to 37°. The upper chamber of the cell was filled with drug solution, usually 25 ml., and covered; the level of the fluids was adjusted to the same height to prevent a hydrostatic pressure difference between the two compartments. Four units of this type were set up in the same thermostated water bath and agitated as described previously.

At selected time intervals over an 8- to 10-hr. period, samples of the receiving media were removed and assayed spectrophotometrically for transferred drug. The samples were read on a Beckman DU spectrophotometer at 273 and 262 m μ for caffeine and nicotinic acid, respectively. The blank consisted of fluid taken from a cell containing only the diffusion medium. The volume of sample removed from the receiving chamber was, in each case, replaced by an equal volume of diffusion medium. Six to eight replications were performed on each run. When linear relationships were expected, the data were treated by the method of least squares and the lines of best fit were reported.

RESULTS AND DISCUSSION

Preliminary Screening of Film Systems—The selection of films for further study of their permeability properties was primarily based upon a preliminary study of selected film formulations. The results are presented in Table II and Fig. 3.

The permeability of the cellulose acetate phthalate films studied was severely limited, as is apparent from the relatively small

quantities of the drug that traversed the films over the 8-hr. period. Although plasticization of the CAP films by the inclusion of polyethylene glycol 400 (43% w/w polymer) produced approximately a tenfold difference in drug permeability relative to the un-plasticized film, total drug permeability in the plasticized film was still less than 3%. The increase in permeability was likely a consequence of the unbound water-soluble plasticizer being leached from the membrane. The practical upper limit of polyethylene glycol content in the films was 43%. Higher concentrations imparted tackiness to the film.

Ethylcellulose produced films which were quite brittle and showed negligible drug permeability. The addition of methyl(hydroxypropyl)cellulose to the ethylcellulose film enhanced film clarity, decreased brittleness, and increased drug permeability.

The addition of methyl(hydroxypropyl)cellulose improved the overall properties of the ethylcellulose films, particularly with regard to brittleness. However, the films were observed to lose their integrity at methyl(hydroxypropyl)cellulose contents greater than that contained in the tested film (58% w/w polymer). This was quite apparent from the rapid passage of the drug across the disintegrating films.

Prior to the 2-hr. period, a relatively small quantity of drug was found to permeate the untreated PVM-MA film (Table II and Fig. 3). The rate of drug passage became greatly accelerated between

2 and 4 hr. The increase in permeability is attributed to the observed swelling of the film resulting from the hydration of acid anhydride groups on the polymer. In addition to a Donnan-type swelling effect (4), a polymer chain expansion likely arises from the mutual electrostatic repulsion of the resulting ionized carboxyl groups (5). The effect serves to diminish further the consolidation of the membrane and thereby increases its permeability. The apparent acidic pK's of the carboxyl groups have been reported (5, 6) as having values of 4.85 and 8.95. The swelling of the films may therefore be expected to become increasingly pronounced with an increase in pH of the diffusion media.

It was found that the initial delay in the enhanced permeability of PVM-MA films could be essentially abolished through pretreatment of the films by storage in a humidity chamber, for 48 hr., at 25°

Figure 4—Permeation of caffeine through PVM-MA 169 polymer films in distilled water and pH 1.30 buffer solution as influenced by the polysorbate 20 content and thickness of the films. At pH 1.30 the films studied included polymer: polysorbate 20 weight of 9:1 (—●—), 2:1 (—▲—), and 1:1 (—■—), with corresponding thicknesses of 0.069, 0.071, and 0.066 mm., respectively. In distilled water the films included were 4:1 (—○—), 2:1 (—△—), and 1:1 (—□—) with corresponding thicknesses of 0.068, 0.068, and 0.066 mm., respectively.

Table III—Permeation (*P*) and Correlation (*r*) Coefficients for PVM-MA Films of Varying Weight Ratio of Polymer to Polysorbate 20 (*R*)

^a *P* is defined by Eq. 3 and has units of hr.^{−1}. ^b This relatively low value of the correlation coefficient is attributable to the considerable swelling of the films observed at this pH, with accompanying changes in thickness and area, which vitiates the vigorous applicability of Eq. 1.

and 52.4% relative humidity, to allow film hydration prior to testing. Figure 3 presents a comparison of results obtained with caffeine using treated and untreated films.

Among the films included in the preliminary study, the PVM-MA films appeared most promising with respect to their potential applicability for controlled drug release. Films formed from the PVM-MA and polysorbate 20 were therefore selected for further study with respect to the influence of various factors anticipated to affect their permeability properties. Only caffeine at an initial concentration of 2% w/v and humidity-chamber pretreated films were employed in this further work.

Effect of Polysorbate 20 Content on the Permeability of PVM-MA Films—The PVM-MA polymer itself is water dispersible to a considerable extent. The presence of polysorbate 20 in films formed from the polymer renders them insoluble in water. However, they are still subject to appreciable swelling. Powell (7) has shown that the insolubilization of PVM-MA films by polysorbate 20 results from crosslinking of polymer chains by the polysorbate 20. The crosslinking occurs through esterification of acid anhydride groups on the polymer and hydroxyl groups of the sorbitan ester. Figure 4 illustrates the influence of polysorbate 20 content on the permeability of the PVM-MA films. The results correspond to films prepared from weight ratios of polymer to polysorbate 20 of 9:1, 2:1, and 1:1, having thicknesses from 0.066 to 0.071 mm. Films studied in distilled water (pH 6.70) were found more permeable to caffeine as compared to results obtained with a solution buffered at pH 1.30 with hydrochloric acid. As expected, less swelling of the films was noted for the films immersed in the diffusion medium of lower pH. Table III summarizes these results. Assuming that the permeability constants of the films are directly related to the reciprocal of the film thicknesses for the small range of differences involved allows their normalization to a constant standard thickness. The values for the permeability constants listed in Table III have been corrected to a constant film thickness of 0.071 mm. to allow the relative magnitude of the effects studied to be more readily discerned.

The permeability coefficients, *P*, listed in Table III are defined by the following equations where *V*₁, *V*₂, and *C*₁, *C*₂ refer to the volumes and drug concentration within the compartments of the permeation cell at any time, *t*. The subscript 2 refers to the receiving cell that was devoid of drug at zero time. The final concentration ultimately approached in the receiving compartment, designated with the subscript 2, is symbolized by *C*_∞ and is defined by Eq. 2 where *C*₀ refers to the initial concentration of drug in Compartment 1.

$$\log \left(1 - \frac{C_2}{C_\infty} \right) = - \frac{V_2 + V_1}{V_1} 2.303 Pt \quad (\text{Eq. 1})$$

$$C_\infty = \frac{C_0 V_1}{V_2 + V_1} \quad (\text{Eq. 2})$$

$$P = - \frac{0.071 V_1 (\text{slope})}{h (V_2 + V_1) 2.303} \quad (\text{Eq. 3})$$

Values of *P* obtained from Eq. 3 are normalized to a thickness of 0.071 mm.; the symbol *h* in the equation denotes the actual mea-

sured thickness of a film. The slope referred to in Eq. 3 is a least-squares regression value obtained from plots of C_2 as a function of time in accordance with Eq. 1. Such plots were always observed to be reasonably linear as indicated by the values of the corresponding correlation coefficients listed in Table II. This indicates that sufficient agitation was maintained in the diffusion cell to allow its description in terms of two compartments.

Greater extents of crosslinking in the films are likely responsible for the observed reduction of swelling and permeability of the films observed to accompany an increased polysorbate 20 content.

Effect of PVM-MA Polymer Molecular Weight—Films were prepared with a ratio of polymer to polysorbate 20 of 2:1 and 1:1 using higher (169) and lower (139) molecular weight grades of the PVM-MA polymer. Using pH 1.30 diffusion medium, the film composed of the lower molecular grade polymer was more permeable to the drug. The permeability coefficients, corrected to constant film thickness, are listed in Table III. The greater permeability of the lower weight grade polymer film is not surprising, considering their greater solubility and potential for being leached from the film. The effectiveness of polysorbate 20 crosslinking in maintaining the integrity of the film may be expected to be diminished as a consequence of the relative reduction in the size of the interacted components.

Effect of pH on PVM-MA Film Properties—As could be predicted from the theoretical considerations previously mentioned, the swelling of PVM-MA 169 (2:1 and 4:1) films was considerably retarded in the pH 1.30 buffered diffusion medium as compared to its immersion in buffers of pH 5.83 and 7.20. The pH of the latter medium exceeds the first acidic pK of the polymeric fixed carboxyl groups and allows the establishment of a fixed anionic charge density within the film. The fixed charge is undoubtedly responsible for the observed swelling and the marked increase in the permeability of the films at higher pH values. The permeability constants are listed in Table III. Although it is not readily apparent from these values, the effect of pH might be expected to be retarded by a further increase in polysorbate 20 crosslinking within the films.

SUMMARY AND CONCLUSIONS

The application of insoluble films to the coating of tablets or for the manufacture or coating of capsules must be accompanied by an ability to predict and to control the permeability properties of the films. The present study is a first exploratory step toward this goal. The study revealed that the PVM-MA films possess promise with regard to their application to the control of drug release. The permeability properties of the PVM-MA films can be controlled through adjustment of the polysorbate 20 content, molecular weight of the polymer, and the initial extent of hydration of the film. However, the influence of pH on the permeability of the films precludes a film-controlled uniform drug-release rate in all regions of the gastro-

intestinal tract. In cases where it may be desirable to delay drug release until the dosage form reaches the intestinal tract, the increased permeability of the film observed at higher pH could prove to be advantageous. It is conceivable, however, that when a uniform drug-release rate is desired, the expected changes in permeability of the film in response to variation of pH in the gastrointestinal tract may in part be circumvented by the inclusion of buffering agents in the drug formulation contained within the film envelope. The continual presence of a constant pH in at least one side of the film could function to reduce the change in film swelling and allow the permeability of the film to approximate more closely the relatively uniform rates obtained in either acidic or alkaline media. In this manner, the effects of the variations in the external environment could be ameliorated. The PVM-MA films do possess sufficient potential for eventual practical application and thereby warrant further studies into the influence of environment (particularly *in vivo*), film formulation, and the effect of the drug and other components of the dosage form on the controlled drug release imposed by the insoluble PVM-MA films. However, in any practical application, the elastic properties of the films and their ability to resist rupture due to mechanical abuse and osmotic pressure gradients are considerations of fundamental importance to the safety of any proposed product. These factors must be considered in future work.

Bead Polymerization Technique for Sustained-Release Dosage Form

S. C. KHANNA*, T. JECKLIN†, and P. SPEISER

Abstract □ The bead polymerization technique has been studied for the preparation of a sustained-release dosage form. This technique has been employed in aqueous outer phase for many water-insoluble monomers with and without drug. Different concentrations of water-soluble acidic monomers (α - and β -methacrylic acids) have been incorporated with these water-insoluble monomers in an attempt to improve the solubility and swelling property of the beads and hence the release of drug embedded in them in artificial gastrointestinal buffer juices. To prove the applicability of this method for the preparation of a pharmaceutical dosage form, the beads of various monomers and their mixtures in the presence of different drugs have been prepared. The influence of drug on the property of the beads has also been studied.

Keyphrases □ Sustained-release dosage form—bead polymerization □ Polymerization process—sustained-release dosage form □ Diagram—bead polymerization apparatus □ Particle-size determination—bead polymers □ Drug effect—bead polymer formation

The sustained-release dosage form constitutes an important part of modern pharmaceutical technology. Such an oral dosage form is often desirable to impart sustained-release or long-acting therapeutic effects and is commercially useful. A variety of methods and techniques has been employed for preparing such a dosage form, and approximately 1000 pharmaceutical patents have been issued in the last 15 years. The natural and

synthetic polymers, waxes, and many other materials, either alone or combined, have been frequently employed for coating powder particles or granules, using conventional (1), spray drying (2), and other methods of coating in an attempt to prepare sustained-release dosage forms. Beads of different waxes (3) and epoxy resins (4) have also been reported for obtaining such products. The methods so far have mostly employed polymers, but polymerization techniques in which the drug can be embedded during polymerization of a single monomer or the combination of a few monomers have received little or no attention.

The monomers and catalyst used for polymerization are relatively toxic substances. However, the pure polymers obtained from these monomers are nontoxic and harmless to human beings. Most monomers employed in this study are those whose polymers in one form or another have already been in use for pharmaceutical purposes, *e.g.*, acrylates (5) and vinyl acetate (6).

In the present study, the possibility of using one of the methods of polymerization, known as bead polymerization or pearl polymerization, for the preparation of a sustained-release dosage form has been explored (7). Various monomers alone or in combination with others have been prepared in bead form with and without drugs. The effect of drugs on the properties of the beads obtained has also been investigated.

METHODS OF POLYMERIZATION

Polymerization can be carried out by the following four methods: (a) bulk or block polymerization; (b) bead or pearl polymerization; (c) emulsion polymerization; and (d) solution polymerization. The latter two polymerization methods can be employed for pharmaceutical purposes but are less common because of the high content of the monomers left in the polymers after the polymerization is over. The bulk polymerization method may become inconvenient for thermolabile drugs because heat of polymerization is evolved during the process. This can be quite high for many monomers and may cause decomposition of the drug.

Bead polymerization was first carried out in 1931 (8). However, this method was successfully applied only after effective suspension stabilizers were found. The bead polymerization method is similar to the bulk polymerization with respect to reaction kinetics, but the monomer or the mixture of monomers is dispersed by strong mechanical agitation into droplets in a second liquid phase in which both the monomer and the polymer formed are essentially insoluble. The monomer droplets, which are larger than those of a true emulsion, are then polymerized by heating with the catalyst. The dispersion is maintained during this time by continuous agitation. The suspending liquid, mostly water, acts as a cooler when the high amount of the heat of polymerization is evolved during the process. Suitable agents are added to the suspended liquid to hinder the coalescence of the droplets during polymerization. The polymerization takes place in the individual monomer droplets; these polymerized droplets are called beads or pearls. These beads can easily be separated from the aqueous phase when stirring is discontinued. Thus the bead polymerization method overcomes the

disadvantages of the other polymerization methods and has the further advantage that the drug is homogeneously distributed in the uniform tiny spheres.

EXPERIMENTAL

Materials Used—Monomers—α-Methacrylic acid,¹ methyl methacrylate,¹ vinyl acetate,¹ crotonic acid¹ (β-methacrylic acid), and divinylbenzene in ethylvinylbenzene as 45–55% solution.¹

Polymers—Polyvinylacetate with 8% crotonic acid.²

Catalyst—α,α'-Axi-diisobutyronitrile¹ and benzoyl peroxide.¹

Suspension Stabilizers—Carboxyvinyl polymers³ and polyvinylpyrrolidone.⁴

Drugs—Chloramphenicol USP, *N*₁-6-methoxy-2-(methoxymethyl)-4-pyrimidinyl sulfanilamide,⁵ chlorothiazide, pentobarbital and its sodium salt, papaverine base, hydrocortisone, and 1-ethyl-1-phenylglutarimide.⁶

Method of Preparation—Apparatus—A three-necked flask connected to a reflux condenser and an inert gas (nitrogen or carbon dioxide) supply was used. Through the remaining central wide opening, a stirrer was inserted. The flask was maintained at a constant temperature with a thermostatic water bath to control the reaction of the polymerization process (Fig. 1).

Procedure—The continuous outer phase consisting of water, protective colloid, and other additives (described under individual preparations) was heated in the three-necked flask to the desired temperature. The monomer, with or without drug, was added to the continuous phase and stirred at the optimum speed to form the desired size of monomer droplets. The catalyst was then added to effect the polymerization reaction under the inert gas flow. When the droplets were polymerized completely into solid beads, they were removed and washed with excess water or acidic aqueous solution to remove the impurities on the surface. These were then dried at an appropriate temperature with or without a vacuum. The different formulas prepared are given in Tables I–IV.

Determinations—Yield of Beads—The total amount of beads obtained after washing and drying was weighed, and this weight was taken as the yield for that preparation (Tables I–IV).

Amount of Drug in Beads—The polymer beads obtained were powdered and passed through a fine sieve. Approximately 0.5 g.

¹ Purchased from Fluka AG, Buchs, Switzerland. Pure monomers are stabilized with 0.01% hydroquinone. These were distilled under vacuum at appropriate temperature before use in presence of copper powder to remove hydroquinone.

² Supplied by Ciba AG, Basel, Switzerland.

³ Carbolopol 934 and 941, B. F. Goodrich Chemical Co., Ohio.

⁴ Kollidone 25, BASF, Ludwigshafen, West Germany.

⁵ Ba 35 092, Ciba AG, Basel, Switzerland.

⁶ Doriden, Ciba AG, Basel, Switzerland.

accurately weighed powder was suspended in different 1-l. buffer solutions for 2 days. The amount of the drug dissolved in these buffer solutions from these powders was determined spectrophotometrically (Tables I–IV).

Particle-Size Distribution—A known amount of beads was used for sieve analyses to determine the particle-size distribution. The results for a few preparations of Tables I and II are presented as percent cumulative undersize of beads (Figs. 2 and 3).

RESULTS AND DISCUSSION

Choice of Monomers and Polymers for Polymerization—The choice of the monomers and the polymer to be added to them for polymerization in bead form depends on the following considerations:

1. The composition employed should be easily capable of polymerization at a relatively low temperature in the presence of the drug.

2. The polymer obtained should be mechanically hard, chemically stable, and free from monomers.

3. The beads should show specific properties of dissolution and/or diffusion of the embedded drug in gastrointestinal fluids. The presence of acidic groups in the beads increases the solubility in the neutral and alkaline buffer solutions (artificial duodenum and intestinal juices, i.e., sustained dose) (9). The presence of network-

forming monomers in copolymers such as divinylbenzene decreases the swelling and solubility of copolymers in buffer solution.

Choice of Additives in the Outer Phase—The right type and amount of protective colloids in the aqueous outer phase prevent the monomer droplets from deforming and sticking to each other during polymerization. The choice in the outer phase depends mainly on the properties of the monomers used, the protective property at the selected pH, and the presence of electrolytes. The concentration of the protective colloid in the outer phase affects the bead size and may even lead to the formation of emulsions in the high concentrations. Hence, for each preparation, the optimum amount of protective colloid must be determined. The presence of the electrolyte, sodium sulfate, in the aqueous phase is necessary to decrease the solubility of the water-soluble monomer such as α -methacrylic acid in water (salting-out effect). Figure 4 shows the solubility of α -methacrylic acid from the mixtures of methyl methacrylate and α -methacrylic acid in water and 20% w/v sodium sulfate solution. However, the presence of such an electrolyte in water increases the interfacial tension between the monomeric phase and the outer aqueous phase. This latter effect may be strong enough to disturb the bead polymerization system, so it is always desirable to balance these two effects carefully. In principle, many protective colloids can be used, provided the electrolyte causes no salting-out effect on them in the aqueous phase. Carboxyvinyl polymers are stable in the presence of electrolytes between pH 4 and 11 and are employed in this study when electrolytes are present in the aqueous outer phase; otherwise, polyvinylpyrrolidone is the protective colloid used.

When the right type and amount of the protective colloid are used in the outer aqueous phase, the polymers prepared show mostly spherical form. However, the formation of a certain percentage of small agglomerates, twins, and deformed beads cannot be completely avoided. The appearance of the beads, whether transparent or opaque, depends on the solubility of the drugs in the inner monomeric phase. The preparation takes mostly the color of the drug used.

The yield of the beads ranges from 75 to 95% for different preparations. This loss may be due either to the formation of micelles or tiny spherical particles which are lost during filtration and washing of the beads or to the evaporation of a small amount of monomer at the polymerization temperature. Hence the polymerization should be carried out below the boiling temperature of the monomer to avoid the loss due to the latter reason. Further, it may be observed from Tables I–IV that the yield in the presence of drug is always less than when the drug is absent. This loss can be due to the preferential solubility of the drug in, or the affinity of the drug for, the aqueous

outer phase rather than those in or for the monomeric phase. This type of loss is further proved by determining the amount of drug present in the beads after polymerization is over (Tables I–IV). Drugs having no affinity for the monomeric phase could not even be embedded in the beads during polymerization as in the examples of chlorothiazide with vinyl acetate and crotonic acid (Table II).

The beads show a large range of particle size distribution varying between 0.3- and 1.0-mm. diameter. In the presence of drugs—either soluble in both the phases as chloramphenicol or insoluble in both the phases as chlorothiazide—the beads obtained are smaller in size than in the absence of drugs (Figs. 2 and 3). These two examples are chosen to investigate the influence of incorporation of soluble and insoluble drugs in the monomeric phase on the size distribution of beads. Chloramphenicol is soluble in the monomeric phase as well as in the outer aqueous phase while chlorothiazide is practically insoluble in both phases. The drug soluble in the outer phase may be affecting the interfacial tension between the two phases while the insoluble drug may be acting as a fine-mesh barrier between droplets and hence decreasing the particle size of the beads (10).

SUMMARY

The method of bead polymerization in aqueous phase has been studied for embedding drugs in polymers. Various polymers and copolymers, either in the presence or in the absence of the drugs, have been studied to prove the widespread applicability of the bead polymerization method. The presence of the drug, either soluble or insoluble, in the outer aqueous phase decreased the bead size and yield of the products. The amount of the drug which could be embedded in the polymer beads depended on the affinity and solubility of the drug for the monomers.

Mechanism of Dimethyl Sulfoxide-Induced Hemolysis

WILLIAM P. NORRED, HOWARD C. ANSEL, IVAN L. ROTH*, and JAMES J. PEIFER†

Abstract □ A study has been made of the possible mechanism by which dimethyl sulfoxide induces hemolysis of rabbit erythrocytes *in vitro*. Erythrocytes were shown by spectral analysis to remove dimethyl sulfoxide from aqueous solution and to resist the agent's release upon washing. Electron microscopy revealed the increased formation of lesions in the erythrocyte membrane with increasing concentrations of dimethyl sulfoxide. Dimethyl sulfoxide was also shown to be increasingly capable of removing fatty acids from the erythrocyte membrane with an increase in concentration. Results of the study indicate that dimethyl sulfoxide is capable of causing the hemolysis of erythrocytes by virtue of its affinity for the erythrocyte membrane and the disruption of its integrity, in part due to its lipid solvency action.

Keyphrases □ Erythrocyte hemolysis—dimethyl sulfoxide induced □ Mechanism—dimethyl sulfoxide-induced hemolysis □ Dimethyl sulfoxide retention—erythrocytes □ Fatty acid removal, erythrocytes—dimethyl sulfoxide □ Electron microscopy—erythrocyte lesion determination □ UV spectrophotometry—analysis

Although dimethyl sulfoxide (DMSO) was first synthesized in 1867 (1), it has only recently become the object of intensive scientific investigation. Used for years by the chemical industry as a solvent, the compound became of special interest to biologists after it was found to have a wide range of solvent action for chemicals employed in various laboratory procedures (2-7). DMSO was subsequently utilized investigatively as the solvent for poorly soluble drugs to be employed parenterally in the clinical treatment of cancer and leprosy (8, 9).

Much of the recent flourish of investigation activity centered about DMSO has been prompted by reports of the agent's apparent great ability to traverse biologic membranes and exert its pharmacologic activity (10-14), as well as to increase the degree and rate of penetration of other drugs across biologic membranes (15-17).

DMSO has also received considerable attention concerning its ability to serve effectively as a cryoprotective agent in the preservation of various body organs, tissues, and cells (7, 17-35), including red blood cells (31-35).

One difficulty concerning the use of DMSO as a cryoprotective agent in the preservation of blood for transfusion has been its nature to permeate the erythrocyte along with the subsequent difficulty experienced

in its removal from the blood preparative to transfusion (32, 34, 35). Cellular destruction, resulting in hemolysis, commonly accompanies attempts to rid the cells of DMSO by washing (25, 36).

The hemolytic activity of DMSO, *in vitro* and *in vivo*, has been noted in reports from this (36) and from other laboratories (25, 37, 38). It was the purpose of the present work to investigate the mechanism by which DMSO exerts its hemolytic effects against the erythrocyte.

EXPERIMENTAL

Materials—The DMSO employed in this investigation was reagent grade and was obtained commercially.

Blood Samples—In previously reported studies the hemolytic activity of DMSO against human and rabbit erythrocytes was quite comparable (36, 37). This was verified in preliminary experiments to the present work using blood obtained from the forearm veins of several Caucasian donors, 20-25 years of age, and from rabbits by cardiac puncture. For convenience, rabbit blood was employed throughout this study. Fresh blood was obtained immediately prior to each experiment and defibrinated by gentle swirling with glass beads for approximately 5 min. The defibrinated blood was then transferred by decantation to a clean container and employed in the following procedures.

Absorption of DMSO by Red Blood Cells—To assess the capabilities of DMSO to enter and/or bind with the erythrocyte, red blood cells were incubated with solutions of DMSO, and any alteration in the absorbance of the original DMSO test solution was determined spectrophotometrically.

Erythrocytes were separated from the defibrinated blood sample by centrifugation and decantation. Then the cells were washed five times with normal saline solution and reconstituted to the original blood volume. This cell suspension was then employed to prepare test samples containing volumes of erythrocytes ranging in concentration from 0.06 to 0.48%, with 0.004% DMSO in normal saline. The suspensions were allowed to incubate for 30 min. at 37°, after which time the cells were settled by centrifugation at 13,500×g for 15 min. The supernatant was then examined spectrophotometrically with a Beckman DU for its DMSO content, using a wavelength of 208 mμ. The amounts found were compared to the amounts originally present in the test solutions, and the amounts absorbed determined by difference.

Preparation of Erythrocyte Ghosts for Electron Microscopy—One percent suspensions of defibrinated blood were prepared in 0.9% sodium chloride and varying proportions of DMSO, and incubated at 37° for 45 min. Control suspensions of blood in 0.9% sodium chloride were prepared and concurrently processed with the DMSO-containing suspensions.

Keyphrases □ Erythrocyte hemolysis—dimethyl sulfoxide induced □ Mechanism—dimethyl sulfoxide-induced hemolysis □ Dimethyl sulfoxide retention—erythrocytes □ Fatty acid removal, erythrocytes—dimethyl sulfoxide □ Electron microscopy—erythrocyte lesion determination □ UV spectrophotometry—analysis

Although dimethyl sulfoxide (DMSO) was first synthesized in 1867 (1), it has only recently become the object of intensive scientific investigation. Used for years by the chemical industry as a solvent, the compound became of special interest to biologists after it was found to have a wide range of solvent action for chemicals employed in various laboratory procedures (2-7). DMSO was subsequently utilized investigatively as the solvent for poorly soluble drugs to be employed parenterally in the clinical treatment of cancer and leprosy (8, 9).

Much of the recent flourish of investigation activity centered about DMSO has been prompted by reports of the agent's apparent great ability to traverse biologic membranes and exert its pharmacologic activity (10-14), as well as to increase the degree and rate of penetration of other drugs across biologic membranes (15-17).

DMSO has also received considerable attention concerning its ability to serve effectively as a cryoprotective agent in the preservation of various body organs, tissues, and cells (7, 17-35), including red blood cells (31-35).

One difficulty concerning the use of DMSO as a cryoprotective agent in the preservation of blood for transfusion has been its nature to permeate the erythrocyte along with the subsequent difficulty experienced

in its removal from the blood preparative to transfusion (32, 34, 35). Cellular destruction, resulting in hemolysis, commonly accompanies attempts to rid the cells of DMSO by washing (25, 36).

The hemolytic activity of DMSO, *in vitro* and *in vivo*, has been noted in reports from this (36) and from other laboratories (25, 37, 38). It was the purpose of the present work to investigate the mechanism by which DMSO exerts its hemolytic effects against the erythrocyte.

EXPERIMENTAL

Materials—The DMSO employed in this investigation was reagent grade and was obtained commercially.

Blood Samples—In previously reported studies the hemolytic activity of DMSO against human and rabbit erythrocytes was quite comparable (36, 37). This was verified in preliminary experiments to the present work using blood obtained from the forearm veins of several Caucasian donors, 20-25 years of age, and from rabbits by cardiac puncture. For convenience, rabbit blood was employed throughout this study. Fresh blood was obtained immediately prior to each experiment and defibrinated by gentle swirling with glass beads for approximately 5 min. The defibrinated blood was then transferred by decantation to a clean container and employed in the following procedures.

Absorption of DMSO by Red Blood Cells—To assess the capabilities of DMSO to enter and/or bind with the erythrocyte, red blood cells were incubated with solutions of DMSO, and any alteration in the absorbance of the original DMSO test solution was determined spectrophotometrically.

Erythrocytes were separated from the defibrinated blood sample by centrifugation and decantation. Then the cells were washed five times with normal saline solution and reconstituted to the original blood volume. This cell suspension was then employed to prepare test samples containing volumes of erythrocytes ranging in concentration from 0.06 to 0.48%, with 0.004% DMSO in normal saline. The suspensions were allowed to incubate for 30 min. at 37°, after which time the cells were settled by centrifugation at 13,500×g for 15 min. The supernatant was then examined spectrophotometrically with a Beckman DU for its DMSO content, using a wavelength of 208 mμ. The amounts found were compared to the amounts originally present in the test solutions, and the amounts absorbed determined by difference.

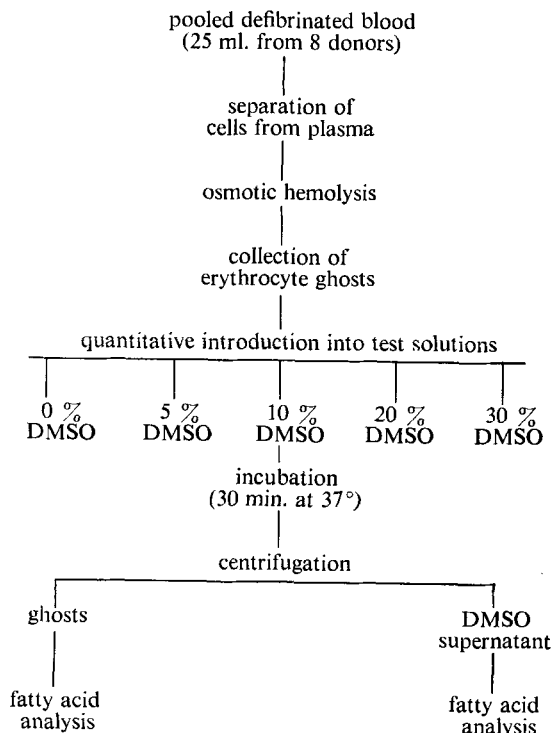

Preparation of Erythrocyte Ghosts for Electron Microscopy—One percent suspensions of defibrinated blood were prepared in 0.9% sodium chloride and varying proportions of DMSO, and incubated at 37° for 45 min. Control suspensions of blood in 0.9% sodium chloride were prepared and concurrently processed with the DMSO-containing suspensions.

After the incubation period, erythrocyte ghosts were prepared essentially by the procedure used by Hillier and Hoffman (39) in their study of the ultrastructure of the human and animal erythrocyte membrane. By this method, hemoglobin-free ghosts are prepared by subjecting the cells to a series of osmotic shocks by washing successively in sodium chloride solutions of decreasing tonicity. The present method differed from that of Hillier and Hoffman only in that the final wash was conducted with distilled water in the present instance rather than with saline of extremely low tonicity. Following each saline washing the cells were resuspended in a solution of lower tonicity, centrifuged at $3500\times g$ for 5 min., until finally they were triple-washed with distilled water and resuspended to one-fourth of the volume of the original suspension of defibrinated blood.

In mounting the ghosts for examination by electron microscopy, one drop of the aqueous suspension was placed on each of several collodion-coated copper grids of 200 mesh and allowed to remain undisturbed for approximately 5 min. Excess liquid was then drawn off the grid using absorbant paper, and the grid was allowed to dry overnight.

It was found unnecessary to employ staining or shadowing procedures. The grids were examined in an RCA EMU 2 electron microscope operating at a voltage of 50 kw. Micrographs were photographically enlarged as noted.

Fatty Acid Analysis—To determine the solvent characteristics of the various DMSO solutions on the erythrocyte membrane, an analysis was performed to establish the degree of fatty acid removal from the membrane. Ghosts were prepared from 25 ml. of pooled defibrinated blood (Scheme I) by successive exposure to solutions of decreasing tonicity and resuspended in 25 ml. of distilled water. One milliliter of the ghost suspension was introduced into 24 ml. of each of the various DMSO test solutions. The samples were incubated 30 min. at 37° , then centrifuged at $20,000\times g$ for 20 min. to settle the ghosts. The supernatant was decanted and the ghosts were resuspended in 10 ml. of 50% ethanol to inhibit enzyme activity. Ethanol was also added to the supernatant to a concentration of 50%. The samples were saponified with 2 M KOH and the total fatty acids isolated with chloroform. The fatty acids were converted to methyl esters using BF_3 -reagent and procedures described by Metcalfe and Schmitz (40). Quantitation of total fatty acids was based on addition of behenic acid (22:0) as an internal standard and gas-liquid chromatography analysis of the methyl esters using a Packard model 845 instrument equipped with dual hydrogen flame detectors and techniques previously described (41).

Figure 1—Spectral absorbance of DMSO (0.004%) in the presence of washed rabbit erythrocytes in 0.9% NaCl. Data are the averages of three samples.

RESULTS AND DISCUSSION

Absorption of DMSO by Red Blood Cells—Ansel and Leake (36), reporting on the *in vitro* hemolysis of erythrocytes in the presence of DMSO, noted that without the presence of added saline, DMSO is incapable of maintaining the integrity of the erythrocytes, and hemolysis is total at all DMSO concentrations. To prevent osmotic hemolysis, the presence of an extracellular material to which the red blood cell membrane is impermeable is required. In the presence of 0.6% sodium chloride the red blood cells are protected from hemolysis until the DMSO concentration is raised to above 25%. At DMSO concentrations above 30% in the absence of saline and above 45% in the presence of saline, the blood was denatured as observed by brown discoloration of blood cells and released hemoglobin and the flocculation of the cell components.

The ability of erythrocytes to hold DMSO was examined in the present study by incubating previously washed erythrocytes in 0.9% saline solutions containing a fixed quantity of DMSO, and comparing the spectrophotometric absorbance for DMSO in the control sample (without cells) and in the supernatant of the various cell samples. In each of the experiments conducted, the spectral absorbance of extracellular DMSO decreased with increased concentration of cells present. Figure 1 represents one experiment which typifies the data obtained in this series. The data indicate that DMSO is removed from the extracellular medium and held by the erythrocytes. This would tend to support the experiences of others (25, 36) who have found the removal of DMSO from blood cells prior to transfusion so difficult.

The hygroscopic nature of DMSO undoubtedly plays a role in its ability to traverse biologic membranes and perhaps to affect the configuration of membrane proteins. DMSO has a strong affinity for water molecules, with a maximum hydration of DMSO in aqueous solution being three water molecules per DMSO molecule (42). It has been suggested that the hydrogen bonds which exist between water and DMSO are stronger than the hydrogen bonds which exist between water molecules (43). Because of its comparatively small size, the DMSO molecule is thought to be capable of penetrating regions on certain protein subunit interfaces more readily than other bulkier solvents (44).

Rammler and Zaffaroni (44) suggest that the ability of DMSO in high concentrations to cross rapidly the dermal protein barrier, whose conformational integrity is dependent upon bound water, is the result of reversible configuration changes of these proteins due to water substitution by DMSO.

Since the principal component of the living cell is water, and the native form of biopolymers such as proteins, polysaccharides, and nucleic acids is surrounded by arrays of water molecules (the hydration sheath), these seem to suggest the manner in which DMSO gains entrance to the cell and is bound within (44). Substitution or removal of the hydration sheath would be expected to alter the configuration of the biopolymers and consequently the cell or tissue. Since in many instances it has been found that the cells apparently so affected are not permanently altered, the reversible process could be envisaged as occurring either as diffusion or active transport of the major amount of DMSO from the tissue and the gradual removal of the protein-bound DMSO by competitive bonding with cellular water (44).

Figure 2—Erythrocyte ghosts ($\times 6900$) hemolyzed by osmotic pressure.

In studying the metabolism and distribution of DMSO in man and in animals, Gerhards and Gibian (45) found that in human blood about 30% of DMSO is bound to plasma protein and 25%

Figure 3—Erythrocyte ghosts ($\times 7350$) exposed to 5% DMSO in 0.9% NaCl for 45 min. at 37°.

to the formed elements, the remainder being free. Denko *et al.* (46), using ^{35}S -labeled DMSO and rat blood, found that DMSO radioactivity is associated predominantly with the serum albumin. They reported that the biologic half-life of DMSO- ^{35}S is prolonged by 25% in hard tissues and thus may indicate some tissue binding.

Huggins (31) reported on his observations of the interaction between DMSO and human plasma proteins, noting that true denaturation of plasma protein seems to occur at DMSO concentrations approximating 50%. He stated that precipitation of protein by DMSO occurred with individual plasma fractions—albumin, fibrinogen, and gamma globulin—and appears to be a general effect rather than denaturation of a specific plasma component. DMSO has also been reported to be a good solvent for a number of proteins (47).

DiStefano and Klahn (38) concluded that DMSO probably exerts its hemolytic effect by direct action on the blood cells, although they hesitated to suggest a mechanism for this action.

It is likely that part of the means by which DMSO is capable of acting as a hemolytic agent is its initial ability to gain entrance into the red blood cell (due to its hygroscopicity and small size) and its affinity for proteins, resulting in their disfiguration, denaturation, or dissolution, and thus a loss of cellular integrity.

Electron Microscopy—An ultrastructural examination of the erythrocyte membrane was made following exposure to various DMSO concentrations. It is important to note that the particular cells photographed in each instance are representative of the general appearance of the field of cells examined.

Figure 2 shows the control erythrocytes which were osmotically hemolyzed in the presence of hypotonic saline and then mounted on a collodion-coated copper grid. These cells are intact, with a fine granular appearance. This type of granularity has been noted by other investigators (39, 48, 49). Hillier and Hoffman (39) observed erythrocyte membranes at much higher magnification ($\times 100,000$ to $\times 200,000$) and noted that the granularity is due to closely packed "cylinders" approximately 30 Å thick with a diameter of 100 to 500 Å. They termed these structures "plaques."

Figure 3 shows the appearance of erythrocytes exposed to 5% DMSO and then osmotically hemolyzed. The membranes are intact and have the same general appearance as the osmotically hemolyzed control cells. Some of the cells show the presence of

Figure 4—Erythrocyte ghosts ($\times 6750$) exposed to 20% DMSO in 0.9% NaCl for 45 min. at 37°.

Figure 5—Erythrocyte ghosts ($\times 6400$) exposed to 30% DMSO in 0.9% NaCl for 45 min. at 37°.

Figure 6—Erythrocyte ghosts ($\times 7200$) exposed to 40% DMSO in 0.9% NaCl for 45 min. at 37°.

folds, which probably occurred as the saclike membrane collapsed upon itself in attaching to the surface of the collodion membrane.

Figure 4 shows cells after treatment with 20% DMSO, followed by osmotic hemolysis. Definite lesions in the membrane are visible, and more cell fragments are present than in the previous samples. The particles seen on the collodion membrane surrounding the ghosts are interesting. A possible explanation is that these particles are cellular plaques which have been removed from the membrane surface by the action of the DMSO. Hillier and Hoffman (39) noted a similar phenomenon when treating cells with a variety of lipid solvents such as alcohol-ether-chloroform. They suggested that the plaques themselves may be insoluble in the solvent, but are attached to an underlying fibrous membrane by some type of lipid. A lipid solvent may then remove the lipid component, releasing the plaques and thereby cause lesions in the membrane surface. Since the total lipid of the red cell lies mainly within the membrane (50), the solvency of DMSO toward lipoidal and nonlipoidal materials (51) and the concepts of Hillier and Hoffman would seem to support the suggestion that the loss of the erythrocyte's integrity in the presence of DMSO is due to the dissolution of one or more of the membrane components. Another possible mechanism for the disruptive influence of DMSO on the cell membrane has been hypothesized by Puig Muset and Martin-Estève (52). They propose that DMSO might produce some change in the isomeric conformation of cellular fatty acids, as oleic acid and linoleic acid, with a resulting alteration in the permeability barriers of the cell.

Table I—Fatty Acid Content of Erythrocyte Ghosts Following Incubation with DMSO^a

% DMSO	Fatty Acid Content	
	mcg.	% of Total (Control)
0 (Control)	646	100 (Standard)
5	562	87.0
10	478	74.0
30	382	59.2

^a Each sample was incubated for 30 min. with the stated concentration of DMSO.

Figure 5 shows erythrocytes after 30% DMSO treatment, followed by hemolysis. Gross disruption of the membrane has resulted. As could be expected, these cells were partially hemolyzed after incubation with the DMSO, even though the surrounding medium was isotonic with sodium chloride (36).

When cells were treated with 40% and higher concentrations of DMSO, a brown flocculation was observed in the test tubes. The appearance of the cells is shown in Fig. 6. Hemoglobin could not be removed by introduction of the cells into solutions of decreasing tonicity, and in the micrograph appears to be outside the cells but coagulated. The diameter of the ghosts is smaller than the osmotic controls, and the general appearance is that of coagulation of membrane components, possibly due to an alteration in protein configuration.

Fatty Acid Analysis—The lipid studies in this work were limited to the determination of total fatty acid removal from erythrocyte ghosts following incubation for 30 min. in various concentrations of DMSO. As can be seen in Table I, increasing amounts of fatty acids were removed from erythrocyte ghosts with increasing concentrations of DMSO. Work now in progress will attempt to identify the specific fatty acids removed from the erythrocyte by DMSO and to quantitate the rate and extent of such removal.

In conclusion, it appears as though the affinity of DMSO for the erythrocyte membrane and its lipid solvency contribute to the disruption of the integrity of the erythrocyte, resulting in hemolysis, and at high concentrations, in denaturation.

Constituents from *Gymnema sylvestre* Leaves V: Isolation and Preliminary Characterization of the Gymnemic Acids

JOSEPH E. SINSHEIMER, G. SUBBA RAO*, and HUGH M. McILHENNY†

Abstract □ The objectives of this investigation were to isolate and characterize the constituents of gymnemic acid, the antisweet principle of *Gymnema sylvestre* leaves, and to make them available for further biological testing. Gymnemic acid was found to be a complex mixture of at least nine closely related acidic glycosides. Solvent extraction and chromatography of gymnemic acid resulted in the isolation of gymnemic acids A–D (the major constituents) and V in crystalline form. Acids A–D are glycosides which yield glucuronic acid on hydrolysis while acids C and D also yield glucose. The gymnemic acids isolated in this study are compared to those described in the literature.

Keyphrases □ *Gymnema sylvestre* leaves—constituents □ Gymnemic acids— isolation characterization □ Column chromatography— separation □ TLC— separation □ Reverse phase chromatography— separation □ IR spectrophotometry— glycosidic structure □ UV spectrophotometry— glycosidic structure □ NMR spectroscopy— glycosidic structure

While the unique property of the leaves of *Gymnema sylvestre* R. Br. (*Asclepiadaceae*) to inhibit temporarily

the ability to taste sweet substances has been known in India since antiquity (1, 2), the first such report to be published in the Western literature appears to be that of Falconer (3) in 1847. Chemical investigations were initiated by Hooper (4, 5) who isolated the antisweet principle as an amorphous monobasic acid, $C_{32}H_{55}O_{12}$, which he named gymnemic acid. Further, Hooper described gymnemic acid as a glycoside since it reduced Fehling's solution after treatment with dilute hydrochloric acid. In 1892, Shore (6) reported a modified procedure to isolate gymnemic acid in white crystalline form and suggested the acid to be a derivative of anthracene. Several years later, Power and Tutin (7) isolated racemic glucose as its osazone from the leaves but were unable to detect any sugar after acidic hydrolysis of gymnemic acid. Upon potassium hydroxide fusion of gymnemic acid, Power and Tutin obtained acetic acid and a mixture of protocatechuic and *p*-hydroxybenzoic acids, while alkaline potassium permanganate oxidation afforded formic acid.

Constituents from *Gymnema sylvestre* Leaves V: Isolation and Preliminary Characterization of the Gymnemic Acids

JOSEPH E. SINSHEIMER, G. SUBBA RAO*, and HUGH M. McILHENNY†

Abstract □ The objectives of this investigation were to isolate and characterize the constituents of gymnemic acid, the antisweet principle of *Gymnema sylvestre* leaves, and to make them available for further biological testing. Gymnemic acid was found to be a complex mixture of at least nine closely related acidic glycosides. Solvent extraction and chromatography of gymnemic acid resulted in the isolation of gymnemic acids A–D (the major constituents) and V in crystalline form. Acids A–D are glycosides which yield glucuronic acid on hydrolysis while acids C and D also yield glucose. The gymnemic acids isolated in this study are compared to those described in the literature.

Keyphrases □ *Gymnema sylvestre* leaves—constituents □ Gymnemic acids— isolation characterization □ Column chromatography— separation □ TLC— separation □ Reverse phase chromatography— separation □ IR spectrophotometry— glycosidic structure □ UV spectrophotometry— glycosidic structure □ NMR spectroscopy— glycosidic structure

While the unique property of the leaves of *Gymnema sylvestre* R. Br. (*Asclepiadaceae*) to inhibit temporarily

the ability to taste sweet substances has been known in India since antiquity (1, 2), the first such report to be published in the Western literature appears to be that of Falconer (3) in 1847. Chemical investigations were initiated by Hooper (4, 5) who isolated the antisweet principle as an amorphous monobasic acid, $C_{32}H_{55}O_{12}$, which he named gymnemic acid. Further, Hooper described gymnemic acid as a glycoside since it reduced Fehling's solution after treatment with dilute hydrochloric acid. In 1892, Shore (6) reported a modified procedure to isolate gymnemic acid in white crystalline form and suggested the acid to be a derivative of anthracene. Several years later, Power and Tutin (7) isolated racemic glucose as its osazone from the leaves but were unable to detect any sugar after acidic hydrolysis of gymnemic acid. Upon potassium hydroxide fusion of gymnemic acid, Power and Tutin obtained acetic acid and a mixture of protocatechuic and *p*-hydroxybenzoic acids, while alkaline potassium permanganate oxidation afforded formic acid.

In 1958, Khastgir *et al.* (8) reinvestigated Hooper's gymnemic acid but failed to obtain a crystalline product even after silicic-acid chromatography. However, the following year Warren and Pfaffmann (9) isolated the antisweet principle in crystalline form, m.p. 199° (dec.) and, subsequently, Pfaffmann (10) reported the detection of glucose, arabinose, and glucuronolactone upon acidic hydrolysis of gymnemic acid. Recently Yackzan (11, 12), while studying the biological effects of *G. sylvestre* fractions, carried out limited chemical work on gymnemic acid and indicated the presence of hydroxyl and carboxyl groups and one or more glycosidic linkages. Yackzan also assigned a molecular weight of about 600 for gymnemic acid based upon an ultracentrifuge technique.

Thus, at the beginning of the present investigation, knowledge regarding the chemical nature of gymnemic acid was scanty, and its antisweet activity was the only established biological property. However, during the course of this investigation, this situation has undergone considerable change. Cochran and Maassab (13) have observed significant antiviral activity for gymnemic acids made available from these laboratories. Also, Stöcklin (14, 15) has greatly advanced the chemistry of gymnemic acid.

It is the purpose of this paper to describe the isolation and preliminary characterization of the gymnemic acids. This is in support of potential interest in the antiviral field, continuing interest as antisweet compounds, and as a comparison to the acids and methods reported by Stöcklin *et al.* (14).

EXPERIMENTAL¹

Plant Material—Dry leaves of *G. sylvestre* were purchased from Prachi Gobeson Co., Calcutta, India, and the Himalaya Drug Co., Bombay, India. Identification of the plant material was established through an examination of a flowering top specimen as reported in the previous investigation from these laboratories (16) and through its property of suppressing selectively the ability to taste sugar.

Reagents—All common reagents and solvents utilized in this investigation were of analytical reagent grade. The following reagents were from the sources indicated: silica gel G (Warner-Chilcott Labs.); deuterium oxide, tetramethyl silane, silicic acid (100 mesh), ion-exchange resins (Rohm & Haas), IR 120 (H⁺) and IRA 401 (Cl⁻) (Mallinckrodt); Woelm neutral alumina, activity grade 1 (Alupharm Chemicals); Teflon-6 (70/80 mesh) (Analabs); Glucostat reagent (Worthington Biochemical Corp.); and D-glucuronolactone, D-glucuronic acid, D-glucose, and D-arabinose (Calbiochem).

Thin-Layer Chromatography—Silica gel G TLC plates were prepared by coating five 20 × 20-cm. glass plates at a thickness of 250 μ with a slurry composed of 18 g. of adsorbent and 45 ml. of water. After air drying for 30 min. at room temperature (27°), plates were activated in an oven at 105° for 1 hr. prior to use.

Activated TLC plates were scored into 1-cm. channels before sample application. Sample size was usually 10–50 mcg. for purified compounds and 100–250 mcg. for crude fractions. Chromatograms

Table I—Thin-Layer Chromatography of the Gymnemic Acids

Gymnemic Acid ^a	<i>R_f</i> Value in Solvent System ^b

D	0.09	0.10	0.25	0.09	0.35	0.14	0.12

^a Listed in the decreasing order of *R_f* values. ^b Solvent Systems: I, chloroform–formic acid–methanol (4:1:1) (aged for 3 hr. at 27°); II, chloroform–acetic acid–methanol (5:1:1); III, chloroform–formic acid–methanol–*t*-butanol (4:1:1:1) (aged for 3 hr. at 27°); IV, isopropanol–ammonium hydroxide–chloroform–*t*-butanol (5:2:1:1); V, isopropanol–ammonium hydroxide–isoamyl alcohol (3:2:1); VI, isopropanol–ammonium hydroxide–diethyl carbonate–isoamyl alcohol–*t*-butanol (3:2:2:1:1); and VII (14), butyl formate–methyl ethyl ketone–formic acid–water (5:3:1:1).

were developed to a distance of 13–14 cm. by ascending technique. Developing tanks were lined with filter paper and were saturated with appropriate solvent mixture for at least 30 min. Solvent systems employed for the gymnemic acids are listed in Table I. Spray reagents used for visualizing components on chromatograms were: benzoyl chloride–sulfuric acid reagent (17), ceric sulfate–sulfuric acid reagent (15, 18), and modified Liebermann–Burchard reagent (19).

Isolation of Crude Gymnemic Acid—Dry, powdered leaves of *G. sylvestre* (260–280 g.) were wrapped in cheese cloth in bundles of about 40 g. each and were loosely packed in the side chamber of a continuous extractor. Initial defatting of leaves was carried out with 4 l. of petroleum ether (b.p. 30–60°) for 18 hr. This was followed by extraction with either water or 95% ethanol, 4 l., for a period of 18 hr. The extracts were filtered and adjusted to pH 2 with 10% HCl to precipitate Hooper's gymnemic acid (4) in a yield of 3–4% of the dry leaves. These fractions were found to consist of at least nine components upon TLC in Solvent Systems I–VII.

Warren and Pfaffmann's gymnemic acid (9), recrystallized three times from diethyl carbonate, was obtained as white microcrystals, m.p. 199–201° (dec.) [lit. (9) m.p. 199° (dec.)]. This gymnemic acid sample gave two spots during TLC in Solvent System VII.

Preliminary Separation of the Gymnemic Acids—*Acetone Extraction: Silicic-Acid Chromatography*—With the aid of a mechanical shaker, 51 g. of crude gymnemic acid mixture was extracted with 175 ml. of acetone in a glass-stoppered 250-ml. conical flask for 48 hr. The acetone extract was filtered and evaporated to dryness to yield 22.17 g. of acetone-soluble acids. No further investigation of the acetone-insoluble fraction was undertaken.

The acetone-soluble fraction was chromatographed over 450 g. of silicic acid in a glass column (34 × 1200 mm.) prepared with the aid of chloroform. The acetone-soluble fraction, plated on 50 g. of silicic acid with the help of 200 ml. of methanol, was applied to the silicic acid column by the use of chloroform for transfers. Elution was commenced with chloroform at a flow rate of 16–17 ml./hr., while collecting one fraction of 400 ml./day. Polarity of the eluting solvent was gradually increased (as shown in Table II) and all of the fractions collected were analyzed by TLC in Solvent System III.

Ethyl Acetate: Continuous Extraction Separation—In a glass mortar, 20 g. of crude gymnemic acid mixture was finely ground, dissolved in 200 ml. of methanol, and then plated on 100 g. of silicic acid. Two 50-g. portions of silicic acid plated material were first extracted with chloroform (1 l.) and then with ethyl acetate (1 l.), each for 18 hr. in two separate continuous extractors.

The combined chloroform extract, upon evaporation to dryness, yielded 4.15 g. of a green residue which was found to contain only trace amounts of gymnemic acids upon TLC in Solvent System III. However, removal of solvent from the pooled ethyl acetate extract gave 4.86 g. of a light-yellow residue which was observed to be rich in gymnemic acids A–D by TLC. This fraction was named "ethyl acetate acids."

A 4.2-g. quantity of ethyl acetate acids was chromatographed on 100 g. of silicic acid by means of a glass column (23 × 500 mm.).

¹ Melting points were taken on a Kofler hot stage and are uncorrected. Spectra were recorded on Perkin-Elmer models 137B and 337 infrared, Beckman DK-2A UV, and Varian A-60A NMR spectrometers. Microanalyses were performed by Spang Microanalytical Laboratory, Ann Arbor, Mich. Extraction of the plant material was carried out in a Pyrex glass (Corning 3885) side-chamber continuous extraction apparatus. Adjustments of pH were followed with a Beckman Zeromatic pH meter. Centrifugation was carried out with an International Centrifuge model UV at about 2500 r.p.m. All concentrations and evaporations in this investigation were performed under reduced pressure at temperatures not exceeding 50° in either a Buchler Rotary Evapo-Mix (test tube model) or a Rinco flash evaporator.

^a Detection by TLC in Solvent System III. ^b Purification procedures: (i), adsorption chromatography on deactivated silica gel; (ii), reverse phase partition chromatography on Teflon-6; (iii), preparative TLC. ^c Homogeneous by TLC in Solvent Systems I-VII. ^d Stearic acid isolated from these fractions. ^e Isolated as amorphous solid.

The ethyl acetate fraction in 50 ml. of methanol was plated on 10 g. of silicic acid prior to its application to the column. Development of the column was initiated by chloroform followed by solvents with increasing polarity (as shown in Table III). Solvent flow rate was maintained at 10 ml./hr. and fractions (1/hr.) were collected by means of a fraction collector. All fractions collected were individually analyzed by TLC in Solvent System III.

Ethanol Extraction Method—Ethanol (95%) extraction of petroleum ether defatted leaves (105 g.) was performed as described under *Isolation of Crude Gymnemic Acid*. The filtered ethanol extract was concentrated to about 1 l., and petroleum ether was added until no more precipitation occurred (2 l.). The precipitate was collected by centrifugation which, after drying, gave 11.25 g. of a dark-green residue (17.1% of dry leaves).

The residue in 100 ml. of ethanol was plated on 50 g. of silicic acid and the dry plated material was extracted in a continuous extractor, first with chloroform (2 l.) and then with ethyl acetate (2 l.), each for 18 hr. Evaporation of the ethyl acetate extract to dryness afforded 1.93 g. of a light-green residue (1.8% of dry leaves). The presence of gymnemic acids A-D in this ethyl acetate residue was confirmed by TLC in Solvent Systems I-III, while similar TLC analysis of the original ethanol extract of leaves revealed it to contain gymnemic acids A-D and V-Z.

PURIFICATION OF THE GYMNEMIC ACIDS

Adsorption Chromatography on Deactivated Silica Gel—Samples of gymnemic acid mixtures (0.8 g. each) from the preliminary separation procedures rich in acids A, B, or C, as indicated in Tables II and III, were individually chromatographed on 125 g. of deactivated silica gel (125 g. of silicic acid blended with 25 ml. of water) in glass columns² (23 × 600 mm.). These columns were prepared with ethyl acetate, and gymnemic acid mixtures were applied after plating them on 1-g. quantities of deactivated silica gel with the help of 25-ml. portions of methanol. Columns were eluted with ethyl acetate at a flow rate of 10 ml./hr., and 250 fractions (5 ml. each) were collected in each case. All fractions were analyzed by TLC in Solvent System III.

Gymnemic Acid A—A total of 4.16 g. of gymnemic acid A was obtained by eight separate deactivated silica gel adsorption chromatographic separations. Acid A was found to be homogeneous by TLC

in Solvent Systems I-VII. An analytical sample was prepared by four recrystallizations from ethyl acetate and was obtained as white microcrystals, m.p. 279–283° (dec.) [lit. (14) m.p. 285° (dec.)]; $\lambda_{\text{max}}^{\text{MeOH}}$ 201 m μ (a 15.92); $\nu_{\text{max}}^{\text{KBr}}$ 3450 (intermolecular H-bonded, polymeric O—H), 2990 (C—H), 1710 (C=O), 1640, 855, 810 (trisubstituted C=C), 1384 (methyl of —O—COCH₃), 1440 (methylene of —CH₂—O—COR), 1260 (H-bonded O—H), 1070, 1045, (C—O of C—OH), and 920 cm.⁻¹ (β -pyranose ring vibration) (20).

Anal.—Found: C, 63.78; H, 8.31.

Gymnemic acid A was found to be identical to gymnemic acid A₁ isolated by Reichstein's group (14) by TLC in Solvent Systems I-VII and by IR spectroscopy.

Gymnemic Acid B—Gymnemic acid B was isolated in a combined yield of 0.09 g. by deactivated silica gel chromatography of two separate fractions indicated in Tables II and III. Acid B was observed to be homogeneous by TLC in Solvent Systems I-VII. When recrystallized three times from ethyl acetate, gymnemic acid B was obtained as white microcrystals, m.p. 220–225° (dec.); $\lambda_{\text{max}}^{\text{MeOH}}$ 201 m μ (a 15.42); $\nu_{\text{max}}^{\text{KBr}}$ 3450 (O—H), 2990 (C—H), 1710 (C=O), 1625 (trisubstituted C=C), 1450 (side-chain methylene), 1375 (side-chain methyl), 1260 (H-bonded O—H), 1080 and 1040 cm.⁻¹ (C—O of C—OH).

Anal.—Found: C, 63.94; H, 8.53.

Gymnemic Acid C—Two separate deactivated silica gel chromatographic separations of fractions described in Tables II and III gave a total of 0.05 g. of gymnemic acid C. Acid C was found to be homogeneous by TLC in Solvent Systems I-VII. After three recrystallizations from ethyl acetate containing a few drops of methanol, acid C was obtained as white microcrystals, m.p. 215–220° (dec.); $\lambda_{\text{max}}^{\text{MeOH}}$ 201 m μ (a 8.18); $\nu_{\text{max}}^{\text{KBr}}$ 3500 (O—H), 2980 (C—H), 1710 (C=O), 1625 (trisubstituted C=C), 1440 (side-chain methylene), 1370 (side-chain methyl), 1250 (H-bonded O—H), 1070 and 1040 cm.⁻¹ (C—O of C—OH).

Anal.—Found: C, 57.22; H, 7.70.

Reverse Phase Partition Chromatography on Teflon-6—Teflon-6 (100 g.), which had been left at 0° overnight, was added to 100 ml. of the organic phase of a *n*-butanol–water–methanol (10:10:1) mixture cooled to 0°. The uniform slurry formed by vigorous stirring was immediately transferred to a jacketed glass column³ maintained at 17 ± 0.5°. The column was allowed to equilibrate by a flow of 100 ml. of the aqueous phase of the above solvent mixture at a rate of 20 ml./hr.

The sample to be chromatographed (0.5–0.8 g.) was dissolved in a minimum amount of methanol and diluted to four times its volume with the aqueous phase of the solvent mixture. This sample

² Columns with minimum hold-up volumes below packing and to the tip of the column were required to avoid remixing of separated components and to obtain desired resolution.

Table III—Silicic-Acid Chromatography of Ethyl Acetate Acids

Solvent	Fractions (10 ml. each)	Weight, g.	Gymnemic Acids Detected ^a	Purifica- tion Pro- cedure ^b	Purified ^c Gym- nemic Acid Isolated	Weight, g.

^a Detection by TLC in Solvent System III. ^b Purification procedures: (i), adsorption chromatography on deactivated silica gel; (ii), reverse phase partition chromatography on Teflon-6. ^c Homogeneous by TLC in Solvent Systems I-VII.

solution was then applied to the Teflon-6 column and developed with the aqueous phase of the solvent mixture. A flow rate of 10 ml./hr. was maintained and 5-ml. fractions were collected with the aid of a fraction collector. Fractions were combined on the basis of TLC results in Solvent System III.

Gymnemic Acid D—Column RPC of the fractions rich in acid D from preliminary separation methods (see Tables II and III) yielded a total of 0.08 g. of gymnemic acid D. Acid D was found to be homogeneous by TLC in Solvent Systems I-VII. Three recrystallizations from ethyl acetate containing a few drops of methanol yielded acid D as white microcrystals, m.p. 210–220° (dec.); $\lambda_{\text{max}}^{\text{MeOH}}$ 201 m μ (α 9.69); $\nu_{\text{max}}^{\text{KBr}}$ 3440 (O—H), 2940 (C—H), 1715 (C=O), 1620 (trisubstituted C=C), 1450 (side-chain methylene), 1380 (side-chain methyl), 1265 (H-bonded O—H), 1070 and 1040 cm.⁻¹ (C—O of C—OH).

Anal.—Found: C, 59.90; H, 8.00.

Preparative Thin-Layer Chromatography—Preparative TLC plates³ were activated at 100° for 15 min. prior to use. With the help of a microcapillary, 130 mg. of gymnemic acid mixture in about 0.5 ml. of methanol was applied as a streak at a distance of 2 cm. from the bottom of the plate. Chromatograms were developed in Solvent System II to a distance of 15 cm. Resolved components were located as dark bands against a fluorescent background. Separated bands were individually removed from the chromatograms by means of a razor blade and collected in separate 125-ml. conical flasks. To each flask, 50 ml. of ethyl acetate-methanol mixture (50:1) was added and allowed to stand at room temperature for 12 hr. with occasional shaking. Ethyl acetate-methanol extracts were then filtered through a fine sintered-glass funnel and solvents removed *in vacuo*.

Gymnemic acids A–D, isolated by preparative TLC (14 chromatograms) from the various fractions shown in Table II, were found to be identical to those obtained by adsorption and partition chromatographic procedures. Yields of acids A–D secured by the preparative TLC method are shown in Table II.

Gymnemic Acid V—Gymnemic acid V was isolated in a combined yield of 0.01 g. from the fractions indicated in Table II by chromatography on six preparative TLC plates. Acid V was found to be homogeneous by TLC in Solvent Systems I–VII. Recrystallization from ethyl acetate gave acid V as white microcrystals, m.p. 310–312°; $\lambda_{\text{max}}^{\text{EtOH}}$ 201 m μ (α 3.38); $\nu_{\text{max}}^{\text{KBr}}$ 3445 (O—H), 2945 (C—H), 1720 (C=O), 1640 (trisubstituted C=C), 1460 (side-chain methylene), 1385 (side-chain methyl), 1265 (H-bonded O—H), 1075 and 1045 cm.⁻¹ (C—O of C—OH).

Anal.—Found: C, 68.94; H, 9.68.

Gymnemic Acids W–Z—Isolation of gymnemic acids W–Z was accomplished by preparative TLC of the various fractions described in Table II; 14 plates were utilized. Acids W–Z were obtained as light-yellow, amorphous solids, and several recrystallizations from ethyl acetate-methanol failed to yield better products. However, acids W–Z were observed to be homogeneous by TLC in Solvent Systems I–VII. Table II summarizes yields of gymnemic acids W–Z. No further investigation of these acids was carried out.

Isolation and Characterization of Stearic Acid—Evaporation of solvent from ethyl acetate fractions 1 and 2 obtained during silicic-acid chromatography of acetone-soluble gymnemic acids (Table II) gave a yellow, oily residue (84.6 mg.) which upon four recrystallizations from methanol deposited 14.3 mg. of white crystals, m.p. 69–70°; $\nu_{\text{max}}^{\text{KBr}}$ 1700, 1300, 940 (carboxylic acid dimer), eight evenly spaced bands between 1320 and 1190 (16 methylene groups in long-chain *n*-alkyl fatty acid) (21), 728 and 720 cm.⁻¹ (methylene chain rocking).

Anal.—Calcd. for C₁₈H₃₆O₂: C, 75.99; H, 12.76. Found: C, 75.52; H, 12.96.

An 8-mg. sample of the isolated acid was treated with methanolic boron trifluoride (22), and the reaction product was recrystallized twice from ethanol to give white crystals of methyl ester, m.p. 38–38.5°; $\nu_{\text{max}}^{\text{KBr}}$ 1730 cm.⁻¹ (ester carbonyl).

The isolated acid and its methyl ester were identified as stearic acid and methyl stearate, respectively, upon comparison with reference compounds, undepressed mixed melting point, and superimposable IR spectra being the criteria for identity.

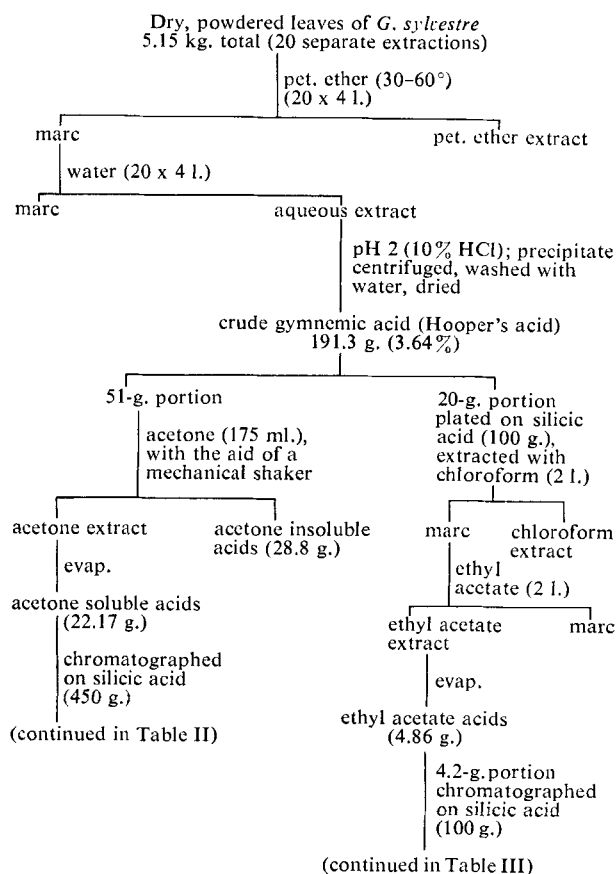

Identification of Gymnemic Acid Sugars—Thirty-milligram quantities of the gymnemic acids were refluxed with 4 ml. of 3 *N* ethanolic hydrochloric acid for 72 hr. The warm hydrolysates were treated with 5 mg. of activated charcoal,⁴ filtered, and concentrated to 3-ml. volumes *in vacuo*. The concentrates were then diluted to 30 ml. with water to separate insoluble aglycone substances which were removed by centrifugation after 1 hr. of refrigeration. The supernatants, adjusted to pH 5–5.5 with 5 *N* sodium hydroxide, were evaporated to dryness, the residues extracted with 2.5 ml. of pyridine-water (4:1), and filtered from sodium chloride solids. The filtrates were evaporated to dryness and residues shaken with 10 ml. of water. The yellow aqueous extracts were filtered onto columns containing 5 ml. of an anion-exchange resin.⁵ These columns were preconditioned with 10 volumes of 3 *N* hydrochloric acid and washed with water to neutrality prior to use. Column effluents and 25 ml. of water washings were collected and applied to a second column containing 5 ml. of a strongly basic ion-exchange resin.⁶ Neutral sugar residues were recovered from the column effluents and 25 ml. of additional water washings by evaporation to dryness. Elution of the basic ion-exchange resin columns with 25 ml. of 1 *N* hydrochloric acid and evaporation of the effluents to dryness gave the acidic sugar fractions. Neutral and acidic sugar fractions were prepared as 2% solutions in 10% isopropanol in water for PC examination in System A (23), ethyl acetate-pyridine-water (12:5:4), and in System B (24), *n*-butanol-benzene-formic acid-water (100:19:10:25) (aged for 3 days at 27°). Detection of sugars was carried out with silver nitrate, aniline diphenylamine, aniline phthalate (23), and modified aniline hydrogen phthalate (24) reagents. Sugars in hydrolysate fractions were identified by direct comparison to reference sugar samples and to reference sugar

⁶ Amberlite IRA 401(CO₃⁻), prepared by converting 5 ml. of Amberlite IRA 401(Cl⁻) (Rohm & Haas Co.) to the carbonate form with 50 ml. of 5% sodium carbonate.

³ E. Merck AG precoated silica gel GF254 plates (thickness 2 mm.).

Scheme I—Flow sheet for the isolation of gymnemic acids

samples which had been subjected to the ethanolysis procedure.

Five-milligram quantities of the gymnemic acids were also hydrolyzed by the following procedure.

The sample was suspended in 1 ml. of Kiliani mixture (acetic acid–water–hydrochloric acid, 35:55:10) (25, 26) and refluxed for 5 hr. The residue obtained after evaporation of the reaction mixture was dissolved in 1 ml. of water and extracted with chloroform (3 × 2.5 ml.). The aqueous layer was evaporated to dryness to give the sugar residue which was then chromatographed as described previously.

Characterization of Glucuronic Acid—The ethyl acetate acids fraction (3 g.) (Scheme I) was hydrolyzed and an acidic sugar fraction was isolated in a manner similar to that described for the individual gymnemic acids (ethanolysis procedure). Methyl-β-D-glucofuranosiduronolactone was prepared from both acidic sugar fraction and reference D-glucuronolactone by the following procedure.

To 108 mg. of acidic sugar fraction in 4 ml. of methanol was added 100 mg. of a cation-exchange resin.⁷ The suspension was refluxed with stirring for 6 hr., clarified with 10 mg. of activated charcoal,⁴ and filtered. The yellow filtrate was evaporated to dryness *in vacuo* and dried over anhydrous calcium sulfate to yield a yellow syrup (95 mg.). This syrup was plated on 0.75 g. of activated silica gel⁸ and chromatographed on a column (13 × 230 mm.) of activated silica gel (10 g.). Elution was carried out with 6% methanol in benzene.

Fractions were monitored by silica gel G TLC with development by 20% methanol in benzene and detection with silver nitrate reagent (23).

Fractions containing material of R_f 0.36 were combined to give 18 mg. of a colorless syrup which was dried over anhydrous calcium sulfate under vacuum. The IR spectrum (neat) of this product exhibited an absorption band at 1790 cm^{-1} (γ -lactone) and the

spectrum was superimposable with that of reference methyl D-glucuronolactone. When 10.8 mg. of the product was seeded with a trace of reference crystalline methyl D-glucuronolactone, gradual crystallization occurred. Recrystallization of the product from ethanol yielded large prisms (3 mg.), m.p. 139°. The melting point of the product was not depressed on admixture with reference methyl-β-D-glucofuranosiduronolactone and the NMR (D_2O) spectra of the two samples were identical.

RESULTS AND DISCUSSION

Isolation of the Gymnemic Acids—Early in this investigation it became apparent that gymnemic acid described in the literature was a mixture of acidic glycosides. TLC of Hooper's (4) gymnemic acid⁹ indicated the presence of at least nine components which were named¹⁰ gymnemic acids A–D and V–Z. The R_f values of these nine gymnemic acids in seven TLC systems are listed in Table I. Gymnemic acid as described by Warren and Pfaffmann (9) with its established antisweet property was found by TLC analysis to consist of acids A and B, the former being the major constituent. Indications of antiviral activity were noted for the gymnemic acid fractions rich in acid A (13).

Plant Extraction and Preliminary Separation—Based upon this information, attempts were made to secure gymnemic acid fractions rich in acid A. By following Hooper's (4) procedure, a crude gymnemic acid mixture was obtained from the aqueous extracts of petroleum ether-defatted *G. sylvestre* leaves by precipitation with 10% hydrochloric acid. Preliminary separation of the gymnemic acids was achieved by (a) acetone extraction: silicic-acid chromatography and (b) ethyl acetate: continuous extraction as summarized in Scheme I. A rapid and milder procedure involving direct ethanol extraction of defatted leaves and precipitation of the acidic glycosides with petroleum ether was also employed to confirm that previously isolated gymnemic acids represented products present in the dried leaves and not artifacts produced during the process of isolation.

Purification of the Gymnemic Acids—The gymnemic acid fractions, obtained during the preliminary separation step *via* silicic acid chromatography, were repeatedly decolorized with activated charcoal⁴ in methanolic solutions until cream-white products were secured. Further purification of the gymnemic acids was carried out by following one of the three procedures: (a) adsorption chromatography on deactivated silica gel; (b) reverse phase partition chromatography (RPC) on Teflon-6; or (c) preparative TLC as summarized in Tables II and III.

In general, preparative TLC procedure was found to be useful for purifying all the gymnemic acids. Gymnemic acids A–D and V were obtained in crystalline form by this procedure. However, gymnemic acids W–Z could be obtained only as amorphous solids despite several recrystallizations. All nine gymnemic acids isolated by preparative TLC were shown to be homogeneous by TLC in seven solvent systems, I–VII. Table II summarizes the results obtained with preparative TLC. Adsorption chromatography on deactivated silica gel proved to be a convenient method for the rapid purification of gymnemic acid A, and to a lesser extent acids B and C, while RPC on Teflon-6 was valuable for obtaining pure acid D. The Teflon-6 RPC was modified from the procedure of Fritz and Hendrick (27) and found to be superior to the silanized diatomaceous earth¹¹ RPC for retaining the stationary phase with prolonged use.

Final purification of the isolated gymnemic acids was carried out by several recrystallizations from either ethyl acetate alone or ethyl acetate containing a few drops of methanol.

Preliminary Characterization of the Gymnemic Acids—This report is limited to preliminary characterization of the major gymnemic acids A–D. Initial characterization work was performed

⁹ Equivalent results were obtained with gymnemic acid commercially available from K & K Laboratories, Inc.

¹⁰ This nomenclature is based upon the order of elution of the components during silicic-acid column chromatography and their abundance in the crude acid mixture. Thus, the four major constituents were named gymnemic acids A–D, acid A being the first major component to elute from the column. Similarly, the minor constituents were named gymnemic acids V–Z, the sequence in which they eluted during chromatographic separation.

⁸ Silicic acid, 100 mesh (Mallinckrodt), was activated at 105° for 24 hr.

Table IV—Sugar Content of the Gymnemic Acids

Sample	Treatment ^a	Glucostat Test	Sugars Detected ^b by Paper Chromatography
Ethyl acetate fraction	Ethanolysis	Positive	Arabinose Glucose Glucuronic acid Glucuronolactone
Gymnemic acid A	Ethanolysis, hydrolysis	Negative	Glucuronic acid Glucuronolactone
Gymnemic acid B	Ethanolysis, hydrolysis	Negative	Glucuronic acid Glucuronolactone
Gymnemic acid C	Ethanolysis, hydrolysis	Positive	Glucose Glucuronic acid Glucuronolactone
Gymnemic acid D	Ethanolysis, hydrolysis	Positive	Glucose Glucuronic acid Glucuronolactone

^a Ethanolysis was carried out by refluxing with 3 *N* ethanolic HCl for 72 hr. and hydrolysis by refluxing with Kiliani mixture (25) for 5 hr.

^b Colors produced by sugars after treating with modified aniline hydrogen phthalate reagent (24) and heating for 3 min. at 105° were visible (UV): arabinose, red (reddish brown); glucose, green (brown); glucuronic acid and glucuronolactone, brown (brown).

with acid A and with the ethyl acetate acids fraction which represented an enrichment of acids A–D. That the remaining gymnemic acids were closely related to acid A was evident by their various physical properties. Of particular significance was their IR spectra which were remarkably similar except for minor variations in the intensity of absorption peaks.

Glycosidic Properties of the Gymnemic Acids—With the aid of anthrone (28) and chromotropic acid (29) tests, reducing sugars were detected in hydrochloric acid hydrolysates of the gymnemic acids. Neutralized and desalted sugar fractions were then separated into neutral and acidic components. Neutral sugars were collected as effluents from a strongly basic ion-exchange resin in the carbonate form (30). Elution of the anionic resin with hydrochloric acid released sugar acids.

The conditions employed for acidic hydrolysis of the gymnemic acids were dependent upon the subsequent use of the hydrolysates. Thus, while hydrolysis in ethanolic hydrochloric acid was found to be faster and less destructive, it led to formation of ethyl glycosides of the sugars. This limited the detection of free reducing sugars and also gave rise to artifacts during chromatographic analysis. Hydrolyses with the Kiliani mixture (25, 26) were performed as a supplement to ethanolysis studies which assured that the sugars released were in the free reducing state. This procedure had value as a direct route for the identification of sugars. However, the harsh conditions of the Kiliani method led to degradation of both sugar and aglycone moieties, limiting its use in sugar isolations.

All sugar fractions were examined by PC and compared to suspected reference sugars which had been subjected to the similar hydrolysis procedures. Chromogens used were: silver nitrate as a nonspecific but sensitive reagent, aniline diphenylamine for its characteristic color variations with sugars, aniline phthalate for its specificity for reducing sugars, and modified aniline hydrogen phthalate for its specificity as well as distinct color production with reducing sugars. The presence of glucose in the neutral sugar fractions was confirmed by the Glucostat test,¹² a specific enzymatic procedure for β -D-glucose.

The procedures applied for the detection of sugars in various gymnemic acid fractions and their results are summarized in Table IV. Glucuronic acid was found in the hydrolysates of gymnemic acids A–D. Identification of glucuronic acid by PC was aided by the presence of an additional highly mobile spot due to glucuronolactone, which arises during hydrolysis as an equilibrium product of glucuronic acid (31). Glucose was observed to be the only neutral sugar constituent in the hydrolysates of gymnemic acids C and D.

Acidic hydrolysis of the ethyl acetate parent fraction gave rise to arabinose in addition to glucose, glucuronic acid, and glucuronolactone. In order to substantiate that arabinose did originate from the ethyl acetate fraction, a mixture of reference glucose and glucuronic acid was subjected to identical acid hydrolysis, and neutral and acidic sugar fractions were isolated as in the case of gym-

nemic acid sugars. Analysis of the reference neutral sugar fraction by PC failed to detect any trace of arabinose. Since gymnemic acids A–D do not contain arabinose, its origin is assigned to at least one of the minor gymnemic acids. Pfaffmann (10) reported the detection of arabinose along with glucose and glucuronolactone from the hydrolysate of his sample of gymnemic acid which has subsequently been shown to be a mixture (14).

The ethyl acetate parent fraction was also utilized in the present study as a source for the isolation of glucuronic acid to confirm the PC results. Isolation was in the form of methyl- β -D-glucuronolactone by the method of Osman *et al.* (32). The isolated compound was identical with the methyl glycoside of reference glucuronolactone by undepressed mixed melting point, chromatography, IR, and NMR analyses.

Positive color reactions with Liebermann-Burchard (19) and benzoyl chloride-sulfuric acid (17) reagents suggested gymnemic acids A–D to be glycosides of either steroid or triterpenoid alcohols. Further, the strong hydroxyl absorption around 3500 cm^{-1} and the characteristic bands in the region 700–1200 cm^{-1} (33) in their IR spectra, and a high percentage of oxygen content (about 30%) as indicated by elemental analyses, were consistent with the glycosidic character of the gymnemic acids.

Comparison of Gymnemic Acids Isolated by Various Investigators—While the current investigation was in progress, Stöcklin *et al.* (14) reported their isolation of the antisweet principle of *G. sylvestre* leaves, which they named gymnemic acid A₁. This isolation in a yield of about 0.004% was achieved by a complex procedure involving several treatments with both acid and base.

Reichstein's group called their parent fraction, from which gymnemic acid A₁ was secured, gymnemic acid A. Fraction A showed a single spot during TLC in four solvent systems.¹³ However, in Solvent System VII, their gymnemic acid A was found to be a mixture composed of acids A₁, A₂, A₃, and A₄. Gymnemic acids A₁ and A₂ were shown to be identical to the two spots produced by Warren and Pfaffmann's gymnemic acid in the same TLC system. Acid A₁ is the major constituent in both the fractions isolated by the Swiss group and by Warren and Pfaffmann.

Direct TLC comparison of gymnemic acids A–D, isolated in the present investigation, with acids A₁–A₄ obtained by Reichstein's group established that in TLC Systems I–VII acids A and B were identical to acids A₁ and A₂. However, acids C and D did not correspond to acids A₃ and A₄.

Stöcklin *et al.* (14) felt that gymnemic acid A₁ was the native antisweet principle of *G. sylvestre* leaves. Because of the harsh conditions employed in the isolation procedure, there existed the possibility of their acids A₂ and A₃ being artifacts originating from acid A₁. In this study, the ethanol extraction and petroleum ether precipitation method is presented as evidence for the natural occurrence of gym-

¹² Glucostat test was performed according to Method I-A described in the literature accompanying the reagent kit (Worthington Biochemical Corp.).

¹³ Adsorbent, silica gel G; solvent systems: ethanol–water–ammonium hydroxide (18:2:1), isopropanol–water–ammonium hydroxide (9:1:1), chloroform–methanol–ammonium hydroxide (5:1:1), and *n*-butanol–water–acetic acid (10:1:1).

nemic acids A–D. This fact, coupled with the nonidentity of gymnemic acids A₃ and A₄ with acids C and D from these laboratories or any of the minor acids, suggests that acids A₃ and A₄ are degradation products.

Further, gymnemic acid A (A₁–A₄) was shown by the Swiss group to contain glucuronic acid as the sole sugar residue. This is in agreement with the authors' gymnemic acids A and B which also contain only glucuronic acid. In contrast, presence of both glucuronic acid and glucose in gymnemic acids C and D from this study has been established.

Structural elucidation of gymnemic acids A–D will be the subject of forthcoming papers from the authors.

Constituents from *Gymnema sylvestre* Leaves VI: Acylated Genins of the Gymnemic Acids— Isolation and Preliminary Characterization

JOSEPH E. SINSHEIMER and G. SUBBA RAO*

Abstract □ With the aid of a selective enzyme system, genins G, K, N, and gymnestrogenin were isolated and shown to be the aglycones of gymnemic acids A–D, respectively. Genin G was found to be an acylated derivative of gymnemagenin containing formic, acetic, isovaleric, and tiglic acids, while genin K differed from G by the absence of the acetic acid residue. Genin N was observed to be gymnestrogenin tiglate. Genin J, probably an artifact originating from genin G, was also isolated and indicated to be gymnemagenin esterified with acetic, isovaleric, and tiglic acids. The sugar moieties of acids A and B are not acylated, while those of acids C and D are indicated to be esterified with ferulic acid.

Keyphrases □ *Gymnema sylvestre* leaves—acylated genins, isolation □ Genins, acylated—*G. sylvestre* gymnemic acids □ Paper chromatography—identity □ TLC—identity □ IR spectrophotometry—structure □ GLC—identity

In the preceding paper (1), the authors described the isolation and preliminary characterization of the major constituents, acids A–D, of gymnemic acid, the anti-sweet principle of *Gymnema sylvestre* R. Br. (*Asclepiadaceae*) leaves. Gymnemic acids A–D were shown to be acidic glycosides containing glucuronic acid as the sugar component, while acids C and D were also observed to possess glucose. This paper deals with further developments in the structural elucidation of these gymnemic acids.

Acidic or enzymatic hydrolysis of individual gymnemic acids yielded genin mixtures consistent with the presence of acylated genins in the parent glycosides. Characterization of neutral components, obtained after acidic and basic hydrolyses of individual acids A–D, was carried out to establish their genin structure after complete deacylation. Identification of carboxylic acids in the basic hydrolysates of gymnemic acids A–D was then performed to characterize further each gymnemic acid. A selective enzyme procedure, recently developed by Kapadia (2), was utilized to secure the intact acylated genins of the gymnemic acids which were then available for structural investigation. A comparative study of the acylated genins obtained in this investigation with those isolated by Stöcklin *et al.* (3) was also conducted.

EXPERIMENTAL¹

Reagents—Firebrick (Gas-Chrom RA, 80/100 mesh) and neopentylglycolsuccinate, regular (HI-EFF) (both from Applied Science Labs.); β -glucuronidase aryl sulfatase from *Helix pomatia*,

B grade, 160,000 Fishman units/ml. (Calbiochem); and a commercial insecticide ("Real-Kill," Real-Kill Products, Division of Cook Chemical Co., Kansas City, Mo.).

Paper Chromatography—Hydroxamic derivatives (4) (from 10 mcg. of reference carboxylic acids and 100–500 mcg. of sample fractions) were spotted on Whatman No. 1 paper (57 × 19.5 cm.) and saturated for 16 hr. with the aqueous phase of solvent systems employed for development. Chromatograms were developed by descending technique to a distance of 48 cm. For analysis of hydroxamic derivatives of carboxylic acids, Solvent System A, *n*-butanol–dimethyl formamide–water (9:1:1), and Solvent System B, *n*-butanol–acetic acid–water (4:1:5) (4), were employed. Ferric chloride spray reagent was used to visualize hydroxamic acids on chromatograms (4).

Thin-Layer Chromatography—Silica gel G TLC of the genins was performed as in the case of the gymnemic acids (1). Solvent Systems I–IV are described in Table I. Ceric sulfate–sulfuric acid reagent (6) was used as the chromogen.

Identification of ferulic acid by silica gel G TLC was carried out in the following solvent systems: V, ethanol–water–ammonium hydroxide (90:25:4); VI, benzene–dioxane–acetic acid (90:25:4); and VII, *n*-butyl ether (water-saturated)–acetic acid (10:1) (7). Detection of ferulic acid on chromatograms was by spraying with diazotized sulfanilic acid reagent (8).

Gas-Liquid Chromatography—Preparation of a stationary phase of firebrick (Gas-Chrom RA, 80/100 mesh) treated with 10% neopentylglycolsuccinate and 2% phosphoric acid, and packing of columns [1.52 m. × 0.32 cm. (5 ft. × 0.125 in.) copper] were carried out as described in the literature (9–11). Columns were conditioned for 12 hr. as follows: oven temperature, 195°; detector temperature, 200°; injection port temperature, 200°, and carrier gas, helium, at 40 p.s.i. Carboxylic acids (sample size: reference acids, 15 mcg.; sample fraction, ~200 mcg.) were chromatographed under the following conditions: oven temperature, 125°; detector temperature, 210°; injection port temperature, 200°; carrier gas, helium, 60 ml./min. (80 p.s.i.); hydrogen, 50 ml./min. (16 p.s.i.); air, 380 ml./min. (16 p.s.i.); attenuation, 1; and range, 50.

Acidic Hydrolysis—Thirty-milligram quantities of the gymnemic acids were refluxed with 4 ml. of 3 *N* ethanolic hydrochloric acid for 72 hr. The warm hydrolysates were treated with 5 mg. of activated charcoal² and concentrated to 3 ml. The concentrates were diluted with water to precipitate genins which were collected by centrifugation after 1 hr. of refrigeration. After washing with water twice, genin precipitates were dried to yield white residues weighing 12–15 mg. TLC Systems I–III (Table I) were employed to analyze these genin residues.

Basic Hydrolysis and Identification of Carboxylic Acids—Basic hydrolysis of gymnemic acids was performed by refluxing 20-mg. samples in 5 ml. of 5% methanolic potassium hydroxide solution for 2 hr. Cooled reaction mixtures were poured into 10-ml. portions of water and precipitated genins were filtered off. After removal of methanol from alkaline filtrates *in vacuo*, they were acidified with 2 *N* sulfuric acid and extracted with ether (6 × 10 ml.). Ether extracts were dried over anhydrous sodium sulfate, filtered, and evaporated to dryness *in vacuo*. Yellow oily residues weighing 4–7 mg. were obtained in each case. These residues were dissolved in minimal amount (~0.1 ml.) of either ether or methanol, and 3–6 μ l. of these fractions were analyzed for the presence of free carboxylic acids by GLC. Table II summarizes GLC results. Identification of ferulic acid was carried out by TLC in Solvent Systems V–VII.

Methyl esters of carboxylic acids present in these described fractions were prepared by treatment with diazomethane (12) and

¹ Melting points were recorded on a Kofler hot stage and are uncorrected. IR spectra were taken on Perkin-Elmer spectrophotometer models 137B and 337. F&M model 700 gas chromatograph was employed for GLC of carboxylic acids. Enzymatic hydrolyses were carried out in either a Precision constant-temperature water bath or a Precision incubator maintained at the desired temperature. Microanalyses were performed by Spang Microanalytical Laboratory, Ann Arbor, Mich.

Table I—Thin-Layer Chromatography of the Genins

Genin	R_f Value in Solvent System ^a			
	I	II	III	IV
G	0.64	0.63	0.70	0.73
J	0.55	0.49	0.62	0.67
K	0.47	0.38	0.54	0.63
N	0.39	0.35	0.50	0.61
Gymnestro- genin	0.32	0.16	0.44	0.56
Gymnema- genin	0.23	0.10	0.27	0.40

^a Solvent Systems: I, benzene-methanol-acetic acid (45:8:4) (5); II, chloroform-methanol (9:1) (3); III, benzene-chloroform-methanol (5:8:3); and IV, benzene-methanol (7:3).

then converted to hydroxamic acids by reacting with hydroxylamine according to the procedure of Bayer and Reuther (4). These hydroxamic acids were analyzed by PC in Solvent Systems A and B for the presence of formic and acetic acid derivatives.

Results of these chromatographic identifications of carboxylic acids in the hydrolysates of various gymnemic acids are given in Table III.

Isolation of Genins—Gymnemagenin—Gymnemic acid A (30 mg.) was refluxed with 5 ml. of 8% sulfuric acid in 50% aqueous ethanol for 6 hr. The reaction mixture was then concentrated to about 1 ml. *in vacuo* and poured into 20 ml. of ice water. The precipitated material was collected by centrifugation, dried, and refluxed with 5 ml. of 5% methanolic potassium hydroxide for 6 hr. Concentration of the reaction mixture to about 1 ml. and pouring into 20 ml. of ice water yielded 18.1 mg. of a white residue. Recrystallization of this residue from chloroform-methanol gave gymnemagenin as white needles, m.p. 329.5–331° [lit. (3) m.p. 328–335°]; $\nu_{\text{max}}^{\text{KBr}}$, 3450 (O—H), 2900 (C—H), 1635 (trisubstituted C=C), 1250 (H-bonded O—H), 1070 and 1040 cm^{-1} (C—O or C—OH).

Anal.—Calcd. for $\text{C}_{30}\text{H}_{50}\text{O}_6$: C, 71.11; H, 9.95. Found: C, 70.95; H, 9.91.

Identity of gymnemagenin with that isolated by Reichstein's group (3) was established by undepressed mixed melting point, superimposable IR spectra, and TLC in Solvent Systems I–IV.

Gymnestrogenin—To a suspension of 10 mg. of gymnemic acid D in 10 ml. of water, 0.1 ml. of β -glucuronidase (*Helix pomatia*) preparation and 2 drops of insecticide (Real-Kill) were added and kept at $40 \pm 1^\circ$ for 5 days. The enzyme digest was then boiled for 1 min., cooled, diluted with 50 ml. of ethanol, and filtered through a bed of diatomaceous earth.³ The filtrate was evaporated *in vacuo* and the residue obtained was extracted with chloroform (4 \times 10 ml.). Pooled chloroform extracts, upon removal of solvent, gave 2.9 mg. of a white residue which was recrystallized from chloroform-methanol to yield fine needles of gymnestrogenin, m.p. 286–288° [lit. (13) m.p. 288–289°]; $\nu_{\text{max}}^{\text{KBr}}$, 3470 (O—H), 2945 (C—H), 1635 (trisubstituted C=C), 1070 and 1040 cm^{-1} (C—OH).

Gymnestrogenin was observed to be homogeneous by TLC in Solvent Systems I–IV and identical to a reference sample (13) by TLC, undepressed mixed melting point, and superimposable IR spectra.

Genin G—To a suspension of 100 mg. of gymnemic acid A in 50 ml. of water, 0.2 ml. of β -glucuronidase (*Helix pomatia*) and 5 drops of insecticide were added and kept at $40 \pm 1^\circ$ for 5 days. Isolation of 34.6 mg. (34.6%) of hydrolysis product was carried out as in the case of gymnestrogenin. This product was observed to be homogeneous by TLC in Solvent Systems I–IV. Recrystallization of the hydrolysis product from petroleum ether-chloroform gave genin G as shiny white crystals, m.p. 164–166°; $\nu_{\text{max}}^{\text{KBr}}$, 3450 (O—H), 2960 (C—H), 1740 (C=O), 1460 and 1385 (side-chain methylene and methyl of $-\text{CH}_2-\text{O}-\text{COCH}_3$, respectively), 1260 (H-bonded O—H), 1080 and 1040 cm^{-1} (C—OH).

Anal.—Calcd. for $\text{C}_{48}\text{H}_{86}\text{O}_{11}$: C, 69.51; H, 8.95. Found: C, 69.52; H, 9.11.

Genin J—A 450-mg. sample of the parent gymnemic acid mixture isolated by the ethyl acetate procedure (1) was dissolved in 150 ml. of 0.01 *N* potassium bicarbonate, 1 ml. of β -glucuronidase (*Helix pomatia*) preparation added, and kept at $37 \pm 0.5^\circ$ for 5 days (3).

Table II—Gas-Liquid Chromatography of the Carboxylic Acids from the Gymnemic Acids

Acid	R_t , min. ^a
Formic, acetic ^b	1.57
Propionic	2.51
Isobutyric	3.06
<i>n</i> -Butyric	4.15
Isovaleric	4.93
Tiglic	10.81
Unidentified	20.05
Unidentified	21.54

^a Relative to solvent front. Ferulic acid could not be chromatographed under the conditions employed. ^b Identification of these two acids was accomplished by paper chromatography of their hydroxamic acid derivatives (3, 4).

The enzyme digest was then diluted with 750 ml. of ethanol, filtered through a bed of diatomaceous earth and the filtrate evaporated *in vacuo* to yield 398.7 mg. of a pale-yellow residue. This residue was found by TLC (Table I) to be a mixture composed of genins G, J, K, gymnestrogenin, and gymnemagenin.

A 2.6-mg. quantity of genin J was isolated from the above genin mixture by preparative TLC⁴ using Solvent System II for development. Recrystallization from petroleum ether-chloroform yielded genin J as white crystals, m.p. 195–196° [lit. (3) m.p. 193–196°]; $\nu_{\text{max}}^{\text{KBr}}$, 3450 (O—H), 2960 (C—H), 1740 (C=O), 1460 (side-chain methylene), 1390 (side-chain methyl), 1260 (H-bonded O—H), 1080 and 1040 cm^{-1} (C—OH). Genin J was found to be homogeneous by TLC in Solvent Systems I–IV.

Genin K—To a suspension of 20 mg. of gymnemic acid B in 10 ml. of water, 0.1 ml. of β -glucuronidase (*Helix pomatia*) and 2 drops of insecticide were added and kept at $40 \pm 1^\circ$ for 5 days. Isolation of genin K from the hydrolysate was carried out as described for gymnestrogenin. A yield of 6.1 mg. of genin K was obtained. Recrystallization from petroleum ether-chloroform gave genin K as white crystals, m.p. 146–148°; $\nu_{\text{max}}^{\text{KBr}}$, 3450 (O—H), 2950 (C—H), 1710 (C=O), 1455 and 1390 (side-chain methylene and methyl, respectively), 1265 (H-bonded O—H), 1080 and 1045 cm^{-1} (C—OH). Genin K was observed to be homogeneous by TLC in Solvent Systems I–IV.

Genin N—A 10-mg. quantity of gymnemic acid C was subjected to enzymatic hydrolysis with the selective β -glucuronidase (*Helix pomatia*) preparation as described in the isolation of genin K. The hydrolysis product (3.6 mg.) was found to consist of genin N with trace amounts of genins G and K, based upon TLC in Solvent Systems I–IV.

RESULTS AND DISCUSSION

Detection of the Acylated Genins—Stöcklin *et al.* (3) observed that hydrolysis of their gymnemic acid A mixture⁵ by the snail (*Helix pomatia*) β -glucuronidase yielded a genin mixture composed of genins G, J, K, and gymnemagenin. A direct TLC comparison of this genin mixture with that obtained during similar enzymatic hydrolysis of gymnemic acid A from these studies established the two genin mixtures to consist of identical components. Also, TLC analysis of nonsugar fractions secured by acidic hydrolysis of gymnemic acids A–D from these studies revealed them to be mixtures of closely related genins.

The production of genin mixtures during acidic hydrolysis of the gymnemic acids is consistent with the reported (3) presence of acyl groups which would undergo partial hydrolysis in acid medium (14). Indeed, when the genin mixture resulting from gymnemic acid A was refluxed with 5% methanolic potassium hydroxide solution, it yielded a single compound, gymnemagenin,⁶ in a completion of

⁴ E. Merck silica gel GF 254 preparative plates (thickness 2 mm.).

⁵ The Reichstein group described this mixture to be composed of acids A₁–A₄, of which acids A₁ and A₂ were found to be identical to the authors' acids A and B (1).

⁶ Gymnemagenin was found to be identical to a reference sample isolated by Reichstein's group (3) by TLC, undepressed mixed melting point, and superimposable IR spectra. Structure I has been recently assigned for gymnemagenin (15, 16).

Table III—Constituents of Gymnemic Acids A–D

Gymnemic Acid	Sugar	Acylated Aglycone	Parent Genin	Carboxylic Acids ^a in Aglycone				
				Sugar Residue	Formic	Acetic	Iso-valeric	Tiglic
A	Glucuronic acid	G	Gymnema-genin	None	+	+	+	+
		J	Gymnema-genin	—		+	+	+
B	Glucuronic acid	K	Gymnema-genin	None	+		+	+
C	Glucuronic acid	N	Gymnestro-genin	Ferulic ^b				+
D	Glucose	—	Gymnestro-genin	Ferulic				
	Glucuronic acid							
	Glucose							

^a Results obtained from alkaline hydrolysis of genins G, J, and K have been supported by preliminary NMR and mass spectrometric studies (26).

^b This distribution of ferulic and tiglic acid is deduced by comparison to gymnemic acid C and not by direct identification of the acids in the hydrolysate of genin N.

the hydrolysis. Alkaline hydrolysis of the genin mixture obtained by the Swiss investigators also gave them gymnemagenin. Similarly, acidic and basic hydrolyses of gymnemic acid B afforded gymnemagenin, while acids C and D upon identical treatment produced gymnestrogenin.⁷ Chromatographic examination of alkaline hydrolysates of the gymnemic acids confirmed the presence of carboxylic acids, thus establishing these glycosides to be acylated derivatives.

Identification of the Carboxylic Acids—From the hydrolysate obtained after enzymatic and alkaline hydrolyses of their gymnemic acid A₁–A₄ mixture, Reichstein's group (3) identified formic, acetic, *n*-butyric, isovaleric, and tiglic acids by GLC and PC. Gymnemic acid A (the present authors' designation), when subjected to a similar detection procedure, revealed the presence of formic, acetic, isovaleric, and tiglic acids in the basic hydrolysate, while gymnemic acid B yielded all these acids except acetic acid. Ferulic and tiglic acids were found in the alkaline hydrolysate of gymnemic acid C while acid D yielded only ferulic acid. The basic hydrolysate of the ethyl acetate parent mixture (I) of gymnemic acids A–D was also examined by GLC and PC. In addition to those compounds given above as arising from acids A–D, trace amounts of *n*-butyric (as noted by the Swiss investigators), isobutyric, propionic, and two unidentified acids were detected (Table II).

Isolation of the Acylated Genins—During enzymatic hydrolysis of their gymnemic acid A mixture, Stöcklin *et al.* (3) found that cleavage of acyl groups present in these glycosides had occurred along with liberation of glucuronic acid. These investigators indicated that this cleavage of acyl groups could be due to either saponification under the alkaline condition (0.01 *N* potassium bicarbonate) employed or to the action of esterase enzymes known to be present in snail β -glucuronidase preparations (3, 17–19). In the present investigation, hydrolysis of individual gymnemic acids by similar enzyme preparation⁸ in neutral solutions also cleaved acyl groups along with glycosidic linkages. This suggested esterase activity of the β -glucuronidase preparation to be responsible for the hydrolysis of acyl groups.

During a structural elucidation of the cardenolide glycoside, acospectoside A, Kapadia (2) recently developed a procedure for a selective enzymatic hydrolysis of the glycosidic linkage in the presence of an acyl group. This was accomplished by inhibiting esterase

activity of the enzyme preparation through addition of a few drops of the insecticide which contains an esterase inhibitor, *O,O*-dimethyl-*O*-(2,2-dichlorovinyl) phosphate (DDVP) (25). In the present investigation, a similar selective enzyme system made from the commercial β -glucuronidase (*Helix pomatia*) preparation was also found to cleave selectively glycosidic linkages in the gymnemic acids.

By use of this selective enzyme preparation, gymnemic acids A, B, and D were observed to produce single genins G, K, and gymnestrogenin, respectively, in neutral solutions at $40 \pm 1^\circ$. However, if hydrolysis was allowed to proceed beyond 6 days, degradation products of the initially formed genins also appeared. Accordingly, crystalline genins G, K, and gymnestrogenin were isolated from the corresponding enzyme digests by allowing hydrolysis to proceed for 5 days. Similar hydrolysis of gymnemic acid C yielded a new genin, N,⁹ as a major product with trace amounts of genins G and K. The latter two genins can be assigned to traces of acids A and B originally present in the gymnemic acid C sample employed. These enzymatic hydrolyses were followed by TLC in Solvent System II.

Stöcklin *et al.* (3) attempted to isolate the acylated genins from the snail enzyme hydrolysate of their gymnemic acid A mixture by silicic-acid chromatography. This resulted in the isolation of genin J in crystalline form, m.p. 193–196°, while genins G and K were obtained as amorphous solids. However, the latter two genins yielded crystalline acetate derivatives.

Due to its apparent structural similarity and potential utility in the structure proof of the acylated genins, genin J was also isolated in this investigation. This was accomplished by preparative TLC from the genin mixture obtained by nonselective enzymatic hydrolysis of the parent mixture of acids obtained by the ethyl acetate procedure (1).

Characterization of Acyl Functions—Reichstein's group (3), based upon elemental analysis and the identification of carboxylic acids in their gymnemic acid mixture, postulated gymnemic acid A₁

⁷ Gymnestrogenin was observed to be identical to a reference sample isolated by Stöcklin (13) directly from the leaves of *G. sylvestre* and he has also designated Structure II to this compound.

⁸ The β -glucuronidase preparation from the snail, *Helix pomatia*, has been demonstrated to effect the cleavage of β -linked D-glucose (20) as well as D-glucuronic acid (21) present in several steroid and triterpenoid glycosides. In addition, this snail enzyme preparation has been found to cleave D-glucose residues from various glycosides that were resistant to similar hydrolysis by other enzymes known to cleave β -linked D-glucose, e.g., strophanthobiasin (20, 22, 23). It may be mentioned here that gymnemic acids A–D could not be hydrolyzed by either β -glucuronidase (bovine liver) or β -glucosidase (almond emulsion) preparations (24).

⁹ Naming of the new aglycone, genin N, is a continuation of Stöcklin's nomenclature (13).

(the present authors' acid A), $C_{40}H_{74}O_{16}$, to be the glucuronide of gymnemagenin containing 1 mole of formic, acetic, isovaleric, and tiglic acids through ester linkages. Similarly, genin J, $C_{40}H_{64}O_8$, was hypothesized to be mono-*o*-isovaleryl-mono-*o*-tiglyl-gymnemagenin. Except for the IR spectra, no further work on genins G, J, K, and their acetates has been reported by Reichstein's group.

The present authors' experiments utilizing the selective enzyme preparation clearly established genins G, K, N, and gymnestrogenin to be the aglycones of gymnemic acids A, B, C, and D, respectively. Basic hydrolysis of genins G, J, and K showed them to be acylated derivatives of gymnemagenin, while similar hydrolysis of genin N proved it to be an acylated derivative of gymnestrogenin. These relationships are summarized in Table III. It may be noted that genin J differs from genin G only by absence of a formyl group. It is suggested that genin J arises primarily as an artifact of the further hydrolysis of genin G rather than from a minor gymnemic acid. This is based upon the isolation of genin G in significant yields after nonspecific enzymatic hydrolysis of the ethyl acetate-extracted acids, a fraction relatively free of minor gymnemic acids.

A distribution of carboxylic acids between sugar and aglycone portions of gymnemic acids A-D is also indicated in Table III. Basic hydrolysis of both gymnemic acid A and genin G yielded identical mixtures of formic, acetic, isovaleric, and tiglic acids. Similarly, alkaline hydrolysis of gymnemic acid B and genin K gave identical carboxylic acid mixtures (formic, isovaleric, and tiglic acids). This deleted the possibility of hydroxyl groups in the sugar moieties of gymnemic acids A and B being esterified. However, since gymnemic acid D yields gymnestrogenin upon selective enzyme treatment and liberates ferulic acid only after its basic hydrolysis, it is indicated that ferulic acid is present in the sugar part of this glycoside. Based upon the similarity between gymnemic acids C and D, both in their genin and sugar portions, it is postulated that the ferulic acid found in the basic hydrolysate of acid C is also present in the sugar residue of this acid. However, an identification of carboxylic acids in a basic hydrolysate of genin N, the aglycone of gymnemic acid C, has not been carried out due to a lack of pure sample.

Investigations directed toward the position assignment of acyl and sugar residues in the basic genin structure of gymnemic acids A-D are currently in progress.

Inhibition of Sulfathiazole Crystal Growth by Polyvinylpyrrolidone

A. P. SIMONELLI, S. C. MEHTA, and W. I. HIGUCHI

Abstract □ The results of polyvinylpyrrolidone inhibition of sulfathiazole single crystal growth are presented. It was found that the minimum concentration of polyvinylpyrrolidone required to inhibit completely crystal growth was a linear function of the supersaturation ratio with an intercept of ~ 1.15 exhibited on the latter axis. It was also found that the minimum concentration of polyvinylpyrrolidone required for complete inhibition of crystal growth was a function of the molecular weight of polyvinylpyrrolidone used for the inhibition study. The results of inhibition studies using molecular weights of polyvinylpyrrolidone of 10,000, 40,000, and 360,000 are presented. The data suggest that the inhibition point depends on the relative rates of transport of polyvinylpyrrolidone and sulfathiazole to the crystal surface from the bulk of the solution. A model is presented that appears to be consistent with the data.

Keyphrases □ Sulfathiazole crystal growth—polyvinylpyrrolidone effect □ Crystal growth, sulfathiazole—mechanism, polyvinylpyrrolidone inhibition □ Polyvinylpyrrolidone molecular weight effect—sulfathiazole crystal growth □ Model, kinetic—polyvinylpyrrolidone effect, sulfathiazole crystal growth

The growth of crystals may create undesirable changes in many pharmaceutical preparations such as suspensions for intramuscular or subcutaneous injection, oral suspensions, suppositories, and ointments containing undissolved drug particles. Crystal growth may cause these preparations to change drastically their particle-size distribution. Associated crystal growth formulation problems include adverse changes in syringeability, dispersibility, and irritability to the patient upon administration (1–3).

Crystal growth may also play an important role in polymorphic reversion. When polymorphism is present, the various crystal modifications of solid drugs can exhibit drastically different physical characteristics. Most important of these characteristics from a drug-availability standpoint are differing solubilities and dissolution rates as they can significantly alter important pharmacokinetic factors such as rates of absorption, drug availability, and resulting physiological concentrations. Since the higher energy crystal form of the drug exhibits higher activity, maintaining the physical stability of the high energy polymorphic form of drugs in suspension despite their instability becomes very important and has posed many problems to formulators. The importance of this problem is compounded by the fact that the reversion of the unstable form to the more stable form produces a less soluble form of the drug and in doing so increases the rate of crystal growth due to the resulting higher supersaturations. Such changes are realized if the unstable modification is exposed to the conditions of temperature and solvent (4–7) which permit rapid crystal growth of the more stable phase. Unless there is inhibition, such changes may lead to

marked variances in a formulation's performance as a physical or drug delivery system.

Crystal growth and the associated polymorphic reversion have been extensively studied, and it has been found that a number of additives such as polymers and surfactants prevent these undesirable changes in pharmaceutical preparations (8–10). A survey of the literature, however, shows that very little is known regarding the role played by these agents in these situations except for their classifications as dispersion or suspending agents. Recognizing the need for studies designed to shed some light on the mechanism of this phenomenon, this study was initiated as a logical extension of the previous investigation regarding the growth of single crystals. While this report deals only with the sulfathiazole–polyvinylpyrrolidone (PVP) system, the underlying principles are sufficiently general to be extrapolated to other drug–polymer systems. Sulfathiazole was chosen because it has exhibited polymorphic behavior and is widely used as a suspension.

APPARATUS AND PROCEDURE

The apparatus and procedure used to study crystal growth rates have been described in another communication (11). The effect of additives upon the rate of crystal growth was determined by adding polymer in increments as a function of time through a sampling hole in the container lid. A stopwatch was used to obtain the time of each measurement of the crystal dimension and the time of inhibitor addition.

RESULTS AND DISCUSSION

Since the growth of the long axis of a single crystal of sulfathiazole in the absence of inhibitor must serve as a base line and integral part of this study, Fig. 1, which illustrates the growth rate of sulfathiazole as a function of the supersaturation ratio (11), is included. The supersaturation ratio, S , is the supersaturated solution concentration of sulfathiazole divided by the solubility of sulfathiazole. Figure 1 shows that the crystal growth rate of sulfathiazole is a linear function of the supersaturation ratio at higher supersaturations and that extrapolation of the linear portion of the curve yields an intercept on the supersaturation ratio axis at about a value of 1.15. Below a supersaturation ratio of 1.15, crystal growth may occur and may be surface controlled (11). Figure 1 also clearly shows that the stirring rate exerts a strong influence on the observed crystal growth rate above this supersaturation ratio and strongly indicates that in this region the growth rate must be diffusion controlled.

The effect of addition of PVP to the supersaturated solution was next investigated. It was found that the resulting effect on the sulfathiazole crystal growth rate was dependent upon the concentration of PVP in solution. To investigate this aspect further the polymer was added in lambda increments as a function of time. Between additions of polymer, the length of the crystal was also measured as a function of time and in this way the effect of PVP on the growth rate was established. Figure 2 shows typical results of such an experiment. The crystal length is plotted *versus* time and each arrow indicates the time of an addition of a solution of PVP by means of a lambda pipet. Interestingly the direction as well as the magnitude of the PVP effect was apparently dependent on the PVP concentration.

Figure 1—Crystal growth of sulfathiazole in water along the long axis as a function of supersaturation at different stirring speeds. Key: Δ , 10 r.p.m.; \bullet , 150 r.p.m.; and \square , 400 r.p.m.

The initial additions of PVP showed no apparent effect; then further additions of PVP apparently decreased the growth rate; the rate of growth then apparently increased with other additions of PVP; and finally, still further additions of PVP caused complete crystal growth inhibition. This experiment was repeated a large number of times, and the results showed that this behavior was qualitatively reproducible, *i.e.*, the acceleration of growth before complete inhibition. The rate of acceleration, however, was not quantitatively reproducible. The reason for this becomes apparent if the growth pattern of the crystal is noted during the experiment, because the addition of PVP not only caused changes in the rate of crystal growth but also caused changes in the growth pattern. This is illustrated in Fig. 3 which shows the appearance of the crystals at various stages of the experiment. Initially the crystal face outline has smooth linear lines which converge to sharp points. This outline is maintained during its

Figure 2—A typical plot of crystal growth of sulfathiazole as a function of time, with incremental additions of PVP to the solution made also as a function of time. Each arrow indicates the time of addition of PVP solution in lambda increments.

Figure 3—Appearance of crystal surface outline at various stages of the experiment: A, original crystal at $t = 0$; B, after normal growth; and C, after the addition of PVP, showing polymer inhibition.

enlargement as crystal growth proceeds in the absence of PVP. After the addition of PVP, however, the smooth linear lines during the accelerated growth period are replaced by randomly jagged lines which converge to indefinite intersection points. These intersection points are rounded as opposed to the sharp points previously observed.

Although the accelerated growth rate was not quantitative, the point of complete inhibition was reproducible and indicated that it would provide meaningful data regarding the influence of PVP. For this reason the minimum concentration of PVP for complete inhibition was noted as a function of the supersaturation ratio (Fig. 4). The relationship shown by Fig. 4 appears to be linear with an x-axis intercept and, as expected, it shows that higher PVP concentrations are needed as the supersaturation increases. It should be emphasized that each point plotted in Fig. 4 was the result of a large number of PVP additions to the solution with subsequent observation of the crystal length between additions to determine its rate of crystal growth. When the crystal ceased to grow, the sum of the PVP additions was calculated and the PVP concentration in the solution determined. This value was checked by mounting a new crystal and exposing it to the above inhibitory concentration of PVP to elimi-

Table I—Comparison of PVP Equivalent and Molar Weights Needed for Crystal Growth Inhibition

PVP Molecular Weight	Ratio of Slopes ^a	
	Equiv. Weight Basis (ψ) ^b	Molar Weight Basis (α) ^c
10,000	1.00	1.00
40,000	1.49	0.37
360,000	4.30	0.12

^a Relative to the 10,000 molecular weight slope. ^b ψ , also equal to the number of equivalents needed for inhibition relative to the 10,000 molecular weight PVP. ^c α , also equal to the number of moles needed for inhibition relative to the 10,000 molecular weight PVP.

nate the possible error of dilution introduced by the frequent addition of PVP in the initial experiment.

As a result the values of the minimum concentration of PVP for complete inhibition plotted in Fig. 4 should be considered only as upper limits as the process of adding discrete amounts almost assures some degree of overshooting the minimum value. To eliminate or to decrease significantly the magnitude of this overshoot would require a countless number of additional experiments for each point. However, this was not done as the data at hand are sufficiently precise to provide firm establishment of the model which will be subsequently proposed.

This inhibition was further investigated to include the effect of PVP molecular weight. Figure 4 shows the resulting plots from different experiments using PVP molecular weights of 10,000, 40,000, and 360,000. As can be seen, the necessary grams of PVP per 100 ml. of solution to cause inhibition of crystal growth at any supersaturation ratio increases with increasing molecular weight of PVP. In addition the rate of increase of the grams of PVP per 100 ml. of solution needed as a function of increasing supersaturation ratio is much faster for PVP polymers of high molecular weight than those of lower molecular weight.

At this point of discussion, it was felt that the polymers should be compared on the basis of their relative concentrations of the recurring vinyl pyrrolidone segment,

rather than relative concentrations of molecules because it was desired to compare their effectiveness on an equivalent weight basis. For this reason, concentrations were expressed in terms of gram percent rather than moles/liter. It should be noted, however, that if the

Figure 4—Minimum concentration of different molecular weights of PVP required to cause inhibition of crystal growth of sulfathiazole as a function of supersaturation. Key: ○, 10,000 molecular weight; △, 40,000 molecular weight; and □, 360,000 molecular weight.

Figure 5—Kinetic model describing the concentrations of sulfathiazole and PVP as a function of distance from the crystal surface.

necessary concentrations of PVP were expressed in terms of molarity, the effects of polymer molecular weight would be very different from those noted using gram percent. As a matter of fact, the range of their relative molecular weights, 1:4:36, is sufficiently large to cause the relationship to be reversed, i.e., the higher molecular weight PVP requires less moles for inhibition. Table I shows the results of a comparison of the slopes of best fit linear curves drawn through the corresponding data points.

These relationships imply that this is not an equilibrium process but must involve dominating kinetic factors. If an equilibrium process was in control, it would not be expected that more equivalents of the higher molecular weight PVP would be needed due to the better adsorption tendencies of the higher molecular weight polymers. This would be true if all segments have equal covering ability. This can be rationalized on the basis that a higher molecular weight PVP molecule contains more units per molecule than its lower molecular weight counterpart and therefore can make more attachments to a crystal surface with which to anchor itself.

It can be inferred that diffusional processes are controlling the effective concentration of PVP required for inhibition by considering the following:

1. The rate of crystal growth appears to be controlled by the rate of diffusion of sulfathiazole to the surface as shown by the stirring rate dependence of the crystal growth studies.
2. The PVP molecular weight dependence of the PVP inhibition suggests that the rate of PVP diffusion to the surface may be rate determining; otherwise, it would be expected that the minimum equivalent weight of PVP needed to inhibit sulfathiazole crystal growth should be independent of the molecular weight as the PVP polymer consists of identical recurring units.
3. Finally the marked inhibition concentration dependency of PVP on the supersaturation ratio also supports the hypothesis that the rate of diffusion of PVP to the surface is rate determining. For a nondiffusional model, it would be expected that the PVP concentration needed should be invariant and not a function of the supersaturation ratio.

This rationalization prompted the proposal of the kinetic model which is illustrated in Fig. 5. It is easily seen that in this model the relative concentrations of drug and PVP at the surface of the crystal will depend on the relative concentration in the bulk of the solution and the relative rates of diffusion through the diffusion layer. If this is true the relative rates of deposition of both species on the surface of the crystal must also depend on the relative rates of diffusion to the surface, as it would be expected that the relative rates of deposition must be dependent on the relative concentrations of both species at the surface. Since the data show that a minimum concentration of PVP is needed for inhibition to occur, it can be postulated that if the rate of deposition of PVP is relatively slow as compared to that of the sulfathiazole, it is buried by the avalanche of precipitating sulfathiazole molecules. If, on the other hand, its rate is relatively rapid, it in turn can bury the precipitating sulfathiazole

molecules and sufficiently cover the crystal surface to cause inhibition of crystal growth. This model can be used to explain adequately all the results reported in this study. For example this model would predict that a higher PVP concentration would be needed to cause crystal growth inhibition at higher supersaturation ratios of sulfathiazole as the sulfathiazole molecules would increase their diffusional rate to the surface, necessitating that the PVP do so also.

Since this model readily lends itself to a mathematical treatment, quantitative relationships were derived to test the validity of the model. Assuming a steady state, the rate of diffusion of drug, G_D , and PVP, G_p , are given by the following equations:

$$G_D = K_D D_D (C_D^h - C_D^0) \quad (\text{Eq. 1})$$

$$G_p = K_p D_p (C_p^h - C_p^0) \quad (\text{Eq. 2})$$

where C_D and C_p denote the concentration of drug and PVP, respectively; the superscripts h and 0 denote the concentrations in the bulk of the solution and at the crystal surface, respectively; and K_D and K_p are the corresponding proportionality constants.

Since the model assumes that inhibition occurs when the relative diffusional rate of PVP to the surface is sufficiently rapid, it can be stated that for complete inhibition to occur the following condition must prevail:

$$G_p \geq k' G_D \quad (\text{Eq. 3})$$

where k' is the proportionality constant relating the minimum PVP rate of diffusion for inhibition to the drug rate of diffusion. Substitution of Eqs. 1 and 2 into Eq. 3 and rearrangement of the resulting equation lead to the following equation for the minimum bulk concentration of PVP, $(C_p^h)_M$, needed for crystal growth inhibition of sulfathiazole:

$$(C_p^h)_M = \frac{k D_D}{D_p} [C_D^h - C_D^0] + C_p^0 \quad (\text{Eq. 4})$$

where¹ $k = (K_D/K_p)k'$.

The supersaturation ratio, S , is defined as

$$S = \frac{C_D^h}{C_D^0} \quad (\text{Eq. 5})$$

where C_D^0 is the solubility of the drug.

Equations 4 and 5 yield

$$(C_p^h)_M = \frac{k D_D C_D^0 (S)}{D_p} + C_p^0 - \frac{k D_D C_D^0}{D_p} \quad (\text{Eq. 6})$$

Equation 6 predicts that a plot of $(C_p^h)_M$ versus S is a straight line with a slope of $k K_D C_D^0 / D_p$ which intercepts the supersaturation ratio axis at:

$$S = \frac{C_D^0}{C_D^s} - \frac{C_p^0 D_p}{k D_D C_D^s} \quad (\text{Eq. 7})$$

The above predicts that in the absence of PVP the intercept is equal to C_D^0/C_D^s when $(C_p^h)_M = 0$, and experimentally this appears to be equal to 1.15. In the presence of PVP, however, experimental results indicate that the intercept essentially remains unchanged and this appears to differ with the results predicted by Eq. 7. If one examines the relative magnitudes of the first and second terms of Eq. 7, however, it can easily be shown that the second term is negligible. The first term is equal to ≈ 1.15 , assuming this is independent of the presence of PVP. The second term can be set equal to C_p^0/slope . Since C_p^0 is $\ll 10^{-5}$ g./100 ml. and the slope is 1.5 to 5.5×10^{-6} , Eq. 7 predicts that the intercept is essentially unchanged with the addition of PVP.

Equation 6 was derived for the sulfathiazole-PVP system but will be applicable to any drug-inhibitor system that is described by this model. If the drug is changed, Eq. 6 predicts that the minimum concentration of inhibitor needed for complete crystal growth inhibition, $(C_p^h)_M$, would be directly proportional to the solubility and diffusion coefficient of the drug. Perhaps of more significance is that Eq. 6 predicts that $(C_p^h)_M$ is directly proportional to the supersatura-

Table II—Comparison of Experimental PVP Molecular Effectiveness to the Expected Effectiveness^a

tion ratio and inversely proportional to the diffusion coefficient of the polymer.

These predictions can be used as a test for the applicability of the model to a given system. The data previously presented in this study clearly show that $(C_p^h)_M$ is directly proportional to the supersaturation ratio. If $(C_p^h)_M$ is also inversely proportional to the respective PVP diffusion coefficients, then the slopes of the three straight lines obtained for the three different molecular weight PVP compounds should be in the same ratio as their reciprocal diffusion coefficients assuming that each segment has equal covering capability regardless of the molecular size.

For this purpose, the diffusion coefficients of the three species of PVP used in this study, 10,000, 40,000, and 360,000 molecular weight were independently determined in a diffusion cell using a membrane filter by a method previously reported (12). The diffusion coefficients were found to be 1.55×10^{-6} , 7.33×10^{-7} , and 3.55×10^{-7} cm.²/sec. for the 10,000, 40,000, and 360,000 molecular weight polymers. A set of straight lines were simultaneously fitted to the data points of all three PVP compounds using a common intercept of 1.15 and ratio of slopes that were proportional to their respective reciprocal diffusion coefficients. A common intercept was used as predicted by Eq. 6. Figure 4 shows that the agreement is well within experimental error and lends strong support for the proposed model.

Although the diffusional rate of PVP to the surface has been established as the controlling process, it would be of interest to determine the relative effectiveness of the different molecular weight PVP molecules once they arrive at the surface. It would be expected that the 360,000 molecular weight PVP would be 9 times more effective than the 40,000 molecular weight PVP and 36 times more effective than the 10,000 molecular weight PVP. Table II shows the results of calculations which strongly support the equivalency of molecular segments in covering the surface regardless of molecular weight and that the apparent relative molecular effectiveness is due to the relative PVP rates of transport to the crystal surface.

Yet to be explained is the small amount of PVP needed for complete inhibition of crystal growth of sulfathiazole. This result suggests that the PVP must be strongly bound to the sulfathiazole crystal surface. This should not be unexpected as the PVP consists of a recurring group which allows it to form many attachments to the surface. This possibility was tested out by running an inhibited crystal from a PVP solution of a given sulfathiazole supersaturation ratio in a solution of comparable supersaturation ratio but without PVP. The crystal did not grow, indicating that the PVP was not removed from the crystal surface and therefore it was indeed strongly bound.

To investigate this further, calculations were made using Eqs. 1 and 2 to estimate the relative rates of transport of sulfathiazole and PVP from the bulk of the solution to the crystal surface. The results of these calculations confirmed the above, as they clearly showed that the relative rates of deposition of PVP as compared to sulfathiazole was not sufficiently large to provide for a tightly packed film over the sulfathiazole crystal surface.

Although no further evidence was obtained, sufficient data are at hand to permit a mechanistic speculation. It is believed that these results can be explained on the basis that the polymer forms a non-condensed netlike film over the crystal surface of sulfathiazole. This

¹ In an idealized situation, $K_D = K_p$ and therefore $k = k'$. The more general treatment presented in this discussion—viz., $k \neq k'$, is preferred as it might allow for nonideal factors such as nonlinear concentration gradients and different sites of deposition.

Figure 6—Net inhibition model illustrating the inhibition by PVP on one surface of the crystal.

is illustrated by Fig. 6. This model, of course, will permit the sulfathiazole to grow out through the openings of the net. In order to do so, however, the crystal will need to grow in fingerlike protrusions (Fig. 7). In addition the radii of these protrusions will be governed by the effective pore size of the polymer net. If this is true the curvature of these protrusions will require higher supersaturation ratios to grow, as can be shown using the Kelvin equation (12):

$$\ln \frac{P}{P_0} = \frac{2\gamma M}{RTdr} \quad (\text{Eq. 8})$$

where P = vapor pressure of a small drop or particle of radius r (\sim micron), P_0 = vapor pressure of a planar surface ($r \sim$ large), γ = interfacial tension or free energy of the crystal, M = molecular weight, d = density, R = gas constant, and T = absolute temperature.

In the case of a particle suspended in a saturated solution, it can be assumed that the ratio P/P_0 can be approximated by the ratio of the respective activities in the solution, a/a_0 , where a is the activity of a small spherical particle and a_0 is the activity of a large particle. If activity coefficients of both particles are the same, the activities can be replaced by their respective solubilities. This ratio, however, defines the supersaturation ratio that a large crystal will be exposed to if placed in a solution which is saturated with respect to the small particle. This, of course, is the supersaturation ratio which has been utilized in all previous graphs, as the single crystal used in the previous experiments can be considered the equivalent of a large particle. As a result, Eq. 8 can be expressed by the following equation:

$$\ln S = \frac{2\gamma M}{RTdr_p} \quad (\text{Eq. 9})$$

where S is the supersaturation ratio (relative to the solubility of a large particle) of a solution in which a protrusion with a curvature that is equivalent to a particle of radius r_p will have equal probabilities of growth or dissolution.

Equation 9 shows that as the effective radius of a protrusion decreases, the protrusion will require a correspondingly larger super-

Figure 7—Net inhibition model illustrating a cross section of the protrusions growing through the openings of a polymer net.

saturation ratio before it will grow. This indicates that a netlike coverage of PVP that controls the effective radius of protrusions from the crystal surface can cause the crystal to require a higher supersaturation ratio than if it were absent in order for the crystal to grow. Furthermore, the tighter the net the smaller the effective radii of the resulting protrusions and the higher the minimum supersaturation ratio required for crystal growth to occur.

This speculation can be combined with the kinetic diffusion model to describe a possible mechanism of inhibition by PVP of a sulfathiazole crystal exposed to its supersaturated solution. The experimental data previously presented in this study showed that the crystal growth inhibition of sulfathiazole by PVP is related to the relative transport rates to the crystal surface. This implies that the point of inhibition is related to the relative rates of deposition. The PVP reaching the surface forms a netlike structure (since complete coverage does not occur at the point of inhibition) which allows the sulfathiazole to grow out in fingerlike protrusions (suggested by fingerlike growth before the point of inhibition). Due to the higher curvature of these protrusions, however, the minimum supersaturation ratio for growth increases as shown by Eq. 9. This curvature, on the other hand, is determined by the effective pore size of the polymer net. The effective pore size of the net is determined by the relative PVP to sulfathiazole transport rate. Since the relative PVP to sulfathiazole transport rate governs the relative ratio of PVP and sulfathiazole deposited on the crystal surface, it follows that the higher the relative PVP rate, the smaller the effective pore size of the polymer net and the higher the supersaturation required for growth to be maintained. This model is consistent with all the data reported in this study.

Rate of Crystal Growth of Sulfathiazole and Methylprednisolone

S. C. MEHTA, P. D. BERNARDO*, W. I. HIGUCHI, and A. P. SIMONELLI

Abstract □ The results of crystal growth rate studies using single crystals of sulfathiazole and methylprednisolone are presented. The growth rate of sulfathiazole crystals growing in a supersaturated aqueous solution showed stirring rate dependence from 10 to 400 r.p.m. The same stirring rate dependence was found for all three faces studied. In alcohol solutions, however, the stirring rate dependence appeared to disappear above 150 r.p.m., suggesting that at the higher stirring rates the rate of crystal growth of sulfathiazole is surface controlled. A plot of the growth rate *versus* the supersaturation ratio appeared to be linear for all studies with intercepts exhibited on the supersaturation ratio axis. The intercept appeared to be a function of its solvent varying from 1.07 to 1.43 and to be a function of the polarity of the alcohol. The crystal growth rate of methylprednisolone, on the other hand, showed no stirring rate dependence in the range from 20 to 400 r.p.m. and appears to be surface controlled even at low stirring rates.

Keyphrases □ Crystal growth rates—single crystal method □ Sulfathiazole crystals—growth rate □ Methylprednisolone crystals—growth rate □ Stirring rate effect—crystal growth □ Refractive index—crystal axes determination

There are a number of situations where an understanding of the growth behavior of crystals may provide a basis for improving pharmaceutical formulations. Crystal growth in a suspension formulation, as a result of temperature fluctuations or Ostwald ripening, may lead to undesirable changes in its particle-size distribution. Such changes whether they affect the ease of administration, efficacy, or the esthetic appearance of suspensions constitute "physical instability." Investigations (1-5) of crystal growth behavior involving systems of pharmaceutical interest are relatively few. Furthermore, most of these studies have not been mechanistically oriented, *i.e.*, aimed at establishing the molecular mechanisms. Generally such studies have only answered the question of whether or not crystal growth occurs under the particular prevailing condition.

The present report describes the results of crystal growth studies involving the two drugs, sulfathiazole and methylprednisolone. A simple but convenient method to study crystal growth is described. The crystal growth rate data were obtained as a function of supersaturation, crystal orientation, and stirring rate and

same crystal can be exposed to a variety of conditions, all of which are affecting the same surface.

2. Nucleation does not present a problem as it is readily detectable. This is not true for the gross volume technique, and its presence must be determined by separate means such as a Coulter counter technique. If the proper growth rate is to be determined in a gross volume technique, the rate of nucleation must also be determined and its contribution subtracted.

3. The random heterogeneity of the surface free energy at the solid-liquid interface of all particles is not a problem in single crystal methods.

4. The need for a significant quantity of material to be transferred from the solution phase to the solid phase which causes the supersaturation ratio to be significantly decreased during experiments using the gross volume technique is also not present in single crystal work.

In addition, single crystal techniques, unlike gross volume techniques, not only permit the linear growth rate of each face of a crystal to be studied independently but also under varying conditions. This is essential in mechanistic studies. Finally the single crystal technique will also permit the crystal growth rate experiments to serve as a baseline for subsequent crystal growth inhibition studies. Furthermore, in order to separate diffusion-controlled cases from surface-controlled rates, it was decided to employ variable stirring conditions as well as varying supersaturation conditions.

Table I—Solubility of Sulfathiazole and Methylprednisolone in Different Solvent Systems at 30°

Solvent	Solubility, g./100 g.	$\lambda_{\max.}$, m μ
Sulfathiazole		
Water	0.065	282
95% v/v Ethanol in water	1.06	288
50% v/v Ethanol in water	1.30	
60% v/v Ethanol in sec-butanol	0.555	
Methylprednisolone		
Water	0.0072	249
1% v/v Ethanol in water	0.0077	
2% v/v Ethanol in water	0.0085	

MATERIALS

All solvents utilized in the experiments were distilled. The sulfathiazole crystals used in the crystal growth experiments were prepared by double recrystallization either from 95% ethanol or from water. The methylprednisolone crystals used in these studies

were prepared by recrystallization either from a 50% v/v alcohol-water mixture or from acetone.

The crystalline modifications of both compounds were the same as those designated as the most stable forms (Form I) in previous studies (6, 7) and were confirmed by melting point, refractive index, X-ray diffraction, and IR spectra.

In addition, refractive index determinations were used to characterize the long axes of the individual crystals of both compounds. The refractive index of the long axis of the hexagonally shaped face of sulfathiazole crystal was found to be 1.674, in agreement with the reported value (8). For methylprednisolone the refractive index along the long axis of the rod-shaped crystal was found to be 1.602 (9).

The supersaturated solutions used in these studies were prepared by either of two methods, saturating at higher temperatures using steam heat or by solvent mixing. Because of chemical instability, supersaturated methylprednisolone solutions were always prepared by solvent mixing.

APPARATUS AND PROCEDURE

Figure 1 shows the apparatus used to study the growth rate of sulfathiazole. The temperature of the system was controlled at 30°

Figure 10—Crystal growth rate of sulfathiazole in 50% v/v ethanol-water along the long axis as a function of supersaturation at different stirring speeds. Key: \blacksquare , 10 r.p.m.; \circ , 150 r.p.m.; and \blacktriangle , 400 r.p.m.

by means of a water jacket through which 30° water was circulated. For crystal growth studies, a single crystal of sulfathiazole is mounted in a slit made in a piece of rubber for this purpose (10). See Fig. 2. This piece of rubber is held by a tungsten wire attached to a stainless steel coupling. This coupling permits the crystal holder to be removed to facilitate the delicate and tedious process of mounting the crystal. In addition the coupling prevents the crystal from lateral movement during the experiment after the crystal holder is mounted in place. After a mounted crystal is immersed in the supersaturated solution, a microscope calibrated in microns is used to study crystal growth through an optical-glass window. Figure 2 shows the manner in which the length, width, and thickness of a crystal are followed as a function of time. The supersaturated solution was stirred at a constant rate during an experiment by means of a synchronous motor mounted on the container lid. The effect of the stirring rate on crystal growth rate, on the other hand, was studied by interchanging motors of different speeds. A stopwatch was used to obtain the time of each crystal measurement. During the experiment, samples were periodically withdrawn from the solution and assayed spectro-

photometrically in order to determine the concentration of the solution.

RESULTS AND DISCUSSION

The solubilities of sulfathiazole and methylprednisolone were determined in the following manner. Excesses of the amounts of the recrystallized compounds needed to produce saturated solutions

Figure 14—Crystal growth rate of sulfathiazole in 40% v/v sec-butanol-60% v/v ethanol along the axis designated as width as a function of supersaturation at different stirring speeds. Key: ■, 10 r.p.m.; ○, 150 r.p.m.; and ▲, 400 r.p.m.

were placed in volumetric flasks with the solvents and agitated in a water bath at 30°. Duplicate samples were withdrawn at 12–24-hr. intervals, filtered through a 0.45- μ Millipore filter, and analyzed spectrophotometrically. The solubilities of sulfathiazole and of methylprednisolone in the various solvents used are listed in Table I.

Sulfathiazole Studies—Figure 3 represents the results of a typical sulfathiazole crystal growth experiment in 95% v/v ethanol where the growth in microns along the long axis was measured and plotted as a function of time. The growth-time plots were always found to be linear with little scatter, except in cases where the apex of the crystals was initially not sharp due to prior washing in a solvent. In the latter situations the slopes of the plots became linear after a short initial period during which time sharpening of the crystal edges occurred. Size variations of the crystals employed in these experiments were found to have little or no effect upon the rate of growth over a crystal length range of 450 to 2000 μ . Also the method of preparation of the seed crystals usually had no effect upon the growth rates.

From limiting linear portions of the data such as those presented in Fig. 3, the rates were obtained by determining the slopes for each experiment and are plotted in Figs. 4–15 for each of the three dimensions of the sulfathiazole crystal in a number of solvents under different stirring rates. These rates have been presented as a function of the supersaturation ratio, S , which is the supersaturated solution concentration divided by the solubility. The data for sulfathiazole crystal growth studies in water (Figs. 4–6) appeared to be linearly dependent upon the supersaturation ratio, S , for all stirring speeds and for all three dimensions. Least-squares parameters calculated for these studies are tabulated in Table II and showed that a common intercept of $S = 1.17$ was consistent with all of the water experiments.

The stirring rate dependence found in these experiments strongly supports a diffusion-controlled process in region $S > 1.17$.

^a See Appendix. ^b Both slope and intercept were allowed to vary. ^c Curve was forced through average intercept for all three axes, $S = 1.10$.

The growth rates of all of the dimensions appear to be determined by the transport of solute through the solvent at even the highest stirring speeds. For comparison purposes, the growth rate curves as a function of the stirring rate shown by Figs. 4, 5, and 6 were arbitrarily fitted by linear curves passing through the 1.17 intercept, with arbitrary slopes chosen so that a constant slope ratio as a function of the stirring rate was maintained in all three figures; i.e., the ratios of the slope at 400 r.p.m. to that at 150 r.p.m. to that at 10 r.p.m. was constant. The agreement of these arbitrary curves with the experimental data points strongly suggests that the stirring rate dependence is the same for all three dimensions.

The intercept value of about $S = 1.17$ might be related to a "critical" supersaturation for two-dimensional nucleation. Therefore, at very low supersaturation ratios, crystal growth may occur extremely slowly or may be dependent upon the existence of screw dislocations.

Sulfathiazole crystal growth experiments with the other solvent systems studied (Figs. 7–15) generally appeared to show stirring rate dependence at the lower speeds but interestingly the rates were much less stirring dependent at the higher speeds in these solvents than in the water experiments. The growth rates observed in 95% v/v ethanol, 50% ethanol-water, and 40% butanol-60% ethanol were found to be essentially independent of stirring rates above 150 r.p.m. The growth rates at 10 r.p.m. were generally much slower in these studies. See Tables III–V.

These experiments in the alcohol-containing solvents appear to be consistent with the interpretation that at lower agitation conditions (~ 10 r.p.m.) the crystal growth rates are solvent diffusion controlled at the higher supersaturations. However, at higher

stirring rates, the crystal growth rates are surface controlled rather than diffusion controlled.

In all the plots shown in Figs. 7–15, there appear to be significant intercepts on the supersaturation axes as were found to be the case in the water experiments Figs. 4–6. In the cases of ethanol and ethanol–water experiments, the intercepts are the order of $S \approx 1.1$. For the 40% *sec*-butanol–60% ethanol the intercept is much larger, the order of $S \approx 1.43$. These intercepts might again be related to the “critical” supersaturation for two-dimensional nucleation in the respective solvents. It is noteworthy to mention at this point that in *n*-propanol, crystal growth of sulfathiazole did not occur even at supersaturation of 2.2, and that in *sec*-butyl alcohol a supersaturation ratio of 5.5 showed no growth. The observations in conjunction with the S -intercepts found in the present studies suggest a direct relationship between the “critical S ” for two-dimensional nucleation and alcohol solvent polarity—*viz.*, the higher the alcohol solvent polarity the smaller the S -intercept.

METHYLPREDNISOLONE CRYSTAL GROWTH IN WATER

The growth rate along the rod axis (refractive index = 1.602) of the methylprednisolone crystal in water at various supersaturations and stirring speeds was also studied. The results are shown in Fig. 16. The data at all stirring speeds appear to be linear with supersaturation and show a small intercept on the S -axis. The least-squares linear curves were calculated and the slopes and intercepts tabulated in Table VI. As opposed to sulfathiazole crystals, Table VI clearly shows that the rates for methylprednisolone appeared to be virtually independent of stirring for all stirring rates over the range of 20 to 400 r.p.m. This supports a mechanism in which the crystal growth rate of methylprednisolone in water is surface controlled in the range of agitation rates employed in these studies.

Figure 16—Crystal growth rate of methylprednisolone in water as a function of supersaturation at different stirring speeds. Key: \blacktriangle , 20 r.p.m.; \square , 150 r.p.m.; \circ , 240 r.p.m.; and \diamond , 400 r.p.m.

Table VI—Linear Least-Squares Parameters for Methylprednisolone Using Water as the Solvent

Stirring, r.p.m.	Intercept ^a	Slope ^a
20	1.43	18.732
150	1.27	17.498
240	1.37	19.163
400	0.90	13.329
All data points	1.23	16.896

^a Both slope and intercept were allowed to vary.

For this reason a least-squares linear curve was calculated using all the methylprednisolone growth rates regardless of stirring rate, and this curve was drawn in Fig. 16.

SUMMARY

These results show the advantage of using a single crystal technique to obtain quantitative data regarding the growth rate of crystalline drugs. In particular, it permits meaningful quantitation of the stirring rate dependence and the effect of the composition of the solution on the crystal growth rate. This permits an insight as to the controlling mechanism operative under the conditions of the experiment.

APPENDIX: LEAST-SQUARES PARAMETERS

It is generally accepted that the results of a least-squares optimization of the data will depend on the function chosen, *i.e.*, straight line, parabola, exponential, *etc.* It is not always recognized, however, that one must be careful to use the appropriate least-squares treatment if one is to fit the best linear curve to the experimental data. For example, one can assume that the experimental error resides solely in the y data, in the x data, or in both. Obviously the best fit curve obtained will depend on which approach was used.

It also should be noted that the least-squares approach (a mathematical interpretation as opposed to a physical interpretation) should not contradict any known facts and/or limitations set by the experimental system. For example, if it is known that the data plot passes through the origin, then a least-squares set of equations which ignores this requirement may not only result in an artificial intercept but also an incorrect slope.

By definition, a crystal must be exposed to a supersaturation ratio greater than 1 in order for it to grow. Therefore, any optimization of the authors' data that yields a curve which displays a positive y -intercept must be incorrect. This means the least-squares approach to be used must yield an x -intercept of the supersaturation ratio axis if the most correct slope is to be calculated.

In addition, it is reasonable to assume that all curves of a given system should be represented by the same intercept for the following reason. At the x -intercept, the crystal growth is obviously independent of the stirring rate and most likely is regulated by a surface-controlled process. If this is true, all curves must intercept at the same point as the only difference between curves is the stirring rate.

With the above in mind, the following approach was arbitrarily used to determine the intercepts and slopes for the systems studied. First the least-squares parameters were determined allowing both the intercept and slope to vary, *i.e.*, $y = mx + b$ where m is the slope and the x -intercept is b/m . The average x -intercept for all curves in a given system was calculated and assumed to be the best estimate of the supersaturation ratio axis intercept. The best estimate for the slope of each curve was then determined using the least-squares equations for $y = m(x - \bar{I})$, where \bar{I} is the average intercept for the system.

Theoretical Model Studies of Drug Absorption and Transport in the Gastrointestinal Tract I

AKIRA SUZUKI, W. I. HIGUCHI, and N. F. H. HO

Abstract □ The simultaneous chemical equilibria and mass transfer of basic and acidic drugs through a two-phase compartment model were theoretically investigated. The model consisted of a well-stirred bulk aqueous phase, an aqueous diffusion layer, and a lipid barrier for perfect and imperfect sink cases. The nonsteady and quasi-steady-state changes in the concentration-distance distributions in the lipid phase were studied. The rate of change of the total drug concentration in the bulk aqueous phase was described in the general form of a first-order equation useful for the evaluation of experiments. A limiting steady-state relationship involving the transport rate with the partition coefficient, pH at the aqueous-lipid interface, dissociation constant of the drug, aqueous and lipid diffusion coefficients, and thickness of the diffusion layer was derived. Increasing the agitation rate in the aqueous phase markedly affects the pH profiles for the rate of transport. The pH-partition theory is shown to be a limiting case of the more general approach presented.

Keyphrases □ Drug absorption, transport—theoretical model □ Model, two-phase compartment—theoretical investigation □ Chemical equilibria, mass transfer—two-phase compartment model □ Agitation rate effect—rate transport pH profiles

The increasing interest in the mechanistic understanding rather than in only a mathematical representation of drug transport and absorption phenomena should dictate systematic physical model analyses of various *in vitro* situations. Thus, detailed theoretical considerations of diffusion and equilibria involving multibarrier systems and the carrying out of appropriate model experiments are necessary for the isolation of the important *in vivo* factors.

Recent investigations (1-4) in these laboratories have been devoted to the physical model approach to a number of situations in this regard. The present paper is concerned with the problem of treating the time dependency and the pH-buffer dependency for the transport of basic and acidic solutes into and across lipoidal barriers. It is, to some extent, an extension of the works of Howard *et al.* (3) and Stehle (4) and should be useful in the understanding of gastrointestinal and buccal absorption problems. In the accompanying paper (5), the techniques developed here are applied to some of the

data on *in situ* drug absorption published by Koizumi *et al.* (6, 7).

THEORY

General Description of the Model—The simultaneous mass transfer and chemical equilibrium reactions in a system consisting of two homogeneous phases will follow the one-dimensional model in Fig. 1. The bulk aqueous phase is well stirred and consists of a basic drug and buffer. At $x \leq -h$,

$$(TR)_{-h} = (R)_{-h} + (RH^+)_{-h} \quad (\text{Eq. 1})$$

$$(TB)_{-h} = (B^-)_{-h} + (HB)_{-h} \quad (\text{Eq. 2})$$

where (TR) is the total drug concentration of R and RH^+ species and (TB) is the total buffer concentration of B^- and HB species. It is assumed that electrical neutrality holds everywhere in the aqueous phase. Consequently, at $x \leq 0$,

$$(H^+) + (RH^+) + (Na^+) - (OH^-) - (B^-) = 0 \quad (\text{Eq. 3})$$

where (Na^+) is the cation concentration derived from the buffer. It is further assumed that the following equilibrium reactions are instantaneous,

$$\frac{(R)(H^+)}{(RH^+)} = K_{a,R} \quad (\text{Eq. 4a})$$

$$\frac{(B^-)(H^+)}{(HB)} = K_{a,HB} \quad (\text{Eq. 4b})$$

$$(H^+)(OH^-) = K_w \quad (\text{Eq. 4c})$$

where $K_{a,R}$, $K_{a,HB}$, and K_w are the dissociation constants of drug, buffer, and water, respectively.

Under the assumption of quasi-steady-state conditions existing within the aqueous diffusion layer, the total flux of the drug to the water-lipid interface is expressed by the equation

$$G = -D_{RH} \frac{d(RH^+)}{dx} - D_R \frac{d(R)}{dx} \quad (\text{Eq. 5})$$

$$(-h \leq x \leq -0)$$

where G is the total flux of the drug and D_{RH} and D_R are the diffusion coefficients; upon integration, the solution is

$$Gh = D_{RH}(RH^+)_{-h} + D_R(R)_{-h} - D_{RH}(RH^+)_{-0} - D_R(R)_{-0} \quad (\text{Eq. 6})$$

In an analogous procedure for the buffer species,

$$D_{HB}(HB)_{-h} + D_B(B^-)_{-h} - D_{HB}(HB)_{-0} - D_B(B^-)_{-0} = 0 \quad (\text{Eq. 7})$$

data on *in situ* drug absorption published by Koizumi *et al.* (6, 7).

THEORY

General Description of the Model—The simultaneous mass transfer and chemical equilibrium reactions in a system consisting of two homogeneous phases will follow the one-dimensional model in Fig. 1. The bulk aqueous phase is well stirred and consists of a basic drug and buffer. At $x \leq -h$,

$$(TR)_{-h} = (R)_{-h} + (RH^+)_{-h} \quad (\text{Eq. 1})$$

$$(TB)_{-h} = (B^-)_{-h} + (HB)_{-h} \quad (\text{Eq. 2})$$

where (TR) is the total drug concentration of R and RH^+ species and (TB) is the total buffer concentration of B^- and HB species. It is assumed that electrical neutrality holds everywhere in the aqueous phase. Consequently, at $x \leq 0$,

$$(H^+) + (RH^+) + (Na^+) - (OH^-) - (B^-) = 0 \quad (\text{Eq. 3})$$

where (Na^+) is the cation concentration derived from the buffer. It is further assumed that the following equilibrium reactions are instantaneous,

$$\frac{(R)(H^+)}{(RH^+)} = K_{a,R} \quad (\text{Eq. 4a})$$

$$\frac{(B^-)(H^+)}{(HB)} = K_{a,HB} \quad (\text{Eq. 4b})$$

$$(H^+)(OH^-) = K_w \quad (\text{Eq. 4c})$$

where $K_{a,R}$, $K_{a,HB}$, and K_w are the dissociation constants of drug, buffer, and water, respectively.

Under the assumption of quasi-steady-state conditions existing within the aqueous diffusion layer, the total flux of the drug to the water-lipid interface is expressed by the equation

$$G = -D_{RH} \frac{d(RH^+)}{dx} - D_R \frac{d(R)}{dx} \quad (\text{Eq. 5})$$

$$(-h \leq x \leq -0)$$

where G is the total flux of the drug and D_{RH} and D_R are the diffusion coefficients; upon integration, the solution is

$$Gh = D_{RH}(RH^+)_{-h} + D_R(R)_{-h} - D_{RH}(RH^+)_{-0} - D_R(R)_{-0} \quad (\text{Eq. 6})$$

In an analogous procedure for the buffer species,

$$D_{HB}(HB)_{-h} + D_B(B^-)_{-h} - D_{HB}(HB)_{-0} - D_B(B^-)_{-0} = 0 \quad (\text{Eq. 7})$$

Figure 1—Two-phase diffusion model consisting of a bulk aqueous phase, aqueous diffusion layer, and a lipid phase. Concentration distribution of total drug species is governed by steady-state rate into the diffusion layer, and concentration of the diffusing nonionized drug in the lipid phase is governed by nonsteady-state rate determined by numerical finite-difference methods.

in which case the total flux of the buffer is zero.

If only the nonprotonated drug molecule is capable of diffusing into the lipid phase, the equilibrium assumed to be established instantaneously at the aqueous-lipid interface is expressed by the partition coefficient,

$$P = (R)_{+0}/(R)_{-0} \quad (\text{Eq. 8})$$

$$(x = 0)$$

where P is the partition coefficient; (R) is the concentration of the nonionized drug; and the subscripts, -0 and $+0$, refer to the aqueous and lipid side of the interface, respectively. The continuity of flow through the interface is given by

$$G = -D_{R, oil} \left(\frac{\partial(R)}{\partial x} \right)_{x=0} \quad (\text{Eq. 9})$$

where $D_{R, oil}$ is the diffusion coefficient of R in lipid. In this model the flux of the total drug species in the aqueous diffusion layer is taken to be the same as the flux of the nonionized drug from the interface to the lipid phase. Within the lipid, Fick's second law applies:

$$\frac{\partial(R)}{\partial t} = D_{R, oil} \frac{\partial^2(R)}{\partial x^2} \quad (\text{Eq. 10})$$

$$(x > 0)$$

and at $x = L$ two extreme boundary conditions can exist, that is, (a) for the impermeable boundary,

$$\left(\frac{\partial(R)}{\partial x} \right)_{x=L} = 0 \quad (\text{Eq. 11a})$$

(b) for the perfect sink,

$$(R)_{x=L} = 0 \quad (\text{Eq. 11b})$$

Changes in the Concentration-Distance Distribution in the Aqueous and Lipid Phases with Time—The simultaneous time change of the total drug concentration-distance distribution in the aqueous phase in which steady-state conditions are assumed and that for the diffusing basic drug molecule in the lipid phase in which nonsteady-state conditions exist cannot be solved analytically. Numerical methods and the utilization of a high-speed computer are necessary.

In using the finite-difference method (8), the lipid compartment is divided into a number of cells of equal intervals as shown in Fig. 1. Accordingly, the concentration of drug in the bulk aqueous phase and each cell in the lipid phase and at the interface can be calculated by solving the following set of differential equations:

$$\frac{d(TR)_{-h}}{dt} = -\frac{A}{V} G \quad (\text{Eq. 12})$$

$$\frac{d(R_i)}{dt} = \frac{G}{\Delta x} - \frac{D_{R, oil}[(R_i) - (R_{i+1})]}{(\Delta x)^2} \quad (\text{Eq. 13})$$

Figure 2—Model used to estimate $F(t)$ by linear approximation of the concentration curves in the lipid phase. Key: A, impermeable boundary case; and B, perfect-sink case.

$$\frac{d(R_i)}{dt} = \frac{D_{R, oil}}{(\Delta x)^2} [(R_{i-1}) - 2(R_i) + (R_{i+1})] \quad (\text{Eq. 14})$$

$$(i = 2, 3, 4 \dots n - 1)$$

and at $x = L$, for the impermeable boundary or no-sink case,

$$\frac{d(R_n)}{dt} = \frac{D_{R, oil}}{(\Delta x)^2} [(R_{n-1}) - (R_n)] \quad (\text{Eq. 15a})$$

and for the perfect-sink case,

$$\frac{d(R_n)}{dt} = \frac{D_{R, oil}}{(\Delta x)^2} [(R_{n-1}) - 3(R_n)] \quad (\text{Eq. 15b})$$

where A is the surface area, V is the volume of the bulk aqueous phase, (R_i) is the concentration of neutral drug in the i th cell, Δx is the length of each cell, n is the total number of cells, and the other terms are defined as before.

Since the concentration of drug species at the various aqueous boundaries is dependent upon pH, the hydrogen-ion concentration must be known. From Eqs. 1 through 4 the hydrogen-ion concentration in the bulk phase is given by

$$(H^+)_{-h}^4 + \{K_{a, R} + K_{a, HB} + (TR)_{-h} + (Na^+)_{-h}\} (H^+)_{-h}^3 + \{[(TR)_{-h} + K_{a, R} - (TB)_{-h}]K_{a, HB} - (K_{a, R} + K_{a, HB})(Na^+)_{-h}K_w\} (H^+)_{-h}^2 - \{K_{a, HB}(TB)_{-h} + (K_{a, R} + K_{a, HB})K_w + K_{a, R}K_{a, HB}(Na^+)_{-h}\} (H^+)_{-h} - K_{a, R}K_{a, HB}K_w = 0 \quad (\text{Eq. 16})$$

Table I—Numerical Dimensions of Constants and Initial Drug and Buffer Concentrations Used for Computation

$V = 10 \text{ cm.}^3$	$A = 10 \text{ cm.}^2$	$h = 10^{-2} \text{ cm.}$
$K_{a, R} = 10^{-8}$	$D = 10^{-5} \text{ cm.}^2 \text{ sec.}^{-1}$	for all diffusion coefficients
Initial concentrations: $(TB)_{-h} = 10^{-2} M$ $(TR)_{-h} = 10^{-4} M$		
	No-Sink Case	Perfect-Sink Case
L	10^{-1} cm.	$5 \times 10^{-2} \text{ cm.}$
$(Na^+)_{-h}$	0	$1/2(TB)_{-h}$
P	1, 100	100
$pK_{a, HB}$	4, 6, 8, 10, 12	4, 6, 8, 10

Figure 3—Time-dependent concentration distribution curves of total drug species (TR) in the aqueous phase and the nonprotonated drug (R) in the oil phase for the no-sink case: (A) initial bulk aqueous pH = 3.05 and partition coefficient $P = 100$; (B) pH = 8.82, $P = 100$; (C) pH = 8.82, $P = 1.0$.

Table II—Change in the Bulk and Surface pH with Time for the No-Sink Case in a Low Buffer Capacity System with $P = 100$

$K_{a,HB}$	Initial		After 500 sec	
	pH _{-h}	pH ₋₀	pH _{-h}	pH ₋₀
10^{-6}	3.05	3.05	3.05	3.05
10^{-8}	6.01	5.71	5.98	5.95
10^{-10}	7.79	6.84	7.67	7.33
10^{-12}	8.82	7.70	8.71	8.22

The equation for the hydrogen-ion concentration at the interface is derived from Eqs. 3, 4, and 6-9; thus,

$$(H^+)_{-0}^2 + [\beta + \gamma\eta + \alpha + \gamma(Na^+)_{-0}](H^+)_{-0} + [(\alpha + \beta)\eta - \gamma K_w - \gamma\delta + (\gamma\eta + \beta)(Na^+)_{-0}](H^+)_{-0} - [(\beta + \gamma\eta)K_w - \beta\delta + \beta\eta(Na^+)_{-0}](H^+)_{-0} - \beta\eta K_w = 0 \quad (\text{Eq. 17})$$

where

$$\alpha = \frac{1}{K_{a,R}} \left\{ [D_R(R)_{-h} + D_{RH}(RH^+)_{-h}] + \frac{2hD_{R,oil}(R_i)}{\Delta x} \right\}$$

$$\beta = D_R + \frac{2hPD_{R,oil}}{\Delta x}$$

$$\gamma = D_{RH}/K_{a,R}$$

$$\delta = \frac{K_{a,HB}}{D_B} [D_B(B^-)_{-h} + D_{HB}(HB)_{-h}]$$

$$\eta = \frac{K_{a,HB}D_B}{D_{HB}}$$

Here, it is assumed that $(Na^+)_{-h} = (Na^+)_{-0}$. Finally, the concentration of the diffusing specie at the aqueous side of the interface, *i.e.* $(R)_{-0}$, is expressed by

$$(R)_{-0} = \frac{\alpha K_{a,R}}{\beta + \gamma(H^+)_{-0}} \quad (\text{Eq. 18})$$

Rate of Change of the Total Concentration of Drug in the Bulk Aqueous Phase—To relate the theory of the diffusion model to the usual treatment of experimental data, *i.e.*, the rate of change of the total drug concentration in the bulk aqueous phase, it is useful to rewrite Eq. 12 in the following manner,

$$\frac{d(TR)_{-h}}{dt} = -\frac{AD_R}{Vh} F(t)(TR)_{-h} \quad (\text{Eq. 19})$$

where $F(t)$ is defined as

$$F(t) = G/G_{\max}, \quad (\text{Eq. 20})$$

and

$$G_{\max} = \frac{D_R(TR)_{-h}}{h} \quad (\text{Eq. 21})$$

Equation 20 is the ratio of the actual flux to the maximum flux which takes place when all of the drug species in the bulk aqueous phase is nonprotonated and the concentration of R at the interface is zero. By performing the integration, Eq. 19 becomes

$$\ln \frac{(TR)_{-h}}{(TR)_{-h,t=0}} = -\frac{AD_R}{Vh} \int_0^t F(t) dt \quad (\text{Eq. 22})$$

$$(0 < F(t) \leq 1)$$

and by utilizing the mean-value theorem to evaluate the integral,

$$\ln \frac{(TR)_{-h}}{(TR)_{-h,t=0}} = -\frac{AD_R}{Vh} F(\Phi)t \quad (\text{Eq. 23})$$

$$(0 \leq \Phi \leq t)$$

If $F(\Phi)$ is relatively invariant with Φ , an apparent first-order decrease in the drug concentration with time will be observed. In general, the slope of $\ln (TR)_{-h}$ versus t plots is

$$K_u = -\frac{AD_R}{Vh} F(\Phi) \quad (\text{Eq. 24})$$

Figure 4—First-order plot of the change in the total drug concentration in the bulk aqueous phase with time. No-sink case for different initial bulk aqueous pH.

Approximation of the Function $F(t)$ —Since the function $F(t)$ influences the apparent first-order rate constant, the elucidation of the nature of the function in terms of the partition coefficient, pH at the interface, diffusion coefficients, and thickness of the diffusion layer would lead to meaningful physical interpretation. For this purpose, an approximation of $F(t)$ is derived for two cases, perfect-sink and no-sink situations.

No-Sink Case—The analysis is based on the model for the concentration-distance distribution changes with time in Fig. 2A. It assumes a linear approximation of the nonsteady-state concentration profile of R at time t in the lipid phase. From Eqs. 8 and 9,

$$G = \frac{D_{R,oil} P(R)_{-0}}{\Delta l} \quad (\text{Eq. 25})$$

where Δl is the distance from the interface to the point where $(R)_{+0}$ is zero and changes with time such that $0 < \Delta l < L$. Furthermore, assuming that the flux G has not changed appreciably during the period needed to build up the concentration distribution in the lipid phase, the total amount of drug transported through the interface is approximated by

$$\int_0^t G dt = \int_0^1 (R)_{oil} dx \quad (\text{Eq. 26a})$$

Thus,

$$Gt = \frac{1}{2} (R)_{-0} P \Delta l \quad (\text{Eq. 26b})$$

and it follows from Eqs. 25 and 26b that

$$\Delta l = (2D_{R,oil}t)^{1/2} \quad (\text{Eq. 27})$$

Solving for $(R)_{-0}$ with the aid of Eqs. 6 and 25 and $D_{RH} = D_R$,

$$(R)_{-0} = \frac{(TR)_{-h}}{1 + [(H^+)_{-0}]/(K_{a,R}) + (hD_{R,oil}P)/(D_R \sqrt{2D_{R,oil}t})} \quad (\text{Eq. 28})$$

and with Eq. 27,

$$(R)_{-0} = \frac{(TR)_{-h}}{1 + [(H^+)_{-0}]/(K_{a,R}) + (hD_{R,oil}P)/(D_R \sqrt{2D_{R,oil}t})} \quad (\text{Eq. 29})$$

It is convenient to define a new function $f(t)$ as the approximation of $F(t)$. By means of Eqs. 1, 4, 6, 20, and 21, the function can be simply expressed by

$$f(t) \sim F(t) = G/G_{\max.} =$$

$$1 - \frac{\{1 + [(H^+)_{-0}]/(K_{a,R})\}(R)_{-0}}{(TR)_{-h}} \quad (\text{Eq. 30})$$

Figure 5—Change in the diffusion efficiency coefficient with time for the no-sink case. The numerically calculated coefficient $F(t)$ by Eq. 20 is compared with the approximation $f(t)$ by Eq. 31.

and the substitution of Eq. 29 leads to

$$f(t) = \frac{1}{\{1 + [(H^+)_{-0}]/(K_{a,R})\} T + 1} \quad (\text{Eq. 31})$$

where

$$T = \frac{D_R}{hP} \left(\frac{2t}{D_{R,oil}} \right)^{1/2} \quad (\text{Eq. 32})$$

Therefore, in this case of an impermeable boundary in the lipid phase, the time-dependent nature of the function $f(t)$ makes it evident that first-order diffusion kinetics are not applicable.

Perfect-Sink Case—In this situation the diffusion of the drug can be divided into two stages (Fig. 2B). The first stage is the period of nonsteady-state rate in the lipid phase leading to the second stage of quasi-steady-state conditions. In other words, $F(t)$ will eventually be constant (time independent) after an initial lag period.

In the nonsteady-state period the approximate function $f(t)$ given by Eqs. 31 and 32 can be applied. From Eq. 27, with $\Delta l = L$ always, the time lag is

$$\tau = \frac{L^2}{2D_{R,oil}} \quad (\text{Eq. 33})$$

where τ is the lag time, and L is the thickness of the lipid phase.

In the steady-state period, Eq. 25 can be rewritten as

$$G = \frac{D_{R,oil} P(R)_{-0}}{L} \quad (\text{Eq. 34})$$

After the substitution of Eqs. 21, 28, and 34 into 20, the function¹ $f(T)$ takes the same form as Eq. 31; that is,²

$$f(T) = \frac{1}{\{1 + [(H^+)_{-0}]/(K_{a,R})\} T + 1} \quad (\text{Eq. 35})$$

where, in this case,

$$T = \frac{D_R L}{PhD_{R,oil}} \quad (\text{Eq. 36})$$

Therefore, in the perfect-sink case, a $\log (TR)_{-h}$ versus t plot should be linear after a lag period.

¹ Note that $f(t)$ is replaced by $f(T)$ since the function is time-independent in the steady-state period for the perfect-sink case.

² While this theoretical treatment is based on an amine drug, the following equation can also be derived in an analogous manner for an acidic drug, like a barbiturate,

$$f(t) = \frac{1}{\{1 + (K_{a,R})/[(H^+)_{-0}]\} T + 1} \quad (\text{Eq. 35a})$$

where $K_{a,R}$ is the dissociation constant of the acidic drug and T is either Eq. 32 or 36, depending upon the perfect- or no-sink case.

Figure 6—Time-dependent concentration distribution profiles in aqueous and lipid phases for the perfect-sink case. Partition coefficient $P = 100$. (A) Dissociation constant of buffer, $K_{a,HB} = 10^{-6}$. (B) $K_{a,HB} = 10^{-8}$. (C) $K_{a,HB} = 10^{-10}$. Sodium-ion concentration was one-half of the total buffer concentration always.

CALCULATIONS

Computations were carried out for a range of parameters with the aid of the IBM 360/67 digital computer. Table I gives the dimensions of the constants and initial drug and buffer concentrations. The dissociation constant of the buffer and partition coefficient were varied. The detailed method of computation is given in the *Appendix*.

RESULTS AND DISCUSSION

In this section the interphase diffusional transport of an amine drug is analyzed for a wide range of pH and partition coefficients, other parameters being constant. It is discussed in relation to two extreme situations, the no-sink (impermeable lipid boundary at $x = L$) and the perfect-sink cases. In contrast to the later, the former case simulates the situation of retarded drug absorption in a simple way when the rate-determining step is due to one kind of interfacial barrier, like an impermeable membrane. There are also intermediate situations, *i.e.*,

$$\left(\frac{\partial(R)}{\partial x} \right)_{x=L} = C \quad (\text{Eq. 37})$$

where C is some nonzero value.

No-Sink Case—Typical changes of drug concentration-distance distribution curves in the aqueous and lipid phases with time are shown in Fig. 3. Steady-state and nonsteady-state conditions prevail

Table III—The Initial Slope K_u and $F(t)$ Values for the No-Sink Case with $P = 100$

in the respective diffusion layer and lipid phase. Because of the impermeable barrier, at sufficiently long times there will be a concentration buildup in the lipid that approaches some equilibrium concentration as determined by the partition coefficient.

Upon comparing Figs. 3A and B, the pH effect on the distribution profiles is evident. When $pK_{a,HB} = 4$ [and the bulk pH ~ 3 with $(Na^+) = 0$], the ratio of the initial bulk aqueous concentration of nonprotonated drug to the total concentration is only 1.11×10^{-5} . This results in a relatively small concentration gradient in the diffusion layer and, consequently, in a small amount of nonprotonated drug being transported into the lipid phase, even though the partition coefficient is favorable. On the other hand, when $K_{a,HB} = 10^{-12}$ (and the bulk pH ~ 8.8), the initial $(R)_{-h}/(TR)_{-h}$ is 0.887. Here the flux in the diffusion layer and the amount transported into the lipid are large. In Figs. 3A and C the results indicate that the rate of diffusion is influenced more by the amount of the free amine drug available for transport at the interface rather than the partition coefficient. In this regard, the pH profile of the diffusion model should be considered. Based on Eqs. 16 and 17, Table II shows the pH of the bulk aqueous phase and the interface for various $K_{a,HB}$ values and at different times with $P = 100$. Since $(Na^+) = 0$, the buffer capacity is very low. It is found that $pH_{-0} < pH_{-h}$ initially and can be explained by the fact that RH^+ and R species, as well as buffer, have some flux according to the concentration gradient within the diffusion layer and some RH^+ arriving at the interface dissociates into H^+ and R. The pH_{-h} will decrease in time and eventually will be equal to pH_{-0} when the diffusion rate is zero.

The semilogarithmic plots of $(TR)_{-h}$ versus t (Fig. 4) do not show a true linear relationship, as expected from Eq. 22, since the slope K_u is time dependent. When pH_{-0} of the system is approximately equal to or greater than the pK_a of the drug, the initial rate is very rapid; however, due to the backup drug concentration in the lipid later on, the rate approaches zero. In Table III the initial apparent first-order rate constant is given and the function F , determined in various ways for the first 250-sec. period, shows good agreement. $F(\Phi)$ was calculated by using Eq. 23 and the initial slope from Fig. 4, $F(t)$ by the computer-simulated transport program from the general Eqs. 20 and 21, and $f(t)$ by Eqs. 31 and 32. However, in Fig. 5 the functions F and, therefore, the rate constants are always changing with time. That the rate constant in early period (~ 500 sec.) from the log $(TR)_{-h}$ versus t plot is apparently constant with time can be explained by the fact that it is less sensitive to time than the differentially calculated K_u . Also, after 500 sec., the $F(t)$ and $f(t)$ tend to diverge. Since the derivation of $f(t)$ is based on a linear approximation of the flux in the lipid (see Fig. 2A), the function $f(t)$ becomes a poorer approximation of $F(t)$ when backup occurs in the lipid compartment at the impermeable boundary.

Perfect-Sink Case—In Fig. 6 the concentration distribution curves are shown for various values of $K_{a,HB}$ with $P = 100$. Nonsteady-state diffusion in the lipid occurs in the initial period. Later, when

the concentration-distance profile is linear, the system is at steady state and the diffusional rate is first order with respect to the total drug concentration in the bulk aqueous phase (Fig. 7). From Fig. 8, which shows the time change in $(TR)_{-h}$ and Q, the amount of nonprotonated drug in the sink, the lag time can be obtained by extrapolation and also predicted by Eq. 33. The results of this perfect-sink case are summarized in Table IV. Because of the strong buffer capacity, $(Na^+)_{-h} = (Na^+)_{-0} = 1/2(TB)$, the pH of the bulk aqueous phase and at the interface is nearly the same. There is good agreement between the lag time values obtained from the theory and the computer-simulated experiments and between the steady-state rate constants obtained in part from rigorous calculation by Eq. 19 and the approximation by Eqs. 35 and 36. Referring to Fig. 9, one can readily follow the course of the interphase transport by an analysis of $f(T)$. The curve is characterized by a rapid change with time, followed by an asymptotic relationship during the steady-state period. As the pH is more alkaline, the function $f(T)$ approaches 1 and the apparent first-order rate constant increases in magnitude.

Significance of the Function $f(T)$ for the Perfect-Sink Case—Thus far, the rate-determining factors have been discussed from the general viewpoint of the partition coefficient and the pH at the interface influencing the amount of nonionized drug available

**Figure 7**—First-order change in the total drug concentration in the bulk aqueous phase with time. Perfect-sink case for different initial bulk aqueous pH.

Figure 8—Time change in the total amount of drug in the bulk aqueous phase and in the sink.

for diffusion across the lipid phase. It is useful to examine the nature of the time-independent function $f(T)$ by Eqs. 35 and 36 and the steady-state rate constant K_u (Eq. 24) relative to pH_{-0} .

As shown in Fig. 10, when the $(pH_{-0} - pK_a)$ for a basic drug becomes increasingly positive and T is sufficiently small, say 10^{-6} to 10^{-8} , $f(T)$ is unity in the limit. Consequently, a few selected and interesting cases can be pointed out. If

$$\lim f(T) = 1, \text{ then } K_u = -\frac{AD_R}{Vh}$$

$$P \rightarrow \infty$$

$$(H^+)_{-0} \lesssim K_a$$

$$h = \text{constant}$$

On the other hand, if

$$\lim f(T) = 1, \text{ then } K_u \sim 0$$

$$h \rightarrow \infty$$

$$P \rightarrow \infty$$

$$(H^+)_{-0} \lesssim K_a$$

In both of these cases the rate-determining factor is the flux across the aqueous diffusion layer. These examples emphasize the importance of the aqueous diffusion layer, which is affected by the

Figure 9—Change in the diffusion efficiency coefficient with time for the perfect-sink case. After lag time, $F(t)$ calculated is the same as the approximation $f(t)$.

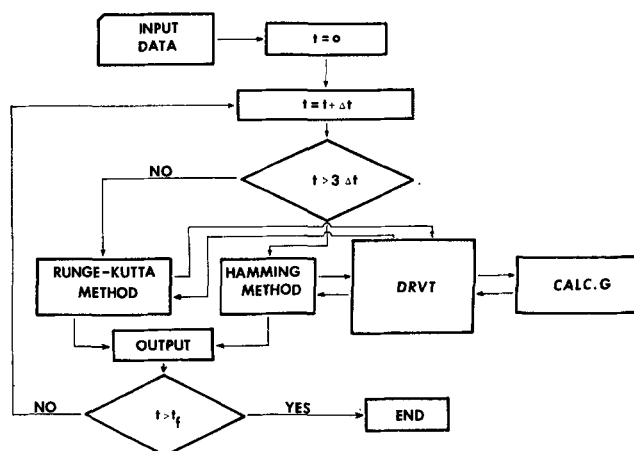

Figure 10—Relationship of the pH at the aqueous-lipid interface and the pK of the drug with the diffusion efficiency coefficient for various T , which includes all transport parameters such as diffusion and partition coefficients, thickness of diffusion layer, and lipid phases.

degree of stirring or agitation. More significantly, it shows that the pH -partition theory (9) is only a special case of the theory presented here. A very small value of $D_{R,oil}$ can also slow down the rate. In accordance with the pH -partition theory, the $f(T)$ and, consequently, $K_u \sim 0$ when the $(pH_{-0} - pK_a)$ becomes more negative.

Another interesting point in Fig. 10 is the shifting of the $f(T)$ versus $(pH_{-0} - pK_a)$ profiles with various T values. For $T = 10$, the profile approaches the dissociation curve characteristic of the basic drug; for other T values the profile deviates to the left of the dissociation curve.

From Eq. 36 it can be seen that increasing the partition coefficient, increasing h , increasing $D_{R,oil}$, decreasing D_R , or decreasing L , all have the effect of shifting the profile leftward away from the dissociation curve. The effect of agitation mentioned previously is particularly noteworthy in this regard. Thus it is important for investigators to recognize that the degree of agitation may not only influence the drug-absorption rate but that it can significantly influence the rate versus pH profiles. Another interpretation of the curves in Fig. 10 can be given; that is, at a constant diffusion layer thickness and a given rate of diffusion, the effect of a low concentration of non-

Scheme I—Flow diagram for the computation of concentration distributions

ionized species at the interface is balanced by a high partition coefficient and vice versa. All of these conclusions also apply to the case of acidic drugs in an analogous way.

In the study of rat intestinal and gastric absorption of sulfonamides, Koizumi *et al.* (6, 7) derived a first-order rate constant,

$$K_u \sqrt{M} = \frac{abP}{1 + aP} \quad (\text{Eq. 38})$$

where M is the molecular weight of the sulfonamide, K_u is the absorption rate of the nonionized moiety, a and b are constants, and P is the partition coefficient.

Equation 38 was found to be in good agreement with a large number of *in situ* experiments. It is noteworthy that the substitution of Eq. 35 or 35a into 24 gives

$$K_u = -\frac{AD_R}{Vh} \cdot \frac{BP}{1 + BP} \quad (\text{Eq. 39})$$

Both equations have the same form, although the methods of derivation are different. In the next paper, the results of Koizumi *et al.* and others will be discussed and compared with a similar model as presented in this study but modified to simulate the gastric and intestinal membrane.

APPENDIX

Numerical Calculating Procedure—To calculate the change of $(TR)_{-h}$, the concentration profile of R in the lipid phase with time and other parameters, the procedure shown in Scheme I is used. The input data are given in Table I. After $t = 0$, a series of calculation procedures undergo integration for each time increment, $t + \Delta t$. The $(TR)_{-h}$ and (R_i) at time t are determined by the stepwise integration of Eqs. 12–15a or 15b, depending upon the choice of the perfect-sink or no-sink case, by the Runge-Kutta technique for the initial period, $t \leq 3\Delta t$, and thereafter by the predictor-corrector method of Hamming (10). The calculation of the derivatives in Eqs. 12–15 is performed in the subroutine DRVT after evaluating G in the subroutine CALCG.

The procedure of subroutine CALCG is as follows. The first step involves the calculation of $(H^+)_{-h}$ from the fourth-power polynomial Eq. 16 by the Newton-Raphson method. Then $(R)_{-h}$, $(RH^+)_{-h}$, $(B^-)_{-h}$, and $(HB)_{-h}$ are obtained from Eqs. 1, 2, and 4, respectively. The next step is the evaluation of $(H^+)_{-0}$ from Eq. 17. In turn, $(B^-)_{-0}$, $(HB)_{-0}$, $(RH^+)_{-0}$ and $(R)_{-0}$ are found, using Eqs. 4, 7, and 18 and finally G by Eq. 6.

Theoretical Model Studies of Drug Absorption and Transport in the Gastrointestinal Tract II

AKIRA SUZUKI*, W. I. HIGUCHI, and N. F. H. HO

Abstract □ Multicompartment diffusional models for the absorption of neutral, acidic, basic, and amphoteric drugs were investigated. The general model consisted of a bulk aqueous phase, an aqueous diffusion layer, n -compartments of homogeneous and heterogeneous phases, and a perfect sink. With the mathematical techniques reported previously, equations were derived in general terms for the nonsteady- and steady-state periods. Utilizing the steady-state diffusion efficiency function of the barrier systems, the first-order rate constants for various examples of two- and three-compartment models were obtained from the general model and some computations were given. Various sets of *in situ* experimental rat data have been analyzed by means of the different models. These

include the intestinal, gastric, and rectal absorption of sulfonamides and barbituric acid derivatives. Self-consistent dimensional constants and diffusion coefficients were arrived at and the correlations obtained with the models have been found to be generally satisfactory.

Keyphrases □ Theoretical models—drug absorption, transport, gastrointestinal tract □ Drug absorption, transport, gastrointestinal tract—theoretical models, equations derived □ Kinetics—drug absorption, transport □ Sulfonamides—absorption, diffusion data, rats □ Barbituric acid derivatives—absorption, diffusion data, rats

In a previous paper the diffusion of basic and acidic drugs across an aqueous diffusion layer and a lipid compartment in a homogeneous two-phase model was presented (1). It provided a mathematical technique whereby more complicated models can be handled. A

function was also derived which was found useful in analyzing the diffusion rate with respect to the partition coefficient, surface and bulk pH, dissociation constant, diffusion coefficients, and diffusion layer thickness.

ionized species at the interface is balanced by a high partition coefficient and vice versa. All of these conclusions also apply to the case of acidic drugs in an analogous way.

In the study of rat intestinal and gastric absorption of sulfonamides, Koizumi *et al.* (6, 7) derived a first-order rate constant,

$$K_u \sqrt{M} = \frac{abP}{1 + aP} \quad (\text{Eq. 38})$$

where M is the molecular weight of the sulfonamide, K_u is the absorption rate of the nonionized moiety, a and b are constants, and P is the partition coefficient.

Equation 38 was found to be in good agreement with a large number of *in situ* experiments. It is noteworthy that the substitution of Eq. 35 or 35a into 24 gives

$$K_u = -\frac{AD_R}{Vh} \cdot \frac{BP}{1 + BP} \quad (\text{Eq. 39})$$

Both equations have the same form, although the methods of derivation are different. In the next paper, the results of Koizumi *et al.* and others will be discussed and compared with a similar model as presented in this study but modified to simulate the gastric and intestinal membrane.

Theoretical Model Studies of Drug Absorption and Transport in the Gastrointestinal Tract II

AKIRA SUZUKI*, W. I. HIGUCHI, and N. F. H. HO

Abstract □ Multicompartment diffusional models for the absorption of neutral, acidic, basic, and amphoteric drugs were investigated. The general model consisted of a bulk aqueous phase, an aqueous diffusion layer, n -compartments of homogeneous and heterogeneous phases, and a perfect sink. With the mathematical techniques reported previously, equations were derived in general terms for the nonsteady- and steady-state periods. Utilizing the steady-state diffusion efficiency function of the barrier systems, the first-order rate constants for various examples of two- and three-compartment models were obtained from the general model and some computations were given. Various sets of *in situ* experimental rat data have been analyzed by means of the different models. These

include the intestinal, gastric, and rectal absorption of sulfonamides and barbituric acid derivatives. Self-consistent dimensional constants and diffusion coefficients were arrived at and the correlations obtained with the models have been found to be generally satisfactory.

Keyphrases □ Theoretical models—drug absorption, transport, gastrointestinal tract □ Drug absorption, transport, gastrointestinal tract—theoretical models, equations derived □ Kinetics—drug absorption, transport □ Sulfonamides—absorption, diffusion data, rats □ Barbituric acid derivatives—absorption, diffusion data, rats

In a previous paper the diffusion of basic and acidic drugs across an aqueous diffusion layer and a lipid compartment in a homogeneous two-phase model was presented (1). It provided a mathematical technique whereby more complicated models can be handled. A

function was also derived which was found useful in analyzing the diffusion rate with respect to the partition coefficient, surface and bulk pH, dissociation constant, diffusion coefficients, and diffusion layer thickness.

In contrast to the two-phase model, this study describes a more general model in an attempt to simulate the diffusion of drug across the biological membrane and is easily adaptable to various conditions as the case may be. It utilizes the same mathematical techniques and computer method of numerical calculation heretofore mentioned. The appropriate theoretical relationships are also applied to some *in situ* experiments on absorption of sulfonamides and barbiturates in the rat intestine, stomach, and rectum.

THEORY

General Description of the Multicompartment Model and Non-steady-State Diffusion—The general theory involves the simple diffusion in one dimension through multicompartment, each compartment being homogeneous or heterogeneous in phase according to the situation and representing different structural regions of the system (Fig. 1). The first compartment consists of a bulk aqueous phase and a diffusion layer of thickness L_1 . The i th compartment ($i = 2, 3, \dots, n$) represents a portion of the membrane having distinct but uniform diffusional characteristics. The present general treatment will be assumed to be heterogeneous, *i.e.*, consisting of aqueous and lipid phases. Its thickness is L_i and the volume fraction of lipid is α_i . After the n th compartment, there is a perfect sink.

Let us now consider the drug also in general terms. The ionic equilibria of an amphoteric drug in water are

and

$$K_1 = \frac{(R_w^0)(H^+)}{(R_w^+)} \quad (\text{Eq. 2})$$

$$K_2 = \frac{(R_w^-)(H^+)}{(R_w^0)} \quad (\text{Eq. 3})$$

where (R_w^+) , (R_w^-) , and (R_w^0) are the concentrations of the cationic, anionic, and unionized drug species, respectively, in water (subscript w); K_1 and K_2 are the dissociation constants; and (H^+) is the hydrogen-ion concentration. For a basic drug, K_1 is its dissociation constant with $K_2 = 0$; for an acidic drug, K_2 is its dissociation constant with $K_1 = \infty$; for a neutral drug, $K_1 = \infty$ and $K_2 = 0$.

In the initial period, one assumes steady-state fluxes in the diffusion layer and nonsteady-state fluxes in the outer compartments. Therefore, applying Fick's first law,

$$G = -D_w \frac{d(R_w^+)}{dx} - D_w^- \frac{d(R_w^-)}{dx} - D_w^0 \frac{d(R_w^0)}{dx} \quad (\text{Eq. 4})$$

where G is the total flux of the drug species in the diffusion layer and D is the diffusion coefficient.

The description of the concentration-distance change with time is complex. Each compartment, except the first, is divided into unit cells of equal intervals, Δx_i . The distribution of drug between the lipid and aqueous phases in each cell is assumed to be instantaneously established and follows the Nernst relationship:

$$(R_0^+)_ij = P_i^+(R_w^+)_ij \quad (\text{Eq. 5a})$$

$$(R_0^0)_ij = P_i^0(R_w^0)_ij \quad (\text{Eq. 5b})$$

$$(R_0^-)_ij = P_i^-(R_w^-)_ij \quad (\text{Eq. 5c})$$

where P_i^+ , P_i^0 , and P_i^- are the partition coefficients of the cationic, nonionic, and anionic species, respectively; and the subscripts i , j , o , and w denote the i th compartment, j th cell, lipid, and aqueous phases, respectively. It is also assumed that the hydrogen-ion concentration in each compartment is constant; *i.e.*, the buffer capacity is large. The total drug concentration Y_{ij} of the j th cell in the i th compartment is

$$Y_{ij} = \alpha_i[(R_0^+)_ij + (R_0^0)_ij + (R_0^-)_ij] + (1 - \alpha_i)[(R_w^+)_ij + (R_w^0)_ij + (R_w^-)_ij] \quad (\text{Eq. 6})$$

Figure 1—General diffusion model consisting of an aqueous compartment with a diffusion layer followed by n compartments and a perfect sink. Each heterogeneous compartment contains lipid of volume fraction α and an aqueous phase $(1 - \alpha)$. Each compartment of thickness L is subdivided into j number of cells. R is the ratio of the true interfacial area to the geometrical surface area between compartments.

From Eqs. 2, 3, 5, and 6, the following are obtained

$$(R_0^+)_ij = C_{0,i}^+ \cdot Y_{ij} \quad (\text{Eq. 7a})$$

$$(R_0^0)_ij = C_{0,i}^0 \cdot Y_{ij} \quad (\text{Eq. 7b})$$

$$(R_0^-)_ij = C_{0,i}^- \cdot Y_{ij} \quad (\text{Eq. 7c})$$

$$(R_w^+)_ij = C_{w,i}^+ \cdot Y_{ij} \quad (\text{Eq. 7d})$$

$$(R_w^0)_ij = C_{w,i}^0 \cdot Y_{ij} \quad (\text{Eq. 7e})$$

$$(R_w^-)_ij = C_{w,i}^- \cdot Y_{ij} \quad (\text{Eq. 7f})$$

where

$$C_{0,i}^+ = P_i^+(H^+)_i^2/\beta_i \quad (\text{Eq. 8a})$$

$$C_{0,i}^0 = P_i^0(H^+)_i K_1/\beta_i \quad (\text{Eq. 8b})$$

$$C_{0,i}^- = P_i^- K_1 K_2/\beta_i \quad (\text{Eq. 8c})$$

$$C_{w,i}^+ = (H^+)_i^2/\beta_i \quad (\text{Eq. 8d})$$

$$C_{w,i}^0 = (H^+)_i K_1/\beta_i \quad (\text{Eq. 8e})$$

$$C_{w,i}^- = K_1 K_2/\beta_i \quad (\text{Eq. 8f})$$

$$\beta_i = \alpha_i [P_i^+(H^+)_i^2 + P_i^0 K_1 (H^+)_i + P_i^- K_1 K_2] + (1 - \alpha_i) [(H^+)_i^2 + K_1 (H^+)_i + K_1 K_2] \quad (\text{Eq. 9})$$

where $C_{w,i}^-$, $C_{w,i}^0$, and $C_{w,i}^+$ are the fractions in the respective anionic, nonionic, and cationic forms of the total concentration of the particular species in the aqueous phase of the i th compartment; and $C_{0,i}^-$, *etc.*, are defined in the same manner. Equations 7–9 indicate that the concentration of drug species in a particular phase of a unit cell, for example, $(R_0^0)_ij$, is interdependent with other species in the various phases through Y_{ij} and its magnitude is determined by the coefficient $C_{0,i}^0$, which in turn is directly influenced by the $(H^+)_i$ and the partition coefficient of the species.

The flux from the j to the $j + 1$ th cell in the i th compartment is expressed by

$$G_{i(j \rightarrow j+1)} = \{ \alpha_i [D_0^+ (R_{0,ij}^+ - R_{0,i+1}^+) + D_0^0 (R_{0,ij}^0 - R_{0,i+1}^0) + D_0^- (R_{0,ij}^- - R_{0,i+1}^-)] + (1 - \alpha_i) [D_w^+ (R_{w,ij}^+ - R_{w,i+1}^+) + D_w^0 (R_{w,ij}^0 - R_{w,i+1}^0) + D_w^- (R_{w,ij}^- - R_{w,i+1}^-)] \} / \Delta x_i \quad (\text{Eq. 10})$$

In terms of the total concentration in the cell, Eq. 10 is rewritten as follows:

$$G_{i(j \rightarrow j+1)} = \frac{D_{\text{eff}(i)} (Y_{ij} - Y_{i,j+1})}{\Delta x_i} \quad (\text{Eq. 11})$$

where the effective diffusion coefficient in the compartment, $D_{\text{eff}(i)}$, is

$$D_{\text{eff}(i)} = \alpha_i [D_0^+ C_{0,i}^+ + D_0^0 C_{0,i}^0 + D_0^- C_{0,i}^-] + (1 - \alpha_i) [D_w^+ C_{w,i}^+ + D_w^0 C_{w,i}^0 + D_w^- C_{w,i}^-] \quad (\text{Eq. 12})$$

Using the finite-difference method and Eq. 11, the nonsteady-state concentration change in the j th cell of the i th compartment with time may be expressed by the following equation,

$$\begin{aligned} \frac{dY_{ij}}{dt} &= \frac{G_{i(j-1 \rightarrow j)} - G_{i(j \rightarrow j+1)}}{\Delta x_i} \\ &= \frac{D_{eff(i)}}{(\Delta x_i)^2} (Y_{i,j-1} - 2Y_{ij} + Y_{i,j+1}) \\ (j &= 2, 3, 4 \dots j_1 - 1) \end{aligned} \quad (\text{Eq. 13})$$

Now that the diffusional movement from cell to cell in a compartment has been described, one must further account for the continuity of the flow between compartments by applying the boundary condition that the total flux to the interface is equal to the total flux from the interface. Therefore,

$$\begin{aligned} G_{T(i \rightarrow i+1)} &= \frac{AR_i D_{eff(i)}}{0.5 \Delta x_i} (Y_{i,j_1} - Y_{int(i,i+1)}) \\ &= \frac{AR_{i+1} D_{eff(i+1)}}{0.5 \Delta x_{i+1}} (P_{eff(i,i+1)} Y_{int(i,i+1)} - Y_{i+1,1}) \end{aligned} \quad (\text{Eq. 14})$$

$$f = \frac{L_1/D_{eff(1)}}{L_1/D_{eff(1)} + L_2/[R_2 P_{eff(1 \rightarrow 2)} D_{eff(2)}] + L_3/[R_3 P_{eff(1 \rightarrow 2)} P_{eff(2 \rightarrow 3)} D_{eff(3)}] + L_4/[R_4 P_{eff(1 \rightarrow 2)} P_{eff(2 \rightarrow 3)} P_{eff(3 \rightarrow 4)} D_{eff(4)}] + \dots} \quad (\text{Eq. 21})$$

where $G_{T(i \rightarrow i+1)}$ is the total flux immediately to or from the boundary, the subscript j_1 is the last cell of the i th compartment, R_i and R_{i+1} are the ratio of the actual surface area of the i th and $i+1$ th compartment, respectively, to the geometrical surface area A and, accordingly, R_i and $R_{i+1} \geq 1$. The $Y_{int(i,i+1)}$ is the total concentration at the interface on the i th-compartment side and $P_{eff(i,i+1)} Y_{int(i,i+1)}$ is the total concentration at the interface on the $i+1$ th compartment side where $P_{eff(i,i+1)}$ is the effective partition coefficient between the respective compartments. Under the assumption that the activity of the unionized drug species on both sides of the boundary is the same, it follows that

$$C_{w,i}^0 Y_{int(i,i+1)} = C_{w,i+1}^0 P_{eff(i,i+1)} Y_{int(i,i+1)} \quad (\text{Eq. 15a})$$

and, consequently,

$$P_{eff(i,i+1)} = \frac{C_{w,i}^0}{C_{w,i+1}^0} \quad (\text{Eq. 15b})$$

The average rate of change in concentration in the last cell of the i th compartment is

$$\frac{dY_{i,j_1}}{dt} = \frac{1}{\Delta x_i} \left[G_{i(j_1-1 \rightarrow j_1)} - \frac{G_{T(i \rightarrow i+1)}}{AR_i} \right] \quad (\text{Eq. 16a})$$

and in the first cell of the $i+1$ th compartment is

$$\frac{dY_{i+1,1}}{dt} = \frac{1}{\Delta x_{i+1}} \left[\frac{G_{T(i \rightarrow i+1)}}{AR_{i+1}} - G_{i+1,(1 \rightarrow 2)} \right] \quad (\text{Eq. 16b})$$

By substitution of Eqs. 11 and 14, the corresponding equations for 16a and b are

$$\frac{dY_{i,j_1}}{dt} = \frac{D_{eff(i)}}{\Delta x_i} \left[\frac{Y_{i,j_1-1} - Y_{i,j_1}}{\Delta x_i} - \frac{Y_{i,j_1} - Y_{int(i,i+1)}}{0.5 \Delta x_i} \right] \quad (\text{Eq. 17a})$$

$$\frac{dY_{i+1,1}}{dt} = \frac{D_{eff(i+1)}}{\Delta x_{i+1}} \left[\frac{P_{eff(i,i+1)} Y_{int(i,i+1)} - Y_{i+1,1}}{0.5 \Delta x_{i+1}} - \frac{Y_{i+1,1} - Y_{i+1,2}}{\Delta x_{i+1}} \right] \quad (\text{Eq. 17b})$$

Thus, Eqs. 13, 17a, and 17b describe the nonsteady-state diffusion across the barrier system in a general manner. The method of numerical calculation of the rate and concentration-distance distribution was described previously (1).

Steady-State Diffusion—Previously, the mathematical technique for obtaining the steady-state rate, lag time, and rate constant for the diffusion of drug across a two-phase homogeneous barrier was described under the assumption of an initial quasi-steady-state flux in the aqueous diffusion and a perfect sink. Similarly, one

derives the steady-state rate equation,

$$\frac{d(TR)_{w,1}}{dt} = -K_u (TR)_{w,1} \quad (\text{Eq. 18})$$

where $(TR)_{w,1}$ is the total concentration of drug in the water phase (Compartment 1) and the rate constant K_u is

$$K_u = \frac{AD_{eff(1)}}{VL_1} \quad (\text{Eq. 19})$$

where V is the volume of the bulk aqueous phase, L_1 is the thickness of the aqueous diffusion layer, and the function f is the diffusion efficiency coefficient of the barriers in the system. In the nonstationary-state period, the function f is time dependent; however, after the lag time, τ , i.e.,

$$\tau = 0.5 \left[\frac{L_2^2}{D_{eff(2)}} + \frac{L_3^2}{D_{eff(3)}} + 2 \frac{(R_2/R_3) L_2 L_3}{P_{eff(2 \rightarrow 3)} D_{eff(3)}} \right] \quad (\text{Eq. 20})$$

for a three-compartment model,¹ the f is time independent and is given by the general relationship,

APPLICATION OF THE STEADY-STATE THEORY TO SOME SPECIFIC MODELS

The foregoing general steady-state theory can be applied to some specific multicompartment models. To reiterate some of the assumptions made, (a) after a lag period the concentration gradient of the diffusing species in each compartment is linear and, subsequently, (b) the drug diffuses across the barriers at a steady-state rate into a perfect sink. The various models are shown in Figs. 2–3 and the lag time can be estimated from Eq. 20 for each model. In addition to the previous assumptions, it is specified that only unionized molecules can partition into the lipid phase, i.e., $P_i^+ = P_i^- = 0$, and that the aqueous diffusion coefficients in a compartment ($D_{w,i}$) of all ionized and unionized species are equal. Also, let the partition coefficient $P_i^0 = P$ and the fraction of undissociated molecules in the aqueous phase in a compartment $X_i = C_{w,i}^0$ (see Eq. 8). The effective diffusion coefficient in a compartment ($D_{eff(i)}$) consisting of a homogeneous phase is simply the diffusion coefficient of the drug in that phase; otherwise, in a heterogeneous compartment it is given by Eq. 12.

With the appropriate substitution of Eqs. 2, 3, 8, 9, 12, 15b, and 21 according to the model into Eq. 19, the absorption rate constant for basic, acidic, or amphoteric drugs can be derived in such a form that is convenient for analysis with experimental data.

Model I: Aqueous-Lipid Compartments—This model consists of a bulk aqueous phase with a diffusion layer and a lipid phase ($\alpha_2 = 1$). With the effective partition coefficient between compartment $P_{eff(1 \rightarrow 2)} = PX_1$ and $D_{eff(2)} = D_o$, the rate constant is given by

$$K_u = B_1 \cdot \frac{1}{1 + B_2/PX_1} \quad (\text{Eq. 22})$$

where

$$B_1 = \frac{AD_{w,1}}{VL_1} \quad (\text{Eq. 22a})$$

$$B_2 = \frac{L_2 D_{w,1}}{L_1 R_2 D_o} \quad (\text{Eq. 22b})$$

Model II: (a) Aqueous-Lipid-Aqueous and (b) Aqueous-Aqueous-Lipid Compartments—In Model IIa, there are three homogeneous compartments in which the two aqueous phases are separated by a lipid one. The aqueous phases may be of different composition and pH. The relationships, $P_{eff(1 \rightarrow 2)} = PX_1$ and $P_{eff(2 \rightarrow 3)} = 1/PX_3$

¹ For more than three compartments, τ will be of the same form except that the cross terms will be more complicated.

Figure 2—Some specific models used for the application of the steady-state transport theory.

are readily derived and, when introduced into Eq. 19,

$$K_u = B_1 \cdot \frac{1}{1 + (B_2/PX_1) + (B_3X_3/X_1)} \quad (\text{Eq. 23})$$

where B_1 and B_2 are defined by Eqs. 22a, 22b, and

$$B_3 = \frac{L_3D_{w,1}}{L_1R_3D_{w,3}} \quad (\text{Eq. 23a})$$

It is noted that the first and second compartments of Model IIa are the same as in Model I. Comparing Eqs. 22 and 23, the third compartment in the series is accounted for by the addition of a third term in the denominator of the rate-constant equation. The rate-determining factors may be easily deduced by Eq. 23. When the lipid compartment is the rate-determining barrier, the determining factors may be low lipid diffusivity and/or the concentration of unionized drug at the aqueous-lipid interface through X_1 and the partition coefficient. In turn, X_1 depends upon the pH and the nature of the drug, *i.e.*, whether it is amphoteric, acidic, basic, or neutral. Also, if the partition coefficient is high, the transport across the first and the

third compartments will be rate determining and the lipid compartment behaves essentially as a control reservoir.

In Model IIb the sequence of the compartments is different from the previous model. The second aqueous compartment may be thought to be analogous to the presence of a mucoid or thick proteinaceous layer intervening between the bulk aqueous and lipid phases. This model is similar to the membrane described by Robertson (2) in which he assumed that it consisted of phospholipids with a protein envelope. Although identical in form to Eq. 23, the rate-constant equation is

$$K_u = B_1 \cdot \frac{1}{1 + (B_2X_2/X_1) + (B_3/PX_1)} \quad (\text{Eq. 24})$$

and the coefficients are

$$B_2 = \frac{L_2D_{w,1}}{L_1R_2D_{w,2}} \quad (\text{Eq. 24a})$$

$$B_3 = \frac{L_3D_{w,1}}{L_1R_3D_0} \quad (\text{Eq. 24b})$$

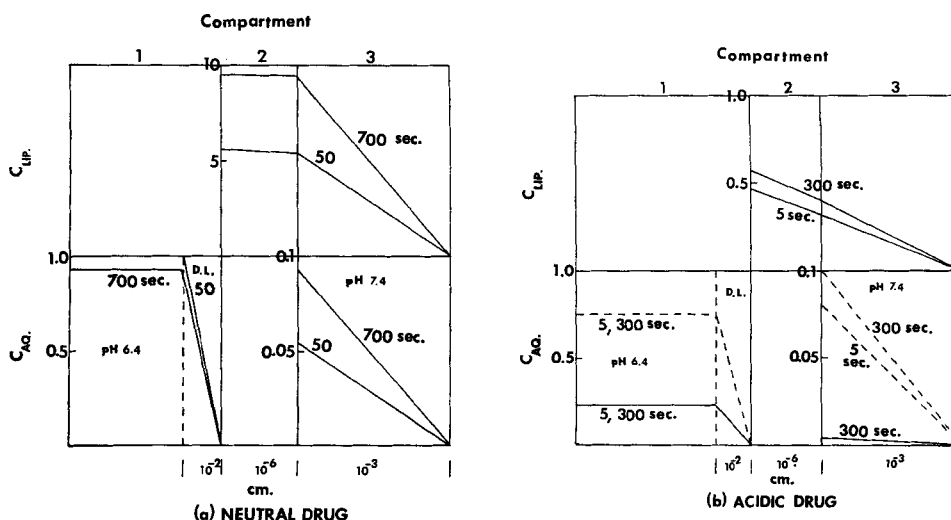

Figure 3—Time-dependent concentration distribution profiles in the aqueous and lipid phases of Model IV. The model consists of an aqueous compartment followed by lipid and heterogeneous compartments. $V = 10 \text{ cm.}^3$, $A = 10 \text{ cm.}^2$, $R_2 = 100$, $R_3 = 1$, $\alpha_1 = 0$, $\alpha_2 = 1$, $\alpha_3 = 0.1$, $D_w = 10^{-6} \text{ cm.}^2 \text{ sec.}^{-1}$, $D_0 = 10^{-12} \text{ cm.}^2 \text{ sec.}^{-1}$, $P = 100$. In 3a, only a neutral drug is used. In 3b an acidic drug ($pK_a = 6$) is used. Key: —, unionized form; and ---, ionized form.

Table I—Comparison Between the Numerically Calculated and Estimated Values of the Lag Time τ and the Steady-State Diffusion Efficiency Coefficient F in Model IV

Drug	$\tau_{calc.}$ sec.	$F_{calc.}$	$\tau_{est.}^a$ sec.	f
Acidic	10	0.976	8	0.98
Neutral	200	0.90	140	0.90

^a $\tau_{est.}$ calculated from Eq. 20 and f from Eq. 21.

Model III: Aqueous-Lipid/Aqueous Compartments—Unlike the previous cases, this model provides for a heterogeneous phase system to simulate a membrane consisting of lipoidal cells in an aqueous intercellular fluid environment. In this way, all molecular species existing in the aqueous diffusion layer are able to permeate through the heterogeneous compartment; however, the rate is determined by the effective permeability coefficient,

$$K_{eff(1 \rightarrow 2)} = P_{eff(1 \rightarrow 2)} D_{eff(2)}$$

$$= \alpha_2 D_0 P X_1 + (1 - \alpha_2) D_{w,2} X_1 \left[1 + \frac{(H^+)_2}{K_1} + \frac{K_2}{(H^+)_2} \right] \quad (\text{Eq. 25})$$

and, with $X_2 = (R_w^0)_2 / [(R_w^0)_2 + (R_w^+)_2 + (R_w^-)_2]$ and Eqs. 2–3, it follows that

$$K_{eff(1 \rightarrow 2)} = \alpha_2 D_0 P X_1 + (1 - \alpha_2) D_{w,2} \frac{X_1}{X_2} \quad (\text{Eq. 26})$$

Therefore,

$$K_u = B_1 \cdot \frac{1}{1 + B_2/[P X_1 + B_3(X_1/X_2)]} \quad (\text{Eq. 27})$$

where B_1 is defined as before,

$$B_2 = \frac{L_2 D_{w,1}}{L_1 R_2 D_0 \alpha_2} \quad (\text{Eq. 27a})$$

$$B_3 = \frac{(1 - \alpha_2) D_{w,2}}{\alpha_2 D_0} \quad (\text{Eq. 27b})$$

As the volume fraction of lipid approaches unity ($\alpha_2 \rightarrow 1$), the model becomes more like Model I. Higuchi and Higuchi (3) also made a theoretical analysis of the diffusional movement of drugs through heterogeneous barriers; however, their results are somewhat different from the authors'. They also considered the effect of the shape and size of the internal phase and drug interactions with the internal phase.

Figure 4—Change in the function F with time during the nonsteady- and steady-state transport of neutral and acidic drugs in Model IV.

Figure 5—Total amount of drug accumulated in the perfect sink with time according to Model IV.

Model IV: Aqueous-Lipid-Lipid/Aqueous Compartments—For this model, consisting of barrier compartments of homogeneous aqueous and lipid phases in series followed by a heterogeneous compartment, or parallel barrier, numerical calculations were performed. Figures 3a and b show the concentration-distance distribution changes with time for a neutral drug, such as dibutylphthalate or cholesterol, and an acidic drug, pKa = 6. A pH₁ of 6.4 in the bulk aqueous phase and pH₂ of 7.4 in the heterogeneous phase were chosen for their close association with physiological

Table III—Maximum Rate Constants of Gastric Absorption in Rats and Some Physical Constants of Barbituric Acids^a

conditions. Other dimensional values are given in Fig. 3a. The steady-state rate constant is

$$K_u = B_1 \cdot \frac{1}{1 + (B_2/PX_1) + B_3/[PX_1 + (B_4X_1/X_3)]} \quad (\text{Eq. 28})$$

where

$$B_3 = \frac{L_3 D_{w,1}}{L_1 R_3 D_{0,3} \alpha_3} \quad (\text{Eq. 28a})$$

$$B_4 = \frac{(1 - \alpha_3) D_{w,3}}{\alpha_3 D_{0,3}} \quad (\text{Eq. 28b})$$

and B_1 and B_2 are the same as in Eqs. 22a and b. The magnitude of X_1 and X_3 depends upon the environment of the first and third compartments, respectively, and the nature of the drug.

Between the cases of the acidic and neutral drugs, the total rate of diffusion is slightly faster with the acidic drug. Despite the low concentration of the unionized form of the acidic drug in the bulk aqueous phase, the instantaneous equilibrium conversion of unionized to anionic species at the boundary of the lipid and heterogeneous compartments ($\text{pH}_3 - \text{pK}_a > 1$) and the rapid effective diffusivity of both anionic and nonionic species in the last compartment led to a higher concentration gradient in the lipid than that for the neutral drug case. Thus, the "push-pull" effect is shown. In the case of the neutral drug, the relatively low partitioning from the lipid to the heterogeneous compartment, which is essentially aqueous in char-

acter ($\alpha_3 = 0.1$), resulted in a back-up effect or a small lipid concentration gradient.

Figure 4 gives the change in the total rate in the form of $F = (VL_1)/(AD_{w,1}) \cdot K_u$ with time. Previously (1), it was shown that the function F comes from the rigorous numerical calculation of the

dynamic flux of drug through the system and the function f is the useful approximation of F in analytic form. At steady state, both F and f should give the same results. The numerical calculations of the lag time τ and the function F at quasisteady state in Table I are in good agreement with the estimated τ (Eq. 20) and f (Eq. 21). Figure 5 shows the total amount of neutral and acidic drug in the sink as a function of time.

APPLICATION OF THEORETICAL MODELS TO ABSORPTION OF SULFONAMIDES AND BARBITURATES IN RATS

In this section an attempt is made to analyze the movement of drugs across cell membranes in the studies of Kakemi *et al.* of the kinetics of absorption of sulfonamides and barbiturates in the intestinal, gastric, and rectal tracts (4–7). Utilizing theoretical models and introducing physical dimensions, some of which are associated with various membranes and others determined by *in vitro* experiments, the authors attempt to calculate for physical constants self-consistent with experimental data and to discuss factors controlling the rate of movement.

Regression Analysis Results and Dimensional Constants—Tables II and III give the experimental results of Kakemi *et al.* only in the gastric absorption of sulfonamides and barbiturates, while the results of intestinal and rectal absorption are found elsewhere

Figure 8—Comparison of in situ and theoretical absorption rates of sulfisoxazole through the stomach from solutions of various pH.

(5, 6). Their steady-state first-order rate constant, K_u , for an aqueous-lipoidal barrier model has the same general form as Eq. 19, although derived differently. Before applying Models I, II_a, and III to their results, it is necessary to specify the pH of the compartments following the first bulk aqueous compartment. To account for the possibility of the simultaneous diffusion of buffer species and the subsequent effect on the pH of the aqueous phase in the membrane compartments, it is arbitrarily assumed that $\text{pH}_i = (\text{pH}_1 + 7.4)/2$, where $i = 2$ or 3 for the respective Model II_a or III. Also, the volume fraction of lipid in the heterogeneous compartment of Model III was taken to be 0.5. Through the use of (a) the values of the maximum experimental K_u , pK_{a1} , and pK_{a2} , (b) the partition coefficient relative to isoamyl acetate–water, such as those found in Tables II and III, and (c)

the application of Hartley's method of nonlinear regression analysis (8), the coefficients B_1 , B_2 , and B_3 of the rate-constant Eqs. 22 (Model I), 23 (Model IIa), and 27 (Model III) were determined and these are found in Tables IV–VI. From these coefficients, self-consistent combinations of dimensional constants and diffusion coefficients for each model were calculated. To derive the results in Tables VII–IX, the following procedure was taken: (a) assume $L_1 = 10^{-2}$ cm., $L_2 = 10^{-6}$ cm., $\alpha = 0.5$ in the case of Model III, and $R_2 = 500$ for the intestinal tract in the case of Model I (9); (b) assume $D_{w,1} = 1 \times 10^{-6}$ cm.² sec.⁻¹ for the barbituric acid derivatives³ and by comparing B_1 of the sulfonamides and barbiturates in the gastric tract, take $D_{w,1} = 5 \times 10^{-6}$ cm.² sec.⁻¹ for the sulfonamides; (c) calculate D_0 for the sulfonamides from B_2 of the intestinal tract, R_2 of the gastric and rectal tract, and the rest of the parameters. Between the barbiturates and the sulfonamides, the $D_{w,1}$ of the latter drug does not seem unreasonable on the basis of the higher average molecular weight. The $D_0 = 1 \times 10^{-12}$ cm.² sec.⁻¹ found for the sulfonamides compares well with the diffusion coefficients (10^{-10} – 10^{-12} cm.² sec.⁻¹) of some organic solutes through lipid bilayer membranes (10) and of various sulfonamides through red blood cells (11). It is observed that the D_0 for the barbiturates is smaller than that for the sulfonamides by a factor of 10. This cannot be easily explained by the usual Stokes-Einstein diffusion equation.

The theoretical K_a of the sulfonamides in the intestinal, gastric, and rectal tracts and of the barbiturates in the gastric tract for the various models was calculated, using the dimensional constants and the diffusion coefficients in Tables VII–IX, and plotted against the K_a of the *in situ* experiments. Figure 6 shows the $K_{a,\text{expt.}}$ versus $K_{a,\text{theory}}$ plot only for the gastric absorption of sulfonamides according to Models I, IIa, and III and of barbiturates for Model I. The strong correlation observed here in these figures was also consistent throughout the other cases. However, at this point one cannot determine which physical model is more applicable, except to say that the constants determined previously are self-consistent.

Comparison of the pH Profile of the Absorption Rate with Experiments and Physical Models—The relative absorption rates versus bulk aqueous pH for sulfisoxazole in the intestinal, gastric, and rectal tracts are shown in Figs. 7–9 and for hexobarbital in the gastric tract in Fig. 10. The calculated results of the physical models are compared with experimental data.

In the cases of gastric and intestinal absorption of sulfisoxazole, the physical models show a large deviation in the acidic region and a relatively good fit on the alkaline side of the profile, particularly with Model III. The profile of Model I is symmetrical about the dissociation curve. This is not surprising in view of the lengthy discussion given earlier (1). On the other hand, asymmetry of the profiles of Models IIa and III about the dissociation curve is found. This is explainable by the influence of the effective pH in the aqueouslike compartments of the membrane, which was assumed to be the arithmetic average of the pH of the bulk drug solution and the physiologic pH of 7.4 on the distribution and transport of drug species in the membrane.

Because of the restriction that the (H^+) in any compartment (particularly, the first compartment) is constant, the present models cannot adequately account for the shift of the maximum experimental rates in Figs. 7 and 8 to higher pH values of the bulk solution relative to the pH of the dissociation curve at which the fraction of the unionized drug form is maximum. There is experimental evidence⁴ in the case of gastric absorption of sulfisoxazole that increasing the buffer capacity of the drug solution tends to shift the maximum rate closer to the pH maximum of the dissociation curve. Thus, an accurate accounting of the pH at the surface and within the aqueous phases of the membrane and also protein binding in the physical models may explain the shift of the experimental maximum rate to the more alkaline side. Although there can be a difference between the surface and bulk solution pH, it seems doubtful that they are related through the surface potential (12) in *in situ* experiments; that is, $pH_s = pH_{\text{soln.}} + e\psi_0/kT$. Instead it is suggested that surface pH might be related to acid production in the cells and diffusion into the bulk solution.⁵

In the absorption rate versus bulk pH profile for the rectal absorption of sulfisoxazole (Fig. 9) and gastric absorption of hexobarbital (Fig. 10), there was relatively good agreement between the *in situ* experimental results and physical models. Maximum absorption of sulfisoxazole was observed at the isoionic point and the absorption rate of hexobarbital corresponded with the pKa.

In conclusion it is difficult to select the physical model that best describes the *in situ* absorption experiments in the intestinal, gastric,

³ Kakemi *et al.* found $D_{w,1} = 0.815 - 1.27 \times 10^{-6}$ cm.² sec.⁻¹ at 37° for the barbiturates.

⁴ Refer to Fig. 5 in Reference 4.

⁵ Theoretical models involving the effect of the surface potential on the one hand and acid production with simultaneous reaction and diffusion on the other hand are being investigated.

or rectal tracts since all of the models studied showed fairly good agreement. More knowledge of the structure and microenvironment of the membrane as well as drug interactions with cellular substances is necessary before modification of the physical models can be made. Furthermore, the models generally have more quantitative parameters in detail which the usual *in situ* experiments alone cannot provide. However, the physical model approach to drug transport studies is being further investigated.

Interfacial Barriers in Interphase Transport III: Transport of Cholesterol and Other Organic Solutes into Hexadecane-Gelatin-Water Matrices

ABDEL-HALIM GHANEM, W. I. HIGUCHI, and A. P. SIMONELLI

Abstract □ The purpose of this study was to quantitate the transport behavior of several organic solutes in matrix systems composed of micron-size hexadecane droplets dispersed in an aqueous gelatin gel where the oil-water interfacial barrier to transport was expected to play an important role. Two interrelated experiments were conducted. The first was the one-dimensional aqueous uptake of the solute by the matrix which was a continuous layer placed at the bottom of a beaker. The other experiment was solute uptake and release from aggregates of oil droplets suspended in an aqueous medium. Solute investigated were ^{14}C -labeled cholesterol, diethyl-phthalate, ^{14}C -labeled octanol, and ^{14}C -labeled progesterone. The data have been analyzed by various physical models. It was found that cholesterol transport essentially was controlled by the oil-water interfacial barrier in both kinds of experiments—even when the matrix thickness was as large as 3.7 mm. For the other solutes, the oil-water interfacial barriers were found to be controlling in the experiments with aggregates (10–1000 μ). However, in the experiments with the continuous matrix layers, bulk matrix diffusion factors as well as the oil-water interphase transport were found to be important for these solutes. The techniques developed in this investigation should be useful: (a) in the quantitation of interfacial barriers in oil-water interphase transport of solutes, and (b) in the separation of various bulk diffusional resistances from interfacial resistances in complex multiphase matrices.

Keyphrases □ Interphase transport—interfacial barriers □ Hexadecane-gelatin-water matrix—organic solute transport □ Matrix layer—solute uptake □ Aggregated gelatin encapsulated hexadecane droplets—solute transport □ Electrolyte, polysorbate 80, concentration effects—interphase transport

Recent studies in these laboratories have been aimed at the mechanistic understanding of various factors influencing the interphase transport of drugs and other biologically interesting substances. These investigations (1–4) have considered, for example, the simultaneous multiphase interactions involving pH and the buffer

Figure 1—Schematic diagram showing the apparatus used for the continuous matrix layer (CML) uptake experiments.

parameters, the oil-water partition coefficients, and the diffusion coefficients. More recently (5–8), utilizing a novel technique, the existence and the importance of the
