or rectal tracts since all of the models studied showed fairly good agreement. More knowledge of the structure and microenvironment of the membrane as well as drug interactions with cellular substances is necessary before modification of the physical models can be made. Furthermore, the models generally have more quantitative parameters in detail which the usual *in situ* experiments alone cannot provide. However, the physical model approach to drug transport studies is being further investigated.

Interfacial Barriers in Interphase Transport III: Transport of Cholesterol and Other Organic Solutes into Hexadecane-Gelatin-Water Matrices

ABDEL-HALIM GHANEM, W. I. HIGUCHI, and A. P. SIMONELLI

Abstract □ The purpose of this study was to quantitate the transport behavior of several organic solutes in matrix systems composed of micron-size hexadecane droplets dispersed in an aqueous gelatin gel where the oil-water interfacial barrier to transport was expected to play an important role. Two interrelated experiments were conducted. The first was the one-dimensional aqueous uptake of the solute by the matrix which was a continuous layer placed at the bottom of a beaker. The other experiment was solute uptake and release from aggregates of oil droplets suspended in an aqueous medium. Solute investigated were ^{14}C -labeled cholesterol, diethyl-phthalate, ^{14}C -labeled octanol, and ^{14}C -labeled progesterone. The data have been analyzed by various physical models. It was found that cholesterol transport essentially was controlled by the oil-water interfacial barrier in both kinds of experiments—even when the matrix thickness was as large as 3.7 mm. For the other solutes, the oil-water interfacial barriers were found to be controlling in the experiments with aggregates (10–1000 μ). However, in the experiments with the continuous matrix layers, bulk matrix diffusion factors as well as the oil-water interphase transport were found to be important for these solutes. The techniques developed in this investigation should be useful: (a) in the quantitation of interfacial barriers in oil-water interphase transport of solutes, and (b) in the separation of various bulk diffusional resistances from interfacial resistances in complex multiphase matrices.

Keyphrases □ Interphase transport—interfacial barriers □ Hexadecane-gelatin-water matrix—organic solute transport □ Matrix layer—solute uptake □ Aggregated gelatin encapsulated hexadecane droplets—solute transport □ Electrolyte, polysorbate 80, concentration effects—interphase transport

Recent studies in these laboratories have been aimed at the mechanistic understanding of various factors influencing the interphase transport of drugs and other biologically interesting substances. These investigations (1–4) have considered, for example, the simultaneous multiphase interactions involving pH and the buffer

Figure 1—Schematic diagram showing the apparatus used for the continuous matrix layer (CML) uptake experiments.

parameters, the oil-water partition coefficients, and the diffusion coefficients. More recently (5–8), utilizing a novel technique, the existence and the importance of the

Figure 2—Dark-field photomicrograph of aggregates before treatment with formaldehyde solution.

oil-water interfacial barriers have been quantitated for several systems.

The present communication describes the results of experiments on the transport of solutes into and out of gelatin matrices in which micron-size droplets of hexa-

Figure 3—Photomicrograph of the aggregates after treatment with an 18.5% formaldehyde solution.

decane were dispersed. The findings of this study have been correlated with the previous research in these laboratories and demonstrate when an oil-water interfacial barrier is rate determining (5-7) and when bulk matrix diffusional factors are dominant (1-3).

EXPERIMENTAL

General Considerations—Essentially two kinds of interrelated experiments were conceived. The first of these was the one-dimensional aqueous uptake of the solute by a dispersion of oil droplets in a continuous gelatin matrix layer polymerized with a formaldehyde solution. The second type of experiment was the determination of the uptake and release of solute from an aqueous suspension of aggregates of the oil droplets prepared by first treating the gelatin stabilized oil-in-water emulsion with concentrated sodium sulfate (5) and then with a formaldehyde solution. As will be seen, this combined approach provides the means to determine the relative importances of oil-water interfacial barriers and bulk diffusion in complex heterogeneous matrices of this type.

Materials—The gelatin, hexadecane, sodium sulfate, and diethylphthalate employed in these studies were previously described

Figure 4—Comparison of experimental ^{14}C -labeled cholesterol uptakes (CML and AGE techniques) with theoretically computed values based upon the interfacial barrier model as a function of oil volumes and polysorbate 80. C_a is counts/min./ml. of solute in the aqueous polysorbate 80 remaining versus time in hours. Initial ($t = 0$) ^{14}C -cholesterol concentration was 3.4×10^{-8} g./ml. and initial aqueous volumes were 50 ml. in all experiments. Key:

(5, 6). Formaldehyde AR grade¹ was used. Solutes other than diethylphthalate investigated in these studies were ^{14}C -4-cholesterol,² ^{14}C -4-progesterone,³ and ^{14}C -1-octanol.⁴

Procedure for the Continuous Matrix Layer (CML) Uptake—Figure 1 shows a schematic diagram of the experimental apparatus which consists of a water-jacketed beaker (A) with a plastic cover (B) that prevents evaporation and supports a synchronous motor (C).⁵ Two holes have been drilled in the cover, one for sampling and the other for a four-blade glass stirring rod.

A specified amount of the hexadecane-in-water emulsion stabilized with gelatin was prepared as previously reported (6). The emulsion at 40° was transferred to the beaker, and the temperature was immediately dropped to 10° by placing the beaker in an ice water bath for 1 hr. Then 25 ml. of a 3.7% formaldehyde solution (pH 9.0) at 10° was added to the beaker and allowed to interact with the gel for 1 hour at the same temperature. The formaldehyde was then leached out by washing with water several times over a period of 12–18 hr. In this manner, matrices of different thicknesses (volumes corresponding to 1, 2, 4, and 8 ml.) were prepared and

were found to be stable in water or in polysorbate 80 solution (0.05–0.1%) over a period of 10 days.

The uptake experiments were carried out in the following manner. The aqueous solution of the organic solute was added to the beaker containing the prepared matrix system. Stirring was immediately initiated using either a 50 or a 150 r.p.m. synchronous motor. The temperature was kept at $23 \pm 2^\circ$. Samples of 1.0 ml. were removed at predetermined time intervals for quantitative analysis.

Procedure for the Transport Studies with Aggregated "Gelatin-Encapsulated" Hexadecane Droplets (AGE)—Fifty grams of an 18% solution of sodium sulfate was added to 70 g. of the previously described (5) hexadecane-gelatin emulsion. The mixture was stirred for 6–8 hr. at 50° (5). The mixture was then transferred to an ice water jacketed Waring blender operating at a speed of 1500–2000 r.p.m. and cooled to 10° . Then 100 ml. of an 18.5% formaldehyde solution (pH 9.0, temperature 10°) was added to the mixture and allowed to react for 1 hr. with continuous stirring. The material was then washed with water and stored in water until use in the uptake experiment.

field photomicrograph of the aggregates before treatment with formaldehyde. Figure 3 shows a photomicrograph of the aggregates after treatment with formaldehyde solution. Visual examination of these aggregates showed that about 10% were singlets, about 20% were aggregates of 2–10, about 40% were from 10 to 20, 20% were from 20 to 100, and 10% from 100 to 200.

"Coarse" aggregates were also prepared in a similar manner but by using a 22% sodium sulfate solution instead of 18% as was used in the case of the "fine" aggregate preparation. Visual examination of this preparation indicated that about 10% were singlets, 20% were from 2 to 10, 20% from 10 to 50, 30% from 50 to 200, and 30% from 200 to 500.

The solute uptake experiments were carried out as follows. The stock aggregates in water were stirred for a few minutes, a portion was filtered, and then allowed to remain for 2 hr. on the filter. A predetermined amount (0.75, 1.5, or 3.0 g.) was transferred to a 150-ml. plastic beaker⁶ which was found to resist sticking of the aggregates to the beaker wall—a problem encountered with glassware. Exactly 100 ml. of the aqueous medium containing the solute was then added to the beaker. Stirring was initiated immediately by means of a synchronous motor (150 or 300 r.p.m.) with a magnetic head coupling to a magnetic stirring bar. In order to achieve good dispersion of the aggregates, the magnetic head was placed slightly off-center of the beaker. The temperature was kept at $23 \pm 2^\circ$. At different time intervals, a sample of 5 ml. was withdrawn by a 10-ml. syringe, and approximately half of it was filtered through a silver filter membrane⁷ using a 10-mm. diameter stainless steel filter holder.⁸ Part of this filtrate was used for analysis.

The diethylphthalate release studies with these aggregates were carried out in the same way except that the prepared aggregates were treated in the following manner. A suspension of about 60 g. of the aggregates in about 200 ml. of water containing 1.2 ml. of

diethylphthalate was slowly stirred for 48 hr. with a magnetic stirrer. The mixture was then filtered, washed twice with 50 ml. of water, and stored in 200 ml. of a 0.03% diethylphthalate solution. The concentration of diethylphthalate in the encapsulated oil was determined by total extraction of diethylphthalate (5).

Assay Procedure—Where radioactive-labeled materials were employed, the Beckman LS 200B liquid scintillation system⁹ was used. In the diethylphthalate experiments, a spectrophotometric analysis¹⁰ ($\lambda = 273.5 \text{ m}\mu$) was employed.

EXPERIMENTAL RESULTS AND THEORETICAL TREATMENT

¹⁴C-Labeled Cholesterol Transport from Aqueous Polysorbate 80 Solution into the Hexadecane-Gelatin Matrix Layer (CML) and into Dispersed Aggregates (AGE)—The results of the ¹⁴C-4-cholesterol uptake experiments using both techniques (CML and AGE) for three oil volumes and two polysorbate 80 concentrations¹¹ (0.05 and 0.1%) are presented in Figs. 4 and 5. The uptake rates were found to be generally slow and, for the CML as well as the

AGE experiments, the rates were dependent strongly on the oil volumes in the system. Figure 5 presents the influence of the stirring rates and the aqueous ¹⁴C-4-cholesterol concentration upon the CML uptake experiments. As can be seen, stirring had a negligible effect upon the rates. Also the uptake rates were found to be directly proportional (first order) to the cholesterol concentration.

The CML and the AGE uptake rates were found to be essentially identical when the mass of the oil phases were the same, as was the case for the experiments shown in Fig. 4. As the primary oil particle-size distributions were the same for the CML and AGE studies, this finding is particularly significant.

In order to explain these data, let us consider the various possible rate-determining mechanisms by referring to the models given in Fig. 6. In general, for the CML case there are three possible processes, any of which can be the rate-determining one. These are: (a) diffusion through the aqueous diffusion layer of thickness h , (b) diffusion through the matrix itself, or (c) interfacial barrier transport. For the AGE experiment these three processes may still apply, but the magnitudes of aqueous diffusion and the matrix diffusion resistances would be expected to be much smaller than for those in the CML situation. The interfacial barrier, however, would be expected to be about the same for both the CML and the AGE situations, even though the preparation procedures differed somewhat (see *Experimental*).

All of these experimental results for cholesterol uptake in both systems support the mechanism in which an interfacial barrier is rate determining. First, the absolute rates were essentially the same for the CML and the AGE experiments in every situation. Secondly, the rate of stirring had no influence on the CML uptake rates. Thirdly, the uptake rates showed a strong oil volume (or a layer thickness) dependence with the CML experiments. This would not have been expected if either transport in the aqueous diffusion layer or transport through the matrix itself was rate determining. Thus all of the data support the overwhelming importance of the interfacial process in both situations.

These conclusions justify the quantitative treatment based upon an interfacial barrier control developed previously (5). Thus employing the primary oil droplet size distribution data obtained earlier (6) and the independently determined partition coefficients, the theoretical uptake rates were calculated using different interfacial barrier permeability coefficients. These theoretical calculations

150	○	□	△	◇

tions have revealed that a single permeability coefficient value of $P = 5 \times 10^{-9}$ cm./sec. quantitatively describes all of the data (Figs. 4 and 5). The smooth curves presented in these plots correspond to the theoretical uptake calculations utilizing this P value. The agreement, as can be seen, is quite satisfactory.

Transport of Diethylphthalate into the Hexadecane-Gelatin Matrix Layer (CML) and into and out of Dispersed Aggregates (AGE)—The results of the diethylphthalate uptake experiments employing the AGE method are presented in Figs. 7 and 8. In Fig. 7, the influence of the electrolyte concentrations on the uptake rate is demonstrated. As can be seen, the significant effects are large at times, i.e., near equilibrium. The initial rate appears to be relatively independent of the electrolyte concentration. In Fig. 8, comparisons of the uptake behavior are shown for three different concentrations of the aggregates in water and in 7% sodium sulfate. The strong dependence upon the oil volume is apparent.

The curves given in Figs. 7 and 8 are the theoretically computed values based upon the known primary particle distribution (6), the independently determined partition coefficients, and a permeability coefficient, $P = 1.0 \times 10^{-5}$ cm./sec. The good agreement of the experimental data with theoretical computations in regard to the time dependence and the oil volume dependence demonstrates that the interfacial barrier model (5, 6) is operative. Furthermore, this good correlation of the experiment with the theoretical calculations states that the electrolyte influence upon the uptake rate is a partition coefficient effect and not an effect upon the permeability coefficient, as was also found with the nonaggregated, nonencapsulated, hexadecane-gelatin-water systems (6).

Results of the diethylphthalate release rate experiments with the dispersed aggregates are given in Figs. 9 and 10. The effects of dif-

ferent electrolyte concentrations upon the release rate are shown in Fig. 9 for both the "fine" and "coarse" aggregate systems. Figure 10 presents the data on the oil volume effect for the release of diethylphthalate into water and 7% sodium sulfate.

The curves in Figs. 9 and 10 give the theoretically computed values for the release of diethylphthalate using the primary droplet size distribution data (6), the independently determined partition coefficient for each situation, and a P value of 1.0×10^{-5} cm./sec. The good agreement obtained for the uptake (Figs. 7 and 8) using the same P value clearly shows that the same interfacial barrier model is governing the transport of the solute in both situations. It is noteworthy that the aggregate size differences between the "fine" and "coarse" aggregates do not appear to be significant (Fig. 9). It was also found that experiments at 150 and 300 r.p.m. showed no differences in these experiments.

Results of some of the diethylphthalate uptake experiments employing the matrix layer method (CML) are presented in Figs. 11 and 12. Figure 11 shows the matrix volume and the stirring rate effects upon the solute uptake rates. Figure 12 presents the influence of electrolyte concentration on the diethylphthalate CML uptake rates.

In contrast to the cholesterol CML and AGE experiments (Figs. 4 and 5), in which the rates in both kinds of experiments were comparable and in good agreement with the interfacial barrier model, the diethylphthalate CML and AGE experiments show large differences in several respects. First, the diethylphthalate CML rates are generally much slower than the AGE rates. Secondly, there is an appreciable initial stirring rate effect in the diethylphthalate CML experiments. Finally, the CML matrix volume effects (Fig. 11) are relatively much smaller than those observed with the diethylphthalate AGE experiments and the cholesterol CML and AGE experiments. All of these findings dictate, that in the diethylphthalate CML experiments, the interfacial barrier is not, or at least not by itself, rate determining.

The CML data in Figs. 11 and 12 have been further theoretically treated employing a matrix-bulk diffusion model developed in these laboratories (3) using the mixture relationships (1, 2) that assume rapid equilibrium between the oil droplets and the gel matrix. The comparison of the experimental data with this theory has so far not been very satisfactory. Consequently, a model in-

Figure 13—Comparison of experimental ^{14}C -labeled octanol uptakes (AGE technique) with theoretically computed values (interfacial barrier model) as a function of aggregate weights. C_a is counts/min./ml. of the solute in water remaining versus time in minutes. One hundred milliliters of ^{14}C -1-octanol solution in water was added to: ○, 0.75 g. (a); □, 1.5 g. volving the simultaneous consideration of (a) the aqueous diffusion layer, (b) bulk gelatin-matrix diffusional parameters, and (c) the interfacial transport barrier of the oil droplets is being developed (9).

Transport Studies with Other Solutes Employing the AGE Technique—Uptake studies with ^{14}C -1-octanol and ^{14}C -4-progesterone

are shown in Figs. 13 and 14, respectively. These experiments with octanol (Fig. 13) compare very well with the theoretically computed values using the primary droplet size distribution (6), independently determined partition coefficient, and a P value of $1 \times 10^{-4} \text{ cm./sec.}$ Figure 14 compares the experimental ^{14}C -4-progesterone uptake rates from polysorbate 80 solutions¹² by the aggregates with theoretically computed values employing the same primary droplet size distribution (6), the partition coefficients, and a P value of $1.0 \times 10^{-5} \text{ cm./sec.}$ The ^{14}C -labeled progesterone results which show good agreement with the theoretical calculations indicate that the polysorbate 80 concentration effect is primarily a partition coefficient effect rather than a permeability coefficient effect. More work is underway to distinguish whether the free solute, the micelle-solubilized solute, or both are involved in the interfacial event.

DISCUSSION

These techniques and their general applicability to various solute transport situations should be uniquely helpful in many biological and pharmaceutical problems. One aspect of the studies underway in these laboratories is aimed at the molecular mechanistic understanding of transport factors at biological membranes and tissues.

Sedimentation Kinetics of Flocculated Suspensions I: Initial Sedimentation Region

J. THURØ CARSTENSEN* and KENNETH S. E. SU

Abstract □ Depending on the concentration of a suspension, it will exhibit one of three sedimentation patterns pertaining to low, intermediate, and high concentrations of solids, respectively. Of these, only the dilute region has been thoroughly investigated in the past from a theoretical and experimental standpoint. Pharmaceutical suspensions are mostly of the intermediate type. It is shown here that if the models by Kynch, Michaels, and Bolger pertain, and if the sedimented cake experiences an exponential compaction from the onset, experimental data are consistent with theory and lead to the relation: $x = x_0 \exp[-kt] + C \cdot [1 - \exp(-kt)] \cdot \exp[-\omega t]$, where k is a sedimentation rate constant pertaining to a constant density plug, and ω is a sedimentation rate constant pertaining to the cake. It has also been found that, empirically, the sedimentation heights in the initial stage may be presented by the relation: $[x_0^2 - x^2] = \beta t$, where x denotes height, and t time.

Keyphrases □ Sedimentation kinetics—flocculated suspensions □ Kinetic equations—suspension sedimentation □ Suspensions, flocculated—sedimentation cakes □ Viscosity effect—suspension cake concentrations

Stokes's law has been known for over a century (1) but, nevertheless, as pointed out by Kynch (2), a satisfactory theory of sedimentation of multiparticle, coarse suspensions has never been put forth. Although it might appear that sedimentation should follow Stokes's law, Higuchi (3) and Hiestand (4) have shown that both in peptized and flocculated systems such a simple point of view is in agreement with neither theory nor fact. In most of the investigations reported in the past, attempts have been made to modify Stokes's law in some way (5–9) to account for sedimentation behaviors. The more dilute a suspension is, the more closely should the fall of each particle or floc adhere to Stokes's law. Pharmaceutical suspensions are, however, rarely very dilute, and their behavior would not be expected to fall in this category.

Michaels and Bolger (10) have reported a linear pattern for sedimentation rates for dilute suspensions ($<1\%$). These authors, as well as Haines and Martin (7), point to the fact that very concentrated suspensions follow yet another pattern, a fact that will not be a point of discussion here but will be reserved for a subsequent study (11). Suspensions of "intermediate" concentration, however, have a downward curvature, *i.e.*, the sedimentation boundary moves downward with greater and greater velocity until a certain critical height, H_0 , is reached, at which time (t_0) the rate decreases abruptly.

Examples of this pattern may be found described occasionally in pharmaceutical literature, the work by Benedict *et al.* (12) being an example. Pharmaceutical suspensions are mostly of the intermediate type. They, also, are of the floc-aggregate type described by Michaels and Bolger (10), and the considerations in the following apply to this type system.

Robinson (8) considered the sediment to be of uniformly increasing concentration during the descent of

the boundary; Ward and Kammermeyer (9) showed that the ensuing equations apply only to special systems. Michaels and Bolger (10) and Gaudin and Fuerstenau (13, 14) have, furthermore, demonstrated that the density of the sediment remains constant at and for some (time-dependent) distance below the boundary, with a cake of higher density building up at the bottom, and that, therefore, the system is uniform at time zero only. The terms cake and sediment will be used for these two phases in the following. These views correlate with the simplest of the models proposed by Kynch (2).

From a pharmaceutical point of view, it is important to determine the pattern (and predict ultimate heights) of suspension sedimentation. It is one of the objectives of this communication to establish graphical means of describing the descent of the sedimentation boundary in the initial stage, *i.e.*, prior to the critical height, H_0 . Another objective is to attempt to correlate the initial sedimentation pattern with existing views on the sedimentation process and arrive at a general equation for the initial sedimentation of flocculated suspensions in the intermediate concentration range.

EXPERIMENTAL

The system used here is the same as that employed by Michaels and Bolger (10) except that concentrations are higher. At higher concentrations, air entrapment might be a source of variation, and an apparatus such as shown in Fig. 1 was used. Previous investigators of dilute suspensions (8) have pointed out that initial turbulence was a source of variation, without spelling out the extent of this variation. The method of providing a uniform starting suspension used here was the same as that employed by Michaels and Bolger (10) (turning the tube end-over-end 10 times). This, of course, causes initial turbulence; the extent to which this affected results was gauged by performing each experiment at least three times.

The size of aggregates is a dynamic property and forming the aggregate under high shear (Waring blender) will not necessarily give a representative floc-aggregate (10) in the sense that the size will subsequently remain constant during settling. Some experiments were, therefore, conducted by allowing a mildly agitated suspension to equilibrate. The sedimentation experiment was repeated until the curves were reproducible. This appeared to require about 24 hr. Reproducible curves all show the convexity noted in the top curve of Fig. 2. Where suspensions were made in a blender, they were also checked on successive days until the sedimentation rates had changed to a constant value.

The general procedure used, then, was as follows: 25 g. of colloidal kaolin NF¹ was rinsed with 500 ml. of water which had previously been distilled over potassium permanganate. The volume was then adjusted to 500 ml. and the suspension transferred to a tube of the type shown in Fig. 1. The suspension was thoroughly deaerated by applying aspirator vacuum to one of the outlets of the two-way stopcock. The tube was occasionally turned end-over-end, and finally after no more visible escape of air, the tube was turned end-over-end 10 times, then opened to the atmosphere and placed vertically; the movement of the interface was followed by use of a high precision cathetometer² and an electric timer. After 24 hr., the

² Gaertner Scientific Corp., Chicago, Ill.

Figure 1—Apparatus set-up for sedimentation studies.

tube was again evacuated, turned end-over-end 10 times, opened to the atmosphere, and the procedure carried out again. This was then repeated until three successive, reproducible curves were obtained.

Part of the supernatant was then replaced by an equal volume of glycerin and the procedure repeated. Data were obtained at four glycerin concentrations; at each point where supernatant was replaced by glycerin, the viscosity of the supernatant was checked by means of an Ostwald-Fenske viscometer. All experiments were carried out in a constant-temperature room ($25 \pm 0.3^\circ$). In one set of experiments, lower (constant) temperatures were obtained by circulating constant temperature water through the jacket of the tube. It should be noted that the apparatus cannot be insulated and that good temperature control throughout the length of the tube is only possible at temperatures less than 5° above or below the temperature of the surrounding area.

Figure 2—Sedimentation curves in water as a function of time of a suspension made at low shear. Triangles and small circles by the upper curve are points from different runs.

Figure 3—Sedimentation curves in 10% v/v glycerin in water at various temperatures. The temperature was varied from experiment to experiment as a means of varying the viscosity.

A note on some visual manifestations may be in order here. The interface is well defined and horizontal during the free-fall period. When the point of transition into the second, slower phase of the sedimentation is approached, a fairly heavy concentration of fine particles appears above the interface for a short while. At the critical time t_0 , which is reproducible to within 5%, the surface suddenly becomes ragged, and at that particular time the second phase starts. The patterns associated with the second phase are the subject of a separately reported study (11). A set of runs was performed at 7, 9, and 11 % by weight of kaolin in water as well.

RESULTS AND DISCUSSION

All of the tested systems showed convex curvature in the initial phase, such as shown in Figs. 2 and 3. This evidently differs from the linearity exhibited by more dilute systems.

If the sedimentation patterns found here for flocculated suspensions in the intermediate concentration range are analogous to those suggested for dilute systems by Kynch (2), Michaels and Bolger (10), and Gaudin and Fuerstenau (13–15), then, at time t , there will be a -centimeters of suspension containing the initial volume fraction ϕ_0 of solids, and b -centimeters of suspension containing the volume fraction in the cake (ϕ). The height of the sediment will be $x = a + b$. As time progresses, a will diminish at the expense of b . The a -values deduced from the data by Michaels and Bolger (Fig. 6, Reference 10) are reproduced in Fig. 4, and it is seen that an equation of the form $a = x_0 \exp [-kt]$ is a good fit. The decrease in a may, therefore, be considered to be of the form:

$$a = x_0 \exp [-kt] \quad (\text{Eq. 1})$$

Figure 4—The graph shows the result of logarithmic treatment of data reported by Michaels and Bolger (10). If the logarithm of the length of the constant-density plug is plotted as a function of time, then a straight line results, as shown in the plotting used here. The data refer to a 1.9% calcium oxide suspension.

Figure 5—Sedimentation data from a 7% by weight kaolin suspension plotted according to Eq. 7, using three values of k . Key: Curve A, $k = 0.005 \text{ min}^{-1}$; Curve B, $k = 0.01 \text{ min}^{-1}$; Curve C, $k = 0.025 \text{ min}^{-1}$. Temperature: 28° .

To describe the time dependence of x , it is necessary to know how b changes with time. It has been shown (11, 16) that the cake (in the final phase) experiences an exponential decay, so $db/dt = -\omega \cdot b$. In the initial phase, it also experiences a build-up from the temporal contribution of the sediment. If the cross-sectional area is denoted Q , then the amount of solids in the cake at time t is $b \cdot Q \cdot \phi$; the amount of solids in the suspension above the cake is $Q \cdot a \cdot \phi_0$ (since it contains the initial volume fraction of solids). The original amount of solids was $x_0 \cdot Q \cdot \phi_0$, so material balance dictates that $Q \cdot a \cdot \phi_0 + b \cdot Q \cdot \phi = x_0 \cdot Q \cdot \phi_0$, or $a \cdot \phi_0 + b \cdot \phi = x_0 \cdot \phi_0$. This may be rewritten:

$$\phi = \frac{[x_0 - a] \cdot \phi_0}{b} \quad (\text{Eq. 2})$$

Figure 6—Sedimentation data from 5% kaolin suspensions in aqueous glycerin vehicles, plotted according to Eq. 7. Curve notations are shown in Table I, indicating the employed k -values and the viscosity corresponding to each line.

Table I— k - and ω -Values at Various Viscosities

Curve in Fig. 6	Viscosity, cps.	Rate Constant k , min^{-1} , $\pm 10^{-3}$	Compaction Constant ω , min^{-1} , $\pm 10^{-4}$
A	0.87	0.035	0.0055
B	0.96	0.032	0.0049
C	1.12	0.028	0.0046
D	1.19	0.024	0.0046
E	1.35	0.023	0.0039
F	1.40	0.022	0.0032
	2.40	0.013	0.0023

The total change of b with time, then, is:

$$\frac{db}{dt} = \frac{k \cdot \phi_0 \cdot a}{\phi} - \omega \cdot b \quad (\text{Eq. 3})$$

Inserting Eqs. 1 and 2 into Eq. 3 yields:

$$\frac{db}{dt} = k \cdot \frac{\exp[-kt]}{1 - \exp[-kt]} \cdot b - \omega \cdot b \quad (\text{Eq. 4})$$

which has the solution:

$$b = C \cdot \{1 - \exp[-kt]\} \cdot \exp[-\omega t] \quad (\text{Eq. 5})$$

The expression for $x = a + b$, then is:

$$x = x_0 \exp[-kt] + C \cdot \{1 - \exp[-kt]\} \cdot \exp[-\omega t] \quad (\text{Eq. 6})$$

For the purpose of plotting, this is rearranged:

$$\log \left(\frac{x - x_0 \exp[-kt]}{1 - \exp[-kt]} \right) = -\frac{\omega}{2.3} \cdot t + \log C \quad (\text{Eq. 7})$$

The data may now be plotted using estimates of k ,³ and by applying successive values of k , a best k -value (i.e., the k -value that imparts linearity⁴ to the data when treated according to Eq. 7) can be arrived at. An example of this is shown in Fig. 5. If done manually, two or three k -values are arrived at (e.g., 0.034, 0.035, and 0.036 min^{-1}) which produce lines without apparent curvature. The value giving the best statistical fit (17, 18) is then chosen. With the aid of a computer, the iteration procedure can be accomplished rapidly. Figure 6 and Table I show data at various viscosities plotted according to Eq. 7. With the proper k -value, linearity prevails to within 15 cm. of the critical height.

The dependency of k on the viscosity is of interest, and Fig. 7 shows that the logarithm of the rate constant is linearly related to the logarithm of the viscosity. The slope is reasonably close to minus unity, so that k is inversely proportional to viscosity. This type behavior might suggest that Stokes's law, with some modification, applies, since the Stokes velocity is also inversely proportional to viscosity. In a suspension, the forces involved are both of van der Waals and electrical nature (15, 19–23). In causing flocculation they might be playing a part directly in the sedimentation process, i.e., the rate constant might be associated with a flocculation rate. By such a visualization, the initial perturbation causes an equilibrium floc, A_j (containing on the average j single particles) to be broken up into smaller flocs, A_i . This, of course, is a highly simplified picture, because $A_j \rightarrow A_i$ could not be a single-step process. Furthermore, both i and j would present averages of a population of numbers.

It would also have to be assumed that A_j , once formed, would appear immediately in the cake; in spite of these shortcomings, the viewpoint explains the inverse relationship between rate constant and viscosity, and can not be eliminated as a possibility. W. Higuchi *et al.* (24, 25) have shown that k_{ij} approaches some factor times k_{11} , the rate constant for combination of single particles, and have also shown that $k_{11} = 8k_0T/3\eta$. It is not possible to test this hypothesis on more concentrated systems with the data presented here;

³ First estimates of k (and ω) can be obtained from Eq. 6 by feathering technique if k and ω are not of the same order of magnitude.

⁴ The value giving the best statistical fit (17, 18), i.e., the one producing the least residual sum of squares.

Figure 7—A plot of the logarithm of the rate constant k versus the logarithm of the viscosity. The drawn line has a slope of minus unity: k is in units min.^{-1} and viscosity is in cps.

to such an end it would be necessary to perform experiments where the initial perturbation (deflocculation) could be varied in a quantitative way. Experimental procedures in previous publications as well as this work have simply been designed to achieve a reproducible perturbation, so that data are comparable; it may be, for the reasons quoted, that data may not be comparable from author to author.

The values of ω are obtained from the slopes in Fig. 6 and are listed in Table I. The values are plotted as a function of viscosity in Fig. 8. The general range of the ω -values is in good agreement with data on cake contraction reported by Carstensen and Su (11) who found ω -values in the range of $0.2\text{--}0.4 \text{ hr.}^{-1}$ (i.e., $0.003\text{--}0.007 \text{ min.}^{-1}$). It would appear from Fig. 8 that ω is inversely proportional to the viscosity.

At higher concentrations the critical height, H_0 , increases and the curves show less distinct breaks. Evaluation of data by Eq. 7 becomes less exacting, and k values are at best $\pm 20\%$. The k -values seem to taper off at a value of 0.01 hr.^{-1} as shown in Fig. 9, but ω -values decrease with increasing concentration.

As a last comment on the treatment of the preceding, attention should be called to the fact that an obvious approximation is made in assuming the cake to be of uniform concentration along the entire length b . However, attempts to present ϕ as a function of x lead to forms of Eq. 3 that cannot be solved analytically. That the approximation is not unrealistic is apparent both from the X-ray data by Gaudin and Fuerstenau (13, 14) and by the linearity which can be achieved by inserting proper k -values in Eq. 7. On the other hand, deviation from linearity close to the critical height undoubtedly reflects the effect of the approximation.

It is often convenient, in the laboratory, to have a rapid method available for plotting; the treatment just outlined, clearly, is not rapid. For routine plotting, the initial convex portion of the curve may be approximated by a parabola, i.e., $x_0^2 - x^2 = \beta t$, where x_0 is the initial height. Data are plotted in this fashion in Figs. 10 and 11, and, with exception of the initial turbulent period (8), the data fit such a relationship well. It should be noted that this means of presentation is purely empirical, and that the comments to follow may not have general applicability but may merely apply to the kaolin-glycerin-water system. The value of this type of practical approach

Figure 8—A plot of the compaction-rate constant, ω , versus reciprocal viscosity.

Figure 9—Sedimentation data from 7, 9, and 11% kaolin suspensions in water, plotted according to Eq. 7, all using a k -estimate of 0.01 min.^{-1} .

is that it allows rapid extrapolation and implies at what time the critical height is being approached.

Analogies have been made in the past (26) between the fall of the boundary to the flow of liquid through a porous plug in an infinitely long medium. By applying the Poiseuille equation⁵ such a view would require that $V/t = \pi Pr^4/8L\eta$, where V/t is volume flow per unit time, P is pressure head, r is a capillary radius parameter, and L is the length of the plug. Since each milliliter flowing through the plug is associated with a height decrease of $1/\pi R^2$, the velocity of the interface would be: $V/(t\pi R^2) = (Pr^4)/(8L\eta R^2) = \beta/(2L) = (dx)/(dt)$, where R is the radius of the tube and the sedimentation constant $\beta = Pr^4/4\eta R^2$. If L approximately equals x , a formal integration would yield $x^2 - x_0^2 = -\beta t$, assuming the pressure head to be constant. This is not theoretically justifiable. Although, as required by the treatment, the sedimentation constant appears to be inversely proportional to the viscosity, it should also be inversely proportional to R^2 ; data reported elsewhere (11) show this not to be the case. The squared-heights fitting is, therefore, only empirical.

Figure 10—Squared-heights curves for 5% kaolin suspensions in 10% v/v glycerin in water at three temperatures.

⁵ Use of the Kozeny-Carmen equation (27, 28) does not change the consequences of the arguments outlined.

Figure 11—Squared-heights curves for 5% kaolin suspensions in water and 5% v/v glycerin in water.

SUMMARY

By assuming the sedimentation process to consist of the descent of a constant density plug and simultaneous build-up of a higher density cake, it has been shown that sedimentation data are consistent with theory, if it is assumed that the exponential contraction of the cake is initiated at zero time. The point in time, t_0 , the critical time, where the boundary of the sediment and the cake coincide, denotes the end of the initial stage of sedimentation.

Empirically, sedimentation data in the initial stage are amenable to plotting by graphing the square of the height as a function of time. The slope of these lines appears to be proportional to the ratio of density difference to viscosity.

NOMENCLATURE

- a = length of sediment (cm.) (constant-density plug).
- b = height of cake (cm.).
- C = preexponential factor for cake contraction (cm.).
- H_0 = critical height (cm.) at which point the first phase of sedimentation ends and the second phase starts.
- k = rate constant for sediment (min.^{-1}).
- L = length of constant-density plug falling through infinitely long column of liquid (cm.).
- P = pressure head (dynes/cm.²).
- R = radius of tube (cm.).
- t_0 = time at which H_0 occurs; critical time (min.).
- V = volume (cm.³).
- x = height of sediment interface above bottom of tube (cm.).
- x_0 = initial height (cm.).
- β = sedimentation constant (cm.²/min.).
- η = viscosity, centipoise or poise, as indicated.
- ϕ = volume fraction of suspended matter in cake.
- ϕ_0 = volume fraction of suspended matter in sediment.

ω = compaction rate constant (min.^{-1}), i.e., exponential decay constant for cake height.

Sedimentation Kinetics of Flocculated Suspensions II: Sedimentation below the Critical Height

J. THURØ CARSTENSEN* and KENNETH S. E. SU

Abstract □ Aside from the phenomenological equation by Egolf and McCabe and by Robinson, no attempts have appeared in literature in the past to quantitate terminal sedimentation characteristics of flocculated suspensions. The physical factors involved are suggested here, taking into account electrical effects and geometric factors contributing to friction. The equation of settling emerges as a linear combination of exponential decays—viz., $[x - H_u] = A_1 e^{-\omega_1 \tau} + A_2 e^{-\omega_2 \tau}$, where x is the height of the sediment at time τ , H_u is the final height, and A and ω are constants. From the data it would appear that the friction, B , exerted is both viscosity (η) and dimension (R) dependent and of the form $B(\eta, R) = \Gamma \cdot e^{\xi \eta} e^{\mu R}$, where μ , ξ , and Γ are system-dependent constants.

Keyphrases □ Sedimentation kinetics—flocculated suspensions, equations □ Kinetics, sedimentation, flocculated suspensions—critical height, equations derived □ Suspensions, flocculated—sedimentation kinetics, equations

Sedimentation of flocculated suspensions has been the subject of several publications in the past (1–12); such systems have been shown (1, 7, 9–13) to sediment first at a rapid rate, primarily governed by gravitational and frictional forces. At a particular, well-reproducible point, the rate changes abruptly, and further sedimentation appears to be governed by forces over and above those just mentioned. With a few exceptions (1, 3, 13), all of the cited references attempt to modify Stokes's law to explain experimental data. In no case [except indirectly by Robinson (7)] has cognizance been taken of interparticle forces in relation to sedimentation rates.¹

The treatment to follow deals with the second phase of sedimentation of flocculated suspensions of intermediate concentration, and attempts to account for the effect of such forces.

As shall be shown the final sedimentation pattern follows a linear combination of exponential decays. No previous treatment has led to such a pattern for the second stage of sedimentation or to the type plot encountered in concentrated suspensions, although the data in several examples in literature (2, 6, 7, 9) imply such a relationship.

THEORETICAL

London-van der Waals forces (14, 15) are responsible for the stability of the flocculated state, and in general, at small separations, the potential energy between two particles will be negative. At intermediate distances (16–19), however, the potential energy becomes positive because of the repulsion of double layers. Since the true charge of the particle surface cannot be determined by experiment, quantitation of such forces is difficult, and the upper limit for distances over which these forces will be effective cannot be stated *a priori*.

¹ A sizable amount of information regarding interparticle forces has been obtained by rheological approaches, notably the studies by Higuchi and Stehle (25), Gillespie (26, 27), Goodeve (28), and Vand (19).

Since the authors are dealing with the phase of sedimentation which occurs at a critical height, H_0 , it may be advantageous, at the onset, to use a coordinate system slightly different from the one customarily used. Usually the position of the boundary is measured from the bottom of the tube and denoted x ; time, t , is measured from the time sedimentation starts. Here, if the height H_0 occurs at time t_0 , the position and time axes are chosen with the points t_0 and H_0 as the origin. Distance is now denoted y ($y = H_0 - x$), i.e., positive in downward direction and positive for the times τ ($\tau = t - t_0$) in question. It shall be assumed that the center of gravity of the sediment is at one-half the height of the boundary of the sediment, i.e., its position is $y = H_0/2$ originally, and at time τ it is $H_0 - x + x/2 = H_0 - x/2 = y$.

The forces exerted on the sediment are gravitational forces, frictional and reactional forces, and forces that are electrical in nature. The gravitational force is in the y -direction and of magnitude $M[1 - (\rho_0/\rho)]g$, where ρ and ρ_0 are the densities of solid and liquid, M is the mass of the sediment, and g is the gravitational acceleration. The frictional and reactional forces are in a direction opposite to y and must be related to viscosity and to wall and bottom effects, i.e., to the geometry of the vessel. The functional relationship is not equated to $6\pi\eta r$, nor is an attempt made at this particular point in the development to formulate the diameter dependency, but the force is described as a velocity-dependent $[-B(\eta, R)dy/d\tau]$ and a velocity-independent $[-\psi(R)]$ component. The electrical force is assumed to be a repulsion (i.e., in a direction opposite to the direction of the y -axis) and with regard to magnitude it is assumed to increase the closer the floc-aggregates are to one another; they are related to distance between flocs which in turn is related to the liquid volume of the cake, i.e., $\pi R^2(x) = 4\pi r^3 n/3$, where R is the radius of the tube, and where n is the number and r the "radius" of the floc-aggregates. These forces are assumed to be of the form θy . The sum of all the forces then equals the mass of the sediment times its acceleration, i.e.,

$$M[1 - \rho_0/\rho]g - B(\eta, R) \frac{dy}{d\tau} - \psi(R) - \theta y = M \frac{d^2 y}{d\tau^2} \quad (\text{Eq. 1})$$

This may be rewritten

$$\frac{d^2 y}{d\tau^2} + \frac{B(\eta, R)}{M} \frac{dy}{d\tau} + \frac{\theta}{M} y = [1 - \rho_0/\rho]g - \frac{\psi(R)}{M} \quad (\text{Eq. 2})$$

It is apparent from inspection of Eqs. 1 and 2 that

$$y^* = \frac{M[1 - \rho_0/\rho]g - \psi(R)}{\theta}$$

is a particular solution to the differential equation. The remaining solutions are obtained by inserting an expected solution of the form $y = -A \cdot e^{-\omega \tau}$ into the homogeneous equation corresponding to Eq. 2. This yields:

$$-A \cdot e^{-\omega \tau} \left[\omega^2 - \frac{B(\eta, R)}{M} \omega + \frac{\theta}{M} \right] = 0 \quad (\text{Eq. 3})$$

When the expression in brackets is equated to zero, Eq. 3 is satisfied; the characteristic roots are:

$$\omega = \frac{B(\eta, R)}{2M} \pm \sqrt{\left[\frac{B(\eta, R)}{2M} \right]^2 - \frac{\theta}{M}} \quad (\text{Eq. 4})$$

The roots shown in Eq. 4 may be simplified if $B(\eta, R)/M \gg \theta/B(\eta, R)$ in which case they are:

$$\omega_1 = \frac{B(\eta, R)}{M} \quad (\text{Eq. 5})$$

Figure 1—Graph showing the method for determining the critical height (H_0) in a 5.54-cm. i.d. tube, 10% v/v glycerin and 11% w/v kaolin, and the critical time (t_0).

and

$$\omega_2 = \frac{\theta}{B(\eta, R)} \quad (\text{Eq. 6})$$

The complete solution, in terms of y , is:

$$y = \frac{M[1 - \rho_0/\rho]g - \psi(R)}{\theta} - A_1' \cdot e^{-\omega_1\tau} - A_2' \cdot e^{-\omega_2\tau} \quad (\text{Eq. 7})$$

where the exponents in Eq. 7 have the meaning denoted in Eqs. 5 and 6. It is noted that $y^* = M[1 - \rho_0/\rho]g - \psi(R)/\theta$ corresponds to y_∞ by virtue of Eq. 7, and, therefore, is related to H_u , the ultimate height, by the relation $y_\infty = y^* = H_0 - H_u/2$. Inserting this into Eq. 7 and rearranging, yields:

$$x - H_u = A_1 e^{-\omega_1\tau} + A_2 e^{-\omega_2\tau} \quad (\text{Eq. 8})$$

where $A_1 = 2A_1'$ and $A_2 = 2A_2'$.

It is apparent from Eq. 8 that the terminal sedimentation pattern should be characterized by a linear combination of two exponential decays. By the assumption leading to Eqs. 5 and 6, $\omega_1 \gg \omega_2$ and the first term on the right hand side of Eq. 8 should be predominant at small values of τ and the last term should predominate at high values of τ .

EXPERIMENTAL

A previously described setup and methodology (1) were used: tubes 1.25 m. high, and of inside diameter 2.46, 2.72, 4.60, or 5.54 cm. were used as sedimentation vessels. The exact inside dimension was determined for each tube by introducing known amounts of water and checking heights with a precision cathetometer. The system studied was an 11% weight per volume kaolin² suspension

Figure 3—Sedimentation pattern in a tube of 4.60-cm. i.d. of an 11% w/v suspension of kaolin in 5% v/v glycerin solution at heights below the critical height, H_0 . The left ordinate is adjusted for final height, H_u ; the right ordinate axis shows the actual heights (x). The curve shown in full is the theoretical curve; $10 \cdot e^{-0.31\tau} + 20 \cdot e^{-0.0233\tau}$. The points shown are experimental points.

in water, 5% v/v glycerin, or 10% v/v glycerin. The suspensions were made in a Waring blender and transferred to the sedimentation tubes. The tops of the tubes were connected by means of a 24/40 ground joint to a stopcock, and after transfer, the stopcock was attached to the tube, and the suspension thoroughly deaerated by means of aspirator vacuum. Once deaerated, the tubes were turned end-over-end 10 times, the stopcock opened, the tube placed vertically and securely on a stand, and the position of the sedimentation boundary noted every 5 min.; timing intervals were made shorter when the critical height, H_0 , was approached. This height, as well as the critical time, t_0 , was then determined by graphical interpolation as shown in Fig. 1. Following this the position of the boundary was noted every 5 min. for 0.5 hr., and then hourly for 50 hr. (except for necessary schedule interruptions). Subsequently, the sedimentation height was recorded twice daily until a point in time had been reached where less than 0.2 mm. change occurred in a 24-hr. period; this usually required 7–13 days. Each set was obtained in duplicate. All sedimentation heights were determined by means of a cathetometer, and readings were accurate to 0.1 mm. The tubes used were not jacketed, but the experiments were carried out in a constant-temperature room at $25 \pm 0.6^\circ$. The viscosity of the super-

Figure 4—Decay pattern of 11% w/v kaolin suspension in 5% v/v glycerin solution at high time values where ω_2 and A_2 predominate. Test was performed in a tube of 4.60-cm. i.d. The curves are separated by 0.1 and 0.2 logarithmic units as indicated. The plots demonstrate estimation of final sedimentation height prior to the time when it is reached. Key: \circ , $H_u = 27.3$ cm. (scale minus 0.2); \bullet , $H_u = 27.8$ cm. (scale minus 0.1), and \ominus , $H_u = 28.4$ cm.

natant was checked after each experiment by means of an Ostwald-Fenske viscometer.

RESULTS

A typical sedimentation curve is shown in Fig. 2; the shape is of the same nature as the one described elsewhere (1); the scale is selected so as to show both the initial and the beginning of the second phases of sedimentation, and the characteristic point separating the two curves. Even with the scale used it is apparent that some slight curvature exists in the second phase. In proper scale, all of the sedimentation curves have the shape shown in Fig. 3 when x is plotted as a function of τ .

Once the ultimate height, H_u , is attained, a first estimate of the parameters ω_2 and A_2 can be made, by using values of τ higher than 15 hr. In this case (as seen in Table I) $A_2e^{-\omega_2\tau} \gg A_1e^{-\omega_1\tau}$ and Eq. 8 becomes $[x - H_u] = A_2e^{-\omega_2\tau}$. The logarithmic form of this is

$$\log [x - H_u] = -\frac{\omega_2}{2.3} \tau + \log A_2 \quad (\tau > 15 \text{ hr.}) \quad (\text{Eq. 9})$$

An example of this is shown in Table II and Fig. 4. It should be noted that the final height may be estimated well in advance of its actual occurrence from linearity as opposed to curvature of this type plot. Estimated values were always within 0.5 mm. of the actual, experimentally determined, final height.

By means of the estimates of A_2 and ω_2 the value of $[x - H_u] - A_2e^{-\omega_2\tau}$ can be determined at values of τ less than 15 hr., so the two

other parameters may be estimated by rearrangement of Eq. 8:

$$\log \{[x - H_u] - A_2e^{-\omega_2\tau}\} = -\frac{\omega_1}{2.3} \tau + \log A_1 \quad (\text{Eq. 10})$$

An example of this is shown in Table III and Fig. 5. By this plotting a better estimate of A_2 is obtained as shown in Fig. 5. The difference between this estimate and the original estimate was always within error of the graphical estimate in Fig. 4. With the estimates of A_1 , ω_1 , A_2 , and ω_2 , statistically best values may be obtained by computer, using iteration techniques (20-22). It should be noted, however, that graphical and manually generated estimates are quite good. Construction of the theoretical curve from the parameter estimates arrived at in Tables II and III and Figs. 4 and 5 is shown in Table I, and the curve drawn in full in Fig. 3 is taken from this table. It is quite obvious from the figure that the data fit the curve well. Averages of duplicate determinations of A_1 , ω_1 , A_2 , and ω_2 from all the sedimentation tests are listed in Table IV.

DISCUSSION

In not too concentrated suspensions the sedimentation pattern is characterized first by a settling pattern which is linear (9) or parabolic with time (1) caused, respectively, by free fall or constant-density plug descent (1, 9). Attempts to describe mathematically the phase that follows the initial settling have been made by Robinson (7) and by Egolf and McCabe (13). Robinson found the dependency of the initial settling rates on concentration and then

^a Eleven percent w/v of kaolin in 5% v/v glycerin in a tube of 4.60-cm. i.d.

applied these findings to experimental data; since in that context, the sedimentation volume represents a suspension of time-dependent concentration (disregarding the supernatant) the settling rates should constantly change in a predictable fashion.

Egolf and McCabe suggested a phenomenological log-log relationship between absolute height and time for the phase following the initial settling. Ward and Kammermeyer (8) tested both models in different type systems (carbonates, silica, and magnesium oxide), and found fair agreement with regard to the shape of the curves, but large (20–40%) quantitative deviations in the second phase of sedimentation. These authors concluded that the application of the approaches of Robinson (7) and Egolf and McCabe (13) is limited to prediction of settling of only such systems that are closely related to the ones used to develop the appropriate equations and factors. Reflecting on the later findings that the initial settling is in the form of a constant-density plug (1, 9–11), it would appear that it may be erroneous to assume that the sediment may be viewed as a uniform suspension of constantly changing concentration; this may be the source of the cited quantitative deviations.

The approach taken here is to account for the forces involved (even though all of them cannot be expressed explicitly *a priori*)

Figure 5—Decay pattern of 11% w/v kaolin suspension in 5% v/v glycerin solution at low time values where ω_1 and A_1 predominate. Data pertain to 4.60-cm. i.d. tube. The plots demonstrate refinement of the estimate of A_2 . Key: A, $A_2 = 19.2$ cm.; B, $A_2 = 20.0$ cm.; and C, $A_2 = 20.5$ cm.

and then to try to gain insight into them, quantitatively and qualitatively, by way of experimental results. Experimental variation limits the number of conclusions that may be drawn from the A_1 - and ω_1 -values. It will be noted from Table IV that the coefficient of variation for these two parameters is 5%; this prohibits any conclusions that may be drawn regarding the viscosity dependency of ω_1 (and, therefore, also of $B(\eta, R)$). The data would imply that either ω_1 does not vary with changing R , or, possibly, it decreases with increasing R .

On the other hand, ω_2 is quite reproducible ($\pm 1\%$); it appears from the results in Table IV that $\omega_2 \{ \omega_2 = \theta \cdot [B(\eta, R)]^{-1} \}$ decreases with both increasing R - and η -values, and suggest the radial dependence of $B(\eta, R)$ to be of the form $e^{\mu R}$; in this case Eq. 6 takes the form:

$$\log \omega_2 = \log \theta - \log C^* - \frac{\mu}{2.3} R \quad (\text{Eq. 11})$$

where C^* is a constant. Figure 6 shows the data plotted in this fashion, and the plots are fairly linear; the slopes (calculated by least-squares fit of the data in Table IV) are shown in Table V, and are, as seen, fairly close to one another.

The data in Table IV would also suggest the dependence of ω_2 on viscosity to be an exponential decay; if this is the case, then $B(\eta, R) = \Gamma \cdot e^{\mu R} \xi \eta$; inserting this in Eq. 6 yields:

$$\log \omega_2 = \log \frac{\theta}{\Gamma} - \frac{\mu}{2.3} R - \frac{\xi}{2.3} \eta \quad (\text{Eq. 12})$$

If $\log \omega_2$ is plotted as a function of viscosity, four straight lines should result, one for each tube. The data plotted in this fashion are shown in Fig. 7. It is seen that fairly good linearity is exhibited, and the values of the slopes as shown in Table V are close to each other. Least-squares values of the intercepts from Figs. 6 and 7 are also shown in this table. The intercepts in Fig. 6 should be $[2 + \log \theta / \Gamma - (\mu \cdot R / 2.3)]$ and the intercepts in Fig. 7 should be $[2 + \log \theta / \Gamma - (\xi \cdot \eta / 2.3)]$. It is, therefore, possible to get a crude estimate of $\log [\theta / \Gamma]$ by means of the intercept values. Results of this type calculation are shown in Table V and values derived from the

two figures show acceptably good agreement, especially considering that they have been obtained from extrapolated figures (intercepts).

This fact in combination with the linearity of the plots in Figs. 6 and 7, the closeness of the values of the slopes, and the adherence of all the data to an equation of the type of Eq. 8 lends credence to the views presented here.

It should be mentioned, qualitatively, that increasing concentrations tend to decrease (or mask) the values of A_1 , and that this parameter eventually is of such small magnitude that it can no longer be detected within experimental error. In the same vein, H_0 becomes larger with increasing solids content and, eventually, at a critical concentration the initial constant-density plug phase will disappear, and at a second critical concentration, the A_1 -term will disappear. The entire sedimentation pattern will then be a simple logarithmic decay curve. The critical concentration for kaolin in 10% v/v glycerin in a tube of 2.5-cm. i.d. is 8-10 w/v percent. Data of this nature have been reported occasionally in literature in the past, the data by Haines and Martin (6) being a notable example.

The final height, H_u , as reported here, may still be subject to some decrease by consolidation processes such as described by Ratcliff (23, 24). This phase has not been a subject of this investigation.

SUMMARY

The sedimentation of flocculated suspensions takes place in successive stages; the sedimentation phase following the initial phase has been studied and found, based on consideration of the forces involved, to be confined to follow the following equation: $[x - H_u] = A_1 e^{-\omega_1 \tau} + A_2 e^{-\omega_2 \tau}$. Experimental data have supported the presented

concepts and suggest that the frictional term in the equation of motion is of the form $B(\eta, R) = \Gamma \cdot e^{\mu R} e^{\xi \eta}$.

NOMENCLATURE

A, A_1, A_2	
A_1', A_2'	= preexponential factors in descent of sedimentation boundary
$B(\eta, R)$	= viscosity dependent component of frictional force
C^*	= preexponential factor for radial dependence of ω_2
g	= gravitational acceleration
H_0	= critical height
M	= mass of sediment
r	= radius of floc
R	= radius of tube
t	= time measured from start of sedimentation
t_0	= critical time
x	= height of sedimentation boundary above bottom of tube
y	= distance of sedimentation boundary from critical height (= $H_0 - x/2$)
y_{∞}, y^*	= y -value at infinite time (= $H_0 - H_u/2$)
$\psi(R)$	= viscosity independent component of frictional force
ρ_0	= density of fluid
ρ	= density of suspended solid
τ	= time measured from critical time (= $t - t_0$)
μ	= exponential factor to radial dependence of ω_2
Γ	= preexponential factor to radial dependence of ω_2
θ	= dimensional factor in electrical repulsion term
ξ	= exponential factor to viscosity dependence of ω_2
$\omega, \omega_1, \omega_2$	= exponential decay constants in descent of sedimentation boundary

Cholesterol Biosynthesis and Lipid Biochemistry in the Scolex of *Echinococcus granulosus*

GEORGE A. DIGENIS*, RALPH E. THORSON†, and ARPINE KONYALIAN

Abstract □ When live scolices of *Echinococcus granulosus* were incubated with labeled mevalonate *in vitro*, no radioactivity was incorporated into the parasites' cholesterol fraction. However, labeled cholesterol was recovered after a scolices' homogenate was incubated with 4-¹⁴C-cholesteryl acetate. It is suggested that the scolex of *E. granulosus* is unable to biosynthesize cholesterol and that it obtains cholesterol in an esterified form from the host, which is subsequently hydrolyzed within the scolex to free cholesterol. The fatty acid content of *E. granulosus* was examined by gas-liquid chromatography.

Keyphrases □ *Echinococcus granulosus* scolices—cholesterol biosynthesis □ Cholesterol biosynthesis—*E. granulosus* scolices □ Lipid biochemistry—*E. granulosus* scolices □ Hydrolytic activity, *E. granulosus* scolices—4-¹⁴C-cholesteryl acetate □ TLC—separation □ GLC—identity □ Scintillometry—analysis

It is a well-known fact that, in vertebrates, cholesterol is biosynthesized from acetate or mevalonate. In many insects, however, radioactive acetate or mevalonate is not incorporated into cholesterol; some insects do not even synthesize squalene, the noncyclic precursor of sterols (1, 2).

In 1954, Butenandt and Karlson (3) first isolated 25 mg. of ecdysone, the molting hormone, from 500 kg. of silkworm pupae. The compound [shown later to be a steroid (4)] was effective in accelerating molting, even in quantities below 7.5×10^{-8} mcg., when injected into ligated fly abdomens. In 1963, Karlson and Hoffmeister (5) demonstrated the incorporation of radioactivity

from tritium-labeled cholesterol into ecdysone in *Calliphora* larvae, indicating that cholesterol is a precursor to ecdysone. Clark and Bloch (6) showed that 95% of the dietary cholesterol in the beetle *Dermestes vulpinus* could be replaced by β -sitosterol for structural utilization, but 5% of it remained essential for metabolic function; Clayton (7), working with the cockroach *Blattella germanica*, obtained similar results. According to Karlson (8), only a small part of the cholesterol injected into insects was converted to ecdysone; the majority still fulfilled cellular functions. Smissman *et al.* (9) isolated dehydroepiandrosterone, pregnenolone, and progesterone as the products of normal insect metabolism of dietary sterols in the confused flour beetle, *Tribolium confusum*. Horn *et al.* (4) isolated crustecdysone from crayfish, a compound which proved to be both chemically and biologically similar to ecdysone. Carlisle (10) demonstrated the biological activity of extracts from crabs, copepods, and locusts on the immature shore crab *Carcinus maenas*, indicating the presence of a common set of interactive ecdysones in crustaceans and insects.

The hormone that has an effect opposite to that of ecdysone on the molting stages of insects was first isolated from the abdomens of *Cecropia* males by Williams (11). Karlson and Schmialek (12) injected extracts of the excretions of the beetle *Tenebrio molitor* into mature larvae of the same species and noted the retardation of pupation in 88% of the treated larvae. Cholesterol Biosynthesis and Lipid Biochemistry in the Scolex of *Echinococcus granulosus*

GEORGE A. DIGENIS*, RALPH E. THORSON†, and ARPINE KONYALIAN

Abstract □ When live scolices of *Echinococcus granulosus* were incubated with labeled mevalonate *in vitro*, no radioactivity was incorporated into the parasites' cholesterol fraction. However, labeled cholesterol was recovered after a scolices' homogenate was incubated with 4-¹⁴C-cholesteryl acetate. It is suggested that the scolex of *E. granulosus* is unable to biosynthesize cholesterol and that it obtains cholesterol in an esterified form from the host, which is subsequently hydrolyzed within the scolex to free cholesterol. The fatty acid content of *E. granulosus* was examined by gas-liquid chromatography.

Keyphrases □ *Echinococcus granulosus* scolices—cholesterol biosynthesis □ Cholesterol biosynthesis—*E. granulosus* scolices □ Lipid biochemistry—*E. granulosus* scolices □ Hydrolytic activity, *E. granulosus* scolices—4-¹⁴C-cholesteryl acetate □ TLC—separation □ GLC—identity □ Scintillometry—analysis

It is a well-known fact that, in vertebrates, cholesterol is biosynthesized from acetate or mevalonate. In many insects, however, radioactive acetate or mevalonate is not incorporated into cholesterol; some insects do not even synthesize squalene, the noncyclic precursor of sterols (1, 2).

In 1954, Butenandt and Karlson (3) first isolated 25 mg. of ecdysone, the molting hormone, from 500 kg. of silkworm pupae. The compound [shown later to be a steroid (4)] was effective in accelerating molting, even in quantities below 7.5×10^{-8} mcg., when injected into ligated fly abdomens. In 1963, Karlson and Hoffmeister (5) demonstrated the incorporation of radioactivity

from tritium-labeled cholesterol into ecdysone in *Calliphora* larvae, indicating that cholesterol is a precursor to ecdysone. Clark and Bloch (6) showed that 95% of the dietary cholesterol in the beetle *Dermestes vulpinus* could be replaced by β -sitosterol for structural utilization, but 5% of it remained essential for metabolic function; Clayton (7), working with the cockroach *Blattella germanica*, obtained similar results. According to Karlson (8), only a small part of the cholesterol injected into insects was converted to ecdysone; the majority still fulfilled cellular functions. Smissman *et al.* (9) isolated dehydroepiandrosterone, pregnenolone, and progesterone as the products of normal insect metabolism of dietary sterols in the confused flour beetle, *Tribolium confusum*. Horn *et al.* (4) isolated crustecdysone from crayfish, a compound which proved to be both chemically and biologically similar to ecdysone. Carlisle (10) demonstrated the biological activity of extracts from crabs, copepods, and locusts on the immature shore crab *Carcinus maenas*, indicating the presence of a common set of interactive ecdysones in crustaceans and insects.

The hormone that has an effect opposite to that of ecdysone on the molting stages of insects was first isolated from the abdomens of *Cecropia* males by Williams (11). Karlson and Schmialek (12) injected extracts of the excretions of the beetle *Tenebrio molitor* into mature larvae of the same species and noted the retardation of pupation in 88% of the treated larvae. In

1961, Schmialek (13) isolated 60 mg. of an oil from 80 kg. of *Tenebrio feces*, which was identified as farnesol and its oxidation product farnesal. Later it was shown that insects can biosynthesize labeled farnesol and farnesal from tagged mevalonic acid (14). Using the farnesol isolated by Schmialek (13), as well as the commercial compound, Wigglesworth (15) showed that farnesol reproduces all the effects of a juvenile hormone when applied to the surface of the cuticle of the insect *Rhodnius prolixus*. The main effects were retention of larval characters and partial reversal of metamorphosis in the molting adult. Other active compounds also have been isolated from the microsporidian *Tribolium castaneum* (16), various other microorganisms (17), and even from the balsam fir tree (18). It appears from these studies that in insects the pathway of mevalonate is directed toward the synthesis of specific hormones and not cholesterol, whereas in vertebrates part of the mevalonate is incorporated into cholesterol.¹

The work on cholesterol biosynthesis in cestodes is still in its infancy. Frayha (20) observed that 1-¹⁴C-acetate did not incorporate into the cholesterol fraction of *E. granulosus* scolices; but when 26-¹⁴C-cholesterol was fed to mice infected with the parasite, the label did appear in the cholesterol isolated from the scolices. Indeed, Meyer *et al.* (21) reported the *Spirometra mansonoides* lacks the mechanisms required for the synthesis *de novo* of its sterols.²

The authors of this article (23) have recently shown that lipid extracts of *Echinococcus granulosus*, a cestode, contained substances with both stimulatory and depressive effects on the growth of excysted cysticercoids of *Hymenolepis diminuta* in *in vitro* cultures. Since mevalonate has been shown to be a precursor of farnesol and farnesal in insects (14), an attempt was made to correlate the biological activity of the different lipid fractions of *E. granulosus* scolices with their biosynthesis from mevalonate.

MATERIALS AND METHODS

Collection and Preparation of Scolices—The livers and lungs of the sheep and cattle infected with cysts of *E. granulosus* were obtained within 2 hr. of slaughter. The hydatid fluid and scolices³ were collected aseptically from the cysts according to the previously published methods (23) to be used in both the authors' biosynthetic studies and hydrolytic studies.

Biosynthetic Studies—For the biosynthetic studies, the live³ scolices were washed four times with an aqueous buffer solution (pH 7.4) of disodium monohydrogen phosphate and potassium dihydrogen phosphate (25).

The washed scolices were then incubated in a water bath shaker for 5 hr. at 37° with 4 ml. of phosphate buffer (pH 7.0), 1 ml. of anti-

biotic solution,⁴ and 1 ml. of 2-¹⁴C-DL-mevalolactone⁵ (specific activity 3.11×10^5 c.p.m./0.04 μ M/ml.). At the end of the incubation period, 2 ml. of 3 N H₂SO₄ was added to the flask.⁷ The scolices were separated by low-speed centrifugation, washed several times with distilled water, and then transferred to a 125-ml. conical flask. A quantitative sample taken from a combination of the incubation supernatant fluid and the scolices washings was analyzed for radioactivity. From this figure the amount of the label actually taken up by the scolices was determined to be 1.33×10^5 c.p.m.

Isolation and Fractionation of the Lipids—The total lipids were extracted from the scolices and fractionated by thin-layer chromatography (TLC); the cholesterol was isolated according to the previously published methods (23).

Saponification of Neutral Fats—The lipids of Band III were saponified by refluxing them in 5 ml. of 5% ethanolic KOH for 24 hr. under nitrogen. At the end of the time, 5 ml. of distilled water was added to the mixture, and the ethanol was evaporated by bubbling nitrogen into the gently warmed (ambient 45°) flask. The solution was then extracted with three separate 5-ml. portions of ether. The ether extracts were dried over sodium sulfate, and the solvent was evaporated under nitrogen. The residue was taken up in a minimal amount of chloroform which was transferred into a liquid scintillation vial, evaporated, and assayed for ¹⁴C.

The aqueous layer, containing the saponifiable fraction of the lipids, was acidified to pH 2.0 with 2 N H₂SO₄ and then extracted four times with ether. The ether fractions were dried overnight over anhydrous Na₂SO₄ and, subsequently, concentrated to a volume of about 5 ml. An aliquot from the solution was assayed for ¹⁴C.

In another experiment the ether solution of the saponifiable fraction of lipids from scolices (not treated with radioactive mevalonate) was prepared for GLC analysis by prior treatment with diazomethane according to the method of Beames (26).

Gas-Liquid Chromatography—Gas-liquid chromatography (GLC) of the fatty acids was performed by a Pye argon chromatography apparatus equipped with a 1.21-m. (4-ft.) glass column (4 mm. in diameter) packed with 10% ethylene glycol adipate on diatomaceous earth (Celite 545, 80/100 mesh). Ten-microliter samples were injected. The gas-flow rate was 30 ml./min. and the column temperature was 180°. The calibration of the GLC instrument, as well as the quantitation and identification of chromatograms, was performed according to previously published procedures (27).

Enzyme Activity of a Scolex Homogenate—The hydrolytic action of homogenates from *E. granulosus* scolices on cholesteryl acetate was investigated as follows: 1 g. of live scolices³ was homogenized in a Potter-Elvehjem homogenizer for 3 min. The homogenate was incubated with 1 ml. of antibiotic solution,⁴ 4 ml. of phosphate buffer pH 7.0, and 6.0 mg. of radioactive 4-¹⁴C-cholesteryl acetate⁸ in a water bath at 37° for 24 hr. with vigorous and continuous shaking. At the end of the incubation period, the lipids were extracted from the mixture with chloroform. The residue, obtained by evaporation of the chloroform extracts, was subjected to TLC, and its cholesterol fraction was isolated as described before (23) and analyzed for its radioactivity content.

Scintillation Counting—All radioactivity measurements of the cholesterol samples were performed in a Packard Tricarb scintillation spectrometer model 3003 with an efficiency of 70% and a background count of 8 c.p.m. The samples were counted in liquid scintillation glass vials (20-ml. capacity) with 18 ml. of liquid scintillation cocktail containing 4 g. of 2,5-diphenyloxazol (PPO) as primary scintillator and 50 mg. of dimethyl-1,4-bis[2(5-phenyloxazol)benzene] (POPOP) as secondary scintillator per liter of toluene. Samples that were insoluble in the cocktail were first solubilized in 3

¹Durr (19) recently provided evidence for the incorporation of mevalonic acid into the nonsaponifiable lipids of omental and subcutaneous adipose tissue of man, epididymal fat pad of rat, and the fat tail of the Syrian sheep. His stoichiometric studies showed that about one-half of the incorporated radioactivity in the nonsaponifiable lipids was in squalene, 20% in lanosterol and cholesterol, and the remainder in unidentified substances.

²However, Ginger and Fairbairn (22) working with *Hymenolepis diminuta* demonstrated the incorporation of 1-¹⁴C-acetate into the cestode's cholesterol fraction.

³The viability of the collected scolices was determined by their motility and staining properties (1:1000 eosin solution) according to the procedure described by Meymerian *et al.* (24).

⁴The antibiotic solution was prepared by diluting with distilled water, 200,000 units of penicillin G and 200 mg. of streptomycin to a final volume of 400 ml.

⁵Purchased from the Radiochemical Centre, Amersham, Bucks, England.

⁶This abbreviation will be used throughout this paper to denote the number of counts per minute.

⁷Microscopic examination (24) of a sample of the scolices showed them to be totally killed by the sulfuric acid treatment.

⁸Radioactive cholesteryl acetate with a specific activity of 1.55×10^4 c.p.m./mg. was synthesized by treating 4-¹⁴C-cholesterol with acetic anhydride in the presence of anhydrous pyridine (28). The ester was shown to be pure by mixed melting point (115–116°) with authentic cholesteryl acetate and by TLC in two solvents (29). Subsequent radioautography of the chromatograms exhibited only one radioactive spot.

Table I—Incorporation of 2-¹⁴C-DL-Mevalolactone into Various Lipid Fractions of *E. granulosus* Scolices

Band	c.p.m.	Incorporation, %
I	1096	0.82
Ia	5	Negligible
Ib	115	0.08
Ic	148	0.20
Id	502	0.37
II	171	0.13
IIa	Negligible	Negligible
IIb (ecdysone level)	8	0.01
IIc	34	0.02
IId	93	0.07
IIe	9	0.01
III	826	0.62
Unsaponifiable fraction of Band III	Negligible	Negligible
Saponifiable fraction of Band III	827	0.62

ml. of dioxane and then added to 15 ml. of the cocktail. In the case of samples that were too small to be eluted from the TLC plates, the silica gel was scraped off, mixed with the cocktail, and counted according to the method of Snyder and Stephens (30). All samples were counted twice for at least 10 min.

RESULTS

In a duplicate determination, 3.0 g. of live scolices of *E. granulosus* was incubated at 37° with 1 ml. of 2-¹⁴C-mevalolactone (specific activity 3.11×10^5 c.p.m./0.04 μ M/ml.). At the end of the incubation period (5 hr.), the lipids⁹ were extracted from the scolices and fractionated by TLC using 0.25-mm. thick layers of silica gel G with methylene chloride-acetone (92:8, v/v) as a developer. The three zones obtained¹⁰ were designated Bands I, II, and III (23), Bands II and III being the origin and front, respectively.

It was observed that the eluate from Band I inhibited growth markedly (length 0.5 to 1.0 mm.) as compared with the growth of worms under the influence of Band III or in a control (9.5 to 10 mm.) (23). Band I was subjected to further chromatography on a 20 \times 20-cm. silica gel¹¹ plate with chloroform-acetone (90:10, v/v) as eluant. Four different zones were observed which were designated Band Ia (origin), Ib (R_f = 0.36), Ic (R_f = 0.74), and Id (R_f = 0.93). The extent of the incorporation of 2-¹⁴C-mevalonate into the various lipid fractions of *E. granulosus* scolices is presented in Table I.

When Band Ic, containing the free cholesterol,^{12,13} was eluted from the TLC chromatogram, it yielded 4 mg. of residue which was

dissolved in 10.0 ml. of benzene. When 2.5 ml. from this solution was mixed with scintillation cocktail and its radioactivity counted, it was found to have a specific activity of 37 c.p.m./mg. To show whether or not the label was incorporated into cholesterol, 7.5 ml. from the cholesterol solution was mixed with 10 ml. of benzene containing 0.047 g. of pure, unlabeled cholesterol. The benzene was evaporated under a stream of nitrogen and the residue recrystallized once from 95% ethanol. No radioactivity was detected in the recrystallized cholesterol. In contrast, however, the supernatant solution was found to contain all the radioactivity (110 c.p.m.), indicating that Ic contained compound(s) other than cholesterol¹⁴ to which the label was incorporated.

Band III, which was shown to contain the neutral fat fraction of the lipids (31), was eluted and saponified. Aliquots from the saponifiable and nonsaponifiable fractions were counted for radioactivity. The results in Table I demonstrate that the entire radioactivity of Band III from the 2-¹⁴C-mevalonate was incorporated into the saponifiable fraction.

With the significance of the saponifiable fraction in mind, the authors proceeded to determine by GLC the type and quantity of the fatty acids in this fraction. The results are shown in Table II.

The presence of hydrolytic enzymes in the scolices was indicated when a homogenate from 1 g. of live scolices was incubated with 6.0 mg. of radioactive cholesteryl acetate⁸ at 37°. After incubation, free cholesterol was isolated from the mixture, and it was found to be radioactive (1056 c.p.m.). No radioactive cholesterol was detected in a control mixture¹⁵ without the scolex homogenate.

DISCUSSION

With the recent findings on insect lipid biochemistry in mind, the authors have attempted to elucidate the mevalonate-cholesterol biosynthetic pathway of *E. granulosus*. First, however, a very brief description of the parasite's life cycle is necessary. The adult worm discharges eggs in the feces of the primary host, often a dog. When the eggs are ingested by an intermediate host, such as cow, sheep, or man, the eggs hatch in the duodenum. The released oncospheres then travel *via* the lymphatics and bloodstream to various parts of the body, usually the liver or lungs, where they become hydatid cysts. In man these cysts may grow to 15–20 cm. in diameter after several years. Within the cysts are found scolices which, if ingested by a suitable host, become adult worms within 7 weeks.

The only effective¹⁶ treatment of the hydatid disease (echinococcosis), surgical removal of the cyst, suffers from both (a) a relatively high risk if secondary cyst infection by the viable hydatid scolices within the cyst and (b) the possibility of a violent and sometimes fatal anaphylactic reaction by the patient to the cyst fluid.

It seems to the authors that a more knowledgeable approach to the treatment and (or) control of echinococcosis could be made if more was known about the biochemistry of the parasite. Also, the possibility of finding an endocrine system in parasites similar to the one producing ecdysis in insects presents itself.

Cholesterol appears to be the major sterol in helminths. Fairbairn and Jones (34) showed that 75% of the unsaturated sterols of *Ascaris lumbricoides* was cholesterol. Thompson *et al.* (35) reported that 98 and 85% of the unsaponifiable matter of adult *Taenia taeniaeformis* and *Moniezia* sp. (respectively) were cholesterol. The authors' studies recently showed that in *E. granulosus* scolices, free cholesterol per dry weight constituted a high 3.03% (23, 32) as compared to 1.4% for *Taenia taeniaeformis* reported by von Brand *et al.* (36).

The authors' results showing the lack of incorporation of 2-¹⁴C-mevalonate into cholesterol by the scolices suggest that the terpenic pathway is directed towards compounds other than cholesterol. The scolices' apparent "inability to synthesize" their own cholesterol is substantiated by the results of Frayha (20) who demonstrated that 1-¹⁴C-acetate did not incorporate into the cholesterol fraction of *E. granulosus* scolices. He also demonstrated the passage of 26-¹⁴C-

⁹ The classic saponification of the lipids prior to fractionation by TLC was avoided because a correlation between the biological activity of the various lipid fractions and their biosynthesis from mevalonate was sought.

¹⁰ The visualization and the elution of the substances from the zones obtained by TLC fractionation were performed as described previously (23).

¹¹ Chromagram, Eastman Kodak Co., Inc., Rochester, N. Y.

¹² It was previously shown (23, 32) that when the lipid fraction of 0.495 g. of lyophilized scolices¹⁸ was subjected to a similar TLC fractionation, it yielded 0.022 g. of residue from Band I. Further purification of the residue showed that 0.015 g. of it was cholesterol in its free form. Only trace amounts of cholesterol were shown to exist in their esterified form in Band III.

¹³ One gram of lyophilized scolices was found equivalent to 14.5 g. of wet live scolices (32).

¹⁴ Preliminary examination of Ic by combined GLC-mass spectroscopy revealed that this fraction consisted of cholesterol and other compounds, the identities of which are under investigation.

¹⁵ The control mixture consisted of 6.0 mg. of radioactive cholesteryl acetate, 1 ml. of antibiotic solution, and 4 ml. of phosphate buffer (pH 7.0).

¹⁶ Chemotherapy appears to be difficult since the permeability of the membrane (particularly the internal germinal membrane) surrounding the hydatid cyst is known to be highly selective (33).

Table II—Major Fatty Acid Composition of the Scolex of *E. granulosus*

Fatty Acid	Shortened Designation	Methyl Esters as Percentage of Total Esters
n-Dodecanoic	12:0 ^a	0.35
Tetradecanoic	14:0	1.67
	14:1	1.34
Hexadecanoic	16:0	8.17
	16:1	2.95
Heptadecanoic	17:0	0.63
	17:1	1.78
Octadecanoic	18:0	23.5
	18:1	27.7
	18:2	7.44
	18 un ^b	1.86
Eicosanoic	20:0	6.03
	20:1	2.4
	20:2	0.67
	20:3	0.74
	20:4	5.21
	20 un ^b	2.60

^a The numerals following the colon refer to the number of double bonds in the molecule, whereas the numerals before the colon refer to the chain length (number of carbon atoms) of the fatty acid. ^b This abbreviation denotes unknown number of unsaturations.

cholesterol from the host (infected mice) to the scolices of *E. granulosus* (20). Furthermore, Meyer *et al.* (21) reported that the cestode *Spirometra mansonoides* lacked mechanisms required for the *de novo* synthesis of sterols.

The fact that free radioactive cholesterol was isolated from the scolices upon incubation with radioactive cholesteryl acetate indicates the presence of an enzyme system within the cyst responsible for the hydrolysis of the cholesteryl ester. This finding was consistent with the results of Lee *et al.* (37) who reported the presence of nonspecific esterases in various tapeworms.

Based on these recent findings, it seems reasonable to assume that cholesterol passes, probably in an esterified¹⁷ form, from the host through the cyst membrane into the scolices where the cholesteryl ester is hydrolyzed to free cholesterol by an esterase system within the scolices.

ACKNOWLEDGMENTS AND ADDRESSES

Received October 13, 1969, from the Departments of Pharmaceutical Chemistry and Tropical Health, Schools of Pharmacy and Public Health, American University of Beirut, Beirut, Lebanon.

Accepted for publication December 29, 1969.

Presented to the Pharmacognosy and Natural Products Section, APHA Academy of Pharmaceutical Sciences, Miami meeting, May 1968.

These studies were supported in part by research grants from the Medical Research Committee, American University of Beirut, and from the National Institute of Allergy and Infectious Diseases, National Institutes of Health, Public Health Service (AI-02205-08 and AI-07218-01).

Thanks are extended to Dr. George J. Frayha, Department of Tropical Health, American University of Beirut, for useful discussions. The assistance of Miss Diana Walstad in the preparation of this manuscript is gratefully acknowledged.

Metabolic Fate of *N*- γ -Phenylpropyl-*N*-benzyloxy Acetamide (W-1372) in Rats, Dogs, and Monkeys

JEROME EDELSON, J. F. DOUGLAS, and B. J. LUDWIG

Abstract □ The absorption, distribution, and metabolic fate of *N*- γ -phenylpropyl-*N*-benzyloxy acetamide (W-1372) was studied in the rat, dog, and monkey. W-1372- ^{14}C was readily absorbed by all three species. Following an oral dose, peak blood levels of radioactivity were attained within 1 hr. in the monkey and in 2 hr. in the dog. The blood half-life of radioactivity following oral administration was 11.5 hr. in the dog. In the rat, maximum blood concentration of ^{14}C was reached 1 hr. following intraperitoneal administration, and the half-life was about 2 hr. Distribution studies of labeled drug in the rat indicate that the administered radioactivity is largely excreted within 24 hr. The major metabolites of W-1372 are hippuric acid, benzoic acid, *N*- γ -phenylpropyl-*N*-benzyloxyamine, and carbon dioxide.

Keyphrases □ *N*- γ -Phenylpropyl-*N*-benzyloxy acetamide (W-1372)—metabolism □ Absorption, distribution, metabolic fate—W-1372- ^{14}C □ Inverse isotope dilution—analysis □ Hippuric acid, benzoic acid, *N*- γ -phenylpropyl-*N*-benzyloxyamine, carbon dioxide—W-1372- ^{14}C metabolites □ TLC—identification □ IR spectrophotometry—identification

N- γ -Phenylpropyl-*N*-benzyloxy acetamide (W-1372) is a new hypolipidemic agent that has been shown by Berger *et al.* (1, 2) to reduce the extent of atherosclerotic lesions and to lower serum cholesterol levels in animals maintained on a high-cholesterol diet. This manuscript describes studies from this laboratory on the absorption, distribution, and metabolic fate of W-1372 in the rat, dog, and squirrel monkey.

METHODS

Preparation of *N*- γ -Phenylpropyl-*N*-benzyloxy-benzyl-7- ^{14}C Acetamide (W-1372-Benzyl- ^{14}C)—*N*- γ -Phenylpropyl-*N*-hydroxy acetamide, 965 mg., was added to a solution of 115 mg. of sodium in 10 ml. of anhydrous ethanol. After 2 mc., 633 mg., of benzyl chloride-7- ^{14}C was added, the reaction mixture was heated to reflux for 4 hr. and left at room temperature overnight. The solvent was removed *in vacuo* and the residue was stirred with 40 ml. of water and 40 ml. of ethyl ether. The organic phase was separated and the aqueous phase was again extracted with an equal volume of ether. The organic phases were combined and dried over anhydrous sodium sulfate. After removal of the solvent, the residue was molecularly distilled (90°/0.004 mm.) to yield 681 mg. of W-1372-benzyl- ^{14}C , specific activity 1.69×10^6 d.p.m./mg.

The product gave only one radioactive spot in TLC in methanol-acetone-acetic acid (95:95:10), and its IR spectrum was identical to that of authentic W-1372.

Preparation of *N*- γ -Phenylpropyl-*N*-benzyloxy Acetamide-acetyl-1- ^{14}C (W-1372-Acetyl- ^{14}C)—Acetyl chloride-1- ^{14}C , 1.0 mc., 791 mg., was added to a solution of 4.84 g. of *N*- γ -phenylpropyl-*N*-benzyloxyamine in 20 ml. of ethyl ether. The reaction mixture was heated to reflux for 30 min., and the solid which formed, *N*- γ -phenylpropyl-*N*-benzyloxyamine hydrochloride, was removed by filtration. The filtrate was washed consecutively with 10 ml. of 0.1 *N* hydrochloric acid, 10 ml. of 0.1 *N* sodium hydroxide, and 10 ml. of water. The remaining organic phase was dried and molecularly distilled, as previously described, to yield 2.73 g. of W-1372-acetyl- ^{14}C , specific activity 8.24×10^6 d.p.m./mg. Its purity was verified by TLC as previously described.

Absorption and Blood Concentration—Three male Sprague-Dawley rats, weighing about 200 g. each, received intraperitoneally

Figure 1—Blood radioactivity after intraperitoneal administration of W-1372-benzyl- ^{14}C to the rat.

a solution containing 40 mg. of W-1372-benzyl- ^{14}C in 0.5 ml. of polyethylene glycol 400. Blood samples were taken from the tail vein at appropriate intervals and assayed for radioactivity by liquid scintillation counting.¹

A male beagle hound, weighing 11 kg., was given a capsule containing 1.258 g. of W-1372-benzyl- ^{14}C . Blood samples were taken from the vein to the toe nail at intervals and assayed for radioactivity.

Two 800-g., male squirrel monkeys received, by stomach tube, 50.8 mg. of W-1372-benzyl- ^{14}C dissolved in 2.0 ml. of polyethylene glycol 400. At appropriate intervals, blood was removed from the jugular vein and assayed for radioactivity.

Tissue Distribution in the Rat—A male Sprague-Dawley rat, weighing 150 g., received intraperitoneally 42.2 mg. of W-1372-benzyl- ^{14}C dissolved in 1.0 ml. of polyethylene glycol 400. Urine and feces were collected for 24 hr. The animal was then sacrificed and the organs were excised. The tissues and the remainder of the carcass were dissolved in 6 volumes of 1 *M* hydroxide of hyamine (Packard Instrument Co., Downers Grove, Ill.) by digesting for 18 hr. at 50°. An aliquot of each solution was taken and assayed for radioactivity in a liquid scintillation spectrometer.

A second rat, weighing 180 g., was given intraperitoneally a solution containing 51.2 mg. of acetyl-labeled W-1372 in 1.0 ml. of propylene glycol. The animal was placed in a metabolism chamber for 24 hr. and then sacrificed. The tissues were processed and analyzed for radioactivity. The carbon dioxide of respired air was trapped in 2.5 *M* sodium hydroxide, and the radioactivity of an aliquot of this solution was measured.

Inverse Isotope Dilutions—Typical inverse isotope dilution experiments were carried out as follows: a male Sprague-Dawley rat, weighing about 200 g., received intraperitoneally 12.7 mg. of W-1372-benzyl- ^{14}C dissolved in 1.0 ml. of polyethylene glycol 400. Urine was collected for 24 hr. and its radioactivity measured. Isotope dilutions were carried out on aliquots of urine as follows.

1. Nonradioactive hippuric acid, 1000 mg., was added to the first 1.0-ml. aliquot, followed by the addition of 20 ml. of water and

¹ The scintillating fluid consisted of a solution of 7 g. of 2,5-diphenyl-oxazole, 250 mg. of 1,4-bis-2-(4-methyl-5-phenyloxazolyl)benzene, and 125 g. naphthalene in 1 l. dioxane.

Figure 2—Blood radioactivity after oral administration of W-1372-benzyl- ^{14}C to the dog.

sufficient 50% sodium hydroxide to yield a clear solution. Acidification of the mixture with concentrated hydrochloric acid precipitated the hippuric acid. The solid was removed and recrystallized from water to constant specific activity; m.p. 189–190°.

2. Nonradioactive benzoic acid, 1000 mg., was added to a second 1.0-ml. aliquot of urine and the mixture was diluted with water and heated until homogeneous. Upon cooling, benzoic acid crystallized and was removed by filtration. It was recrystallized from water to constant specific activity; m.p. 121–122°.

3. Nonradioactive *N*- γ -phenylpropyl-*N*-benzyloxyamine hydrochloride, 1000 mg., was added to a 2.0-ml. aliquot of urine. A few drops of concentrated hydrochloric acid were added, followed by sufficient hot ethanol to dissolve the solid. Water, 100 ml., was

Figure 3—Blood radioactivity after oral administration of W-1372-benzyl- ^{14}C to the squirrel monkey.

Table I—Tissue Distribution of ^{14}C in a Rat 24 hr. after Intraperitoneal Administration of 42.2 mg. W-1372-Benzyl- ^{14}C

Organ	Radioactivity Recovered—	
	d.p.m. $\times 10^3$	%
Urine	39,100	54.7
Carcass	23,250	32.7
Stomach and intestines	7,980	11.1
Liver	1,135	1.6
Kidney	661	0.9
Lung	71.4	0.1
Heart	27.9	0.04
Spleen	17.4	0.02

added, and the mixture was made alkaline with 25 ml. of 10% sodium hydroxide and extracted with two 150-ml. portions of ether. The ether phase was dried over anhydrous sodium sulfate, and hydrogen chloride gas was bubbled into the ether solution to precipitate the hydrochloride of *N*- γ -phenylpropyl-*N*-benzyloxyamine. The solid was separated and recrystallized from ethanol to constant specific activity; m.p. 134–135°.

4. Nonradioactive benzaldehyde, 1000 mg., was added to a 2.0-ml. aliquot of urine; ethanol was added until the mixture was homogeneous. Sodium acetate, 1.5 g., and 1.0 g. semicarbazide hydrochloride were added, and the mixture was vigorously shaken and heated in a boiling water bath for 10 min. On cooling, the semicarbazone of benzaldehyde crystallized. The derivative was repeatedly recrystallized from 50% aqueous ethanol to constant specific activity; m.p. 221–223°.

To quantitate the various metabolites occurring in the urine in a combined form, an aliquot of urine was hydrolyzed by the addition of an equal volume of concentrated hydrochloric acid, and the mixture was heated on a steam bath for 10 min. Nonradioactive carrier was then added and the inverse isotope dilution carried out for total metabolites as described for the free metabolites.

RESULTS AND DISCUSSION

Absorption and Blood Concentration in the Rat, Dog, and Squirrel Monkey—After intraperitoneal administration to rats, benzyl-labeled W-1372 was rapidly absorbed, and a maximal blood concentration of radioactivity was reached after 1 hr. This level of blood radioactivity was maintained for 30 min. and was followed by a first-order decline. The half-life of ^{14}C in the blood was approximately 2 hr. (Fig. 1).

In the dog the drug was readily absorbed after an oral dose of W-1372-benzyl- ^{14}C , and a peak blood level of ^{14}C was obtained within 2 hr. Under these conditions the disappearance of radioactivity from the blood followed first-order kinetics and the ^{14}C half-life was estimated to be 11.5 hr. (Fig. 2).

W-1372 was also rapidly absorbed by the squirrel monkey since the maximum blood concentration of radioactivity was reached during the 1st hour after oral administration of benzyl-labeled drug (Fig. 3). In this study the disappearance of radioactivity from blood did not follow the kinetics of a single-compartment model but occurred at two distinct rates. It is difficult to estimate the half-life during the initial depletion pattern. However, after 7 hr., the elim-

Table III—Urinary Excretion of Hippuric and Benzoic Acids by Animals Given W-1372-Benzyl-¹⁴C

Species	No. of Animals	Dose (mg.), Route	% of Urinary Radioactivity as Hippuric and Benzoic Acids
Rat, Sprague-Dawley	5	12-71, i.p.	85.6
Dog, beagle hound	5	25-520, i.p. and p.o.	65.8
Monkey, squirrel	3	16-32, i.p.	68.7

ination of blood radioactivity follows first-order kinetics with a half-life of approximately 13.5 hr.

Tissue Distribution in the Rat—Radioactivity from the intraperitoneal administration of W-1372-benzyl-¹⁴C was principally excreted in the urine within 24 hr. Significant amounts of ¹⁴C were also found in the carcass and gastrointestinal tract at this time (Table I).

Radioactivity from W-1372-acetyl-1-¹⁴C was largely eliminated as respiratory carbon dioxide. Over 60% of the radioactivity of the dose administered was exhaled within 24 hr. while less than 6% was voided in the urine during this period. The distribution of the residual radioactivity is shown in Table II.

Identification and Quantitation of Urinary End Products—The major urinary end products of W-1372 in the three species studied, rat, dog, and monkey, were benzoic acid and hippuric acid. Quantitatively these compounds accounted for at least 65% of the urinary radioactivity. Table III shows the average values obtained with a number of animals of each species. In a single experiment on dog urine, the authors found an additional 1.9% of the urinary radioactivity present as benzoate conjugated with glucuronic acid. This value was determined by the increase in the amount of free benzoic acid present after hydrolysis with β -glucuronidase.

These conversions of W-1372 in the animal body would be anticipated from the metabolic fate of the related compound, benzyl *N*-benzyl carbethoxyhydroxamate (W-398), which is converted into benzoic acid and hippuric acid in both the rat and man (3, 4).

The deacetylated derivative of W-1372, *N*- γ -phenylpropyl-*N*-benzyloxyamine, was also identified and quantitated in the urine of animals receiving W-1372-benzyl-¹⁴C. The *N*- γ -phenylpropyl-*N*-benzyloxyamine was present in both the free and bound form since

^a Values obtained by inverse isotope dilution. ^b Total metabolite after acid hydrolysis of urine.

acid hydrolysis of the urine liberated additional free amine. This increase was particularly significant for the dog. The nature of the conjugate has not been elucidated. Trace amounts of benzaldehyde were also identified in acid-hydrolyzed urine, but this may have arisen from the degradation of some metabolite. The quantities of the various metabolites occurring in the urines of various animal species are summarized in Table IV.

Analysis of *p*-Aminosalicylic Acid, Its Salts and Dosage Forms, by Nonaqueous Titration

JAMES HUNT and MARTIN I. BLAKE

Abstract \square *p*-Aminosalicylic acid, its salts, and its dosage forms are determined by visual or potentiometric titration with sodium methoxide in benzene-methanol using dimethylformamide as the titration solvent. *p*-Aminosalicylic acid and its decomposition product *m*-aminophenol may be differentiated with this titration system. Salts of *p*-aminosalicylic acid are converted to the acid form by ion-exchange chromatography prior to titration. The procedure is applied to several dosage forms.

Keyphrases \square *p*-Aminosalicylic acid and salts—analysis \square Dosage forms, *p*-aminosalicylic acid and salts—analysis \square Column chromatography—separation \square Potentiometric titration—analysis

The USP XVII method (1) for the determination of *p*-aminosalicylic acid (PAS), its salts and dosage forms, involves the diazotization reaction and is based on procedures developed by Tarnoky and Brews (2) and Pesez (3, 4). The use of an external indicator and the non-selectivity of the reaction have been noted by Chatten (5) as shortcomings of the procedure. *m*-Aminophenol (MAP), the major breakdown product of PAS, is also diazotized in the titration process; in the official monographs the MAP content is determined separately by colorimetric analysis.

A variety of analytical methods has been proposed for the determination of PAS and its salts. These have been extensively reviewed by Lach and Cohen (6).

A number of nonaqueous titrimetric procedures have appeared in the literature. They have been reviewed by Kucharsky and Safarik (7) and are briefly noted here. Chatten (8) reported the visual titration of PAS with potassium hydroxide in methanol as titrant, acetone as the titration solvent, and thymol blue as indicator. For sodium *p*-aminosalicylate, methanol served as the titration medium and perchloric acid in dioxane as titrant. These methods were reported to be specific even in the presence of MAP. Butler and Ramsey (9) titrated PAS and its sodium salt potentiometrically with perchloric acid in glacial acetic acid. An acetic acid-carbon tetrachloride solvent mixture served as the titration medium. Stockton and Zuckerman (10) determined sodium *p*-aminosalicylate and its solutions by potentiometric titration with perchloric acid in propylene glycol and isopropyl alcohol (1:1), using the same solvent mixture as the titration medium. The decomposition products MAP and sodium bicarbonate did not interfere. Das and Palit (11) employed the same titrant and solvent system.

In the present study, PAS is titrated with sodium methoxide in benzene-methanol (10:1). The titration medium is dimethylformamide. The difference in the acidic properties of PAS and MAP permitted a dif-

ferentiating titration of the two components. The salts of PAS are converted to the acid by ion-exchange chromatography prior to titration. The techniques are applied to several dosage forms.

EXPERIMENTAL

Apparatus—Titrations were performed visually or potentiometrically with a Fisher titrimeter, model 35, equipped with a sleeve-type calomel and platinum electrode system. A 50-ml. buret (1 cm. i.d.) was employed as a chromatographic column. It was plugged at the base with glass wool to support the resin column.

Reagents—(a) *p*-Aminosalicylic acid, *m*-aminophenol, and sodium and calcium *p*-aminosalicylate were the best quality available from commercial sources. The *m*-aminophenol was further purified by recrystallizing from hot water. (b) Tenth normal sodium methoxide in benzene-methanol (10:1) was prepared and standardized as described earlier (12). (c) Other chemicals and all solvents used in this study were reagent grade and were used without further purification. (d) Powder, capsule, and tablet dosage forms were supplied by Dorsey Laboratories, Lincoln, Neb. A solution of sodium *p*-aminosalicylate was obtained from Hines Veterans Administration Hospital, Hines, Ill., prepared as directed in their hospital pharmacy formulary.

Preparation of Column—A weak cation-exchange resin (Amberlite IRC-50) and a strong cation-exchange resin (Dowex 50W-X8) were used in this study. The resin columns were prepared as described earlier (13, 14).

General Assay Procedure—One-half to one milliequivalent of sodium or calcium *p*-aminosalicylate, accurately weighed, was dissolved in the smallest volume of dimethylformamide and the solution passed through the column containing the weak resin. Effluent was collected in a 100-ml. graduated cylinder. Additional dimethylformamide was added to the column until 75 ml. of ef-

Figure 1—Typical titration curve for MAP.

fluent was collected. The effluent was titrated visually to the first permanent blue color using thymol blue as indicator (0.3% in methanol) or potentiometrically with the Fisher titrimeter. By the latter method, the end-point was determined from the inflection of the curve obtained by plotting volume of titrant versus millivolt readings.

Analysis of Dosage Forms—Capsules and Tablets—Twenty tablets were weighed and powdered, or 20 capsules were emptied as completely as possible and the contents weighed. A sample of the powder mass equivalent to between 0.5 and 1.0 meq. of *p*-aminosalicylate salt was dissolved in 25 ml. of dimethylformamide with the aid of magnetic stirring. The solution was treated as described under *General Assay Procedure*.

Chocolate-coated tablets of calcium *p*-aminosalicylate were soaked in distilled water until the coating dissolved. This required no longer than 5 min. The tablets were dried rapidly between filter paper and the dried tablets were assayed as described previously.

Solution—One milliliter of a solution, labeled to contain 1 g. of sodium *p*-aminosalicylate per 5 ml., was transferred by pipet to the column containing the weak resin. The column was eluted with dimethylformamide until a total of 75 ml. of effluent was collected. The effluent was titrated as described previously.

Official Assay Procedure—*p*-Aminosalicylic acid, the sodium and calcium salts, and their dosage forms were assayed as described in USP XVII (1).

Differentiating Titration of *p*-Aminosalicylic Acid and *m*-Aminophenol—Samples containing 1 meq. of MAP and a series of mixtures containing 1 meq. of PAS and varying amounts of MAP were titrated visually and potentiometrically in dimethylformamide with 0.1 *N* sodium methoxide as titrant.

Table II—Analysis of PAS and MAP Mixtures

Meq. Ratio of Components, PAS-MAP	Recovery, %	
	PAS	MAP
Visual Titration		
1.00:1.00	101.41 ± 0.98 ^a

Figure 2—Differentiating titration of mixtures of PAS and MAP in varying meq. ratios: A, 1:0.20; B, 1:0.25; C, 1:0.33; D, 1:0.50; and E, 1:1.0.

Chromatographic Separation of *p*-Aminosalicylic Acid and *m*-Aminophenol—A series of mixtures corresponding to those described in the previous section was passed through a chromatographic column containing a strong cation-exchange resin. Aliquots of the mixture were treated as described in the *General Assay Procedure*, except that a strong resin (Dowex 50W-X8) was used in place of the weak resin.

RESULTS AND DISCUSSION

A major drawback to the official assay procedure for PAS, its salts and dosage forms, is that the breakdown product MAP also responds to the assay. As a result, apparently quantitative recoveries may be obtained even though extensive decomposition may have taken place. Although the USP includes a limits test for MAP based on colorimetric analysis, it would be desirable to have a simple titrimetric procedure which would be specific for PAS. Most non-aqueous titration procedures proposed in the literature involve the titration of the amino group with perchloric acid in a suitable solvent system. Although Chatten (5,8) titrated the carboxyl group in PAS with potassium hydroxide in methanol, the sodium salt was determined with perchloric acid.

In the present study, PAS was titrated visually with sodium methoxide using thymol blue as the indicator. The end-point was readily detectable with one drop of titrant. The sodium and calcium salts and their dosage forms were titrated similarly after treatment with the weak cation-exchange resin (Amberlite IRC-50), which converted the salt to the free PAS. The results of the analyses are recorded in Table I. Comparative assays were performed by the official procedure. In almost every case the percent recovery by the official assay was essentially the same or higher than by the proposed method.

MAP was not titratable visually with sodium methoxide. Samples dissolved in dimethylformamide produced an indicator color change with the first drop of titrant. However, suitable inflections were obtained by potentiometric titration. A typical titration curve is shown in Fig. 1. The average percent recovery based on a series of 10 titrations was 99.22 ± 1.09%.

The effect of the presence of added MAP on the titration of PAS was tested. A series of mixtures of PAS and MAP, listed in Table II, was titrated visually with sodium methoxide. The presence

of MAP did not interfere with the visual end-point determination in the titration of PAS. This is probably attributable to the large difference in pKa values for these compounds: 3.25 for PAS (15) and 9.71 for MAP (16). When the mixtures were titrated potentiometrically, two inflections in the titration curve were obtained, indicating the feasibility of a differentiating titration procedure. The titration curves for the series of mixtures are shown in Fig. 2, and the analysis data are listed in Table II. In the titration curves the first inflection is attributable to PAS, while the second end-point is due to the MAP. Although the differentiating titration may not be useful for determining the MAP content when present in low concentrations (e.g., 10% or less), both the visual and the potentiometric titration procedures are specific for the PAS content.

The weak cation-exchange resin (Amberlite IRC-50) was found to be effective for converting the salts of PAS to the free acid. The PAS was eluted from the column with dimethylformamide and the eluate titrated with sodium methoxide. When mixtures of PAS (or its salt form) and MAP listed in Table II were passed through the resin column, both PAS and MAP appeared in the eluate. A differentiating titration yielded quantitative recoveries for both components. Apparently the PAS and MAP are too weakly basic to be retained by a carboxylic acid-type resin. When the strong cation-exchange resin (Dowex 50W-X8) was used in place of the weak resin, the MAP was retained by the column while the PAS passed through and was recovered quantitatively in the eluate. The percent recovery based on the potentiometric titration of seven samples was $100.22 \pm 0.56\%$. A sulfonic acid-type resin (Dowex 50W-X8) is a sufficiently strong acid to extract the MAP from the mixture.

In preliminary studies, ethylenediamine, acetone, isopropyl alcohol, methyl isobutyl ketone, acetonitrile, and dimethylformamide were examined as solvents for the differentiating titration of PAS and MAP. Dimethylformamide was found to produce the most reproducible and clearly defined end-points. The sleeve-type calomel and platinum electrode system produced good differentiating titration curves where the conventional sleeve-type and glass electrode system was unsuccessful in differentiating PAS and MAP.

SUMMARY

The proposed assay procedure has advantage over the official assay in that the PAS content is determined by direct visual titration. MAP, if present, does not interfere with the end-point detection. Quantitative separation of MAP from PAS may be achieved

by passing the mixture through a column of strong cation-exchange resin (Dowex 50W-X8). The MAP is retained by the column while the PAS appears in the eluate. Mixtures of MAP and PAS may be differentiated by potentiometric titration. While this procedure is not suitable for determining low concentrations of MAP, as is required for the official dosage forms (1% or less), it is useful for studying the kinetics of the decomposition of PAS in dosage forms, particularly solutions.

Improved Differential Spectrophotometric Determination of Rifamycins

CARMINE R. PASQUALUCCI*, ARISTIDE VIGEVANI, PIETRO RADAELLI, and GIAN G. GALLO

Abstract □ A differential spectrophotometric method for the determination of rifamycin B, rifamide, rifamycin SV, and rifampin, based on the oxidation by NaNO_2 of the hydroquinone moiety of the compounds, is described. The application of the method to the determination of rifamycin B in fermentation broths and of rifampin in capsules and in syrup is reported. Precision and accuracy data are given.

Keyphrases □ Rifamycins, dosage forms—differential determination □ Fermentation broths—rifamycin determination □ Hydrolytic oxidation—rifamycin determination □ Colorimetric analysis—spectrophotometry

Rifamycin B (I) (1) is a metabolite produced by *S. mediterranei*, while rifamide (II) (2), rifamycin SV

(III) (3), and rifampin¹ (IV) (4) are the derived semi-synthetic antibiotics presently in therapeutic use.² All these rifamycins³ possess a characteristic chromophoric group which permits their spectrophotometric determination (2, 5-7). Furthermore, based on the quinone-hydroquinone nature of the chromophore, a differential spectrophotometric method has been described for rifamycin B and SV (8). The subjects of the present

¹ The international nonproprietary name for this compound is rifampicin.

² Rifamide as Rifocin M; rifamycin SV as Rifocin; rifampin as Rifadin.

³ Rifamycins LXIII (rifamycin LXII: G. C. Lancini, G. G. Gallo, G. Sartori, and P. Sensi, *J. Antibiot.* (Tokyo), **22**, 369(1969).

of MAP did not interfere with the visual end-point determination in the titration of PAS. This is probably attributable to the large difference in pKa values for these compounds: 3.25 for PAS (15) and 9.71 for MAP (16). When the mixtures were titrated potentiometrically, two inflections in the titration curve were obtained, indicating the feasibility of a differentiating titration procedure. The titration curves for the series of mixtures are shown in Fig. 2, and the analysis data are listed in Table II. In the titration curves the first inflection is attributable to PAS, while the second end-point is due to the MAP. Although the differentiating titration may not be useful for determining the MAP content when present in low concentrations (e.g., 10% or less), both the visual and the potentiometric titration procedures are specific for the PAS content.

The weak cation-exchange resin (Amberlite IRC-50) was found to be effective for converting the salts of PAS to the free acid. The PAS was eluted from the column with dimethylformamide and the eluate titrated with sodium methoxide. When mixtures of PAS (or its salt form) and MAP listed in Table II were passed through the resin column, both PAS and MAP appeared in the eluate. A differentiating titration yielded quantitative recoveries for both components. Apparently the PAS and MAP are too weakly basic to be retained by a carboxylic acid-type resin. When the strong cation-exchange resin (Dowex 50W-X8) was used in place of the weak resin, the MAP was retained by the column while the PAS passed through and was recovered quantitatively in the eluate. The percent recovery based on the potentiometric titration of seven samples was $100.22 \pm 0.56\%$. paper are the modification of the differential spectrophotometric method, its extension to rifamide and rifampin, and its application to pharmaceutical preparations.

THEORY AND PROCEDURE

The differential spectrophotometric methods are suitable for the determination of substances in the presence of high concentrations of foreign-absorbing components. In the case of rifamycins the quinone-hydroquinone system, together with the position of the absorption maximum in the visible region, makes the method specific for this family of antibiotics. Thus, rifamycins can be determined in fermentation broths, in pharmaceutical preparations, and in bio-

Figure 1—Visible spectra of the hydrolytic oxidation of rifamide into rifamycin S (4.00 mcg./ml. of rifamide in pH 4.63 acetate buffer containing 0.01% w/v NaNO_2). 1: initial curve (rifamide), 2: final curve (rifamycin S); the curves were recorded at 5-min. intervals.

Table II—Differential Absorptivities (a) of the Rifamycins

	$\lambda_{\text{max.}}$	a
Rifamycin B	425 $m\mu$	21.5
Rifamide	424 $m\mu$	14.0
Rifamycin SV	447 $m\mu$	15.6
Rifampin	473 $m\mu$	14.7

logical fluids, all cases in which the presence of foreign components must be overcome. The authors have studied the differential method in the case of rifamycin B, rifamide, rifamycin SV, and rifampin, and they describe its application to the determination of rifamycin B in the fermentation broth and of rifampin in some pharmaceutical forms.

The previous differential spectrophotometric method (8) is not applicable for the determination of rifamycin B in the fermentation broth. In fact, the use of HAuCl_4 as the oxidizing agent and of alcoholic benzoate buffer causes the formation of precipitates, which hinder the photometric reading. The authors adopted as the oxidizing agent a solution of NaNO_2 in aqueous acetate buffer, pH 4.63. The same oxidizing agent was also chosen for the determination of rifamycin SV, rifampin, and rifamide. With rifamide it must be pointed out that a hydrolytic oxidation to rifamycin S occurs, with the splitting of the glycolic amide moiety. This was demonstrated by the visible spectrum of the reaction solution (Fig. 1) and by isolation and identification (TLC, IR, NMR, and UV) of the final product.

The effect of the concentration of the oxidizing agent on the reaction time was studied for all the rifamycins and the results are given in Table I. On the basis of these data, a reaction time of 5 min. and a NaNO_2 concentration of 0.1% were chosen. In fact, under these conditions the rifamycins are completely transformed to the oxidized forms. In Table II the wavelengths and the differential absorptivities of the examined rifamycins, determined on the pure compounds in the conditions of the method, are reported.

The general procedure of the differential determination is as follows: the rifamycin to be determined (as powder, suspension, or solution) is dissolved in a water-miscible solvent at a concentration of about 1 mg./ml. Two equal portions of this solution are separately diluted to a concentration of 20–40 mcg./ml., one with the pH 4.63

acetate buffer solution (Solution A) and the other one with the oxidizing pH 4.63 acetate buffer solution containing 0.1% w/v NaNO₂ (Solution B). The absorbance of the solution diluted with Solution A is determined against the solution diluted with Solution B with a spectrophotometer at the appropriate wavelength. The amount of rifamycin is calculated from the measured absorbance.

EXPERIMENTAL⁴

Reagents and Solutions—*Solution A*—Acetate buffer at pH 4.63, prepared according to *Reference 9*.

Solution B—Solution A containing 0.1% w/v of NaNO₂.

All the reagents and solvents were pure grade (obtained from C. Erba).

Procedures—*Determination of Rifamycin B in the Fermentation Broth*—Two 1-ml. portions of the broth in two 50-ml. volumetric flasks were made to volume, one with Solution A and the other with Solution B. The absorbance of the solution diluted with Solution A was determined at 425 mμ in a 1-cm. cell against the solution diluted with Solution B. The rifamycin B concentration in the fermentation broth was obtained by the formula:

$$\text{rifamycin B (mcg./ml.)} = \frac{A_{425} \cdot 50,000}{21.5} \quad (\text{Eq. 1})$$

where A_{425} is the absorbance at 425 mμ and 21.5 is the absorptivity of rifamycin B determined by this method. If the concentration of rifamycin B is higher than 1500 mcg./ml., a higher dilution of the broth is necessary. The precision and accuracy data are reported in Tables III and IV, respectively.

Determination of Rifampin in Capsules—The capsules were opened; about 30 mg. of the powder, accurately weighed, was placed in a 20-ml. volumetric flask and made to volume with methanol. Two 1-ml. portions of this solution were treated and examined at 473 mμ, as described for rifamycin B. The content of rifampin was obtained by the formula:

$$\text{rifampin \% (w/w)} = \frac{A_{473} \cdot 100}{14.7 \cdot p} \quad (\text{Eq. 2})$$

where A_{473} is the absorbance at 473 mμ, 14.7 is the absorptivity of rifampin determined by this method, and p is the weight of the powder expressed in grams.

Determination of Rifampin in Syrup—About 1.5 g. of syrup, exactly weighed, was placed in a 20-ml. volumetric flask and made to volume with methanol. Two 1-ml. portions of this solution were treated and examined at 473 mμ, as described for rifamycin B. The titer of rifampin was obtained by the formula:

$$\text{rifampin \% (w/w)} = \frac{A_{473} \cdot 100}{14.7 \cdot p} \quad (\text{Eq. 3})$$

where the symbols have the same meaning reported in the preceding method.

The precision and accuracy data of the rifampin determination are reported in Tables III and V, respectively.

Determination of Tablet Strength by the Diametral-Compression Test

J. T. FELL* and J. M. NEWTON†

Abstract □ The strength of lactose tablets has been measured by application of the diametral-compression test. The relative value of tensile, compressive, and shear stresses within the tablet varies, depending on the characteristics of the tablets and the surface providing the applied compression. It has been shown that to obtain reproducible results for the strength of tablets prepared at a given compression force, the tablet must break in such a manner that the tensile stress is the major stress. For a given tablet, this may require the placing of suitable padding material between the tablet and the compressing surfaces. Assessment of the type of failure can be made visually and under the correct conditions, the results expressed as a tensile strength. There are, however, a range of conditions which ensure tensile failure resulting in different values for the tensile strength. These values are characteristic of the tablet and test conditions and are not absolute values of tensile strength.

Keyphrases □ Tablet strength determination—diametral-compression test □ Tensile strength, tablets—measurements □ Compression effect—tablet fracture □ Fracture mode, tablets—testing

The authors have previously described the use of the diametral-compression test to assess the tensile strength of lactose tablets (1). This test is carried out by a procedure similar to that often used to assess the crushing strength of tablets, *i.e.*, diametral compression between two flat platens. The determination of a tensile strength, as opposed to a crushing strength, from this procedure depends upon the correct state of stress developing within a specimen of known shape and dimensions. Consider the stress distribution within a tablet, which is in the form of a cylinder, placed between the platens of a loading system. Under conditions of ideal line loading, the values of tensile σ_1 , compressive σ_2 , and shear stress τ can be calculated by elastic theory (2) and are illustrated in Fig. 1. The value for the maximum tensile stress σ_0 is constant over the whole of the load diameter and has a magnitude:

$$\sigma_0 = \frac{2P}{\pi Dt} \quad (\text{Eq. 1})$$

where

P = applied load
 D = tablet diameter
 t = tablet thickness

The values for the compressive and shear stresses are a minimum at the center of the load diameter and infinitely high immediately under the load points (Fig. 1). These high values for shear and compressive stresses will prevent the initiation of failure in tension. In practice, ideal line loading will never occur, the load will be distributed over an actual contact area. The stress distribution across the load diameter, when the contact

(b) Relative magnitude of tensile σ_1 , compressive σ_2 , and shear τ stresses compared with maximum tensile stress σ_0 . Curve i = σ_1/σ_0 ; Curve ii = τ/σ_0 ; Curve iii = σ_2/σ_0 . P = applied load.

width is $1/10$ of the specimen diameter and uniform contact pressure is applied, calculated from elastic theory (2), is shown in Fig. 2. The tensile stress is constant over most of the load diameter, except for the regions near the loading area, but the shear and compressive stresses have been considerably reduced in this area. Thus, it is possible to have failure of the specimen initiated in tension, and the tensile strength can be calculated from Eq. 1. In practical terms, therefore, to obtain tensile failure of constant magnitude, the conditions of the test must ensure that a maximum length of the load diameter is under constant tensile stress, associated with minimum values for shear and compressive stresses, below the loading area.

The mechanical properties of the specimen and load platens determine the stress distribution within the specimen (3). In the case of pharmaceutical tablets compressed between metal platens, tablets are often soft compared with the platens. Hence, there will be a spreading of the load at the contact points due to flattening of the tablet, preventing line loading and reducing shear and compressive stresses. Under these conditions, failure will occur in tension and the results should be reproducible, providing that distribution of the load is not so great that the stresses within the central portion of the tablet are affected. When, however, tablets have a high elastic modulus, the conditions of ideal line loading are approached, and failure may be initiated by shear or

P = applied load.

compression. To obtain the correct conditions for tensile failure of such specimens, a narrow pad of a soft material is placed between platens and the specimen (3–6). The pad should be soft enough to allow distribution of the load over a reasonable area, minimizing shear and compressive stresses but not so soft that the distribution of load is excessive. Various suggestions have been made for the type and dimension of padding (4–6). Rudnick *et al.* (3) consider that the choice is best made from experimental observation, the type of failure being recognizable by examination of the specimen after testing. The three types of failure listed by these workers (3) are: compression and/or shear failure—here the specimen fractures in an irregular manner resulting in several irregular fragments; normal tensile failure—here the specimen splits into two halves along the loaded diameter; and triple cleft failure—the specimen splits symmetrically about the loaded diameter into four pieces. The tongue and groove shape of the outer surface and a clean central fracture are characteristics of the last method of failure. Rudnick *et al.* (3) consider this type to be a variation of the normal tensile fracture due to experimental conditions, and data from such systems can be used to calculate tensile strength. These three types of failure are illustrated by the photographs of tablets subjected to diametral compression (Fig. 3).

The applications of these principles to the determination of the strength of tablets prepared from lactose are reported in this paper.

EXPERIMENTAL

Materials—The samples of lactose used were: (a) a $< 32\text{-}\mu$ size fraction from a single batch of crystalline lactose (British Drug House laboratory reagent grade), (b) spray-dried lactose A, a $< 32\text{-}\mu$ size fraction from a single batch of spray-dried lactose (McKesson Robbins), and (c) spray-dried lactose, Samples B, C,

and D, which were produced under known conditions using an experimental spray drier.

Methods—*Compression of Tablets*—Tablets of the different samples of lactose were prepared on an Instron physical testing instrument, floor model, modified to take a conventional tablet punch and die system [1.27-cm. (0.5-in.) diameter flat-faced punches] (Fig. 4). The powder samples (0.5 g.) were dried at 90° for 15 hr.

^a The variance ratios are expressed as the ratio of the largest to smallest variance according to normal statistical convention ("Statistical Analysis in Chemistry and Chemical Industry," by C. A. Bennett and N. C. Franklin, John Wiley, New York, N. Y., 1954, p. 109). A significant difference, at 0.05% level, in the variance ratio is indicated by underlining the value.

and then stored in a desiccator over silica gel until required. The samples were quickly transferred to the die, previously painted with a 1% suspension of magnesium stearate in carbon tetrachloride, and compressed at a crosshead speed of 0.1 cm./min. When the required

load level had been reached, the crosshead was reversed at the same speed. The tablets were carefully removed from the die, weighed, their diameter and thickness measured using a micrometer, and stored in a desiccator over silica gel until required. Tablets at a range of compression loads were produced.

Strength of Tablets—The tensile strength of the tablets was measured by the application of the diametral-compression test described previously (1). This test consisted of compressing tablets diametrically between the platens of an Instron physical testing instrument at the rate of 0.1 cm./min. Tablets prepared from crystalline lactose and spray-dried lactose A fractured in tension between the steel platens of the Instron physical testing instrument (Fig. 3A). Tablets prepared at loads above 500 kg. from spray-dried lactose B, C, and D, however, fractured as described by Rudnick *et al.* (3) as compression or shear failure (Fig. 3B). To ensure that these tablets fractured in tension, various padding materials, e.g., various thickness of paper, cardboard, and blotting paper, were placed between the tablet and the steel platens and the mode of fracture observed. Of the materials tested, it was found that three sheets of blotting paper, each 0.03 cm. thick, produced the conditions which resulted in tensile failure of the specimens. The breaking load of five tablets of each sample of lactose was determined with and without the addition of padding material.

RESULTS AND DISCUSSION

The assessment of the strength of tablets is an important aspect of the control of pharmaceutical tablets and investigations into the process of compaction. Various techniques have been used including fracture resistance (7), bending strength (8), tensile strength (9),

Figure 5—The tensile strength of tablets of crystalline and spray-dried lactose A, prepared at known compression forces, when tested in the absence and presence of padding material. Key: X, crystalline lactose; O, spray-dried lactose A; ---, in the presence of padding material; and —, in the absence of padding material.

and crushing strength (10). Of these tests, the crushing strength is extensively used and most commercial instruments are designed to be used for this particular assessment. Brook and Marshall (11) have recently investigated the variability of such instruments, which record in different ways the load at which the tablet breaks when compressed by some means between two metal surfaces. The distribution of forces within the tablet and the related mode of fracture when tablets are tested by this procedure have not, however, been taken into account. In many cases, fracture can occur by tensile failure, resulting from correct stress conditions in the tablet. Here, variation in strength values will be due to tablet and testing instrument variation. In other cases, however, conditions of tensile failure will not apply, resulting in an additional variable of uncertain magnitude. The importance of considering the mode of fracture can be seen from the introductory remarks on the distribution of forces within the test specimen. When tablets do not break in tension in a diametral-compression test, variation in the breaking load can occur, caused by variations in the relative shear, compression, and tension forces involved. This effect is illustrated in Table I where the mean values of the breaking load of compacts when subjected to the diametral-compression test are recorded. Also given are the variance and variance ratio of the results when the tablets are tested with and without the presence of padding between the platens and the tablet. The important feature of the results is that when failure of the tablets occurs in tension, irrespective of the test conditions, there is always a low variance of the value of the load at which the tablet breaks (Table I). There is usually no significant difference, at the 5% level, between the variance of the breaking load with and without padding. When tablets do not break in tension (spray-dried lactose B, C, and D), there is a high variance of the breaking load and a significant difference in the variance of the breaking with and without padding (Table I). Only when the tablets break in tension is it possible to apply Eq. 1 and express the results for tablet strength as tensile strength.

Introduction of too soft a padding can, in fact, have the opposite effect to that just noted. Rudnick *et al.* (3) predicted from statistical theory that the amount of material subjected to a maximum tensile stress is greater when a hard rather than a soft contact surface is used. This would result in a lower strength and variance when a hard contact surface is used. This prediction was confirmed experimentally by Addinall and Hackett (12) in a detailed study of the effect of different packing pieces on the tensile strength of autoclaved plaster. The results in Fig. 5, which show the tensile strength calculated from Eq. 1, confirm these findings. The tensile strength of compacts prepared from crystalline lactose and spray-dried lactose A increased when padding was introduced. There is also a slightly greater variance of the breaking load when padding is present. In the presence or absence of padding, all tablets of these two materials fractured in tension. This raises the question as to which of the values represents the tensile strength of the tablet. Rudnick *et al.* (3) consider that there is no such value as a true tensile strength, but values obtained under any conditions are true values for those conditions. If it is required to compare the tensile strength of tablets, the conditions of the test must be the same, and tensile failure must be assured in all cases. Thus, to compare tablets prepared from spray-dried lactose B, C, and D with

crystalline and spray-dried lactose A, the results in which a padding was used must be considered. For comparisons between tablets of crystalline and spray-dried lactose A, the values without padding are preferable.

A further consideration in the choice of test conditions is the actual strength of the tablets. Thus, tablets produced at low-compression forces, producing weaker tablets, often failed in tension without the need for padding. Therefore, if the tablets have a low tensile strength, it is unlikely that padding will be required.

CONCLUSIONS

The authors consider that the results indicate that it should be possible to choose test conditions, ensuring their validity by simple observation of the mode of fracture, which will improve the reproducibility of the assessment of the strength of tablets and enable meaningful comparisons to be made between the strength of tablets of different materials. For routine evaluation the results need not be expressed in terms of tensile strength, the breaking load under conditions of tensile failure being satisfactory.

Dissolution Rate Studies I: Design and Evaluation of a Continuous Flow Apparatus

JAMES E. TINGSTAD and SIDNEY RIEGELMAN

Abstract ☐ An apparatus for the study of dissolution rate under conditions of continuous flow is described. Typical data are presented; the effect of sample size, surfactant, and flow rate on the dissolution behavior of prednisone powder and prednisone tablets is shown. The requirements of an ideal standard method for studying dissolution rates are discussed, and the major advantages of this method over present methods are pointed out. The method: (a) is more flexible, (b) produces data in a differential form, (c) utilizes a small-volume system which assures greater homogeneity, (d) prevents excessive accumulation of solute in the system, and (e) provides agitation and solvent flow in a controlled, measurable, and physically meaningful manner.

Keyphrases ☐ Dissolution apparatus—design, evaluation ☐ Diagram—dissolution apparatus ☐ Prednisone—dissolution rate profile ☐ Surfactant concentration effect—prednisone dissolution ☐ Sample size effect—prednisone dissolution ☐ Flow rate effect—prednisone dissolution

There is little doubt that the determination of dissolution rates is an important tool in the design, evaluation, and control of solid dosage forms. Parrott *et al.* (1) has stated: "The release of a drug from the primary particle and its subsequent availability to the body is governed by the dissolution rate of the particle." Nelson (2-4) also pointed to the significance of dissolution rate in determining drug availability in his series of publications on the dissolution rates of weak acids and bases and their salts.

For obvious reasons, it would be ideal if one relatively simple and inexpensive apparatus and method could be used to determine the dissolution rates of most drugs and drug products. However, standing in the way of the one-method concept is the fact that a great variety of factors influence the results obtained from dissolution rate tests. These include factors intrinsic to the products, such as physical-chemical properties of the drug and the variations in the composition of the formulation, and factors extrinsic to the products, such as the type and volume of solvent, the degree, type, and uniformity of agitation, the geometry of the container, the state of homogeneity existing in the system, and adsorption or adherence of the drug to solid surfaces of the apparatus. In light of these factors, a single method is feasible only if it has adequate flexibility to allow sufficient controlled variation of experimental conditions to ensure, regardless of what drug is studied, that the results will reflect primarily the intrinsic variables rather than the extrinsic.

Flexibility is a necessary requirement for a standard dissolution rate method for another important reason. There is presently an acknowledged scarcity of data showing correlation between *in vitro* dissolution rates and *in vivo* absorption, but the great current interest and activity in this area indicate that more and more data will be forthcoming. As the knowledge in this

area accumulates, problems and deficiencies in the *in vitro* methods will come to light, necessitating changes in equipment and procedures. The more flexible the standard method is, the more easily such changes can be made to accommodate the new findings.

In addition to flexibility, there are two other basic requirements that a standard dissolution rate method should meet. It should yield accurate, meaningful, and reproducible data that can be quantitatively related to theoretical dissolution rate equations, and it should be sensitive enough to detect small differences among various drugs and among different formulations of the same drug. Unfortunately, present dissolution rate methods lack the necessary flexibility, their basic design introduces far too many uncontrolled variables into the dissolution process, their method of agitation cannot be quantitatively related to dissolution rate equations except by including it in the constant, and they produce data in such a way that only gross differences in formulations can be detected.

The serious deficiencies in these methods can best be shown by first looking at the Noyes-Whitney equation (5) which, in theory, describes the dissolution process: $da/dt = KS(C_s - C)$, where da/dt is the dissolution rate expressed as amount dissolved per unit time, S is the surface area of undissolved solute presented to the solvent, C_s is the concentration of solute in a saturated solution, C is the solute concentration in the bulk of the medium at any time, and K is a constant dependent on a variety of factors including the temperature, viscosity, pH characteristics, degree of agitation of the medium, and the diffusion coefficient of the solute molecules. While numerous attempts have been made to expand this equation to include various additional factors (6-9), none of these has led to an expression which adequately takes into account all the variables involved.

The dissolution process is particularly complicated when considering solid dosage forms. In the case of pure powdered drug, assuming immediate wetting, the surface area will continually decline as more and more particles dissolve. With capsules and tablets, however, the situation becomes more involved because, as they disintegrate or disperse in the medium, the amount of exposed surface area initially increases, going through a maximum and then decreasing in the conventional pattern.¹ How quickly a tablet disintegrates and the granules and drug particles disperse depends, among other factors, upon the composition of the formulation, the amount of pressure used in compression, the

¹ Wagner (10) has suggested an interesting statistical approach of the empirical linearization of the dissolution data using product or log product paper, which apparently takes into account the variation of dissolution surface area.

amount of entrapped air (which affects both the wetting and the bulk density of the particles), the volume of the liquid, the geometry of the container, and the degree and type of agitation.

Since these systems are so variable and complex, a dissolution rate method which seeks to meet the requirements listed for a universal method must help solve, not add to, the inherent problems involved in studying the dissolution process. Unfortunately, present methods are almost exclusively based on a static system involving solvent present in "bulk" form; the system is stirred by a motor-driven propeller or wire mesh basket or by a rocking device, and discrete samples are withdrawn and analyzed at various times (11). The basic disadvantages of these methods, inherent in the basic design, are: (a) a lack of flexibility, (b) a lack of homogeneity (caused by both the large volumes and agitation methods employed), (c) a variable concentration gradient, (d) a method of agitation that is semiquantitative at best and relates poorly to theoretical dissolution rate equations, and (e) the data produced tend to obscure the details of the dissolution process.

The inherent lack of homogeneity in these methods results from both the agitation methods and large volumes employed. Agitating the liquid by stirring with a wire mesh basket² or a propeller, or by a rocking motion, causes a variable shear rate of transfer over the surface of the particles, which results in excessive variations in their individual rates of dissolution. The movement of solvent over any particle will depend on the position of the particle in the vessel and the character of the stirring process at each position within the container.

The latter varies markedly with the geometry of the vessel, the volume of the liquid, and the speed and form of motion created by the agitator. While it is possible to standardize many of the geometric and mechanical factors, nevertheless the agitation varies at different positions in the container. In addition, various sized granules and particles disperse differently throughout the system. While a tablet is disintegrating, the granules tend to collect at the bottom of the container, the remainder of the tablet is in the basket in the center of the system, some of the granules are stuck in the screen, and the fine particles are dispersed throughout the medium. As a result, the apparatus introduces an inherent variability into the dissolution process, a variability that is extrinsic to the product under study, and one which cannot be eliminated merely by standardizing the procedure.

The lack of homogeneity caused by the agitation methods could be minimized by keeping the volume of the system small (e.g., 50 ml. or less), but this is not feasible with present methods. As mentioned earlier, the basic equations describing the dissolution process include a term for concentration gradient ($C_s - C$), and since C_s remains constant, it is important that C (the solute concentration in the bulk of the system) be kept as low as possible. With the present static methods, and considering the low solubility of many drugs, using

small volumes would result in a significant increase in C as the experiment progressed.

There is another reason why it is important to keep C as low as possible. The ultimate objective in dissolution rate studies is to discern dosage form effects that may later influence the absorption of the drug within the gastrointestinal tract. In the *in vivo* situation, the dissolution process most likely takes place from particles adhering to or very near the mucosal surface. Therefore, the diffusional pathway to the absorption site is very short, and the drug molecules are almost instantly absorbed into what is, for all practical purposes, a perfect sink—the body fluids. Consequently, the chances of achieving good *in vitro-in vivo* correlations in this area are better if the *in vitro* system more closely approaches these perfect sink conditions.

The need for such a perfect sink (i.e., a relatively large volume of solvent) necessitates using a relatively high rate of agitation. But studies of Levy *et al.* (13) have shown that quite often the rate of agitation must be kept low in order to establish meaningful *in vitro-in vivo* correlations. In addition, it is often necessary to use low agitation in order to detect subtle differences between formulations. But low agitation of a relatively high-volume system results in poor homogeneity, and the sample withdrawn for analysis might not be representative of the whole system. Thus, an inherent disharmony exists in these systems between the requirements for homogeneity, large volumes, and low stirring rates.

A further disadvantage of present methods has to do with the empirical nature of stirring or rocking as a device for ensuring homogeneity and moving solvent/solute molecules. Since these agitation methods are empirical, they cannot be related to fundamental dissolution rate equations except by including them in a catchall constant, which is a very superficial solution to the problem. This makes it critical that the various test systems be standardized as much as possible—one stirring rate, one type of container, one volume of solvent, *etc.* But this greatly reduces investigative flexibility, which is a prime requisite for a good standard method, as pointed out previously. Furthermore, the results obtained with such rigid standard procedures will be less and less quantitative and meaningful as drugs of lower and lower solubility are studied, because at fixed volumes the concentration gradient will vary more significantly. And yet it is precisely these drugs that are often most important to study from a drug availability standpoint.

There is one other disadvantage of present methods which should be mentioned. Because they are based on a concept of a static fixed volume, they produce data expressed as an integral function. That is, since the dissolved molecules are accumulating in the solution, the resultant data represent an integral function of the dissolution process rather than a differential function. Thus, these methods produce average dissolution rates at best, and this makes it difficult to detect subtle but possibly important differences in formulations. In other words, two formulations may differ significantly in their dissolution rate behavior; but with present methods these differences would be, in effect, hidden under the

² This refers to the proposed USP-NF Dissolution Test, Method I (12).

Figure 1—Sketch of the dissolution rate apparatus. Arrows indicate direction of solvent flow.

integral curve representing the accumulated drug dissolved up to that time. This will become more apparent in viewing the following experimental results.

In light of the serious deficiencies in present methods, it is apparent that a new "standard" dissolution rate method is needed, one that: (a) has a much higher degree of flexibility, (b) yields data in a differential form which can then be converted to the integral form if desired, (c) utilizes a relatively homogeneous low-volume system, (d) prevents excessive accumulations of solute in the system, and (e) provides solvent flow in a controlled, precise, measurable manner which can be mathematically related to fundamental dissolution rate equations. This communication describes just such an apparatus and method, the basic idea for which was first suggested by Olson (14) and subsequently investigated by Hamlin and Rowe (15) and Langenbucher (16). The apparatus described herein is very similar to that used by these previous workers, with certain modifications.

EXPERIMENTAL

Description of Apparatus—The apparatus is described in Fig. 1. The dissolution cell is a glass cylinder 6.1 cm. long, 1.9 cm. in diameter, and has a volume of 17 ml. This cell was constructed from two small-volume glass filter funnels (Millipore catalog number XXLO-025.00), cut down in height and attached back to back. This allows use of filter membranes of sufficient retentive characteristics to limit the dissolution process to the dissolution cell and prevent solid particles from reaching the spectrophotometer. The dissolution chamber can be dismantled, cleaned, and dried for subsequent determinations with minimal effort. The pump is a centrifugal constant-capacity pump (Cole-Parmer) of low cost. The solvent flow to the system is controlled by external valves, with the excess capacity of the pump being recirculated to the reservoir from which the pump draws the solvent. The flowmeter is a Gilmont size 3 and the filters (shaded area) are standard coarseness sintered glass. The spectrophotometer (Beckman model

DB) has an attached recorder. The air trap prevents air bubbles from distorting the spectrophotometric reading.

General Procedure—The dissolution cell and the filters are thoroughly cleaned of residue from the previous run and the apparatus is assembled. The pump is then turned on and the entire system flushed with solvent until the spectrophotometric reading recedes to zero (a few minutes). Then the dissolution cell and the filters are disassembled and dried, and the sample (in these experiments, a tablet or weighed quantity of powder) is placed on the lower filter. The dissolution cell is then clamped into place and the upper filterpiece/air trap attached with a similar clamp. The apparatus is then submerged in a constant-temperature bath, including the flowmeter, lower filter, dissolution cell, and the lower part of the upper filterpiece/air trap. The solvent reservoir and as much connecting tubing as possible are also in the bath. As soon as the cell has reached the bath temperature, the pump is turned on and the flow regulated to the desired flow rate, which is then held constant. At lower flow rates, the flow remained constant; at higher flow rates, occasional adjustments in the valve system were necessary to maintain a constant flow rate. The air outlet, open when the pump is turned on, is closed as soon as the liquid level in the air trap is above the outlet tube to the spectrophotometer. The absorbance is continuously recorded on the strip chart, and the "waste" solution is either discarded or saved in an appropriate receptacle.

For these experiments, prednisone USP³ (screened 80 mesh) and prednisone tablets USP, 5 mg.,⁴ were studied using as solvents either distilled water or various aqueous solutions of sodium lauryl sulfate USP. The bath temperature was $25.0 \pm 0.1^\circ$. The absorbance was read at 239 m μ using a 1-cm. cell and a molar absorptivity of 15,500. In the concentration ranges studied, the Beer-Lambert law was found to be valid. All determinations were in duplicate. The following experiments were performed primarily to test the usefulness of this apparatus and method. More complete and detailed studies, where the emphasis is on investigating the dissolution process rather than evaluating the method, are in progress.

Effect of Surfactant Concentration—The dissolution behavior of a 5-mg. sample of prednisone powder was studied using various concentrations of sodium lauryl sulfate in distilled water as the solvent. The flow rate was 20.2 ml./min.

Effect of Sample Size—The dissolution behavior of various sized samples of prednisone powder (5, 10, 15, and 20 mg.) was studied using 0.02% w/v sodium lauryl sulfate as the solvent. The flow rate was 20.2 ml./min.

Effect of Flow Rate—The dissolution behavior of 5-mg. prednisone tablets was studied using distilled water as the solvent and varying the flow rate between 10 and 54 ml./min.

RESULTS AND DISCUSSION

Typical dissolution curves for prednisone powder (upper plot) and prednisone tablets (lower plot) as recorded on the strip chart are reproduced in Fig. 2. The tracings are presented for illustrative purposes. No quantitative comparison of the two should be made, since different experimental conditions were used (tablet: 5 mg. prednisone and water as the solvent; powder: 10 mg. prednisone and 0.02% sodium lauryl sulfate as the solvent; in both cases, the flow rate was 20.2 ml./min.). The curves record absorbance, but this is easily converted to dissolution rate (mg./min.) by converting absorbance to concentration (mg./ml.) and multiplying by flow rate (ml./min.).

The roughness of the tablet curve, contrasted with the smooth curve for the powder, is not surprising, since the granules in the tablet do not release the drug at an even rate. Figure 2 shows that a very meaningful and revealing quantitative "dissolution rate profile" (a continuous tracing of the differential function) can be directly obtained with this method. Such a profile has obvious advantages in the development, evaluation, and control of solid dosage forms. The profile gives the formulator and the control analyst a good closeup view of how the tablet or capsule is performing in the dissolution system.

Figure 2—Typical dissolution rate curves for prednisone powder (upper plot) and prednisone tablets (lower plot) as recorded on the spectrophotometer strip chart.

The tablet curve in Fig. 2 shows that a definite maximum dissolution rate is reached. In these experiments the peak dissolution rate correlates reasonably well with the total amount of drug dissolved at the end of 5, 10, and 15 min. The total amount of drug dissolved (the integral of da/dt) was obtained by cutting out and weighing the area under each curve. Figure 3 shows the correlation between peak dissolution rate and amount dissolved in the first 15 min. in the tablet experiments. Since (as expected) the values for the integral were more reproducible than the peak dissolution rate, the area under the curve for various time periods was used in subsequent plots.

Effect of Surfactant Concentration—When first working with prednisone powder using water as the solvent, it was observed that the powder agglomerated into one mass in which a considerable amount of air was entrapped. The problem was greatly reduced by including a surfactant in the solvent, but concentrations had to be kept low because of excessive foaming. Wetting was not complete at the highest (0.05%) concentration employed. The influence of surfactant (Fig. 4) emphasizes that the dissolution processes (as commonly considered) is really a combination of two distinct processes: wetting of the solid and subsequent dissolution. As long as the powder is not completely wet, the effective surface area can be considerably less than the total surface area, because a significant amount of the solid is involved in solid-air and solid-solid interfaces rather than in a solid-liquid interface. In such cases, attempts should be made to wet the sample first before trying to perform highly definitive quantitative dissolution rate studies. The desirability of considering the wetting process in dissolution rate studies has been emphasized by Finholt (17).

Since the amount of sodium lauryl sulfate used in the system is

Figure 3—Plot illustrating the correlation between peak dissolution rate and amount dissolved in the first 15 min. for prednisone tablets.

Figure 4—Plot showing the effect of the sodium lauryl sulfate (SLS) concentration on the dissolution behavior of prednisone powder. The amount dissolved represents the area under the curve for the first 5 min.

well below the critical micelle concentration ($\sim 0.2\%$), it is likely that the surfactant used in these experiments had negligible effect on the saturation solubility of the prednisone. While surfactant solutions were used in studying the dissolution behavior of prednisone powder, water proved to be satisfactory for the tablets.

Effect of Sample Size—As mentioned earlier, it is important to keep the concentration of dissolved drug well below saturation. This will depend upon the dissolution rate, the solubility of the drug, and the flow rate. To get some indication of the degree of saturation in these systems, the sample size was varied in the prednisone powder studies and its effect on dissolution rate observed. If the system was close to saturation, increasing the sample size would have only a small effect on the dissolution rate because the concentration gradient ($C_s - C$) would rapidly disappear.⁵ Figure 5 shows this effect on the total amount dissolved in 5 min., using sample weight to the two-thirds power as the abscissa. While this coordinate is not entirely accurate (it assumes that the solid is composed of uniform spheres), it does suffice to show that added surface area does significantly increase the dissolution rate, a clear indica-

Figure 5—Plot illustrating the effect of sample size on the dissolution behavior of prednisone powder. The amount dissolved represents the area under the curve for the first 5 min.

⁵ With this flow method, ($C_s - C$) would remain essentially constant using a constant surface pellet. With tablets, powders, etc., the concentration gradient does not remain constant, but the continuous flow of fresh solvent into the system will help keep the concentration gradient at a high level.

Figure 6—Plot showing the effect of flow rate on the dissolution behavior of prednisone tablets. The amount dissolved represents the area under the curve for the first 15 min.

tion that the system is not close to saturation. This was confirmed by determining, in a separate experiment, that these systems were about one-tenth saturated. It should be pointed out that the flow rate in these studies was 20.2 ml./min. It is desirable to repeat this study at lower flow rates for various systems, since the lower the flow rate, the more critical the problem with saturation. However, these experiments have been deferred until more modifications have been made in the equipment.

This emphasizes the flexibility inherent in this method as compared to present methods. If two drugs had widely different solubilities, present methods would dictate changing the volume of the system (i.e., the "dissolution chamber") and the stirring rate (to retain some measure of homogeneity), which would very likely result in a major change in many undefinable variables. With the authors' flow method, drugs of different solubilities can easily be accommodated simply by changing the flow rate (a clearly defined and easily measured parameter) and the amount of solvent used; the size of the dissolution cell would remain the same. While it is true that such changes would produce some undefinable changes in the flow system, it is also true that such changes are very likely to be much less than with present systems.

Effect of Flow Rate—As mentioned, one of the major advantages of this method is that solvent flow around the solid can be carefully and quantitatively controlled. Solvent flow affects the dissolution process by: (a) physical abrasion of the solid, (b) affecting the solution concentration in the effluent, and (c) probably reducing the diffusion layer thickness around each particle. Thus, flow rate, a physically relatable parameter, affects dissolution rate in a quantitative, definable way. Precisely what that effect is must await further studies, but Fig. 6 illustrates that flow rate does, in fact, have the expected significant effect on dissolution rate.

While the development of this apparatus is in its initial stages, it is apparent that the basic design offers many advantages over present methods, many of which have already been discussed. The vertical alignment of the dissolution cell helps ensure that the liquid flow through the cell will be reasonably homogeneous, even when flow rates are very low or comparatively high. Of course, some inherent variation still exists in the flow method because: (a) at times it may be necessary to increase flow rate to the point where the flow becomes turbulent, and (b) the flow of solvent will not be exactly the same past each and every particle. However, it is obvious that such problems of deviations from ideal will be much less with a smaller, more homogeneous system such as the authors' flow system. The small (17 ml.) volume of the system also ensures homogeneity. If a change of solvent pH is desired in the same experiment (simulating the *in vivo* change from stomach to duodenum), this can quickly and easily be done by switching from one reservoir to another. In contrast, this would be a major problem with present methods.

The number of definitive studies on the apparatus has been minimal, but even with the limited data gathered to date, several postulates arise:

1. The ascending curve for a tablet represents the disintegration

and dispersal processes, although they still continue after the peak dissolution rate is reached.

2. At a fixed flow rate, the maximum dissolution rate and/or the time needed to achieve maximum dissolution rate may be useful parameters for comparison of tablet additives relative to the pure (wetted) powder.

3. The descending curve appears to be exponential in shape and, therefore, it may be possible to express the slope in terms of a rate constant or a half-life.

It should be emphasized that the described apparatus is a prototype, and numerous improvements are both possible and probable as more experience is gained. For example, as Langenbucher (16) points out, the cross-sectional area of solvent flow is a variable that must be taken into account. It is also probable that the volume of the dissolution cell should be reduced to a minimum to optimize homogeneity of the system. Fortunately, with this method, reducing system volume is no problem; cell size is limited only by the physical size of the sample and the need to keep the filters of sufficient cross-sectional area to avoid excessive clogging. In addition, the size and shape of the air trap should probably be altered toward a minimum size and optimum shape, because any mixing and pooling of solution beyond the dissolution cell tend to distort the spectrophotometric tracing. An inexpensive integrator can easily be attached to the spectrophotometer to obtain the integral curve as well as the differential tracing.⁸ It would be better if the solvent flow was electronically controlled to keep flow rate constant automatically. Finally, the system should lend itself easily to automation.

But despite the preliminary nature of this work, there is little doubt that, based on theoretical considerations, and the results of these experiments, this method is far superior to present methods both for fundamental and practical studies. It is by far the best candidate for a "standard" method among the presently available procedures. Not only is it superior to present methods, but it possibly has the inherent flexibility that may allow it to meet, with appropriate modifications, most or all of the requirements listed for the ideal dissolution rate method.

⁸ With present dissolution rate methods, the integral curves obtained can be differentiated by appropriate means, but these would be only average figures unless measurements were made on a continuous basis—and this requires a flow system. But for continuous measurement, the homogeneity of the system becomes even more critical for assay purposes, and it is likely that stirring rates would have to be increased.

Automated Fluorometric Procedure for Unit Dose Analysis of Digitoxin and Digoxin in Tablet Formulations

L. F. CULLEN, D. L. PACKMAN, and G. J. PAPARIELLO

Abstract □ A sensitive and specific automated procedure is described for the unit dose analysis of digitoxin and digoxin in tablet formulations. The technique is based on the fluorometric measurement of the dehydration products of the cardiotonic steroids, resulting from their reaction with hydrogen peroxide in concentrated hydrochloric acid. The automated system is capable of analyzing 12 tablets per hour with a relative standard deviation of $\pm 1.4\%$ at the 0.05-mg. digitoxin level. Accuracy of the procedure was determined by collecting comparative data on digitoxin tablets by both the automated method and the manual USP procedure. Specificity of the method, with respect to the analysis of intact digitoxin in the presence of the products of photochemical, alkaline hydrolytic, and thermal degradation, was demonstrated by comparison to quantitative TLC values. This method has also been shown to be applicable to the unit dose analysis of digoxin in the 0.02 to 1.0 mg./tablet range.

Keyphrases □ Digitoxin—automated fluorometric method, tablets □ Digoxin—automated fluorometric method, tablets □ Automated methods—digitoxin, digoxin, unit dose analysis in tablets, diagram □ Automatic analyzer—diagram, digitoxin, digoxin determination □ TLC—analysis

Determining the precise amount of digitoxin in tablets is of the utmost interest to the pharmaceutical industry. These tablets are of low dosage, *i.e.*, 0.05–0.20 mg. per tablet, and, consequently, require unit dose analysis as a control on the homogeneity of the product. An attempt was made to automate these unit dose assays to gain the advantages of reproducibility, rapidity, and sensitivity offered by an automatic analyzer system.

Khoury (1) described an automated sulfuric acid-induced fluorescence method for the single-tablet analysis of cardiac glycosides. However, it was found that this procedure was not applicable to the analysis of digitoxin tablets which contain sugars and dyes. Since these interfering inactive components are common formulating materials, the present investigation was undertaken to develop a technique which would overcome these shortcomings.

The majority of the analytical methods reported for the quantitative determination of digitoxin are either colorimetric (2–9) or fluorometric (10–12). The colorimetric procedures did not exhibit the necessary sensitivity or specificity for single-tablet analysis at the normal digitoxin dosage levels. Thus, fluorometric procedures were investigated.

Wells *et al.* (12) presented a sensitive and specific fluorometric method for the analysis of digitoxin and digoxin in biological fluids and tissues. The technique is based on the fluorometric measurement of the dehydration products of the cardiotonic steroids resulting from the reaction of the glycosides with hydrogen peroxide in concentrated hydrochloric acid. Detailed discussions of the influence of time, temperature, and reagent concentrations on the excitation and emission properties of

the glycosides and the mechanism of fluorescence formation were described by Wells *et al.* (12) and also Jelliffe (13). This procedure has been adapted and modified for continuous analysis by use of an automatic analyzer system.¹ Applicability of this method to the unit dose analysis of digoxin in the 0.02–1.0 mg. per tablet range requires only a simple change in the fluorometer filter system.

EXPERIMENTAL

Apparatus—A standard Technicon automatic analyzer system consisting of the following modules: (a) solid-prep sampler, programmed at 12 samples/hr.; (b) proportioning pumps² (two required); (c) continuous filter, speed 2; (d) fluorometer,³ equipped with fluorescent lamp (Turner 110-853), quartz flowcell,⁴ and filters: digitoxin analysis, primary—Corning⁵ No. 7-59 and secondary—Wratten⁶ No. 8; digoxin analysis, primary—Corning No. 7-60 and secondary—Wratten No. 3; and (e) linear recorder.

Reagents and Solutions—(a) Seventy percent SDA No. 30 alcohol (ethanol-methanol, 10:1) in water (v/v); (b) concentrated hydrochloric acid; (c) 0.1% ascorbic acid in methanol; (d) 0.065 *M* hydrogen peroxide in methanol (prepared by adding 1.0 ml. of reagent grade 30% hydrogen peroxide to 200 ml. of absolute methanol)—this reagent should be prepared fresh daily and maintained in an ice bath on the automated manifold; and (e) standard digitoxin and digoxin solutions—prepare a 0.5 mg./ml. solution of analytical reference standard⁷ digitoxin or digoxin in 70% denatured alcohol were used. The standard calibration curve is derived from a series of diluted solutions ranging in concentration from 0.05–0.25 mg./ml.

Automated Methodology—A diagram of the flow system indicating the automated equipment arrangement for the analytical procedure is shown in Fig. 1. In performing the analyses, three standards of the appropriate levels of the cardiotonic steroid are placed on the sample plate, followed by samples of the intact or powdered tablets. At the end of a series of 12 samples, two standards are inserted to minimize the effects of reagent changes and instrumental variations. Samples are introduced into the solid-prep unit, programmed at 12 samples/hr. with its diluent volume precalibrated to deliver 150 μ l., and homogenized in the 70% denatured alcohol. During the period of homogenization, the sample is diluted and dissolution of the drug occurs. A portion of the mixture is aspirated into the flow system and automatically filtered to remove insolubles. To prevent mechanical obstruction from the insoluble excipient materials at the tubing connections, a decantation trap is placed between the solid-prep unit and the proportioning pump to remove the majority of the solid matter, thus extending the operational time of the automated system before a breakdown period is required. The residual insolubles are removed by the continuous filter module. After passage through the filter module, the filtrate is segmented with air and then combined with streams of the ascorbic acid reagent, concentrated hydrochloric acid, and the hydrogen peroxide reagent. The sample stream is passed through time-delay coils to permit complete fluorometric development. Since

a slight fluctuation in the temperature of the final solution at the time of sample measurement in the flowcell has a significant effect on the noise level in the sample response, it is necessary to introduce a water-cooled mixing coil into the system prior to the entrance of the sample stream into the flowcell. The constant and controlled temperature of the final solution results in a significant increase in the precision of the procedure by eliminating the noise in the sample response. Calculations are made using corresponding fluorescent intensities of standards and solid dosage formulation samples.

Under the exact analytical conditions described, digitoxin exhibits excitation and emission wavelength maxima at 395 and 570 $m\mu$, respectively. Excitation and emission wavelength maxima for digoxin are 350 and 490 $m\mu$, respectively. These wavelength maxima are centered well within the optimum spectral transmission characteristics of the selected filters. Spectral measurements were made on a Farrand spectrofluorometer,⁸ following preparation of the samples with the automatic analyzer flow system. The spectral data are in exact agreement with those reported by Wells *et al.* (12).

TLC System—Silica gel GF precoated glass plates (10 × 20 cm. with a 250- μ adsorbent layer)⁹ were activated by heating at 105° for 20 min. prior to use. The chromatogram was developed in a saturated

chamber with a benzene-95% ethanol (7:3, v/v) solvent system. When the solvent front ascended approximately 15 cm. from the origin, the plate was removed and air-dried. Visualization was effected by spraying the plate with chloramine-trichloroacetic acid reagent (14) and heating at approximately 105° for 10 min. Following this heating period, the plates were inspected under shortwave (253.7 $m\mu$) and longwave (366.0 $m\mu$) UV light.

RESULTS AND DISCUSSION

Suitability as Stability Method—Specificity of the method for analysis of intact digitoxin in the presence of its photochemical, alkaline hydrolytic, and thermal degradation products was demonstrated by comparing analytical values of intentionally degraded samples to those obtained by quantitative TLC. In the TLC procedure, the digitoxin was separated from its degradation products on the chromatographic plate. A zone of the silica gel encompassing the intact digitoxin spot was scraped from the plate. The digitoxin was eluted from the adsorbent with 70% denatured alcohol and then assayed by the automated procedure to obtain a

^a Tablets analyzed were prepared by the following manufacturers: Wyeth Labs., Inc.; The Upjohn Co.; E. R. Squibb & Sons; Parke, Davis & Co.; Eli Lilly & Co.; Davies, Rose-Hoyt; and Abbott Labs. Companies are not necessarily listed in order as given above.

^b Data from a single assay on a 10-tablet composite sample.

quantitative value. The data obtained are summarized in Table I. Since there is good agreement between the values by the two techniques, it is concluded that the fluorometric procedure is stability indicating.

Linearity and Sensitivity—Figure 2 is a reproduction of an actual recording curve obtained by analyzing standards of digitoxin in the 0.05–0.20-mg. range. The uniformity of replicate analyses at the various concentrations and the return to the base line between samples, indicating no sample overlap, can be noted. When the values for the standards of Fig. 2 are plotted, a linear relationship exists between fluorescent intensity and digitoxin concentration in the range studied. This curve also contains a recording of the steady state, during which time a 0.20-mg. standard was continuously sampled, which further defines the excellent flow characteristics of this automated system.

In the application of the method to the analysis of digoxin samples, it was also observed that a linear relationship exists between fluorescent intensity and digoxin concentration (Fig. 3).

The flow diagram of Fig. 1 is applicable to the analysis of digitoxin and digoxin samples which initially contain 0.02–1.0 mg. of the cardiac glycosides. At the 0.02-mg. level, the final concentration of the drug in the flowcell is approximately 0.07 mcg./ml.

Precision—Repeatability of the automated technique was demonstrated by performing 30 replicate assays on aliquots of both

digitoxin and digoxin standard solutions. Relative standard deviations of ± 1.4 and $\pm 1.0\%$ were determined at the 0.05- and 0.20-mg. digitoxin levels, respectively, and $\pm 1.2\%$ at the 0.25-mg. digoxin level. In addition, a series of 20 replicate assays run on a composite sample of a tablet formulation at the 0.10-mg. digitoxin per tablet level produced a relative standard deviation of $\pm 1.0\%$.

Accuracy—The accuracy of the proposed procedure was evaluated by comparing the results obtained by the automated system with the manual USP XVII colorimetric procedure (9) on several different marketed digitoxin tablet formulations. Comparative results are shown in Table II. The agreement between the two techniques demonstrates that the automated method provides an accurate means of evaluating digitoxin content.

The effect of common inert tablet components on this fluorometric procedure for digoxin and digitoxin was investigated to uncover any possible interfering material. The inactive components evaluated were lactose, sucrose, calcium sulfate, magnesium stearate, stearic acid, alginic acid, microcrystalline cellulose (Avicel), ion-exchange resin (Amberlite IRP-88), methylcellulose (Methocel), and starch. It was found that none of these materials interfered.

Presented to the Technicon International Congress on Automated Analysis, Chicago meeting, June 1969.

Physical Chemistry of Ergot Alkaloids and Derivatives I: Ionization Constants of Several Medicinally Active Bases

H. V. MAULDING and M. A. ZOGLIO

Abstract □ A novel procedure is presented for determination of the ionization constants of several pharmacologically active naturally occurring ergot alkaloids and their congeners. For this purpose use was made of the complexation and consequent solubilization of these poorly soluble molecules by certain xanthenes with special emphasis on 7- β -hydroxypropyltheophylline. This method allows an approach to investigation of the approximate pK_a values of the proteinaceous alkaloids such as ergotamine which resisted the usual means available for measurement of dissociation constants. It is also illustrative of the weak attractive forces present in complexes of this nature.

Keyphrases □ Ergot alkaloids, congeners—ionization constants, determination □ Dissociation-constant determination—methodology □ Titration, aqueous—dissociation-constant determination

Difficulties were experienced on attempted evaluation of the ionization constants for various ergot alkaloids and their analogs. The insolubility of the bases in aqueous media has been discussed previously by the authors (1–3). This limitation is likewise encountered in ethanol–water solutions sometimes employed with apparent success in pK_a measurements (4). The alkaloidal base, ergotamine, exhibits little solubility in polar solvents such as ethanol and propylene glycol, and this is the situation with many related compounds. Ergotamine and other ergot alkaloids possess an UV spectrum but only small differences are discernible between the ionized species at pH 2 and the neutral species at pH 11, thus precluding this route for analysis of the ionization constants. Somewhat erratic solubility properties have been noted in this laboratory for ergot alkaloids and derivatives when the cyclic tripeptide moiety is intact, leading to a lack of precision and confidence in a pK_a obtained by this technique.

Preliminary investigations and previous communications (1–3) indicated an elevation in solubility of the neutral molecule as well as prevention of its precipitation upon inclusion of certain xanthenes. A study was undertaken to detect if this phenomenon would have applicability in measurement of ionization constants of these relatively complex molecules.

EXPERIMENTAL

Dissociation constants were determined by titration of the hydrochlorides or methanesulfonates of the bases in aqueous solution (0.005 mole of the methanesulfonate salt or 0.005 mole of the base solubilized by 5 ml. 0.1 *N* HCl in 92.5 ml. freshly boiled water) along with 10–20 g. 7- β -hydroxypropyltheophylline (see Table I). This solution was titrated with 10 equal increments (0.5 ml.) of

carbonate-free 0.1 *N* KOH. The pH was taken initially, following each portion of KOH titrant, and nine values for the ionization constant calculated in each case (5).

The same procedure was carried out with the two relatively soluble bases, methysergide and methylegonovine, except the xanthine was omitted.

MATERIALS

Ergotamine base was twice recrystallized from acetone–water (90 ml. acetone:10 ml. water); methysergide base was recrystallized four times from methanol–water (10 ml. methanol:40 ml. water), followed by drying at 50° (1 mm.) for 24 hr.

Other alkaloidal bases and methanesulfonate salts were chromatographically pure (traces of contaminants) and were dried overnight at 50° (1 mm.).

7- β -Hydroxypropyltheophylline, m.p. 135–138° (Ganes Chemical Works, Inc., New York) was used.

Tris(hydroxymethyl)aminomethane (THAM) (primary standard), pK_a = 8.18 at 20° (Fisher Sci. Co., Fairlawn, N. J.) was used.

The pH values were measured on a Metrohm pH meter using electrodes¹ standardized on 0.05 *M* potassium hydrogen phthalate (pH 4.0, 24°) and 0.05 *M* sodium borate (pH 9.20, 24°). All measurements were made at 24°.

RESULTS AND DISCUSSION

Utilization of mixed solvent systems in evaluation of dissociation constants for substances showing poor aqueous solubility has been made rather frequently since the procedure was first reported (6). Although this expediency should probably be avoided whenever

¹ Corning triple-purpose glass electrode No. 476020 and calomel electrode No. 476002, Corning Glass Works, Medfield, Mass.

possible (5), there are circumstances where it must be resorted to for obtaining anything resembling satisfactory pKa values.

It has been seen in this laboratory that ergotamine and other alkaloids of ergot having a cyclic tripeptide attached to the lysergic or isolysergic portions of the molecule generally exhibit low solubility not only in water but in many water-miscible solvents. This fact tends to complicate titrimetric analysis. Fortunately the ionization constants of protonated amines, such as dihydroergocristine methanesulfonate, are frequently little different in mixed solvents than in water alone.

Neutral xanthines possess the ability to solubilize the free alkaloids to some extent (1), and it was hoped by this means titration could be carried out. The xanthine, 7- β -hydroxypropyltheophylline, was chosen for extensive work because of its high water solubility relative to caffeine, theophylline, and others. The results of the study are listed in Table I.

The compounds in Table I have three or more nitrogen atoms present in their structures; however, only the ring nitrogen located in the tetrahydropyridine or hexahydropyridine moieties of the lysergic and isolysergic acid portions (7-9) need be considered in this work. The indole nitrogen (amine) in the lysergic or isolysergic acid fragment is weakly basic and of no consequence in normal pH ranges (7). The amide nitrogen present in methysergide and methylergonovine (Table I, Compounds 1 and 2) displays insignificant pH effect over the interval investigated, and this holds for the additional peptide nitrogens of the more complex molecules (Table I, Compounds 3-9).

The pKa values were calculated using the expression

$$\text{pKa} = \text{pH} + \log \frac{BH^+}{B} \quad (\text{Eq. 1})$$

where BH^+ = alkaloidal salt concentration (HCl or methanesulfonate) and B = alkaloidal base concentration. No correction was necessary for OH^- or H^+ ions in the range of pH's studied. KOH titrant was added in 10 equal increments and the pKa value obtained for each of the nine points (5). Results with a precision of less than ± 0.04 were rejected.

A slight perturbation of the ionization constant was evidenced with the more soluble compounds in Table I, methysergide and methylergonovine, on inclusion of xanthine. Since these materials have the capacity to complex as well as ergotamine and the other ergot derivatives studied (1-3), this parameter is present in all compounds under consideration. Measured pKa values for these two substances declined upon introduction of 7- β -hydroxypropyltheophylline in quantities of 2 to 30 g./100 ml. solvent. There was little change in the measured pKa (Table I, Column 3) following this initial drop of 0.1-0.2 units, 0.15 (± 0.05),² on addition of xanthine. Extrapolations of the data as a plot of pKa versus percent xanthine would certainly produce erroneous values. This may be seen in Fig. 1 in the case of methysergide, where extrapolation would lead to a pKa somewhat lower than it actually is. It may be noted in Fig. 1 that there appears this small initial alteration of the ionization constant on addition of the xanthine followed by a degree of leveling.

In some of the proteinaceous alkaloids, such as dihydroergocristine and dihydroergocryptine, the end values could be obtained for the previously stated equation before precipitation of the free base took place, where $BH^+/B = 39/1$ to $9/1$. In these instances the dissociation constants derived from these calculations were found to be greater by the previously stated increment, 0.15 (± 0.05)² than the observed pKa when sufficient xanthine was present to solubilize the alkaloid. The quantities of 7- β -hydroxypropyltheophylline used (Table I, Column 2) were those experimentally found to hold the base in solution. This lowering of the ionization constant occurred with THAM and remains fairly constant over a wide pro-

Figure 1—Plot of $-\log K_a$ (pKa) measured for methysergide (0.01 mole of HCl salt in 100 ml. water; precision of experimental results not indicated but greater than ± 0.03 in every case) against the concentration of 7- β -hydroxypropyltheophylline (g./100 ml.). Key: ○, pKa at zero xanthine concentration—thermodynamic pKa; and ●, measured pKa in presence of amount of xanthine indicated on abscissa.

portion of xanthine levels. Caffeine, theophylline, and other analogs give satisfactory results for many of these ergot derivatives when employed for pKa determination.

The numbers in Table I (superscript ²) are the corrected pKa values for Compounds 3-9 and are the best obtainable from available data. Each of these values is derived by addition of this factor² to the measured pKa (Column 3), excepting Compounds 1 and 2 where the thermodynamic ionization constant could be found by titration. Although no claim is made regarding their exactness, these values should closely approach the thermodynamic ionization constant.

This method offers a serviceable approach to determination of the ionization constants of the ergot alkaloids and derivatives of proteinaceous nature. It is extremely reproducible and easy to apply. The small effects demonstrated by rather large quantities of complexing agent on the pKa give more circumstantial evidence for the weak attractive forces present between the two types of molecules.

ACKNOWLEDGMENTS AND ADDRESSES

Received October 13, 1969, from the *Pharmacy Research and Development Department, Sandoz Pharmaceuticals, Hanover, NJ 07936*

Accepted for publication November 20, 1969.

The authors acknowledge the technical assistance of M. Wagner and V. Nieman.

² The value, 0.15 (± 0.05), does not refer to the precision of the experimental results but to a lowering of the pKa value by 0.1 to 0.2 on addition of xanthine. The precision of all values obtained with xanthine are listed in Column 2, Table I.

Physiological Studies on Ergot: Influence of 5-Methyltryptophan on Alkaloid Biosynthesis and the Incorporation of Tryptophan Analogs into Protein

J. E. ROBBERS and H. G. FLOSS*

Abstract □ Time-course studies were performed which compared the influence of 5-methyltryptophan to tryptophan on alkaloid formation in ergot strain SD-58. Evidence was obtained that confirms the role of tryptophan as an inducer of alkaloid synthesis. Additional studies were conducted to determine the incorporation into protein of the tryptophan analogs: 5-methyltryptophan, 7-methyltryptophan, and 1-*N*-methyltryptophan, when they are supplied exogenously to the fungus. Incorporation was observed; however, it was insignificant when compared to the amount of tryptophan incorporated.

Keyphrases □ Ergot alkaloid production—shake cultures □ Tryptophan, 5-methyltryptophan effect, alkaloid production—comparison □ Protein incorporation—tryptophan and analogs

The important role of tryptophan in ergot alkaloid biosynthesis has been clearly established. Floss and Mothes (1) have obtained data which suggest that tryptophan is also involved in an induction phenomenon besides serving as a precursor in the formation of the ergoline ring system. These workers found that tryptophan stimulates alkaloid formation when added at the beginning of the culture period but not when added after alkaloid production had started, that a variety of tryptophan analogs stimulate alkaloid production even though they are not incorporated into the alkaloids, and that mycelia grown in the presence of tryptophan or its analogs retain the ability to produce more alkaloid than the controls even after replacement into fresh culture medium.

One of the disadvantages of this earlier work was that the percentage increase in alkaloid production due to tryptophan analogs was small because these experiments were carried out with cultures that produced large amounts of alkaloids. By using a fully synthetic culture medium, it was thought that the effect of tryptophan and its analogs could be demonstrated more dramatically. Eliminating yeast extract from the medium reduces the growth of the organism to about one-fourth that of the complete medium; however, the amount of alkaloid produced per gram of mycelium is unchanged.

The purposes of this investigation were to study the induction phenomenon in a more precise manner over the time period in which alkaloid production is initiated in the fungus and to compare the effect of 5-methyltryptophan with that of tryptophan.

In the series of experiments previously mentioned, Floss and Mothes (1) also found uptake into the mycelia of radioactivity from the methyltryptophan analogs. However, the metabolic fate of the analogs was not determined except for nonincorporation into alkaloids. Recent studies by Lark (2) have shown that *Escherichia coli* can incorporate 5-methyltryptophan into protein. Consequently, the present authors have attempted to de-

Figure 1—Time-course study comparing the influence of tryptophan and 5-methyltryptophan on alkaloid production in *Claviceps* strain SD-58. Key: ●, control; ▲, tryptophan; and ■, 5-methyltryptophan.

termine if methyl analogs of tryptophan are incorporated into protein by the ergot fungus.

EXPERIMENTAL

Induction of Alkaloid Production—*Claviceps* strain SD-58 was grown for 5 days in shake culture in a medium containing the following ingredients: 50 g. mannitol, 50 g. sucrose, 5.4 g. succinic acid, 3.0 g. Difco yeast extract, 0.1 g. KH_2PO_4 , 0.3 g. $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$, 0.0044 g. $\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$, and boiled tap water, 1 l. The mycelia from one culture were placed into 0.01 *M* phosphate buffer and resuspended. Using aliquots of this suspension as inoculum, three groups of flasks containing the inoculum medium without yeast extract were prepared. One group of cultures also contained 4×10^{-3} *M* DL-tryptophan and a second group contained 4×10^{-3} *M* DL-5-methyltryptophan. A flask from each of the three groups was harvested every day starting at the 2nd day of growth. Quantitation of the alkaloids in the culture filtrate was effected by extracting the alkaline culture filtrate with CHCl_3 and redissolving the dried CHCl_3 extract in 2% succinic acid solution. This procedure prevented tryptophan and 5-methyltryptophan from interfering in the quantitation. A colorimetric determination was performed using van Urk's reagent (3, 4).

Analog Incorporation into Protein—Ergot strain SD-58 was grown in shake culture in the mannitol-sucrose-succinic acid-yeast extract medium previously described. Tritiated tryptophan, 5-methyltryptophan, 7-methyltryptophan, and 1-*N*-methyltryptophan were added, one to a culture, at the start of the growth period. The tritiated compounds were from the same source as in a previous study (1). On the 3rd and 6th days of growth the mycelia were removed by filtration and dried. The protein was extracted from the mycelia using trichloroacetic acid precipitation methods (5) and quantitated with the biuret reaction. A second purification was effected by redissolving the protein in 1 *N* NaOH and repeating the

Table I—Incorporation of ³H-Labeled Tryptophan and Methyltryptophans into Elymoclavine and Protein

	Tryptophan	5-Methyl-tryptophan	7-Methyl-tryptophan	1-N-Methyl-tryptophan

precipitation and quantitation methods. Using a measured amount of the repurified protein, which was dissolved in a 1 *N* NaOH solution, the incorporation of radioactivity into the protein was determined.

Approximately 50 mg. of protein powder obtained from each culture was hydrolyzed for 24 hr. at 125° with a saturated solution of barium hydroxide in an evacuated sealed glass tube. The barium was removed from the hydrolysate through the addition of 2 *N* sulfuric acid to pH 6 and subsequent centrifugation to remove the barium sulfate.

To investigate the presence of tritiated tryptophan and tryptophan analogs in the protein hydrolysates, ascending paper chromatography in *n*-butanol-acetic acid-water (4:1:1) was employed. By cutting the chromatogram into 1-cm. horizontal strips starting at the point of origin, placing these strips in toluene scintillation counting solution, and counting the radioactivity, the zones of activity on the chromatograms were determined, and the *R_f* values were compared with reference compounds.

Elymoclavine was isolated from 6-day-old culture filtrates by partitioning and recrystallizing from methanol to a constant specific radioactivity.

RESULTS AND DISCUSSION

The time-course study showing that tryptophan and 5-methyltryptophan stimulate alkaloid production early in the growth phase of the fungus (Fig. 1) confirms and extends earlier observations (1). Under the modified conditions, the effect of 5-methyltryptophan can be seen more clearly than in the earlier experiments. At Day 11, tryptophan induces a 495% increase and 5-methyltryptophan a 341% increase in alkaloid production over the control culture, whereas the previous work (1) shows only a 61% increase in alkaloids for each compound after 22 days. The time-course experiment was repeated four times and the results were found to be reproducible. Figure 1 represents the results from a single experiment. Stimulation of alkaloid production in *Claviceps* has also been reported by Baxter and Zahid (6). These data give supportive evidence to the postulation (1) that tryptophan is an inducer of alkaloid biosynthesis.

An explanation of this phenomenon becomes more difficult when one considers the work recently reported by Lingens *et al.* (7, 8) on the regulation of aromatic amino acid biosynthesis in *Claviceps*. Using alkaloid-producing mycelia of a strain of *Claviceps paspali*, they found (7) that L-tryptophan inhibited one of the isoenzymes of 3-deoxy-D-arabinoheptulosonic acid-7-phosphate (DAHP) synthetase, reversed the inhibition of chorismate mutase by phenylalanine and tyrosine, and also activated this enzyme; but unlike the situation in other microorganisms, it did not inhibit anthranilate synthetase. 5-Methyltryptophan elicited the same effect as tryptophan on DAHP synthetase and apparently (8) also on chorismate mutase. In similar studies with *Claviceps* strain SD-58, however, it was found that anthranilate synthetase was inhibited by tryptophan (8). A weak point of the latter result is that it was not known whether the mycelium produced alkaloids under the culture conditions used.

The results clearly show that in strain SD-58 the addition of 5-methyltryptophan leads to increased alkaloid production. On the other hand, the incorporation study shows that 5-methyltryptophan cannot replace tryptophan as alkaloid precursor (Table I). Likewise, the organism can grow in the presence of 5-methyltryptophan

without added tryptophan, yet 5-methyltryptophan is not incorporated into protein to any significant extent (Table I). This leaves unexplained the source of the endogenous tryptophan. One simple explanation would be that in ergot strain SD-58, 5-methyltryptophan cannot replace tryptophan as feedback regulator of aromatic amino acid biosynthesis. As another possibility, an anthranilate synthetase isoenzyme could exist in the fungus which is not inhibited by tryptophan or 5-methyltryptophan.

There is a low level of incorporation of radioactivity into protein when tritiated methyl analogs of tryptophan are fed to ergot strain SD-58 (Table I). However, their absolute incorporation appears insignificant when compared to the incorporation of tryptophan (approximately 80 times greater in the 3-day-old cultures). The decreased incorporation into protein of labeled tryptophan between Day 3 and Day 6 can be attributed to a dilution effect caused by the synthesis of nonlabeled endogenous tryptophan and has been observed before (5). Because of this low level of incorporation, it was not possible to determine conclusively if the activity was due to the direct incorporation of the analogs or if the analogs were metabolized to intermediates that could be utilized in amino acid biosynthesis and thus be incorporated into protein in this manner. However, the results from the chromatographic investigation of the protein hydrolysate tend to support the former viewpoint.

Quinine—Effect on *Tetrahymena pyriformis* II: Comparative Activity of the Stereoisomers, Quinidine and Quinine

K. A. CONKLIN*, P. HEU, and S. C. CHOU

Abstract □ Treatment of heat-synchronized *Tetrahymena* with quinine or quinidine resulted in inhibition of synchronized cell division. Syntheses of DNA, RNA, protein, and lipids were also effectively blocked by both drugs. The effects of quinine and quinidine were quantitatively the same in all instances, indicating that the intracellular action of the two drugs in *Tetrahymena* is similar.

Keyphrases □ Quinine, quinidine effect—*Tetrahymena pyriformis* □ Quinidine, quinine effect—RNA, DNA, protein, lipid synthesis □ Thymidine-, uracil-, amino acids-¹⁴C—*Tetrahymena pyriformis* utilization

Quinine and quinidine are, respectively, the levo- and dextrorotatory stereoisomers of 6-methoxy- α -(5-vinyl-2-quinuclidinyl)-4-quinolinemethanol and exhibit similar physical and chemical properties. Biologically the drugs are similar with respect to absorption, distribution, excretion, and antimalarial activity (1), but quinidine is more effective than quinine as an antifibrillatory agent (2). Whether this difference in biological activity is due to different actions at the subcellular level has yet to be determined.

The authors investigated the action of the two drugs on the free-living protozoan *Tetrahymena pyriformis*. *Tetrahymena* is ideal for the study of drug action because: (a) this organism is easily grown in culture medium; (b) the cells can be synchronized which allows for the study of the effects of drugs on a population of cells that are all in the same growth phase; and (c) the direct action of drugs on DNA, RNA, protein, and lipid synthesis can be studied while the cells are in their normal growth environment.

EXPERIMENTAL

Cultures of *T. pyriformis*, strain GL, were grown, synchronized by heat treatment (3), harvested, and washed in Ringer's buffer as described previously (4). The following procedures were used to determine the effect of quinine and quinidine on synchronized *Tetrahymena* in Ringer's buffer.

Effect of Quinine and Quinidine on Synchronized Cell Division—At the end of the heat treatment (EHT), 5-ml. aliquots of washed cells were pipetted into 25-ml. conical flasks containing either quinine hydrochloride or quinidine sulfate and into a control flask without drug. The drug concentrations were 1.3, 2.5, and 3.8×10^{-4} M. The flasks were placed on a rotator at 28° for the duration of the experiment. Cell samples were taken at regular intervals and fixed in 0.7% formalin in Ringer's buffer; the number of cells per milliliter was determined by direct cell counts (4). The effectiveness of the drugs was determined by the observed degree of inhibition of the first (80 min. after EHT) and second (200 min. after EHT) synchronized divisions.

Effect of Quinine and Quinidine on DNA, RNA, Protein, and Lipid Syntheses after EHT—At EHT, 2-ml. aliquots of washed cells were pipetted into 25-ml. flasks containing measured amounts of quinine or quinidine plus 2.5 μ Ci./ml. of ³H-thymidine, 2.0 μ Ci./ml. of ¹⁴C-uracil, 0.25 μ Ci./ml. of ¹⁴C-amino acids, or 0.25 μ Ci./ml. of ¹⁴C-

Table I—Inhibition of Synchronized Cell Division by Quinine (Q) and Quinidine (QD)

		Concentration, moles/l. $\times 10^4$

acetate. The drugs were used at 1.3, 2.5, and 3.8×10^{-4} M, and flasks containing just the radioactive precursor served as controls. The flasks were incubated on a rotator at 28°, and incorporation of radioactive precursors was followed for 80 min. by the filter paper disk procedures of Byfield and Scherbaum for DNA, RNA, and protein (5) or Byfield *et al.* for lipids (6).

RESULTS AND DISCUSSION

Table I shows the effect of quinine and quinidine on the first and second synchronized cell divisions. The actions of the drugs at all levels tested were quantitatively the same, both drugs showing partial inhibition at 1.3 and 2.5×10^{-4} M and complete inhibition at 3.8×10^{-4} M.

To determine if arrest of cell division was due to inhibition of DNA, RNA, or protein biosyntheses, the effect of the drugs on incorporation of radioactive precursors (thymidine, uracil, and amino acids, respectively) into the macromolecules was followed. The results (Table II) show that both quinine and quinidine were effective inhibitors of all three pathways and that equal concentrations of the two drugs produced approximately the same degree of inhibition. These results indicate that both drugs have similar actions on these biosynthetic pathways and that the inhibition of cell division is not due to inhibition of one specific cellular function.

One possible explanation for inhibition of both nucleic acid and protein syntheses is that the drugs block energy metabolism in *Tetrahymena*. To investigate this possibility, the authors studied the incorporation of acetate into the acid-insoluble lipid fraction. This test has been used by others to determine the state of the energy-generating systems in *Tetrahymena* (7, 8). The results (Table II) show that both drugs were effective inhibitors of lipid synthesis, and the degree of inhibition was the same for equal concentrations of the two drugs. As stated previously for quinine (4), these results indicate that the primary action of the drugs in *Tetrahymena* may be inhibition of energy production with the action on DNA, RNA, and protein syntheses being secondary. In support of this, quinidine is known to inhibit oxygen uptake (9, 10) and the oxidation of free fatty acids (11) and carbohydrates (11, 12) in cardiac muscle, and quinine is known to inhibit pyruvate oxidation through the citric acid cycle (13), isolated respiratory enzymes (14), and oxygen uptake (15) of *Plasmodium*.

Tetrahymena has proved to be a very useful tool for studying the mechanism of action of certain drugs (4, 7, 16, 17). The results presented using this system demonstrate that, for each parameter investigated, there was no significant difference in the action of quinine or quinidine (*p* always greater than 0.2). These data suggest that the intracellular action of the two drugs in *Tetrahymena* is the

Physiologic Surface-Active Agents and Drug Absorption VII: Effect of Sodium Deoxycholate on Phenol Red Absorption in the Rat

STUART FELDMAN*, MICHAEL SALVINO, and MILO GIBALDI

Abstract □ The influence of sodium deoxycholate on the absorption of phenol red in the rat was studied using three techniques to assess absorption—viz., urinary excretion data after oral administration to intact animals, loss of drug from *in situ* intestinal loops, and transfer of drug across the isolated everted intestine. Each of the methods provided evidence that the bile salt markedly enhances the absorption of phenol red by altering the permeability of the intestinal membranes. In the intact rat, these effects appear to be reversible.

Keyphrases □ Phenol red absorption, rat—sodium deoxycholate effect □ Sodium deoxycholate—effect on phenol red absorption, rat □ Colorimetric analysis—phenol red

The role of bile salts in the intestinal solubilization and absorption of fats and fat-soluble vitamins has been studied extensively (1-3). Recently, it has been reported that bile salts may also enhance the intestinal absorption of poorly lipid-soluble substances. Mayersohn *et al.* (4) reported a 1.5- to 1.8-fold increase in the urinary recovery of riboflavin in man when sodium deoxycholate was administered 0.5 hr. prior to the oral in-

gestion of the vitamin. The results suggest that the bile salt enhancement of riboflavin absorption may be due to changes in the permeability of the gastrointestinal membranes to the transport of the vitamin. Feldman and Gibaldi (5, 6) have shown that relatively low micellar concentrations of sodium taurodeoxycholate markedly increase the permeability of everted rat intestine to salicylate ion.

The purpose of the present investigation was to determine the effects of an unconjugated bile salt, sodium deoxycholate (SDC), on the absorption of a water-soluble, poorly absorbed compound, phenol red, in the rat using several experimental techniques to assess absorption.

EXPERIMENTAL

Absorption Studies in Intact Rats—Male Sprague-Dawley rats weighing between 200 and 300 g. were used in all experiments. The animals were fasted 24 hr. (with water allowed *ad libitum*) prior to gastric intubation of 1.5 ml. of a 1-mg./ml. phenol red solution in distilled water containing 100 mM sodium deoxycholate (SDC).

Physiologic Surface-Active Agents and Drug Absorption VII: Effect of Sodium Deoxycholate on Phenol Red Absorption in the Rat

STUART FELDMAN*, MICHAEL SALVINO, and MILO GIBALDI

Abstract □ The influence of sodium deoxycholate on the absorption of phenol red in the rat was studied using three techniques to assess absorption—viz., urinary excretion data after oral administration to intact animals, loss of drug from *in situ* intestinal loops, and transfer of drug across the isolated everted intestine. Each of the methods provided evidence that the bile salt markedly enhances the absorption of phenol red by altering the permeability of the intestinal membranes. In the intact rat, these effects appear to be reversible.

Keyphrases □ Phenol red absorption, rat—sodium deoxycholate effect □ Sodium deoxycholate—effect on phenol red absorption, rat □ Colorimetric analysis—phenol red

The role of bile salts in the intestinal solubilization and absorption of fats and fat-soluble vitamins has been studied extensively (1-3). Recently, it has been reported that bile salts may also enhance the intestinal absorption of poorly lipid-soluble substances. Mayersohn *et al.* (4) reported a 1.5- to 1.8-fold increase in the urinary recovery of riboflavin in man when sodium deoxycholate was administered 0.5 hr. prior to the oral in-

gestion of the vitamin. The results suggest that the bile salt enhancement of riboflavin absorption may be due to changes in the permeability of the gastrointestinal membranes to the transport of the vitamin. Feldman and Gibaldi (5, 6) have shown that relatively low micellar concentrations of sodium taurodeoxycholate markedly increase the permeability of everted rat intestine to salicylate ion.

The purpose of the present investigation was to determine the effects of an unconjugated bile salt, sodium deoxycholate (SDC), on the absorption of a water-soluble, poorly absorbed compound, phenol red, in the rat using several experimental techniques to assess absorption.

EXPERIMENTAL

Absorption Studies in Intact Rats—Male Sprague-Dawley rats weighing between 200 and 300 g. were used in all experiments. The animals were fasted 24 hr. (with water allowed *ad libitum*) prior to gastric intubation of 1.5 ml. of a 1-mg./ml. phenol red solution in distilled water containing 100 mM sodium deoxycholate (SDC).

Table I—Total Urinary Excretion of Phenol Red in Individual Rats after Oral Administration of a 1.5-mg. Dose with and without 150 μ mole Sodium Deoxycholate (SDC)

Rat	Control, % of Dose	SDC, % of Dose
1	4.9	8.0
2	3.2	9.7
3	2.9	11.7
4	4.6	10.9
5	2.7	6.3
Mean \pm SD	3.7 \pm 1.0	9.3 \pm 2.2

A solution of 1 mg./ml. phenol red served as the control. The studies were performed in a crossover fashion with each animal serving as his own control. Following intubation, the animal was placed in a restraining cage. Urine was collected quantitatively every hour for 8 hr. and then at convenient intervals until no measurable levels of phenol red could be detected in the urine (16–24 hr.). Urination was induced by causing the rats to inhale ether vapors for a few seconds. The collected urine was assayed colorimetrically for phenol red using methods described previously (7). The total amount of phenol red excreted in each urine sample was determined by means of standard curves. In a second set of experiments, the test animals were injected intraperitoneally with 1.5 ml. of a 1-mg./ml. phenol red solution. Immediately following the injection, 1.5 ml. of 100 mM SDC was administered by gastric intubation.

The same animals were used in control studies in which the phenol red injection was followed by gastric intubation of 1.5 ml. distilled water in place of the bile salt. Urine was collected and assayed as described previously.

Absorption Studies from *In Situ* Intestinal Loops—The method of Levine *et al.* (8) was utilized to study the *in situ* absorption of phenol red from the rat small intestine. Fasted Sprague-Dawley rats weighing between 195 and 240 g. were used for this portion of the study. The animals were anesthetized with ether and maintained under light anesthesia during the surgical procedures. A midline incision was made, the small intestine was located, and two loops, each 5.08 cm. (2 in.) long, were formed. The first loop was approximately 15.24 cm. (6 in.) from the pylorus with 2.54 cm. (1 in.) of intestine separating the two consecutive loops. One-half milliliter of a 1-mg./ml. phenol red solution in the presence or absence of SDC was injected into a loop, through a ligature, by means of a syringe and blunt needle. In experiments utilizing 100 mM SDC, the loops in any animal contained either phenol red or phenol red plus the bile salt. The solutions were placed in the intestinal loops in a crossover fashion. The midline incision was then closed and the animals were allowed to recover. The animals were sacrificed after 3 hr. and the loops were excised, homogenized,¹ and assayed for phenol red content according to Levine (9). The percent of phenol red absorbed from each loop was calculated after correcting for assay recovery based on the amount of phenol red recovered from loops after 3 hr. *in vitro* incubation experiments in pH 7.2 buffer at 37°.

Drug Transfer in Isolated Everted Rat Intestine—Two consecutive everted rat small intestine segments, each 10 cm. in length, were prepared by methods previously described (5). Each segment was suspended in 80 ml. of mucosal solution consisting of modified Krebs-Henseleit buffer at pH 7.4 containing 0.2 mg./ml. phenol red and, in bile salt experiments, 100 mM SDC. Since both phenol red and SDC are negatively charged at pH 7.4, little or no interaction was expected between the two compounds. All solutions were adjusted to 150 mM Na⁺ by the addition of sodium chloride.

The mucosal solution was oxygenated continuously by a mixture of oxygen-carbon dioxide (95:5) and maintained at 37 \pm 0.1° by means of a water bath. The serosal solution consisted of 2 ml. of modified Krebs-Henseleit buffer, pH 7.4. The experimental procedure for sampling of the serosal solution has been discussed previously (5). Each experiment was run over a 2-hr. period, and the consecutive segments were placed in either the phenol red control buffer or phenol red-SDC-buffer in a crossover fashion.

The serosal samples were diluted appropriately with distilled water, alkalized with 3 N NaOH, and assayed for phenol red spectrophotometrically at 560 m μ . Neither SDC nor "blank" fluid interfered with the assay procedure.

RESULTS

Absorption in Intact Rats—Table I shows the urinary recovery of phenol red, expressed as percent of dose, after oral administration of 1.5 ml. of a 1-mg./ml. phenol red solution in the presence or absence of 150 μ mole SDC. The results show that coadministration of the bile salt with phenol red results in an approximately three-fold increase in the urinary recovery of phenol red. Differences are significant at the 99.5% level of confidence as determined by Student's *t* test (10). A representative plot of the excretion rate of phenol red *versus* time for both experimental situations is presented in Fig. 1.

Studies in which phenol red was injected intraperitoneally and SDC given orally indicate that the bile salt has no influence on the urinary recovery of phenol red. The mean percent of phenol red recovered in the urine after oral administration of the bile salt was 41.2 \pm 11.3% (mean \pm SD, four rats), essentially identical to the control value of 42.4 \pm 11.7% (mean \pm SD, four rats).

This finding rules out an effect of the bile salt on the net distribution and elimination patterns of phenol red and suggests that the increase in urinary recovery of phenol red is due to increased gastrointestinal absorption of the compound in the presence of the bile salt.

Absorption from Intestinal Loops—It was of interest to consider the absorption of phenol red from a well-defined section of the rat small intestine. The intestinal loop preparation was well suited for these experiments. Utilization of this technique made it possible to study the absorption of phenol red in the presence and absence of the bile salt without the complicating problems of enterohepatic circulation and intestinal transit. Also, it was possible by using this technique to control the initial concentration of bile salt present at a specific site within the intestinal lumen.

The results obtained from the intestinal loop experiments are presented in Table II. The percent of phenol red absorbed in control studies was 5.6%. This value is in good agreement with the value of 7% reported by Levine (9). In the presence of 10 mM sodium deoxycholate, the mean percent absorbed was 24.3%. A still larger increase in phenol red absorption was observed in the presence of 100 mM SDC (69.3%).

Phenol Red Transfer across Everted Rat Intestine—The effect of SDC on the intestinal transfer of phenol red is noted in Table III. The results are consistent with the findings of the *in vivo* and *in*

Figure 1—Urinary excretion rates of phenol red after oral administration with and without sodium deoxycholate (SDC). Key: ●, SDC; and ○, control.

Table II—Effect of Sodium Deoxycholate (SDC) on the Absorption of Phenol Red from Rat Intestinal Loops

Solution	No. of Loops	Absorbed \pm SD, %
Control	3	5.6 \pm 1.2
10 mM SDC	6	24.3 \pm 15.1
100 mM SDC	3	69.3 \pm 3.5

situ studies. The bile salt produced a 75% increase in the steady-state transfer rate of the drug across the isolated tissue preparation.

DISCUSSION

Each of the three methods used to assess absorption of phenol red in the rat provided evidence that sodium deoxycholate at concentration exceeding the critical micelle concentration markedly alters the permeability of the gastrointestinal membranes to this poorly absorbed compound. It is of particular interest to note that the *in vitro* technique, *i.e.*, the everted intestinal preparation, provided an excellent indication of *in vivo* absorption phenomenon with respect to the bile salt effect. Until recently, the isolated everted intestine technique has been used almost exclusively for studying active accumulation and transport of various nutrients. The present study indicates that this *in vitro* technique may also have considerable value in studying drug absorption which usually involves passive rather than active processes.

Care, of course, must be used in extrapolating the results of any *in vitro* model to predict results in the intact biologic system. Invariably, quantitative differences are noted and, in some instances, qualitative differences may be observed as well. The isolated everted intestine appears to be considerably more permeable to phenol red than the intact intestine. The clearance of phenol red from the mucosal solution, *i.e.*, the steady-state transfer rate divided by the mucosal concentration, is about 0.8 ml./hr. This value is of the same order of magnitude as the clearance of salicylate—*viz.*, 1.2 ml./hr. (5). However, the rate of intestinal absorption of salicylate is several orders of magnitude greater than that of phenol red. Chalfin *et al.* (11), Tidball *et al.* (12), and Baker *et al.* (13) previously found the small intestine to be considerably more permeable when everted than when not everted. Despite this significant qualitative shortcoming of the everted gut technique with respect to phenol red transfer, the effect of the bile salt on membrane permeability is as adequately demonstrated with this preparation as with the other techniques employed.

An important qualitative difference observed between the isolated and intact rat intestine is the ability to reverse the bile salt effect on membrane permeability. The authors have previously demonstrated that the effect of bile salts on the permeability of the everted intestine was not reversible (6). However, the results of *in vivo* absorption studies in rats suggest that this may not be the case in the intact intestine. Oral dosing studies carried out in a crossover fashion gave no indication that the effects of the orally administered bile salt were irreversible. Urinary excretion data obtained from control studies in two rats, 3 days after each had received SDC, were essentially identical to those obtained from control studies in rats who had no previous exposure to SDC.

The intestinal loop experiments summarized in Table II indicate a dose-dependent effect of the bile salt on the intestinal membranes. One-half milliliter of a 10 mM SDC solution resulted in a mean absorption rate that was four times greater than control values. The results were extremely variable from loop-to-loop as indicated by the very large coefficient of variation, *i.e.*, about 60%. This finding is in contrast to the twelvefold increase in phenol red absorption (coefficient of variation of 5%) produced by a 100 mM solution of SDC. The 5- μ mole dose of SDC may be in the range of the minimum effective dose (MED) of deoxycholate needed to alter intestinal permeability while the 50- μ mole dose is clearly above the MED.

Table III—Effect of 100 mM Sodium Deoxycholate (SDC) on the Steady-State Transfer Rate of Phenol Red across the Everted Rat Small Intestine—Mucosal Drug Concentration Maintained at 0.2 mg./ml.

Rat	Control, mcg./min.	SDC, mcg./min.
1	2.72	4.41
2	2.62	4.90
3	2.38	4.18
Mean \pm SD	2.57 \pm 0.17	4.50 \pm 0.37

During the course of these studies, it was observed that there was an increase in the volume of fluid within the intestinal loop after the 3-hr. exposure to 100 mM SDC. This is consistent with the earlier observation of Feldman *et al.* (14) who reported an increase in fluid volume within the gastric pouch after exposure to 26 mM SDC. Despite the rather marked influx of fluid into the intestinal lumen, enhanced absorption of phenol red occurred in the presence of the bile salt. In control studies, little fluid remained within the intestinal lumen after the 3-hr. absorption period, indicating significant net water absorption in the absence of the bile salt.

The mechanism of action of the bile salt in altering the permeability of the intestinal tract to various drugs is still not certain. It has been suggested that the mechanism may involve an interaction of the bile salt micelle with membrane lipid, particularly phospholipid (15). This aspect of the problem is under further investigation.

Determination of Dialkyltriazenoimidazoles by Nonaqueous Titration

PAUL D. STERNGLANZ

Abstract □ An analytical method for dialkyltriazenoimidazoles has been developed. It serves as a reliable purity check on these anticancer drugs whose effectiveness is a function of their purity. The method consists of titration in nonaqueous media with perchloric acid. The titrant, perchloric acid, is dissolved in a nitroethane-chlorobenzene mixture. Samples are dissolved in glacial acetic acid or in acetonitrile. Poor solubility of some of the compounds is overcome by the selection of an appropriate solvent system, chosen to give also optimum titration end-points. The electrode system consists of conventional glass and calomel electrodes. The method is directly applicable to the unstable 5(or 4)-[3,3-bis(2-chloroethyl)-1-triazeno]imidazole-4(or 5)-carboxamide, without interference by its transformation product, 1-(2-chloroethyl)-3-[5(or 4)-carbamoyl-imidazol-4(or 5)-yl]-*v*-triazolinium chloride, usually present in small amounts.

Keyphrases □ Dialkyltriazenoimidazoles—analysis □ Anticancer drugs—purity determination □ Potentiometric nonaqueous titration—analysis

Dialkyltriazenoimidazoles (I, 2) (I) exemplified by II–IV have shown much promise as useful chemotherapeutic drugs (3–7). 5(or 4)-(3,3-Dimethyl-1-triazeno)imidazole-4(or 5)-carboxamide (II) is receiving clinical trial as an anticancer agent (8, 9). 5(or 4)-[3,3-Bis(2-chloroethyl)-1-triazeno]imidazole-4(or 5)-carboxamide (IV) is highly active against experimental leukemia (4, 7), and methyl 5(or 4)-(3,3-dimethyl-1-triazeno)-imidazole-4(or 5)-carboxylate (III) has shown activity as both an antileukemic and an antimicrobial agent (5). For these reasons, a simple assay method that could be applied equally well to all three triazenoimidazole derivatives, as well as to other derivatives of the general structure of I, would be potentially very useful. In addition, Compound IV is unstable at room temperature, but it can be preserved for months at -15° . Its transformation product (V) has been assigned (10) the structure of a *v*-triazolinium salt formed by internal alkylation. Since the transformation product V has no demonstrated biological activity, it is important that its presence does not influence the assay of IV.

A colorimetric method for dialkyltriazenoimidazoles in plasma and urine has been reported recently (11). However, this method may not distinguish between IV and V and is less suitable as an assay method of solid samples. In contrast, the proposed method is applicable equally well to the three imidazole derivatives II, III, or IV; neither the transformation product V nor lactose, a formulating agent for oral administration, interferes. The method is based on a modification (12) of the nonaqueous titration of weak bases with perchloric acid.

Solutions of Compounds III and IV are prepared in acetonitrile and of Compound II in glacial acetic acid, respectively, the choice being dictated by solubility. The titrant is perchloric acid dissolved in acetic acid or in a nitroethane-chlorobenzene mixture. Either

titrant can be used for the titration of Compounds II and III. However, perchloric acid must be dissolved in a nitroethane-chlorobenzene mixture for the titration of Compound IV. This titrant, recently recommended by Huber (12), has not been applied to any extent in nonaqueous titrimetry. The special titrant was chosen because the presence of glacial acetic acid causes poor end-points in titrations of Compound IV and mixtures of IV and V.

- II, $R_1 = \text{NH}_2$, $R_2 = R_3 = \text{CH}_3$
III, $R_1 = \text{OCH}_3$, $R_2 = R_3 = \text{CH}_3$
IV, $R_1 = \text{NH}_2$, $R_2 = R_3 = \text{CH}_2\text{CH}_2\text{Cl}$

EXPERIMENTAL

Apparatus—A Corning model 12 research pH meter (with expanded scale) was used with a Sargent/Jena combination electrode (E. H. Sargent, item S-30072-15 or miniature S-30070-10). The aqueous KCl in the reference electrode compartment was replaced by 0.1 *M* LiClO₄ in isopropanol.

Preparation of Titrant (12)—Place about 500 ml. of nitroethane in a 1000-ml. volumetric flask; cool in an ice bath; and add 2.1 ml. perchloric acid (72% w/w) and then, dropwise, 5 ml. acetic anhydride. Fill to the mark with chlorobenzene. Let stand overnight. Standardize against either potassium acid phthalate (National Bureau of Standards Sample No. 84) or against 1,3-diphenylguanidine (Standard Grade, G. F. Smith Chemical Co., Columbus, Ohio).

Procedure—Use 0.05 to 0.07-mmol sample; dissolve III or IV in 15 to 20 ml. acetonitrile and II in 15 to 20 ml. glacial acetic acid. The compounds are only partially soluble but will dissolve completely during titration under magnetic stirring. Titrate with standard 0.025 *N* perchloric acid to the potentiometric end-point.

The titrant is introduced from a 5-ml. buret with 0.01-ml. subdivisions.

If mixtures of Compound IV and lactose are analyzed, the sample size should be adjusted so that the lactose will not exceed 350 mg. Although the lactose is insoluble in acetonitrile and is not expected to interfere, amounts exceeding 350 mg. have been found to affect the electrode response adversely.

RESULTS AND DISCUSSION

Preliminary experiments had shown that the solubility of the imidazole derivatives in solvents suitable for titration was poor; for example, less than 0.1% of Compound IV dissolves in acetonitrile. This seemed to be an obstacle for a titration method but, fortunately, the undissolved particles of the imidazole derivatives go into solution while the stirred suspension is being titrated.

Poorly soluble compounds are generally not assumed to be analyzable with the same precision and accuracy as those of good solubility because titration end-points are less distinct in dilute solu-

Table I—Assay of Triazenoimidazole Derivatives by Nonaqueous Titration

	% Purity Found	Standard Deviation	Number of Determinations
Compound II ^a	99.1	0.79	5
Compound III ^a	99.7	0.20	5
Compound IV ^b	96.8	0.55	5

^a Absence of impurities in Compounds II and III was confirmed by elemental analysis and TLC. ^b Contamination of IV by V was found by direct determination of V; the amount of V ranged from 2.5 to 4.2% (13).

tion. However, Table I proves that the precision and accuracy of the proposed method are good.

In Table II the analyses of synthetic mixtures of IV with lactose, and of IV with V and lactose, are shown. Comparison of the amount of Compound IV actually present (indicated in Column 4) and found (indicated in Column 5) shows that neither lactose nor Compound V interferes in the analysis of IV. The weighed amount of IV (in Column 1) differs from the actual amount present (in Column 4) because IV contains an average amount of 3% transformation product V.

Compounds II, III, and IV are weaker bases than imidazole ($\text{pK}_a' = 7.20$ for imidazolium ion in water) (14). The base-weakening effect is attributed to the electronegativity of the triazeno and carboxamide or carboxylate groups. The bis(2-chloroethyl)triazeno group of Compound IV is much more base weakening than the dimethyltriazeno group of Compounds II and III.

Glacial acetic acid cannot be used in the titration of IV for two reasons: Compound IV is too weak a base and, therefore, poor titration breaks would be obtained and, furthermore, the transformation product V, present as an impurity in IV, interferes. Bases too weak to be titratable in acetic acid often become titratable in acetic anhydride. This is the case with Compound IV, and good titration breaks are obtained; but acetic anhydride cannot be used in this particular analysis either, because the transformation product V would be simultaneously titrated with IV.

In acetonitrile, the situation is different; Compound IV is sufficiently basic to be titratable (if acetic acid is absent) while the transformation product V remains neutral. Perchloric acid in acetonitrile would be a good titrant but it is unstable. Perchloric acid in acetic acid is very stable but causes poor end-points in the titration of IV. Perchloric acid in nitroethane-chlorobenzene gives the best results and is therefore used.

The author thanks Dr. Y. F. Shealy for the imidazole derivatives and for helpful criticism.

After the procedures had been devised, some of the titrations were performed by Greenwood Laboratories, Chadds Ford, Pa.

Structure-Activity Relation in Organophosphorus-Inhibited Acetylcholinesterase Reactivators III: Methiodides of Hydroxyimino Derivatives of Pyridylethanes

PALMARISA FRANCHETTI*, MARIO GRIFANTINI, and MARIA L. STEIN

Abstract □ The methiodides derived from 2-hydroxyimino-1-pyridyl-ethan-1-ones, 2-hydroxyimino-1-pyridyl-1-hydroxyethanes, and 1,2-di(hydroxyimino)-1-pyridylethanes were tested as reactivators of phosphorylated acetylcholinesterase. The most active member, 2-hydroxyimino-1-(2'-pyridyl)-ethan-1-one, displays a rate of reactivation, in the case of tetraethyl pyrophosphate poisoning, slightly higher than that of the well-known reactivator 2-hydroxyiminomethyl-1-methyl-pyridinium iodide.

Keyphrases □ Acetylcholinesterase reactivators—structure-activity relationship □ Pyridylethane derivatives (methiodide salts)—synthesis □ Reactivators—organophosphorus-inhibited acetylcholinesterase □

It has recently been shown (1, 2) that methiodides of pyridine oximes, containing the ketoxime group on a position of the side chain one carbon atom distant from the ring, are able to reactivate organophosphorus-inhibited acetylcholinesterase. The compounds hitherto considered were 2-hydroxyimino derivatives of 1-pyridylethanes further substituted in position 2 by phenyl or amide groups; because these groups can shield the hydroxyimino group in relation to the active site of the enzyme, it was of interest to replace them with hydrogen.

Therefore, the methiodides derived from the three isomers of each of the following types of bases were synthesized: *anti*-2-hydroxyimino-1-pyridyl-ethan-1-ones (I), 2-hydroxyimino-1-pyridyl-1-hydroxyethanes (II), and *anti*-1,2-di(hydroxyimino)-1-pyridylethanes (III).

Wilson *et al.* (3) have already examined the reactivating property of the methiodide salts of 1-(3'-pyridyl)-2-hydroxyimino-ethan-1-one and 1-(4'-pyridyl)-2-hydroxyimino-ethan-1-one, finding them less active than 2-hydroxyiminomethyl-1-methyl-pyridinium iodide (2-PAM). The picolinic isomer is a new compound, and its synthesis makes it possible to correlate the activities of the three isomeric methiodides (IVa-c) to their structure. It should be noted that Wilson *et al.* have proposed for Products Ib and Ic the configuration *syn* to the keto group; however, the authors find that Ib and Ic, like the new Compound Ia, form complexes with copper and nickel salts and, by reaction with hydroxylamine, give the *anti*-1,2-di(hydroxyimino)-1-pyridylethanes. The

anti-configuration should therefore be assigned to all the isomers I (4).

The methiodide salts of Compounds II and III were synthesized to ascertain how the biological activity varies with changing of the carbonyl adjacent to the ring.

EXPERIMENTAL¹

***anti*-2-Hydroxyimino-1-(2'-pyridyl)-ethan-1-one (Ia)**—To a stirred solution of 12 g. of isopentyl nitrite, cooled with ice, 2.3 g. of Na dissolved in 50 ml. of anhydrous EtOH was added dropwise. Stirring was continued for 12 hr.; 250 ml. of water was then added and the solution was extracted with ether. The water solution was acidified to pH 5-6 with dilute acetic acid and extracted with ethyl acetate; after evaporation of the solvent, the residual oil was chromatographed on silica gel, eluting with ethyl acetate. By evaporation of the first eluates, a product was obtained which was recrystallized from benzene; m.p. 113-115°.

Anal.—(C₇H₈N₂O₂) C₇H₈N₂O₂ $\lambda_{\text{max}}^{\text{EtOH}}$ (log ϵ): 254 m μ (4.06).

The product gives colored precipitates with copper and nickel salts.

***anti*-1-Hydroxy-1-pyridyl-2-hydroxyiminoethanes (IIa-c)**—To 0.3 g. of sodium borohydride in 4 ml. of water and 5 ml. of methanol, 1 g. of the corresponding α -hydroxyiminoketone in 20 ml. of methanol was added dropwise with stirring. After 2 hr. the solution was neutralized with dilute acetic acid and reduced under vacuum to one-fourth of its original volume. The solution was extracted with ethyl acetate, and the products were purified by chromatography on silica gel (ethyl acetate-methanol, 80:20) followed by crystallization from ethyl acetate-ethyl ether; m.p. IIa 111-112°, IIb 99-101°, and IIc 97-99°.

Anal.—(C₇H₈N₂O₂) C₇H₈N₂O₂.

***anti*-1,2-Di(hydroxyimino)-1-pyridylethanes (IIIa-c)**—One gram of Compound I was refluxed for 2 hr. with 0.55 g. of hydroxylamine hydrochloride in 30 ml. of EtOH. The solution was then diluted with water, made basic with aqueous NaHCO₃, and extracted with ethyl acetate. The residue obtained after evaporation of the solvent was crystallized from EtOH; m.p. IIIa 143-145°, IIIb 173-175°, and IIIc 184-187°.

Anal.—(C₇H₈N₂O₂) C₇H₈N₂O₂.

The *anti*-configuration of the dioximes was established on the basis of the red-orange colored complexes obtained with the nickel salts (5).

N-Methyl Pyridinium Iodides (Table I)—The Products IVa and Va were obtained by heating the corresponding bases in anhydrous EtOH with methyl iodide at 60° for 48 hr. in sealed vessels; the residue obtained by evaporation of the solvent was washed with ethyl acetate and crystallized. The Products Vb, VIa, VIb, and VIc were obtained in a similar manner, performing the reaction in acetone at room temperature; Vc was obtained from IIc in ether after 10 days of reaction. Products Va and Vc were very hygroscopic.

All the quaternary salts were subjected to biological assay. The *in vitro* reactivating velocity of acetylcholinesterase inhibited by tetraethyl pyrophosphate (TEPP) or diisopropyl phosphorofluoridate (DFP) was measured according to the technique described

¹ Melting points are uncorrected. When no unusual spectral features were observed with the compounds described, no absorption peaks are reported. Where analyses are indicated only by symbols of the elements, analytical results obtained for these elements were within $\pm 0.4\%$ of the theoretical values.

by Ashani *et al.* (6). The results are shown in Table II, together with the values of pK_a for the same compounds.

RESULTS AND DISCUSSION

The values of the hydrolysis rate in Table II indicate that pyridine derivatives, containing a hydroxyimino group in the β -position of the side chain, show reactivating ability. This is particularly evident in the series of Compounds IV. Among the three positional isomers the most active is the picolinic derivative, which, together with the nicotinic one, has an activity slightly higher than that of 2-PAM in the case of TEPP poisoning. The nearly equivalent activity for the two isomers is remarkable, in contrast to what is observed with the pyridine aldoxime methiodides where the nicotinic isomer is inactive (8). For DFP-poisoned acetylcholinesterase, the three isomers show nearly equivalent activity.

Structural modifications of the carbonyl group lead to a diminution of activity that can be ascribed to the different nucleophilicity of the hydroxyimino groups. This is particularly evident in the series of Compounds V; reduction of the carbonyl function to an alcoholic one results in a strong diminution of acidity, which is probably responsible for the inactivity of these compounds. The introduction of a second hydroxyimino group generally leads to less active compounds in comparison to the ketones.

From these results, compared with those discussed in the preceding notes (1, 2), it is possible to conclude that voluminous groups attached to the terminal carbon atom of the side chain in this type of compound decrease the ability to reactivate inhibited acetylcholinesterase; a shielding effect on the active site of the enzyme by the phenyl and arylamide groups present in the compounds described in preceding notes can then be postulated.

Independence of Antimineralocorticoid and Catatoxic Effects of Various Steroids

B. SOLYMOSS, M. KRAJNY*, and S. VARGA

Abstract □ Several steroids were assayed by means of Kagawa's test to determine whether the catatoxic or detoxifying effect depends upon antimineralocorticoid potency. In adult male rats, ethylestrenol, norbolethone, progesterone, triamcinolone, prednisolone, and hydroxydione were found free of antimineralocorticoid effects at the dose of 1 mg. Similar results were obtained in young female rats pretreated with as much as 10 mg. of these steroids. Thus, this type of nonspecific resistance-increasing effect of certain steroids appears to be unrelated to antimineralocorticoid potency.

Keyphrases □ Steroids—antimineralocorticoid, catatoxic effects, independence □ Antimineralocorticoid activity—steroids □ Catatoxic activity—steroids □ Atomic absorption spectroscopy—analysis

Recently it was observed in this laboratory that pretreatment with antimineralocorticoid or anabolic steroids diminishes the anesthesia induced by pentobarbital, progesterone, or hydroxydione and prevents the toxicity of digitoxin, dimethylbenz(a)anthracene, indomethacin, and a large variety of unrelated compounds (1-3). This protection is at least partly due to the induction of drug-metabolizing enzymes since spironolactone, norbolethone, or ethylestrenol increases the nicotinamide adenine dinucleotide phosphate (NADPH)-dependent aliphatic hydroxylation of pentobarbital and hexobarbital as well as the *N*-dealkylation of aminopyrine in the hepatic microsomes (4, 5).

The pharmacologic classification of steroid hormones and their derivatives is based upon the fact that some of their actions are separable and independent whereas others are merely inseparable subordinate manifestations of one of these basic activities (1, 6). The stimulation of drug-metabolizing enzymes has already been attributed to different hormonal actions. In studying the role of androgens, Quinn *et al.* (7) observed that the enzymatic degradation of hexobarbital is faster in males than in females. Booth and Gillette (8) found that the activation of drug-metabolizing enzymes by testosterone derivatives more closely parallels their anabolic than their androgenic activity. Regarding the role of female sex hormones, it was found that chronic treatment of ovariectomized rats with progesterone increases the hepatic detoxification of chlorpromazine (9). Remmer (10) noted that glucocorticoids also influence the enzymatic degradation of drugs.

It is of interest whether the catatoxic effect of steroids is dependent on one of their specific hormonal properties. Obviously, not all these steroids share androgenic, anabolic, luteoid, or glucocorticoid activities. However, depending on dosage and under special circumstances, anabolic steroids and progesterone can reveal antimineralocorticoid properties (11). To determine whether the antimineralocorticoid activity is a common

function of catatoxic steroids, the authors investigated the effect of norbolethone, ethylestrenol, and progesterone as well as of triamcinolone or prednisolone in Kagawa's test (12), and compared the results with the classic antimineralocorticoid action of spironolactone and SC-11927. The hormonally inactive hydroxydione was used as a control. In a repetition of this experiment on young female rats, the steroids were administered in the same manner and at the same dosage as in the previous detoxification studies (1-5).

MATERIALS AND METHODS

First Experiment—One hundred and forty-four male Sprague-Dawley rats of the Holtzman Farms (Madison, Wis.) with a mean initial body weight of 150 g. (range 140-160 g.) were bilaterally adrenalectomized, under ether anesthesia, by the lumbar route and maintained on sucrose and tap water. Approximately 24 hr. postoperatively the rats were divided and treated as indicated in Table I. Sodium chloride¹ (2.5 ml. of 0.85% solution), desoxycorticosterone acetate (DOC-Ac)² (6 or 12 mcg. in 0.2 ml. Mazola corn oil), as well as spironolactone,³ SC-11927,³ ethylestrenol,⁴ norbolethone,⁵ progesterone and prednisolone,⁶ triamcinolone,⁷ or hydroxydione⁸ (1 mg. in 0.5 ml. Mazola corn oil) were administered subcutaneously.

The bladder of the animal was emptied by applying slight pressure before placing four or five of them in a metabolic cage. During the period of urine collection, no food or water was provided. Voiding was again induced at the end of a 4-hr. period for complete recovery of urine. Using the Unicam SP 90 atomic absorption spectrophotometer, pooled specimens were analyzed three times for total sodium and potassium excretion (13); these values were used for the calculation of the $\log (\text{Na} \times 10)/\text{K}$ ratio. Blocking activity was measured by reversal of the Na/K effect of DOC, as described by Kagawa (12).

Second Experiment—One hundred and seventeen female Sprague-Dawley rats of the Holtzman Farms with a mean initial body weight of 100 g. (range 90-110 g.) were divided and treated as indicated in Table II immediately after adrenalectomy. Spironolactone, SC-11927, ethylestrenol, norbolethone, progesterone, triamcinolone, prednisolone, or hydroxydione was administered twice daily for 3 days (10 mg. in 1 ml. H₂O *per os*). Groups 13-22 were maintained on Purina Laboratory Chow and 0.85% NaCl as drinking fluid during the first 2 days of this pretreatment; on the 3rd day they received sucrose cubes and tap water. Approximately 72 hr. postoperatively, the pretreatment was followed by the administration of NaCl, DOC, and various steroids as well as by urine collection and electrolyte determinations, as described in the first experiment.

The differences between the Na/K excretion values were statistically evaluated by variance analysis.

RESULTS

The end-point for antimineralocorticoid activity is based on the log urinary Na/K ratio, which may reflect various changes in the in-

dividual cations. Accordingly, Tables I and II list both Na and K means in order that distinctive electrolyte effects of the steroids can be surfaced for interpretation.

First Experiment (Table I)—Compared with the adrenalectomized controls (Group 1), 6 mcg. of DOC-Ac (Group 2) lowered the urinary log (Na × 10)/K ratio and 12 mcg. (Group 3) was even more active ($p < 0.05$ as compared with Group 2). As expected, both spironolactone (Group 4) and SC-11927 (Group 5) reversed the effect of 12 mcg. DOC-Ac. No significant antimineralocorticoid activity was revealed by ethylestrenol (Group 6), norbolethone (Group 7), progesterone (Group 8), or hydroxydione (Group 11). Triamcinolone (Group 9) and prednisolone (Group 10) even further diminished the urinary Na/K ratio, already decreased by 12 mcg. DOC-Ac (Group 3).

Second Experiment (Table II)—In comparison to the adrenalectomized controls (Group 12), 6 mcg. of DOC-Ac (Group 13) also significantly lowered the urinary log (Na × 10)/K ratio in young female rats, and 12 mcg. (Group 14) was still more active ($p < 0.05$ as compared with Group 13). Spironolactone (Group 15) or SC-11927 (Group 16) counteracted the effect of 12 mcg. DOC-Ac (Group 14). None of the other steroids (Groups 17-22) revealed antimineralocorticoid properties.

DISCUSSION

Kagawa (11) showed that the influence of spironolactone and its derivatives on renal electrolyte excretion is due to a specific antagonism of mineralocorticoid effects. Thus, as expected, spironolactone and SC-11927 reversed the action of 12 mcg. DOC-Ac in both experiments.

It was demonstrated that high doses of testosterone and of many of its derivatives have antimineralocorticoid properties; 18,19-dinor-

testosterone proved to be active even in small amounts (11). Under the experimental conditions reported here, ethylestrenol or norbolethone failed to show antimineralocorticoid activity, even when a high-dose level was maintained over several days as in the second experiment. Progesterone also proved to possess a DOC-Ac blocking potency similar to that of spironolactone; however, it also resembled DOC-Ac in its effect on electrolyte excretion when given alone and in large doses (14). This complex action and the differences in dosage might explain why progesterone failed to exhibit antimineralocorticoid effects in the experiments. In agreement with expectations, triamcinolone, prednisolone, or hydroxydione was completely devoid of any antimineralocorticoid activity in both experiments. After the administration of triamcinolone or prednisolone, there was a marked decrease in urinary log (Na × 10)/K ratio in male (first experiment) but not in female rats (second experiment). This is probably due to the rats receiving large doses of these steroids for 3 days, thus leading to potassium depletion; therefore, in the actual Kagawa test the last dose of triamcinolone or prednisolone did not so markedly influence potassium excretion.

The lack of correlation between the anabolic, androgenic, luteoid, or glucocorticoid activity of some steroids and their resistance-increasing effect against various compounds was obvious without detailed investigations. The present results demonstrate that even under the experimental conditions used in the detoxification experiments (1-5), the highly active microsomal enzyme inducers, ethylestrenol and norbolethone, do not share the antimineralocorticoid activity of spironolactone and its derivatives. It is noteworthy that spironolactone pretreatment prevents the anesthetic effect of progesterone, DOC-Ac, and hydroxydione, even after bilateral nephrectomy (15). Thus, the catatoxic effect of spironolactone is also manifest under conditions in which its classic antimineralocorticoid property could not play any role.

Table II—The Effect on Kagawa's Test of High Doses of Various Steroids Administered to Young Female Rats

Group	Number of Animals	Treatment ^a		Urinary Excretion ^b		log Na × 10/K Ratio in Urine
		Steroid, 10 mg.	DOC-Ac, mcg.	Na	μequiv. of K	
12	18	—	—	1250	450	1.44
13	9	—	6	1010 ^c	520	1.29 ^c
14	18	—	12	800 ^c	630 ^c	1.11 ^c
15 ^d	9	Spironolactone	12	1320 ^e	480 ^e	1.44 ^e
16	9	SC-11927	12	1300 ^e	510 ^e	1.41 ^e
17	18	Ethylestrenol	12	940 ^e	700	1.13
18	9	Norbolethone	12	590 ^e	480	1.09
19	9	Progesterone	12	630 ^e	480	1.12
20	9	Triamcinolone	12	1090 ^e	850 ^e	1.11
21	9	Prednisolone	12	950 ^e	830 ^e	1.06
22	9	Hydroxydione	12	750	630	1.08

^a In addition all animals were adrenalectomized 72 hr. earlier and then treated with steroids (10 mg. twice daily) and given 2.5 ml. 0.85% NaCl s.c. at the beginning of urine collection. ^b Total electrolyte excretion in sample of nine animals. ^c = $p < 0.05$ as compared with Group 12. ^d Groups 15-18 received the most potent catatoxic steroids. ^e = $p < 0.05$ as compared with Group 14.

These results support the view that the catatoxic action of different steroids is not subordinate to any presently known specific hormonal action (1).

Subcutaneous Absorption Kinetics of Benzyl Alcohol II

BERTON E. BALLARD and EFRAIM MENCZEL*

Abstract □ Under multiple-dosing conditions at a subcutaneous site, equations were derived which permit one to estimate the number of doses, n , required to approach within $\pm 1\%$ (or any other fixed fraction) of the asymptotic minimum level: $n \geq 3.3219 [(t_{0.5})/\tau] \log_{10} Q$, where $Q > +1$. Here $t_{0.5}$ is the absorption half-life of benzyl alcohol from a subcutaneous absorption cell, τ is the dosing interval, Q (always positive) equals $(\beta - 1)/(\alpha - 1)$, α equals B'_{min}/B_{min} (and is 0.99 or 1.01 in this example), and β equals B''/B_{min} , where B'' equals $Bi - Bm$. Definitions: B'_{min} = amount of benzyl alcohol in the cell per unit area of subcutaneous tissue one τ after the n th dose, B_{min} = asymptotic minimum amount of benzyl alcohol in the cell per unit area, Bi = initial dose of benzyl alcohol per unit area, and Bm = constant maintenance dose of benzyl alcohol per unit area ($Bi \geq Bm$). The benzyl alcohol disappears from the cell in an apparent monoexponential manner.

Keyphrases □ Benzyl alcohol—subcutaneous absorption □ Kinetics—benzyl alcohol, subcutaneous absorption □ Equations—dosage numbers/subcutaneous area for asymptotic minimum level

In a recent report from this laboratory (1), a multiple-dosing procedure was used in connection with a study of the subcutaneous (s.c.) absorption kinetics of benzyl alcohol (BA) dissolved in normal saline (NS). The BA in NS solution was contained in a glass absorption cell affixed to the moist s.c. tissue of an anesthetized rat by a silicone adhesive. The solution was kept homogeneous by means of a vibrating stirrer. The use of this cell made it possible to control the area of s.c. tissue exposed to the drug solution at all times and to sample the cell's contents periodically.

Although the number of doses per unit area (p.u.a.) of s.c. tissue needed to approach within $\pm 1\%$ of the asymptotic minimum value were shown in Table IV of the previous report (1), details of the mathematical calculations were omitted. The purpose of this note is to derive the equations needed to make this estimation.

THEORETICAL

Under multiple-dosing conditions, where the mean volume of drug solution in the cell was nearly constant throughout the experiment, and the drug was administered at the times zero, τ , 2τ , 3τ , ..., the following equation can be derived (1):

$$Bc = B' \frac{(1 - e^{-Pn\tau})}{(1 - e^{-P\tau})} \quad (\text{Eq. 1})$$

where Bc in this case is the amount of drug in the cell p.u.a. just after the administration of the n th dose p.u.a. In Eq. 1 it is assumed that the drug disappears from the cell in an apparent monoexponential manner and the initial dose p.u.a., Bi , equals the constant maintenance dose(s) p.u.a., Bm , in magnitude. Thus

$$B' = Bi = Bm \quad (\text{Eq. 2})$$

The term P in Eq. 1 is the mean penetration coefficient having the units of time^{-1} , n is the integer number of initial and maintenance doses administered, and τ is the constant dosing time interval.

When Bi is larger than Bm , then

$$Bi = B'' + Bm \quad (\text{Eq. 3})$$

where B'' is the amount of drug p.u.a. in the cell administered along with Bm as a part of the initial dose p.u.a. and $Bi \geq Bm$. The amount

These results support the view that the catatoxic action of different steroids is not subordinate to any presently known specific hormonal action (1).

Subcutaneous Absorption Kinetics of Benzyl Alcohol II

BERTON E. BALLARD and EFRAIM MENCZEL*

Abstract □ Under multiple-dosing conditions at a subcutaneous site, equations were derived which permit one to estimate the number of doses, n , required to approach within $\pm 1\%$ (or any other fixed fraction) of the asymptotic minimum level: $n \geq 3.3219 [(t_{0.5})/\tau] \log_{10} Q$, where $Q > +1$. Here $t_{0.5}$ is the absorption half-life of benzyl alcohol from a subcutaneous absorption cell, τ is the dosing interval, Q (always positive) equals $(\beta - 1)/(\alpha - 1)$, α equals B'_{min}/B_{min} (and is 0.99 or 1.01 in this example), and β equals B''/B_{min} , where B'' equals $Bi - Bm$. Definitions: B'_{min} = amount of benzyl alcohol in the cell per unit area of subcutaneous tissue one τ after the n th dose, B_{min} = asymptotic minimum amount of benzyl alcohol in the cell per unit area, Bi = initial dose of benzyl alcohol per unit area, and Bm = constant maintenance dose of benzyl alcohol per unit area ($Bi \geq Bm$). The benzyl alcohol disappears from the cell in an apparent monoexponential manner.

Keyphrases □ Benzyl alcohol—subcutaneous absorption □ Kinetics—benzyl alcohol, subcutaneous absorption □ Equations—dosage numbers/subcutaneous area for asymptotic minimum level

In a recent report from this laboratory (1), a multiple-dosing procedure was used in connection with a study of the subcutaneous (s.c.) absorption kinetics of benzyl alcohol (BA) dissolved in normal saline (NS). The BA in NS solution was contained in a glass absorption cell affixed to the moist s.c. tissue of an anesthetized rat by a silicone adhesive. The solution was kept homogeneous by means of a vibrating stirrer. The use of this cell made it possible to control the area of s.c. tissue exposed to the drug solution at all times and to sample the cell's contents periodically.

Although the number of doses per unit area (p.u.a.) of s.c. tissue needed to approach within $\pm 1\%$ of the asymptotic minimum value were shown in Table IV of the previous report (1), details of the mathematical calculations were omitted. The purpose of this note is to derive the equations needed to make this estimation.

THEORETICAL

Under multiple-dosing conditions, where the mean volume of drug solution in the cell was nearly constant throughout the experiment, and the drug was administered at the times zero, τ , 2τ , 3τ , . . . , the following equation can be derived (1):

$$Bc = B' \frac{(1 - e^{-Pn\tau})}{(1 - e^{-P\tau})} \quad (\text{Eq. 1})$$

where Bc in this case is the amount of drug in the cell p.u.a. just after the administration of the n th dose p.u.a. In Eq. 1 it is assumed that the drug disappears from the cell in an apparent monoexponential manner and the initial dose p.u.a., Bi , equals the constant maintenance dose(s) p.u.a., Bm , in magnitude. Thus

$$B' = Bi = Bm \quad (\text{Eq. 2})$$

The term P in Eq. 1 is the mean penetration coefficient having the units of time^{-1} , n is the integer number of initial and maintenance doses administered, and τ is the constant dosing time interval.

When Bi is larger than Bm , then

$$Bi = B'' + Bm \quad (\text{Eq. 3})$$

where B'' is the amount of drug p.u.a. in the cell administered along with Bm as a part of the initial dose p.u.a. and $Bi \geq Bm$. The amount

of drug in the cell p.u.a. at any time, B_c , can be calculated from

$$B_c = B''e^{-Pt} + Bm \left[\frac{(1 - e^{-Pn\tau})}{(1 - e^{-P\tau})} \right] e^{-P\tau} \quad (\text{Eq. 4})$$

where t is clock time starting at zero following the administration of the first dose p.u.a., and T is a new clock time starting just after the administration of the last maintenance dose.

The minimum amount of drug p.u.a. in the cell,¹ $B_{\min.}^{(n)}$, one τ after the administration of the n th dose p.u.a., can be calculated from

$$B_{\min.}^{(n)} = B''e^{-Pn\tau} + Bm \left[\frac{(1 - e^{-Pn\tau})}{(1 - e^{-P\tau})} \right] e^{-P\tau} \quad (\text{Eq. 5})$$

After a very large (or infinite) number of maintenance doses p.u.a. has been administered, according to Eq. 5, the asymptotic minimum amount of drug p.u.a.,¹ $B_{\min.}^{\infty}$, can be calculated from

$$B_{\min.}^{\infty} = Bm \left(\frac{e^{-P\tau}}{1 - e^{-P\tau}} \right) \quad (\text{Eq. 6})$$

Let

$$\alpha_n = \frac{B_{\min.}^{(n)}}{B_{\min.}^{\infty}} = \frac{B_{\min.}^{(n)}/V}{B_{\min.}^{\infty}/V} \quad (\text{Eq. 7})$$

where α_n is a ratio of amounts or concentrations of drug with V being the constant for cell volume (or apparent distribution volume for the body). In this paper the value of $B_{\min.}^{(n)}$ or $(B_{\min.}^{(n)}/V)$ was arbitrarily set equal to $\pm 1\%$ of $B_{\min.}^{\infty}$ or $(B_{\min.}^{\infty}/V)$, so that the value of α_n in Eq. 7 would be either 0.99 or 1.01, depending upon whether $B_{\min.}^{\infty}$ or $(B_{\min.}^{\infty}/V)$ was being approached from below or above.

Substitution of Eq. 7 into Eq. 5 yields

$$\alpha_n B_{\min.}^{\infty} = B''e^{-Pn\tau} + Bm \left[\frac{(1 - e^{-Pn\tau})}{(1 - e^{-P\tau})} \right] e^{-P\tau} \quad (\text{Eq. 8})$$

Rearranging Eq. 8 yields

$$\alpha_n = \left(\frac{B''}{B_{\min.}^{\infty}} \right) e^{-Pn\tau} + \left(\frac{Bm}{B_{\min.}^{\infty}} \right) \left(\frac{1 - e^{-Pn\tau}}{1 - e^{-P\tau}} \right) e^{-P\tau} \quad (\text{Eq. 9})$$

Let

$$\beta = \frac{B''}{B_{\min.}^{\infty}} = \frac{B''/V}{B_{\min.}^{\infty}/V} \quad (\text{Eq. 10})$$

where β is a ratio of amounts or concentrations of drug. Substitution of Eqs. 6 and 10 into Eq. 9 yields

$$\alpha_n = \beta e^{-Pn\tau} + 1 - e^{-P\tau} \quad (\text{Eq. 11})$$

or

$$(\alpha_n - 1) = e^{-Pn\tau}(\beta - 1) \quad (\text{Eq. 12})$$

For α arbitrarily close to 1, say $|\alpha - 1| = 0.01$, it is desired to find the smallest n such that

$$|\alpha_n - 1| = |e^{-Pn\tau}(\beta - 1)| \leq |\alpha - 1| \quad (\text{Eq. 13})$$

Solving Eq. 13 for n gives

$$n \geq \frac{1}{P\tau} \ln \left(\frac{\beta - 1}{\alpha - 1} \right) \quad (\text{Eq. 14})$$

Since $P = \ln 2/t_{0.5}$, substitution of P into Eq. 14 gives

$$n \geq \left(\frac{t_{0.5}}{\tau} \right) \left(\frac{1}{\ln 2} \right) \ln \left(\frac{\beta - 1}{\alpha - 1} \right) \quad (\text{Eq. 15})$$

¹ The notation in this paper differs somewhat from that used previously (1). The term $B_{\min.}$ has been changed to $B_{\min.}^{(n)}$ because $B_{\min.}$ in these derivations depends in part upon n . The term $B_{c\min.}$ has been changed to $B_{\min.}^{\infty}$ to indicate more clearly that the asymptotic minimum amount of drug p.u.a. is evaluated at infinite time.

Let

$$Q = \left(\frac{\beta - 1}{\alpha - 1} \right) \quad (\text{Eq. 16})$$

where Q is always positive and greater than 1.² Substitution of Eq. 16 into Eq. 15 yields

$$n \geq 3.3219 \left(\frac{t_{0.5}}{\tau} \right) \log_{10} Q \quad (\text{Eq. 17})$$

The time, t , needed for amounts or concentrations to reach within $\pm 1\%$ of the corresponding asymptotic values one τ after the n th dose is

$$t = n\tau \quad (\text{Eq. 18})$$

RESULTS AND DISCUSSION

Table I summarizes the data needed to estimate the doses, n , and the time, t , to approach within $\pm 1\%$ of the asymptotic value $B_{\min.}^{\infty}$ or $(B_{\min.}^{\infty}/V)$.

The methods described are exact when it has been demonstrated that monoexponential loss of drug occurs from a compartment such as a subcutaneous absorption cell. However, when the concentration-time course of drug in a compartment is best described by a polyexponential function (2), the methods described for calculating n and t must be used with caution. Also, other phenomena discussed by Wagner *et al.* (3) may invalidate these procedures for multiple-dosing calculations. Two examples using literature data indicate how Eqs. 17 and 18 can be used to solve for the quantities n and t . The first example involves multiple intramuscular injection of drug; the second involves continuous intravenous infusion of drug.

Example 1—Multiple Intramuscular Injection—Boxer *et al.* (4) injected streptomycin hydrochloride solutions intramuscularly into dogs at regular dosing intervals and followed changes in the plasma drug concentration with time. They derived an equation which permitted them to use the serum drug concentrations obtained at a given time after the initial dose was administered, but before the second dose was administered, to predict the serum drug concentration in the body at the same time interval after the last dose given after an infinite number of doses had been administered. The equation is

$$C_H = C_k \left(\frac{1}{1 - e^{-k\tau}} \right) \quad (\text{Eq. 19})$$

where C_H is the actual concentration to be expected at the corresponding time interval after a steady state has been established, C_k is an experimentally determined concentration at a time in the interval between the initial and second doses; k is the rate constant for the disposition of drug in the body, assuming it to be a single compartment; and τ is the dosing interval.

In the derivation of Eq. 19, Boxer *et al.* (4) assumed that the absorption rate of streptomycin hydrochloride from the intramuscular site was extremely (or infinitely) rapid, so that the disappearance of drug from the serum could be described by a monoexponential function. There is evidence to indicate that drug absorption rate from this site is not instantaneous (5–8). However, Eq. 19 can be a useful first approximation for the mathematical analysis of some clinical data involving blood or serum levels of drug.

Data in the left half of Table IV of the Boxer *et al.* paper (4) show that the calculated value of C_k 3 hr. after the initial dose, and before the second dose was given, was 26.3 mcg./ml.; τ is 3 hr., the mean value of k is $0.39 (\pm 0.028)$ hr.⁻¹; and the biological half-life in the dog is 1.78 hr. According to Eq. 19, the calculated value of C_H is 38.1 mcg./ml. The initial dose equals the maintenance dose ($\beta = 0$), and substitution of these values into Eq. 17 gives the following value for n :

² By appropriate substitution into Eq. 17, where $\beta \geq 0$, it follows that when $\alpha > \beta$, then $\alpha = 0.99$ and $Q > +1$. When $\alpha < \beta$, then $\alpha = 1.01$ and $Q > +1$. It also follows that $\alpha \neq \beta$, because Q can never equal 1. Should $Q = 1$, then no doses would be required to reach the desired level, which is an obvious impossibility.

Table I—Number of Total Doses Necessary to Approach within $\pm 1\%$ of B_{\min}^{∞} , and the Constants Needed for Its Calculation^a

Constant	Animal

n^k	>16	>18	>11	>10
	(16.28)	(18.33)	(11.57)	(10.75)
t (hr.) ^l	8	9	5.5	5

^a For some constants in this table, extra digits were obtained by computational means and are indicated by subscripts. Subscripts are listed to minimize rounding-off errors in subsequent calculations, and do not imply that four significant figure experimental accuracy was achieved. ^b BA absorption half-life in cell. ^c The dosing interval, τ , is 0.5 hr. ^d Calculated from Eq. 6. ^e Initial dose p.u.a. ^f Mean maintenance dose p.u.a. ^g Calculated from Eq. 3. ^h The term α is defined in Eq. 7. ⁱ The term β is defined in Eq. 10. ^j Calculated from Eq. 16. ^k Number of total doses p.u.a. needed for B_{\min}^{∞} to approach within $\pm 1\%$ of B_{\min}^{∞} one τ after the n th dose as calculated from Eq. 17. ^l Time needed for amounts in the cell to reach within $\pm 1\%$ of the asymptotic value of B_{\min}^{∞} calculated from Eq. 18.

$$n \geq 3.3219 (1.78/3) \log_{10} (-1/-0.01) \geq 3 \quad (\text{Eq. 20})$$

Thus, about 3 hr. after three doses have been administered, the concentration of drug in the serum should be within 1% of that found 3 hr. after the last dose given after an infinite number of doses had been administered. While the experimental value of 39.4 mcg./ml. found 3 hr. after three doses had been given does not quite fall within $\pm 1\%$ of the theoretical value of 38.1 mcg./ml., it is close, particularly if one takes into account the uncertainty in the value for k .³ The time needed to reach this level can be calculated from Eq. 18 and is 9 hr.

Example 2—Continuous Intravenous Infusion—Wagner and Alway (9) studied data obtained from the continuous intravenous infusion of lincomycin hydrochloride to humans. Consider the case where the infusion rate, k_0 , is 50,000 mcg./hr.; the apparent half-life for the disappearance of the drug from the body by all processes, assuming that it is a single compartment, is 3.91 hr. ($k = 0.177 \text{ hr.}^{-1}$); and the volume constant, V , or the apparent volume of distribution is 26,000 ml. Using Eq. 21, it is possible to calculate the concentration, C , of lincomycin in the fluids of distribution at any time:

$$C = \frac{k_0}{Vk} (1 - e^{-kt}) \quad (\text{Eq. 21})$$

The concentration, C^{∞} , in the body at infinite time is

$$C^{\infty} = \frac{k_0}{Vk} \quad (\text{Eq. 22})$$

Substituting the appropriate values into Eq. 22, the value of C^{∞} is 10.9 mcg./ml.,⁴ and a concentration 1% less than this is 10.8 mcg./ml.

How long would the infusion apparatus have to run to reach the value of 10.8 mcg./ml.? As a first approximation, a continuous intravenous infusion of a drug can be thought of as a process where a large number of small doses are administered at very frequent time intervals (e.g., intravenous drip). For the present discussion, let $\tau = 3.91 \times 10^{-4} \text{ hr.}$ (1.4 sec.), $t_{0.5}/\tau = 10^4$, and $\alpha = 0.99$. The first dose is equal in magnitude to all succeeding doses, so that $\beta = 0$. The amount of drug administered in the first dose equals $k_0\tau$, and is 19.6 mcg. The number of doses needed to reach the 10.8-mcg./ml. level can be calculated from Eq. 17:

$$n \geq 3.3219 (10^4) \log_{10} (-1/-0.01) \geq 6.64 \times 10^4 \quad (\text{Eq. 23})$$

³ The value of k in this report is related to the K found by Boxer *et al.* (4) by the following equation: $k = (K \pm \text{one standard error}) (-2.303) = (-0.17 \pm 0.012 \text{ hr.}^{-1}) (-2.303) = 0.39 \pm 0.028 \text{ hr.}^{-1}$.

⁴ This value of C^{∞} has been reached or exceeded in some clinical studies with this drug (10-13).

and the time needed to reach the serum concentration of 10.8 mcg./ml. calculated from Eq. 18 is 26.0 hr.

If 200,000 mcg. of lincomycin hydrochloride was injected intravenously in an instantaneous manner into the same subject, and the "continuous" infusion was then begun immediately (1.4 sec. later), how long would it take for the serum concentration of the drug to reach 10.8 mcg./ml.? The value of β can be calculated by substitution into Eq. 10:

$$\beta = \frac{B''/V}{B_{\min}^{\infty}/V} = \frac{(200,000 \text{ mcg.} - k_0\tau)/26,000 \text{ ml.}}{10.9 \text{ mcg./ml.}} = 0.706 \quad (\text{Eq. 24})$$

To be mathematically exact in Eq. 24, one maintenance dose, $k_0\tau$, must be subtracted from the 200,000-mcg. initial dose. From a practical standpoint in this example, the $k_0\tau$ term can be ignored because it was made negligibly small compared to the 200,000-mcg. first dose. The α -term remains at 0.99. Substitution of α and β and $t_{0.5}/\tau = 10^4$ into Eqs. 16 and 17 gives a value of n of 4.88×10^4 . The time needed for the serum concentration to reach 10.8 mcg./ml. as calculated from Eq. 18 is about 19 hr. Thus, the time needed to approach within $\pm 1\%$ of C^{∞} was reduced about 7 hr. when the initial dose was set at a value four times greater than the hourly amount delivered by the infusion apparatus.

Ethylene Oxide Penetration of the Silicone Coating Used as a Lubricant on Disposable Syringe Rubber Plunger Tips and Hypodermic Needles

YU YIN CHEN

Abstract □ The ability of 100% ethylene oxide to penetrate the silicone coating used on disposable hypodermic needles and syringe rubber plunger tips has been determined. It was shown that ethylene oxide has the ability to penetrate through the silicone coating and thus kill the spores of *Bacillus subtilis* var. *niger*, ATCC 9372, which were introduced underneath the silicone coating.

Keyphrases □ Ethylene oxide penetration—silicone lubricant □ Silicone lubricant effect—ethylene oxide bactericidal action □ *Bacillus subtilis*—ethylene oxide penetration determination

With the introduction of medical devices made from comparatively low melting point plastics, the ability to sterilize these instruments by autoclaving was no longer feasible; subsequently, ethylene oxide has been utilized and found effective (without high temperature) as a chemical sterilant.

Recent usage of silicone as a lubricant for disposable hypodermic needles and syringe rubber plunger tips raised the question of whether the ethylene oxide gas can penetrate the silicone coating and sterilize the surface beneath. It was, therefore, the purpose of this study to test the effectiveness of 100% ethylene oxide [4-hr. cycle, 48.8° (120° F.)] as a penetrating sterilant through a silicone coating. A number of preliminary tests were necessary to establish procedures and suitable materials. In the selection of materials it was necessary to obtain a nonbacteriostatic solvent capable of dissolving silicone (to expose the organisms which were

covered by it), due to its immiscibility with the water present in the culture medium. Initial tests indicated *n*-hexane (1), purified (Curtin Co.), was an effective solvent. In turn, methanol (Baker analyzed reagent) was added to increase the miscibility of the *n*-hexane. The bacteriostatic properties of *n*-hexane had to be determined to assure that there was no killing factor other than ethylene oxide.

MATERIALS AND METHODS

Bacillus subtilis var. *niger*, ATCC 9372, was selected as the test organism since its spores are known to be highly resistant to ethylene oxide gas [Beeby and Whitehouse (2); Ernst and Shull (3, 4); Kelsey (5); and Phillips (6)]. Sterile trypticase soy broth (TSB) was used as the culture medium (20 ml. per culture tube), and disposable hypodermic syringes (2.5 ml.) and needles [16 gauge × 3.81 cm. (1.5 in.)] were used as the test samples. Commercial silicone fluid M360 (Dow Corning Co.), a colorless, highly water-repelling, non-toxic, nonvolatile, low-surface tension, and chemically thermally inert substance (1) was used as the coating agent.

Spore Strips Treated with *n*-Hexane—To determine whether *n*-hexane had a bacteriostatic effect on *B. subtilis* var. *niger* spores, three different concentrations (10³, 10⁵, and 10⁷) of spore strips (American Sterilizer Co.) were immersed in *n*-hexane for 1 hr. These were then divided into two groups. The first group was cultured in TSB; the other was mixed with 1 ml. of 90% methanol (shaken for 20 min. on an automatic shaker) and then cultured in TSB for 48 hr. at 32°.

Vegetative Cells Treated with *n*-Hexane—To determine the bacteriostatic properties of *n*-hexane on vegetative cells of *B. subtilis* var. *niger*, four separate amounts (0.1, 0.2, 0.5, and 1.0 ml.) of *n*-hexane were mixed with 0.5 ml. of 90% methanol and 0.06 ml.

Table I—Effect of *n*-Hexane on Spore Strips of *B. subtilis* var. *niger*

Concentration of Spores	Total No. of Samples	24-hr. Growth	48-hr. Growth
10 ³	5 Without methanol	1 Light growth 4 No growth	1 Heavy growth 4 No growth
10 ³	5 With methanol	4 Light growth 1 No growth	4 Heavy growth 1 No growth
10 ⁵	5 Without methanol	5 Medium growth	5 Heavy growth
10 ⁵	5 With methanol	5 Heavy growth	5 Heavy growth
10 ⁷	5 Without methanol	5 Heavy growth	5 Heavy growth
10 ⁷	5 With methanol	5 Medium growth	5 Heavy growth

Table II—Effect of *n*-Hexane on Vegetative Cells of *B. subtilis* var. *niger*

Amount of <i>n</i> -Hexane, ml.	Total No. of Samples	Amount of Organisms, ml.	24-hr. Growth
0.1	10	0.06	All heavy growth
0.1	10	0.005	All heavy growth
0.2	10	0.06	All heavy growth
0.2	10	0.005	All heavy growth
0.5	10	0.06	All heavy growth
0.5	10	0.005	All heavy growth
1.0	10	0.06	All heavy growth
1.0	10	0.005	All heavy growth

Table III—Effect of *n*-Hexane on Spores Suspended in Methanol

Amount of <i>n</i> -Hexane, ml.	Total No. of Samples	24-hr. Growth	48-hr. Growth
0.1	10	10 Light growth	10 Heavy growth
0.2	10	8 Heavy growth 2 No growth	8 Heavy growth 2 No growth
0.5	10	8 Heavy growth 2 No growth	10 Heavy growth
1.0	10	8 Heavy growth 2 No growth	10 Heavy growth

of a heavy growth culture of *B. subtilis* var. *niger* and were shaken for 1 hr. on an automatic shaker (Group 1). Following the same method, a second group was mixed with a small amount of the heavy growth culture (0.005 ml.). Both groups were then cultured in TSB for 24 hr. at 32°.

Spores in Methanol Treated with *n*-Hexane—To determine a possible bacteriostatic effect of *n*-hexane on spores in the methanol suspension, spores (15×10^6 per ml.) were diluted with 90% methanol to approximately 1000 spores per ml. Spore samples (1 ml. each) were thoroughly mixed for 30 min. (on automatic shaker) with different amounts (0.1, 0.2, 0.5, and 1.0 ml.) of *n*-hexane and then cultured in TSB for 48 hr. at 32°.

Samples Inoculated with Spores and Coated with Silicone—To determine whether silicone fluid inhibits the germination and/or growth of spores, 20 rubber plunger tips were dipped into a spore suspension (15×10^6 per ml.) and then allowed to air dry for 6 hr. at 25°. A measurement (using Sahli-type hemoglobin pipet to pick up the spore solution adhering to the plunger tip) was made which was 20 λ and contained approximately 300,000 spores adhering to the rubber surface.

In addition, 20 needles were immersed into the 15×10^6 spore solution for 4 hr. and then allowed to air dry for 6 hr. at 25°. The pour plate counting method determined that approximately 32,000 spores were under the coating per needle (number of spores under coating = number of spores rinsed off before coating—number of spores rinsed off after coating). Experimental needles and rubber plunger tips were then coated with silicone (the thickness of the coating and technique were as normally used by the manufacturer, which is a maximum of 1 mg./cm.² of exposed surface area of rubber tip and 1 mg. per needle). Controls were not coated with silicone. All the samples were then cultured in TSB for 24 hr. at 32°.

Inoculated Samples Sterilized by Ethylene Oxide—To determine the ability of 100% ethylene oxide gas to penetrate and sterilize through the silicone coating, the rubber tips and needles were inoculated with spores, coated with silicone (same method as mentioned previously), and assembled as a syringe. The syringes were then sterilized with 100% ethylene oxide with a concentration of approximately 2628 mg./l. for 4 hr. at 48.8° (120°F.) and 4 p.s.i. pressure. Then the experimental group had the silicone coating removed with *n*-hexane, and a control group was left coated. Both groups were cultured in TSB at 32° for 10 days.

Table IV—Effect of Silicone Coating on the Inoculated Samples—Not Sterilized

Treatments	Samples	24-hr. Growth
With coating	10 Plungers	All heavy growth
With coating	10 Needles	All heavy growth
Without coating	10 Plungers	All heavy growth
Without coating	10 Needles	All heavy growth

Table V—Effect of Ethylene Oxide Sterilization on Inoculated Samples

Treatment	Samples	10-Day Cultivation
Coating removed	10 Plungers	All no growth
Coating removed	10 Needles	All no growth
Coating not removed	10 Plungers	All no growth
Coating not removed	10 Needles	All no growth

RESULTS

The results are shown in Tables I through V.

DISCUSSION AND CONCLUSION

The results of Table I show that a concentration of 10^8 spores on paper strips, after immersion in *n*-hexane, was not successfully cultured. The *n*-hexane, being nonsoluble in water, formed a layer in the liquid growth medium; however, when mixed with 90% methanol, *n*-hexane solubility was increased, thereby releasing the spores for germination and growth. There is no indication that *n*-hexane acts as a bacteriostatic agent to both the spores and vegetative forms of *B. subtilis* var. *niger*; therefore, *n*-hexane was used as a solvent for the silicone fluid.

The number of microorganisms involved did not prove to be an influencing factor for the bacteriostatic character of *n*-hexane. The results of Table II indicate that a small number of microorganisms was not inhibited by any of the levels of *n*-hexane.

Results of Table IV indicate that the silicone coating (which was coated by the spray method) did not cover a great number of the inoculated spores (10^6); therefore, the silicone coating was not considered a complete masking factor.

Results of this study indicated that 100% ethylene oxide does penetrate the silicone fluid used as a coating agent and does kill the test organisms present on the surface and beneath the coating.

Sterol Metabolism X: Epimeric 23-Hydroxycholesterols

JOHAN E. VAN LIER and LELAND L. SMITH

Abstract □ Synthesis of the epimeric 23-hydroxycholesterols has been achieved by sodium borohydride reduction of 3β -hydroxycholest-5-en-23-one. Tentative configurational assignments were made based on specific rotation data. The configurations of the epimeric 24-hydroxycholesterols are discussed, and a reconsideration of their configurational assignment is suggested.

Keyphrases □ 23-Hydroxycholesterols, epimeric—synthesis □ Absolute configuration—23-hydroxycholesterols, epimeric □ IR spectrophotometry—identification □ Adsorption chromatography—identification

Although naturally occurring 20-, 22-, 24-, 25-, and 26-hydroxysterols have been studied extensively, 23-hydroxysterols have received relatively little attention. 23-Hydroxysterols have limited representation in nature in the fungal metabolite 23*S*-hydroxylanosterol (lanosta-8,24-dien- 3β ,23*S*-diol)(1), the chiograsterols (2), the plant hormone antheridiol (3), and possibly a 23-hydroxycholesterol (cholest-5-ene- 3β ,23-diols) sulfate in human infant meconium (4). Other 23-hydroxylated steroids include several bile acids (5), the jervine and veratramine classes of steroidal alkaloids (6), and a variety of triterpenoid compounds (7–18). In view of a continuing interest in the autoxidation of cholesterol in the side chain (19, 20) and in the occurrence of side-chain-oxidized cholesterol derivatives in human tissues (21–23), the authors sought to prepare the as yet undescribed epimeric 23-hydroxycholesterols for record purposes.

THEORETICAL

Sodium borohydride reduction of 3β -hydroxycholest-5-en-23-one (24) gave a mixture of epimeric 3β ,23-diols separable by chromatography. Twice the yield of the lower melting, chromatographically more mobile, more levorotatory epimer was obtained compared to the higher melting, more polar, more dextrorotatory epimer. Although the epimeric 3β ,23-diols were resolved from one another by adsorption chromatography, they were unresolved on gas chromatography; their corresponding 3β ,23-diacetates also were not resolved.

The 23-hydroxycholesterol epimers could be distinguished from one another by means of their IR absorption spectra, but except for minor differences in ion intensity the epimers were not distinguishable by their mass spectra, either as the free 3β ,23-diols or as their 3β ,23-diacetates. Mass spectra of the 3β ,23-diols were characterized by a strong molecular ion (m/e 402) and by ions at m/e 384 ($M-18$)⁺ and m/e 369 ($M-33$)⁺, representing loss of water and of a methyl radical and water, respectively. Mass spectra of the 3β ,23-diacetates exhibited no molecular ion; the highest mass observed, also the base peak, was m/e 426 ($M-60$)⁺, representing loss of the elements of acetic acid. The next highest mass at m/e 366 ($M-120$)⁺ corresponds to loss of two molecules of acetic acid.

Assignment of absolute configuration to the epimers may be made by analogy to arguments advanced in assignment of absolute configuration to the epimeric 23-lanosterols (25). Since *S*(+)-4-methylpent-3-en-2-ol and *S*(+)-4-methylpentan-2-ol derived therefrom have the same absolute configuration and sign of specific rotation

(26, 27), these two secondary alcohols serving as model compounds for assignment of the respective 23-hydroxylanosterol and 23-hydroxycholesterol derivatives imply that the more dextrorotatory epimers in both sterol series have the same absolute configuration. The absolute configuration of 23-hydroxysterols corresponding to that of *S*(+)-4-methylpentan-2-ol and *S*(+)-4-methylpent-3-en-2-ol is the $23\beta_F$ -configuration by Plattner's convention (28). The $23\beta_F$ -configuration corresponds to the $23S$ -configuration by the Cahn-Ingold-Prelog sequence rule nomenclature for the more dextrorotatory 23-hydroxycholesterol (25). Because of a change in priority of the C₂₂-steroid residue relative to the terminal isobutyl group of 23-hydroxycholesterol, the more dextrorotatory $23\beta_F$ -hydroxycholesterol and the lanost-8-ene- 3β , $23\beta_F$ -diol(25) derived by catalytic reduction of 23*S*-hydroxycholesterol are of the $23R$ -configuration.

Other than the as yet undescribed cholest-5-ene- 3β ,21-diol and (25*S*)-cholest-5-ene- 3β ,26-diol, all possible cholesterol derivatives hydroxylated in the side chain have now been prepared and absolute configurations assigned. However, previously assigned absolute configurations (29, 30) of the epimeric 22-hydroxycholesterols have been recently reversed, the naturally occurring epimer now being termed cholest-5-ene- 3β ,22*R*-diol (31–33). Furthermore, it appears that revision of the previously accepted absolute configurations of the epimeric 24-hydroxycholesterols is in order. The prior assignment of the $24\beta_F$ (24*S*)-configuration (29) to the naturally occurring, more levorotatory 24-hydroxycholesterol cerebrosterol (cholest-5-ene- 3β ,24-diols) (34–36) was made in reference to molecular rotations of model levorotatory *n*-alkylisopropylcarbinols, in the same manner as used by Entwistle and Pratt (25) and by the authors with methylisobutenylcarbinol and methylisobutylcarbinol for assignment of configuration to the 3β ,23-diols. The model levorotatory alkylisopropylcarbinols used for this purpose (29) were erroneously given the *S*-configuration¹ which led to a $24\beta_F$ -assignment for the levorotatory 24-hydroxycholesterol epimer. However, when proper recognition is made that the levorotatory model compounds used for this assignment are of the *R*-configuration, a revision of absolute configuration obtains, and the more levorotatory, naturally occurring 24-hydroxycholesterol cerebrosterol becomes cholest-5-ene- 3β ,24*R*-diol.²

In view of the revised absolute configurational assignments of the 22-hydroxycholesterols (31–33), the presently suggested revised absolute configurational assignments of the 24-hydroxycholesterols, and the absolute configurations of the 23-hydroxycholesterols assigned herein, it is now apparent that the three hydroxycholesterols of β_F -configuration: $22\beta_F$ (22*R*)-hydroxycholesterol, $23\beta_F$ (23*R*)-hydroxycholesterol, and $24\beta_F$ (24*S*)-hydroxycholesterol, are the more dextrorotatory of their respective epimeric pairs. This deduction follows from recognition that the dextrorotatory enantiomers of the appropriate model secondary alcohols *S*(+)-6-methylheptan-2-ol (38), *S*(+)-4-methylpentan-2-ol (26, 27), and *S*(+)-3-methylbutan-2-ol (29) have the same *S*-configuration.

¹ Model *n*-alkylisopropylcarbinol Compounds XXX (p. 1987) of Klyne and Stokes (29) used for assignment of absolute configuration to the 24-hydroxycholesterol epimers appear to have the *S*-configuration but are stated to be levorotatory, whereas model Compound XXI [*S*(+)-3-methylbutan-2-ol] is dextrorotatory and its enantiomeric model Compound XXII [*R*(-)-3-methylbutan-2-ol] is levorotatory (p. 1986). From the printed figures, both Models XXX and XXI have the *S*-configuration, but XXX should have the *R*-configuration to be levorotatory (37). This point is repeated by Fieser and Fieser (6).

² Prior reports from this laboratory (21–23) have used without revision the absolute configuration of cerebrosterol as assigned by Klyne and Stokes (29) but converted to the Cahn-Ingold-Prelog sequence rule nomenclature, thus 24*S*-hydroxycholesterol (cholest-5-ene- 3β ,24*S*-diol). These prior usages should now be revised. On the same basis the more levorotatory epimer of another 24-hydroxysterol epimeric pair previously assigned $24\beta_F$ (24*S*)-configuration (38) should also be revised.

EXPERIMENTAL³

3 β -Hydroxycholest-5-en-23-one—A solution of 40 mg. of 3 β -hydroxynorchol-5-en-23-ic acid, m.p. 188–190°, $\bar{\nu}_{\text{max}}^{\text{KBr}}$ 3300, 2650, 1680, 1270, and 1040 cm.⁻¹, in 5 ml. of dry pyridine–acetic anhydride (2:1) was held overnight at room temperature. The mixture then was diluted with 50 ml. of distilled water. The precipitated acetate was filtered, washed with water, dried under vacuum ($\bar{\nu}_{\text{max}}^{\text{KBr}}$ 2650, 1720, 1680, 1250, and 1040 cm.⁻¹), and dissolved in 50 ml. of absolute diethyl ether. One drop of dry pyridine and 0.7 ml. of thionyl chloride were added, and after 3 hr. at room temperature the ether was evaporated under vacuum. Crystallization from diethyl ether–hexane gave 318 mg. of the acid chloride acetate, m.p. 149–154°, $\bar{\nu}_{\text{max}}^{\text{KBr}}$ 1800, 1720, 1250, 1030, and 760 cm.⁻¹ [lit. m.p. 155–156° (24)]. To 240 mg. of magnesium turnings was added under nitrogen 1.45 g. of freshly distilled isobutyl bromide in 30 ml. of absolute diethyl ether. The mixture was stirred vigorously until the reaction started, and gentle stirring was continued until all magnesium dissolved. The Grignard solution was cooled to –5° and 1 g. of cadmium chloride was added. After stirring for 10 min., 30 ml. of dry benzene was added, and after 15 min. the acid chloride acetate (318 mg.) in 10 ml. of dry benzene was added. The stirred mixture was allowed to come to room temperature and was held overnight. The mixture was cooled in an ice bath and the complex destroyed by cautious addition of 10 ml. of 2 N sulfuric acid and then 100 ml. of water. The reaction mixture was extracted three times with 100-ml. portions of diethyl ether; the combined ether extracts were washed with sodium bicarbonate solution, with water, and with saturated sodium chloride solution, and were dried over anhydrous sodium sulfate. The dried solution was evaporated under vacuum, redissolved in 50 ml. of methanol containing 50 mg. of sodium methoxide, and refluxed for 45 min. After cooling, 100 ml. of water was added, and the mixture was neutralized with 2 N sulfuric acid and extracted three times with 100-ml. portions of diethyl ether. The ether extract was washed with sodium bicarbonate solution, with water, and with saturated sodium chloride solution before drying over anhydrous sodium sulfate and evaporated under vacuum. Gas chromatographic analysis of the product indicated the presence of four components. The reaction products were dissolved in a small amount of methylene chloride and chromatographed on a 2.5 × 60-cm. column packed with synthetic polysaccharide (Sephadex LH-20) prepared with methylene chloride. Elution with neat methylene chloride (13.5-ml. fractions taken automatically) gave several fractions which were analyzed individually by TLC. From Fraction No. 13 there was obtained on evaporation of the solvent 145 mg. of the desired 23-ketone, m.p. 136–140° [lit. m.p. 141–143° (24)]; $\bar{\nu}_{\text{max}}^{\text{KBr}}$ 3400, 1700, and 1050 cm.⁻¹; R_c 0.93 in benzene–ethyl acetate (3:2).

An unidentified steroidal ketone was recovered from Fraction No. 14, obtained from the polysaccharide column from which the 23-ketone had just been eluted. Evaporation of the methylene chloride gave 70 mg. of material; upon recrystallization from hexane–diethyl ether, there was obtained 18 mg. of white crystals, m.p. 119–125°; $\bar{\nu}_{\text{max}}^{\text{KBr}}$ 3520, 3450, 1730, 1720, 1060, and 1020 cm.⁻¹; $\bar{\nu}_{\text{max}}^{\text{CCl}_4}$ 3630, 1740, 1155, 1055 cm.⁻¹; R_c 0.89 in benzene–ethyl acetate (3:2); magenta color with 50% sulfuric acid.

Anal.—Calcd. for C₂₄H₃₆O₃: C, 77.34; H, 9.74. Found: C, 77.08; H, 9.95.

Cholest-5-ene-3 β ,23 α_F (23S)-diol—A solution of 150 mg. of 3 β -hydroxycholest-5-en-23-one dissolved in 20 ml. of methanol was treated overnight at room temperature with an excess of sodium borohydride. The solvent was evaporated under vacuum and the residue was dissolved in 100 ml. of diethyl ether and washed with 2 N sulfuric acid, with water, with sodium bicarbonate solution, with water, and with saturated sodium chloride solution. The ether solution was dried over anhydrous sodium sulfate and evaporated under

vacuum. The solid residue was found by TLC to be a mixture of epimeric 23-hydroxycholesterols. The mixed epimers were chromatographed on a 2.5 × 60-cm. column of silica gel prepared and irrigated with hexane–diethyl ether (3:1) with 15-ml. fractions being collected automatically. TLC examination of each fraction established that the more mobile epimer was present in Fractions 36–46, and the more polar epimer in Fractions 48–60. Fractions 46–48 contained both epimers. The mixed fraction was rechromatographed on a 20 × 20-cm. chromatoplate of silica gel HF₂₅₄ 1 mm. thick, irrigated with benzene–ethyl acetate (3:2). Recovery of both resolved 3 β ,23-diols from the chromatoplate afforded additional material which was added to the appropriate initial fraction. Crystallization from hexane–ethyl acetate of the fractions containing the more mobile epimer gave 91 mg. (67%) of the 3 β ,23 α_F (23S)-diol. Recrystallization from diisopropyl ether–diethyl ether gave the analytical sample, m.p. 136–137°; $[\alpha]_D$ –30°; $\bar{\nu}_{\text{max}}^{\text{KBr}}$ 3400 and 1050 cm.⁻¹; R_c 0.84 in benzene–ethyl acetate (3:2); blue-purple color with 50% sulfuric acid; r_T 2.25 (3% QF-1), 1.66 (3% SE-30); mass spectrum: m/e 402 (100%), 384 (32%), 369 (13%), 351 (11%), 300 (14%), 291 (16%), 273 (23%), 255 (17%), etc.

Anal.—Calcd. for C₂₇H₄₆O₂: C, 80.53; H, 11.52. Found: C, 80.25; H, 11.82.

Cholest-5-ene-3 β ,23 α_F (23S)-diol 3 β ,23-Diacetate—A solution of 55 mg. of the more mobile 3 β ,23 α_F -diol in 5 ml. of dry pyridine–acetic anhydride (2:1) was held overnight at room temperature and worked up by precipitation with 10 ml. of water. The diacetate was discarded. After washing the derivative several times with distilled water, the sample was dried under vacuum and recrystallized from methanol, yielding 50 mg. of 3 β ,23S-diacetate, m.p. 143–146°; $[\alpha]_D$ –35°; $\bar{\nu}_{\text{max}}^{\text{KBr}}$ 1730, 1240, and 1030 cm.⁻¹; R_c 1.43 in benzene–ethyl acetate (3:2); blue-purple color with 50% sulfuric acid; r_T 4.62 (3% QF-1), 2.69 (3% SE-30); mass spectrum: m/e 426 (100%), 366 (10%), 351 (7.5%), 326 (5.7%), 282 (11%), etc.

Anal.—Calcd. for C₃₁H₅₀O₄: C, 76.49; H, 10.36. Found: C, 76.26; H, 10.45.

Cholest-5-ene-3 β ,23 β_F (23R)-diol—Crystallization from hexane–ethyl acetate of the appropriate fractions containing the more polar epimer afforded 44 mg. (33%) of the 3 β ,23 β_F -diol. Recrystallization from diisopropyl ether–diethyl ether gave the analytical sample, m.p. 175–176°; $[\alpha]_D$ –22°; $\bar{\nu}_{\text{max}}^{\text{KBr}}$ 3400 and 1050 cm.⁻¹, different from the spectrum of the 23S-epimer; R_c 0.74; blue-purple color with 50% sulfuric acid; r_T 2.25 (3% QF-1), 1.66 (3% SE-30), unseparable by gas chromatography from the 23S-epimer; mass spectrum: essentially the same as for the 23S-epimer.

Anal.—Calcd. for C₂₇H₄₆O₂: C, 80.53; H, 11.52. Found: C, 80.35; H, 11.56.

Cholest-5-ene-3 β ,23 β_F (23R)-diol 3 β ,23-Diacetate—Acetylation of 17 mg. of the 3 β ,23 β_F -diol in the same manner used for the 3 β ,23 α_F -diol gave 11 mg. of the 3 β ,23 β_F -diacetate, crystallized from methanol, m.p. 111–114°; $[\alpha]_D$ –9°; $\bar{\nu}_{\text{max}}^{\text{KBr}}$ 1730, 1240, and 1030 cm.⁻¹, different from the spectrum of the 23-epimeric diacetate; R_c 1.43; blue-purple color with 50% sulfuric acid; r_T 4.62 (3% QF-1), 2.69 (3% SE-30), inseparable by gas chromatography from the 23S-epimer.

Anal.—Calcd. for C₃₁H₅₀O₄: C, 76.49; H, 10.36. Found: C, 76.74; H, 10.48.

³ Melting points were taken on a calibrated Kofler block under microscopic magnification. Optical rotations were obtained in 1.0% solutions in chloroform using a 2-dm. tube. IR absorption spectra were recorded over the range 4000–400 cm.⁻¹ with a Perkin-Elmer model 337 spectrophotometer equipped with a beam condenser. Adsorption TLC was conducted using silica gel HF₂₅₄ (E. Merck GmbH., Darmstadt, Germany) and the solvent system benzene–ethyl acetate (3:2). Thin-layer chromatographic mobilities (R_c) are expressed in terms of cholesterol as unit mobility. Gas chromatography was conducted on a Hewlett-Packard F and M model 402 gas chromatograph using 3% QF-1 and 3% SE-30 columns as described previously in detail (22). Retention times (r_T) are given in terms of cholesterol as unit time.

New Compounds: Mannich Bases from 1,2-Diphenylindolizine—*N*-Substituted Cyclohexylaminomethyl Derivatives

WILLIAM B. HARRELL*, SHAO-WEN KUANG, and CROSSLEY O'DELL

Abstract □ Seven new Mannich bases, involving *N*-substituted cyclohexylamines and 1,2-diphenylindolizine, have been synthesized as potential biologically active compounds.

Keyphrases □ Mannich bases—synthesis □ *N*-Substituted cyclohexylamines—synthesis from 1,2-diphenylindolizine □ 1,2-Diphenylindolizine—Mannich base synthesis

In previously reported work, it has been shown that certain Mannich bases derived from indolizines exhibited CNS-depressant activity (1–3). As part of a continuing exploration of indolizines with potential biological activity, a series of Mannich bases involving *N*-sub-

stituted cyclohexylamines was synthesized from 1,2-diphenylindolizine (4) (Table I).

EXPERIMENTAL¹

The appropriate secondary amine (0.045 mole) was combined with 30 ml. of 1,4-dioxane and 2.25 ml. of 40% aqueous formaldehyde (0.030 mole). The mixture was placed in the refrigerator and allowed to stand for 48 hr. To the mixture was then added 4.1 g. of 1,2-diphenylindolizine (0.015 mole); the resulting clear solution was stirred at room temperature for 72 hr., during which

¹ Melting points were taken on a Thomas-Hoover melting-point apparatus and are uncorrected. Elemental analyses were obtained from Strauss Microanalytical Laboratories, Oxford, England.

Time Integral of Drug Concentration in the Central (Plasma) Compartment

Keyphrases ☐ Drug concentration time integral—central compartment ☐ Absorption comparison method—different formulations

Sir:

A well-known result in pharmacokinetics is that the time integral of the concentration of a drug in the central (plasma) compartment is equal to the total amount of drug absorbed divided by the product of the volume of distribution for the compartment and the elimination rate constant. The result is of great practical importance in that amounts of drug absorbed from different formulations of a drug can be readily compared by administering the different formulations to the same subject. Standard statistical designs, such as

balanced incomplete block designs, can thus be employed. The result has been proved for one-compartment and two-compartment systems under suitable conditions. The usual procedure has been to obtain an expression for the concentration in the central compartment (by solving the appropriate differential equations) and to integrate this expression over time to obtain the stated result. A recent example of this procedure is given in Eqs. 11a through 14a of Gibaldi *et al.* (1). The purpose of the present note is to show that the result is a direct consequence of two basic assumptions and thus holds under quite general conditions. In fact, the present proof is implicit in the derivation given for nonintravenous routes of administration in Eq. 22a of the reference.

The two basic assumptions are:

1. Elimination of the drug takes place only from the central compartment, that is, the compartment over

Time Integral of Drug Concentration in the Central (Plasma) Compartment

Keyphrases ☐ Drug concentration time integral—central compartment ☐ Absorption comparison method—different formulations

Sir:

A well-known result in pharmacokinetics is that the time integral of the concentration of a drug in the central (plasma) compartment is equal to the total amount of drug absorbed divided by the product of the volume of distribution for the compartment and the elimination rate constant. The result is of great practical importance in that amounts of drug absorbed from different formulations of a drug can be readily compared by administering the different formulations to the same subject. Standard statistical designs, such as

balanced incomplete block designs, can thus be employed. The result has been proved for one-compartment and two-compartment systems under suitable conditions. The usual procedure has been to obtain an expression for the concentration in the central compartment (by solving the appropriate differential equations) and to integrate this expression over time to obtain the stated result. A recent example of this procedure is given in Eqs. 11a through 14a of Gibaldi *et al.* (1). The purpose of the present note is to show that the result is a direct consequence of two basic assumptions and thus holds under quite general conditions. In fact, the present proof is implicit in the derivation given for nonintravenous routes of administration in Eq. 22a of the reference.

The two basic assumptions are:

1. Elimination of the drug takes place only from the central compartment, that is, the compartment over

which the time integral of concentration can be estimated by suitable sampling techniques.

2. Elimination from this compartment is first order.

Suppose that the amount of drug in the central compartment at any time is X , that the volume of distribution for the compartment is V , and that the elimination rate constant is k_e . Then the rate of elimination is $k_e X$, and the amount of drug eliminated between times t and $(t + dt)$ is $k_e X dt$. Consequently the total amount of drug absorbed (D)—which must equal the total amount eliminated—is given by

$$D = \int_0^{\infty} k_e X dt \quad (\text{Eq. 1})$$

Dividing both sides of the equation by $k_e V$ and defining the concentration C as X/V give the required result:

$$D/k_e V = \int_0^{\infty} C dt \quad (\text{Eq. 2})$$

As is clear from its derivation, the result is independent of the method of administration of the drug and is true for a system comprising any number of compartments with any type of transfer between them, provided only that the two basic assumptions are true. The same argument yields an analogous result for n th-order elimination from the central compartment (*i.e.*, rate of elimination = $k_e X^n$ where $n \neq 0$). In this case, it is seen that

$$D/k_e V^n = \int_0^{\infty} C^n dt \quad (\text{Eq. 3})$$

Acospectoside A III: Selective Conversion into Acovenoside B Using Snail Enzyme with Inhibited Esterase Activity

Keyphrases ☐ Acospectoside A, hydrolysis—snail enzyme ☐ Acovenoside B formation—acospectoside A hydrolysis ☐ TLC—identity ☐ Paper chromatography—identity ☐ IR spectrophotometry—identity ☐

Sir:

The use of snail (*Helix pomatia*) enzyme preparation for the hydrolysis of glucose residues in cardenolide

glycosides, first advocated by Reichstein *et al.* (1), is well known. In the author's structural studies (2, 3) on acospectoside A (I) (4), the cleavage of the terminal glucose residue could not be realized using several known glucosidase preparations, *i.e.*, emulsin, strophanthobiase, β -glucosidase, invertase, taka-diastase, and cellulase. However, by using the snail enzyme the splitting of glucose could be accomplished, though to a small extent leading to acovenoside B (II) (5, 6) and the hydrolysate contained acobioside A (III) (7) and acovenoside A (IV) (5, 6) and glucose as major products. It was further shown that II and III result by cleavage of the terminal glucose residue and C-1 ester group, respectively, while IV results by subsequent hydrolysis of II and III with esterase and β -glucosidase, respectively. These and other data enabled the determination of the structure of acospectoside A as 1-*O*-acetyl-acobioside A (I).

The low yield of II may be attributed to the higher order of activity of the esterase component, as compared to the β -glucosidase component, of the snail enzyme preparation. To secure higher yields of II, it was thought that by blocking the esterase component of the mixture the β -glucosidase activity might consequently be favored. This was actually realized by "poisoning" the esterase component by employing a commercial insecticide preparation¹ containing 2,2-dichlorovinyl dimethyl phosphate (a choline esterase inhibitor) as an active ingredient. The result was the formation of acovenoside B (II) as the sole crystalline product in about 27% yield. The identity of the product was established by direct comparison (mixed melting point, TLC, paper chromatography, and IR spectra) with an authentic sample.

In natural product studies, the need is frequently encountered to effect selectively the cleavage of an ester or a glycosidic linkage in the presence of the other. The availability of an enzyme preparation, such as that of snail, which would effect both, and a method to inhibit one and thus promote the other² have obvious advantages in structure elucidation work. A recent example of the application of the herein reported technique is the case of gymnemic acid A, a complex triterpenoid ester glucuronoside with reported (9) antisweet and antiviral activities, in which Rao and Sinsheimer (10, 11) induced selective sugar cleavage with the snail enzyme without affecting the ester groups and thus obtained only one product. This stands in contrast to the mixture of at least four components obtained earlier by Stocklin *et al.* (12) by treatment of their gymnemic acids with snail enzyme. The utility of the method was also tested by Rao and Sinsheimer (10, 11) in three other instances, gymnemic acids B, C, and D, which again afforded single genins designated K, N, and M.

¹ Real-Kill, an insecticide marketed by Real-Kill Products, Division of Cook Chemical Co., Kansas City, Mo., was employed as esterase inhibitor. In a typical procedure, a mixture of 75.6 mg. of I, 70 mg. of snail enzyme (Helicase, marketed by Industrie Biologique Francaise, S. A. Gennevilliers, France), and 0.4 ml. of Real-Kill in 12 ml. of water was left with stirring at room temperature for 5 days.

² Another method has recently been reported (see Reference 8) for the selective inhibition of the β -glucosidase activity in the snail enzyme which resulted in enhanced esterase activity. The results are being separately published.

which the time integral of concentration can be estimated by suitable sampling techniques.

Received September 4, 1969.

Accepted for publication November 21, 1969.

This communication is a part of the paper presented to the Ninth Annual Meeting of the American Society of Pharmacognosy, Iowa City, Iowa, July 1968 (see *Reference 13* for the published abstract).

This investigation was supported by Grant HE11212 from the National Institutes of Health, U. S. Public Health Service, Bethesda, Md.

The author thanks Drs. G. S. Rao and J. E. Sinsheimer, College of Pharmacy, University of Michigan, Ann Arbor, Mich., for communicating the results of their studies on gymnemic acids prior to publication. Thanks are also due to Professor T. Reichstein, University of Basel, for an authentic sample of acovenoside B and the enzyme preparation, cellulase, and to Drs. M. B. E. Fayez and T. B. Zalucky for their kind cooperation in a certain phase of this work.

Cytotoxic Activity of Imidazole Derivatives

Keyphrases ☐ Imidazole derivatives—synthesis ☐ Cytotoxicity—imidazole derivatives

Sir:

In this communication, we wish to report the synthesis and cytotoxic activity of a number of imidazole derivatives (Compounds 1–8). The synthesis of these imidazole derivatives was accomplished by the reaction of α -haloketones with guanyldiazones of aromatic aldehydes. The method of preparation of these compounds was very much similar to the one reported by Beyer *et al.* (1). The imidazole derivatives, Compounds 1–8, were characterized by IR and UV spectroscopy.

All these compounds were subjected to L-1210 *in vitro* assay for cytotoxic activity (2). In these screening experiments, the samples were weighed (about 5–10 mg.) into glass homogenizers (32-ml. size) and sterilized

Table I—Screening Data

Compd.	R	R ₁	R ₂	ID ₅₀	ID ₉₀
1	Phenyl	H	Phenyl	0.022	0.038
2	Phenyl	Me	Phenyl	0.96	1.5
3	Phenyl	H	3,4-Methylene-dioxyphenyl	0.29	0.47
4	3,4-Dihydroxy-phenyl	H	3,4-Methylene-dioxyphenyl	27	50
5	<i>m</i> -Nitrophenyl	Me	Phenyl	40	50
6	<i>p</i> -Nitrophenyl	H	<i>m</i> -Nitrophenyl	1.25	2.0
7	Methyl	H	<i>m</i> -Nitrophenyl	21	50
8	Methyl	H	<i>o</i> -Hydroxy-phenyl	9.0	21

with 0.1 ml. of 70% ethanol and about 0.1 ml. of dimethylsulfoxide (DMSO) to help them solubilize. The sample was ground with sterile water to make a suspension containing L-1210 leukemic cells. The tubes were stoppered and incubated at 37° for 3 days; then cell counts were made on each tube by a Coulter counter. The percent inhibition and the ID₅₀ and ID₉₀ were calculated.

The assay values for the compounds are shown in Table I. Values of 1 or less for ID₅₀ were considered potentially active.

Three compounds showed ID₅₀ values less than 1. Based on these encouraging results, attempts are being made in our laboratories to synthesize a wide variety of these imidazole derivatives and to test them for L-1210 *in vitro* assay for possible cytotoxic activity. Obviously, more extensive testing will be required before any structure–activity correlation can be drawn.

with 0.1 ml. of 70% ethanol and about 0.1 ml. of dimethylsulfoxide (DMSO) to help them solubilize. The sample was ground with sterile water to make a suspension containing L-1210 leukemic cells. The tubes were stoppered and incubated at 37° for 3 days; then cell counts were made on each tube by a Coulter counter. The percent inhibition and the ID₅₀ and ID₉₀ were calculated.

The assay values for the compounds are shown in Table I. Values of 1 or less for ID₅₀ were considered potentially active.

Three compounds showed ID₅₀ values less than 1. Based on these encouraging results, attempts are being made in our laboratories to synthesize a wide variety of these imidazole derivatives and to test them for L-1210 *in vitro* assay for possible cytotoxic activity. Obviously, more extensive testing will be required before any structure–activity correlation can be drawn.

Antigenicity of a Polypeptide with a Known Sequence of Amino Acids

Keyphrases ☐ Polypeptides—known amino acid sequence ☐ Antigenicity—polypeptide

Sir:

Random copolymers containing varying amounts of the amino acid residues, alanine, glutamic acid, and

Figure 1—The precipitin curve.

tyrosine, have been shown to be antigenic (1-3). However, due to the unknown primary amino acid sequence of these random polymers, it is difficult to describe the locus of the active site of these antigenic polymers. To overcome this difficulty, the use of linear polypeptides with a known repeating sequence of amino acids has been suggested. For this purpose, poly-(L-tyrosyl-L-glutamyl-L-alanylglycyl)glycine-1-¹⁴C ethyl ester was recently synthesized (4), and we wish to report the antigenic properties of this polymer.

After obtaining preimmunization sera, four rabbits were treated at weekly intervals with 500 mcg. of poly-(tyr-glu-ala-gly)gly-1-¹⁴C ethyl ester. The first 2 weeks they were injected intradermally using complete Freund's adjuvant as suspension medium, and the 3rd week they were injected subcutaneously. The injection on the 4th week was done intravenously using buffered saline. Bleedings were conducted on the following week, and the serum from each animal was found to give a precipitin reaction with the polymer. The preimmunized sera under the same conditions gave a negative precipitin reaction. The quantitative determination of the antibody was obtained by the addition of dilutions of poly-(tyr-glu-ala-gly)gly-1-¹⁴C ethyl ester to 1-ml. samples of the pooled rabbit sera. The precipitates were kept at 4° for 48 hr., washed twice with small volumes of buffered saline, and collected by centrifugation. The total amount of protein precipitated was estimated by analysis for nitrogen by a micro-Kjeldahl method (5). The amount of antigen contained in each precipitate was estimated by use of the Folin-Ciocalteu method. From these results the precipitin curve shown in Fig. 1 was obtained.

From these results it can be seen that this polypeptide is antigenic; further studies pertaining to the specificity of its antibodies are presently in progress.

Quantitative Correlation of Absorption and *In Vitro* Dissolution Kinetics of Aspirin from Several Dosage Forms

Keyphrases ☐ Aspirin dosage forms—dissolution, absorption ☐ Absorption—dissolution, aspirin—correlation

Sir:

Several types of *in vivo-in vitro* correlation are described in the pharmaceutical literature (1). The most informative of these, but the most difficult to achieve, is the quantitative correlation between *in vitro* dissolution and *in vivo* absorption, particularly one involving several different dosage forms. An example is found in the report of Levy *et al.* (2) who were able to correlate the absorption of aspirin from three different dosage forms with a function of the dissolution rate, using the beaker method (3) at 50 r.p.m. A plot of the percent absorbed at time *T* versus the percent dissolved in (*T*-lag time)/2 gave a straight line with a slope of unity.

The present report introduces a new dissolution method, which has permitted an absolute quantitative correlation between the absorption and *in vitro* dissolution of aspirin from these three dosage forms. These findings extend the work of Levy *et al.* (2) because this type of 1:1 correlation was not attainable with the beaker method.

A schematic diagram of the rotating-flask apparatus used to determine dissolution is shown in Fig. 1. The apparatus consists of a spherical glass flask suspended in a constant-temperature bath. The globe is supported by glass rods, fused to its sides, which form the horizontal axis of the sphere. One support rod is coupled to a constant-speed motor, which provides rotation about the horizontal axis. A sampling port is molded into the sphere to permit introduction of the dosage form and periodic withdrawal of samples. The volume of the dissolution medium (in this case 400 ml.) and the position of the sampling port are such that fluid

This communication is a part of the paper presented to the Ninth Annual Meeting of the American Society of Pharmacognosy, Iowa City, Iowa, July 1968 (see *Reference 13* for the published abstract).

This investigation was supported by Grant HE11212 from the National Institutes of Health, U. S. Public Health Service, Bethesda, Md.

The author thanks Drs. G. S. Rao and J. E. Sinsheimer, College of Pharmacy, University of Michigan, Ann Arbor, Mich., for communicating the results of their studies on gymnemic acids prior to publication. Thanks are also due to Professor T. Reichstein, University of Basel, for an authentic sample of acovenoside B and the enzyme preparation, cellulase, and to Drs. M. B. E. Fayez and T. B. Zalucky for their kind cooperation in a certain phase of this work.

Cytotoxic Activity of Imidazole Derivatives

Keyphrases ☐ Imidazole derivatives—synthesis ☐ Cytotoxicity—imidazole derivatives

Sir:

In this communication, we wish to report the synthesis and cytotoxic activity of a number of imidazole derivatives (Compounds 1–8). The synthesis of these imidazole derivatives was accomplished by the reaction of α -haloketones with guanyldiazones of aromatic aldehydes. The method of preparation of these compounds was very much similar to the one reported by Beyer *et al.* (1). The imidazole derivatives, Compounds 1–8, were characterized by IR and UV spectroscopy.

All these compounds were subjected to L-1210 *in vitro* assay for cytotoxic activity (2). In these screening experiments, the samples were weighed (about 5–10 mg.) into glass homogenizers (32-ml. size) and sterilized

Table I—Screening Data

Compd.	R	R ₁	R ₂	ID ₅₀	ID ₉₀
1	Phenyl	H	Phenyl	0.022	0.038
2	Phenyl	Me	Phenyl	0.96	1.5
3	Phenyl	H	3,4-Methylene-dioxyphenyl	0.29	0.47
4	3,4-Dihydroxy-phenyl	H	3,4-Methylene-dioxyphenyl	27	50
5	<i>m</i> -Nitrophenyl	Me	Phenyl	40	50
6	<i>p</i> -Nitrophenyl	H	<i>m</i> -Nitrophenyl	1.25	2.0
7	Methyl	H	<i>m</i> -Nitrophenyl	21	50
8	Methyl	H	<i>o</i> -Hydroxy-phenyl	9.0	21

with 0.1 ml. of 70% ethanol and about 0.1 ml. of dimethylsulfoxide (DMSO) to help them solubilize. The sample was ground with sterile water to make a suspension containing L-1210 leukemic cells. The tubes were stoppered and incubated at 37° for 3 days; then cell counts were made on each tube by a Coulter counter. The percent inhibition and the ID₅₀ and ID₉₀ were calculated.

The assay values for the compounds are shown in Table I. Values of 1 or less for ID₅₀ were considered potentially active.

Three compounds showed ID₅₀ values less than 1. Based on these encouraging results, attempts are being made in our laboratories to synthesize a wide variety of these imidazole derivatives and to test them for L-1210 *in vitro* assay for possible cytotoxic activity. Obviously, more extensive testing will be required before any structure–activity correlation can be drawn.

Quantitative Correlation of Absorption and *In Vitro* Dissolution Kinetics of Aspirin from Several Dosage Forms

Keyphrases ☐ Aspirin dosage forms—dissolution, absorption ☐ Absorption—dissolution, aspirin—correlation

Sir:

Several types of *in vivo-in vitro* correlation are described in the pharmaceutical literature (1). The most informative of these, but the most difficult to achieve, is the quantitative correlation between *in vitro* dissolution and *in vivo* absorption, particularly one involving several different dosage forms. An example is found in the report of Levy *et al.* (2) who were able to correlate the absorption of aspirin from three different dosage forms with a function of the dissolution rate, using the beaker method (3) at 50 r.p.m. A plot of the percent absorbed at time *T* versus the percent dissolved in (*T*-lag time)/2 gave a straight line with a slope of unity.

The present report introduces a new dissolution method, which has permitted an absolute quantitative correlation between the absorption and *in vitro* dissolution of aspirin from these three dosage forms. These findings extend the work of Levy *et al.* (2) because this type of 1:1 correlation was not attainable with the beaker method.

A schematic diagram of the rotating-flask apparatus used to determine dissolution is shown in Fig. 1. The apparatus consists of a spherical glass flask suspended in a constant-temperature bath. The globe is supported by glass rods, fused to its sides, which form the horizontal axis of the sphere. One support rod is coupled to a constant-speed motor, which provides rotation about the horizontal axis. A sampling port is molded into the sphere to permit introduction of the dosage form and periodic withdrawal of samples. The volume of the dissolution medium (in this case 400 ml.) and the position of the sampling port are such that fluid

Figure 1—Schematic diagram of dissolution apparatus. The flask has a diameter of about 16 cm. (6.5 in.)

does not enter the port, regardless of the position of the flask as it proceeds through a revolution. These measures prevent the accumulation of undissolved solid in the port. The port is stoppered to prevent loss of the dissolution medium to the water bath. A review of the literature on dissolution methodology suggests that this method is unique, although the hydrodynamics of the present system may be similar to that found in the apparatus described by Ferrari and Khoury (4) or in the apparatus utilized by Simoons (5).

The dissolution rate of aspirin from three commercially available dosage forms—conventional tablets, buffered tablets, and timed-release tablets—was determined at 37° and 1.2 r.p.m. in 0.1 N HCl. Samples of the dissolution fluid were taken at frequent intervals by means of a filter pipet. The samples were then hydrolyzed and assayed spectrophotometrically at 302.5 mμ for salicylic acid. The dissolution data on each dosage form were compared with percent absorbed-time data on the same dosage forms in man from the literature (2, 6). The correlation is shown in Fig. 2 which is a plot of percent absorbed to time *T* versus percent dissolved *in vitro* at time *T*. Regression lines, calculated by the method of least squares, using all data were as follows:

$$\text{percent absorbed} = 0.79(\text{percent dissolved}) + 2.44 \quad (\text{Eq. 1})$$

Figure 2—Plot of percent of dose of aspirin absorbed to time *T* after drug administration versus percent dissolved *in vitro* at time *T*. Key: ○, conventional tablets; ●, buffered tablets, and △, timed-release tablets.

$$\text{percent dissolved} = 1.08(\text{percent absorbed}) + 4.48 \quad (\text{Eq. 2})$$

The solid line in Fig. 2 represents Eq. 1. Using the method described by Mather (7) for interclass correlation where both variables are normally distributed, the correlation coefficient was found to be 0.92 corresponding to $p < 0.001$.

Penicillin Stability to Alcohols

Keyphrases □ Penicillin G, potassium, stability—alcoholic solution
□ Stability—alcoholic potassium penicillin G solution

Sir:

There is considerable confusion in the literature with regard to the stability of penicillin solutions in the presence of alcohols. Several textbooks and other published works state that penicillin solutions are inactivated by alcohols and glycerol (1-14), and this statement is also found in the most recent volume of the *United States Pharmacopeia* under the monograph for Potassium Penicillin G (15). Perhaps because of this statement, at least one textbook on microbiology cautions that patients with venereal disease being treated with penicillin should avoid an intake of alcoholic beverages (16). Historically, one can trace the probable origin of the belief that penicillin is inactivated by alcohols to a report by Abraham and Chain (17) who reported in 1942 that alkali salts of penicillin rapidly lose their biological activity when dissolved in primary alcohols. Presumably, alcoholysis proceeds with the ultimate formation of the appropriate inactive monoester of penicilloic acid (Scheme I).

However, in 1948, Chain *et al.* (18) conclusively demonstrated that this decomposition of penicillin

Figure 1—Schematic diagram of dissolution apparatus. The flask has a diameter of about 16 cm. (6.5 in.)

does not enter the port, regardless of the position of the flask as it proceeds through a revolution. These measures prevent the accumulation of undissolved solid in the port. The port is stoppered to prevent loss of the dissolution medium to the water bath. A review of the literature on dissolution methodology suggests that this method is unique, although the hydrodynamics of the present system may be similar to that found in the apparatus described by Ferrari and Khoury (4) or in the apparatus utilized by Simoons (5).

The dissolution rate of aspirin from three commercially available dosage forms—conventional tablets, buffered tablets, and timed-release tablets—was determined at 37° and 1.2 r.p.m. in 0.1 N HCl. Penicillin Stability to Alcohols

Keyphrases \square Penicillin G, potassium, stability—alcoholic solution
 \square Stability—alcoholic potassium penicillin G solution

Sir:

There is considerable confusion in the literature with regard to the stability of penicillin solutions in the presence of alcohols. Several textbooks and other published works state that penicillin solutions are inactivated by alcohols and glycerol (1-14), and this statement is also found in the most recent volume of the *United States Pharmacopeia* under the monograph for Potassium Penicillin G (15). Perhaps because of this statement, at least one textbook on microbiology cautions that patients with venereal disease being treated with penicillin should avoid an intake of alcoholic beverages (16). Historically, one can trace the probable origin of the belief that penicillin is inactivated by alcohols to a report by Abraham and Chain (17) who reported in 1942 that alkali salts of penicillin rapidly lose their biological activity when dissolved in primary alcohols. Presumably, alcoholysis proceeds with the ultimate formation of the appropriate inactive monoester of penicilloic acid (Scheme I).

However, in 1948, Chain *et al.* (18) conclusively demonstrated that this decomposition of penicillin

Scheme 1—Alcoholysis of potassium penicillin to inactive potassium penicilloate

salts in methanol occurred only in the presence of zinc, copper, or tin, which were contaminants in the alcohol that was used to demonstrate deactivation of penicillin as previously reported (17). They postulated that rather than a direct alcoholytic fission of the penicillin β -lactam ring, alcoholysis probably resulted through an intermediate oxazolone (penicillenic acid), formed by attack of the metal ion on the sulfur of the molecule (18). This inactivation of penicillin by metal-contaminated alcohol was retarded by dimercaptopropanol (18). These findings were later confirmed by Parnaby, who pointed out that alcoholic penicillin solutions were as stable as aqueous penicillin solutions (19).

Brodersen (20), while studying the kinetics of penicillin-penicillinase reactions, found that ethanol could be used to halt the enzymatic reaction without inactivating residual penicillin. At about the same time, other workers were using ethanol to eluate adsorbed penicillin from charcoal chromatographic columns in relatively good yields, which offers additional evidence that alcohols do not adversely affect penicillin stability (21). Indeed, penicillin has even been used in the past as a preservative of beer (22).

Finally, one can point to Fleming's original report on penicillin in which he indicates that penicillin activity could be extracted into ethanol from concentrated fermentation media (23).

Clearly, full consideration of the meaning of these early studies has not been given, and the concept of penicillin-alcohol "incompatibility" remains to this day. Curiously enough, with the voluminous literature available on all aspects of penicillins, a review by Doyle and Nayler (24) is the only report that we have found that clearly points out that penicillins are stable in the presence of alcohols.

Preliminary studies in our laboratory indicated that potassium penicillin G, following incubation with various concentrations of ethanol contained in nutrient broth, human serum, and human plasma, indeed continued to exhibit antibacterial activity against a known penicillin-sensitive strain of *Staphylococcus aureus*. Similar *in vitro* activity of penicillin in the presence of benzyl alcohol was demonstrated as well.

Thus, to derive more quantitative data and to establish that penicillin is stable in the presence of alcohols, we initiated a series of simple confirmatory experiments

Table I—Assay Results for Residual Potassium Penicillin G

Day after Preparation of Solution	Potassium Penicillin G Remaining, %				
	Predicted ^a	Solution A ^b	Solution B ^c	Solution C ^d	Solution D ^e
1	98.3	99.0	97.0	99.0	96.9
2	96.7	96.3	94.0	97.4	97.1
3	95.0	95.5	96.3	93.5	94.4
4	93.4	92.0	94.9	90.0	89.8
5	91.0	92.0	90.0	92.5	88.4

9	84.0	86.4	85.2	84.0	83.2
10	83.0	85.1	84.1	85.0	82.0

^a Calculated from published tables (20). ^b Potassium penicillin G control solution. ^c 40% ethanolic potassium penicillin G solution. ^d 70% ethanolic potassium penicillin G solution. ^e 0.5% benzyl alcohol potassium penicillin G solution.

on the subject. Ethanol and benzyl alcohol were utilized, the latter because sterile distilled water containing benzyl alcohol as a preservative is used in many hospitals as a diluent for the preparation of solutions of penicillin for parenteral administration.

Experimental—Materials—The penicillin used was commercially available potassium penicillin G. All solutions used in this study were prepared with a 1% phosphate buffer pH 6.0 (2.0 g. dibasic potassium phosphate, 8.0 g. monobasic potassium phosphate, and sufficient distilled water to make 1000 ml.) to contain a final concentration of 2000 u./ml. of potassium penicillin G. Subsequent sterilization of these solutions was done by Millipore filtration (0.22- μ pore size), after which they were stored at room temperature in previously sterilized glass flasks fitted with screw caps.

Assay Procedure—The method used to determine residual penicillin was an iodometric titration adapted from Alicino (25) and Mundell *et al.* (26) as described by Grove and Randall (27). At predetermined times (Table I), 2-ml. aliquots from each of the test solutions were aseptically removed and assayed for total penicillin. Each assay was done in duplicate, and the results were averaged. As a precautionary measure to detect accidental contamination by microorganisms, each day a small amount from each penicillin test solution was diluted with sterile saline and the resulting mixture was passed through a Millipore filter apparatus. Three further rinses with saline through the filter served to remove all residual penicillin, after which the membrane filter was removed, incubated on a suitable solid medium according to standard procedures, and observed for evidence of bacterial or fungal growth. No contamination was noted for all solutions throughout the course of this study.

Preparation of Penicillin Test Solutions—Penicillin Control (Solution A)—A sterile and buffered penicillin solution was prepared as described under *Materials*.

Ethanol Penicillin Solutions (Solutions B and C)—Two separate penicillin solutions were prepared as directed for Solution A, except that a portion of the water in each solution was replaced with 95% ethanol to furnish final concentrations of 40% (Solution B) and 70% (Solution C) ethanol, respectively.

Benzyl Alcohol Penicillin Solution (Solution D)—A sterile aqueous solution of benzyl alcohol (0.5%) was used as the vehicle to prepare the buffered penicillin solution.

Results and Discussion—The data from Table I show that the amounts of potassium penicillin G remaining in the control solution (Solution A) at specific times after the start of the experiment coincide rather well with predicted values which were calculated from published tables (20). Furthermore, it is noteworthy that the observed residual penicillin concentrations in the ethanol (Solutions B and C) as well as the benzyl alcohol (Solution D) solutions compared favorably with those of the penicillin control (Solution A).

Thus, these experiments have shown that potassium penicillin G can be mixed with ethanol solutions of concentrations as high as 70% for up to 10 days, with no greater loss than penicillin in aqueous solution. In a similar manner, it has been shown that benzyl alcohol, at a concentration of 0.5%, will not cause a decrease in stability of potassium penicillin G when in contact with the antibiotic for periods up to 10 days.

Books

REVIEWS

Experimental Methods in Pharmacology. By CHARLES O. WARD. St. John's University Press, Jamaica, NY 11432, 1969. 119 pp. 15 x 23 cm.

This small book briefly describes 62 experiments under 18 different chapter headings. Some of the subjects covered are local anesthetics, psychotropic drugs, anticonvulsants, muscle relaxants, topical drugs, antihistamines, and diuretics. Most of the experiments described are time-tested. Unfortunately the book is not of general value even though it is well suited to the author's laboratory. The descriptions of the experiments are very short and in many cases not too informative. Many numbers are missing for dosages and stimulus parameters; no statement of the intent of the blank spaces is given. This reviewer presumes that the student is to furnish the numbers by reference to the literature.

In some cases the experiments are so inadequately described as to be seriously misleading. An example is the experiment on measuring blood flow with a rotameter. The obvious requirement that flow

measurements must have simultaneous pressure measurements to have physiological meaning is ignored. In addition the use of the carotid artery is questionable because of the parallel flow (unmeasured) through three other large arteries.

The book is marred by many typographical errors; some of these are quite humorous, such as untravenously and cammula. Dosages are given in variable units; cc. of solution per kgm. or by weight per kgm. Anesthesia seems to have been omitted in some experiments in which it seems indicated. In an experiment in which painful stimuli are applied to a guinea pig, no description of the animal's response is given.

This edition of "Experimental Methods in Pharmacology" cannot be recommended for general use. The ideas behind it are excellent, and a revision based on discussions with other pharmacology teachers would be a welcome addition.

Drug Abuse: Social and Psychopharmacological Aspects. Compiled and edited by JONATHAN O. COLE and J. R. WITTENBORN, Charles C Thomas, 301-327 East Lawrence Ave., Springfield, IL 62703, 1969. xiii + 170 pp. 15.5 × 23.5 cm. Price \$9.50.

This book is drawn from reports presented during the Fifth Annual Meeting of the American College of Neuropsychopharmacology. While there is no primary focus to the papers included, they are representative of current research related to the growing social and medical concern of drug abuse.

One paper should be of particular interest because of the controversial nature of the topic and the scarcity of scientific research in this area. This study of the long-term effects of LSD administration in volunteer graduate students suggests that the use of LSD under controlled circumstances with selected individuals may be less hazardous and have less far-reaching consequences than previously thought. However, other studies reported in this book seem to present evidence to the contrary, confirming the need for more extensive research into these problems.

Data from a study of marijuana indicate that marijuana use begins as a group experience engaged in by peers, and not as the pusher engaging the youth.

This book includes eleven studies concerning various aspects of drugs and drug abuse. While the editors admit that no answers are presented, they are hopeful that this volume will serve to stimulate research in these and related areas.

Drugs and Youth. Edited by J. R. WITTENBORN, HENRY BRILL, JEAN PAUL SMITH, and SARAH A. WITTENBORN, Charles C Thomas, 301-327 East Lawrence Ave., Springfield, IL 62703, 1969. xiv + 485 pp. 18 × 26 cm. Price \$22.75.

This book, "Drugs and Youth," is based on the proceedings of the Rutgers Symposium on Drug Abuse held in June, 1968, at the Rutgers Interdisciplinary Research Center. The one hundred fifty participants in the three-day symposium were scientists, law enforcement officials, and members of the judiciary.

The book is divided into six major sections, the first being introductory material of a broad nature. Part II deals with morphine, heroin, and cocaine. Amphetamine-type and barbiturate tranquilizer-type drugs are covered in the third section, followed by marijuana and LSD in Part IV.

The concluding two sections deal with drug abuse and the law, and action to be taken, respectively.

Although the book takes a broad look at the problems of drugs and youth with a sociological emphasis, it should be of interest to all persons working in the area of drug abuse.

Techniques of Medication. By ERIC W. MARTIN, STEWART F. ALEXANDER, WILLIAM E. HASSAN, JR., and BURTON L. SHERMAN, J. B. Lippincott, East Washington Square, Philadelphia, PA 19105, 1969. vii + 239 pp. 18.3 × 26.1 cm. Price \$18.00.

This book is devoted to discussing those factors that often are not emphasized in the administration of a drug. In addition to the rational selection of a drug, factors such as route of administration and form of medication will often determine the usefulness of a medication. The authors have done well in attempting to discuss this comprehensive area. The book is introduced by discussing the trends in therapeutics and principles of medication. The second chapter is devoted to prescription writing and the factors that must be considered in a prescription. These factors would include dosage, directions to the patient, and legal and professional aspects.

This is followed by sections dealing with various routes of medication (dermatomucosal, parenteral, and gastrointestinal) and outlining the principles of medication that must be considered. These principles include topics such as dosage forms, techniques of administrations, and care of needles and syringes. The next section discusses nicely the handling of medication by nurses. This section is written in clear, easy-to-follow outline form. The book closes with a com-

prehensive discussion of the legal aspects of medication. These include factors such as prescribing errors, inadequate testing, and sensitivity reactions.

This book incorporates the basic concepts of a book published by Austin Smith in 1948 entitled "Technic of Medication." The authors of this volume are to be complimented on bringing this important topic up to date and providing a practical manual on medication techniques for physicians, medical students, nurses, and pharmacists. All members of the health team must not only know their drugs but, equally important, they must know how to use them.

Industrial Toxicology. By LAWRENCE T. FAIRHALL. Second Edition (Facsimile of 1957 Edition). Hafner Publishing Co., New York, NY 1969. xii + 376 pp. 18.3 × 26.3 cm. Price \$12.00.

A continuing demand for this standard reference work in industrial toxicology has justified this reprinting of the 12-year old second edition. It is likely that part of such a demand is based on the desires of some to replace their much-used and worn-out copies. Fairhall has had a well-established and long-standing reputation as a source of information about elements and compounds of toxicologic significance in industry. This book, though hardly expected to be up to date, still contains much data of current value and is a useful guide to some of the outstanding older literature.

With a compendium type of format, this volume is presented in two parts. Part I deals with inorganic substances, mostly elements and their salts, oxides, or compounds with hydrogen. The larger Part II, entitled *Carbon Compounds*, deals with numerous organic chemicals. For each substance or compound, its chemical and physical characteristics, industrial uses, toxicity, and general approach to methods of analysis are described in a concisely documented form. There is little consideration of mechanisms of toxic action and no discussion of the treatment of poisoning by the agents described. An appendix contains tables listing urinary metabolites of 73 compounds, threshold limit values of numerous toxic gases, vapors, fumes and dusts, and the LD₅₀'s by oral administration in rats of 104 organic chemicals.

Obviously, much new knowledge concerning substances of industrial toxicologic importance has developed since this edition was published in 1957, and several more recent books are available that contain such information. Hence, the later works must be relied upon as prime references in the field, with Fairhall serving a valuable supplementary and back-up function. An example of an area in arrears in this book is the timely topic of pesticides. Some of the well-known controversial persistent pesticides such as aldrin, dieldrin, endrin, heptachlor, and heptachlor epoxide are not described, though threshold limit values and LD₅₀'s for aldrin and dieldrin are tabulated in the appendix.

For numerous agents described, however, little or no new information has been produced since 1957, and for these substances Fairhall stands as a definitive reference. This volume is still an important component of any library purporting to cover toxicology comprehensively or industrial toxicology specifically.

Although the book takes a broad look at the problems of drugs and youth with a sociological emphasis, it should be of interest to all persons working in the area of drug abuse.

Techniques of Medication. By ERIC W. MARTIN, STEWART F. ALEXANDER, WILLIAM E. HASSAN, JR., and BURTON L. SHERMAN, J. B. Lippincott, East Washington Square, Philadelphia, PA 19105, 1969. vii + 239 pp. 18.3 × 26.1 cm. Price \$18.00.

This book is devoted to discussing those factors that often are not emphasized in the administration of a drug. In addition to the rational selection of a drug, factors such as route of administration and form of medication will often determine the usefulness of a medication. The authors have done well in attempting to discuss this comprehensive area. The book is introduced by discussing the trends in therapeutics and principles of medication. The second chapter is devoted to prescription writing and the factors that must be considered in a prescription. These factors would include dosage, directions to the patient, and legal and professional aspects.

This is followed by sections dealing with various routes of medication (dermatomucosal, parenteral, and gastrointestinal) and outlining the principles of medication that must be considered. These principles include topics such as dosage forms, techniques of administrations, and care of needles and syringes. The next section discusses nicely the handling of medication by nurses. This section is written in clear, easy-to-follow outline form. The book closes with a com-

prehensive discussion of the legal aspects of medication. These include factors such as prescribing errors, inadequate testing, and sensitivity reactions.

This book incorporates the basic concepts of a book published by Austin Smith in 1948 entitled "Technic of Medication." The authors of this volume are to be complimented on bringing this important topic up to date and providing a practical manual on medication techniques for physicians, medical students, nurses, and pharmacists. All members of the health team must not only know their drugs but, equally important, they must know how to use them.

Industrial Toxicology. By LAWRENCE T. FAIRHALL. Second Edition (Facsimile of 1957 Edition). Hafner Publishing Co., New York, NY 1969. xii + 376 pp. 18.3 × 26.3 cm. Price \$12.00.

A continuing demand for this standard reference work in industrial toxicology has justified this reprinting of the 12-year old second edition. It is likely that part of such a demand is based on the desires of some to replace their much-used and worn-out copies. Fairhall has had a well-established and long-standing reputation as a source of information about elements and compounds of toxicologic significance in industry. This book, though hardly expected to be up to date, still contains much data of current value and is a useful guide to some of the outstanding older literature.

With a compendium type of format, this volume is presented in two parts. Part I deals with inorganic substances, mostly elements and their salts, oxides, or compounds with hydrogen. The larger Part II, entitled *Carbon Compounds*, deals with numerous organic chemicals. For each substance or compound, its chemical and physical characteristics, industrial uses, toxicity, and general approach to methods of analysis are described in a concisely documented form. There is little consideration of mechanisms of toxic action and no discussion of the treatment of poisoning by the agents described. An appendix contains tables listing urinary metabolites of 73 compounds, threshold limit values of numerous toxic gases, vapors, fumes and dusts, and the LD₅₀'s by oral administration in rats of 104 organic chemicals.

Obviously, much new knowledge concerning substances of industrial toxicologic importance has developed since this edition was published in 1957, and several more recent books are available that contain such information. Hence, the later works must be relied upon as prime references in the field, with Fairhall serving a valuable supplementary and back-up function. An example of an area in arrears in this book is the timely topic of pesticides. Some of the well-known controversial persistent pesticides such as aldrin, dieldrin, endrin, heptachlor, and heptachlor epoxide are not described, though threshold limit values and LD₅₀'s for aldrin and dieldrin are tabulated in the appendix.

For numerous agents described, however, little or no new information has been produced since 1957, and for these substances Fairhall stands as a definitive reference. This volume is still an important component of any library purporting to cover toxicology comprehensively or industrial toxicology specifically.

The Biochemistry of Alkaloids: Molecular Biology, Biochemistry and Biophysics, Vol. 3. By TREVOR ROBINSON. Springer-Verlag, New York, NY, 1968. 149 pp. 17 × 25 cm. Price \$9.75.

I enjoyed the opportunity of reviewing this book which was both readable and interesting. Although the author, in his preface, makes no attempt to state whether the monograph is intended primarily as a text or reference book, it would appear to me that its greatest

Drug Abuse: Social and Psychopharmacological Aspects. Compiled and edited by JONATHAN O. COLE and J. R. WITTENBORN, Charles C Thomas, 301-327 East Lawrence Ave., Springfield, IL 62703, 1969. xiii + 170 pp. 15.5 × 23.5 cm. Price \$9.50.

This book is drawn from reports presented during the Fifth Annual Meeting of the American College of Neuropsychopharmacology. While there is no primary focus to the papers included, they are representative of current research related to the growing social and medical concern of drug abuse.

One paper should be of particular interest because of the controversial nature of the topic and the scarcity of scientific research in this area. This study of the long-term effects of LSD administration in volunteer graduate students suggests that the use of LSD under controlled circumstances with selected individuals may be less hazardous and have less far-reaching consequences than previously thought. However, other studies reported in this book seem to present evidence to the contrary, confirming the need for more extensive research into these problems.

Data from a study of marijuana indicate that marijuana use begins as a group experience engaged in by peers, and not as the pusher engaging the youth.

This book includes eleven studies concerning various aspects of drugs and drug abuse. While the editors admit that no answers are presented, they are hopeful that this volume will serve to stimulate research in these and related areas.

Drugs and Youth. Edited by J. R. WITTENBORN, HENRY BRILL, JEAN PAUL SMITH, and SARAH A. WITTENBORN, Charles C Thomas, 301-327 East Lawrence Ave., Springfield, IL 62703, 1969. xiv + 485 pp. 18 × 26 cm. Price \$22.75.

This book, "Drugs and Youth," is based on the proceedings of the Rutgers Symposium on Drug Abuse held in June, 1968, at the Rutgers Interdisciplinary Research Center. The one hundred fifty participants in the three-day symposium were scientists, law enforcement officials, and members of the judiciary.

The book is divided into six major sections, the first being introductory material of a broad nature. Part II deals with morphine, heroin, and cocaine. Amphetamine-type and barbiturate tranquilizer-type drugs are covered in the third section, followed by marijuana and LSD in Part IV.

The concluding two sections deal with drug abuse and the law, and action to be taken, respectively.

Although the book takes a broad look at the problems of drugs and youth with a sociological emphasis, it should be of interest to all persons working in the area of drug abuse.

The Biochemistry of Alkaloids: Molecular Biology, Biochemistry and Biophysics, Vol. 3. By TREVOR ROBINSON. Springer-Verlag, New York, NY, 1968. 149 pp. 17 × 25 cm. Price \$9.75.

I enjoyed the opportunity of reviewing this book which was both readable and interesting. Although the author, in his preface, makes no attempt to state whether the monograph is intended primarily as a text or reference book, it would appear to me that its greatest

utility would be in the former category, especially in a graduate course in alkaloids.

The material covered is thorough and the author's viewpoint regarding the unbalanced progress in the study of alkaloid biochemistry is heartily supported by the reviewer, *i.e.*, quite a bit is known about alkaloid biosynthesis but very little is known about function or degradative pathways. For example, the author cites the work of Fairbairn, who showed that the morphine alkaloids are not end products of metabolism but appear to be actively turned over at a rapid rate. Similar studies of this type are sadly lacking and much more work is needed in this area. It may well be that alkaloids are active metabolites within plants.

In any book there is a certain lag period between the literature survey, writing, and official publication. The lag period works against areas of research which are making active progress. A specific example of material which has been greatly extended since publication of the book is the work on the biosynthesis of indole alkaloids. This problem has now been pretty well cleared up and a monoterpenoid precursor is well established for the C₉ or C₁₀ unit involved. This is not a criticism of the author but is cited to point out some problems even with monographs of this type. Indeed, overall I believe the book to be quite up to date.

In summary, the book is clearly written, well organized, and readable. The major alkaloids are covered according to structural types and their biochemistry discussed. I would recommend its use in courses of natural products and especially in courses emphasizing alkaloids. It is a welcome addition to the library of books dealing with natural products.

In any book there is a certain lag period between the literature survey, writing, and official publication. The lag period works against areas of research which are making active progress. A specific example of material which has been greatly extended since publication of the book is the work on the biosynthesis of indole alkaloids. This problem has now been pretty well cleared up and a monoterpenoid precursor is well established for the C₉ or C₁₀ unit involved. This is not a criticism of the author but is cited to point out some problems even with monographs of this type. Indeed, overall I believe the book to be quite up to date.

In summary, the book is clearly written, well organized, and readable. The major alkaloids are covered according to structural types and their biochemistry discussed. I would recommend its use in courses of natural products and especially in courses emphasizing alkaloids. It is a welcome addition to the library of books dealing with natural products.

α -Chymotrypsin: A Case Study of Substituent Constants and Regression Analysis in Enzymic Structure-Activity Relationships

CORWIN HANSCH and EUGENE COATS

Keyphrases ☐ α -Chymotrypsin—structure-activity relationship ☐ Structure-activity relationship— α -chymotrypsin substituent constants ☐ Regression analysis— α -chymotrypsin structure-activity relationship ☐ Inhibitors— α -chymotrypsin ☐ Substrates— α -chymotrypsin

One of the central problems in drug research is the development of a systematic approach for the elucidation of structure-activity relationships. The problem is so pressing and so complex that it must be approached on many levels simultaneously. In this report the authors are concerned with purified enzyme, one of the simplest systems. The concept of drug-receptor sites, which has developed in recent years (1), is much like that of the active sites on enzymes. In some instances, enzymes are the active sites. Thus it seemed reasonable to make a survey of the structure-activity work on one of the most thoroughly studied enzymes, chymotrypsin.

The hydrolytic enzymes have been the subject of the most extensive studies of structure-activity interrelation. Although an enormous amount of work has been devoted to all aspects of such enzymes, the understanding of their mechanism of action is still quite incomplete (2-4). Of this class of enzymes the most extensively studied is chymotrypsin. Its modes of action in the hydrolysis of esters and amides have been reviewed from various points of view (2-9). The present survey is from a particular point of view, namely that of extrathermodynamic structure-activity relationships.

In surveying the literature, the authors have selected for analysis only those sets of data for which suitable substituent constants are available. Even with this limitation, the data are so voluminous and scattered that they cannot claim to have included all possible examples. Their object has been to try to characterize in a gross fashion some common characteristics of substrates and inhibitors, which have been defined by the constants K_m and K_i . This effort is not intended to be the final definitive study but rather an initial study which hopefully will encourage others to undertake better designed experiments to explore more thoroughly substituent effects for which, at present, ideal data are lacking.

Considerable evidence now supports the view that chymotrypsin operates by what is called a double-displacement mechanism (2, 4, 10, 11); that is, the enzyme is first acylated and then the acyl intermediate is hydrolyzed to products:

The kinetic implications of this mechanism have been worked out by Gutfreund and Sturtevant (10, 11). In the early stages of the reaction, it is customary to assume that $k_2[ES] \gg k_{-2}[ES'][P_1]$ and that $k_3[ES'] \gg k_{-3}[E][P_2]$. If a large amount of substrate is present, then it may be assumed that $[S] = [S]_0$ where $[S]_0$ is the initial substrate concentration. Application of the steady-state approximation to ES yields:

$$\{(k_2 + k_3')[S]_0 + k_3K_m\}[E] = k_3'K_m[E]_0 + \frac{k_3'K_m[S]_0[E]_0}{K_m + [S]_0} \exp \left[- \left(\frac{(k_2 + k_3')[S]_0 + k_3'K_m}{K_m + [S]_0} \right) t \right] \quad (\text{Eq. 4})$$

where $[E]_0 = [E] + [ES] + [ES']$ is the total enzyme concentration, t represents time, $K_m = (k_{-1} + k_2)/k_1$, and $k_3' = k_3K_i/(K_i + [H^+])$. The rates of product appearance are:

$$V = \frac{d[P_1]}{dt} = \frac{k_2}{K_m} [E][S]_0 \quad (\text{Eq. 5})$$

$$\frac{d[P_2]}{dt} = k_3'[E]_0 - k_3' \frac{K_m + [S]_0}{K_m} \quad (\text{Eq. 6})$$

Measurements which are made at times large enough so that the exponential term in Eq. 3 can be neglected can be treated using Eq. 6:

$$V = \frac{d[P_1]}{dt} = \frac{d[P_2]}{dt} = \frac{k_2k_3'[S]_0[E]_0}{(k_2 + k_3')[S]_0 + k_3'K_m} \quad (\text{Eq. 7})$$

Lineweaver-Burk plots at different values of $[S]_0$ yield the apparent constant:

$$K_{m(\text{app.})} = \frac{k_3'}{k_2 + k_3'} K_m \quad (\text{Eq. 8})$$

From the development of Eq. 8, it is clear that the apparent K_m with which the authors are concerned is a complex constant. The problem is even more complicated if one assumes two or more binding sites to be involved which might or might not lead to productive reactions (2). In fact, the picture is so complex that for structure-activity studies, one must proceed with an open mind and examine what empirical evidence is available simply to improve one's ability to design better experiments with which to make still closer approximations. The dangers of relying on $K_{m(\text{app.})}$ as a meaningful constant are apparent from Eq. 8, and they have also been stressed by Bender and Kézdy (2).

While considerable effort (2, 9, 10, 12) has been made to define the kinetic parameters associated with Eqs. 1-3, the present consideration will be limited to the hopefully less complex parameters $K_{m(\text{app.})}$ and K_i . Despite many theoretical points for concern about the complex nature of K_m , Neurath and Hartley (13) have summarized considerable evidence to show that K_m is a close approximation to the simple binding constant K_s . This review further supports this idea and attempts to characterize more sharply the enzymic areas surrounding the catalytic site.

The general approach to the formulation of extra-thermodynamic models has been well analyzed for nonenzymic reactions by Leffler and Grunwald (14). For enzymic processes, hydrophobic forces become extremely important, and these must play an important

part in any model (15-18). The approach in such studies has been to factor effects of substituents on rate or equilibrium constants into free energy-related terms as follows:

$$-\Delta G = RT \ln K \quad (\text{Eq. 9})$$

$$\delta_X \Delta G = \delta_X \Delta G_{\text{hydrophobic}} + \delta_X \Delta G_{\text{electronic}} + \delta_X \Delta G_{\text{steric}} \quad (\text{Eq. 10})$$

That is, the effect of substituent X on the free energy change in a rate or equilibrium process characterized by k is factored in operational terms as shown in Eq. 10. Extrathermodynamic numerical solutions to Eq. 10 can be obtained by the use of suitable substituent constants:

$$\delta_X \log K = a\pi_X + b\sigma_X + cE_{sX} + d \quad (\text{Eq. 11})$$

Other free energy-based parameters such as polarizability may also be employed in Eq. 11, so the pertinent substituent parameters determining biological response can be sorted out *via* regression analysis. In Eq. 11, the parameter π is defined (19) as: $\pi_X = \log P_X - \log P_H$, where P_X is the octanol-water partition coefficient of a derivative and P_H is that of a parent molecule. Hydrophobic binding is operationally defined by the octanol-water reference system. Electronic effects of X , represented by Hammett's σ -parameter and its various modifications (14), are related to highly specific electronic effects not contained in π . To represent the steric effects of X , Taft's E_s parameter (20) can be used (21, 22). Here again, as with π and σ , there is overlap between π and E_s . Steric effects are highly specific effects such as those involved in the formulation of E_s . These parameters have been successfully employed in the delineation of the roles of substituents in a variety of systems (18) including a number of interest here, namely, simple proteins (23) and enzymes (16).

While the parameters σ and E_s have been extensively studied and their use justified by many good correlations in relatively simple systems, partition coefficients have been much less studied. That they can be used to correlate quantitatively binding constants of small molecules to proteins is illustrated (17) in Eq. 12:

$$\log 1/C = 0.75(\pm 0.07) \log P + \begin{matrix} n & r & s \\ 2.30(\pm 0.15) & 42 & 0.960 & 0.159 \end{matrix} \quad (\text{Eq. 12})$$

In Eq. 12, C is the molar concentration of organic compound necessary to produce a 1:1 complex with purified bovine serum albumin, and P is the octanol-water partition coefficient. This linear free energy relationship correlates the affinities of 42 miscellaneous (phenols, anilines, naphthalenes, alcohols, *etc.*) organic compounds for a hydrophobic site on serum albumin. This equation and many similar ones (17, 18, 23) appear to justify the octanol-water partition coefficient as a meaningful parameter for estimating hydrophobic character of a molecule. The relative constant π is the corresponding parameter for a substituent (19, 24).

While the present authors have used octanol-water as a reference system, Scholtan has shown in a rather extensive study that the isobutanol-water system appears to yield comparable results (25). Wildnauer and

Canady (26) have recently shown that for certain chymotrypsin inhibitors, aliphatic hydrocarbons such as pentane, hexane, heptane, and water serve as suitable reference systems. They also correlated inhibitor potency with surface area of the inhibitor (26).

Since α -chymotrypsin has been readily available in crystalline form for some time, it has been the subject of extensive investigation. The detailed studies of Niemann, Bender, Baker, and others (see 27–32), dealing with the selectivity and inhibition of the enzyme, along with recent sequence analyses and X-ray crystallographic work (33) provide data for structure–activity analysis. A variety of data is most important; a correlation of one or two sets of data for such a complex process as enzyme substrate interaction leaves one with the feeling that other workers using different molecules might find quite different results. It is only after many sets of quite different data can be treated with a consistent result that one can place much confidence in such extrathermodynamic correlations.

One unfortunate observation of the present survey is that most of the studies of substrates and inhibitors were designed without giving much thought to the present state of the ability to treat substituent effects in quantitative terms; that is, instead of varying one of two parts of substrate or inhibitor molecules with substituents for which reliable physicochemical parameters are known, workers have often studied a small set of congeners in which gross changes have been made which preclude treatment by present methods of analysis. It is hoped that a result of the analyses in this report will be the encouragement of better designed studies for quantitative structure–activity analysis.

In attempting to understand substituent effects on the interaction of substrates and inhibitors with α -chymotrypsin, the model of Hein and Niemann (30, 31) is of help in orienting the discussion. Actually, their nomenclature will be employed to designate the space around an asymmetric center held on the active site of the enzyme. As will become apparent, the results of this analysis do not support the necessity of postulating the large number of microscopic binding constants in which each of the less than perfect modes of interaction plays a definite part in holding substrate to enzyme. The view taken here is similar to that of Bender and Kézdy (2) that the 12 possible modes of interaction between, say, an L-substrate and the enzyme violate the rule of “scientific simplicity,” and this complexity should not be invoked until absolutely necessary. The general picture of the Hein-Niemann model is shown in Structure I. In this generalized model, NHCOR_1 repre-

sents the *N*-acyl portion; R_2 is the side chain in the α -position; COR_3 is the ester or amide bond that is hydrolyzed; and ρ_1 , ρ_2 , ρ_3 , and ρ_H are the areas of the active site with which the four substituents on the α -carbon interact. Structure I depicts the most specific

of the 12 possible interactions, with all of the others resulting in a less productive or nonproductive complex termed “wrong-way binding.”

Recent experimental evidence now makes it possible to indicate some of the amino acids of the enzyme which are involved in the portions of the active site, as proposed by Hein and Niemann.

ρ_H Area: On the basis of results (34, 35) with α -methylamino acids, it has been concluded that although the hydrolysis rate is lowered, the methyl group has little effect on binding. Hence, the ρ_H area is presumed to be open to solvent.

ρ_1 Area: On the basis of unique dialkylation of the active site by *p*-nitrophenyl-*N*-bromoacetyl- α -amino-isobutyrate, methionine 192 has been identified as being reactive in this area of the active site (36). The ester portion of this reagent was first hydrolyzed by the enzyme, affording *p*-nitrophenol and acylated serine 195. Then the bromoacetyl moiety, now fixed to the enzyme, reacted with methionine 192.

ρ_2 Area: Evidence for a specific role for an amino acid residue interaction with a substrate in this area has not been found. There is some evidence to suggest that a tryptophan residue in this region might participate in a charge transfer reaction (37). X-ray crystallographic studies indicate (33) that tryptophan 215 lies near methionine 192.

ρ_3 Area: By irreversible alkylation studies with diisopropyl fluorophosphate and other reagents, a serine residue has been implicated in this portion of the active site (38). From amino acid sequence studies and X-ray crystallography, it is now fairly certain (33, 39) that this is serine 195. Histidine 57 has also been identi-

fied (40–42) by alkylation and X-ray crystallography in this portion of the active site, and it lies only 4 Å from the serine 195 residue (33).

METHOD

The general approach is to account for substituent effects on the binding of substrate by enzyme, as represented by $\log 1/K_m$ or $\log 1/K_i$, by the linear combination of free energy-based substituent constants (Eq. 11). In Eq. 11, the constants a , b , c , and d are found by the method of least squares. (See Reference 43 for a discussion of this technique and its use in regression analysis.) While E_s has been defined (19) to represent intramolecular steric repulsions, it has been found to be of use in intermolecular interactions as well (21, 22). In testing the value of E_s in chymotrypsin correlations, the authors have also tested Hancock's corrected parameter (44), defined as: $E_s^c = E_s + 0.306(n - 3)$, where n represents the number of α -hydrogens on the substituent alkyl group. In assaying electronic effects of substituents, σ , as well as its variations (14) σ_1 , σ^+ , and σ^- , has been employed.

For hydrophobic interactions, π or $\log P$ has been used. In most of the examples, a large portion of the substrate or inhibitor was held constant, and π can be used to represent the hydrophobic effect of the substituents. For example, in Table I the —CHCO₂CH₃ portion

of the substrates is constant, and π has been used for each of the R functions attached to the α -carbon. For each CH₃ or CH₂ group, the value of 0.50 for π was used to estimate π for higher alkyl functions. The additive constitutive character of π and $\log P$ greatly simplifies such analyses (19, 24).

From the data in Tables I–X, the equations in Table XX have been derived for enzyme substrate binding; from the data in Tables XI–XIX, the equations in Table XXI have been derived for enzyme inhibitor interaction. Only the most significant equations, as de-

termined (43) by an F test ($\alpha \leq 0.10$), are given. In several of the examples, so few data points are available that one cannot be sure that higher order (45) equations are not needed.

The following $\log P$ values in the octanol–water reference system have been measured for the first time: *N*-acetyl-DL-phenylalanine methyl ester, 0.92 ± 0.01 ; ethyl propyl *p*-nitrophenylphosphonate, 2.20 ± 0.01 ; ethyl furoate, 1.52 ± 0.01 ; azulene, 3.20 ± 0.02 ; ethyl isonicotinate, 1.43 ± 0.02 ; ethyl nicotinate, 1.32 ± 0.01 ; ethyl picolinate, 0.87 ± 0.01 ; ethyl anthranilate, 2.57 ± 0.01 ; and ethyl 2-thiophenecarboxylate, 2.33 ± 0.03 . The standard deviations are from four separate determinations using different volume ratios of solvents, except for ethyl picolinate where only three determinations were made. To calculate π -values for the acyl functions of Table VIII, the ethoxy value of -0.23 derived from diethyl ether was subtracted from the measured $\log P$ values for the ethyl esters.

The use of group polarizability (P_E) as reflected in atomic molecular refractivities in quantitative correlations was suggested by the recent study of Agin *et al.* (59). They showed that, as a first approximation, binding of small molecules to macromolecules should be logarithmically related to αI , where α is the polarizability and I is the ionization potential. It is found (49) that little is lost in correlation if I is neglected. Niemann and Hein also considered the importance of polarizability (52). Although there is a large amount of correlation between P_E and π since both are dependent on molar volume, the proper selection of derivatives shows enough independence so that they may be used to characterize enzymic binding areas. For example, $r^2 = 0.3$ for the correlation between π and P_E for the substituents in Table IX. For the 21 groups of Table VII, the cocorrelation is $r^2 = 0.4$.

RESULTS

Equation 13 in Table XX correlates the data of Table I. Using the Hein-Niemann model, the substrate fit to the site of action can be pictured as follows:

In Structure II, the α -hydrogen is not shown; it is below the plane of the page. Since adding terms in E_s or σ to Eq. 13 does not result in a significant reduction in the variance of the data, enzyme substrate binding as defined by K_m depends linearly on the hydrophobic character of R as defined by the octanol-water reference system. In deriving Eq. 13, two cases where R = H or hexyl have not been included. Hein and Niemann pointed out that when R = hexyl, a sharp break occurs in both K_m and K_0 , indicating that groups as long as hexyl do not fit into the ρ_2 area without some steric hindrance. The length of the chain may be involved since the cyclohexylmethyl group, which is just as lipophilic as hexyl (compare π -values, Table I), is well fit by Eq. 13. However, other explanations are possible (see Discussion). This same kind of break comes in data from inhibitor studies (see Eqs. 34 and 35), although at a somewhat longer chain length. The case

where R = H is more active than Eq. 13 would predict. Why this is so is not clear. However, in this example, no binding possibility for the ρ_2 area exists.

The esters of hydrocinnamic acid of Table II are correlated by Eq. 14. These derivatives can be visualized as fitting the model site as in Structure III:

Although only three derivatives are in this set, they have been included simply because the hydrophobic character of the area as characterized by the coefficient with π in Eq. 14 can be compared to that in Eqs. 15 and 16. The mean coefficient with π for these three equations is 0.29 ± 0.1 . The difference between this dependence of binding on π and that of Eq. 13 indicates the pronounced difference between the ρ_2 and ρ_3 areas.

Two sets of data, in which the alkyl group of the ester function pictured in Structures IVa and IVb as binding to the ρ_3 area is varied, are correlated by Eqs. 15 and 16.

In this example the amide moiety might fit into either the ρ_1 or ρ_2 area. In Eq. 15, where a better selection and larger number of derivatives were tested, a dependence is found on both π and E_s . The positive sign of the coefficient with E_s indicates that large functions hinder binding in the ρ_3 area as measured by $1/K_m$. This means that as R becomes larger, interaction of the electron-deficient sp^2 carbon of the ester group with a nucleophile, say serine, becomes unfavorable. Binding is promoted by increasing values of π but to a lesser extent than at ρ_2 (compare slopes in Eqs. 13 and 15). In Eq. 16, the dependence of $1/K_m$ on π is in rough agreement with that of Eqs. 14 and 15. In Eq. 17, good agreement is found between $\log 1/K_m$ and π . So few points are available that no assessment of the roles of E_s or σ can be made.

In a recent study of *p*-nitrophenyl esters of fatty acids, Milstien and Fife (48) found that a plot of $\log k_2/K_m$ versus E_s gave a fair correlation. Such a correlation is expressed in numerical form in Eq. 18. It is seen in Eq. 19 that when hydrophobic bonding is also taken into account, a much better correlation results. The coefficient with E_s is larger than that of Eq. 15, as one would expect, since R is closer to the electron-deficient carbonyl carbon in molecules of Table VI than in those of Table III. One would expect more hindrance to binding of the kind depicted in Structure IV. Studies by Milstien and Fife were made at various hydrogen-ion concentrations. Equations 20 and 21, derived from data obtained from runs made under more basic conditions, yield the

same quality correlations as at the lower pH. Under each of the three different conditions of pH, the dependence of $\log k_2/K_m$ on π and E_s is the same. While there are small differences in the coefficients with these terms from equation to equation, these variations are well within the 95% confidence intervals. There is a significant difference between the intercept of the low pH (Eq. 19) and equations (Eqs. 20 and 21) for work at the higher pH. This is in line with the well-known higher activity of chymotrypsin at higher pH. The work of Milstien and Fife, expressed in units of k_2/K_m , is not directly comparable with the other work using K_m and K_i . It has been included to show that although activity of the enzyme does vary with pH, the relative substituent effects do not; at least this is true for the range of changes and pH range investigated by Milstien and Fife. This would imply that large changes in the geometry of the reaction site, as it is defined by these esters, do not occur with changes in pH. The variations in activity with pH might be attributable to the relative

protonation of the critical imidazole moiety in the ρ_3 area.

Equation 22 correlates a set of substrates (Table VII) in which changes are being made simultaneously in two positions which would affect binding in the ρ_2 and ρ_1 areas of Structure V:

For this set of congeners, poor correlations were obtained using $\Sigma\pi$ for R' and R . Factoring R into two terms, $\pi_R + \pi_{R'}$, improved the correlation; however, from many preliminary calculations, it was observed that π does not correlate substituent effects well for the ρ_1 area. This area does not appear to be hydrophobic in character. The best correlations for this area were obtained using the group polarizability (P_E). Thus it would seem that dispersion forces and steric factors are most important for binding in this area.

In Eq. 23, using π instead of P_E yielded a correlation with r of only 0.556! For this set of substrates, where only the acyl portion is being varied, rather large changes in R result in relatively small changes in K_m . In fact, there is only a 10-fold change in binding for the molecules in Table VIII; thus the ρ_1 area does not appear to be apolar in character, nor does it appear to be sterically demanding, since a wide variety of modifications binding in this area are quite active substrates. Equations 24 and 25 are two further examples where better correlations are obtained with P_E than with π . Using π in Eq. 24 instead of P_E gave a correlation with

$r = 0.627$, while the same procedure with Eq. 25 gave a correlation with $r = 0.709$. The mean coefficient with P_E in the four substrate examples (Eqs. 22–25) is 0.088 ± 0.035 .

The equations in Table XXI summarize the structure–activity relationships of the data from Tables XI–XIX on chymotrypsin inhibitors. One of the best designed sets of inhibitors comes from the work of Baker *et al.* (54). The results are summarized in Eq. 26. Most of his derivatives were methyl ketones; however, a few were phenyl ketones. The constant X was given a value of 0 for the methyl ketones and a value of 1 for the phenyl ketones. Both the π - and σ -parameters are necessary to obtain a good correlation. The fit of these inhibitors to the model of the active site can be depicted as Structure VI:

The dependence of the inhibiting power of these derivatives on hydrophobic binding is strong, although somewhat different from Eq. 13. This is probably due to the fact that $1/K_m$ and I_{50} are not strictly comparable ways of comparing binding affinities. The positive coefficient with σ in Eq. 26 means that electron-withdrawing substituents also promote binding. Since π differs slightly from system to system and this difference is related to σ , part of the effect of σ may simply be that

of correcting π ; this could, in fact, explain part of the difference between Eqs. 26 and 13. However, in the present case this difference must be small, since π -constants are from the phenoxyacetic acid system which, of course, is quite closely related to the phenoxyacetones. Whether the phenyl ring is really fitting into the same area (ρ_2) as the R group of Eq. 13 is, of course, open to question. It is possible that the inhibitors bind in another part of the enzyme and bring about their effects allosterically. The dummy parameter X of Eq. 26 is simply a technique (43) for taking into account the stereoelectronic difference between the methyl and phenyl functions. Using P_E in Eq. 26 instead of π yields a poorer correlation ($r = 0.779$), indicating that this set more closely resembles compounds of Eq. 13 than molecules binding to the ρ_1 area (Eqs. 22–25).

An interesting set of data is that of Berezin *et al.* (56) which gives rise to Eqs. 27–29. Equation 27 correlates the 10 phenols of Table XII, and Eq. 28 correlates the rest of the molecules in Table XII. Cyclohexanol was omitted in the regression analysis because of uncertainty in its hydrogen-bonding ability. The slopes of Eqs. 27 and 28 are quite similar, indicating a common hydrophobic mechanism of action. However, the difference in the intercepts indicates the phenols to be about eight times as effective on an isolipophilic basis. Assuming this to be due to the strong hydrogen-bonding ability of the phenols, the term, HB, has been added for hydrogen bonding, and Eqs. 27 and 28 have been combined into Eq. 29. For phenols, HB is assigned a value of 1; the other molecules were given a value of 0. Cyclohexanol does not fit into the hydrogen-bonding group; that is, giving it a value of 1 for HB results in a poorly calculated $\log 1/K_i$. However, using a value of 0 for hydrogen bonding results in a good calculated $\log 1/K_i$. The similar dependence of inhibitory activity of the com-

pounds represented by Eqs. 13 and 29, as indicated by the coefficients associated with the π and $\log P$ terms, would suggest a common mode of binding by the inhibitors and substrates. The importance of hydrogen bonding might be rationalized as in Structure VII:

It is possible that the acidic proton of the phenols aids in holding the inhibitors between areas ρ_3 and ρ_2 , although there are many other ways in which the phenolic OH could participate in binding inhibitor to enzyme. Structure VII is meant to be suggestive and not to imply that only serine must be involved. Since the slopes of Eqs. 27–29 are the same, one would assume the same mechanism of inhibition as far as the hydrophobic contribution of the inhibitor is concerned. Using P_E in Eq. 29 in place of $\log P$ results in a much poorer correlation ($r = 0.870$). This information also supports binding in the ρ_2 rather than the ρ_1 area.

A smaller set of congeners, acting in a parallel manner to those of Eqs. 26–29, is the group of acids in Table XIII correlated by Eq. 30. This group of acids can be fit to the model as in Structure VIII:

Confidence limits on the coefficient with the $\log P$ term of Eq. 30 are large. While it cannot be said that the dependence on hydrophobic bonding is that of about 1 as was found for substrates and inhibitors reacting with the ρ_2 area, it is reasonably close. The positive coefficient with the pKa term indicates that the more unionized acids are more effective. The poorer correlation with this set (note the confidence intervals and standard deviation) may be due to steric effects involved with the different side-chain lengths between the carboxyl group and the aromatic ring.

The amides in Table XIV, described by Eq. 31, can fit the Hein-Niemann model as in Structure IX. Un-

fortunately, only six derivatives are available to assess complex substituent changes. As Eq. 31 shows, π_R is an important factor, and the slope of this equation is in agreement with that of Eqs. 13 and 29. Using P_E instead of π yields, as expected, a poorer correlation ($r = 0.829$). So few data points are available that no assessment of the role of X could be made. The differences in activity when X is H or CH₃ are small, so that a reasonable correlation can be achieved with the single-variable Eq. 31.

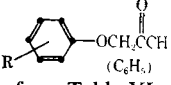

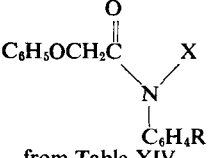

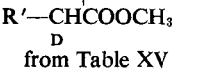

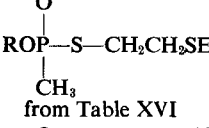

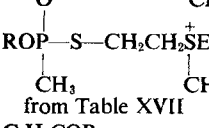

The esters correlated by Eqs. 32 and 33 are comparable to those of Eq. 22, except that D-isomers of Eqs. 32 and 33 are used as inhibitors. Again, using P_E for the acyl function and π for the α -alkyl group gives the best correlation. The higher coefficient with π_R of Eq. 33 indicates binding of this function in the ρ_2 area.

Two models of binding (Structures Xa and Xb) can be used to rationalize these results:

If binding occurs so that R' is in the ρ_2 area and the α -H is in the ρ_H area, then the fit of Structure Xa is obtained. The geometry here is quite different from that of Structure II and may be responsible for the difference in slope for the R term of Eq. 13 and the R' term of Eq. 33. If this is indeed the way binding occurs, the fact that P_E gives a better correlation than π would imply that ρ_3 is similar to ρ_1 (see Discussion). The arrangement in Structure Xb is based on the premise that R' must fit into ρ_2 and R into the ρ_1 area. This places the α -H in the ρ_3 area and the ester function in the ρ_H below the plane of the page. It is unfortunate that more data points are not available so that more

weight could be placed on this equation and the coefficients could be made sharply defined.

Equations 34 and 35, based on data from Tables XVI and XVII, correlate inhibition by two sets of phosphonates. In each set, the authors have omitted the derivative where R = octyl, since, as with Eq. 13, a break occurs at this point. The slopes of Eqs. 34 and 35 are close to those of the other equations where it is expected that binding in the ρ_2 area is occurring. From a comparison of the intercepts of Eqs. 34 and 35, it is clear that the onium compounds are more effective, despite the fact that the onium compounds are, as a whole, less hydrophobic. It may be that the positively charged sulfur aids in binding by interaction with an electron-rich species of the ρ_1 area and, in this fashion, compensates for the lower hydrophobic character.

The three ketones correlated by Eq. 36 are included to show that dependence of inhibitory power on π when the ρ_3 area is presumably involved is essentially the same as for substrates (Eqs. 14–16).

The correlation obtained with the hydrocarbons in Eq. 37 is not as good as that found by Wildnauer and Canady (26) with the molecular area of the inhibitor.

The slope of Eq. 37 is somewhat higher than those for other sets binding in the ρ_2 area. Because of the rather large confidence interval on this slope, one cannot be sure this difference is real.

DISCUSSION

While the sets of data analyzed in this review were by no means ideally designed for assaying the relative importance of hydrophobic, electronic, and steric effects of substituents operating on substrates in the ρ_1 , ρ_2 , and ρ_3 areas of the enzyme, the overall view obtained with grossly different molecular species from many different laboratories gives a consistent picture.

Hydrophobic binding in the ρ_2 area is defined by the slopes of the hydrophobic terms in Eqs. 13, 22, 26, 29, 31, 34, 35, and 37. The mean and standard deviation for the eight values is 1.21 ± 0.23 . There does not appear to be any significant difference for the slopes for the substrates and those for the inhibitors. This finding supports the idea of a common area and mechanism of binding for the two classes of reactants. Inhibition viewed in these terms would appear to be simple occupation of the binding site by the inhibitor.

The data on the ρ_3 area are also gratifyingly uniform. Comparable dependence on hydrophobic binding is seen in the coefficients with the hydrophobic terms in Eqs. 14–16 and 36. The mean and standard deviation for these four sets is 0.29 ± 0.1 . Thus the importance of hydrophobic binding in the ρ_3 area is about one-fourth that of the ρ_2 area. Again, it is seen that substrates and inhibitors show the same dependence on π .

Steric inhibition of binding by the sp^2 carbon of the carbonyl group can be quite important, as shown by Eqs. 15 and 19–21. It is of interest to compare the coefficients of E_s in Eqs. 15 and 19–21 with those obtained for the hydrolysis of esters under homogeneous conditions. Taft (20) has defined E_s as:

$$\log k/k_0 = \delta E_s \quad (\text{Eq. 38})$$

where k_0 refers to the unsubstituted ester and k refers to the rate of acidic hydrolysis of a corresponding substituted acetate: $\text{X}-\text{CH}_2\text{COOR}$. Taft (20) found a value of δ of 0.30 for the alkaline hydrolysis of acetate esters

of the type $\text{RCH}_2\text{OCCH}_3$. This compares with the value of 0.40 in Eq. 15. Present evidence indicates that the geometry of the transition state for acid and alkaline hydrolysis of esters is the same, so that one would expect the same dependence on δ . In Eqs. 19–21, an average value of δ of 1.5 is found. This compares with the values of 1.4, 1.7, and 1.9 found for the methanolysis, *n*-propanolysis, and isopropanolysis, respectively, of esters in which the R group of $\text{RCO}_2-\beta-\text{C}_{10}\text{H}_7$ was varied (20). Methanolysis of *l*-menthyl esters ($\text{RCO}_2\text{C}_{10}\text{H}_{16}$) showed a δ value of 1.7. Thus the serine moiety of chymotrypsin seems to make about the same steric demands on substrates as simple alcohols in homogeneous organic reactions. Of course, in Eqs. 19–21, the effect of E_s on the two constants, K_m and k_2 , is being considered; while in Eq. 15, it is the effect on K_m that is correlated. The result with Eq. 15 implies that the formation of *ES* as characterized by K_m must involve the conversion of the sp^2 carbon of the ester into an sp^3 carbon in the *ES* complex; that is, since the $sp^2 \rightarrow sp^3$ change is involved in the homogeneous hydrolysis of esters, and since the δ values are so close for the enzymic and homogeneous processes, one would surmise that tetrahedral transition states are involved in each case. Although the steric effects in Eqs. 19–21 are involved with two processes, the result with Eq. 15 suggests that the effect of E_s may be primarily on K_m rather than k_2 .

One of the most interesting aspects of this survey is the finding that binding in the ρ_2 area is characterized by π , while that in the ρ_1 area is not well correlated by π but correlates with polarizability as defined by P_E . While such an effect was not anticipated in undertaking the analysis, in retrospect it seems quite logical. This is the area in which a peptide bond of a protein molecule is bound. The binding of such a polarizable group would be facilitated by a polarizing atmosphere.

No doubt, better results would be obtained if, instead of the average polarizability that is embodied in molar refractivity, one could employ directional values. These values for polarization along the three mutually

perpendicular directions are at present known for only a relatively few simple species (60).

It is the authors' interpretation of the correlation data that the area must be polar in character and charge interactions aid in holding polarizable groups in this area. One cannot completely rule out desolvation of the acyl moiety with binding in the area since there is some correlation with π ; however, this would appear to be of secondary importance. Inhibitors and substrates appear to show the same dependence on P_E (compare Eqs. 22 and 33).

One might expect that the ρ_3 area would also be polar in character. The low coefficients with π in Eqs. 14–16 and 36 suggest that it is not lipophilic. Because only alkyl groups on the congeners are binding in this area, the same quality of correlation is obtained using π or P_E . The results with Eq. 33 in which P_E gives a better correlation than π can be interpreted as in Structure Xa to mean that the character of the ρ_3 and ρ_1 areas is similar. It would be worthwhile to study a set of congeners binding in this area which has more variance in polarizability.

The partition coefficient of the whole molecule, or even a constant fraction of it, may not be the decisive feature in the binding process. This is illustrated in the recent study by Baker (61) of compounds in Structure XI. With the $-\text{COO}^-$ function in the *ortho*-position, an active series of inhibitors is obtained. Only a two-fold loss over that of the parent compound occurred. However, placing a $-\text{COO}^-$ function in the *para*-position of the phenoxyacetones resulted in a huge loss in activity. That the binding of the phenoxy moiety

in Structure XI occurs in the ρ_2 area is supported by Eq. 39:

$$\log I_{50} = 0.70(\pm 0.25)\pi + 2.29(\pm 0.18) \frac{n}{4} 0.993 \frac{s}{0.043} \quad (\text{Eq. 39})$$

The slope of Eq. 39 is quite close to that of Eq. 26. One finds a constant increase in inhibitory power for each unit of hydrophobicity of X. Apparently, in the *ortho*-position, the $-\text{COO}^-$ function can remain free of the area and retain its solvation shell. In fact, it may aid binding by interaction with the polarizing ρ_1 area. This may also be true for the molecules correlated by Eq. 35. However, when in the 4-position, desolvation of the $-\text{COO}^-$ appears to be necessary for the phenoxy ring to move into the area.

A point that is not completely clear is the break in activity which occurs when a certain degree of bulkiness or chain length is reached in a set of congeners. This has been mentioned in connection with Eqs. 13, 24, and 35. Other data are available on this point; however, it is not clear whether the break is a function of

Table XXII—Relation between Lipophilic Character of Side Chain and Change in Character of Binding

chain length, hydrophobicity, or total molecular volume of the chain. There does seem to be a rather close correlation between the break in activity and the π -value; this is illustrated by the examples in Table XXII. Except for the last example, a close relationship is found between the degree of hydrophobic character and the break in the activity parameter. This break appears to occur at about the same point, regardless of the type functional group involved (e.g., phosphate or acetate). The break also occurs at the same π -value, whether one is considering binding (K_m or K_i) or rate of hydrolysis ($V_{\max.}$ or relative rate). This indicates that when a lipophilic moiety of sufficient size is present in the substrate or inhibitor, a decrease in expected activity occurs in a variety of different processes. This could be attributed to a kind of micelle formation¹ on the enzyme of the substrate. While most of the side chains are simple alkyl groups, the two examples where a phenyl and a chlorine moiety are included in the side chain are well in line with the alkyl function, despite the fact that the geometry of the phenyl group, its polarizability, etc., is quite different from the alkane groups. A recheck of Set 8 may be worthwhile since the authors pointed out that a break in activity occurred when the α -alkyl group contained five carbons but, using a cyclohexylmethyl

¹ The authors are indebted to Professor R. Nelson Smith for a number of discussions in which this idea developed.

function, gives normal activity (see Table I). This was taken as evidence that chain length was crucial for the area. The other data of Table XXII make this seem unlikely.

Although only a few studies such as the present for chymotrypsin have been made on purified enzymes (16, 18), some data at hand for comparison indicate that other enzymes have hydrophobic pockets which show the same relationship between $\log P$ and various activities. Three such examples are:

Inhibition of NADH Oxidase Activity by Barbiturates (45)—

$$\log I_{50} = 1.107 \log P + 1.237 \quad \begin{array}{ccc} n & r & s \\ 6 & 0.921 & 0.261 \end{array} \quad (\text{Eq. 40})$$

Inhibition of Adenosine Deaminase by 9-(1-Hydroxy-2-alkyl)adenines (65)—

$$-\log (I/S)_{0.5} = 0.932\pi - 0.483 \quad \begin{array}{ccc} n & r & s \\ 6 & 0.987 & 0.157 \end{array} \quad (\text{Eq. 41})$$

Relative Rate of Hydrolysis of p-Nitrophenyl Esters by Serum Esterase (16)—

$$\log \text{rate} = 0.950 \log P + 3.503 E_s - 0.469 \quad \begin{array}{ccc} n & r & s \\ 6 & 0.976 & 0.497 \end{array} \quad (\text{Eq. 42})$$

In each of the three examples, enzymic activity shows the same dependence on hydrophobic character as defined by the octanol-water reference system. This suggests, but by no means is firm evidence, that the enzymic hydrophobic sites are quite similar to octanol in terms of polarity. This kind of hydrophobic site is quite different from that of serum albumin, hemoglobin, or whole serum when $\log P$ is taken as the reference. In many examples of the binding of quite different kinds of organic compounds to serum protein or homogenized tissue, the coefficient with $\log P$ or π falls in the range 0.5–0.7 (17). While different ways are used in expressing the binding constants which are not strictly comparable, in 24 such examples (18) a mean and standard deviation of slope of 0.58 ± 0.11 were found.

The importance of having suitable reference standards for determining the relationship between apolar character and mode of interaction of organic compounds with biochemical systems can be further extended. Narcosis under proper conditions is a completely reversible process. Simple binding of organic compounds to nerve tissue causes narcosis, so that the molar concentration of drug producing a standard narcosis can be roughly compared to K_m or K_i values from purified enzymes. The following equation illustrates the dependence of such reversible processes on $\log P$.

Tadpole Narcosis by Miscellaneous Organic Compounds—

$$\log 1/C = 0.96 \log P + 0.75 \quad \begin{array}{ccc} n & r & s \\ 44 & 0.967 & 0.303 \end{array} \quad (\text{Eq. 43})$$

In 18 such examples, using various organisms, a mean slope of 1.10 ± 0.14 was found (18). Other processes (17, 18) show the same as well as different dependencies on $\log P$. Too few examples are available at present to draw conclusions of deep significance.

The present study has successfully pulled together a wide variety of data on chymotrypsin substrates and

inhibitors. This extrathermodynamic definition of the characteristics of the areas of interaction in the enzyme is quite consistent, especially when allowance is made for the fact that the information comes from a variety of different laboratories using different experimental techniques with quite a diverse group of organic compounds. It is hoped that this survey of the structure-activity relationship of chymotrypsin will encourage others working in this area to design more suitable substrates and inhibitors which can be used to define the intermolecular interactions more precisely. It seems likely that this approach, tested on chymotrypsin, can be applied to other enzyme substrate or enzyme inhibitor interactions. Also, it seems reasonable to expect that nonenzymic sites of drug action can be mapped using this approach.

Interfacial Barrier Limited Interphase Transport of Cholesterol in the Aqueous Polysorbate 80-Hexadecane System

ANWAR B. BIKHAZI and WILLIAM I. HIGUCHI

Abstract □ The kinetics of transfer of cholesterol from an aqueous polysorbate 80 solution into hexadecane and vice versa was studied by means of the multiparticulate dispersion technique. The experimental data were quantitatively analyzed by the physical model which accounts for the effects of bulk diffusion, interfacial resistance, interfacial area, and the lipid-water partition coefficient. For the 0.1% polysorbate 80, a P value around 1.7 to 2.2×10^{-7} cm. sec.⁻¹ was found that was consistent with all of the data on water-to-oil as well as oil-to-water transfer experiments. These findings suggest such large nonspecific interfacial barriers to be important in many biological and biopharmaceutical situations.

Keyphrases □ Interfacial barrier limited transport—interphase □ Cholesterol interphase transport—aqueous polysorbate 80—hexadecane system □ Emulsions—hexadecane—water—polysorbate 80 □ Particle-size distribution—emulsions □ Partition coefficient, cholesterol—hexadecane—polysorbate 80 system

Recently (1–5), there has been increased interest in the possibility of utilizing physical models to gain an understanding of the transport of drugs and other biologically important substances from body fluids into tissues and across membranes. The main characteristic of the physical model approach is the intimate interaction of realistic physical concepts with well-designed experiments. Thus the previous studies (1–5) have shown that it should be possible to interrelate such factors as the pK_a , the partition coefficient and the diffusional characteristics of the drug, the buffer characteristics and the pH of the aqueous phases involved, and the heterogeneous nature of the membrane, and then to test such relationships experimentally.

One of the factors in interphase transport of drugs which has escaped serious consideration until recently (1, 2) is the possible existence of significant interfacial resistances at the oil–water interface. The present studies along with those of Ghanem *et al.* (1) appear to represent for the first time the likelihood of the frequent domination of interfacial barriers in interphase transport.

The purpose of the present communication is to describe the interfacial barrier-controlled transfer of cholesterol across an oil–water interface. As will be shown, very large interfacial resistances were found. Because of the probable nonspecific nature of the interfacial barrier, these findings may be very pertinent to a number of biological and pharmaceutical situations, for example, the deposition of gallstones, the initiation of

atherosclerosis, and the transport and the absorption of cholesterol and other steroids (6) from the gastrointestinal tract.

EXPERIMENTAL

General Considerations in the Design of Experiments—It was decided to employ the multiparticulate dispersion technique (1, 2) which provides both good reproducibility and sensitivity for interfacial barrier determination. Both water-to-oil (“solute uptake”) as well as oil-to-water (“solute release”) transport experiments were carried out in order to assure the reliability of the interfacial permeability coefficient. Different oil particle-size distributions were utilized to demonstrate further that an interfacial barrier was rate controlling.

Preparation of Stock Emulsions—Two 8% hexadecane–water emulsion stocks using 0.1% polysorbate 80¹ were prepared in such a manner that the particle-size distributions differed significantly. Emulsion I was prepared by mixing 8 ml. of hexadecane² with 1 ml. of 10% aqueous polysorbate 80 solution and then making up to 100 ml. with distilled water. The mixture was then homogenized for 75 sec. in a Waring blender. Emulsion II was prepared by mixing 8 ml. of hexadecane with 0.5 ml. of the 10% polysorbate 80 solution and then making up to 100 ml. with distilled water. This mixture was then homogenized for 45 sec., after which 0.5 ml. of 10% surfactant was added to make the final surfactant concentration of

0.1%. These emulsions were gently shaken for about 15 min. prior to their use in the rate runs.

In addition to these two emulsions, a third emulsion (Emulsion III) was prepared in a similar manner but utilizing a polysorbate 80 ester (Polyol-Free).¹

Figure 2—Comparison of experimental data with theory for the uptake of cholesterol from Emulsion Systems I and II; counts/min./ml. of drug in the aqueous 0.1% polysorbate 80 phase versus time in hours. Key: experimental points from 2% oil of System I, ●; and experimental points from 2% oil of System II, ○. Curves are theoretically computed values. $V_w = 49$ ml. of aqueous polysorbate 80 phase; P value for both systems is 1.7×10^{-7} cm. sec.⁻¹; K value is 200.

Figure 1 shows the cumulative particle-size distribution data from the three emulsions obtained using the Coulter counter.³ The data given in Fig. 1 were used to obtain the differential size distribution in Table I. No significant particle-size distribution changes were found with these emulsions up to 8 hr.

Uptake Experiments—Predetermined dilutions of these stocks were made in 0.1% polysorbate 80 solution. Then 1.5×10^{-7} g. of 4-¹⁴C-cholesterol contained in 3 ml. of a 0.1% polysorbate 80 solution was added into 47 ml. of the diluted emulsions and the mixture shaken gently at 30° in the Burrell Wrist-Action shaker.⁴ Three- or five-milliliter samples were pipetted out at different time intervals and the aqueous phases were analyzed by either filtration (7) of the sample employing 0.20- μ pore size Gelman Metricel filters⁵ (GA-8) or by high-speed centrifugation⁶ at 21,600 \times g for 1.5 min. Out of the clear aqueous solution collected, 1 ml. was pipetted into a liquid scintillation vial. To the latter, 10 ml. of a liquid scintillation cocktail was added, and the samples quantitatively analyzed in the Beckman liquid scintillation system.⁷ In the filtration procedure it was found that a small amount ($\approx 10\%$) of the cholesterol was lost to the filter during filtration. Therefore, a correction for the adsorption loss was obtained by this technique.

Release Experiments—For the release experiments the same procedure was used for the preparation of the stock emulsions. However, radioactive cholesterol was added to the oil (6.68×10^{-7} g. of 4-¹⁴C-cholesterol/ml. of hexadecane) prior to the emulsification step. Aliquots of the stock emulsion containing the 4-¹⁴C-cholesterol were then added at zero time to predetermined volumes of 0.1% polysorbate 80 solutions. Sampling and analysis of the aqueous phases were carried out in the same manner as in the uptake experiments.

Partition Coefficient Determinations—The hexadecane-0.1% polysorbate 80 partition coefficient for the 4-¹⁴C-cholesterol was determined in emulsion systems containing 0.24 to 8% hexadecane and equilibrating for 48 and 72 hr. A value of $200 \pm 10\%$ was found which was used in the analysis of the data.

RESULTS AND ANALYSIS OF THE DATA

In all of the uptake and the release experiments, significant changes in the aqueous cholesterol concentrations were found up to 8 hr. The results of the experiments for uptake and release are

Figure 3—Comparison of experimental data with theory for the uptake of cholesterol from Emulsion Systems I and II. Counts/min./ml. of drug in the aqueous 0.1% polysorbate 80 phase versus time in hours. Key: experimental points from 4% oil of System I, ●; and experimental points from 4% oil of System II, ○. Curves are theoretically computed values. $V_w = 48$ ml. aqueous polysorbate 80 phase; P value for both systems is 1.7×10^{-7} cm. sec. $^{-1}$; K value is 200.

presented in Figs. 2–9. In the uptake plots (Figs. 2–5) the ordinate gives the actual aqueous concentrations of $4\text{-}^{14}\text{C}$ -cholesterol as a function of time. In the release plots (Figs. 6–9) the initial (zero time) expected aqueous concentrations were subtracted from all of the determinations of the aqueous cholesterol.

The following procedure was developed for the analysis of the experimental results. The general relationships apply to both uptake and release, the two situations differing only by the difference in sign of the concentration gradient.

It is helpful to refer to the model in Fig. 10. For an oil droplet of radius a_j , the rate of cholesterol transport into (or out of) the droplet is given by Eq. 1:

$$G_j = \frac{4\pi a_j^2 P D (C_b - C_{bj}')}{D + a_j P} \quad (\text{Eq. 1})$$

where P is the apparent permeability coefficient for the interfacial barrier, D is the relevant diffusion coefficient for cholesterol in the 0.1% polysorbate 80 solution, C_b is the total bulk aqueous cholesterol concentration, and C_{bj}' is defined by Eq. 2:

$$K = \frac{C_{oj}}{C_{bj}'} \quad (\text{Eq. 2})$$

Figure 4—Comparison of experimental data with theory for the uptake of cholesterol from Emulsion Systems I and II. Counts/min./ml. of drug in the aqueous 0.1% polysorbate 80 phase versus time in hours. Key: experimental points from 6% oil of System I, ●; and experimental points from 6% oil of System II, ○. Curves are theoretically computed values. $V_w = 47$ ml. aqueous polysorbate 80 phase; P value for both systems is 1.7×10^{-7} cm. sec. $^{-1}$; K value is 200.

Figure 5—Comparison of experimental data with theory for the uptake of cholesterol from Emulsion III. Counts/min./ml. of drug in the aqueous 0.1% polysorbate 80 ester phase versus time in hours. Key: experimental points from 0.8% oil, ●; and experimental points from 1.2% oil, ○. Curves are theoretically computed values. P value for both dilutions is 2.2×10^{-7} cm. sec. $^{-1}$; K value is 200.

where K is the effective hexadecane–0.1% polysorbate 80 partition coefficient for cholesterol and C_{oj} is the cholesterol concentration in the oil droplet. When G_j is positive the situation is for uptake; when G_j is negative, one has cholesterol release from the droplet.

It is noteworthy that when $a_j P \ll D$, then $a_j P$ may be neglected in the denominator of Eq. 1. In this case, one may write

$$G_j = 4\pi a_j^2 P (C_b - C_{bj}') \quad (\text{Eq. 3})$$

which is the appropriate limiting expression for the interfacial barrier-controlled transfer of cholesterol. One may also write:

$$G_j = V_{oj} \frac{dC_{oj}}{dt} \quad (\text{Eq. 4})$$

where $V_{oj} = \frac{4}{3}\pi a_j^3$ is the volume of the oil droplet and t is the time.

Equations 1, 2, and 4 may be combined to give

$$\frac{dC_{oj}}{dt} = \frac{3DP(C_b - C_{oj}/K)}{a_j(D + a_j P)} \quad (\text{Eq. 5})$$

Now, from material balance considerations in the system, one may write

$$\frac{dC_b}{dt} = -\frac{4\pi}{3V_w} \sum_{j=1}^L a_j^3 \Delta N_j \frac{dC_{oj}}{dt} \quad (\text{Eq. 6})$$

where V_w is the volume of the aqueous phase, ΔN_j is the number of droplets of sizes between a_j and a_{j+1} , and L represents the largest oil droplets in the system.

Figure 6—Comparison of experimental data with theory for the release of cholesterol from Emulsion Systems I and II. Counts/min./ml. of drug in the aqueous 0.1% polysorbate 80 phase versus time in hours. Key: experimental points from 0.24% oil of System I, ●; and experimental points from 0.24% oil of System II, ○. Curves are theoretically computed values. $V_w = 49.88$ ml. aqueous polysorbate 80 phase; P value for both systems is 1.7×10^{-7} cm. sec. $^{-1}$; K value is 200.

Figure 7—Comparison of experimental data with theory for the release of cholesterol from Emulsion Systems I and II. Counts/min./ml. of drug in the aqueous 0.1% polysorbate 80 phase versus time in hours. Key: experimental points from 0.48% oil of System I, ●; and experimental points from 0.48% oil of System II, ○. Curves are theoretically computed values. $V_w = 49.76$ ml. aqueous polysorbate 80 phase; P value for both systems is 1.7×10^{-7} cm. sec. $^{-1}$; K value is 200.

As is easily seen, the two equations, Eqs. 5 and 6, may be used to solve for C_b as a function of time when V_w , D , P , K , and the particle-size distribution (e.g., Table I) are known. However, this cannot be done analytically and one must resort to numerical methods. The flow diagram based on the FORTRAN IV language (IBM 360 digital computer) for solving Eqs. 5 and 6 is given in Fig. 11.

The computer calculations for the various experimental conditions were carried out for both cholesterol uptake and release. These are presented as the smooth curves in Figs. 2–9. As can be seen, a P value of around 1.7 to 2.2×10^{-7} cm. sec. $^{-1}$ was found to give good agreement of all experiments with the theoretical relations of Eqs. 5 and 6. The experiments with the polysorbate 80 ester sample appeared to correspond to slightly higher rates ($P \approx 2.2 \times 10^{-7}$ cm. sec. $^{-1}$) than those with the unpurified surfactant ($P \approx 1.7 \times 10^{-7}$ cm. sec. $^{-1}$).

In all of these calculations, a choice of D from 10^{-6} to 10^{-10} cm. 2 sec. $^{-1}$ made no significant difference in the results. The lower limit (10^{-10} cm. 2 sec. $^{-1}$) would be an unexpectedly low value even when the principal species in 0.1% polysorbate 80 is micellar in nature.

An idea of the sensitivity of the fit of the experimental data to the theoretical predictions can be obtained by referring to Fig. 12. It can be seen that the precision in the determination of P is in the neighborhood of $\pm 10\%$ for the release experiments. For the

Figure 8—Comparison of experimental data with theory for the release of cholesterol from Emulsion Systems I and II. Counts/min./ml. of drug in the aqueous 0.1% polysorbate 80 phase versus time in hours. Key: experimental points from 0.96% oil of System I, ●; and experimental points from 0.96% oil of System II, ○. Curves are theoretically computed values. $V_w = 49.52$ ml. aqueous polysorbate 80 phase; P value for both systems is 1.7×10^{-7} cm. sec. $^{-1}$; K value is 200.

Figure 9—Comparison of experimental data with theory for the release of cholesterol from Emulsion III. Counts/min./ml. of drug in the aqueous 0.1% polysorbate 80 ester phase versus time in hours. Key: experimental points from 0.4% oil, ○; and experimental points from 0.8% oil, ●. Curves are theoretically computed values. P value for both dilutions is 2.2×10^{-7} cm. sec. $^{-1}$; K value is 200.

uptake experiments, while the general agreement of the experimental data with theory is good, somewhat larger discrepancies were found at larger times.

One of the factors which may limit the accuracy of the treatment of the transport by Eqs. 5 and 6 is the particle-size distribution data obtainable with the Coulter counter. The situation in the case of Emulsion I of this study is quite satisfactory as it has yielded a 95% mass balance. In other experiments, comparably good mass balances have been found (1). However, one should question the accuracy of the analysis procedure when, for example, only 66% (Emulsion II) of the oil phase can be accounted for by the Coulter counter data.

Whenever the mass balance is poor, the cause may be attributed to one of five possibilities: (a) volumetric errors in transferring the oil in the stock emulsion to the reaction flask; (b) significant number of droplets below the Coulter counter sensitivity; (c) significant number of droplets too large to be accurately sized; (d) accuracy of the Coulter counter itself; and (e) solubilization of the oil in the aqueous media (intrinsic solubility of solubilization by, for example, surfactant).

In the experiments with Emulsion II, it is most likely that the discrepancy is not likely to be due to the following: (a) because of good precision of the partition coefficient data obtained with many solutes; (b) because this would require an unusual, essentially bimodal, distribution of droplet sizes; (d) because many other emulsions have yielded better mass balances than 66%; and (e) because no time effects on size distribution were observed. It is therefore proposed that the absence of good mass balance in the case of Emulsion II is the result of (c), i.e., the presence of a significant number of large droplets that was not measured by the instrument.

In order to assess the effect of neglecting the large droplets in the calculations with Eqs. 5 and 6, a computation was carried out with a particle-size distribution for Emulsion II (see Table I, Column 9), but for which a 93% mass balance was obtained by including more

Figure 10—The physical model that describes the uptake and/or release of the solute (cholesterol) across the oil droplet. large droplets in the extrapolation. In Fig. 13, the broken curve shows the computed release-time behavior for this situation. As can be seen, for initial release the difference between the 66% mass balance and the 93% mass balance is relatively small and comparable to the scatter of the experimental data.

DISCUSSION

The results of the analysis of data clearly show that an interfacial barrier was operative in these experiments. The effective permeability coefficient value of 1.7 to 2.2×10^{-7} cm. sec. $^{-1}$ corresponds to a rather large interfacial resistance to transport which might appear to be rather surprising for the simple oil-water system in these studies.

It is of interest to compare this value with those reported in the literature for transport of organic compounds across biological and "synthetic" biological membranes. Bean *et al.* (8) reported on the bilayer lipid membrane permeability coefficient of a number of

Figure 12—Sensitivity of the fit of the experimental data to the theoretical predictions. Figure 13—Effect of neglecting the large droplets in the calculations with Eqs. 5 and 6 as computed for Emulsion II. Key: the broken curve, ---, shows the computed release-time behavior for a 93% mass balance; and the full curve, —, shows the computed release-time behavior for a 66% mass balance. P value for both systems is 1.7×10^{-7} cm. sec. $^{-1}$; K value is 200.

organic compounds. The authors found that the permeability coefficients for most simple organic molecules are in the range of 10^{-4} to 10^{-6} cm. sec. $^{-1}$. Holder and Hayes (9) found red blood cell permeability coefficients of a number of sulfonamides to be in the range of 10^{-4} to 10^{-7} cm. sec. $^{-1}$. Rothblat *et al.* recently (10) reported data on the uptake of cholesterol by L_{5178Y} tissue culture cells. A rough calculation with their data yields a permeability coefficient in the neighborhood of 10^{-6} cm. sec. $^{-1}$. Thus the interfacial barrier for cholesterol at the hexadecane-0.1% polysorbate 80 system is of the same order of magnitude if not somewhat greater than those observed in a number of biological situations.

It is hoped that this investigation and the continuing studies will provide a basis for understanding the detailed molecular factors in the various biological and biopharmaceutical situations.

Intermolecular Bonding of the Antibiotic Diumycin

JOEL KIRSCHBAUM, WILLIAM A. SLUSARCHYK, and FRANK L. WEISENBORN

Abstract □ The closely related antibiotics diumycin A and B, with monomeric molecular weights of approximately 1800 daltons in ethanol, aggregate in aqueous buffers to form particles with a molecular weight (mol. wt.) of at least 32,000 daltons. The aggregate of diumycin is essentially unaffected by esterification of the acid, acetylation of hydroxyl groups, high ionic strength buffer, or variations in pH from 2.2 to 12.4. These results indicate that salt linkages and hydrogen bonds contribute only slightly to stabilize the aggregate. The aggregate may be disrupted by: (a) the addition of such hydrophobic bond-breaking agents as buffered aqueous solutions of guanidinium chloride, urea, or formamide; (b) the hydrolytic loss of a lipid side chain (mol. wt. about 400 daltons); or (c) the addition of alcohols. The ability of an alcohol to disrupt the aggregate increases with its hydrocarbon content. From these data, it is concluded that lipid-lipid hydrophobic interactions are responsible for the self-association of diumycin. The aggregate is spherical with a mantle of hydrophilic sugars, including glucose and glucosamine, surrounding a tangle of lipid side chains.

Keyphrases □ Diumycin—intermolecular bonding □ Aggregates, diumycin A, B—ethanolic aqueous buffers □ Hydrogen, lipid-lipid hydrophobic bonding—diumycin □ Sedimentation coefficients—diumycin □ Molecular weight—diumycin

The diumycins are a family of closely related antibiotics isolated from *Streptomyces umbrinus*, with formula molecular weights between 1700 and 2100 daltons, as determined by elemental analysis, including phosphorus content (1).

This paper concerns the ability of diumycin to aggregate in aqueous solvents, an ability shared by many natural products (2–5), and the source of intermolecular binding energy for such aggregation.

EXPERIMENTAL

Sources of Diumycin and Diumycin Derivatives—Diumycin A and B were isolated and characterized by Meyers *et al.* (1). Weisenborn *et al.* (6) prepared the derivatives of diumycin. Hydrolysis of purified diumycin, with 1 M HCl at 100° for 30 min., yields a 358-dalton lipid (6).

Sedimentation Coefficients—Sedimentation coefficients were determined with the aid of a Spinco model E analytical ultra-

Figure 1—Dependence of the sedimentation coefficient of diumycin A on its concentration in 0.2 M NaCl–0.02 M sodium phosphate buffer, pH 6.85.

Figure 2—Molecular weight of diumycin A (10 mg./ml.) in mixtures of ethanol and 0.2 M NaCl–0.02 M sodium phosphate buffer, pH 6.85.

centrifuge, using a calibrated temperature-control unit. Viscosity was measured with the aid of capillary and Zimm viscometers (7). One-milliliter pycnometers were used for density measurements at $20 \pm 0.002^\circ$. Viscosity and density corrections were also taken from the data of Kawahara and Tanford (8) for adjusting the sedimentation coefficients to standard conditions (9), which are the viscosity and density of water at 20° .

Molecular Weights—Molecular weights were determined by the Archibald approach-to-sedimentation equilibrium method (10), using 5 to 10 mg. solute/ml. solvent. The concentration gradients at the meniscus and cell bottom were measured from schlieren patterns recorded on Kodak metallographic plates and enlarged 10-fold on a Nikon magnifier. Total concentration was measured with the aid of a capillary centerpiece in an interference cell. The integral of the concentration gradient was evaluated by the procedure of Engelberg (11). The partial specific volume of $0.61 \text{ cm}^3/\text{g.}$, calculated for diumycin from density data using methodology described by Schachman (12), was decreased by $0.01 \text{ cm}^3/\text{g.}$ for calculations of molecular weight when buffered 8 M urea, 9 M formamide, or 5 M guanidinium chloride was used as the solvent (13).

RESULTS AND DISCUSSION

Although elemental analysis of diumycin, including the determination of phosphorus, indicates a molecular weight of approximately 1900 daltons (1), the apparent molecular weight of diumycin in neutral pH buffer, at a concentration of 3 to 10 mg./ml., is 32,000 daltons (Table I). A minor component has an apparent molecular weight of 65,000 daltons. Dilution disrupts the aggregate (Fig. 1), with several species seen at concentrations below 3 mg./ml. (Table I).

Aggregation in aqueous solvents is observed between pH 2.2 and 12.4, as well as in 1% sodium dodecyl sulfate (Table I). The ineffectiveness of sodium dodecyl sulfate as a disaggregating agent indicates little or no increase in net negative charge on diumycin due to binding of anions (14), with repulsive forces essentially unchanged. The methyl ester and acetate (10 M acetate/1 M diumycin) of diumycin aggregate in aqueous buffer with molecular weights of 32,000 and 38,000 daltons, respectively (Table I). The stability of the 32,000-dalton aggregate under these conditions indicates that ionic forces (noncovalent interactions between polar groups), including salt linkages (14, 15) and hydrogen bonds (16, 17), contribute only slightly to stabilize the 32,000-dalton aggregate. Some involvement of ionic forces is indicated by the molecular weight of 17,000 daltons in 5 M NaCl–0.02 M phosphate buffer (pH 6.85) and the higher concentration of the 65,000-dalton aggregate than the 32,000-dalton aggregate at pH 2.2 and 4.05 (Table I), a reversal of the relative concentrations of the aggregates that are found in solutions containing 0.2 M NaCl.

Stabilization of the aggregate by hydrophobic bonding (18–20) and, in particular, by lipid-lipid hydrophobic bonding (21) is indicated by: (a) the ability of the hydrophobic bond-breaking

		P ^c	1,400	

^a Precision is within 5% accuracy with 15% in low ionic strength solvents. ^b Mixture = diumycin A and diumycin B. ^c P is 0.2 M NaCl–0.02 M sodium phosphate buffer, pH 6.85.

solvent systems of buffered 8 M urea, 9 M formamide, or 5 M guanidinium chloride to disrupt the aggregate (Table I); (b) the inability of a lipidless diumycin to aggregate (Table I); and (c) the increasing efficacy of alcohols as disaggregating agents as the length of their hydrocarbon portion increases (Table I). *n*-Butanol is the most effective and methanol is the least effective disaggregating agent, as measured by the apparent molecular weight of diumycin in 95% NaCl–phosphate buffer–5% alcohol (ROH), where R = –CH₃, –CH₂CH₃, –CH₂CH₂CH₃, or –CH₂CH₂CH₂CH₃.

The molecular weight of diumycin A (10 mg./ml.) in various mixtures of ethanol and 0.2 M NaCl–0.02 M sodium phosphate buffer (pH 6.85) is illustrated in Fig. 2. As the concentration of ethanol increases, the molecular weight decreases from 32,000 daltons to 17,000, 10,000, 4000, and finally 2000 daltons. This indicates that: (a) disaggregation proceeds by repeated halving of the molecule; (b) 16 subunits comprise the 32,000-dalton aggregate; and (c) the monomeric concentration term in an equilibrium expression would have an exponent of 16 and 32 for the 32,000-dalton and 65,000-dalton aggregates, respectively, if it is assumed that the law of mass action is valid in these solvent systems.

Table II—Products of Acid Hydrolysis of Diumycin

H₃PO₄

[3,8,8-trimethyl-11-methylen-12-(2,2-dimethyl-6-methylenecyclohexyl)-2,6-dodecadien-1-ol (diumycinol)]

^a From diumycin A.

Table II lists the products of the acid hydrolysis of diumycin which includes a 25-carbon lipid (3,8,8-trimethyl-11-methylen-12-(2,2-dimethyl-6-methylenecyclohexyl)-2,6-dodecadien-1-ol) and three hydrophilic sugars. The 32,000-dalton aggregate may be depicted as a core of 16 interacting lipid side chains surrounded by the hydrophilic moieties. This picture is in accord with the X-ray diffraction studies of Luzzati (22), who found that such complex lipids as lysolecithin and phosphatidylethanolamine aggregated in aqueous solution. The aggregate became more spherical as the size of the hydrophilic portion increased.

The 65,000-dalton aggregate may result from the ionic bonding (electrostatic interaction) of two 32,000-dalton aggregates. A less likely interpretation is that a second spherical conformation exists which can accommodate exactly twice the number of lipid side chains found in the 32,000-dalton aggregate.

Utilization of a Model Copolymer to Evaluate the Contribution of Hydrophobic Bonding in Drug Binding

JANARDAN B. NAGWEKAR* and HARRY B. KOSTENBAUDER†

Abstract □ A copolymer, having an overall composition of 1 unit of vinylpyridine to 26 units of vinylpyrrolidone, was synthesized. Several alkyl copolymers were made by quaternizing the nitrogen of vinylpyridine units of the copolymer with normal alkyl bromides, ethyl through hexyl. Using an equilibrium dialysis procedure, the interaction of *p*-toluene sulfonic acid sodium with each alkyl copolymer was studied over a temperature range of 15–45°, and the binding constants and thermodynamic parameters were determined. The quaternized vinylpyridine units of the alkyl copolymers constituted the binding sites for the *p*-toluene sulfonate ions. The stability of the complex formed in the reaction increased with an increase in temperature from 15–37° but decreased at 45°. The binding process was found endothermic and associated with positive entropy effects, indicating that the polymeric model system described here demonstrated properties expected for hydrophobic bonding. The effect of urea on the binding of sulfonate ion by one of the alkyl copolymers was studied and found to be in keeping with the claim that urea breaks hydrophobic bond.

Keyphrases □ Vinylpyridine-vinylpyrrolidone copolymers—synthesis □ Equilibrium dialysis—copolymer-*p*-toluene sulfonic acid sodium interaction □ Binding sites—copolymer-*p*-toluene sulfonate ions □ Urea effect—alkyl copolymer binding sulfonate ions □ UV spectrophotometry—identity

During the past 3 decades, several interactions have been reported which involved binding of drugs by plasma proteins; notable examples are penicillins (1), sulfonamides (2–5), methyl orange (6–7), and short- and long-chain fatty acids (8–14). In connection with these binding studies, it has been reported that the interactions primarily take place through ionic forces, but a further contribution to the stability of protein-drug complex is made by the hydrophobic part of a drug molecule. It has also been noticed that the larger the hydrophobic group of a drug molecule, the more stable is the complex. The contributions of hydrophobic groups is attributed to van der Waals forces. However, a close examination of the thermodynamic data has

revealed that van der Waals interactions alone cannot account for the stabilizing effect of hydrophobic groups. It is felt that hydrophobic bonding probably plays an important role in drug-protein complexing.

Hydrophobic bonding is a concept introduced by Kauzmann (15), who postulated its thermodynamic properties by extrapolating the behavior of small-size hydrocarbons in an aqueous medium. A hydrophobic bond is defined as the tendency of hydrophobic groups, mainly the hydrocarbons, to adhere to one another in an aqueous solution. The adherence of hydrophobic groups in an aqueous medium is not thought to be merely a manifestation of van der Waals forces; but the structure of water in close proximity to hydrophobic groups is believed to play a significant role, since such adherence processes are accompanied by entropy effects. The concept of hydrophobic bonding was originated to indicate its contribution in stabilizing the folded configuration of globular proteins. On the basis of a physical model, Nemethy and Scheraga (16) have shown that a hydrophobic bond can be formed between two isolated side chains attached to a rigid peptide backbone of protein. Attempts have been made to estimate the thermodynamic contribution of hydrophobic groups to form a drug-protein complex, but the simultaneous contribution of protein molecules due to their "configurational adaptability" obscured such evaluation (17, 18).

It is known that in the event of drug-protein interaction, the thermodynamic activity of a drug in the body is reduced, the biological action of a drug is influenced, and even the metabolism and excretion are hindered. The extent of participation of hydrophobic bonding in exerting such effects is not completely understood. However, one may expect that the concept of hydrophobic bonding can be applied to advan-

During the past 3 decades, several interactions have been reported which involved binding of drugs by plasma proteins; notable examples are penicillins (1), sulfonamides (2–5), methyl orange (6–7), and short- and long-chain fatty acids (8–14). In connection with these binding studies, it has been reported that the interactions primarily take place through ionic forces, but a further contribution to the stability of protein-drug complex is made by the hydrophobic part of a drug molecule. It has also been noticed that the larger the hydrophobic group of a drug molecule, the more stable is the complex. The contributions of hydrophobic groups is attributed to van der Waals forces. However, a close examination of the thermodynamic data has

revealed that van der Waals interactions alone cannot account for the stabilizing effect of hydrophobic groups. It is felt that hydrophobic bonding probably plays an important role in drug-protein complexing.

Hydrophobic bonding is a concept introduced by Kauzmann (15), who postulated its thermodynamic properties by extrapolating the behavior of small-size hydrocarbons in an aqueous medium. A hydrophobic bond is defined as the tendency of hydrophobic groups, mainly the hydrocarbons, to adhere to one another in an aqueous solution. The adherence of hydrophobic groups in an aqueous medium is not thought to be merely a manifestation of van der Waals forces; but the structure of water in close proximity to hydrophobic groups is believed to play a significant role, since such adherence processes are accompanied by entropy effects. The concept of hydrophobic bonding was originated to indicate its contribution in stabilizing the folded configuration of globular proteins. On the basis of a physical model, Nemethy and Scheraga (16) have shown that a hydrophobic bond can be formed between two isolated side chains attached to a rigid peptide backbone of protein. Attempts have been made to estimate the thermodynamic contribution of hydrophobic groups to form a drug-protein complex, but the simultaneous contribution of protein molecules due to their "configurational adaptability" obscured such evaluation (17, 18).

It is known that in the event of drug-protein interaction, the thermodynamic activity of a drug in the body is reduced, the biological action of a drug is influenced, and even the metabolism and excretion are hindered. The extent of participation of hydrophobic bonding in exerting such effects is not completely understood. However, one may expect that the concept of hydrophobic bonding can be applied to advan-

tage in drug formulation for purposes of: (a) enhancing the stability of certain drugs by complexation with biologically suitable agents capable of forming hydrophobic bonds with drug molecules, and (b) manipulating the release rate of drugs incorporated in a sustained-release dosage form. This necessitates extensive understanding of the properties of hydrophobic bonding. Recently, certain model systems have been studied to determine the thermodynamic parameters of hydrophobic bond formation. These model systems consisted of the adsorption of short-chain fatty acids by polystyrene resin at 4° (19), dimerization of small-chain fatty acids at 25° (20), and the interaction of phenol with short-chain fatty acid anions at 25° (21, 22). None of these model systems includes a water-soluble polymeric system containing definite sites for hydrophobic bond formation with suitable small molecules. It was the purpose of this study to devise such a model polymeric system that would make possible the evaluation of the contribution of hydrophobic bonding.

MODEL SYSTEM

The proposed model system consists of *p*-toluene sulfonic acid sodium (PTSAS) salt and a series of relatively simple, water-soluble copolymers containing definite sites for hydrophobic bonding. The interactions of this system are intended to be studied by equilibrium dialysis. Since the model copolymers considered here are not available commercially, they were synthesized in the laboratory. This research project therefore constitutes two distinct phases: (a) synthesis and characterization of a model copolymer and its derivatives, and (b) binding studies to determine thermodynamic functions of hydrophobic bonding for the model system.

The copolymer is made from two types of monomers, 4-vinylpyridine (hereafter called vinylpyridine) and *N*-vinyl-2-pyrrolidone (hereafter called vinylpyrrolidone); its overall composition is designed to contain about 30 units of vinylpyrrolidone to 1 unit of vinylpyridine. Several alkyl copolymers are prepared by quaternizing the nitrogen of vinylpyridine units of the copolymer with an appropriate *n*-alkyl bromide of a homologous series. The alkyl bromides used are bromoethane through bromohexane. The quaternized units of the copolymer would be expected to constitute the binding sites.

The interactions of PTSAS with each alkyl copolymer were studied at different temperatures using equilibrium dialysis, and the thermodynamic constants were determined. From such data the energy contribution of the methylene groups of the alkyl chain is estimated.

The choice of the model system used was made on the basis of the following considerations. PTSAS is a salt of a strong acid and strong base and will remain completely ionized in aqueous solution. Being an aromatic compound, the complicating feature of micelle formation which occurs with long-chain, aliphatic, water-soluble species (23) can be avoided. Also, PTSAS is amenable to spectrophotometric assay.

Since the phenomenon of hydrophobic bonding has to be studied in aqueous solution, the copolymer employed for this purpose must be water soluble. A copolymer composed mainly of polyvinylpyrrolidone might be expected to be water soluble even when a large fraction of binding sites is occupied. Since both monomers, vinylpyridine and vinylpyrrolidone, are equally reactive, the composition of a copolymer formed should approximate the composition of the feed of reaction (24), which in this case is 1 part of vinylpyridine to 30 parts of vinylpyrrolidone. It may then be reasonably expected that, in this copolymer, any 2 vinylpyridine units would be separated by about 25–35 units of vinylpyrrolidone (Structure I).

It is reasoned that the interaction of negatively charged *p*-toluene sulfonate ions takes place only with positively charged quaternized vinylpyridine units of the copolymer. Thus, the quaternized units represent the binding sites. Electrostatic binding is designed to bring the sulfonate ions sufficiently close to the quaternized units to facilitate hydrophobic bonding taking place between the hydrophobic

portion of the sulfonate ion and the alkyl group of a quaternized vinylpyridine unit. [See Structure I for a schematic representation of the structure of a copolymer molecule showing two vinylpyridine units (quaternized with R = ethyl through hexyl bromide) separated by about 26 units (*n*) of vinylpyrrolidone.] The binding energy involved in such interactions is due to two factors, electrostatic binding and hydrophobic bonding. Since all alkyl copolymers are prepared from the same parent copolymer, the charge density of each alkyl copolymer is probably not significantly different, and the energy contribution of electrostatic binding in all cases should remain the same. Therefore, the difference in the binding energy that may be shown in the binding of *p*-toluene sulfonate ion to various alkyl copolymers can be attributed to the difference in the hydrophobicity of alkyl chains attached to the quaternary nitrogen of vinylpyridine units.

The distance between adjacent binding sites on the polymer is such that the binding of a sulfonate ion to one site does not significantly influence the binding of another ion to the next site.

A potential complicating factor in the interpretation of energetics of binding is a possible secondary interaction of the sulfonate ion with the backbone of a copolymer which is primarily composed of polyvinylpyrrolidone. However, the difference in affinity of the anions for the quaternized site and for the copolymer backbone probably would be sufficient to permit isolation of the respective interactions. It is further believed that this tendency of secondary binding will be considerably reduced if the sulfonate ion, like other anions of similar molecular size (23), requires participation of as many as 10 units of vinylpyrrolidone for its binding.

The purpose of studying the system in 5 *M* urea solution was to provide additional means to test the validity of the present model system, since urea is known to weaken hydrophobic bonding (15, 25, 26).

SYNTHESIS AND CHARACTERIZATION OF A MODEL COPOLYMER AND ITS DERIVATIVES

The main characteristics desired of the model copolymer are: (a) it should be water soluble; (b) its molecular size should be large enough to render it nondiffusible to the cellophane membrane employed during the binding studies; and (c) its molecular composition is such as to contain about 30 units of vinylpyrrolidone to 1 unit of vinylpyridine.

Through a series of systematic experiments, the conditions necessary to yield the copolymer of desired properties were determined. Accordingly, 2.7 moles of vinylpyrrolidone and 0.095 mole of vinylpyridine (distilled at 45° under reduced pressure) were dissolved in about 260 g. of alcohol. To this solution was added 7.4 g. of α,α -azobis-isobutyronitrile previously dissolved in 40 g. of acetone. The reaction mixture was contained in a 2.5-l. capacity bottle with a bakelite stopper. Nitrogen gas was bubbled into the reaction mixture for 15 min. and the bottle was stoppered. The copolymerization was carried out with constant stirring at 60° using a heating plate equipped with a magnetic stirrer. When the reaction mixture became quite viscous in about 4 hr., the stirring was discontinued, but the heating was continued at 50° for another 36 hr. The reaction mixture was diluted with about 1600 ml. of acetone and fractionated by adding ether. Three fractions of the copolymer were obtained subsequent to the addition of about 850-, 750-, and 500-ml. quantities of ether, in that order. The second fraction was collected, dissolved in 2.5 l. of distilled water, filled into several cellophane tubes, and placed in a tank containing 8 gal. of distilled water for dialysis. The water in the bath was being constantly stirred and was replaced with freshly distilled water every 24 hr. Dialysis was continued for 4 days until no copolymer was detected in the water outside the tubes. The tubes were removed from the bath, and the contents were concentrated by blowing warm air over the bags. The concentrated copolymer was dissolved in a

mixed solvent containing 1230 ml. of acetone and 150 ml. of ethanol. The copolymer was precipitated with 1500 ml. of ether, which was added to the copolymer solution in 100-ml. portions with constant stirring. The viscous mass thus obtained was separated by decantation of ether. The polymer phase was further precipitated by adding to it 500 ml. of ether with constant stirring. The ether layer was decanted. The copolymer precipitate was then washed twice with ether, using 500 ml. of ether each time. The copolymer was dried at 60° under reduced pressure.

Analysis of Copolymer—Polyvinylpyrrolidone, when present in an acidic medium, does not absorb in the UV region. However, the copolymer shows a characteristic absorption maximum at 254 m μ . Therefore, it was necessary to synthesize polyvinylpyridine, which would serve as a reference compound for the quantitative determination of the vinylpyridine content in a known amount of copolymer by a spectrophotometric method. Polyvinylpyridine was synthesized by polymerizing vinylpyridine (freshly distilled at 45° under reduced pressure) using the conditions similar to those used for the synthesis of the copolymer. A linear relationship observed between the concentration of polyvinylpyridine and absorbance is shown in Fig. 1a. This offered an effective analytical tool to quantitate the amount of vinylpyridine present in a given quantity of copolymer. The Beer plot obtained for the copolymer is shown in Fig. 1b. With reference to the standard plot (Fig. 1a), it was calculated that the copolymer contained 26 units of vinylpyrrolidone to 1 unit of vinylpyridine. For the sake of convenience, the composition of the copolymer may be expressed as 1:26.

Alkyl Copolymers—Twenty grams of copolymer (1:26) was dissolved in 120 g. of nitromethane, and an appropriate quantity of alkyl bromide was added. The quantity of each alkyl bromide, from 1-bromoethane through 1-bromohexane, used was 16, 18, 30, 34, and 40 g., respectively. The reaction was carried out at 70° with constant stirring for 4 days in a closed glass container. The reaction mixture was brought to room temperature and poured in a thin stream within 15 min. into 1 l. of ether to precipitate the alkyl copolymer. The mixture was constantly stirred during the precipitation. The ether was decanted and the precipitate was dissolved in a mixture of 200 ml. of acetone and 20 ml. of ethyl alcohol. The solution was added to 500 ml. of ether to precipitate the alkyl copolymer. The ether was decanted, and the alkyl copolymer thus obtained was washed three times with 200-ml. portions of ether and dried at 50° under reduced pressure.

Assay of Alkyl Copolymer—The bromide content of the quaternized copolymer was quantitatively determined by a potentiometric titration method using 0.01 *N* silver nitrate solution as a titrant (27). From knowledge of the bromide content in a given quantity of alkyl copolymer, the proportion of quaternized units of vinylpyridine was calculated.

The composition of each alkyl copolymer is expressed in terms of units of vinylpyrrolidone present to 1 quaternized unit of vinylpyridine. The composition of various alkyl copolymers is recorded in Table I. In those cases where the alkyl copolymers are shown to contain more than 26 units of vinylpyrrolidone to 1 unit of vinylpyridine, all the vinylpyridine units were not quaternized by the respective alkyl bromide. However, it was experimentally demon-

Table I—Composition of the Alkyl Copolymers Expressed in Terms of Number of Vinylpyrrolidone Units to One Quaternized Vinylpyridine Unit

Copolymer	Composition
Ethyl	1:26
Propyl	1:29
Butyl	1:29
Pentyl	1:30
Hexyl	1:27

strated that the binding sites are represented solely by the quaternized units of vinylpyridine. Since the difference between the molecular weight of vinylpyridine (mol. wt. 105) and that of vinylpyrrolidone (mol. wt. 111) is small, and since the unquaternized vinylpyridine unit does not constitute a binding site for the sulfonate ion, it is not unreasonable to equate an unquaternized vinylpyridine unit to a vinylpyrrolidone unit while determining the composition of the alkyl copolymers in terms of units of vinylpyrrolidone present to 1 quaternized unit of vinylpyridine, as shown in Table I.

Copolymers of composition 1:20 and 1:34 were also synthesized, and only the hexyl derivatives were prepared.

EXPERIMENTAL

Materials—Ethyl copolymer (1:26), propyl copolymer (1:29), butyl copolymer (1:29), pentyl copolymer (1:30), and hexyl copolymer (1:20, 1:27, and 1:34) were synthesized in the laboratory. *p*-Toluene sulfonic acid sodium salt¹ was recrystallized from acetone-water solution. Sodium chloride (reagent grade); urea USP; and cellophane membrane² were used.

Solution of Alkyl Copolymer—A 2% (w/v) solution of each alkyl copolymer was prepared in 0.1 *M* sodium chloride solution (distilled water). A 2% (w/v) solution of pentyl copolymer was also prepared in 5 *M* urea.

Solution of *p*-Toluene Sulfonic Acid Sodium (PTSAS) Salt—The 0.01, 0.015, 0.02, 0.025, and 0.03 *M* solutions of PTSAS were prepared in 0.1 *M* sodium chloride solution. The ionic strength of each solution was adjusted to 0.13 with NaCl. Similar solutions were also prepared with 5 *M* urea.

Dialysis Procedure—Each dialysis cell consisted of two Plexiglas blocks, 6.3 × 6.3 × 2.6 cm., each half with a cavity having a capacity of 20-ml. Threaded Plexiglas plugs provided access to the cell cavities. To assemble the cells, a cellophane membrane previously freed of water-soluble material was clamped between the two symmetrical halves. Solutions were pipetted into each cavity as required; the stoppers, fitted with polyvinyl chloride washers, were screwed in tightly. The cells were then rotated at 9 r.p.m. in a water bath maintained at 15, 22, 30, 37, or 45 ± 0.2°. The system attained equilibrium within 44 hr. The cells were then removed from the bath, and the contents from the nonpolymer side of each cell were immediately transferred to a 20-ml. container provided with a cap. After the solution attained room temperature, each solution was analyzed for PTSAS by a spectrophotometric method.

Assay Method—PTSAS was assayed with a Beckman DU spectrophotometer at 261 m μ . Two milliliters of the sample solution was diluted to 50 ml. with distilled water and its absorbance noted using water as a blank. To correct for any spectral contribution of trace quantities of diffused macromolecule, dialysis cells were set up containing the solution of an appropriate alkyl copolymer on one side of the membrane and 0.13 *M* sodium chloride solution on the other side.

RESULTS

To ascertain that only the quaternized vinylpyridine units of an alkyl copolymer represented the binding sites, the interaction of 0.02 *M* PTSAS with each of three hexyl copolymers of composition 1:20, 1:27, and 1:34 was studied. The concentration of each hexyl copolymer was expressed in terms of its hexyl-4-vinylpyridinium

bromide content. (This practice of expressing concentration was also adopted with other alkyl copolymers.) A plot of concentration of hexyl copolymer *versus* moles of bound PTSAS was made as shown in Fig. 2. The linear plot obtained clearly indicates that the binding of sulfonate ions by the alkyl copolymer is a function of the concentration of quaternized vinylpyridine units of the latter.

The binding data obtained at various temperatures for each alkyl copolymer derivative were treated according to Eq. 1 (6):

$$1/r = 1/nKa + 1/n \quad (\text{Eq. 1})$$

where r is the number of moles of PTSAS bound per mole of an alkyl copolymer, n is the number of binding sites per mole of the alkyl copolymer, K is the binding constant (liter/mole), and a is the molar concentration of free PTSAS at equilibrium. From the slope ($1/nK$) and intercept ($1/n$), the binding constant, K , was evaluated. The straight lines of the plots were obtained by the method of least squares. Typical Langmuir plots obtained in the studies are shown in Fig. 3. The binding constants are listed in Table II.

The resulting straight lines indicate that each sulfonate anion binds to an identical group present in the alkyl copolymer and that the electrostatic repulsion between sulfonate ion already bound to one site and that bound to the next binding site is negligible.

It was noticed that in none of the cases was the intercept of Fig. 3 equal to unity, indicating that all the binding sites of an alkyl copolymer are not available for interaction with the sulfonate ions. It is likely that a few binding sites remain buried within the macromolecule, because the positively charged binding sites are so widely spaced that absolute rigidity of the macromolecule cannot be attained to prevent it from coiling completely. It also appears that the extent of availability of the binding sites partly depends on temperature, since out of every 10 binding sites, 7 to 8 sites at 15° and 22°, 8 to 9 binding sites at 30° and 45°, and 6 to 7 binding sites at 37° are available for the interaction. Although the number of available binding sites was not the same at all the temperatures

Figure 3—Typical Langmuir plots obtained for binding of PTSAS by ethyl copolymer, ○; and hexyl copolymer, ●; at 30°.

Table II—Binding Constants for the Interaction of PTSAS with Various Alkyl Copolymers over the Temperature Range of 15–45°

Copolymer	Binding Constant, K , l./mole				
	15°	22°	30°	37°	45°
Ethyl	46.00	—	46.66	50.00	32.70
Propyl	61.00	—	85.70	102.14	61.30
Butyl	52.84	54.56	55.00	63.28	42.56
Pentyl	62.80	—	111.00	127.20	58.00
Hexyl	63.36	85.84	94.80	108.08	68.60

studied, the number of binding sites available at any one particular temperature was essentially the same for all the alkyl copolymers.

Thermodynamic Functions—From the data in Table II (excluding the data obtained at 45°) a plot of $\log K$ *versus* $1/T$ was made (Fig. 4). The linear curves (least squares) obtained indicated that over the range 15–37° the enthalpy of binding is constant. The data obtained at 45° are discussed later. From the slope ($-\Delta H/2.303$) of the linear curve, the enthalpy of binding, ΔH , was calculated. The free energy of binding, ΔF , was calculated from the following relationship:

$$\Delta F = -RT \ln K \quad (\text{Eq. 2})$$

Finally, the entropy of binding, ΔS , was calculated from the following expression:

$$\Delta S = \frac{\Delta H - \Delta F}{T} \quad (\text{Eq. 3})$$

The thermodynamic constants obtained for the alkyl copolymers are listed in Table III.

When the corresponding binding constant, K , is plotted against the alkyl copolymer of the ascending homologous series, an ascending zigzag curve is obtained (Fig. 5). The binding constants of the alkyl copolymers with an odd number of carbon atoms in the alkyl chain are higher than those of the alkyl copolymers with the next

5 M Urea	K , l./mole			ΔF , cal./mole			ΔH , cal./mole	ΔS , e.u.
	15°	30°	37°	15°	30°	37°		
Absent	62.8	111.0	127.2	2372	2837	2987	5611	27.77
Present	29.2	40.0	44.0	1932	2221	2331	3433	18.62

even number of carbon atoms. This zigzag pattern is seen to exist at all the temperatures studied. Consequently, the values of thermodynamic functions determined for the series of alkyl copolymers also reflect the same pattern. However, the values of the binding constants, and for that matter those of the thermodynamic functions, increase with increasing alkyl chain length when a series of alkyl copolymers, containing an odd or even number of carbon atoms in the alkyl chain, is considered.

From the comparative data presented in Table IV and Fig. 6, it is clearly seen that the binding of the sulfonate ion by the pentyl copolymer has been influenced very significantly in the presence of 5 M urea. It is also noticed that the binding of the sulfonate ion by the pentyl copolymer increased with increase in temperature from 15–37°. The plot of $\log K$ against $1/T$ (Fig. 7) gives a straight line (least squares), which again suggests that the enthalpy of binding for the system is constant over this temperature range. In the presence of 5 M urea, the free energy of binding for this system became less negative by 400 cal./mole at 15°, 616 cal./mole at 30°, and 556 cal./mole at 37°. Similarly, the enthalpy of binding became less positive by 2200 cal./mole and the positive entropy of binding reduced by about 9 entropy units.

Figure 5—Plots of binding constant vs. alkyl copolymer at 15°, 30°, 37°, and 45°.

Another feature that becomes discernible is that the number of binding sites, which remain available on the pentyl copolymer molecule for binding of the sulfonate ions, is practically the same whether or not urea is present in the system. This may be noted by visual inspection of the intercepts of the plots in Fig. 6. This feature may serve to indicate that the intrinsic nature and behavior of the alkyl copolymers are not significantly modified in the presence of 5 M urea.

DISCUSSION

An examination of the data shows that the stability of the complex formed between an alkyl copolymer and the sulfonate ion increased with increasing temperature over the range 15–37° and that the binding process was endothermic. More importantly, the binding was associated with an increase in entropy, indicating that the model system demonstrates thermodynamic behavior in common with that described for hydrophobic bonding.

From the data of the composition of alkyl copolymers, it can be seen that the charge density of each alkyl copolymer is not significantly different. Therefore, the energy contribution of electrostatic binding of each alkyl copolymer is considered the same. The difference shown by these alkyl copolymers in the values of their respective thermodynamic constants can be attributed to the contribution of the methylene, $-\text{CH}_2-$, groups in the alkyl chains.

Despite the fact that the enthalpy of binding, which may be called enthalpy of hydrophobic bonding, was positive and therefore unfavorable, the bond formation was strengthened at relatively higher temperature. The free energy required to strengthen hydrophobic bond was derived from the substantial gain in entropy during the binding process. In aqueous solution, according to the concept of iceberg formation (28), the hydrocarbon groups of alkyl copolymers and *p*-toluene sulfonate ion are considered to be surrounded by one or more layers of water molecules, which are highly ordered with better hydrogen bonding than the molecules in ordinary liquid water. This brings about a lowering of configura-

Figure 6—Comparison of Langmuir plots for binding of PTSAS by pentyl copolymer in the absence of urea, O, and in the presence of 5 M urea, ●, at 30°.

Figure 7—Comparison of plots of logarithm of binding constant vs. reciprocal of absolute temperature for the binding of PTSAS by pentyl copolymer in the absence of urea, O, and in the presence of 5 M urea, ●.

tional entropy of the hydrocarbon groups. There is also a true hydration about the sulfonate group of the anion and the quaternary nitrogen of the vinylpyridinium groups of the alkyl copolymer. When binding occurs between the reactants concerned, the icebergs become either less ordered or contain fewer water molecules. As a result, the water molecules are released from the ordered structure, producing proportional increase in entropy due to the release of the configurational entropy of the hydrocarbon groups of the reactants.

Although the hydrophobic bonding might be expected to become continually stronger with a rise in temperature, there is a limit of maximum temperature for iceberg structure (16). The limit of maximum temperature depends upon the aliphatic or aromatic nature of the hydrophobic group. Since the π -electron orbitals of aromatic hydrocarbon react with the highly hydrogen-bonded water species, the extent of partial "icecage" formed around the aromatic hydrocarbon is smaller than that formed around the aliphatic hydrocarbon (29). Consequently, the lowering of configurational entropy of the aromatic hydrocarbon group is less than that of the aliphatic hydrocarbon groups. Nemethy and Scheraga (16) have theorized that, when the interaction takes place between the aliphatic side chains, the hydrophobic bond becomes stronger up to 58°; but when the interaction takes place between aromatic hydrocarbons, the hydrophobic bond becomes stronger up to 42°. According to this theory, the lowering of configurational entropy of the phenyl group would be negligible at 45°. Therefore, in the present system, when binding takes place at 45°, the contribution to the total entropy gain by the phenyl group of the sulfonate ion due to the release of its configurational entropy would be negligible. In view of this theory, it is conceivable that the decreased stability of the hydrophobic bond in the model system at 45° is due to the possible breakdown of the partial ice cage around the phenyl group of the sulfonate ion (Table III).

As shown in Fig. 5, the zigzag pattern exhibited in the values of the binding constants is intriguing. This pattern points to the possible role the number of contacts or closeness (established between the interacting hydrophobic groups within the Van der Waals radii) plays to determine the strength of hydrophobic bond (29). If the concept that the carbon atoms of the alkyl chain assume an extended zigzag arrangement in the liquid state (30) is extended to explain the zigzag pattern observed in Fig. 5, it seems probable that the terminal methyl group of the propyl and pentyl chain (containing odd numbers of carbon atoms) orient much closer to the phenyl group of the target sulfonate ion than the terminal methyl group of the butyl and hexyl chain (containing even numbers of carbon atoms).

Also, in view of the fact that in a normal hydrocarbon the angle formed by the two consecutive C—C bonds is approximately 110° and the C—C bond length is 1.54 Å (31), it can be estimated that the terminal methyl group of odd carbon alkyl chain, as compared to that of the even carbon alkyl chain, would be closer to the aromatic ring of the sulfonate ion by a geometric distance of about 0.88 Å. It is, therefore, conceivable that more water molecules are released by complexing the propyl group with the sulfonate ion than by complexing the butyl group, thereby resulting in substantial gain in entropy. Similarly, the pentyl group forms a more stable complex with the sulfonate ion than does the hexyl group.

It is seen that the increment in the binding energy with the increase of two methylene groups in an alkyl chain is not uniform and depends on the temperature of the interaction. The increment of the binding energy varied from -18 to -105 cal. at 15°, -97 to -329 cal. at 30°, and -134 to -330 cal. at 37°, depending on what two alkyl chains were considered. Similar nonuniformity in the increment of free energy has been reported by Nemethy and Scheraga (16) even on the basis of a physical model. Such nonuniformity may be attributed to the fact that the stability of hydrophobic bond is governed by several factors, such as the number of contacts and the closeness of contact between the interacting hydrophobic groups, the structure of iceberg, and the extent of partial ice cage around the hydrocarbons involved. A significant variance in the iceberg structure around the alkyl groups of various alkyl copolymers can be expected, since a variance in the iceberg structure around the lower hydrocarbons, methane, ethane, propane, and butane, has been reported by Clausen and Polgase (32) from solubility studies in water. They also observed a nonuniformity in the decrease of entropy values for the solubility of these hydrocarbons of a homologous series. The decrease in entropy with the additional —CH₂— group from methane to butane was 1.4, 6.4, and 1.0 e.u., respectively.

The effect of urea on the binding of sulfonate ion by the pentyl copolymer is in keeping with the claim that urea breaks hydrophobic bond. From Fig. 7 it is noted, however, that the thermodynamic behavior of the present model system in the presence of 5 M urea remained qualitatively the same. This suggests that the iceberg structure in the immediate vicinity of the alkyl chains of the alkyl copolymers and phenyl group of the sulfonate ion is not completely disrupted but has been significantly modified by the urea molecules, which are known to undergo hydrogen bonding with water.

Determination of Phenoxymethyl Penicilloic Acid and Phenoxyethyl Penicilloic Acid in Urine in the Presence of the Parent Penicillins

JAN BIRNER

Abstract □ Penicillin and the corresponding penicilloic acid are extracted by chloroform from an acidified sample of urine which has been partly saturated by ammonium sulfate. A portion of the extract is dried and redissolved in a small volume of acetone. A measured aliquot is chromatographed on a silica gel thin-layer plate by acetone-acetic acid (19:1). The separated penicilloic acid is detected by starch-iodine spraying. The zones are transferred into glass tubes, nitrated, and neutralized by ammonia. The absorbance of the yellow supernatant, which is proportional to the concentration of penicilloic acid, is measured spectrophotometrically.

Keyphrases □ Penicillin, penicilloic acid in urine—penicilloic acid determination □ Phenoxymethyl penicilloic acid—determination in urine □ Phenoxyethyl penicilloic acid—determination in urine □ TLC—analysis □ Starch-iodine spray—TLC spot identification □ Colorimetric analysis—spectrophotometer

Due to their instability in solution, penicillins taken orally or administered parenterally undergo chemical changes, and the breakdown products are excreted from the body in the urine.

Walkenstein *et al.* (1) found that between 30 and 60% penicillin G in urine remains biologically active, the major degradation product being penicilloic acid. The data were obtained by comparison of radioassays and bioassays of urine. Penicillins can be estimated directly by several methods such as iodometric, hydroxylamine, or biological, but penicilloic acid in the presence of penicillin is usually found by difference. Pan (2) gives a method for the determination of penicilloic acid in penicillin G fermentation broth, which is based on

extraction at different pH values and subsequent colorimetric determination. Phenoxymethyl penicillin (penicillin V) and phenoxymethyl penicilloic acid can be separated by paper chromatography; Roehr (3) gives R_f values in four different systems.

McGilveray and Strickland (4) use TLC for identification of about 10 penicillins in four systems.

It was observed that using silica gel G and acetone-acetic acid (19:1) in TLC penicillin V and phenoxyethyl penicillin (phenethicillin) can be separated from the corresponding penicilloic acids. The separated penicilloic acids, containing a phenolic group in the side chain, may be determined subsequently by a colorimetric method (5) by nitration, neutralization by ammonia, and spectrophotometric measurement. Based on this observation, a method has been developed that permits direct determination of penicilloic acid, in the presence of penicillin, in urine.

The sample, partially saturated by ammonium sulfate, is extracted by chloroform at pH 2, using a 1:5 ratio of water to chloroform. The chloroform extract is dried and redissolved in acetone, and an aliquot is taken for chromatography on silica gel using acetone-acetic acid (19:1). The zones of separated penicilloic acid, located by starch-iodine spraying, are transferred into glass tubes and nitrated in the presence of the silica to form quinoid radicals, which are yellow in color in the presence of ammonia. The silica, which does not interfere in this process, is separated by centrifugation, and the supernatant is used for spectrophotometric measurements.

Determination of Phenoxymethyl Penicilloic Acid and Phenoxyethyl Penicilloic Acid in Urine in the Presence of the Parent Penicillins

JAN BIRNER

Abstract □ Penicillin and the corresponding penicilloic acid are extracted by chloroform from an acidified sample of urine which has been partly saturated by ammonium sulfate. A portion of the extract is dried and redissolved in a small volume of acetone. A measured aliquot is chromatographed on a silica gel thin-layer plate by acetone-acetic acid (19:1). The separated penicilloic acid is detected by starch-iodine spraying. The zones are transferred into glass tubes, nitrated, and neutralized by ammonia. The absorbance of the yellow supernatant, which is proportional to the concentration of penicilloic acid, is measured spectrophotometrically.

Keyphrases □ Penicillin, penicilloic acid in urine—penicilloic acid determination □ Phenoxymethyl penicilloic acid—determination in urine □ Phenoxyethyl penicilloic acid—determination in urine □ TLC—analysis □ Starch-iodine spray—TLC spot identification □ Colorimetric analysis—spectrophotometer

Due to their instability in solution, penicillins taken orally or administered parenterally undergo chemical changes, and the breakdown products are excreted from the body in the urine.

Walkenstein *et al.* (1) found that between 30 and 60% penicillin G in urine remains biologically active, the major degradation product being penicilloic acid. The data were obtained by comparison of radioassays and bioassays of urine. Penicillins can be estimated directly by several methods such as iodometric, hydroxylamine, or biological, but penicilloic acid in the presence of penicillin is usually found by difference. Pan (2) gives a method for the determination of penicilloic acid in penicillin G fermentation broth, which is based on

extraction at different pH values and subsequent colorimetric determination. Phenoxymethyl penicillin (penicillin V) and phenoxymethyl penicilloic acid can be separated by paper chromatography; Roehr (3) gives R_f values in four different systems.

McGilveray and Strickland (4) use TLC for identification of about 10 penicillins in four systems.

It was observed that using silica gel G and acetone-acetic acid (19:1) in TLC penicillin V and phenoxyethyl penicillin (phenethicillin) can be separated from the corresponding penicilloic acids. The separated penicilloic acids, containing a phenolic group in the side chain, may be determined subsequently by a colorimetric method (5) by nitration, neutralization by ammonia, and spectrophotometric measurement. Based on this observation, a method has been developed that permits direct determination of penicilloic acid, in the presence of penicillin, in urine.

The sample, partially saturated by ammonium sulfate, is extracted by chloroform at pH 2, using a 1:5 ratio of water to chloroform. The chloroform extract is dried and redissolved in acetone, and an aliquot is taken for chromatography on silica gel using acetone-acetic acid (19:1). The zones of separated penicilloic acid, located by starch-iodine spraying, are transferred into glass tubes and nitrated in the presence of the silica to form quinoid radicals, which are yellow in color in the presence of ammonia. The silica, which does not interfere in this process, is separated by centrifugation, and the supernatant is used for spectrophotometric measurements.

Figure 1—Starch-iodine-sprayed chromatogram of phenoxymethyl penicilloic acid.

EXPERIMENTAL

Reagents—Ammonium sulfate A.R.; sodium sulfate anhydrous A.R.; chloroform B.P.; sulfuric acid, 12 *N* A.R.; acetone A.R.; silica gel G according to Stahl for TLC; glacial acetic acid; sodium hydroxide, 2.5 *N*; phosphate buffer, 1%, pH 7; *n*-butanol; 10% potassium nitrate in concentrated sulfuric acid; ammonia 0.880 sp. gr. A.R.—water (1:1); starch, soluble A.R.; 0.1 *N* iodine in 4% potassium iodide A.R.

Procedure—*A. Preparation of Thin-Layer Plates and Starch-Iodine Spray*—Using CAMAG hand-operated apparatus, glass plates, 20 × 10 cm., were coated with silica gel slurry sufficient to produce a thickness of 250–300 μ after drying. The plates were dried in an oven at 80° and finally kept at room temperature exposed to the atmosphere. The starch-iodine solution was prepared by mixing 50 ml. of 1% soluble starch solution, 3 ml. of glacial acetic acid, and 1 ml. of 0.1 *N* iodine.

B. Preparation of Penicilloic Acid—1. Prepare phenoxymethyl penicilloic acid by dissolving 8.5 g. of penicillin V in 80 ml. of water and 9 ml. of 2.5 *N* sodium hydroxide. Keep the solution overnight at 4–8°. After addition of 14 ml. of *n*-butanol, neutralize the solution by addition of dilute sulfuric acid, while mixing and cooling, until a precipitate forms. Filter off the precipitate, wash several times with water, and dry for 4 hr. at 36° and then in a desiccator over P_2O_5 ; m.p. 121–122° (dec.).

2. Prepare phenoxethyl penicilloic acid by dissolving 8.5 g. of phenethicillin in 80 ml. of water and 9 ml. of 2.5 *N* sodium hydroxide. Stir the solution for 0.5 hr.; then add 14 ml. of *n*-butanol. Add slowly, while mixing and cooling, 2 *N* sulfuric acid, until the pH reaches approximately 2.8 (approximately 25 ml.). Filter off the precipitate, wash several times with water, and dry at 36° overnight and then in a desiccator over P_2O_5 ; m.p. 113–114°.

C. Preparation of a Sample—Pipet 2 ml. of urine into a suitable glass-stoppered separator, add 1.5 g. of powdered ammonium sulfate, and mix by swirling to dissolve. Add 10 ml. of chloroform by means of pipet and 0.12 ml. of 12 *N* sulfuric acid which results in a pH of approximately 2. Stopper, and shake immediately for 1 min.

After standing for a few minutes to allow the layers to separate, draw off the chloroform layer into a dry test tube, filtering through a small glass funnel containing filter paper on which has been placed about 1 g. of anhydrous sodium sulfate. Transfer 5 ml. of the chloroform extract into a 10–15-ml. test tube fitted with a ground-glass stopper. Remove the chloroform by warming the test tube in a 30–40° water bath while blowing a gentle air current into the tube. Add 0.2 ml. of acetone to the dry residue, stopper immediately with a glass stopper, and gently agitate to dissolve the residue.

D. Separation of Penicilloic Acid from Penicillin and Spectrophotometric Determination of Penicilloic Acid—Stock solutions of the prepared penicilloic acids are made by dissolving in 1% phosphate buffer, pH 7, to furnish a concentration of 10 mg./ml. From these, aliquots are added to normal urine to furnish concentrations ranging from 0.2 to 1.0 mg. acid/ml. Two-milliliter aliquots of these standard solutions are submitted to Procedure C. Using a microsyringe, apply the standards and samples, usually 20- μ l. aliquots, each equivalent to 0.1 ml. of original sample or standard, to the plate in duplicate using four application sites for one plate. Develop without delay the plates containing samples and standards by acetone-acetic acid (19:1) in a covered jar lined with filter paper until the solvent front advances 12–14 cm. After drying, spray the plates with starch-iodine solution. The penicilloic acid appears as an elongated spot starting near the point of application, being more elongated at a higher concentration. The penicillin spots, less marked, appear near the liquid front, and the separation is complete. The amount of the sample applied to the plate may be varied depending upon the concentration.

Scrape the white zones containing penicilloic acid onto a square of glossy paper and quantitatively transfer into 11.5 × 1.5-cm. glass centrifuge tubes. Add 0.5 ml. of 10% potassium nitrate in concentrated sulfuric acid to each tube. Immerse the unstoppered tubes in boiling water for 15 min., stirring occasionally by rotation. After cooling, run 1.5 ml. of distilled water into each tube. Mix the solutions by swirling and cool the tubes in ice water. Add 5 ml. of

Figure 2—Chromatogram for chloroform extract from 0.1 ml. urine from Subject 2, phenoxethyl penicillin-treated. Key: A, phenoxethyl penicillin; B, phenoxethyl penicilloic acid.

half-strength ammonia (ammonia 0.880 sp. gr. mixed with water, 1:1) gradually from a buret and again mix the contents of the tubes by swirling and cool. After cooling, occlude the tubes with a thumb protected by rubber and shake several times. Centrifuge the tubes for 10–15 min. at 2000 r.p.m. Remove and measure spectrophotometrically at 420 mμ the yellow supernatant, using 10-mm. cells and setting the instrument on a clear blank obtained by boiling 0.5 ml. of nitrating mixture diluted with 1.5 ml. of water and 5 ml. of diluted ammonia. From the undeveloped part of the glass plate, scrape off, in duplicate, areas of surface equal to the areas extracted for penicilloic acid and put them through the same procedure as the samples to serve as a blank. Any value obtained from this latter is subtracted from the values for samples and standards.

From the values of the standards, plot a curve and obtain data for samples.

To provide typical natural samples for illustration of the method, an experiment was carried out to determine the amount of penicilloic acid present in samples of urine in a group of four volunteers taking penicillin orally. Two penicillins were used in the experiment—phenoxyethyl penicillin (penicillin V) and phenoxyethyl penicillin (phenethicillin). The amount of penicillin taken orally was 0.5 g. of the potassium salt. The urine samples were collected at 0, 1, 2, 3, 4, and 6 hr. and immediately kept in an ice water bath. All volunteers were adult males, coded 1, 2, 3, and 4, weighing 79.7, 78.8, 50.7, and 78.8 kg., respectively. The amount of penicillin in each sample was determined by biological assay. The result for zero-hour samples was nil both for penicilloic acid and penicillin. From the data given by

Figure 3—Chromatogram of chloroform extract from 0.1 ml. urine from Subject 2, phenoxyethyl penicillin-treated. Key: A, phenoxyethyl penicillin; B, phenoxyethyl penicilloic acid.

assays of penicillin and penicilloic acid, the percentage of the latter was calculated. The data for penicillin V are presented in Table I; the data for phenethicillin are presented in Table II.

A photograph of a developed starch-iodine sprayed plate containing a set of standards of phenoxyethyl penicilloic acid is shown (Fig. 1).

A photograph of a similar chromatogram of samples for phenethicillin from Donor 2 at 0, 1, 2, and 6 hr. is shown (Fig. 2). Samples from this same donor at 1, 2, and 3 hr. and a 25-mcg. standard of penicilloic acid are shown in Fig. 3.

Accuracy of Method—To aliquots of normal urine to which penicillin V had been added to a concentration of 2.5 mg./ml.,

6	41	50	91	55.0	101	80	181	44.2

^a PHA = Phenoxyethyl penicilloic acid.

phenoxyethyl penicilloic acid was added to furnish concentrations of 0, 0.25, and 0.5 mg./ml. These solutions, together with standard phenoxyethyl penicilloic acid preparations as in Procedure D, were submitted to Procedures C and D. Recoveries ranged from 92 to 100%. Similar results were obtained with phenethicillin and phenoxyethyl penicilloic acid.

Extraction Efficiency—Under the described conditions the extraction of phenoxyethyl and phenoxyethyl penicilloic acids from aqueous solutions by chloroform was between 88 and 92% complete. This was confirmed by assaying, by nitration, samples containing 0.5 mg./ml. and 1 mg./ml. directly and after extraction.

DISCUSSION

The yellow quinoid radical produced by nitration of these compounds that originate from the phenolic group could be produced if phenol or its derivatives were present in the sample used for nitration.

During numerous assays of urine samples without penicillin or penicilloic acid, the blank value of the chromatographed chloroform extract was close to or similar to the normal blank value, indicating that phenolic compounds present in urine do not interfere with this assay. The difference in R_f values for penicillins and for the corresponding penicilloic acids probably derives from the fact that the former are monobasic acids, which generally have high values compared with dibasic acids to which class the latter belong. The R_f

value of phenoxyacetic acid in the method used is higher than that of penicillin; possible interference by this acid, if present in the extract, is thus eliminated.

The data given in Tables I and II provide an example only of the information obtainable using this method. No attempt has been made to correlate the results with liquid intake, excretion volumes, or other controllable factors.

Kinetics and Mechanisms of Drug Action on Microorganisms X: Action of Spectinomycin on *Escherichia coli* by Microbial Kinetics

JOBST B. MIELCK and EDWARD R. GARRETT*

Abstract □ The steady-state growth of *Escherichia coli* cultures, $N = N_0 e^{k_0 t}$, is slowly inhibited by spectinomycin to a new steady state with a new rate constant, k_{app} . The k_{app} is linearly dependent on drug concentration, S , above a certain minimum concentration of spectinomycin, S^* ; i.e., $k_{app} = k_0 - k_S(S - S^*)$. This minimum concentration is a function of the concentration of the media and can be assigned to binding or removal of microbiologically effective spectinomycin as protonated material by the components of the media. The logarithm of the inhibitory constant, k_S , linearly increases with the pH of the media to pH 7.6, and this implies that only uncharged material is biologically active. The slow rate of achievement of a drug-equilibrated, steady-state, microbial generation rate can be reconciled with a relatively rapid reequilibrated rate on dilution with fresh media by postulating depletion of a cell-generated vital metabolite linked to the growth rate of the microorganism.

Keyphrases □ Microorganisms—mechanism, kinetics, drug activity □ Kinetics, mechanism—spectinomycin activity □ Spectinomycin action, *E. coli*—kinetics, mechanism □ pH, organism population, nutrient concentration, effects—spectinomycin-affected generation rates □ *E. coli* generation rates—spectinomycin concentration

The aminoglycoside spectinomycin has antibacterial activity against a variety of Gram-positive and Gram-negative microorganisms (1). The inhibitory action is bacteriostatic and is reversed by washing the drug-affected cells (2). The antibiotic forms a stoichiometric 1:1 complex with the 30-S ribosomal subunit extracted from *Escherichia coli*. The formation of this complex blocks some steps in the translocation of the peptidyl-

RNA from the acceptor site for aminoacyl *t*-RNA to the peptidyl donor site. Protein synthesis is thus inhibited (2).

The determination of the generation rates of *E. coli* as a function of the concentrations of a variety of antibiotics and chemotherapeutic agents has established a useful procedure to quantify the effects of drugs on the time course of bacterial generation (3–8).

The purposes of this study are to determine kinetically the inhibitory effects of spectinomycin on the generation rate of *E. coli* in defined concentration ranges and to evaluate the effects of variable inoculum size, concentration, and pH of the culture medium on drug activity.

EXPERIMENTAL

Test Organism—Replicate slants of *E. coli* strain B/r were used in all experiments. The slants had been prepared from a single colony and were stored in a refrigerator at 4°.

Culture Media—Antibiotic medium 3¹ was rehydrated according to the specifications of the manufacturer. The media were filtered twice through Millipore 0.45 μ HA filters and autoclaved at 120° for 15 min. The pH of the media was 7.05 ± 0.05 . Various amounts of Millipore-filtered 1.7 *N* HCl and 2.0 *N* NaOH, respectively, were added aseptically after the sterilization to obtain pH values within a range of 7.50 to 5.87 for the investigation of the anti-

¹ Bacto Antibiotic Medium 3, Difco Laboratories, Detroit, Mich.

phenoxyethyl penicilloic acid was added to furnish concentrations of 0, 0.25, and 0.5 mg./ml. JOBST B. MIELCK and EDWARD R. GARRETT*

Abstract □ The steady-state growth of *Escherichia coli* cultures, $N = N_0 e^{k_0 t}$, is slowly inhibited by spectinomycin to a new steady state with a new rate constant, k_{app} . The k_{app} is linearly dependent on drug concentration, S , above a certain minimum concentration of spectinomycin, S^* ; i.e., $k_{app} = k_0 - k_s(S - S^*)$. This minimum concentration is a function of the concentration of the media and can be assigned to binding or removal of microbiologically effective spectinomycin as protonated material by the components of the media. The logarithm of the inhibitory constant, k_s , linearly increases with the pH of the media to pH 7.6, and this implies that only uncharged material is biologically active. The slow rate of achievement of a drug-equilibrated, steady-state, microbial generation rate can be reconciled with a relatively rapid reequilibrated rate on dilution with fresh media by postulating depletion of a cell-generated vital metabolite linked to the growth rate of the microorganism.

Keyphrases □ Microorganisms—mechanism, kinetics, drug activity □ Kinetics, mechanism—spectinomycin activity □ Spectinomycin action, *E. coli*—kinetics, mechanism □ pH, organism population, nutrient concentration, effects—spectinomycin-affected generation rates □ *E. coli* generation rates—spectinomycin concentration

The aminoglycoside spectinomycin has antibacterial activity against a variety of Gram-positive and Gram-negative microorganisms (1). The inhibitory action is bacteriostatic and is reversed by washing the drug-affected cells (2). The antibiotic forms a stoichiometric 1:1 complex with the 30-S ribosomal subunit extracted from *Escherichia coli*. The formation of this complex blocks some steps in the translocation of the peptidyl-

RNA from the acceptor site for aminoacyl *t*-RNA to the peptidyl donor site. Protein synthesis is thus inhibited (2).

The determination of the generation rates of *E. coli* as a function of the concentrations of a variety of antibiotics and chemotherapeutic agents has established a useful procedure to quantify the effects of drugs on the time course of bacterial generation (3–8).

The purposes of this study are to determine kinetically the inhibitory effects of spectinomycin on the generation rate of *E. coli* in defined concentration ranges and to evaluate the effects of variable inoculum size, concentration, and pH of the culture medium on drug activity.

EXPERIMENTAL

Test Organism—Replicate slants of *E. coli* strain B/r were used in all experiments. The slants had been prepared from a single colony and were stored in a refrigerator at 4°.

Culture Media—Antibiotic medium 3¹ was rehydrated according to the specifications of the manufacturer. The media were filtered twice through Millipore 0.45 μ HA filters and autoclaved at 120° for 15 min. The pH of the media was 7.05 ± 0.05 . Various amounts of Millipore-filtered 1.7 *N* HCl and 2.0 *N* NaOH, respectively, were added aseptically after the sterilization to obtain pH values within a range of 7.50 to 5.87 for the investigation of the anti-

¹ Bacto Antibiotic Medium 3, Difco Laboratories, Detroit, Mich.

bacterial activity of spectinomycin as a function of the pH. Media with half and twice the amount of nutrients, respectively, were prepared and adjusted to a pH of 7.14 ± 0.02 for the study of the binding capacity of the medium for the antibiotic.

Antibiotic—An assayed sample of spectinomycin sulfate² was used (640 ± 35 mcg. base/mg.).

Bacterial Generation—A 5-ml. aliquot of culture medium was inoculated from a fresh slant, and the culture was allowed to grow for 12 hr. at 37.5° in an incubator. A 1.0-ml. sample was then diluted with 9.0 ml. broth at 37.5° , which was diluted 100-fold into a fresh medium after 60 min. The growth of this culture was followed up to 10^7 *E. coli*/ml. Samples of this culture were finally appropriately diluted in a single step, or in several steps, into replicate volumes of 49.0 ml. broth in 125-ml. loosely capped conical flasks to achieve the desired organism concentrations. The cultures were maintained at $37.5 \pm 0.1^\circ$ in a 50-gal. constant-temperature water bath equipped with a shaker. All pipets and media used for the dilutions of the cultures were kept at 37.5° to protect the organisms from temperature shocks.

Total Count Method—One-milliliter samples were withdrawn at 20-min. intervals from the cultures. They were diluted to obtain counts within a range of 10,000 to 30,000 counts/50 μ l. on the Coulter counter, model B.³ The diluent used was a Millipore 0.45 μ HA-filtered aqueous solution of 0.85% NaCl and 1% formaldehyde. The instrument was equipped with a 30- μ orifice; the settings were: an aperture current of 5, amplification of 8, gain of 10, lower threshold of 13, and upper threshold at maximum. The total counts were corrected for the background count of the particular batch of medium used, diluted in the same way as the sample. The background counts in general did not exceed 1000 counts/50 μ l.

Viable Count Method—Samples of 0.50 ml. were withdrawn from the cultures and appropriately diluted into sterilized 0.85% saline solution so that 50 to 150 colonies per plate would result. From these dilutions, aliquots of 1.00 ml. were pipetted onto each of three replicate agar plates. The plates were incubated for 48 hr. at 37.5° and the colonies counted on a Colony counter model C-110.⁴

Effect of Antibiotic Concentration on Generation Rates—Fresh solutions of spectinomycin in distilled water were aseptically prepared for each experiment. They were sufficiently diluted so that aliquots of 1.00 ml. added to the 49-ml. culture volumes yielded the desired graded drug concentrations between 6.00 and 20.0 mcg./ml. The solutions were added to the cultures growing at 37.5° in the logarithmic growth phase at determined organism concentrations. Samples were withdrawn every 20 min. and counted by the respective method. A culture without drug was studied in each experiment to obtain the generation rate constant in absence of drug as a reference. The generation curves for 21.9, 35.0, and 43.8 mcg./ml. spectinomycin at pH 7.05 were obtained by both the viable and total cell count methods (Fig. 1).

Effect of Organism Population on Drug-Affected Generation Rates—Each flask of four sets of four replicate 49-ml. volumes of culture medium of pH 7.05 was inoculated with 1.00 ml. of appropriately diluted culture growing in the logarithmic growth phase. The organism concentrations in the respective sets were 5×10^3 , 5×10^4 , 5×10^5 , and 5×10^6 *E. coli*/ml. at the time of addition of drug. Drug solutions were added to achieve spectinomycin concentrations of 15.0, 24.0, and 30.0 mcg./ml., respectively. One culture in each set contained no drug. Total cell counts were obtained from samples drawn every 20 min.

Reversibility of Drug Action—A 49-ml. volume of culture growing in the logarithmic growth phase at 37.5° contained at time zero a population of 10^6 *E. coli*/ml. (Curve A in Fig. 2). Drug was added to achieve a concentration of 28 mcg./ml. spectinomycin (Curve B in Fig. 2) at time zero. An aliquot of 2.00 ml. of this culture was diluted into 49 ml. of fresh medium at 50 min. after the addition of drug to give 1.12 mcg./ml. (Curve C in Fig. 2). At the same time, 5.00 ml. of the culture of Curve B was diluted into 45.0 ml. of broth that contained 28.0 mcg./ml. spectinomycin (Curve D in Fig. 2), and 2.00 ml. of the drug-free culture of Curve A was diluted into 49 ml. of drug-free broth (Curve A₁ in Fig. 2). At 240 min., 0.80 ml. of the culture of Curve B was diluted into each of two replicate 49-ml. volumes of fresh medium to give 4.48 mcg./ml. (Curve E in

Figure 1—Generation rate curves of *E. coli* at 37.5° and pH 7.05 obtained by total (closed symbols) and viable (open symbols) cell counts. The curves are labeled with the respective concentrations of spectinomycin (mcg./ml.).

Fig. 2). When these cultures containing 4.48 mcg./ml. drug reached the steady-state growth phase, at 355 min. and 6×10^6 *E. coli*/ml., a 1.00-ml. aliquot of spectinomycin solution was added to one of the replicate cultures to establish a drug concentration of 30.5 mcg./ml. (Curve F in Fig. 2). The total number of organisms in the various cultures was obtained from samples withdrawn every 20 min.

Effect of pH on Drug-Affected Generation Rates—Sufficient amounts of 1.7 N HCl and 2.0 N NaOH were added to the culture media to obtain pH values of 5.87, 6.20, 6.53, 6.55, 6.72, 6.87, 7.13,

Figure 2—Generation rate curves of *E. coli* at 37.5° and pH 7.10 on addition and dilution of spectinomycin. The curves, final drug concentrations (mcg./ml.), and apparent steady-state generation rate constants ($10^4 k_{app}$ in sec^{-1}) were A, 0, 6.20; A₁, 0, 6.24; B, 28.0, 0.96; C, 1.12, 5.95; D, 28.0, 0.42; E, 4.48, 5.90; and F, 30.5, 0.79.

Figure 3—Typical generation curves for *E. coli* at 37.5° and pH 6.72. The curves, spectinomycin concentrations (mcg./ml.), and generation rate constants ($10^4 k_{app.}$, sec.⁻¹) were: A, 0, 6.30; B, 32.0, 4.56; C, 40.0, 3.58; D, 53.3, 2.37; E, 66.7, 1.18; F, 72.7, 0.572; and G, 80, 0.

7.22, 7.30, and 7.50, respectively. The pH values of these studies were read at 10^7 *E. coli*/ml., using a Schott model U combination glass electrode and a Beckman Zeromatic pH meter with an expanded scale. From a single slant, separate cultures for each pH were prepared as previously described. At organism concentrations in the range from 8×10^4 to 8×10^6 *E. coli*/ml., 1.00-ml. aliquots of spectinomycin solutions were added to achieve the desired drug concentrations. A typical example is given in Fig. 3. In addition to the data obtained for the total number of organisms as a function of time, the pH in some of the cultures was monitored as a function of the organism concentration.

Effects of Nutrient Concentration on Drug-Affected Generation Rates—Culture media of half and twice the normal concentration of nutrients were prepared and adjusted to pH 7.14 ± 0.02 and 6.87 ± 0.02 , respectively. Microbial cultures were prepared in the previously described manner using these media separately. The respective relative nutrient concentrations, pH values, and the range of spectinomycin concentrations (mcg./ml.) used were: (a) for half the nutrient concentration: at pH 7.10 from 8 to 20 mcg./ml., at pH 7.16 from 6.7 to 12 mcg./ml.; and at pH 6.87 from 23 to 32 mcg./ml.; and (b) for twice the nutrient concentration: at pH 7.16 from 7 to 16 mcg./ml. The drug-free and drug-affected generation rate constants were obtained by total cell counts.

RESULTS

Effect of Drug Concentration on Generation Rates—The number of *E. coli* per milliliter obtained by both total and viable cell counts is plotted on a semilogarithmic scale against time in Fig. 1. The numbers from the respective methods are coincident; thus no kill or death of microorganisms is observed between 0 and 44 mcg./ml. over the time period studied. Thus, this study can be based upon total cell counts obtained within this range of drug concentration.

A typical family of generation curves obtained over a wide range of graded drug concentrations and based on total cell counts is given in Fig. 3. Upon addition of drug to the culture growing in the logarithmic phase, the generation rate is decreased slowly until a new spectinomycin-affected steady-state phase is established. Apparent first-order generation rate constants, $k_{app.}$ in sec.⁻¹, are obtained from the slopes of this linear portion in accordance with the equation

$$\log N = \log N_0 + \frac{k_{app.}}{2.303} t \quad (\text{Eq. 1})$$

where N is the number of microorganisms. A plot of the $k_{app.}$ values obtained at various pH values against spectinomycin concentration, S (Fig. 4), demonstrates the linear dependence of $k_{app.}$ on S at lower $k_{app.}$ values in accordance with the equation

$$k_{app.} = k'_0 - k_S S; k_{app.} < k_0 \quad (\text{Eq. 2})$$

where k'_0 in sec.⁻¹ is the extrapolated value for $k_{app.}$ at $S = 0$, the slope k_S in ml./mcg.-sec. is the inhibitory constant of the antibiotic, and k_0 is the generation rate constant in the absence of the antibiotic. The values for k_S and k'_0 , calculated from least-squares fits, and the experimentally determined k_0 in sec.⁻¹ are listed in Table I.

Effect of pH on Drug-Affected Generation Rate—The apparent first-order generation rate constants, $k_{app.}$, obtained at pH values from 5.87 to 7.50 in the culture media in the absence and presence

of graded spectinomycin concentrations, S , are plotted against S in Fig. 4. The drug-free generation rate constants are independent of pH in this range [Table I and (5)], while the drug-affected generation rate constants decrease with increasing pH at comparable drug concentrations. The calculated inhibitory constant, k_s , and intercepts, k_0' , are listed in Table I. A plot of the log k_s against pH is given in Fig. 5. The drug concentrations, $S = S^*$ (Table I), that produce $k_{app.} = k_0$, the drug-free generation rate constant, can be calculated from Eq. 2. The pH values of the media in drug-free and drug-affected growing cultures were constant to within 1% of their initial values up to 10^8 *E. coli*/ml. (5).

Effect of Organism Populations on Drug-Affected Generation Rates—Apparent first-order generation rate constants, $k_{app.}$, for the logarithmic portion of the growth curves obtained in the presence of three different spectinomycin concentrations over a 1000-fold range in inoculum size at the time of drug addition are given in Table II. Although the data show a trend toward smaller rate constants at lower inoculum sizes, the differences appear insignificant compared to the observed values for $k_{app.}$ at $S = 0$. At high organism concentrations ($N > 10^8$ *E. coli*/ml.) or after long periods of drug-affected generation ($t > 600$ min.), the generation rate of the drug-affected cultures increased markedly and approached a new steady state. Apparently, a very small fraction of the bacteria was resistant to spectinomycin. The estimated fraction of the inoculum that was not inhibited was less than 0.01 when the growth curves of the new steady state were extrapolated to the time of inoculation.

On the basis of these observations, it cannot be concluded that the antibiotic is consumed by the organism or that a drug antagonist is excreted as a function of the numbers of organisms (6). It is, therefore, assumed that the drug concentration is in sufficient excess to remain constant over the time period of observation.

Reversibility of Drug Action—Addition of drug to a culture growing in the logarithmic growth phase (Curve A in Fig. 2, $k_0 = 6.20 \times 10^{-4}$ sec.⁻¹) to establish 28.0 mcg./ml. spectinomycin (Curve B in Fig. 2) resulted in a gradual decrease in the rate of generation over a period of 200 min. until a new steady state ($k_{app.} = 0.96 \times 10^{-4}$ sec.⁻¹) was achieved. Curve A₁ in Fig. 2 ($k_0 = 6.24 \times 10^{-4}$ sec.⁻¹) demonstrates that the technique of diluting the cultures does not significantly affect the generation rate constant. Upon dilution of the culture of Curve B in Fig. 2 into fresh medium where the drug concentration of 28.0 mcg./ml. was reduced to 1.12 mcg./ml. (Curve C in Fig. 2), the generation rate gradually increased over a period of 60 min. until a new logarithmic phase with a generation rate constant of 5.95×10^{-4} sec.⁻¹ was established.

Figure 5—Dependence of the log of the inhibitory constant, k_s , in ml./mcg.-sec. of spectinomycin on the pH of the culture media.

Table II—Effect of Inoculum Size^a on Spectinomycin-Affected Growth of *E. coli*

Inoculum Size, <i>E. coli</i> /ml.	[Spectinomycin], mcg./ml.				S^* , ^b mcg./ml.
	0	15.0	24.0	30.0	
5×10^3	6.18	3.81	0.96	—	7.7
5×10^4	6.00	3.92	1.37	0.173	5.2
5×10^5	6.00	4.05	1.60	0.238	7.3
5×10^6	6.09	4.04	—	—	—

^a At time of drug addition. ^b Calculated drug concentration, $S^* = S$, at $k_{app.} = k_0$ from linear relation $k_{app.} = k_0' - k_s S$.

When the culture of Curve B was diluted 10-fold into a fresh medium where the original drug concentration was maintained, the continuous decrease in the generation rate was not interrupted. However, the generation rate constant, 0.42×10^{-4} sec.⁻¹ established at 220 min., was lower than that of Curve B. The expected value for this rate constant was that for Curve B in Fig. 2, 0.96×10^{-4} sec.⁻¹. The difference in these rate constants could suggest that the activity of spectinomycin is dependent on the concentration of microorganisms. However, the results from the studies of the influence of inoculum size on the generation rate constants over a much wider range of organism concentrations did not show a significant dependence. Dilution of the culture of Curve B at the beginning of its steady-state phase at 240 min. into drug-free medium (Curve E in Fig. 2) yielded a gradual increase in the generation rate over a period of 80 min. as compared to the 60 min. of Curve C in Fig. 2, whereafter a new steady-state phase with a rate constant of 5.90×10^{-4} sec.⁻¹ was established.

When drug was added to a replicate culture of that of Curve E in Fig. 2 to yield a drug concentration of 30.5 mcg./ml., a gradual decrease in the generation rate over 160 min. was observed, when a new logarithmic phase with a generation rate constant of 0.79×10^{-4} sec.⁻¹ was achieved.

Effect of Nutrient Concentration on Drug-Affected Generation Rates—The concentration of nutrients in the culture media has a significant effect on the drug-affected generation rate constants (Table III and Fig. 6). The calculated values for the spectinomycin concentration, $S = S^*$ when $k_{app.} = k_0$, increase nearly twice when the nutrient concentration is doubled. These S^* values were calculated from least-squares fits of the generation rate constants to the drug concentrations in accordance with Eq. 2.

Figure 6—Effect of various nutrient concentrations on the dependence of the generation rate constants of *E. coli* on the spectinomycin concentration. The curves, relative nutrient concentrations and calculated spectinomycin concentration, $S = S^*$ (mcg./ml.) at $k_{app.} = k_0$, were at pH 7.13: A, 0.5, 2.96, and 5.49 respectively; B, 1, 6.9; C, 2, 12.0, and at pH 6.87: A, 1, 7.27; and B, 2, 14.1.

Table III—Effect of Nutrient Concentration on the Biologically Ineffective Spectinomycin Concentration, S^* , against *E. coli*

Nutrients ^a	pH	$10^5 k_s^b$	$10^4 k_0'^c$	$10^4 k_0^d$	S^{*e}

DISCUSSION

The drug-affected, apparent first-order generation rate constant, $k_{app.}$, is linearly related to spectinomycin concentration (Fig. 4 and Eq. 2). Similar equations have been successfully employed to define the antibacterial activity of chloramphenicol (9, 10), tetracycline (9, 10), and, in part, lincomycin (5). They are based on the assumption that the extracellular spectinomycin concentration, S , equilibrates with the drug concentration, S' , in the receptor site compartment or biophase. Here the antibiotic reversibly binds to receptor sites, R , to form the drug-receptor complex, RS' :

The equilibria are characterized by the respective equilibrium constants K_1 and K_2 during the drug-affected steady state. The constant K_2 is the affinity constant of spectinomycin for its receptor site, and the product:

$$K_1 K_2 = k_0 (\text{ml./mcg.}) \quad (\text{Eq. 4})$$

is a quantitative measure of the antibacterial activity. It is implied that the fraction of drug-free receptor sites is proportional to the rate of protein synthesis. A certain fraction of this protein synthesis would be proportional to the rate of generation of bacteria, while a large fraction may be necessary for the maintenance of viability (9). The rate of increase in the number of bacteria may be defined in accordance with this concept (9) by

$$\frac{dN}{dt} = \{q(k_p - k_p') - qk_p K_1 K_2 [S] / (1 + K_1 K_2 [S])\} N \quad (\text{Eq. 5})$$

where k_p is the overall rate constant of protein synthesis; k_p' is the minimum rate constant of protein synthesis necessary for bacterial generation; and q is a proportionality constant linking the rate of population increase of N organisms, dN/dt , to the net rate of protein synthesis and to the total number of organisms, N , in a balanced culture. If only a small fraction of the total number of receptor sites has to be reacted with spectinomycin to achieve complete inhibition of bacterial generation,

$$K_1 K_2 [S] \ll 1 \quad (\text{Eq. 6})$$

As a consequence, Eq. 5 reduces to

$$\frac{dN}{dt} = \{q(k_p - k_p') - qk_p K_1 K_2 [S]\} N \quad (\text{Eq. 7})$$

Combining the constants in Eq. 7 yields

$$\frac{dN}{dt} = (k_0 - k_s [S]) N \quad (\text{Eq. 8})$$

where $k_{app.}$ is defined as

$$k_{app.} = (k_0 - k_s [S]) \quad (\text{Eq. 9})$$

which is identical with Eq. 2 when k_0' is substituted for k_0 . The calculated $k_{app.}$ (Eq. 2) equals k_0 at a concentration S^* (Table I) of spectinomycin. This implies that it takes a definite concentration of antibiotic to be exceeded before antibacterial activity is manifested. It is possible that this amount is bound either by the micro-

organisms or by the constituents of the culture media. If the bacteria were responsible for this binding, the calculated value for S^* would be a function of the inoculum size. The studies conducted with different inoculum sizes showed no such dependency for S^* (Table II), and permitted the conclusion that the organisms were not responsible for the binding of spectinomycin. If the media were responsible for this binding, S^* would vary with the concentration of nutrients. The experiments carried out with culture media that contained half and twice the normally used concentration of nutrients did show that S^* definitely increased with the nutrient concentration; these experiments permitted the conclusion that the constituents of the media effectively inhibited a definite amount of spectinomycin from exercising biological action (Table III). The relative amounts bound, i.e., the ratio of the estimated S^* values, are of the same order of magnitude as the relative nutrient concentrations for studies conducted at the same pH values (Fig. 6). The S^* values also decreased with increasing pH (Table I and Fig. 4), although the data showed great variability. The nature of the dependency of logarithm S^* on pH (Fig. 7) implied that the charged species were preferably bound to the media.

The inhibitory constant, k_s (Eq. 2 and Table I), varied as a function of pH. The linear plot of $\log k_s$ against pH (Fig. 5) has a calculated slope of 1.053 ± 0.056 . The pH region studied includes the pK_a of the doubly protonated spectinomycin, $pK_{a2} = 6.95$ (1). The linearity of this plot is maintained up to significantly higher pH values, i.e., pH 7.5. The pK_a of the singly protonated spectinomycin is 8.70 (1). It is, therefore, expected that the pK_a influences the antibacterial activity and that the uncharged fraction of the total spectinomycin concentration is the only antibacterially active species. The k_s values cannot be obtained at extracellular pH values higher than 7.5. Beyond this pH, the drug-free generation rate constant changes and the generation rate-determining step may be different from that within a range of pH 5.8 to 7.5 where k_0 is independent of pH. It is expected that the curve in Fig. 5 would approach a pH-independent value for k_s at extracellular pH values that exceed the pK_{a1} . An intrinsic activity constant, k_s^* , may be defined with regard to the concentration of unprotonated spectinomycin. Thus, it may be calculated (11) from the unprotonated fraction, f_s , of the total antibiotic concentration and the respective $[H^+]$ and the k_s values (Table I):

$$k_s^* = k_s / f_s = k_s ([H^+]^2 + K_1 [H^+] + K_1 K_2) / K_1 K_2 \quad (\text{Eq. 10})$$

The literature values for the dissociation constants (1) are $K_1 = 1.01 \times 10^{-7}$ and $K_2 = 2.00 \times 10^{-9}$. The mean value obtained for k_s^* was $(2.66 \pm 0.49) \times 10^{-3}$ ml./mcg.-sec.

The rate of achievement of the drug-affected steady-state generation rate with spectinomycin is a slower process than with tetracycline (4), chloramphenicol (7), and lincomycin (5). This is apparent from inspection of Figs. 1–3 where time in excess of 200 min. after drug addition is necessary to obtain a linear semilogarithmic plot of the number of organisms against time. There are several possible explanations for this phenomenon. The assumption of the model of Eq. 3 could imply that the rate of diffusion of drug, S , into the biophase (the compartment where antibiotic concentration, S' , is in instantaneous equilibration with receptor sites, R) is a slow process and is rate limiting. However, when the drug-affected culture media are diluted with fresh media (Curves G and E, Fig. 2), the resumption of the new steady-state generation rate occurs in the relatively short time interval of less than 50 min. Although differences in rates of diffusion of spectinomycin in and out of the biophase, i.e.,

Figure 7—Correlation of the log of S^* , the spectinomycin concentration, S , at $k_{app.} = k_0$ calculated from the linear dependence of $k_{app.}$ on S with the pH of the culture media.

a possible "active" process, could be postulated, it appears more reasonable to be critical of the assumption of rate-determining drug diffusion into the biophase.

An alternate explanation may be that drug action, as manifested by the degree of inhibition of generation rate, increases the sensitivity of the organism to further drug action until the steady-state generation rate is achieved. This "feedback" phenomenon is explainable on the premise that the rapidly equilibrated drug concentration in the biophase is competitive for receptor sites with a metabolic intermediate produced by the growing organism.

An analogy can be drawn to the sulfonamide-*p*-aminobenzoic acid competition. The initial fraction of receptor sites that is drug-receptor complex is reflected by an initial decrease in generation rate. This results in a diminution of the production of a vital metabolic intermediate. Subsequent depletion of excess stores of this intermediate in the normal metabolic or generation processes of the organism results in less amounts to compete with drug concentrations in the biophase, greater fractions of drug-receptor complex, and, consequently, further slowing of generation rates. On dilution of the drug with fresh medium, the drug in the organism's biophase rapidly reequilibrates with the consequence of less drug-bound receptor sites. A new steady-state production of metabolic intermediate may occur. This results in the observed reasonably rapid increase in microbial generation to new steady-state conditions (Fig. 2). A kinetically equivalent phenomenon is that the feedback is mediated by decreasing the number of available receptor sites concomitant with decreasing growth rates.

Pharmacokinetic Evidence for Saturable Renal Tubular Reabsorption of Riboflavin

WILLIAM J. JUSKO and GERHARD LEVY*

Abstract □ Pharmacokinetic relationships have been developed to characterize a multicompartment drug distribution and elimination model which includes a saturable renal tubular reabsorption process. The derived expressions have been applied to serum concentration and urinary excretion data obtained after rapid intravenous administration of riboflavin to man and dog. The mathematical relationships and experimental data demonstrate the dependence of renal clearance on the serum concentration of the drug and on urine flow rate. The results of this study indicate that the renal excretion of riboflavin, like that of several other water-soluble vitamins, involves saturable tubular reabsorption as well as tubular secretion.

Keyphrases □ Riboflavin—saturable renal tubular reabsorption □ Renal tubular reabsorption, secretion—riboflavin □ Flavin—inulin—clearance ratio □ Pharmacokinetics—riboflavin renal clearance

A number of natural substances are known to be reabsorbed from renal tubules by a saturable process. Among these are the water-soluble vitamins: thiamine (1), pantothenic acid (2), and ascorbic acid (3). The renal excretion of another water-soluble vitamin, riboflavin, has been shown (4) to involve tubular secretion in man, and it has recently been suggested (5) that tubular reabsorption of riboflavin occurs in the chicken. In addition,

an analysis of published data (6) indicates that the renal clearance of riboflavin in man decreases at lower serum levels of the vitamin.

A substance that undergoes saturable renal tubular reabsorption will characteristically yield higher renal clearances with increasing serum concentrations (7). The kinetics of this process have not been studied in detail, particularly over a wide concentration range such as is obtained after rapid intravenous injection of the substance. The single-injection technique for the study of renal clearance is often considered unsuitable (7) because of the difficulty of characterizing and accounting for the effect of rapid flux of the drug between plasma and tissue. Thus, this technically simpler method is often rejected in favor of the commonly used constant intravenous infusion method where plasma and tissue levels of the drug are maintained relatively constant. However, the constant infusion method will not reveal a possible concentration dependence of renal clearance unless the study is carried out at several, widely different infusion rates.

The purpose of this report is to present mathematical relationships which may be utilized for pharmacokinetic

a possible "active" process, could be postulated, it appears more reasonable to be critical of the assumption of rate-determining drug diffusion into the biophase.

Pharmacokinetic Evidence for Saturable Renal Tubular Reabsorption of Riboflavin

WILLIAM J. JUSKO and GERHARD LEVY*

Abstract □ Pharmacokinetic relationships have been developed to characterize a multicompartment drug distribution and elimination model which includes a saturable renal tubular reabsorption process. The derived expressions have been applied to serum concentration and urinary excretion data obtained after rapid intravenous administration of riboflavin to man and dog. The mathematical relationships and experimental data demonstrate the dependence of renal clearance on the serum concentration of the drug and on urine flow rate. The results of this study indicate that the renal excretion of riboflavin, like that of several other water-soluble vitamins, involves saturable tubular reabsorption as well as tubular secretion.

Keyphrases □ Riboflavin—saturable renal tubular reabsorption □ Renal tubular reabsorption, secretion—riboflavin □ Flavin—inulin—clearance ratio □ Pharmacokinetics—riboflavin renal clearance

A number of natural substances are known to be reabsorbed from renal tubules by a saturable process. Among these are the water-soluble vitamins: thiamine (1), pantothenic acid (2), and ascorbic acid (3). The renal excretion of another water-soluble vitamin, riboflavin, has been shown (4) to involve tubular secretion in man, and it has recently been suggested (5) that tubular reabsorption of riboflavin occurs in the chicken. In addition,

an analysis of published data (6) indicates that the renal clearance of riboflavin in man decreases at lower serum levels of the vitamin.

A substance that undergoes saturable renal tubular reabsorption will characteristically yield higher renal clearances with increasing serum concentrations (7). The kinetics of this process have not been studied in detail, particularly over a wide concentration range such as is obtained after rapid intravenous injection of the substance. The single-injection technique for the study of renal clearance is often considered unsuitable (7) because of the difficulty of characterizing and accounting for the effect of rapid flux of the drug between plasma and tissue. Thus, this technically simpler method is often rejected in favor of the commonly used constant intravenous infusion method where plasma and tissue levels of the drug are maintained relatively constant. However, the constant infusion method will not reveal a possible concentration dependence of renal clearance unless the study is carried out at several, widely different infusion rates.

The purpose of this report is to present mathematical relationships which may be utilized for pharmacokinetic

characterization, after rapid intravenous injection, of a multiple-compartment model which includes a saturable renal tubular reabsorption process. The derived expressions will be applied to serum concentration and urinary excretion data obtained after rapid intravenous administration of riboflavin to man and dog.

THEORETICAL

Renal Clearance Expressions—A multicompartment model in which drug is administered by single injection into the central compartment (which includes plasma) is depicted in Fig. 1. The distribution of drug between the central compartment (Subscript 1) and the tissue compartment (Subscript 2) is characterized by the apparent first-order transfer rate constants k_{12} and k_{21} . The entry of drug into the renal tubules is assumed to be by a first-order process characterized by the rate constant k_e . This may involve glomerular filtration with or without a tubular secretion component, provided the secretion process is of such high capacity as not to be saturated under the experimental conditions. The tubular reabsorption of the compound (transfer from urine to plasma) is considered to be of relatively low capacity (saturable) so that the Michaelis-Menten parameters T_m (maximum transport capacity) and K_m (Michaelis-Menten constant) are applicable. An extrarenal elimination component, represented by the apparent first-order rate constant k_{13} , is also employed. The renal clearance expressions to be derived are applicable to the described renal excretion mechanisms even if the extrarenal components of the model are more or less complex than those presented here.

The differential equation for the rate of urinary excretion (dX_u/dt) is

$$\frac{dX_u}{dt} = k_e \cdot X_1 - \frac{T_m \cdot C_u}{K_m + C_u} \quad (\text{Eq. 1})$$

where C_u is the concentration of drug in the urine. This is assumed to reflect the concentration of drug at the site of tubular reabsorption. Since

$$X_1 = C_p \cdot V_c \quad (\text{Eq. 2})$$

and

$$k_e = Cl_f/V_c \quad (\text{Eq. 3})$$

therefore,

$$Cl_f \cdot C_p = k_e \cdot X_1 \quad (\text{Eq. 4})$$

where C_p is the plasma concentration of drug, V_c is the volume of the central compartment, and Cl_f is the clearance for drug transfer from plasma to urine. Substituting Eq. 4 into Eq. 1 yields

$$\frac{dX_u}{dt} = Cl_f \cdot C_p - \frac{T_m \cdot C_u}{K_m + C_u} \quad (\text{Eq. 5})$$

Upon dividing both sides of Eq. 5 by C_p , the net or observed renal clearance (Cl_T) is described by

$$Cl_T = Cl_f - \frac{T_m \cdot C_u}{C_p(K_m + C_u)} \quad (\text{Eq. 6})$$

Equation 6 depicts the typical dependence of net clearance on plasma concentration of a drug subject to saturable tubular reabsorption. At relatively high C_p values, the last term of the equation becomes insignificant and $Cl_T \approx Cl_f$, which provides a method of estimating Cl_f .

Equation 6 can be further rearranged to yield

$$C_u = T_m \cdot \frac{C_u}{C_p(Cl_f - Cl_T)} - K_m \quad (\text{Eq. 7})$$

which, with a known Cl_f value, permits a linearization of experimental data whereby T_m and K_m can be determined from the slope and intercept, respectively, of a plot of C_u versus $C_u/C_p(Cl_f - Cl_T)$.

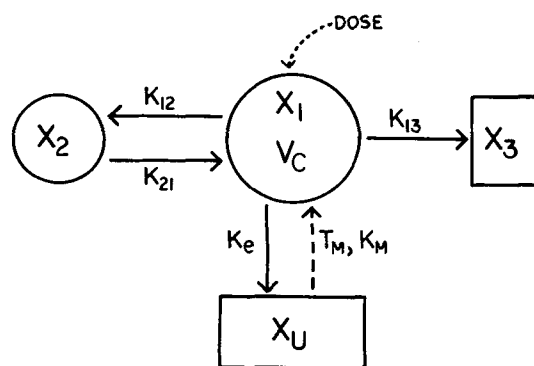

Figure 1—Multiple-compartment open model with central (X_1 , V_c), tissue (X_2), urine (X_u), and extrarenal (X_3) compartments. Symbols next to the arrows represent transfer rate constants between compartments. Apparent volume and amounts of drug are designated by V_c and X , respectively.

Effect of Urine Flow Rate—At relatively high urine concentrations of drug (where $C_u \gg K_m$), Eq. 6 reduces to

$$Cl_T = Cl_f - \frac{T_m}{C_p} \quad (\text{Eq. 8})$$

At relatively low urine concentrations of drug (where $K_m \gg C_u$), Eq. 6 reduces to

$$Cl_T = Cl_f - \frac{C_u \cdot T_m}{C_p \cdot K_m} \quad (\text{Eq. 9})$$

Since

$$\frac{C_u}{C_p} = \frac{Cl_T}{R} \quad (\text{Eq. 10})$$

where R is the urine flow rate, Eq. 9 may be written as

$$Cl_T = Cl_f - \frac{Cl_T \cdot T_m}{R \cdot K_m} \quad (\text{Eq. 11})$$

Equation 8 shows that the net renal clearance (Cl_T) is independent of urine concentration (C_u) at relatively high urine and serum concentrations of drug. Consequently, Cl_T is also independent of urine flow rate under these conditions. On the other hand, Cl_T increases with increasing urine flow rate (R) at low plasma and urine concentrations (Eq. 11). Thus, evaluation of the effect of urine flow on renal clearances will provide further evidence for a saturable renal tubular reabsorption mechanism.

Explicit Solution for Transfer Rate Constants—The remaining differential equations that describe the multicompartment model shown in Fig. 1 are:

$$\frac{dX_1}{dt} = -k_e \cdot X_1 + \frac{T_m \cdot C_u}{K_m + C_u} - k_{12} \cdot X_1 - k_{13} \cdot X_1 + k_{21} \cdot X_2 \quad (\text{Eq. 12})$$

$$\frac{dX_2}{dt} = k_{12} \cdot X_1 - k_{21} \cdot X_2 \quad (\text{Eq. 13})$$

$$\frac{dX_3}{dt} = k_{13} \cdot X_1 \quad (\text{Eq. 14})$$

where the k 's are apparent first-order rate constants dictating the rate of change (dX/dt) in the amounts of drug (X) in the respective compartments.

Equation 2 can be substituted into Eq. 14 to yield

$$\frac{dX_3}{dt} = k_{13} \cdot V_c \cdot C_p \quad (\text{Eq. 15})$$

The volume of the central compartment, V_c , can be determined after single i.v. injection of a drug from

$$V_c = \text{dose}/C_p^0 \quad (\text{Eq. 16})$$

where C_p^0 is the zero-time plasma drug concentration obtained by nonlinear least-squares extrapolation. At time = infinity (∞), X_3^∞ is the difference between the dose of drug administered and the total urinary recovery of the drug. Since

$$X_3^\infty = \int_0^\infty \frac{dX_3}{dt} \cdot dt \quad (\text{Eq. 17})$$

then by substituting from Eq. 15:

$$X_3^\infty = k_{13} \cdot V_c \cdot \int_0^\infty C_p \cdot dt \quad (\text{Eq. 18})$$

of which the integral portion is the area under the plasma level curve (AUC) which can be readily determined. Thus, k_{13} can be calculated from

$$k_{13} = X_3^\infty / V_c \cdot (\text{AUC}) \quad (\text{Eq. 19})$$

Similarly, X_2 as a function of time is

$$X_2^t = k_{13} \cdot V_c \cdot \int_0^t C_p \cdot dt \quad (\text{Eq. 20})$$

Substituting Eqs. 1 and 2 into Eq. 12 yields

$$\frac{dC_p}{dt} \cdot V_c = -\frac{dX_u}{dt} - k_{12} \cdot X_1 - k_{13} \cdot C_p \cdot V_c + k_{21} \cdot X_2 \quad (\text{Eq. 21})$$

which, upon rearrangement, becomes

$$\frac{dC_p}{dt} \cdot V_c + \frac{dX_u}{dt} + k_{13} \cdot C_p \cdot V_c = -k_{12} \cdot X_1 + k_{21} \cdot X_2 \quad (\text{Eq. 22})$$

As evident from Eq. 13, both sides of Eq. 22 are equal to $-dX_2/dt$, or

$$\frac{dX_2}{dt} = -\frac{dC_p}{dt} \cdot V_c - \frac{dX_u}{dt} - k_{13} \cdot C_p \cdot V_c \quad (\text{Eq. 23})$$

All parameters on the right-hand side of Eq. 23 can be determined directly from experimental data and from Eqs. 16 and 19. Thus, successive values of dX_2/dt as a function of time can be calculated. Since

$$X_2^t = \int_0^t \frac{dX_2}{dt} \cdot dt \quad (\text{Eq. 24})$$

values of X_2 as a function of time can be calculated using computer numerical integration¹ of Eqs. 23 and 24. With values of X_2 , dX_2/dt , and X_1 thus obtainable at successive times (Eqs. 24, 23, and 2, respectively), rearrangement of Eq. 13 provides a slope-intercept method for determining the transfer rate constants k_{12} and k_{21} since

$$\frac{dX_2/dt}{X_1} = k_{12} - k_{21} \cdot \frac{X_2}{X_1} \quad (\text{Eq. 25})$$

Calculation of the amounts of drug in the respective compartments of the model as a function of time can then be achieved by use of Eqs. 2 (for X_1), 24 (for X_2), and 20 (for X_3). X_u as a function of time can be determined directly from the urinary excretion data.

EXPERIMENTAL

The studies were carried out in a healthy male human subject (26 years, 85.4 kg.) and an apparently healthy female mongrel dog (29.5 kg.). The human subject received an intravenous dose of 31 mg. riboflavin (FR) as sodium riboflavin-5'-phosphate (FMN).² Urine was collected at appropriate intervals for a total of 48 hr.

Figure 2—Serum concentrations (●) and urinary excretion rates (□) of total riboflavin in a human subject after rapid intravenous injection of 31 mg. riboflavin (FR) as riboflavin-5'-phosphate (FMN). Solid lines represent a least-squares triexponential computer fit of the data.

Blood samples (16 ml. each) were obtained from the antecubital vein at -0.5, 0.25, 0.75, 1.25, 2.25, 3.25, 4.5, 6.5, 8.5, 13.0, and 25.0 hr. after FMN injection. These were midtimes of urine-collection periods. The serum and urine samples were analyzed for FR, FMN, and endogenous creatinine.

Dog Study³—The dog was fasted overnight prior to the experiment but was allowed free access to water. Anesthesia was induced with sodium pentobarbital,⁴ 30 mg./kg., and was maintained for the duration of the experiment by administration of 2-4 mg./kg. of the anesthetic approximately every hour as needed.

The animal was prepared for study using standard surgical techniques with care being taken to minimize blood loss. A tracheal cannula was inserted to prevent obstruction of respiration. A venous cannula in the left foreleg was used for infusion of isotonic saline solution to maintain adequate hydration of the dog. A 300-mg. priming dose of inulin⁵ was injected intravenously 30 min. prior to rapid intravenous administration of 18.3 mg. of riboflavin.⁶ Using a cannula placed in a right foreleg vein, inulin solution (12 mg./ml., 2 ml./min.) was infused for the duration of the experiment. Urine was generally collected every 10 min. for 280 min. from cannulas placed in each ureter. Arterial blood samples (11 ml. each) were collected at the midtimes of the urine-collection periods by means of a cannula placed into a left hindleg artery of the dog. Dilute heparin solution (50 units/ml.) was maintained in the arterial cannula between collection times to prevent clotting of blood in the cannula.

Analytical Methods—Riboflavin and FMN in serum and urine were assayed fluorometrically as described previously (9). Inulin and endogenous creatinine were determined by standard colorimetric techniques (10). There was no interference in the assay of any of the compounds due to the presence of the others.

Data for flavins and inulin were corrected for blank readings of urine and serum obtained prior to administration of the compounds to the test subjects.

¹ Mathematically, this can be done using either the trapezoidal rule or Simpson's rule (8).

RESULTS

Renal Clearances—The declines in serum concentrations and urinary excretion rates of flavin after rapid intravenous injection of the vitamin to the man and the dog are shown in Figs. 2 and 3, respectively. The data are plotted semilogarithmically as a function of time. Graphical analysis of the experimental results by the method of residuals (11) indicated that the decline of all data was triexponential. A nonlinear least-squares computer fit⁷ of the data was obtained using the "NLIN" digital computer program of

Figure 4—Renal clearances of total riboflavin (●) in the human subject as a function of serum total riboflavin concentration. Solid line represents a least-squares fit of the data according to the constants of Table I. Open symbols show simultaneously obtained creatinine clearances.

⁷ The contribution of C.D.C. 6400 computer time by the State University of New York at Buffalo Computer Center is gratefully acknowledged.

Marquardt (12). The general equation which was fit to the data is

$$F = A \cdot e^{-\alpha t} + B \cdot e^{-\beta t} + C \cdot e^{-\gamma t} \quad (\text{Eq. 26})$$

where F represents either flavin plasma levels or urinary excretion rates, t is time, and the remaining symbols are constants. Since the experimental data extended over a range of more than two orders of magnitude, they were converted to their respective logarithm values to reduce bias resulting from the numerical size of the larger values relative to the smaller values. The six parameters which were obtained for each of the four sets of data are shown in Table I; the solid lines of Figs. 2 and 3 represent the computer least-squares fit to the respective data.

All human pharmacokinetic analyses in this study were carried out on the basis of total flavin levels, i.e., riboflavin and riboflavin-5'-phosphate (FMN). This was necessary because of the rapid dephosphorylation of FMN in the blood *in vitro* (13) and because of limited assay sensitivity for FMN in the presence of an excess of riboflavin. However, estimations of renal clearances of FMN during the early sampling periods (when FMN levels were high) showed that the clearance of this substance was similar to that of riboflavin itself.

The renal clearances of flavin in man are shown in Fig. 4 plotted as a function of serum flavin concentration. All renal clearance values were obtained by the usual method of dividing the urinary excretion rate by the midtime serum concentration. The solid line of Fig. 4 represents flavin clearances calculated from the least-squares parameters of Table I. The figure also shows the endogenous creatinine clearances obtained at the same times as a measure of the glomerular filtration rate (GFR). The GFR remained essentially constant for the duration of the experiment, and the average value obtained was 130 ml./min.

The flavin clearances in Fig. 4 show a profile characteristic of saturable tubular reabsorption since the net clearance values progressively diminish as serum levels of the vitamin decline. Tubular secretion of the vitamin also occurs since the net clearance exceeds the GFR. Since the substrate concentration of the tubular secretory process (presumably plasma or cell water concentration of flavin) is appreciably lower than the flavin concentration in the urine, and since the net clearance of flavin increases rather than decreases at

Figure 5—Linearization method for obtaining the Michaelis-Menten constants of the renal tubular reabsorption process according to Eq. 7. The line fitted to the data has a slope of T_m and an intercept of $-K_m$.

Figure 6—Net renal clearance (Cl_T) of riboflavin in man plotted as a function of reciprocal serum concentration. Symbols are experimental data, and the line represents clearances calculated according to Eq. 6 using the derived values of Cl_f , T_m , and K_m .

high plasma concentrations of the vitamin, it was assumed that the secretory process was not capacity limited under the experimental conditions. Tubular secretion and glomerular filtration of flavin were therefore treated pharmacokinetically as apparent first-order processes. On the assumption that the contribution of the tubular reabsorption process to the net clearance is negligible at relatively high serum concentrations of the vitamin, a theoretical Cl_f was calculated from the C_p^0 and dX_u/dt values obtained by computer from plots of these data as a function of time.

This value, 420 ml./min. in man, was taken as an estimate of Cl_f and used in Eq. 7 for linearization of the renal excretion data by a plot of C_u versus $C_u/C_p \cdot (Cl_f - Cl_T)$. The graphical results are shown in Fig. 5. A least-squares fit of the data yielded a slope of 33.3 mcg./min. for T_m and an intercept K_m value of 16.3 mcg./ml. The three renal excretion parameters can be more readily obtained using Eq. 6 with a plot such as shown in Fig. 6. A direct computer fit of Eq. 6 to the experimental data using the Marquardt digital computer program (12) yielded nearly identical values for Cl_f , T_m , and K_m (425 ml./min., 34.1 mcg./min., and 17.9 mcg./ml., respectively). In the human subject, the urine flow rates were essentially constant at about 1 ml./min. The curve shown in Fig. 6 represents the calculated net clearance (Cl_T) of flavin, using the graphically derived values of Cl_f , T_m , and K_m in Eq. 6. The excellent fit of the experimental points to the calculated line demonstrates the suitability of the pharmacokinetic expressions for describing the concentration dependence of the renal clearances of riboflavin.

The renal clearances of riboflavin and urine flow rates obtained in the dog are shown in Fig. 7 as a function of time. The solid line depicts renal clearance values calculated from the least-squares parameters for the dog listed in Table I. The inulin clearances which were obtained as a measure of GFR were relatively constant and averaged 98.0 ml./min. with a standard deviation of 7.6. The fact that the flavin-inulin clearance ratio is greater than unity and the

Figure 7—Renal clearance of riboflavin (●) and urine flow rates (bars) in the dog as a function of time after riboflavin injection. The solid curve is a computer least-squares fit of the renal clearance data according to the constants of Table I.

Figure 8—Effect of urine flow rate on riboflavin clearance in the dog. Open symbols are results obtained during 0–140 min. and solid symbols are results obtained during 140–280 min. after riboflavin administration.

decrease in the clearance values of riboflavin with decreasing serum concentrations indicate that the renal clearance of riboflavin in the dog, as in man, involves both tubular secretion and saturable tubular reabsorption. These data also demonstrate the dependence of net renal clearance on urine flow rate, but the relationship is better exemplified in Fig. 8. In that figure, the net renal clearance of riboflavin is plotted as a function of urine flow rate with the data obtained in the first 140 min. separated from the data subsequently obtained. As predicted by Eq. 5, there is little effect of urine flow on the early riboflavin clearances ($C_p > 0.06$ mcg./ml.), but net clearance increased markedly with increasing urine flow rate when riboflavin serum and urine levels were relatively low.

For the dog, the earlier described computer program (12) was used to calculate Cl_f , T_m , and K_m and values are listed in Table II.

Distribution and Elimination Parameters of the Model—The last portion of the *Theoretical* section includes methods of calculating the rate constants k_{13} , k_{12} , and k_{21} . The volume of the central compartment for man and dog was obtained using Eq. 16, with C_p^0 determined from the least-squares parameters for the serum level data in Table I where

$$C_p^0 = A + B + C \quad (\text{Eq. 27})$$

The areas under the plasma level curves for man and dog were

Figure 9—Plot of pharmacokinetic data from the human according to Eq. 25 to yield an intercept of k_{12} on the ordinate and a slope of $-k_{21}$. Circles are values calculated directly from the experimental data and the line is the computer regression calculation.

Table II—Pharmacokinetic Constants of the Multicompartment Model for Riboflavin Distribution and Elimination in Man and Dog

Constant	Man	Dog
Cl_f , ml./min.	420	232
T_m , mcg./min.	33.3	21.9
K_m , mcg./ml.	16.3	9.61
k_e , hr. ⁻¹	1.80	2.98
k_{13} , hr. ⁻¹	0.133	0.433
k_{12} , hr. ⁻¹	0.768	3.01
k_{21} , hr. ⁻¹	0.872	5.11
V_c , l.	14.0	4.66
V_c , % b.w.	16.4	15.8
Wt., kg.	85.4	29.5
Dose, mg.	31.0	18.3
Urinary excretion, %	89.8	85.0

found to be 1.62 and 1.36 mcg. hr./ml., respectively. The k_{13} values for man and dog, which were calculated by means of Eq. 19, are 0.133 and 0.433 hr.⁻¹, respectively. All numerical integrations were carried out using the trapezoidal rule with sequential areas determined at 0.05-hr. increments.

Figure 9 shows the plot of $dX_2/dt/X_1$ versus X_2/X_1 for the data obtained in the human subject. There is good agreement between the points calculated directly from the experimental data and the computer-calculated regression line. A similar plot was obtained for the dog; the resultant values of k_{12} and k_{21} which were found in the two experiments are listed in Table II.

Since only one man and one dog were employed in the present study, the rate constants and pharmacokinetic parameters listed in Table II cannot be used as a measure of species differences. However, it is interesting to note several similarities in the data of Table II for man and dog. The volume of the central compartment is about 16% of body weight in both. The percent urinary excretion

Figure 10—Amounts of total riboflavin (as fraction of the administered dose) as a function of time in the four compartments of the pharmacokinetic model for man. Data points were obtained experimentally from serum concentrations (for Curve X_1) and urinary excretion rates (for Curve X_u).

Figure 11—Fraction of the riboflavin dose as a function of time in the four compartments of the pharmacokinetic model for the dog. Data points and lines were obtained as in Fig. 10.

and the ratios of $k_e:k_{13}$, $k_{21}:k_{12}$, and $T_m:K_m$ are similar. However, the tubular secretion process (Cl_f) had a relatively much greater capacity in the dog, resulting in more rapid elimination of the vitamin.

The parameters of Table II were used with the appropriate equations of the *Theoretical* section to calculate the fraction of the dose of flavin in the respective compartments of the pharmacokinetic model of Fig. 1. The results of such calculations are shown in Fig. 10 for the man and in Fig. 11 for the dog. The experimental data shown for the central (X_1) and urine (X_u) compartments are in excellent agreement with the calculated curves. As predicted by the several similarities in the parameters listed in Table II, the time courses of fractional drug levels in man and dog are quite similar, except that all processes occur at a more rapid rate in the dog. The parameters and results of Table II and Figs. 10 and 11 were further confirmed using the "MIMED" digital computer analog simulation program (14) with the appropriate differential equations (Eqs. 2 and 12-14).

Calculation of the sum of the fraction of the dose of drug in the various compartments using the derived parameters of the model provides an indication of the overall error involved in the calculations. The discrepancy between the summation of fractional drug levels and the administered dose ranged between 0 and 2%. Since the calculated X_1 and X_u values agreed very well with the experimental data, most of the error can be attributed to calculation of X_2 and particularly X_3 . This is to be anticipated because of the three components of Eq. 23 which must be calculated from the experimental data and the subsequent necessity of integrating this equation at discrete time increments to obtain X_2 values.

DISCUSSION

A pharmacokinetic model has been developed to characterize the kinetics of renal clearance by simultaneous first-order renal excretion and saturable renal tubular reabsorption after rapid intravenous administration of a drug. This model and the results obtained experimentally demonstrate the dependence of renal clearance on the serum concentration of a drug and the rate of urine flow.

It was assumed in the calculations that the urine concentration of drug approximates the concentration at the site of renal tubular reabsorption. If tubular reabsorption occurs in the distal renal tubule, this assumption is probably quite reasonable. The simultaneous occurrence of glomerular filtration, tubular secretion, tubular reabsorption, and water reabsorption produces a proximal to distal gradient in tubular concentrations of drug, and the actual drug concentration at the site of reabsorption will lie between the glomerular filtrate concentration ($\approx C_p$) and the urine concentration in the ureter (C_u). If the actual drug concentration (S) at the site of tubular reabsorption is considered to be the average of the filtrate and urine concentrations,

$$S = \frac{1}{2}(C_p + C_u) \quad (\text{Eq. 28})$$

and since $C_u \gg C_p$, then $S \approx \frac{1}{2}C_u$. Substituting this average concentration into Eq. 6 and rearranging yield

$$Cl_T = Cl_f - \frac{T_m \cdot C_u}{C_p(1/2K_m + C_u)} \quad (\text{Eq. 29})$$

The T_m value, but not the value of K_m , is independent of the assumption represented by Eq. 28. Equation 29 indicates that K_m is simply a proportionality constant which is dependent on the assumption of how best to approximate the drug concentration at the site of reabsorption. It, therefore, should not be used for comparison of data for drugs which are reabsorbed at different sites in the renal tubule.

The renal clearance equations which were developed are independent of the complexity of the extrarenal portion of the model. Drug levels are measured in the serum and urine, and the clearance equations are only concerned with the relationship between the two compartments as reflected by these fluids.

The nonlinear relationship which characterizes the tubular reabsorption mechanism does not permit solution of the extrarenal parameters of the model by use of the usual pharmacokinetic treatments such as described by Rescigno and Segre (15). However, because drug levels were simultaneously determined in two compartments (central and urine), it was possible to develop explicit solutions for the rate parameters k_{13} , k_{12} , and k_{21} . The results of such calculations yield a very good fit to the test data, but the values obtained for X_2 as a function of time may be slightly in error. This error arises from experimental variation in the values of dC_p/dt , dX_u/dt , and C_p ; the necessity of predetermining V_c and k_{13} for use in Eq. 23; and the probable error due to integrating this equation at discrete time increments. The use of computer calculations and least-squares data treatments, however, tends to minimize such error. It is easier to utilize the mathematical relationships described here than to resort to the analog computer for an empirical resolution of the parameters. The linearity of a plot such as is shown in Fig. 9 also provides a test to determine whether or not a more complex model (e.g., two-tissue compartments) might be more appropriate.

The serum concentration and urinary excretion rate data in man and dog could be fitted effectively to a triexponential equation. For a linear multiple-compartment model, such data would be indicative of a three-compartment open model; parameters such as those shown in Table I could be directly utilized for solution of the microscopic transfer rate constants (15). However, because of the nonlinear tubular reabsorption process, this approach was not feasible in this study, and the least-squares triexponential fit of the data (Table I and Eq. 26) was used only for a suitable description of the data which facilitated computer numerical analyses for solution of the pharmacokinetic equations listed in the *Theoretical* section.

With regard to the test compound used in the present study, the data indicate that the renal excretion of riboflavin in man and dog involves a specialized secretory process of apparent high capacity as well as an easily saturated tubular reabsorption process. The first conclusion is based on the renal clearance data which show that riboflavin clearances are much greater than the glomerular filtration rate, even without correction of the clearance data for the moderate extent of serum protein binding of the flavins. Previous work has shown that riboflavin and FMN, in the serum concentration range encountered in this study, are about 60% bound to plasma proteins in man (9). The dog exhibits 19% binding of riboflavin to serum proteins (16). In both species, the extent of flavin binding is independent of serum concentration over the range used

Figure 12—Relationship between renal clearance and serum concentration of riboflavin in a human subject who received 84 mg. riboflavin by intravenous infusion over 2 hr. The open circles are values obtained during the infusion (when serum concentrations were rising) and the solid circles are values obtained postinfusion (when serum concentrations were falling). Based on data from Reference 6. The curve is from Fig. 4 of the present study.

in the present study. It has been further demonstrated that probenecid, a potent inhibitor of many active transport processes (17), inhibits the renal clearance of riboflavin in man (13) and dog (16). Markkanen *et al.* (18) have also shown that probenecid decreases the basal excretion of riboflavin in man and rabbits whose riboflavin intake was limited to that derived from the normal diet. Rennick (19), whose work first demonstrated the tubular secretion of riboflavin in chickens, also noted that this process was inhibited by probenecid.

The decline in renal clearances of riboflavin with decreasing serum levels of the vitamin indicates that the vitamin undergoes saturable tubular reabsorption. The kinetics of this process are well characterized in man and dog by a model which assumes saturable renal tubular reabsorption. Experimental confirmation of the theoretically predicted effect of urine flow rate on the renal clearance of riboflavin in the dog adds further support to this interpretation. Evidence in the literature also suggests a dependence of riboflavin excretion on urine flow rate. Tucker *et al.* (20) and Johnson (21) reported increases in riboflavin excretion in human subjects after diuresis due to increased water intake. A reexamination of data published by Markkanen (22) shows that diuresis induced by acetazolamide and mercaptomerin also increases the basal excretion of riboflavin in rabbits.

The relationship between renal clearance and serum concentration shown in Fig. 4 was determined under dynamic conditions, *i.e.*, when serum concentrations of riboflavin were changing rapidly. These conditions are quite different from the usual conditions for the determination of clearance values, where relatively constant serum concentrations are maintained by continuous infusion of drug. The question then arises whether the clearance *versus* serum concentration profile obtained in the present study is an artifact due to distribution effects. There is strong evidence that this is not so. First, the magnitude of the clearance changes (almost threefold) is much greater than could be explained by distribution effects, particularly since, according to the pharmacokinetic analysis, no more than 18% of the dose of riboflavin reaches the "tissue" compartment. Second, analysis of riboflavin serum and urinary excretion data from the literature (6) provides independent confirmation of the results of the present study. The renal clearance values calculated from these data, which were obtained by infusing a total of 84 mg. riboflavin over 2 hr., are shown in Fig. 12. The clearance *versus* riboflavin concentration profile is essentially the same as was obtained in the present study, although the numerical values are somewhat lower, probably reflecting differences in body size. The clearance values during infusion of riboflavin (*i.e.*, when the serum concentration of riboflavin was rising) agree well with the postinfusion values (*i.e.*, when the serum concentration of riboflavin was falling). This, and the fact that distribution factors would have much smaller effects when the drug is administered by infusion rather than by rapid intravenous injection, strongly support the conclusions of the present study.

It is now apparent that there exist specialized transport mechanisms for riboflavin, other water-soluble vitamins, and certain amino acids and sugars for renal tubular reabsorption as well as intestinal absorption (3, 7, 23, 24). Both mechanisms are easily saturable. The specialized renal tubular reabsorption process helps to prevent a possible depletion of body levels of these essential nutrients. On the other hand, saturability of transport of nutrients across the small intestine sets an upper limit on the amount of these substances which can be absorbed.

Distribution, Excretion, and Metabolism of ¹⁴C-Labeled Quaternary Ammonium Salt of Mepazine and Promethazine in Rats

C. L. HUANG, J. A. YEH, and S. Y. HSU

Abstract □ Studies on the biological fate and antimicrobial activity of mepazine and promethazine methiodide are presented. Synthesis of ¹⁴C-methiodide and estimation of the unchanged compound in biological materials are described. After intraperitoneal administration, the majority of these compounds was excreted in feces. The radioactivity in the liver and kidneys prevailed over other organs. Blood levels were low but above the significant level in both compounds. Brain level of promethazine methiodide-¹⁴C was detectable but that of mepazine methiodide-¹⁴C was insignificant. These compounds displayed a significant antimicrobial activity.

Keyphrases □ Mepazine and promethazine ¹⁴C-methiodides—synthesis □ Biological fate—mepazine and promethazine ¹⁴C-methiodides □ UV spectrophotometry—identity □ Paper chromatography—separation □ Radiochromatography—purity determination

Mepazine and promethazine are derivatives of phenothiazine but they display quite a different mode of action. Pharmacologically, mepazine is less potent than chlorpromazine (1-5). The drug possesses a neuroleptic

effect similar to that of chlorpromazine (6-8); however, mepazine is not a drug of choice for the treatment of psychoses because of the high incidences of side effects such as agranulocytosis, seizures, depression of bone marrow, and jaundice. Promethazine (9, 10) finds its use mainly as a potent antihistaminic drug with a prolonged duration of action and as a drug for motion sickness. The difference in the pharmacological activities between these two drugs appears to be attributable to the effect of the side chains attached to the nitrogen of the phenothiazine ring system. All psychoactive phenothiazine derivatives possess a three-carbon bridge between the terminal and the ring nitrogen, while the presence of a two-carbon bridge between the two nitrogens appears to enhance the antihistaminic effect but diminishes the psychoactive properties of phenothiazine derivatives.

Quaternization of a side-chain nitrogen does not seem to decrease the toxicity of phenothiazine neuroleptics (11, 12). In many cases, toxicity appears to be enhanced.

It is now apparent that there exist specialized transport mechanisms for riboflavin, other water-soluble vitamins, and certain amino acids and sugars for renal tubular reabsorption as well as intestinal absorption (3, 7, 23, 24). Both mechanisms are easily saturable. The specialized renal tubular reabsorption process helps to prevent a possible depletion of body levels of these essential nutrients. On the other hand, saturability of transport of nutrients across the small intestine sets an upper limit on the amount of these substances which can be absorbed.

Distribution, Excretion, and Metabolism of ¹⁴C-Labeled Quaternary Ammonium Salt of Mepazine and Promethazine in Rats

C. L. HUANG, J. A. YEH, and S. Y. HSU

Abstract □ Studies on the biological fate and antimicrobial activity of mepazine and promethazine methiodide are presented. Synthesis of ¹⁴C-methiodide and estimation of the unchanged compound in biological materials are described. After intraperitoneal administration, the majority of these compounds was excreted in feces. The radioactivity in the liver and kidneys prevailed over other organs. Blood levels were low but above the significant level in both compounds. Brain level of promethazine methiodide-¹⁴C was detectable but that of mepazine methiodide-¹⁴C was insignificant. These compounds displayed a significant antimicrobial activity.

Keyphrases □ Mepazine and promethazine ¹⁴C-methiodides—synthesis □ Biological fate—mepazine and promethazine ¹⁴C-methiodides □ UV spectrophotometry—identity □ Paper chromatography—separation □ Radiochromatography—purity determination

Mepazine and promethazine are derivatives of phenothiazine but they display quite a different mode of action. Pharmacologically, mepazine is less potent than chlorpromazine (1-5). The drug possesses a neuroleptic

effect similar to that of chlorpromazine (6-8); however, mepazine is not a drug of choice for the treatment of psychoses because of the high incidences of side effects such as agranulocytosis, seizures, depression of bone marrow, and jaundice. Promethazine (9, 10) finds its use mainly as a potent antihistaminic drug with a prolonged duration of action and as a drug for motion sickness. The difference in the pharmacological activities between these two drugs appears to be attributable to the effect of the side chains attached to the nitrogen of the phenothiazine ring system. All psychoactive phenothiazine derivatives possess a three-carbon bridge between the terminal and the ring nitrogen, while the presence of a two-carbon bridge between the two nitrogens appears to enhance the antihistaminic effect but diminishes the psychoactive properties of phenothiazine derivatives.

Quaternization of a side-chain nitrogen does not seem to decrease the toxicity of phenothiazine neuroleptics (11, 12). In many cases, toxicity appears to be enhanced.

A comparison was made on the distribution, excretion, and metabolism of ^{35}S -labeled promethazine and a quaternary phenothiazine compound (Aprobit) [1-(10-phenothiazinylmethyl)ethyl - 2 - hydroxyethyl-dimethylammonium chloride] on mice (13). Fecal excretion was found to be the major route of elimination of the quaternary phenothiazine compound after oral administration, but the drug was excreted mainly unchanged in urine after parenteral administration. Contrary to this report, the majority of the parenterally administered promethazine methiodide was found in the feces.

This study was undertaken to investigate the tissue distribution and excretion pattern in rats and antimicrobial activity of mepazine methiodide- ^{14}C and promethazine methiodide- ^{14}C . Brain level was low but above the significant level, which indicated a relatively low blood-brain barrier for these compounds. Biliary excretion was revealed to be the major route of elimination of these compounds. These data tend to confirm the belief that the affinity of molecules for the liver cell and consequently the metabolic mechanism of the liver are the decisive factors which determine the biological fate of a compound *in vivo*.

METHOD¹

Synthesis of Mepazine Methiodide (MPZ-MEI) and Promethazine Methiodide (PMZ-MEI)—Mepazine hydrochloride (0.5 g.) was dissolved in water, and the solution was adjusted to pH 10 by adding sodium hydroxide solution. The oily precipitate which occurred was extracted several times with chloroform; the combined chloroform extracts were evaporated *in vacuo* to yield 0.46 g. of a viscous oil. The free mepazine base thus obtained was dissolved in 50 ml. of acetone, and 0.5 ml. of methyl iodide was added. The mixture was left standing for 15 min. Crystals, which appeared in the container, were collected and recrystallized from methanol to yield 0.56 g. (82%) of the product with m.p. 120–122°; λ_{max} . 251 and 255 μ .

Anal.—Calcd. for $\text{C}_{20}\text{H}_{25}\text{IN}_2\text{S}$: C, 53.09; H, 5.53; N, 6.19; I, 28.03; S, 7.08. Found: C, 53.21; H, 5.45; I, 27.92; N, 5.99; S, 7.06.

Similarly, promethazine hydrochloride (0.5 g.) was dissolved in water, adjusted to pH 10, and extracted several times with ether. The combined ether extracts were evaporated *in vacuo* to yield 0.45 g. of an oil. The free base of promethazine was dissolved in 20 ml. of acetone, and 0.3 ml. of methyl iodide in 5 ml. of acetone was added. The mixture was shaken occasionally for 20 min. Then ether was added to the mixture to precipitate the product. The crude product was recrystallized from methanol to yield 0.57 g. (85%) of the quaternary ammonium salt with m.p. 224–225°; λ_{max} . 208 and 252 μ .

Anal.—Calcd. for $\text{C}_{18}\text{H}_{23}\text{IN}_2\text{S}$: C, 50.70; H, 5.40; N, 6.57; S, 7.51. Found: C, 50.80; H, 5.51; N, 6.68; S, 7.58.

Synthesis of Mepazine Methiodide- ^{14}C (MPZ-MEI- ^{14}C) and Promethazine Methiodide- ^{14}C (PMZ-MEI- ^{14}C)—The synthesis of ^{14}C -labeled quaternary ammonium salt of mepazine and promethazine is shown in Scheme I. The free base of mepazine (0.1 g.) obtained as described was dissolved in 5 ml. of acetone, and ^{14}C -methyl iodide (0.25 mc., 8.5×10^{-3} mmole) in 10 ml. of acetone was added. After 15 min., 0.1 g. of unlabeled methyl iodide was added as a carrier. The mixture was shaken for 15 min. and cooled for 10 min. Crystals which appeared in the mixture were collected and recrystallized from methanol. The product, MPZ-MEI- ^{14}C (0.11 g., 82%), had a melting point of 120–122° and specific activity of 0.46 $\mu\text{C}/\text{mg}$.

Scheme I—Synthesis of mepazine methiodide- ^{14}C and promethazine methiodide- ^{14}C

Mixed melting point with an authentic specimen of mepazine methiodide did not show depression (120–122°).

In the same manner, 0.1 g. of the promethazine base obtained as described was dissolved in 5 ml. of acetone, and ^{14}C -methyl iodide (0.25 mc., 8.5×10^{-3} mmole) in 10 ml. of acetone was added. The mixture was shaken for 30 min. and 0.1 g. of unlabeled methyl iodide was added. Then ether was added to the mixture to precipitate the product. The precipitate was collected and recrystallized from ethanol to give 0.12 g. (86%) of the final product, PMZ-MEI- ^{14}C , with a melting point of 224–225° and specific activity of 0.12 $\mu\text{C}/\text{mg}$. The physical properties of this compound were found to be identical with those of authentic promethazine methiodide.

The radiochemical purity of both MPZ-MEI- ^{14}C and PMZ-MEI- ^{14}C was checked by chromatography coupled with a radiochromatogram scanner, Actigraph III. The chromatograms of these compounds showed only one spot with matching R_f values (MPZ-MEI, 0.76; PMZ-MEI, 0.76) and color reactions (MPZ-MEI, pink; PMZ-MEI, purple with 50% sulfuric acid) with the respective parent compound; therefore, both methiodide derivatives were considered to be radiochemically pure.

Tissue-Distribution Studies—For the tissue-distribution studies, each of the preparations (3 mg. of MPZ-MEI- ^{14}C and 10 mg. of PMZ-MEI- ^{14}C) was suspended in sesame oil (1 ml.) and administered intraperitoneally to three rats weighing 250–300 g. The animals were sacrificed at various time intervals of 0.5, 1, 2, 4, and 8 hr. after injection. The liver, kidneys, spleen, heart, lungs, stomach, intestines, muscle, bone, blood, and brain were isolated, rinsed with normal saline solution and briefly dried, and the weights were recorded. A portion of each organ (1 g.) was weighed out, homogenized (except blood and bone) with 5 ml. of ethanol, and centrifuged. This process was repeated three times and the ethanol extracts were combined. An aliquot (2 ml.) was measured in a planchet and dried, and the activity was recorded. The activity remaining in the residue after the methanol extraction was also recorded. An aliquot of blood specimen was measured and dried directly in a planchet, and a portion of the bone (femur, dried at 250° for 2 hr. and ground to a powder) was placed in a planchet to record the activity. All activity recordings were carried out at a constant geometry and corrections were made for the self-absorption. Recoveries of 0.3–0.9 mcg. of added MPZ-MEI- ^{14}C and PMZ-MEI- ^{14}C from tissues were 91 ± 4 and $90 \pm 5\%$, respectively.

Excretion Studies—For the excretion studies, a suspension of MPZ-MEI- ^{14}C (10 mg./kg.) and PMZ-MEI- ^{14}C (25 mg./kg.) in sesame oil was administered intraperitoneally to six rats weighing 280–310 g. The animals were maintained in metabolic cages and were given food and water *ad libitum*. Urine and feces specimens were collected every 12 hr. for the MPZ-MEI- ^{14}C group and every 8

¹ Melting points were taken on a Fisher-Johns apparatus and were corrected. UV absorption spectra were recorded in a Perkin-Elmer model 202 spectrophotometer. Paper chromatograms were developed by an ascending technique in a solvent system, *n*-butanol-ethanol-water (5:2:2). Radiochromatograms were scanned in a radiochromatogram scanner, Actigraph III (Nuclear-Chicago). Albino rats were obtained from Southern Animal Farms, Prattville, Ala. Radioactivity in the tissues was recorded in a G-M counter (Tracerlab, model TGC-2).

Table I—Radioactivity^a Recovered from Urine and Feces of Rats after Intraperitoneal Administration of Mepazine Methiodide-¹⁴C

Time, hr.	Urine, %	Feces, %
12	9.60 ± 1.60	No specimen
24	6.00 ± 0.60	18.20 ± 1.50
36	3.75 ± 0.05	15.90 ± 0.50

hr. for the PMZ-MEI-¹⁴C group of animals. An aliquot (1 ml.) of urine specimens was measured in a planchet and dried, and the activity was recorded in a G-M counter. Feces were powdered and dried. A fraction (1 g.) of the specimen was weighed out and extracted three times with 2-ml. portions of methanol. The combined methanol extracts were evaporated to dryness and the activity of the residue measured.

Metabolic Studies—Two groups of rats (five rats in each group) were administered intraperitoneally with 1 g. each of MPZ-MEI-¹⁴C and PMZ-MEI-¹⁴C, respectively. Pooled urine (20 ml.) from each group of animals was condensed to about 2 ml. An aliquot of 0.5 ml. was placed on Whatman 3 MM paper, and the chromatogram was developed by ascending technique (14) in the solvent system previously mentioned. The chromatogram was scanned in a radiochromatogram scanner, Actigraph III (Nuclear-Chicago), and then sprayed with 50% sulfuric acid to detect nonradioactive metabolites.

Feces collected over a 5-day period from both groups of animals were powdered and extracted successively with ether and methanol in a continuous extraction apparatus. Fatty substances in ether extracts that did not have radioactivity or color reaction with 50% sulfuric acid were discarded. The methanol extracts were combined and reduced to about 1 ml. *in vacuo*. An aliquot of 0.5 ml. was chromatographed and treated as described for the urine specimens.

RESULTS

During the 5-day period, the MPZ-MEI-¹⁴C group of rats excreted a total of about 82% of the administered radioactivity with 24% in the urine and 58% in the feces (Table I). In the PMZ-MEI-¹⁴C group of rats, fecal excretion accounted for about 59% and urinary excretion represented 12% of the administered activity (Table II). In all cases, nearly 70% of the recovered activity in the urine was excreted in the first 24-hr. period. Feces specimens could not be obtained until after the first 24 hr. from the mepazine group and after 40 hr. for the promethazine group of rats. The recordings of the radiochromatogram scanner indicated only one peak on the chromatograms of the urine specimen from both MPZ-MEI-¹⁴C and PMZ-MEI-¹⁴C groups of animals; however, 50% sulfuric acid spray revealed two spots (*R_f* 0.76 and 0.65) on the chromatogram of

MPZ-MEI-¹⁴C urine. The spot with *R_f* 0.76, which appeared to be the major metabolite, was identified to be the unchanged MPZ-MEI-¹⁴C. The second spot with *R_f* 0.65, which represented only a small portion of the urinary metabolites, was tentatively identified to be the *N*-demethylated mepazine. The chromatogram of the PMZ-MEI-¹⁴C urine exhibited only one spot (*R_f* 0.76) after 50% sulfuric acid spray. This spot corresponded to the recorded peak on the radiochromatogram scanner. In contrast to the finding of Hansson and Schmitterlöw (13) on the hydroxyethyl chloride salt of promethazine in mice, fecal excretion was the major route of elimination of both quaternary ammonium salts of mepazine and promethazine in the rats. This difference in the route of excretion appears to be due to the different types of quaternary onium derivative and species of animals used in these studies. This type of excretion was similar to that recorded with trifluoperazine methiodide-¹⁴C (15).

For the activity recording, organs were homogenized and extracted with methanol. Approximately 90% of the activity was extracted in methanol; however, about 10% of the activity appeared to be bound to the protein and was not extracted in methanol.

In the MPZ-MEI-¹⁴C group, the radioactivity in the liver and kidneys was found to prevail over other organs 0.5 hr. after the administration (Table III). Biliary excretion took place rapidly, which was reflected by a sharp rise in the intestinal level after 1 hr.

In the case of PMZ-MEI-¹⁴C, the activity in the kidneys was the highest after 1 hr. (Table IV). Then the activity in the intestines of both MPZ-MEI-¹⁴C and PMZ-MEI-¹⁴C groups reached its peak at 2 and 4 hr. The rapid rate of absorption of these compounds from the injected site was indicated by a rapid decrease of the activity recovered in the abdominal washings.

Blood levels were low but above the detectable level in both groups of animals (Tables III and IV). The brain level of PMZ-MEI-¹⁴C became detectable 1 hr. after the administration, but that of MPZ-MEI-¹⁴C was below the significant level throughout the entire period of the experiment. MPZ-MEI-¹⁴C appeared to have a particular affinity for the bone; activity in the bone started to increase at 0.5 hr. after the administration and reached its peak after 8 hr. (Table III). Since the bone represents an average of 45% of the total body weight of rats, the total activity accumulated in the bone was higher than in most organs except the intestines and liver at 8 hr. A similar finding was recorded with PMZ-MEI-¹⁴C, except that the peak level in the bone was reached at 0.5 hr. In the MPZ-MEI-¹⁴C group, the liver and muscle levels showed a peak at 0.5 hr. and declined rapidly thereafter. Other organs followed a similar pattern, except bone in which the activity continued to accumulate until a peak level was reached at 8 hr. (Table III).

The LD₅₀ of MPZ-MEI-¹⁴C and of PMZ-MEI-¹⁴C on mice was 75 mg./kg. and 95 mg./kg., respectively, which are higher than that of the corresponding parent compounds, mepazine (115 mg./kg.) and promethazine (130 mg./kg.). These compounds displayed a comparable antimicrobial activity to that of trifluoperazine methiodide on *Escherichia coli* and *Staphylococcus aureus* at a concentration of 1 mcg./ml.

CONCLUSION

The intraperitoneally administered quaternary ammonium salts of both mepazine and promethazine were well absorbed by the rats. The majority of the drugs was accumulated in the liver and excreted in the intestines (Tables III and IV). Peak blood level was observed at 2 hr. for MPZ-MEI-¹⁴C and at 1 hr. for PMZ-MEI-¹⁴C. Both compounds showed the highest activity in the intestines 2 hr. after the administration. MPZ-MEI-¹⁴C seemed to have a particular affinity for bones; the activity in the bone of rats started to accumulate at 0.5 hr. and reached its peak level at 8 hr. The total activity in the bone was higher than in most organs except the liver and intestines. The brain level of PMZ-MEI-¹⁴C was above the detectable level at 1 hr.

Urinary excretion of the two compounds was fairly rapid; nearly 70% of the recorded activity in urine was excreted in the first 24-hr.

period. Fecal excretion was the major route of the metabolism of these compounds; 58% of the activity of MPZ-MEI-¹⁴C and 59% of PMZ-MEI-¹⁴C were recovered during the 5-day period. The discrepancy between the results obtained in this study and those of Hansson and Schmitterl w (13) is evidently due to the different quaternary onium derivatives and species of animals used in these studies.

Preparation and *In Vitro* Evaluation of a Sustained-Action Suspension of Dextromethorphan

WILLIAM E. SMITH*, JOHN D. BUEHLER†, and MANFORD J. ROBINSON

Abstract □ A stable suspension having a prolonged *in vitro* release was prepared by synthesizing a poorly water-soluble salt of dextromethorphan, crystallizing this salt as a hydrate, coating the crystals in a solid particle-coating device with a triglyceride fatty acid mixture, and dispersing the coated crystals in an aqueous vehicle. Dramatic differences in physical and release-rate stability were encountered with the same chemical salt when it was coated by different methods and crystallized from different solvent systems.

Keyphrases □ Dextromethorphan—sustained-action suspension □ Sustained action—dextromethorphan suspension □ Suspension—triglyceride fatty acid-coated dextromethorphan salt □ Spray-congealed coating—dextromethorphan crystals □ Release-rate stability—dextromethorphan suspension □ Thermal analysis, differential—dextromethorphan salt

Numerous oral sustained-action products have been marketed in the past 16 years. For most of these products, sustained action has been obtained by coating compressed tablets or large pellets, or by compressing drug in admixture with water-insoluble fillers. Very little data have been presented on the use of coated subsieve-sized particles in the formulation of sustained-action dosage form. Bakan (1) has outlined the use of the coacervation process for preparing sustained-action powders. Several investigators (2-5) have reported on the use of spray-congealing procedures for preparing sustained-action powders.

Coacervation coating and spray-congealing methods have not been widely used to prepare sustained-action products, possibly because these methods require expensive, specialized equipment not commonly utilized by the pharmaceutical industry. A simple, relatively inexpensive, solid particle-coating device (PCD) developed in this laboratory may have greater utility for the preparation of sustained-action dosage forms (6). This report presents an example of subsieve-sized crystals coated in the PCD and use of these coated crystals in the formulation of a stable, liquid, sustained-action suspension of dextromethorphan. It also presents the differences found in physical and release-rate stability which illustrate the importance of certain physical and chemical properties of drug and coating components in the formulation of this dosage form.

EXPERIMENTAL

Materials—A poorly water-soluble form of dextromethorphan was obtained by reacting *d*-methorphan with *o*-(*p*-hydroxybenzoyl) benzoic acid (7). The resulting salt (DMHB) was crystallized from ethanol-chloroform and dimethylformamide-water solvent systems. Mixtures of glyceryl tristearate (GTS)¹ and 12-hydroxystearic

acid (12-HSA)² or GTS and behenic acid (BA)³ were used as coating materials. Chloroform and carbon tetrachloride were used as solvents for these coating materials. The aqueous vehicle for the sustained-action powders contained tragacanth, sorbitol, methylcellulose, sodium cyclamate, saccharin, methyl and propyl paraben, sorbic acid, and imitation black currant flavor.

Equipment and Methodology—Spray-congealed, sustained-action powders were prepared by suspending DMHB crystals in a molten mixture of the coating materials and spraying the resulting suspension in a Niro laboratory model spray drier.⁴ Procedures analogous to those described in previous publications were followed (3, 8). DMHB crystals were coated in the PCD, using solvent solutions of the coating materials and techniques generally in accord with those previously described for use with this apparatus (6). A Fisher subsieve size analyzer⁵ was used to determine the volume-surface mean diameter (d_{vs}) of DMHB, the spray-congealed powders, and the coated DMHB crystals. Coating uniformity and integrity were checked by microscopic examination of a glycerin-H₂O or mineral oil mull of the sustained-action powders. An L & R ultrasonic bath⁶ operating at 73 kc./sec. was used to crystallize the DMHB from the dimethylformamide solvent system. DMHB release was measured using the method described by Souder and Ellenbogen (9), with the exception that the USP intestinal fluid was prefiltered and the undissolved particles containing DMHB were collected on 1.2- μ filter paper.⁷

Figure 2—A typical thermogram for the anhydrous form of DMHB.

RESULTS AND DISCUSSION

The solubility of DMHB in the aqueous vehicle was about 0.9 mg./ml. at 25°. At a concentration below saturation, uncoated DMHB crystals dissolved completely in USP gastric or intestinal fluid in less than 5 min. At the same concentration, the spray-congealed and the coated crystals released DMHB slowly over time in USP gastric and intestinal fluid. Typical release values and the composition of these powders are given in Tables I and II. The d_{50} was about 15 μ for the spray-congealed powders and about 30 μ for crystals coated in the PCD. These results suggested that powders prepared by either process should be suitable for the preparation

Figure 3—A typical thermogram for the "ethanolate" form of DMHB.

Figure 4—A typical thermogram for the hydrate form of DMHB.

of a sustained-action suspension. The particle size was low enough to minimize grittiness and sedimentation propensity. The theoretical density was in a range where the addition of a small amount of sorbitol permitted a match between particle and vehicle density. Only about 10% of the DMHB dose (9.0 mg./ml.) would be needed to saturate the aqueous vehicle, permitting formulation of a suspension with a desirable balance between initial and prolonged release. The *in vitro* release rates of the spray-congealed and the coated DMHB crystals suggested that a suspension of these powders would provide sustained antitussive activity *in vivo*.

An additional requirement for the sustained-action powders is the absence of significant change in chemical potency and release rate over time. This was determined for these formulations by storing them at 37° and under ambient conditions. The results obtained after several months' storage are given in Table III. It is evident that the release rate of the spray-congealed formulation has increased

Table III—Chemical and Release-Rate Stability of DMHB Sustained-Action Powders

markedly, whereas that of the coated crystals has not. Microscopic examination of the spray-congealed powders suggested some change in the crystal form in the GTS-12-HSA matrix. This possibility was confirmed by X-ray diffraction which showed that spray-congealed GTS solidified in the polymorphic α -form. This form is unstable and on storage transformed into the stable β -modification. In contrast, GTS could be obtained in the β -form by spraying from chloroform or carbon tetrachloride. Since there was no other discernible physical change in these powders, it is considered likely that the release-rate increase of the spray-congealed powders was related to polymorphic transition of the GTS. In any event, the changes in release rate of the spray-congealed formulation indicated that only the DMHB crystals coated in the PCD would be acceptable for use in formulating a sustained-action suspension.

DMHB crystallized from the chloroform-alcohol solvent system had a d_{50} of less than 20 μ , and the shape of the individual particles approached sphericity. The particle size and shape were considered optimal for formulation. However, when these crystals were coated and the resultant powder dispersed in the aqueous vehicle, DMHB underwent marked crystal growth. The effect of this crystal growth on coating integrity is shown in Fig. 1 and the resultant increase in release rate is given in Table IV. Chemical analysis of DMHB indicated that, prior to coating, the crystals were either anhydrous or contained varying amounts of alcohol. In contrast, crystals taken from the aqueous suspension contained 3.5–3.8% H₂O. Typical thermograms obtained by differential thermal analysis for the anhydrate, “ethanolate,” and hydrate are given in Figs. 2–4. These results indicate that DMHB crystallized from the chloroform-alcohol solvent system as an “ethanolate” of varying composition (possibly unstable) and, in some instances, was converted to the anhydrate by drying at high temperatures. In aqueous media, these more soluble forms recrystallized in the form of the monohydrate.

It was found that crystals of the monohydrate could be obtained by use of a dimethylformamide-water solvent system, but these crystals were excessively large and acicular in shape. Experimentation with various crystallization techniques established the fact that crystals of a desirable size and shape could be obtained by rapid nucleation through the use of insonation and by slowing crystal growth by careful temperature control. Photomicrographs of the DMHB monohydrate crystals obtained by this procedure appear in Fig. 5. The release rates for an aqueous suspension of coated DMHB monohydrate crystals are listed in Table V. Also given in this table are the release-rate values after 6 months' storage at 37° and 1 year's storage at ambient conditions. Photomicrographs of coated crystals alone and in an aqueous dispersion after 1 year's storage at ambient conditions appear in Figs. 6 and 7. No evidence of change in appearance, potency, or release rate was found for this formulation during this storage time.

Figure 5—DMHB crystals obtained from a dimethylformamide-water solvent system (magnification: 0-1 equals 63.9 μ).

Figure 6—DMHB crystals coated with a mixture of GTS and BA (magnification: 0-1 equals 63.9 μ).

Although this formulation was not tested *in vivo* for antitussive activity, the *in vitro* release values suggest that this preparation would release a desirable amount of dextromethorphan for immediate absorption and the remainder would be released for absorption slowly over time.

In this report, dramatically different behavior has been described for the same chemical salt coated by two different methods and crystallized from two different solvent systems. It is likely that the implications of these observations are not only applicable to the formulation of liquid sustained-release dosage forms but also should be considered in the formulation of other dosage forms. This study

Correlation and Prediction of Rates of Alkaline Hydrolysis of Some Benzoate Esters

RICHARD J. WASHKUHN*, SANGSOM REUTRAKUL, and JOSEPH R. ROBINSON

Abstract □ Rate constants have been determined for the alkaline hydrolysis of 36 *p*-substituted alkyl benzoates, and it is shown that these esters can be characterized on the basis of their rates of alkaline hydrolysis. Application of linear free-energy relationships allows calculation of alkaline hydrolysis rate constants for alkyl or aromatic *p*-substituted benzoate esters not included in this study. It is demonstrated that rates can be predicted for esters whether substituent variation is in the acyl or alkyl portion of the molecule by using the conventional Hammett treatment and the more recent alcohol dissociation model.

Keyphrases □ Benzoate esters—alkaline hydrolysis rates □ Alkaline hydrolysis rates—benzoate ester identification □ Linear free-energy relationships—alkaline hydrolysis rate prediction □ UV spectrophotometry—reaction monitoring

Earlier papers in this series (1-4) demonstrated that precise kinetic measurements can be a powerful tool in the identification of organic compounds. In addition, the large number of rate constants generated in these studies, under constant conditions, provides the necessary data for structure-reactivity relationships, mechanistic interpretations, *etc.* The classes of organic compounds previously considered were: alcohols [rates

of alkaline hydrolysis of their 3,5-dinitrobenzoate esters (1)], sugars [rates of oxime formation (2)], aliphatic amines [rates of cinnamoylation (3)], and aliphatic esters [rates of alkaline hydrolysis (4)]. The present study demonstrates that rates of alkaline hydrolysis can be used to identify aromatic esters and presents linear free-energy relationships to predict rates of alkaline hydrolysis for esters not included in the study.

EXPERIMENTAL

Chemicals—Fisher certified acetonitrile was used without further purification after it was established that it was spectrally pure (from 220-300 $m\mu$) and that it had no anomalous effect on the rate of alkaline hydrolysis. All other chemicals were either analytical or reagent grade. Water was double distilled from acid permanganate in an all-glass distillation apparatus.

All esters were prepared according to procedures outlined by Shriner *et al.* (5) with slight modification. The acyl chloride was reacted with the appropriate alcohol by heating under reflux for 30 min. The reaction mixture was then taken up in chloroform and extracted with 5% Na_2CO_3 followed by water and finally dried with MgSO_4 . After removing the chloroform under vacuum, the ester remaining was purified by repeated recrystallization from water or from the alcohol representing the alkyl portion of the ester or, in the case of liquids, by vacuum distillation.

^a In 50% v/v acetonitrile–0.02 *M* phosphate buffer at 25°. ^b Standard deviation.

Apparatus—pH Measurements and adjustments were made on a Corning model 12 pH meter with an expanded scale using a Beckman type E3 wide-range glass electrode. The pH meter and electrode system was standardized against a phosphate buffer as described by Bates (6).

Water bath temperatures were maintained to 0.1° with Sargent Thermonitor electronic relays. The progress of the reactions was followed on either a Cary model 11 or 14 recording spectrophotometer with thermostated cell compartments.

PROCEDURE

Solvent System—Fifty milliliters of acetonitrile was added to an equal volume of a 0.02 *M* dibasic phosphate buffer, and the resulting solution was brought to the appropriate pH with a few drops of concentrated NaOH solution. The acetonitrile–phosphate buffer solution gives a volume somewhat less than 100 ml. This solution was used for all kinetic determinations.

Continuous Spectrophotometric Procedure—For reactions that had sufficiently rapid rates so that they could be followed directly in the spectrophotometer, the following procedure was used. After equilibrating the solvent system to 25°, 3 ml. of solvent was thoroughly mixed with 50 μ l. of a 1×10^{-2} *M* ester in acetonitrile solution in a 1-cm. photometer cell. The reaction progress was monitored by following the disappearance of ester at an appropriate wavelength, benzoates at 242 $m\mu$, *p*-methyl benzoates at 250 $m\mu$, *p*-chlorobenzoates at 254 $m\mu$, *p*-fluorobenzoates at 244 $m\mu$, *p*-cyanobenzoates at 250 $m\mu$, and by the appearance of acid anion at 290 $m\mu$ in the *p*-nitrobenzoate case.

Discontinuous Spectrophotometric Procedure—For esters with inconveniently long rates of reaction, the following sampling pro-

cedure was used. One hundred milliliters of the buffer solution was prepared and brought to the appropriate pH. Two milliliters of 1×10^{-2} *M* ester in acetonitrile solution was added to the buffer solution, and the resulting mixture was placed in 5-ml. volumetric flasks which were stored in a 25° water bath. At appropriate time intervals the contents of two of the volumetric flasks were used to determine the concentration of remaining ester or acid anion. This sampling procedure was necessary due to the volatility of acetonitrile.

Data Treatment—All experiments were carried out with a large excess of hydroxide ion and thus pseudo-first-order kinetics were observed. Pseudo-first-order rate constants were obtained in the usual manner and were converted to second-order rate constants by dividing by the hydroxide-ion activity.

RESULTS

Second-order rate constants were calculated for the various esters and are presented, together with standard deviations, in Table I. At least two rate determinations were made for each ester, and these were carried out at more than one pH value to ensure that the reactions were first-order in hydroxide ion. The pH range employed for these esters in this solvent system was from 12 to 13.4. Above pH 13.4, phosphate precipitates; below pH 12, the rates are inconveniently slow. The buffer capacity of the solvent system, for concentrations of ester employed in this study, was satisfactory from pH 11 to 13.4.

Correlations of structure and reactivity were made using the Hammett relationship (7)

$$\log \frac{k}{k_0} = \sigma \rho \quad (\text{Eq. 1})$$

and a modified form of the Hammett equation (8)

$$\log \frac{k}{k_0} = \phi M \quad (\text{Eq. 2})$$

For variation in the acyl portion of the ester molecule, substituent constants (σ values) were obtained from the literature (9) and were plotted against log rate constants.¹ For substituent variation in the alkyl portion of the ester molecule, ϕ values (8) were plotted against log rate constants. Representative plots for both of these treatments are shown in Figs. 1 and 2. Slopes, standard deviations, and correla-

Figure 1—Plot of the second-order rate constants for alkaline hydrolysis of alkyl-substituted benzoate esters against ϕ values. Key: \circ , *p*-nitro benzoates; Δ , *p*-fluoro benzoates, and \square , benzoates.

¹ The substituent constant for the *p*-fluoro group is reported to be 0.06 (9) or 0.17 (10). Although neither value gave good correlations, the 0.06 σ value was used in this study.

Figure 2—Plot of the second-order rate constants for alkaline hydrolysis of *p*-substituted alkyl benzoate esters against Hammett's polar substituent constants. Key: ○, methyl benzoate esters; △, *n*-propyl benzoate esters, and □, isopropyl benzoate esters.

tion coefficients for these plots and the remaining esters are shown in Table II.

DISCUSSION

It is apparent from Table I that the rate of alkaline hydrolysis is a useful way to identify these aromatic esters. The ratio of the largest to the smallest rate constants for these 36 esters is about 1600; within a given series the constants are sufficiently different so that any ester is easily differentiated from a similar member. It is also clear from the reported rates that for some esters the rates are prohibitively slow, and this is obviously undesirable. However, sufficient rate data are presented to calculate the rates for a large number of esters. For many of these esters, this procedure will be a rapid, sensitive method which will be useful for characterization.

For esters not included in this study, it is possible to calculate the rate of alkaline hydrolysis under the specific conditions of this study (solvent composition and temperature) by employing linear free-energy relationships. For substituent variation in the acyl component of the ester molecule, the Hammett equation has had great success in correlating rates and structural modifications. Table II, Part 2, shows the excellent results that are obtained for the ester data generated in this study, using this procedure. Note that all of the correlation coefficients are better than 0.994, which is excellent. For changes in the alkyl portion of the molecule, the recently reported ρ values can be correlated with reaction rates. The results of this treatment are shown in Table II, Part 1. The correlation coefficients for this treatment are also excellent. Using both the Hammett relationship, which uses the dissociation of aromatic acids as the model process, and the ϕ values, which are based on the dissociation of alcohols as the model process, it is possible to predict the rate of alkaline hydrolysis for any ester where the σ value (the acyl component) and ϕ value (the alkyl component) have been determined.

Table II—Correlation of Relative Reaction Rates ($\log k/k_0$) with Substituent Constants for Some Aromatic Esters

Ester Series	M^b	SD^c	R^d
Part 1 Substituent Variations in the Alkyl Component^a			
<i>p</i> -Methyl benzoates	0.772	0.030	0.997
Benzoates	0.816	0.023	0.999
<i>p</i> -Fluoro benzoates	0.832	0.039	0.997
<i>p</i> -Chloro benzoates	0.776	0.051	0.994
<i>p</i> -Cyano benzoates	0.771	0.046	0.995
<i>p</i> -Nitro benzoates	0.734	0.018	0.999
Part 2 Substituent Variations in the Acyl Component^e			
Ester Series	ρ^f	SD^c	R^d
Methyl benzoates	2.138	0.079	0.996
Ethyl benzoates	2.213	0.093	0.995
Propyl benzoates	2.184	0.049	0.999
Isopropyl benzoates	2.233	0.061	0.998
Butyl benzoates	2.158	0.077	0.996
Isobutyl benzoates	2.243	0.055	0.998

^a The alkyl substituents for all series in this group were methyl, ethyl, *n*-propyl, isopropyl, *n*-butyl, and isobutyl. ^b M is the least-squares fitted slope of a \log (rate constant) vs. ϕ plot. ^c Standard deviation of points from the line. ^d Correlation coefficient for the line. ^e The acyl substituents for all series in this group were *p*-methyl, *p*-hydrogen, *p*-fluoro, *p*-chloro, *p*-cyano, and *p*-nitro. ^f ρ is the least-squares fitted slope of a \log (rate constant) vs. σ plot.

This is accomplished by simple extrapolation or interpolation of the log rate constant versus substituent constant plot.

Other procedures are available to predict rates of hydrolysis for esters when structure variations are made in both the acyl and alkyl portions of the ester molecule (11). These procedures are empirical in nature and have undesirable features associated with them. A thorough discussion of the two procedures, as well as the mechanistic significance of the slopes generated in this study, will be the subject of another publication.

Gas Chromatographic Method for Determination of Tolbutamide and Chlorpropamide

KHALID SABIH and KHAWLA SABIH

Abstract □ Gas-liquid chromatographic methods for the measurement of tolbutamide and chlorpropamide in blood and urine and in pharmaceutical preparations have been developed. In these procedures the drugs were extracted from acidified plasma or urine with chloroform and converted to the corresponding methyl derivative by treatment with dimethylsulfate in the presence of base. The methyl derivatives of these drugs were analyzed on DC-200 coated on diatomaceous earth (Gas Chrom Q). The method has considerable specificity and sensitivity and can measure as little as 0.1 mcg. of these drugs.

Keyphrases □ Tolbutamide in biological fluids—determination □ Chlorpropamide in biological fluids—determination □ Column chromatography—separation, purification □ TLC—identity □ IR spectrophotometry—identity □ GLC—analysis

Tolbutamide (I) and chlorpropamide (II) are sulfonylurea derivatives and are widely used as oral hypoglycemic drugs in the treatment of diabetes mellitus. Few methods are available for the determination of the concentration of these and related drugs in blood or other biological fluids or materials.

Mesnard and Crockett (1) described a method for the determination of sulfonylurea derivatives in urine. This method involved hydrolysis of these drugs in the presence of a base to obtain the amine, which in turn was treated with a solution of picric acid to produce a colored material. This color was compared with that obtained with a standard. A colorimetric method was described by Spingler (2), which also involved the hydrolysis of tolbutamide to butyl amine followed by formation of a yellow color by reacting butyl amine with dinitrofluorobenzene. Leal (3) precipitated tolbutamide as its silver salt and identified it by its melting point. Kalinowski and Korzyliski (4) and Voicu (5) described a mercuric coulometric method for tolbutamide determination. A photometric method has been described (6) for the determination of tolbutamide in pharmaceuticals. This method involved treatment of a solution of the drug in dimethylformamide (DMF) with a solution of ascorbic acid in DMF, and absorbance was measured at 530 mμ. Thin-layer chromatographic methods were also described recently (7, 8) using silica gel G and GF. A UV method was also described (9) for the determination of several sulfonylurea derivatives. Some of these methods are not very specific and some are not very sensitive.

The difference in absorption and metabolism rates of these drugs and their success as oral antidiabetics has

Figure 1—Typical chromatogram of methylated tolbutamide. The curve represents a 5-μl. injection of 40 mcg. of the drug in 100 μl. chloroform.

stimulated the search for a gas chromatographic method to determine these drugs in biological material and in pharmaceutical preparations. This report describes a gas chromatographic method for the determination of tolbutamide and chlorpropamide in blood and urine and in pharmaceutical preparations. This method involves the conversion of these drugs to their methyl derivatives by treatment of their respective sodium or potassium salt with dimethylsulfate.

EXPERIMENTAL

Reagents—Tolbutamide (The Upjohn Co., Kalamazoo, Mich.); chlorpropamide (Chas. Pfizer and Co., Inc., New York, N. Y.); and dimethyl sulfate (Matheson, Coleman & Bell, Norwood, Ohio) were used. Chloroform redistilled analytical reagent, methanol analytical reagent, and heptane redistilled were used. Methanolic solution of potassium carbonate was made by mixing 1 ml. of 5–10% aqueous solution of K₂CO₃ with 9 ml. of MeOH. Acetate buffer 0.2 M, pH 5.6, was made by mixing 4.8 ml. of AcOH solution (0.2 M; 11.55 ml. in 1000 ml. H₂O) and 45.2 ml. of NaOAc solution (0.2 M; 16.4 g. in 1000 ml. H₂O), and the mixture was diluted with water to 1000 ml.

Figure 2—Typical chromatogram of methylated chlorpropamide. The curve represents a 5- μ l. injection of 28 mcg. of the drug in 100 μ l. chloroform.

Apparatus—An F and M model 5755 B gas chromatograph equipped with a flame-ionization detector was used for chromatography. The column was 1.37 m. (4.5 ft.), 0.33 cm. (0.125 in.) stainless steel tubing packed with diatomaceous earth (Gas-Chrom Q), 80–100 mesh, coated with 5% DC-200. The operating temperatures used for tolbutamide were: column, 205–210°; detector, 320°; and injection port, 330°. Helium was used as the carrier gas with a flow rate of 50 ml./min. For analysis of chlorpropamide, column temperature was 180° and the helium flow rate was 40 ml./min.

Procedure—Standards—A stock solution of 5 mg. of each sulfonylurea drug in 10 ml. chloroform was prepared. Aliquots containing 0, 10, 20, 40, 60, 80, and 100 mcg. were placed in separate centrifuge tubes; the solvent was removed under a stream of air, and each residue was dissolved in 1 ml. of methanolic potassium carbonate followed by 0.1 ml. of dimethyl sulfate. The resulting mixtures were heated on a water bath at 70° for 5 min. Following removal of the methanol at that temperature by a steady stream of air, 1 ml. 0.2 M acetate buffer, pH 5.6, was added and followed by 5 ml. of heptane. Extraction was aided by the use of a vortex mixer. After centrifugation, 4 ml. of the heptane extract from each tube was transferred to a separate 5-ml. flask from which the heptane was evaporated with a stream of air. The resulting residues were dissolved in 100 μ l. of chloroform. One- to five-microliter samples were injected onto the column under the conditions cited above. Figures 1 and 2 show typical chromatograms of tolbutamide and chlorpropamide, respectively.

Pharmaceutical Preparations—One tablet of tolbutamide or chlorpropamide was pulverized in a mortar to a fine powder and triturated with 50 ml. ethanol. The mixture was then filtered and the filtrate transferred to a 100-ml. volumetric flask and made to volume with ethanol. Aliquots were placed in separate centrifuge tubes and the ethanol was removed under a stream of air. The residues were then converted to the methyl derivatives and chromatographed as described.

Biological System—A stock solution containing 5 mg. tol-

butamide or 5 mg. chlorpropamide in 10 ml. 5% aqueous K_2CO_3 was prepared. The proper volume of either solution was added to plasma or urine in amounts of 0, 2.5, 5, 10, 20, 30, and 40 mcg./ml. Two milliliters of the resulting samples were acidified with 1 ml. of saturated solution of NaH_2PO_4 and then extracted with 10 ml. of chloroform by shaking on a vortex mixer for 2 min. The phases were separated by centrifugation and the aqueous layer was removed by aspiration. Five milliliters of the chloroform extracts was transferred to centrifuge tubes and the solvent was removed under a stream of air. Each residue was treated with Me_2SO_4 and chromatographed as described. One-milliliter plasma samples containing either of the sulfonylurea drugs were acidified with 1 ml. of saturated solution of NaH_2PO_4 and extracted with five volumes of chloroform by shaking carefully for 2 min. Layers were separated by centrifugation (2000 r.p.m. for 5–10 min.); emulsions were broken by stirring with a wooden stick and recentrifuged for another 5–10 min. The aqueous layer was aspirated and four-fifths of the chloroform layer was placed in a second centrifuge tube. Solvent was removed under a stream of air, and the sulfonylurea residues were converted to their respective methyl derivatives and chromatographed as described.

Identification of the Methyl Derivative of Tolbutamide—A solution of 1.0 g. tolbutamide in 30 ml. of 10% water-methanol was placed in a three-necked 150-ml. flask fitted with a reflux condenser and a magnetic stirrer. To this solution was added 2.0 g. of K_2CO_3 followed by 20 ml. of dimethyl sulfate. The reaction was allowed to proceed at 70° by heating on a water bath with stirring for 15 min. The reaction mixture was then cooled and extracted three times with 100-ml. portions of heptane. Removal of heptane under reduced pressure gave 0.9 g. of a semisolid material. The original reaction mixture was then treated with 20 ml. of 0.2 M acetate buffer, pH 5.6, and extracted twice with 100-ml. portions of heptane. Removal of heptane under reduced pressure yielded 0.2 g. of a semisolid material. TLC of both extracts using silica gel and chloroform as the moving phase showed only one uniform spot with an R_f value of 0.55. In comparison, tolbutamide did not move under these conditions. The product was purified by column chromatography using silica gel (Merck) and eluted with chloroform. Removal of chloroform under pressure gave 1.0 g. of a colorless oil, which solidified on standing overnight in a cool place, m.p. 33°.

was performed by column chromatography using silica gel (Merck) and eluted with chloroform. Removal of the chloroform under reduced pressure gave a colorless oily liquid which did not solidify on standing.

Anal.—Calcd. for $C_{11}H_{15}ClN_2O_3S$: C, 45.44; H, 5.13; N, 9.67; Found: C, 45.89; H, 5.39; N, 9.32.

RESULTS

Attempts to chromatograph tolbutamide and chlorpropamide on four different stationary phases of varying selectivity were not successful. In both cases, two peaks were obtained. The first peak eluted very close to the solvent front and the second peak showed a marked tailing under different temperature and flow-rate settings.

The methyl derivatives of tolbutamide and chlorpropamide were obtained in quantitative yield and were identified by microanalysis and IR spectroscopy. These derivatives were found to be *N*-methyl tolbutamide and *N*-methyl chlorpropamide.

By utilizing conditions cited in the method, the retention time of methylated tolbutamide was 2.0 min. and that of methylated chlorpropamide was 3.8 min. Chromatograms of control samples did not contain any peak with the retention time of the methyl derivative of tolbutamide or chlorpropamide. The retention times of pure methyl derivatives and that prepared from extracted blood or urine were identical. Chromatograms of extracts of control plasma did not contain any peaks with the retention time of either methyl derivative. Addition of increasing amounts of methylated derivatives to extracts of plasma containing the drugs produced an increase in the respective peak height having the retention time of the standard. The relationship between peak height and quantity of the drugs is linear between 1–50 mcg. in both cases as shown in Fig. 3.

To test the reproducibility of the gas chromatographic method, three samples of plasma containing known amounts of the sulfonyl ureas were made. Each sample was divided into four equal parts; the drugs were extracted from each part and converted to the methyl derivatives as described in the method. Gas chromatography of these samples gave the same peak height in each case with a standard error of ± 0.52 .

In a separate experiment to test the adequacy of the extraction procedure, varying amounts of the drugs were added to plasma samples and the chromatograms of these samples were compared with that of a standard. The recovery ranged between 96–102% of added tolbutamide and 94–100% of added chlorpropamide as shown in Tables I and II, respectively. The extraction method is also applicable to other biological fluids such as urine.

Table II—Recovery of Chlorpropamide from Plasma

Amount Added, mcg.	Amount Recovered, mcg.	Recovery, %
5	4.7	94
10	9.7	97
20	20.0	100
30	28.8	96
40	39.6	94

The methylation procedure of these sulfonylurea drugs was also tested for its completion. Known amounts of these drugs were added to plasma or water and extracted and methylated. The amount methylated was then determined from a standard curve obtained with a pure methylated drug. This showed about 95–100% methylation.

Other commonly used drugs, *e.g.*, phenobarbital, pentobarbital, glutethimide, and diphenylhydantoin, showed no interfering peaks in the same region as methylated tolbutamide or chlorpropamide. These drugs can also be methylated and analyzed using the procedure described in the *Experimental* section.

The amounts of tolbutamide and chlorpropamide were determined using the external standard technique.

DISCUSSION

The presence of two peaks in the chromatograms of unchanged tolbutamide can be attributed to the decomposition of the drug on the column. Methylation of tolbutamide stabilized the molecule and prevented this decomposition. Furthermore, the methylation process was advantageous because it shortened the retention time and reduced the possibility of loss of tolbutamide on the column during chromatography. In the case of chlorpropamide, the molecule decomposed on the column to give a chromatogram of two peaks similar to that of tolbutamide. Methylation of chlorpropamide produced only one symmetrical peak with fairly short retention time.

The IR spectrum of tolbutamide shows, among other bands, a strong absorption band at $1710\text{--}1690\text{ cm}^{-1}$, which is due to the carbonyl ($C=O$) stretching vibrations. The IR spectrum of methylated tolbutamide shows some differences due to the introduction of the methyl group. However, the spectrum again shows a strong absorption band at $1710\text{--}1690\text{ cm}^{-1}$, which again may be attributed to the presence of a carbonyl group in the molecule. This indicated that the methyl group was introduced on the nitrogen atom rather than the oxygen atom to give the *N*-methyl derivative.

The GLC method described is accurate, sensitive, and specific for the measurements of tolbutamide and chlorpropamide concentration in blood and other biological fluids and can be used in clinical laboratories. The method is also applicable to determine the amount of these drugs in pharmaceutical preparations such as tablets. The method requires approximately 2 hr. for analysis of several samples and the gas chromatographic step takes less than 5 min.

Various Species of Sulfathiazole Form I

LATIF S. SHENOUDA

Abstract □ Sulfathiazole crystallized from ethanol, a mixture of ethanol and benzene, a mixture of chloroform and acetone, isopropyl alcohol, or 10% and 1% ammonia solutions gives Form I, which consists of varying proportions of a melting species and another species which undergoes solid-solid transition. This was confirmed both microscopically and by differential scanning calorimetry. Crimping of the samples crystallized from ammonia solutions causes the separation of the peaks representing these species and gives a thermogram identical to that obtained from samples crystallized from alcohol. Grinding appears to destroy the melting species and to have a significant effect on the transition temperature but not on the heat of transition. The calculated average heat of transition, for ground samples crystallized from both ammonia solutions and from alcohol, is 1652 ± 56 cal./mole. IR spectra and X-ray diffraction patterns of the powder did not show any major differences between samples crystallized from either solvent.

Keyphrases □ Sulfathiazole species—Form I □ Grinding, crimping effect—sulfathiazole crystals □ Melting range—sulfathiazole Form I crystals □ Differential scanning calorimetry—identity □ IR spectrophotometry—identity □ X-ray diffractometry—identity

There are conflicting reports as to whether sulfathiazole exists in two or three crystalline forms. Grove and Keenan (1) reported two forms: Forms I and II for which melting points are $175\text{--}176^\circ$ and $201\text{--}202.5^\circ$, respectively. Milosovich (2), using the solubility method, stated that the transition temperature of Form I is $94.5 \pm 2.7^\circ$ with a heat of transition of 1744 cal./mole. On the other hand, Guillory (3), using differential thermal analysis, reported a transition temperature of 161° and a heat of transition of 1420 ± 40 cal./mole for Form I. Three crystalline forms of sulfathiazole were reported by Miyazaki (4) and Mesley and Houghton (5). These forms are symbolized as α or A (I), β or B (II), γ and a third form α' or C. These investigators claimed that the third form of sulfathiazole can only be prepared by crystallization from dilute ammonia solution. Form I can be prepared by crystallization from warm alcohol or a mixture of chloroform and acetone, and Form II by crystallization from *n*-propanol at 80° , *sec*-butanol, or by heating Form I at 180° .

Since sulfathiazole has been used extensively as a model drug in research work in recent years, it was found necessary to conduct a further investigation of the sulfathiazole polymorphic system to see whether or not this drug exists in more than two crystalline polymorphs.

EXPERIMENTAL

Materials and Apparatus—Sulfathiazole NF (Mallinckrodt) was used in this investigation. Group I solvents consists of ethanol USP, a mixture of benzene and ethanol (3:1), a mixture of chloroform and acetone (1:3), isopropyl alcohol, and 1% and 10% am-

monia solutions. Group II consists of *n*-propanol and *sec*-butanol. Unless otherwise specified, all these solvents were reagent grade.

A DSC-1B (Perkin-Elmer) was employed. Nitrogen, as an effluent gas, was used at a rate of 20 ml./min. Indium and tin were used for calibration of the temperature scale. In this investigation, the former was used as the main calibrant for calculating the heat of fusions and transitions since its heat of fusion is known to be 6.8 cal./g. (3, 6). Since a known weight of indium used in this investigation was supplied by the manufacturer, it was found necessary to check it against a substance whose heat of fusion is well documented. Form II of silver nitrate was used for this purpose. The heat of fusion of Form II of this compound is 2760 cal./mole (7). Areas under the peaks were measured with a planimeter. IR spectra were obtained using both KBr disks and mineral oil mulls. X-ray diffraction patterns, using 200-mesh powder, were obtained using a Siemens X-ray diffraction instrument.² Microscopic examinations were done employing a Zeiss polarizing research microscope equipped with a Kofler hot stage.

² The patterns were obtained through the courtesy of Dr. S. C. Mehta at the University of Michigan College of Pharmacy, Ann Arbor, Mich.

¹ Nomenclature used by other investigators.

Figure 1—Thermograms of samples crystallized from alcohol in an ice bath. Key: a, uncrimped and unground; b, crimped and unground; c, ground and crimped; scan speed 40°/min. Peaks appearing below 200° represent the species of Form I and the peak appearing above this temperature represents Form II.

Preparation of Samples—Sulfathiazole was crystallized from a saturated solution in the various solvents. Sulfathiazole was crystallized from 10% ammonia solution on a watch glass. On the other hand, crystallization from 1% ammonia solution was performed in a beaker without stirring; the scaly crystals were filtered and dried at 100° for 30 min. under vacuum and scanned immediately.

Differential Scanning Calorimetry (DSC)—Samples weighing 1–6 mg. were used. A semimicro balance with a sensitivity of 0.01 mg. was used to weigh all samples. A scanning speed of 40°/min. was employed throughout this study, because a scanning speed of 10°/min. gave broad and irregular transition peaks. Using indium as the calibrant, the calculated heat of fusion of Form II of silver nitrate is 2812 ± 46 cal. mole. This value is comparable to the value reported (7).

Since sulfathiazole does not sublime on heating, it was thought at first to run the crystalline material prepared from different solvents without subjecting them to any stress or strain, *i.e.*, without crimping or grinding. The results obtained were compared with experiments performed on the crimped unground and crimped ground samples. Grinding was done using a mortar and pestle.

RESULTS AND DISCUSSION

Microscopic examination of sulfathiazole crystallized from Group I solvents revealed that these samples consist of two species in various proportions. One species undergoes solid–solid transition in a temperature range of 150–166°, depending on the solvent of crystallization. The second species melts between 170–176° with immediate partial crystallization. On further heating of the samples, complete melting was observed at 198–203°. The latter temperature range is the same melting range for sulfathiazole Form II crystallized from Group II solvents or from warm alcohol and heated to 180°. Crystallization of sulfathiazole from the solvents which yield Form I was done on a glass slide. On microscopic examination of the crystals on a hot stage, it was observed that complete melting occurred at 170–176° without crystallization in all cases. The absence of crystallization from the melt is due to the absence of seed material, as was demonstrated when the two species were present.

Since the two species of sulfathiazole Form I are present regardless of solvent system used and since sulfathiazole crystallized from am-

monia presents the point of controversy, it was decided to limit quantitative determination to crystals obtained from 10% and 1% ammonia solutions and to those crystallized from hot alcohol in an ice bath. The DSC results on those samples, subjected to various treatments, are summarized in Table I and their thermograms are shown in Figs. 1–3. Examination of the table and various thermograms in the figures shows that in the region of 140–180°, there are one or two peaks present, depending on the solvent of crystallization and the treatment of the sample. For example, the thermogram for sulfathiazole crystallized from alcohol consists of two peaks regardless of crimping. The first peak represents solid–solid transition and the second represents the melting species. Under the present conditions, *i.e.*, at a scanning speed of 40°/min., it was difficult to calculate the areas under the peak of each species. Slow scanning speed of 10°/min. caused the separation of two peaks, but the peaks were broad and very hard to differentiate from the base line. The total area under the two peaks was measured for a scanning rate of 40°/min., and ΔH was calculated. A large value of ΔH with a very large standard deviation was obtained for both crimped and uncrimped, unground samples. This is an indication of the nonuniformity of samples or, in other words, the samples taken consist of various proportions of the melting species which contribute to this great variation. However, after grinding and crimping the sample, it was found that the peak of the melting species completely disappeared, and only one peak was observed. The calculated heat of transition was found to be 1637 ± 83 cal./mole. On the other hand, uncrimped and unground samples crystallized from ammonia gave one peak on scanning. An exotherm was observed in samples crystallized from 1% ammonia and, in some instances, in samples crystallized from 10% ammonia, indicating some crystallization of the melt. This was confirmed by the microscopic examination, as well as by visual observation in the open pan while scanning. The exotherm was not noticed when the crystallized sample was run after a few days.

After crimping the unground sample, two peaks were obtained similar to those obtained in the case of sulfathiazole crystallized from alcohol. The appearance of two peaks, the first representing solid–solid transition and the second representing melting, may be due to crimping. In the case of samples crystallized from ammonia solutions, crimping caused the separation of the two peaks repre-

Figure 2—Thermograms of samples crystallized from 10% ammonia solution in a crystallizing dish. Key: a, uncrimped and unground; b, crimped and unground; c, ground and crimped; scan speed 40°/min. Peaks appearing below 200° represent the species of Form I and the peak appearing above this temperature represents Form II

Figure 3—Thermograms of samples crystallized from 1% ammonia solution in a beaker without stirring. Key: a, uncrimped and unground; b, crimped and unground; c, ground and crimped; scan speed 40°/min. Peaks appearing below 200° represent the species of Form I and the peak appearing above this temperature represents Form II.

senting the two species. Upon grinding and crimping, the system was apparently stabilized and only one peak was observed. The calculated heats of transition are 1647 ± 49 and 1673 ± 22 cal./mole for both sulfathiazole crystallized from 10% and 1% ammonia, respectively. These values are not significantly different, within experimental errors, from the value obtained when alcohol was used as a crystallizing medium. The values for ΔH obtained from 18 runs gave a calculated average of 1652 ± 56 cal./mole. It appears, therefore, that crimping and grinding have an effect on the thermal behavior of sulfathiazole Form I. Furthermore, grinding caused a shift in transition temperature of about 15 and 20° in the case of sulfathiazole crystallized from ammonia and alcohol, respectively, although the calculated heats of transition are almost the same. This shift in transition temperatures might be due to differences in particle size and change in thermal conductivity of the sample as reported by Guillory (3) and Moustafa and Carless (8). The findings reported here are not different from those reported recently (8). In their report, Moustafa and Carless stated that in no case was melting observed below 200°. The present results, both microscopically and calorimetrically, suggest the presence of a melting species and another that undergoes solid-solid transition. This phenomenon was observed in all cases where Form I was produced and not only in the case of sulfathiazole crystallized from 95% alcohol as reported (8). The same authors reported that vibration milling of Form I crystallized from 95% ethanol resulted in the transition temperature being lowered by 5°. This finding is in agreement with the present observa-

tion, although a more dramatic effect was noticed with grinding. Mesley and Houghton (5) reported differences in the IR spectra of sulfathiazole crystallized from dilute ammonia and from alcohol, although no spectra were presented in their report. In the present study, there were no major differences in either IR spectra or X-ray diffraction patterns of both samples when those patterns were compared with already published ones (8, 9). Since grinding is a prerequisite for the preparation of samples tested by these techniques, and since it has been shown to destroy the melting species in this study, differences in the mentioned patterns were not observed.

It is rather misleading to call the melting species of sulfathiazole a third physical form, since the techniques employed in this investigation did not confirm its presence as a separate and pure entity with great differences in physical characteristics. However, the present results do not preclude the existence of a third form of sulfathiazole. It is probable that a third form does exist, although highly unstable on grinding, and this is probably identical to the melting species reported in this investigation.

The peaks representing Form II in all runs performed in this study were evaluated and compared to those obtained from samples crystallized from Group II solvents and from warm alcohol heated at 180°. Large variation was observed in the case of uncrimped and crimped, unground samples. This is probably due to incomplete crystallization of the melting species. However, grinding the sample resulted in a heat of fusion which compares well with that obtained from pure Form II. The calculated average heat of fusion for this form, whether the starting sample was crystallized from ammonia or alcohol, is 6893 ± 185 cal./mole. This value is comparable to the one reported by Moustafa and Carless (8)—viz., 6615 ± 235 cal./mole. The scanning rate was found to have little or no effect on the value of ΔH of Form II. In this study, it was found that there is a difference of about 2% in the value of ΔH of Form II scanned at 10°/min. and 40°/min. This is the same difference observed when the calibrant was scanned at both rates.

Quantification of the Binding Tendencies of Cholestyramine III: Rates of Adsorption of Conjugated Bile Salt Anions onto Cholestyramine as a Function of Added Inorganic Electrolyte Concentration, Temperature, and Agitation Intensity

WILLIAM H. JOHNS* and THEODORE R. BATES

Abstract □ The *in vitro* rate of binding of several conjugated bile salt anions to cholestyramine was studied at 37°, alone and in the presence of varying concentrations of sodium chloride. The kinetic studies were conducted under relatively mild agitation conditions to simulate reasonably the *in vivo* situation existing in the small intestinal lumen. A second-order kinetic model was found to represent the interaction data most suitably. The rate constants for the adsorption process were found to decrease in the presence of increasing concentrations of inorganic electrolyte, the reductive effect being more pronounced with the trihydroxy conjugates than with the dihydroxy derivative. Langmuir affinity constants were found to parallel the apparent second-order rate constants for systems devoid of added inorganic electrolyte. From studies concerning the influence of temperature on the rate of interaction, calculated apparent energies of activation indicated the existence of a substantially lower *energy barrier* to the binding of the dihydroxy glycine-conjugated derivative, glycodeoxycholate, than for its trihydroxy counterpart, the glycocholate anion. Variation in the intensity of agitation at which the reaction was conducted had a more pronounced effect on the rate of uptake of the glycodeoxycholate anion by the resin than on the glycocholate anion. A log-log relationship was found to exist between the second-order interaction rate constant and the speed of agitation. The results obtained from the temperature and agitation studies suggested that the binding of bile salt anions to cholestyramine apparently occurs by means of a diffusion-controlled process.

Keyphrases □ Cholestyramine binding—conjugated bile salt anions □ Electrolyte-concentration effect—cholestyramine binding □ Agitation, temperature effects—anion adsorption, cholestyramine □ Rate constants—anion adsorption, cholestyramine □ Colorimetric analysis—spectrophotometer

It has been shown that oral administration of the anionic-exchange resin, cholestyramine, results in the lowering of intestinal bile salt concentrations (1) and the interruption of normal enterohepatic circulation of bile salts (2). Cholestyramine also decreases the absorption of dietary cholesterol (3), fatty acids (4), and other materials, both exogenous and naturally occurring in the gastrointestinal tract, which rely on the surface-active properties of bile salts for their efficient intestinal absorption (5, 6). It has been proposed previously that the forces involved in the bile salt anion-cholestyramine interaction are primarily electrostatic in nature and are reinforced by secondary nonelectrostatic forces (7, 8).

The high doses required for efficacy in both clinical (9) and animal studies (10) suggest that cholestyramine is relatively inefficient in its ability to reduce intestinal bile salt levels, even though the capacity expected of such an ion-exchange resin (11) and approached by *in vitro* equilibrium experimentation with cholestyramine (7) would indicate otherwise.

In vivo, the physiologically active glycine- and taurine-conjugated bile salts present in bile are secreted into the lumen of the duodenal segment of the small intestine *via* the common bile duct, where they exist and function as endogenous surfactants in essentially the ionized form (12). Conservation of the secreted bile salts is effectively accomplished by their active reabsorption from the ileal segment of the small intestine (13). Therefore, the resin must interact with bile salt anions during their residence in the duodenal and jejunal regions of the small intestine, prior to their reabsorption from the ileum. If the binding process is inherently slow, or if the presence of physiologic electrolytes or other substances normally present in the intestinal tract tends to retard the rate of adsorption onto the resin, the resin may pass into the large intestine having only been partially utilized, thereby lowering the apparent efficiency of this pharmacologically important adsorbent.

In view of the fact that there would exist two dynamic, competitive reactions in the fluids of the small intestine, that is, the bile salt anion-cholestyramine interaction and the active reabsorption of bile salts from the ileum, it was of interest to investigate the *in vitro* kinetics of the former reaction alone and under the influence of the physiologic electrolyte, sodium chloride. Sodium chloride was previously shown to have an inhibitory effect on the interaction of bile salt anions with cholestyramine, the decrease in apparent capacity being greater for trihydroxy bile salts (*e.g.*, glycocholate and taurocholate) than for dihydroxy derivatives (*e.g.*, glycodeoxycholate) (7). The authors proposed that the electrolyte functioned principally to reduce the charge density on the charged adsorbate and adsorbent species, thereby weakening the electrostatic component of the interaction.

The literature is almost devoid of investigations concerned with the rates of binding of biliary constituents to adsorbents of the ion-exchange type, with the exception of the study of Sawchuk and Nairn (14) on the interaction of the bile pigment, bilirubin, with a series of anionic-exchange resins, including Dowex 1-X2. This work was primarily concerned with the rate of binding as it related to the degree of crosslinkage in the polyvinylstyrene skeleton of the resin polymer and the dependency of the adsorption rate on the particle size of the resin material.

The objectives of the present investigation were to establish and compare the *in vitro* rates of binding of several physiologic, conjugated bile salts to cholesty-

ramine at 37°. Studies of the adsorption-rate process in the presence of varying concentrations of added inorganic electrolyte at 37° were performed in order to appreciate more fully the role these endogenous ions may play in the *in vivo* rates of interaction. The influence of temperature and rate of agitation on the kinetics of the bile salt anion-cholestyramine interaction were also explored to obtain an appreciation for the magnitude of the energy of activation associated with the rate process and to determine whether the adsorption process was film diffusion- or particle diffusion-controlled. Particle diffusion-controlled reactions are rate limited by diffusion of exchangeable ions within the ion-exchange particle itself, whereas film diffusion-controlled exchange is a result of limiting diffusion rates in the diffuse film surrounding the ion-exchange particle.

EXPERIMENTAL

Materials and Methods—The sodium salts of taurocholic,¹ glycocholic,¹ and glycodeoxycholic¹ acids were dried *in vacuo* for at least 48 hr. prior to use. Reagent grade furfuraldehyde,² sulfuric and glacial acetic acids, and sodium chloride were used as received. The cholestyramine³ employed in this investigation was pharmaceutical grade (7).

All binding-rate studies were performed using a 250-ml., three-necked, round-bottom flask maintained at 37 ± 0.1°. Constant agitation of the reaction medium was accomplished by the use of a Cole-Parmer⁴ constant torque overhead stirrer (60 ± 1 r.p.m.) equipped with a Teflon-coated three-blade propeller (blade diameter 5.0 cm.) immersed 3.8 cm. into the reaction medium. In all experiments the concentration of adsorbate initially present was maintained at 1.0 millimolar (mM)⁵ and an equivalent amount of cholestyramine, based on an equivalent weight for the resin of 230, was employed. Each of the binding-rate experiments was performed at least in duplicate, with the rate constants obtained therefrom falling within the limits of experimental error (*i.e.*, a 5% range.)

In the case of the aqueous systems, 57.5 mg. of cholestyramine, dry weight, was allowed contact with 240 ml. of deionized, distilled water at 37° for a period of 0.5 hr. prior to the introduction of a 10-ml. aliquot of a bile salt stock solution. For the studies involving added inorganic electrolyte, identical procedures were followed except that the resin was placed in only 230 ml. of water. Ten-milliliter quantities of concentrated sodium chloride and bile salt stock solutions were simultaneously added to the reaction flask after a half hour.

Samples were withdrawn from the reaction flask at appropriate time intervals using a 1-ml. pipet fitted with a glass wool prefilter; the samples were suitably diluted, if necessary, and spectrophotometrically assayed for the concentration of bile salt remaining free in solution (see *Assay Procedure*).

Since previous work (7) had shown that sodium chloride effectively reduced the capacity of cholestyramine for certain bile salt anions, the concentration of bile salt anion remaining free or unreacted after the reaction had reached completion was determined. Two hundred and fifty-milliliter volumes of a solution containing the same concentration of bile salt, or bile salt and sodium chloride, and the same amount of cholestyramine as that

employed in the rate studies were placed into appropriately sealed bottles and shaken at 37° until equilibrium was established. Equilibration was normally established within a 24–48-hr. period. These equilibrium data were utilized in the kinetic analysis of the results obtained in this investigation.

The experimental protocol for those studies designed to establish the role of temperature and agitation intensity on the rate of the bile salt anion-cholestyramine interaction was essentially the same as that described previously. The temperature studies were performed in an aqueous medium at 25, 37, and 47°. The agitation intensity was maintained constant at 60 r.p.m.

The influence of agitation intensity on the reaction rate was studied in pure aqueous medium at a constant temperature of 37° and speeds of agitation of 40, 60, 70, and 100 r.p.m. In these latter studies, the resin was exposed to the medium, which was agitated at 60 r.p.m., for 30 min. After this period, the intensity of agitation was adjusted to the desired level and the bile salt stock solution was added to the system.

Assay Procedure—The concentrations of sodium glycocholate and taurocholate remaining free in solution at the time of sampling were assayed using essentially the same method as reported by Irvin *et al.* (15). The 1-ml. sample, or a similar volume of a suitable dilution thereof, was heated for 0.5 hr. at 65° in the presence of 6.0 ml. of 16 *N* sulfuric acid and 1.0 ml. of a 3% furfuraldehyde solution. Stabilization of the blue color, which developed on heating, was accomplished by the addition of 5.0 ml. of glacial acetic acid. The absorbance (maximum at 660 mμ), which obeyed the Beer's law relationship, was read using a Bausch and Lomb Spectronic-20, equipped with appropriate photomultiplier tube and filter. A solution containing no bile salt and treated in an identical manner served as the blank for these colorimetric determinations. The concentrations of glycodeoxycholate were determined spectrophotometrically as previously described (7).

RESULTS AND DISCUSSION

Theory—The formation of a 1:1 irreversible complex between an anion and an anionic-exchange resin may be expressed by the following equation, the molecularity of which is based on well-established evidence for reactions of ion-exchange resins in general (16, 17):

where (B⁻) represents the total concentration (mM) of anion present free in solution at any time *t*; (C⁺) the total concentration (meq.) of ionized binding sites on the anionic-exchange resin unoccupied by anions at any time *t*; (B-C) the concentration (meq.) of anion-resin complex formed at any time *t*; and *k* the second-order rate constant for the reaction. A similar reaction scheme, which assumes that the binding process is virtually irreversible, was suggested by Helfferich (18) as being valid in describing ion-exchange reactions, and has been employed by Sawchuk and Nairn (14) to interpret kinetically the binding between bilirubin and an anionic-exchange resin.

In the bile salt-cholestyramine system under discussion in this paper, Eq. 1 must be modified so as to take account of the binding sites on the anionic-exchange resin that have been previously shown (7) to be unavailable for binding bile salt anions. The concentration of available binding sites on cholestyramine (C⁺_a) is therefore equal to the total concentration of sites, (C⁺), minus those that are unavailable, (C⁺_u). Unless this correction is made, the reaction would appear to be incomplete.

Since a 1:1 stoichiometric relationship exists between the cholestyramine and the bile salt anions, (C⁺_a) at any time *t* must equal the concentration of unreacted or free bile salt available for binding to these sites, (B⁻_a). Any measurable concentration of bile salt remaining unreacted after the reaction has reached completion is, therefore, a measure of the concentration of bile salt unavailable for binding, (B⁻_u), and would equal the concentration of unavailable unoccupied sites, (C⁺_u).

The magnitude of (C⁺_a) will depend on the accessibility of binding positions on the interior surfaces of the resin bead which, in turn, is a function of the chemical structure of the bile salt anion and thus its ability to assume an optimal orientation for interaction with these sites.

⁴ Cole-Parmer Co., Chicago, Ill.

⁵ The pH values of 1.0 mM aqueous solutions of the sodium salts of taurocholic, glycocholic, and glycodeoxycholic acids, before and after contact with cholestyramine, remained constant at 5.30, 6.80, and 6.60, respectively. These values were insignificantly influenced by the presence or concentration of the inorganic electrolyte used in some of the studies. Based on the pH values obtained and the highest pK_a values previously reported for these acids (7), it was determined that the bile acids existed almost completely in the ionized form (*i.e.*, 98.9, 99.6, and 99.8% ionized, respectively).

^a Temperature, 37°; agitation intensity, 60 r.p.m. ^b The concentrations of free bile salt remaining unreacted after the reaction had reached completion with respect to the available binding positions on cholestyramine were: glycocholate, at 0 and 50 mM concentrations of NaCl, 0.25 and 0.38 mM; taurocholate, at 0, 25, 50, and 75 mM concentrations of NaCl, 0.21, 0.26, 0.30, and 0.33 mM, respectively; and glycodeoxycholate, at 0 and 50 mM concentrations of NaCl, 0.01 and 0.05 mM. ^c These equilibrium Langmuir constants were obtained from Reference 7. The equilibrium binding of bile salt anions to cholestyramine appears to be essentially temperature independent.

The addition of inorganic electrolyte to the bile salt–cholestyramine system has been shown previously to reduce the capacity of the resin to bind bile salt anions (7). The extent of this reduction, which may either result from a competitive reaction between bile salt and electrolyte anions for available, unoccupied positions on the resin or from the ability of the electrolyte to reduce the charge density on the resin, has been found to be not only a function of electrolyte concentration but also of the structure of the bile salt anion. In any event, $(C^+)_{\infty}$ will be further reduced below that for the binary bile salt anion–cholestyramine system.

Since the reaction under investigation is bimolecular, and essentially irreversible for the bile salts employed (7), the rate expression for the disappearance of bile salt anion from solution, based only on available binding positions on the resin, may be expressed by the following equation:

$$-d(B^-_a)/dt = k' (B^-_a)(C^+)_{\infty} \quad (\text{Eq. 2})$$

The experimental design of the binding-rate studies was such that the initial total concentrations of the reactants were equal [i.e., $(B^-)_0 = (C^+)_0$]. A similar equality exists between $(B^-)_0$ and $(C^+)_{\infty}$. Therefore, at any time t the concentration of free bile salt available for binding, (B^-_a) , would be equal to the concentration of unreacted available adsorption sites on the resin, $(C^+)_{\infty}$. The term (B^-_a) is equivalent to (B^-) minus (B^-_u) , or (B^-) minus $(B^-_{u\infty})$, since the concentration of free bile salt unavailable for binding is a constant and

^a The concentrations of free bile salt remaining unreacted after the reaction had reached completion with respect to the available binding positions on cholestyramine were independent of agitation intensity (Table I, Footnote^b).

therefore independent of time. Substitution of these conditions into Eq. 2, and subsequently integrating the resulting rate expression, yield the apparent irreversible second-order kinetic relationship utilized in the analysis of the bile salt uptake data:

$$\frac{1}{(B^-) - (B^-_{u\infty})} - \frac{1}{(B^-)_0 - (B^-_{u\infty})} = k't \quad (\text{Eq. 3})$$

where k' is the apparent second-order rate constant governing the reaction of bile salt anions with available binding positions on cholestyramine. The concentration of bile salt remaining unreacted in solution after the reaction has reached completion $[(B^-_{u\infty})]$, under the various experimental conditions, are listed as footnotes to Tables I–III.

Attempts to fit all of the binding-rate data to the well-established integrated rate expression (19) for the reversible reaction, $(B^-) + (C^+) \rightleftharpoons (B-C)$, yielded, in a majority of cases, curvilinear rather than the linear plots predicted by this reversible rate expression (19). This finding further supports the use of the apparent irreversible reaction scheme given by Eq. 1.

Effect of Inorganic Electrolyte—The validity of the assumptions made concerning the interactions studied is evidenced by the excellent linearity of the data interpreted by utilization of Eq. 3 (Figs. 1–3). The apparent second-order constants, k' , were calculated from the slope of a regression line through the data points subse-

quent to the initial nonlinear phase. For all of the systems under examination, the apparent lag times (*i.e.*, the extrapolated, least-squares intercepts on the time axis of the linear segments of the plots shown in Figs. 1–3) ranged from 1 to 3 min. As is apparent from an examination of the plots shown in Fig. 1 and the rate-constant data summarized in Table I, the rate constant governing the bile salt–cholestyramine binding process, from a pure aqueous medium, is significantly greater for the dihydroxy derivative, glycodeoxycholate, than for the trihydroxy salts investigated. A comparison of the rate-constant data for the two trihydroxy bile salts studied indicates that the taurine-conjugated derivative, taurocholate, is adsorbed onto the resin at a faster rate than the

glycine-conjugated derivative, glycocholate. Also shown in Table I are the affinity or association constants obtained from a Langmuir interpretation of equilibrium binding data for the bile salts alone (7). The rank order relationship existing between this parameter and the k' values for the binary bile salt–cholestyramine systems suggests that the affinity, which signifies the strength of interaction between adsorbate and adsorbent species, functions as a driving force for the interaction, the rate of binding increasing with increasing interaction strength. This conclusion is in agreement with the statements of Helfferich (20, 21) concerning the role of selectivity in the rate of uptake of simple ions by ion-exchange resins.

The observed rates of interaction in the ternary, bile salt–electrolyte–cholestyramine systems are significantly reduced in comparison to those in the absence of added electrolyte, as is evidenced by a comparison of the appropriate curves presented in Figs. 1 and 2 and the rate constants listed in Table I. The diminution in the rate of adsorption is decidedly more pronounced in the taurocholate- or glycocholate-containing systems than in the glycodeoxycholate-containing system. For example, at an added inorganic electrolyte concentration of 50 mM, there are approximately 53 and 62% decreases in the rates of interaction, respectively, for the former two trihydroxy anions; whereas there is only a 5% reduction in the rate of binding for the latter dihydroxy bile salt anion. These results tend to add supportive evidence to the proposed contributory role of nonelectrostatic interactions in the adsorption process (8),

Figure 5—Arrhenius relationship for glycine-conjugated, bile salt anion–cholestyramine interaction. Key: glycodeoxycholate (□) and glycocholate (■).

Figure 6—Effect of agitation intensity on the rate of binding of glycine-conjugated, bile salt anions with cholestyramine at 37°. Key: 100 (○), 70 (●), 60 (□), and 40 (■) r.p.m.

since electrolytes would be expected to have less of an effect on binding processes which are more nonelectrostatic in nature (*i.e.*, the dihydroxy bile salt-cholestyramine interaction) than on those interactions which are primarily due to an electrostatic mechanism (*i.e.*, trihydroxy bile salt-cholestyramine interactions).

The second-order rate constants appear to decrease with increasing electrolyte concentration, as is clearly exemplified by Fig. 3 and the rate constants listed in Table I for the taurocholate-containing systems. This primary salt effect is most probably due to a reduction in the charge density associated with the two charged reactants produced by the screening effect of the added inorganic electrolyte ions. The overall result is a weakening in the electrostatic forces between the two reactants and hence a corresponding decrease in the rate of interaction. A competition between bile salt and added chloride anions for the charged binding positions on cholestyramine may also be operable in the observed reduction in the uptake rates of taurocholate and glycocholate by the resin.

Effect of Temperature—Presented in Fig. 4 and listed in Table II are the results of the studies concerned with the temperature dependency of the initial rate of interaction between bile salt anions and cholestyramine, at a constant agitation intensity of 60 r.p.m. It is readily apparent from an examination of the rate-constant data that both glycocholate and glycodeoxycholate show an increase in

their rate of binding with increasing temperature. The 10° temperature coefficient for the reaction was estimated to be approximately 2.1 for the former anion and 1.1 for the latter bile salt anion. These temperature coefficient values are of the order of magnitude similar to that reported for other heterogeneous, diffusion-controlled reactions (23, 24).

Apparent energies of activation (E_a) associated with the rates of interaction of glycocholate and glycodeoxycholate with cholestyramine were calculated by means of the Arrhenius equation,

$$\log k' = \log A - \frac{E_a}{2.303R} \frac{1}{T} \quad (\text{Eq. 4})$$

in which k' represents the apparent second-order rate constant, A is the frequency factor, E_a is the energy of activation, R is the gas constant (1.987 cal./deg.-mole), and T is the absolute temperature. The temperature data plotted according to Eq. 4 are shown in Fig. 5. The energy of activation for each adsorbate, as determined from the least-squares slope of the linear plots, was found to be +2.39 kcal./mole for the glycodeoxycholate anion and +10.6 kcal./mole for the glycocholate anion. These findings are consistent with those previously obtained in that the dihydroxy bile salt anion, glycodeoxycholate, was suggested to be capable of a higher degree of nonelectrostatic interaction with cholestyramine than was the trihydroxy derivative, glycocholate (8).

Effect of Agitation Intensity—In order to ascertain whether the speed of agitation, to which the reaction medium was subjected, influenced the rate of the bile salt anion-cholestyramine interaction, studies were performed at a constant temperature of 37° and agitation intensities of 40, 60, 70, and 100 r.p.m. The results of these studies are depicted in Fig. 6 and the second-order rate constants, calculated from the slopes of these linear plots, are listed in Table III. The data obtained indicate that the rates of binding of both glycodeoxycholate and glycocholate anions to cholestyramine increase with increasing rate of agitation of the reaction medium, the former anion being more influenced by this parameter than the latter.

A log-log plot of the apparent second-order rate constants *versus* speed of agitation (r.p.m.) is presented in Fig. 7. The excellent linearity of these curves suggests that agitation intensity affects the rate of interaction in accordance with the following empirical relationship:

$$\log k' = b \log S + \log a \quad (\text{Eq. 5})$$

where S represents the speed of agitation (r.p.m.), k' is the apparent second-order rate constant governing the interaction, and b and a are constants. This mathematical relationship has been commonly employed to aid in distinguishing the process controlling a heterogeneous reaction rate (25). Generally, if the reaction in question is diffusion controlled, then the value of the constant b should closely approach or be equal to unity, which is in agreement with the Nernst-Brunner film theory (25). The applicability of this equation to bile salt anion-cholestyramine interactions becomes evident if one considers the adsorption process, which in essence involves the removal of adsorbate molecules from solution to essentially an undissolved state, as being the reverse of a dissolution process. The magnitude of the constant b for the two adsorbates was obtained from linear regression slope values of the plots illustrated in Fig. 7. The values of b , so determined, were 0.760 and 1.09 for the glycocholate and glycodeoxycholate anions, respectively, which suggest that the adsorption process is primarily diffusion controlled. It appears, therefore, that the rate of binding of bile salt anions to cholestyramine is dependent on the rate of diffusion of the adsorbate through a stagnant film surrounding the individual resin particle beads which is characteristic of film diffusion-controlled exchange reactions. As a result, as the speed of agitation of the reaction medium is increased, the thickness of this film is reduced and hence there is a potentiation in the rate of interaction. The lower b value, as well as the lower second-order rate constant at any speed of agitation, noted for the glycocholate-cholestyramine interaction as compared to that for the glycodeoxycholate anion can be readily explained based on the fact that trihydroxy bile salt anions are hydrated to a greater extent than dihydroxy derivatives (26). The higher apparent molecular weight of the glycocholate anion results in a lower diffusion coefficient for this anion, thus producing both a decrease in its rate of diffusion through the stag-

Figure 7—Log apparent second-order rate constant versus log speed of agitation (r.p.m.) for the interaction of glycine-conjugated, bile salt anions with cholestyramine at 37°. Key: glycodeoxycholate (□) and glycocholate (■).

nant film as well as a decrease in its rate of interaction with this pharmacologically important anionic exchange resin.

SUMMARY

The present investigation has established, apparently for the first time, that the bile salt anion-cholestyramine reaction occurs by means of apparent second-order kinetics and that the reaction rates are dependent on the chemical structure of the bile salt anion participating in the interaction. Under conditions of mild agitation, it was shown that the reaction rates decrease in the following order: glycodeoxycholate > taurocholate > glycocholate, which parallels the affinity with which they bind to the resin. It is also of physiological interest that the addition of inorganic electrolyte to the system markedly depresses the rate of binding of the taurocholate and glycocholate anions to cholestyramine, which helps to explain why the resin is not as efficient as it should be *in vivo* based on the recommended dosage levels prescribed.

Both an increase in the temperature and the agitation intensity employed in the kinetic studies potentiated the rate of interaction between the glycocholate or glycodeoxycholate anion and cholestyramine. These data suggest that the binding process is most probably film diffusion controlled (27).

Additional kinetic studies are being conducted in this laboratory in order to ascertain the influence of such parameters as resin particle size and the influence of other endogenous substances on this pharmacologically important resin-bile salt interaction.

Toxogonin: Blood Levels and Side Effects after Intramuscular Administration in Man

FREDERICK R. SIDELL and WILLIAM A. GROFF

Abstract □ Toxogonin, given intramuscularly to 10 healthy young men in doses of 2.5–10 mg./kg., produced dose-related oxime whole blood levels of 6.3–26.5 mcg./ml. and had a plasma half-time of 82.8 min. Associated side effects included tachycardia, hypertension, and a dose-independent symptom complex consisting of peroral warmth, paresthesia and hypalgesia, and a menthol taste. Some published data on the relative effectiveness of toxogonin and

pralidoxime (chloride and methanesulfonate) suggest further inquiry into toxogonin's therapeutic potential may be needed.

Keyphrases □ Toxogonin, intramuscular injection—oxime blood levels □ Plasma half-life—toxogonin □ Dose relation, toxogonin—plasma blood levels □ Urinary excretion—toxogonin □ Side effects—toxogonin

Until about a decade ago the only therapy for poisoning by cholinesterase inhibitors was atropine or another anticholinergic drug plus supportive therapy. In the 1950's the oximes were developed and their usefulness as

adjuncts to atropine was established (1, 2).

On the basis of therapeutic potency, relatively low toxicity in man, and other factors, the oxime generally adopted for use is pralidoxime chloride (2-PAMCl;

nant film as well as a decrease in its rate of interaction with this pharmacologically important anionic exchange resin.

SUMMARY

The present investigation has established, apparently for the first time, that the bile salt anion-cholestyramine reaction occurs by means of apparent second-order kinetics and that the reaction rates are dependent on the chemical structure of the bile salt anion participating in the interaction. Under conditions of mild agitation, it was shown that the reaction rates decrease in the following order: glycodeoxycholate > taurocholate > glycocholate, which parallels the affinity with which they bind to the resin. It is also of physiological interest that the addition of inorganic electrolyte to the system markedly depresses the rate of binding of the taurocholate and glycocholate anions to cholestyramine, which helps to explain why the resin is not as efficient as it should be *in vivo* based on the recommended dosage levels prescribed.

Both an increase in the temperature and the agitation intensity employed in the kinetic studies potentiated the rate of interaction between the glycocholate or glycodeoxycholate anion and cholestyramine. These data suggest that the binding process is most probably film diffusion controlled (27).

Additional kinetic studies are being conducted in this laboratory in order to ascertain the influence of such parameters as resin particle size and the influence of other endogenous substances on this pharmacologically important resin-bile salt interaction.

Toxogonin: Blood Levels and Side Effects after Intramuscular Administration in Man

FREDERICK R. SIDELL and WILLIAM A. GROFF

Abstract □ Toxogonin, given intramuscularly to 10 healthy young men in doses of 2.5–10 mg./kg., produced dose-related oxime whole blood levels of 6.3–26.5 mcg./ml. and had a plasma half-time of 82.8 min. Associated side effects included tachycardia, hypertension, and a dose-independent symptom complex consisting of peroral warmth, paresthesia and hypalgesia, and a menthol taste. Some published data on the relative effectiveness of toxogonin and

pralidoxime (chloride and methanesulfonate) suggest further inquiry into toxogonin's therapeutic potential may be needed.

Keyphrases □ Toxogonin, intramuscular injection—oxime blood levels □ Plasma half-life—toxogonin □ Dose relation, toxogonin—plasma blood levels □ Urinary excretion—toxogonin □ Side effects—toxogonin

Until about a decade ago the only therapy for poisoning by cholinesterase inhibitors was atropine or another anticholinergic drug plus supportive therapy. In the 1950's the oximes were developed and their usefulness as

adjuncts to atropine was established (1, 2).

On the basis of therapeutic potency, relatively low toxicity in man, and other factors, the oxime generally adopted for use is pralidoxime chloride (2-PAMCl;

Figure 1—Toxogonin (i.m.): plasma oxime values versus time.

2-pyridine aldoxime methochloride). However, largely because of the enthusiasm of Engelhard and Erdmann (3, 4), interest has been generated in a newer oxime, toxogonin [LuH6; *N,N'*-oxydimethylene bis(pyridinium-4-aldoxime)dichloride], said to be more effective than pralidoxime chloride. It is similar structurally to TMB-4 [*N,N'*-trimethylene bis(pyridinium-4-aldoxime) dibromide], which has been shown to be more active than pralidoxime chloride therapeutically (5-8) but also more toxic in man (9, 10).

Most reports on the administration of toxogonin to humans would appear to be those of Erdmann and Engelhard. They reported that toxogonin (250 mg., i.v.) was superior to pralidoxime chloride in three cases of E-605 (parathion) poisoning (11), and they studied symptoms and blood levels of oxime in 12 healthy young male volunteers who were given 250 mg. of toxogonin intramuscularly in a 25% solution (12). The purposes of this study were: to extend these latter observations over a wider dose range, to study the blood levels and excretion patterns of this oxime, and to determine what, if any, undesirable side effects would be produced.

SUBJECTS AND METHODS

The subjects were U. S. Army enlisted men, ages 18 to 24 years (average 21 years), who volunteered for this study. Each had a complete medical evaluation including a physical examination, chest X-ray, electrocardiogram, and laboratory tests [hematocrit, total and differential white blood cell count, urinalysis, including microscopic examination, blood urea nitrogen (BUN), serum glutamic oxaloacetic transaminase (SGOT), alkaline phosphatase, bilirubin, serum creatinine, and red blood cell and plasma cholinesterase], and they were found to be free from any abnormality before being accepted into the study. They were told that they would take part in a study of a new and possibly very effective antidote for nerve agent poisoning; the test procedures were described to them, including the necessity of multiple venipunctures. They were told that there

Figure 2—Toxogonin (i.m.): whole blood oxime levels versus time.

might possibly be some symptoms, but these were left unspecified. The only reward for participation was an extra day off.

The volunteers slept in the ward the evening before the test. Fluid intake was maintained at a high level prior to and throughout the test. During the hour before the drug was administered, three measurements were recorded of supine blood pressure, heart rate, and pupil size. After appropriate control urine and blood specimens had been taken, the subjects ate a light breakfast.

Except to void, the subjects remained in bed during the first 3 hr. of the test; for the remainder of the 24-hr. test period, they were allowed to be up and around the ward. Blood pressure and heart rate were measured every 15 min. for 2 hr. after administration of the drug. Blood samples were taken at 5, 10, 20, 30, 60, 90, 120, and 180 min. after drug. The subjects were asked to void every 30 min. for 3 hr.; for the next 21 hr., all urine was collected, but no attempt was made to follow a definite schedule.

Whole blood, plasma, and urine were analyzed for oxime content by the method described by Groff and Ellin (13). Blood and plasma were analyzed within minutes of collection; the urine was refrigerated and analyzed several days later. Preliminary studies performed by adding a known amount of toxogonin to urine and making daily determinations of toxogonin content showed that there was insignificant (under 5%) deterioration of the oxime over a 1-week period. The oxime content of red blood cells was also measured and will be the subject of a separate report.

Other blood and urine studies (hematocrit, total and differential white blood cell count, SGOT, alkaline phosphatase, BUN, and urinalysis) were performed by routine analytical methods on samples taken at 24 hr. and 7 days. Red cell and plasma cholinesterase of the three subjects receiving the highest dose was measured in samples taken at 20 min., 30 min. (times of peak oxime levels), and 3 hr. after administration of the oxime by methods previously described (14).

The subjects' average weight was 76 kg. (range 56-93 kg.). The volume of injection ranged from 0.64 to 3.1 ml., and the injection was given into the deltoid muscle with a No. 23 needle. Doses were 2.5 mg./kg. (two subjects), 5.0 mg./kg. (two subjects), 7.5 mg./kg. (three subjects), and 10.0 mg./kg. (three subjects). All doses and blood levels are expressed as the salt of the oxime.

Toxogonin was purchased from E. Merck, Darmstadt, West Germany. Recent studies on the sample used showed that it was over 98% pure by UV spectroanalysis and its LD₅₀ [calculated by the method of Bliss (15)] by the intraperitoneal route in 170-200-g. female rats was 109.6 (95% CL: 102.5-117.2) mg./kg. It was dissolved in distilled water to a concentration of 274 mg./ml. and filtered through a Seitz filter. Bacteriological analysis showed it to be sterile.

RESULTS

A. Blood Levels of Oxime—Serial mean plasma and whole blood levels for toxogonin for each dose group are shown in Figs. 1 and 2. Peak blood levels were reached at 20 min. in the two lower dose groups and at 30 min. in the higher dose groups. All groups had plasma values above 5 mcg./ml. by 5 min., and all but the group that received 2.5 mg./kg. maintained a plasma level of about 4 mcg./ml. for over 3 hr. (Because of technical difficulties the analysis of the blood taken at 20 min from one subject who received 10 mg./kg. was not measured; the point is the mean for the other two subjects. The data from this subject were also excluded from dose-response calculations.)

The dose-response relationship, showing the highest plasma value for each subject, is shown in Fig. 3.

The disappearance from plasma of many drugs follows first-order kinetics, $C = C_0 e^{-kt}$, where C = concentration at time t ; C_0 = apparent concentration at zero time, i.e., the y -intercept; and k = the velocity constant characterizing drug-elimination rate from the blood stream. The half-life ($t_{1/2}$) can be determined most simply by plotting blood levels on a logarithmic scale against time on a linear scale and, if the terminal segment of the plot is linear, calculating from its slope the half-life ($t_{1/2}$) and k value (the rate constant characterizing elimination from the blood stream).

Using the method of least squares, the constants $\log C_0$ and k for the equation

$$\log C = \log C_0 - \frac{kt}{2.303} \quad (\text{Eq. 1})$$

Figure 3—Toxogonin (i.m.): peak blood levels versus dose.

were computed from each subject's last 4–6 plasma level values. In each case the coefficient of correlation for the fit of the points to the line was greater than 0.99.

In Fig. 4 the data from four typical subjects are plotted in this manner. The average $t_{1/2}$ was 82.8 min. [the mean values by dose groups were 79.4 min. (2.5 mg./kg.), 85.6 min. (5.0 mg./kg.), 82.7 min. (7.5 mg./kg.), and 84.0 min. (10.0 mg./kg.)]; and the average k value was 0.0083 min.⁻¹ (by dose groups in min.⁻¹: 0.0087 for 2.5 mg./kg., 0.0081 for 5.0 mg./kg., 0.0082 for 7.5 mg./kg., and 0.0083 for 10 mg./kg.).

B. Urinary Excretion—Of the total dose, 84% was excreted into the urine unchanged during the 24-hr. collection period; of this amount, 76% (or 64% of the dose) was excreted in the first 3 hr. (Because of technical problems, data from one subject at the 10-mg./kg. dose could not be used in the urinary analysis.) The percentage of the amount not excreted:

$$\frac{(\text{total amount excreted} - \text{amount excreted by time } t) \times 100}{\text{total amount excreted}}$$

is plotted on a logarithmic scale against time, t , in Fig. 5. Times for 50% excretion for each dose group are 73.0 min. (2.5 mg./kg.), 72.0 min. (5.0 mg./kg.), 110.4 min. (7.5 mg./kg.), and 107.4 min. (10 mg./kg.) and are close to the biological half-life as measured by loss from plasma. This suggests that a large part of the oxime is eliminated rather rapidly by renal mechanisms.

C. Blood Pressure and Heart Rate—All subjects showed a mild to moderate transient increase in blood pressure and heart rate (Figs. 6 and 7). The small number of subjects in each dose group makes exact quantitation of such variables unreliable, but both the systolic and diastolic blood pressures were moderately elevated (11–17 mm. Hg), reaching peak values at about 30 min. after drug administration. The heart rate change was more dose related with an average maximal increase of 8 b.p.m. for 2.5 mg./kg., 15 b.p.m. for 5.0 mg./kg., and 32 b.p.m. for 10 mg./kg. In general the heart rate increased markedly a few minutes after drug administration (data for the lower doses are not shown because heart rates were not measured earlier than 15 min. for the lower dose subjects) and remained elevated for most of the 2-hr. observation period.

D. Other Blood and Urine Studies—No changes were noted in any of the routine blood or urine tests at 24 hr. or 7 days in any subject, nor were there changes in the red blood cell or plasma cholinesterase in the three subjects in whom it was measured.

E. Symptoms—Pain at the site of injection was quite noticeable, particularly with the larger volumes used for the higher doses, and most subjects compared it in intensity to the pain from an injection of plague or Asian influenza vaccine. Within a few minutes the pain seemed to diminish greatly, and by 15 min. most subjects said they did not notice it. A slight residual tenderness of the muscle to percussion was present in all subjects 24 hr. later.

A peculiar symptom complex developed in many subjects. This typically consisted of a generalized warmth, a "hot feeling" over the upper part of the body, within several minutes after the injection. At 5–15 min., this became localized in the face, particularly around the mouth, where it was associated with a "tight feeling" of the skin and muscles of the lower face or forehead and a "numbness" of the circumoral area. Nine subjects (all but one at the highest dose) noted a hot feeling in their throats within 1–3 min. after injection, and three

Figure 4—Toxogonin (i.m.): plasma levels and half-times in four subjects.

of these men (2.5, 5.0, and 10.0 mg./kg.) also spontaneously identified this as a "menthol" taste. One subject at 2.5 mg./kg., one at 5.0 mg./kg., and one at 10.0 mg./kg. reported a numbness in or around the mouth, together with a definite hypalgesia to pinprick in this area including the anterior tongue and gums (two subjects), which lasted from 3 min. to 6 hr. after injection. No depression of the corneal reflex or muscular weakness in the face was observed. When present, the area of involvement was sharply demarcated. In one, it was from midforehead to just under the chin; in another, it had a definite 5.08–7.62-cm. (2–3-in.) radius around the mouth. Most reported a flushing sensation, but one subject said he felt very hot with

Figure 5—Urinary excretion of toxogonin: percent unexcreted versus time.

Figure 6—Toxogonin (i.m.): blood pressure changes versus time.

cool flashes. The skin of several subjects was very warm to the touch and appeared slightly pink. Several noted "pins and needles" sensations in their arms and fingers, not associated with hyperventilation. All three subjects at the highest dose reported their eyes "felt like baseballs" with heaviness in the eyeballs or a feeling that "they're enlarging." Only one subject (7.5 mg./kg.) reported nausea and this was very transient. A dry mouth was a unanimous symptom of all subjects in the highest dose groups.

Except for mild paresthesia and, in two cases, mild hypalgesia, all symptoms had subsided by 1–2 hr.

DISCUSSION

In a study of blood levels and urinary excretion of toxogonin after intramuscular administration to 12 healthy young men, Erdmann *et al.* (12) gave an average dose of 3 mg./kg. They noted a peak whole blood oxime level of about 6 mcg./ml. at 30 min., found 52% of the dose in the urine by 2 hr., and reported that their subjects complained of "heat and tension" in the facial area and a menthol-taste sensation in the nasopharynx. In the study reported here, the two subjects who received 2.5 mg./kg. had a peak whole blood level of oxime of 6.6 mcg./ml. at 20 min., and the average excretion for nine subjects was 53% of the dose by 2 hr. The subjects reported the same symptoms and, in addition, had transient neurological findings.

Calesnick *et al.* (10) found that an intramuscular dose of 15 mg./kg. of pralidoxime chloride produced whole blood oxime levels of 8.9 mcg./ml. at 30 min. and 5.7 at 2 hr., levels exceeded by 5.0 mg./kg. of toxogonin at these times, and a dose of 30 mg./kg. produced whole blood levels (14.5 mcg./ml. and 10.4 mcg./ml. at similar times) below those produced by 7.5 mg./kg. of toxogonin. Thus within the ranges studied, three to four times more pralidoxime chloride than toxogonin is needed for a similar blood level.

Pralidoxime chloride in intravenous or intramuscular doses of less than 15 mg./kg. does not elevate the blood pressure in normal recumbent subjects (10, 16, 17). This sympathomimetic property of

Figure 7—Toxogonin (i.m.): heart rate changes versus time.

toxogonin may be of additional therapeutic benefit for the severely poisoned individual.

The cause of the peculiar symptom complex produced by toxogonin is not clear. Because of their "onion skin" pattern, the sensory disturbances of the face resemble those caused by a lesion of the nucleus or descending fibers of the sensory division of the trigeminal nerve in the medulla or upper spinal cord (18), although the production of such a lesion by a drug would be quite rare.

With high doses of pralidoxime chloride (15–30 mg./kg., i.v.), diplopia has been noted¹ (16). The authors also have observed this with pralidoxime chloride (20–30 mg./kg., i.v.) associated with demonstrable weakness of the muscles supplied by the third, fourth, and sixth cranial nerves. It is possible that this side effect is also central in origin.

The usefulness of toxogonin in clinical therapy is unknown, although, as noted, Erdmann and Clarmann (11) felt that toxogonin was more beneficial than pralidoxime.

The relationship of oxime blood levels to therapeutic efficacy is also unknown. Erdmann *et al.* (12), on the basis of *in vitro* studies (3) showing toxogonin to be 30 times more effective than pralidoxime in reactivating organophosphate-inhibited cholinesterase, suggest that the level of 4 mcg./ml., reported to be an effective *in vivo* level of the methanesulfonate salt of pralidoxime (P2S) by Sundwall (19), would be more than adequate. Using identical *in vitro* techniques in a comparative study, they also found that blood concentrations of 0.1–0.2 mcg./ml. reactivated cholinesterase by the same amount as concentrations of 3 mcg./ml. of pralidoxime (a concentration very close to that suggested by Sundwall from *in vivo* work).

However, several studies in which toxogonin (or the chemically similar TMB-4) has been compared with pralidoxime (or P2S, the methanesulfonate salt of pralidoxime) indicate that perhaps this advantage is not quite so great (20, 21).

Both toxogonin and TMB-4 have two oxime groups per molecule and, therefore, on an equimolar basis might be expected to have twice the efficacy of a compound having a single oxime group, such as pralidoxime. (On the other hand, yoked oxime groups might be less effective than the same number of single oxime units.) It has been shown that toxogonin and TMB-4 are roughly equipotent in treating poisoned mice (22), in reactivating blood (mouse) or brain (mouse and rat) cholinesterase inhibited (*in vivo*) by an organophosphate compound (diethyl *p*-nitrophenyl phosphate)² (23), or in antagonizing the effects of tabun on the isolated rat phrenic nerve preparation (20).

O'Leary *et al.* (6) showed that 10 mg./kg. (28 μ mole/kg.) of TMB-4 with atropine raised the LD₅₀ of sarin in rabbits by a factor of 170, whereas 10 mg./kg. (58 μ mole/kg.) of pralidoxime chloride raised the LD₅₀ by 90, and the same dose of P2S (41 μ mole/kg.) raised it by 35. This indicates that, for equimolar amounts, TMB-4 is roughly 3.9 times more effective than pralidoxime chloride and 7.5 times more effective than P2S. Fleisher *et al.* (5) showed that equimolar doses

¹ B. Calesnick, personal communication.

² Paraoxon.

of TMB-4 were from 1.4–7.0 times more effective than pralidoxime in raising the LD₅₀ of difluorophosphate, sarin, tabun, and tetraethylpyrophosphate in rats.

This latter group of investigators (21) also showed that, in equimolar doses, toxogonin and atropine approximately doubled the LD₅₀ of sarin in rats (1.6X) and guinea pigs (2.2X) over that in animals treated with pralidoxime chloride and atropine. When given on an equiweight basis, the two oximes had nearly the same therapeutic activity. LD₅₀'s done by probit analysis [method of Bliss (15)] from data in Table II of the Wolthuis and Cohen report (20) suggest that toxogonin is about 1.7 times more effective therapeutically than P2S against tabun in rats (also receiving atropine) or 2.6 times more effective on an equimolar basis. Heilbronn and Tolagen (22) also showed that in atropinized mice, toxogonin is 4.6 times more effective against sarin and 9.5 times more effective against tabun than P2S when the dose of each oxime is 20% of its LD₅₀. On an equimolar basis, these ratios are approximately doubled to 7.1 and 14.5.

Overall, it would appear that toxogonin may be more effective therapeutically than pralidoxime chloride or P2S, although in two of the three studies where comparisons were made, the therapeutic difference was not marked.

The data in these reports also indicate that in each case, except the guinea pig experiments, the oxime that is more therapeutically potent also has a lower LD₅₀ (is more toxic). However, the "therapeutic margin" (potency ratio/LD₅₀ ratio) indicates that, in most cases, effectiveness is gained in greater proportion than toxicity, at least when toxogonin and pralidoxime chloride (or P2S) are compared directly.

Potentiometric Titration of Monomeric and Micellar Acylcarnitines

SAMUEL H. YALKOWSKY* and GEORGE ZOGRAFI

Abstract □ Carnitine (β -hydroxy- γ -trimethylammonium butyrate) enzymatically combines with fatty acids to facilitate their transport through mitochondrial membranes and thus their metabolism. In view of this fact, a study of the physical-chemical properties of some acylcarnitines was conducted. Potentiometric titrations were carried out at concentrations at which the acylcarnitines are monomeric and micellar. Unlike the monomeric species, the micellar acylcarnitines do not have a constant pK value but rather one that is dependent on the degree of protonation and hence the net positive charge of the micelle. The pK value for the zwitterionic micelle is about 4.85 and decreases linearly with β at low degrees of protonation. The pK of the zwitterionic micelle was taken as the intrinsic pK of a carboxyl group, and pK differences at any value of β were attributed to electrostatic interactions. This permitted calculation of the surface potential of the micelle. The dependence of the observed pK and the calculated surface potential on β and on ionic strength was shown to be qualitatively consistent with the Debye-Hückel theory for a spherical impenetrable particle.

Keyphrases □ Acylcarnitines, monomeric, micellar—potentiometric titration □ CMC—acylcarnitines □ Surface potential—acylcarnitine micelles □ Ionization, micelles—pK value effect □ Potentiometric titration—monomeric, micellar acylcarnitines

Although the coenzyme A derivatives of fatty acids are metabolized through β -oxidation in the mitochondrion, these activated fatty acids cannot enter the mitochondrion from the cytoplasm unless carnitine (β -hydroxy- γ -trimethylammonium butyrate) is present (1-3). At the mitochondrial membrane surface, fatty acyl coenzyme A derivatives are enzymatically combined with carnitine, producing free coenzyme A and fatty acylcarnitine (I).

The acylcarnitines pass through the mitochondrial membrane and react with intramitochondrial coenzyme A to form free carnitine and fatty acyl coenzyme A. The intramitochondrial acyl coenzyme A is metabolized *via* the β -oxidation cycle, and the carnitine can pass back across the membrane to react with another extramitochondrial acyl coenzyme A molecule. The

fact that several compounds having structures similar to carnitine and acylcarnitine are not able to pass through the mitochondrial membrane suggests that the acylcarnitine structure is specifically required for fatty acid transport (4, 5).

Carnitine and its acylated derivatives (Table I) have three functional groups that can interact with each other and with groups on neighboring molecules. In the case of long-chain acylcarnitines, micelle formation also can occur. These interactions could affect the ionization behavior of such compounds and hence their ability to function in membrane transport. The present study was designed to determine the effects of structural modification and environmental conditions, *e.g.*, ionic strength, pH, and micelle formation, on the ionization behavior of these compounds, with a long-range view of understanding their transport-mediating properties.

EXPERIMENTAL

Materials—The various acylcarnitines used in this study were synthesized by reacting DL-carnitine HCl (Mann Research Laboratories, Inc.) with high purity (99+ %) fatty acids (Applied Science Laboratories) according to the method of Ziegler *et al.* (6).

DL-Acetylcarnitine (Otsuka Pharmaceutical Co.), DL- γ -dimethylamino- β -hydroxy butyric acid HCl (norcarnitine) (Riker Laboratories), γ -amino butyric acid (GABA) (Nutritional Biochemicals Corp.), γ -butyrobetaine (GBB), and DL- γ -amino- β -hydroxy butyric acid HCl (Calbiochem) were used.

All physical constants and tests for purity agree well with literature values (6). Plots of surface tension *versus* concentration for the long-chain acylcarnitines show no minima, suggesting the absence of free fatty acid (7).

Determination of Critical Micelle Concentration—The determination of the critical micelle concentration (CMC) is necessary to evaluate the relative contribution of monomeric and micellar species to the titration behavior of the long-chain acylcarnitines. This was accomplished by determining the concentration at which the break in the log concentration *versus* surface tension plot occurs. The surface tension of solutions containing various concentrations of decyl-, lauryl-, myristyl-, and palmitylcarnitine was determined by the drop volume method as described by Weiner and Zograf (7). Table II lists the CMC values for acylcarnitines in their cationic and zwitterionic forms in the presence and absence of 0.20 M KCl.

The CMC values shown for octylcarnitine were obtained more conveniently by determining the break in the pH *versus* log concentration plots (8). Values obtained in this manner for other acylcarnitines were in excellent agreement with the results of surface tension measurement.

Table I—Critical Micelle Concentrations of Cationic and Zwitterionic Acylcarnitines in Water and 0.20 M KCl at 25°

Compound	Critical Micelle Concentration, moles/l.			
	Cationic Form		Zwitterionic Form	
	H ₂ O	0.20 M KCl	H ₂ O	0.20 M KCl
Octylcarnitine	1.6×10^{-1}	1.0×10^{-1}	1.1×10^{-1}	9.5×10^{-2}
Decylcarnitine	1.5×10^{-2}	7.0×10^{-3}	1.1×10^{-2}	9.0×10^{-3}
Laurylcarnitine	1.5×10^{-3}	7.5×10^{-4}	1.2×10^{-3}	8.5×10^{-4}
Myristylcarnitine	1.5×10^{-4}	9.0×10^{-5}	1.0×10^{-4}	7.5×10^{-5}
Palmitylcarnitine	1.5×10^{-6}	8.5×10^{-6}	—	—

Potentiometric Titration—Potentiometric titrations were carried out using a Beckman 101900 research pH meter equipped with a Beckman 39167 general-purpose glass electrode and a Beckman 19168 silver-silver chloride reference electrode. The instrument was standardized with Beckman pH 4 buffer solution (pH 4.01 at 25°) and calibrated at pH 10.184 by an internal calibration device before and after each titration.

The solutions were prepared by dissolving the undissociated acid in doubly distilled CO₂-free water. The titrant was added in 0.01 mmole or smaller increments by means of an Agla micrometer syringe outfit (Burroughs Wellcome & Co.). The entire titration was run at constant temperature and under nitrogen atmosphere. The apparent ionization constant of zwitterionic compounds such as the acylcarnitines may be defined as:

$$K = \frac{(H^+)(R^\pm)}{(RH^+)} \quad (\text{Eq. 1})$$

where (R[±]) and (RH⁺) are the concentrations of the zwitterionic and cationic species, respectively. The logarithmic form of Eq. 1 is, therefore,

$$pK = pH + \log \left(\frac{RH^+}{R^\pm} \right) \quad (\text{Eq. 2})$$

If β is defined as the fraction of the total acylcarnitine that is protonated or ionized, then

$$\beta = \frac{(RH^+)}{(R^\pm) + (RH^+)} \quad (\text{Eq. 3})$$

and Eq. 2 becomes

$$pK = pH + \log \frac{\beta}{1 - \beta} \quad (\text{Eq. 4})$$

If the hydrogen- or hydroxyl-ion concentration is not negligible compared to the concentration of acylcarnitine, the condition of electrical neutrality must be considered and these equations must be modified according to a standard method described by Albert and Serjeant (9).

RESULTS

Titration of Monomers—The pK values of 0.01 M solutions of carnitine and those acylcarnitines that are monomeric at this concentration are given in Table II. The pK values of other compounds having structures similar to the carnitines are shown for comparison. As expected from Eq. 4, the values are independent of the degree of ionization, β , and of temperature in the range of 20–40°. The pK values obtained at concentrations as high as 0.10 M differed only slightly. The pK of acetylcarnitine is increased by 0.1 pK unit in the presence of 0.2 M LiCl, NaCl, KCl, KBr, or KI, indicating a relatively small ionic strength effect and no specific effect for these ions.

Effects of Concentration—The pK values of cationic decylcarnitine determined potentiometrically are shown in Fig. 1. It can be seen that the pK is constant below the CMC, indicating that the surfactant behaves as a normal electrolyte at these concentrations. Above the CMC (Fig. 1) the pK is dependent on concentration due to the changing ratio of monomeric to micellar surfactant. After this transition region the pK begins to become constant again, due

Figure 1—Effect of micelle formation on the observed pK of decylcarnitine ($\beta = 0.5$).

Figure 2—Titration curves (observed pK versus β) for laurylcarnitine at several concentrations of added KCl. Key: \circ , no salt; \bigcirc , 0.05 M; \square , 0.10 M; and \triangle , 0.20 M.

to the diminishing ratio of the monomeric surfactant to the micellar surfactant. This type of concentration dependence was observed by Ekwall *et al.* for certain cholates (10) and by Tokiwa and Ohki for alkyl amine oxides (11).

Titration of Micelles—At concentrations significantly greater than the CMC (where the contribution of the monomer to the titration curve is negligible) the apparent ionization constant, pK, at any value of β is not independent of β , as is usually the case for monomers. These values, however, are independent of temperature. Figures 2–4 show curves of pK versus β for lauryl-, myristyl-, and palmitylcarnitine at several concentrations of added KCl.¹ Values of pK appear to decrease linearly at lower degrees of ionization and extrapolate to a pK at $\beta = 0$ of 4.85 ± 0.03 . The change in pK with β is less pronounced at high salt concentrations. Figure 5 contains the titration curves of myristylcarnitine in 0.2 M LiCl, NaCl, KCl, KBr, and KI, and indicates that the curves for the three chlorides are identical while those for titration in KBr and KI show significantly higher pK values for each β .

DISCUSSION

The pK values of butyric acid, pentanoic acid, hexanoic acid, and most other aliphatic acids are all about 4.83 ± 0.03 . This value may therefore be taken as the intrinsic pK or pG for an aliphatic carboxylic acid. The difference in pK between each compound listed in Table II and 4.83 is proportional to the work required to bring a proton from infinity to the site of the carboxylate group on the molecule. Thus, if the acid also has a positively charged group, work must be done to bring a proton to the molecule, and the pK decreases. If the acid molecule contains a negatively charged group, free energy is lost by the process of bringing a proton to the molecule and the pK increases. The magnitude of this effect is given by the expression (12)

$$pK - pG = 0.434 \frac{ze}{D_E R k T} \quad (\text{Eq. 5})$$

¹ These curves are also independent of the concentration of acylcarnitine present as long as the ionic strength is not changed. Because of the high CMC of decylcarnitine, titration curves which are free of contributions from monomers present could not be obtained, but significant differences in pK below and above the CMC were noted.

Figure 3—Titration curves (observed pK versus β) for myristylcarnitine at several concentrations of added KCl . Key: \circ , no salt; \square , 0.05 M; \diamond , 0.10 M; and Δ , 0.20 M.

where ϵ is the charge on an electron or carboxylate group; z is the charge of the substituent; R is the distance between the substituent and the carboxyl group; and D_B is the effective dielectric constant separating the substituent and the carboxyl group.

From the data in Table II, it can be seen that carnitine and the acylcarnitines have pK values which are significantly lower than 4.83. These low values are primarily due to the electrostatic interaction between the positively charged nitrogen and the carboxyl group as already discussed. In addition to the above ion-ion interactions, ion-dipole, hydrogen-bonding, and steric interactions involving other groups on the molecule can contribute to the change in the ionization constant of a carboxylic acid. For instance, both the β -hydroxy and β -acyl substituted derivatives have lower pK

^a Literature values (10).

values than compounds having the same structure except for these β -substituents. The pK values of the four acylcarnitines are nearly the same, indicating that the size of the acyl group has little or no effect on the electrostatic interactions of these compounds. The reason for the difference in pK values between carnitine and its esters (about 0.2 pK unit) is unclear. However, it is likely that the ester carbonyl interacts with the carboxyl group and facilitates dissociation of a proton.

The structures of GBB and GABA are identical except for the substituents on the quaternary nitrogen and, likewise, the structures of carnitine, norcarnitine, and γ -amino- β -hydroxy butyric acid differ only in the number of methyl groups on the nitrogen. The fact that the first two compounds have the same pK value and the remaining three pK values are the same indicates that the electrostatic interaction is independent of the minimum distance with which the quaternary nitrogen and the carboxyl group can approach each other. This interpretation is in agreement with the results of other workers (12, 13), who determined that the carboxyl proton and the quaternary nitrogen of GABA are from 4 to 6 Å apart, *i.e.*, that the molecule is almost fully extended. In view of this the cyclic conformation proposed for acetylcarnitine by Fellman and Fujita (14) seems unlikely.

In the titration of a carboxyl group on a positively charged surface, such as the surface of an acylcarnitine micelle, the observed pK at a particular degree of ionization is dependent upon the surface potential of the micelle, ψ . This relationship is expressed by an equation analogous to Eq. 5, known as the general potentiometric equation for polyelectrolytes (12, 15–18). This equation has been shown to be valid for micelles by Tokiwa and Ohki (19, 20):

$$pK = pG + 0.434 \frac{\epsilon\psi}{kT} \quad (\text{Eq. 6})$$

As in Eq. 5 the term pG is related to the work of protonating the carboxyl group in an uncharged environment, *i.e.*, when $\beta = 0$, and the last term in the equation is related to the work required to bring the proton to the micelle surface from infinity. Equation 6 can be rearranged so that ψ is expressed in terms of the difference between the observed and intrinsic pK values:

$$\psi = 2.303 \frac{kT}{\epsilon} (pK - pG) \quad (\text{Eq. 7})$$

This method of determining the surface potential of a micelle is more convenient than the electrophoretic method (21–23) since it is rapid and requires no equipment other than a pH meter. Since it gives the potential at the plane of the carboxyl groups, it has theoretical advantages over the electrophoretic method in that the value is independent of the thickness of the hydration layer. This method is not limited to the present system, but can be applied to any titratable group solubilized at a micelle surface including those of the surfactant itself.

The values of ψ obtained by applying Eq. 7 to the data shown in Fig. 3 are plotted in Fig. 6. The surface potentials of lauryl-, myristyl-, and palmitylcarnitine at $\beta = 0.1, 0.5$, and 1.0 and at

Figure 5—Plots of surface potential versus β for myristylcarnitine at several concentrations of added KCl. Key: \circ , no salt; \bigcirc , 0.05 M; \square , 0.10 M; and \triangle , 0.20 M.

several concentrations of added KCl are shown in Table III for comparison. It can be seen from this table that the surface potentials at a given degree of ionization and, ionic strength show no dependence on the length of the aliphatic chain, suggesting that the surface-charge density and, therefore, the surface packing in the micelle is the same for these three compounds.

In order to interpret quantitatively the effect of β and ionic strength on the surface potential and hence the pK, it is necessary to express ψ in terms of measurable parameters such as micelle radius, b , aggregation number, n , and the net charge on the micelle at a given degree of ionization, Z . Unfortunately, this cannot be done analytically for a small spherical particle such as a micelle but it can be approximated; one such approximation is that of Debye-Hückel (12):

$$\psi = \frac{2kT}{\epsilon} wZ \quad (\text{Eq. 8})$$

where w , the electrostatic factor, is given by

$$w = \frac{\epsilon^2}{2DKT} \left[\frac{1}{b} - \left(\frac{\kappa}{1 + \kappa a} \right) \right] \quad (\text{Eq. 9})$$

where a is b plus the average radius of the electrolyte ions,² D is the dielectric constant at the micelle surface, and κ is the inverse Debye radius which is given by

$$\kappa = \left(\frac{4\pi\epsilon^2 I}{DKT} \right)^{1/2} \quad (\text{Eq. 10})$$

where I is the ionic strength of the solution.

This approximation is valid for impenetrable spherical particles at low surface potential and at low concentrations of 1:1 electrolytes. It is assumed further that the net charge on the particle is spread evenly over the surface. Although this is not the correct physical situation, it has been shown (18, 24, 25) that under these conditions a more rigorous fixed charge model gives almost the same results as a spread charge model. This would be especially true for a micelle in which the individual charges are free to arrange themselves so that they are evenly spaced, i.e., in their lowest energy state. The ability of the cationic and anionic

Table III—Surface Potentials for Acylcarnitines at Several Degrees of Ionization (β) and Several Concentrations of Added Electrolyte

Concentration Added KCl, moles/l.	Surface Potential, mv.		
	Laurylcarnitine	Myristylcarnitine	Palmitylcarnitine
$\beta = 0.10$			
0.00	26.6	29.6	42.6
0.05	24.2	21.9	—
0.10	17.2	17.7	20.1
0.20	14.2	14.8	15.4
$\beta = 0.50$			
0.00	87.1	102	91.7
0.05	73.7	77.0	—
0.10	68.0	66.8	68.0
0.20	62.2	62.7	62.2
$\beta = 1.00$			
0.00	117	117	113
0.05	104	104	—
0.10	97.2	97.2	96.0
0.20	89.0	88.7	90.6

groups of acylcarnitines to arrange themselves in such a manner seems very likely in view of the titration behavior of the monomeric species, which suggested that these groups were far enough apart to interact with neighboring molecules.

If the micelle has an aggregation number of n and a degree of ionization of β , the net charge is given by

$$Z = n\beta \quad (\text{Eq. 11})$$

and Eqs. 6 and 8 become, respectively,

$$\text{pK} = \text{pG} + 0.868 wn\beta \quad (\text{Eq. 12})$$

and

$$\psi = \frac{2kT}{\epsilon} wn\beta \quad (\text{Eq. 13})$$

From Eqs. 12 and 13, it can be seen that at $\beta = 0$, pK must equal pG, and ψ must become zero. Indeed the value of the experimentally

Figure 6—Effects of specific monovalent ions on the titration curves of myristylcarnitine. Key: \triangle , 0.20 M KCl; \bigcirc , 0.20 M LiCl; \square , 0.20 M NaCl; \bullet , 0.20 M KBr; and \blacklozenge , 0.20 M KI.

² Since the distance between charges on the micelle surface is considerably greater than the radius of the electrolyte ions, and since the micelle surface is probably not smooth, it might be more correct to let $a = b$, i.e., to assume that the electrolyte ions behave as point charges.

determined pG is in excellent agreement with the literature value for aliphatic carboxylic acids. The apparent linearity in the pK versus β with ψ versus β curves (Figs. 1-4) at low β is expected from Eqs. 12 and 13. The deviation of all of the curves from linearity at high β is probably due to a change in n or w with increasing charge, or more likely to the failure of the Debye-Hückel approximation at high potential (26). Further investigations of the relationship between w , n , and β are now being carried out using other mathematical treatments and experimental measurements of the micelle size (27).

The fact that the pG values of all of the acylcarnitines are independent of concentration of surfactant and added KCl (Figs. 2-4) indicates that neither K^+ nor Cl^- are bound to the zwitterionic micelle. Figure 5 shows that Li^+ and Na^+ also are not bound to the neutral micelle but that Br^- and, to an even greater extent, I^- appear to be bound (28). This order of ion binding to cationic micelles has been noted previously (29). The fact that Cl^- , Br^- , and I^- do not exhibit different effects on the titration of the monomeric acetylcarnitine suggests that these specific ion effects are, indeed, dependent on the presence of the micellar surface.

CONCLUSIONS

The pK values of micellar surfactants such as the acylcarnitines are not constant but change with β , the degree of ionization of the micelle. The difference between the pK value observed at a particular value of β and the intrinsic pK for a carboxyl group has been utilized to determine the surface potential ψ at that value of β .

A model utilizing the Debye-Hückel approximation has been shown to be qualitatively consistent with experimental results.

The ionization constants and surface potentials of lauryl-, myristyl-, and palmitylcarnitine micelles at any given value of β are independent of chain length but are highly dependent on ionic strength. Specific ion effects are observed for Br^- and I^- but not for Li^+ , Na^+ , K^+ , or Cl^- .

The significant effect of surface charges on the ionization equilibria of this particular micellar system suggests the general importance of these considerations for understanding kinetic and adsorption processes involving charged species at charged interfaces such as micelles, monolayers, bilayers, and biological membranes.

Placental Transfer of Pentobarbital in the Rat

DAVID P. S. MORK*, WAYNE V. KESSLER, and STANLEY M. SHAW

Abstract □ The placental transfer of pentobarbital and/or metabolites was determined in rats using ^{14}C -labeled pentobarbital. The level of pentobarbital and/or metabolites in fetal blood was greatly influenced by the circulating level of pentobarbital and/or metabolites in the mother. Of the total pentobarbital and/or metabolites transferred, the percentage of unbound pentobarbital in fetal blood plasma was influenced by the pentobarbital dose level administered to the pregnant rat. A greater percentage of total pentobarbital and/or metabolites was present as unbound pentobarbital in fetal blood plasma than in maternal blood plasma. Chronic administration of pentobarbital during gestation decreased sensitivity to the pharmacological effects of further drug administration to the newborn. The changes induced by pretreatment were not permanent.

Keyphrases □ Placental transfer, rat—pentobarbital, metabolites □ Pentobarbital, labeled—fetal blood □ Fetal blood concentration, pentobarbital—maternal blood concentration □ Scintillometry—analysis □ TLC—analysis, radioactivity

Placental transfer of pentobarbital in the human at term was reported by Flowers (1). Transfer was determined by measuring pentobarbital in the arterial and venous blood of the umbilical cord. By observing a decrease in the respiratory rate of the newborn, Dreisbach and Synder (2) determined that pentobarbital crosses the placenta of the rabbit at term. In this investigation, ^{14}C -labeled pentobarbital was employed to determine the placental transfer of pentobarbital and/or metabolites, as well as unbound pentobarbital in the rat. In addition, the influence of chronic pentobarbital administration to the pregnant rat on the sleep time and the blood level of bound and/or unbound pentobarbital required for sleep was studied in the newborn.

EXPERIMENTAL

Animal Care and Mating—Sprague-Dawley¹ albino rats (200–210 g.) were housed individually in screen wire-bottom hanging cages in a controlled light environment. Animals were allowed food² and water *ad libitum*. Prior to being used for experimental study, the animals received 5 min. of handling daily for 2 weeks to reduce stress.

For mating, one male was placed with one female at 5:00 p.m. The male was removed at 7:00 a.m. the following morning and a vaginal smear was taken. The slides were fixed in 95% methanol, stained with Giemsa's blood stain,³ and examined microscopically to determine the estrous cycle of the rat. When sperm were present during estrous, the female was assumed to be mated (3). On Day 18 of gestation, wood shavings were added for bedding to satisfy the nesting instinct.

Labeled Pentobarbital—The labeled compound used was 5-ethyl-5-(1-methylbutyl)barbituric-2- ^{14}C acid.⁴ It was converted to the sodium salt with 0.01 N sodium hydroxide, and the resulting solution was used throughout this study. Chemical purity and radiochemical purity were determined chromatographically using unlabeled

authentic pentobarbital and the two solvent systems to be described later. No chemical impurities were found; the radiochemical purity was greater than 99.5%. The specific activity of the labeled pentobarbital injected into rats was 4 $\mu\text{C}/\text{mg}$.

Determination of Radioactivity—Individual tissue samples were placed in tared counting vials containing 1 ml. of a solution of a quaternary ammonium compound,⁵ weighed, and dissolved by heating at 60° for 2 hr. with gentle agitation. The vials were cooled; the samples were decolorized with 0.5 ml. of 30% hydrogen peroxide. Glacial acetic acid, 0.5 ml., was added to minimize protein phosphorescence. After 10 min., 15 ml. of XDC scintillator⁶ was added to each sample. The samples were counted in a Tri-Carb⁷ using the internal standard method (5) to determine the absolute disintegration rates. The maximum counting error was 1%.

Chromatography—TLC plates were prepared with a distilled water slurry of equal parts of two commercial adsorbents.⁸ The plates were air-dried, activated in an oven at 100° for 1 hr., and cooled to room temperature prior to spotting. The plates were developed in either a chloroform-acetone (9:1) solvent or a dioxane-benzene-ammonium hydroxide (4:15:1) solvent (6, 7).

Compounds were visually located using UV light. The chromatograms were then sprayed⁹ and exposed to Kodak No Screen medical X-ray film¹⁰ for a time period which allowed approximately 10^8 disintegrations/cm.² to occur. The films were developed with Kodak chemicals according to manufacturer's instructions. Labeled compounds on a chromatogram were quantitatively removed for counting by scraping the adsorbent containing the compound from the plate. The adsorbent was placed in a counting vial containing 15 ml. of XDC; colloidal silica¹¹ was added to form a thixotropic gel. The total radioactivity on the developed plate was summed and considered as 100% of the radioactivity applied. The radioactivity found in a labeled compound was expressed as a percentage of the total applied.

Optimal Time of Sacrifice—Animals were injected intraperitoneally with a 10-mg./kg. dose of labeled pentobarbital on Day 19 of gestation. Day 19 was selected because most compounds have been shown to cross the placental barrier to the greatest extent near the termination of gestation. Groups of animals were sacrificed with ether 1, 3, 6, 12, or 24 hr. following drug administration. Blood samples were obtained from the heart of the mother and fetus. On the average, the blood sample obtained from each fetus weighed approximately 115 mg. From each mother, certain fetuses were removed, weighed, frozen in liquid nitrogen, placed between sheets of plastic, and pulverized. The powdered fetus was thoroughly mixed and a sample was taken and prepared for counting.

The ^{14}C -radioactivity was determined for blood and tissue samples. In this phase of the investigation, no attempt was made to differentiate between pentobarbital and metabolites. The ^{14}C -radioactivity was expressed as micrograms of pentobarbital per gram of sample.

Effect of Dose Level—Pregnant animals were injected intraperitoneally on Day 19 of gestation with a 5- or 25-mg./kg. dose of labeled pentobarbital. The animals were sacrificed 1 hr. after injection, and samples of various tissues were taken. The ^{14}C -radioactivity was expressed as micrograms of pentobarbital per gram of sample. Maternal and fetal blood were also obtained for determina-

tion of unbound pentobarbital. Each whole-blood sample was centrifuged for 10 min. in a heparinized capillary centrifuge tube¹² which was sealed with a commercial clay.¹³ The capillary tube was broken just above the interface between white blood cells and plasma, and the plasma was spotted on a thin-layer plate. Authentic ¹⁴C-labeled pentobarbital was also spotted for reference. The plate was developed; labeled compounds were located and quantified according to procedures previously described. The percentage of the total ¹⁴C-radioactivity on the chromatogram that represented unbound pentobarbital was determined.

Effect of Pretreatment during Pregnancy on the Sleep Time and Dose Required for Sleeping in the Newborn—Pregnant rats were injected intraperitoneally on Days 11–20 of gestation with 10 mg./kg. of unlabeled pentobarbital. Pregnant control rats received saline solution. The animals were allowed to give birth. Each litter was reduced to six animals to keep maternal care a constant. From each litter, three of the young rats were studied 5 days following birth and the other three were studied 30 days after birth. Rats were weaned 25 days after birth. During the time interval previous to the determination of sleep time, no attempt was made to reduce stress in the 5-day-old animals by daily handling. The 30-day-old rats were handled daily for 10 min. for a period of 6 days prior to sleep studies.

The 5-day-old rats were injected intraperitoneally with 20 mg./kg. of labeled pentobarbital, while the 30-day-old rats received 30 mg./kg. The sleep time was determined by measuring the loss of the righting reflex. Upon return of the righting reflex, blood was removed from the heart to determine the level of bound and/or unbound pentobarbital in the blood which was just below the level required for sleep. Bound and/or unbound pentobarbital was extracted from blood according to the method of Brodie *et al.* (8). This extraction method removes bound and unbound pentobarbital while excluding metabolites of pentobarbital. The petroleum ether layer was added to the XDC scintillator, and ¹⁴C-radioactivity was determined. Counting data were expressed as pentobarbital.

Analysis of Results—The Student *t* test (9) was used to test the results of the treatments for significant differences. All results were tested at the 95% level of significance.

RESULTS AND DISCUSSION

Optimal Time of Sacrifice—The results are presented in Table I. Fetal and maternal blood levels of pentobarbital and/or metabolites at 12 and 24 hr. postinjection were significantly different from each other and from the values at 1, 3, and 6 hr. Values at 1, 3, and 6 hr.

were not significantly different from each other. In general the measurable level of pentobarbital and/or metabolites in all tissues declined rapidly after 3 hr. One hour after injection was the time selected for sacrifice for the remainder of the study.

For each time interval, the ratio of the fetal blood level of pentobarbital and/or metabolites to the maternal blood level was calculated. No significant difference was found between any of the ratios. The results indicate that by 1 hr. after injection an equilibrium had been established between the pentobarbital and/or metabolite level in the maternal and fetal blood.

Effect of Dose—As may be seen in Table II, an increased dose of pentobarbital administered to the pregnant rat resulted in an increased level of pentobarbital and/or metabolites in all of the tissues studied. The ratios of the amount of pentobarbital and/or metabolites in the fetal blood to the amount in the maternal blood were not significantly different for the two dose levels. Thus, the level of pentobarbital and/or metabolites in the fetal blood was directly proportional to the pentobarbital and/or metabolite level in the maternal blood, regardless of the dose administered to the pregnant rat.

Results of the determination of the unbound pentobarbital level in fetal and maternal blood plasma are shown in Table III. The results are expressed as the percentage of the total ¹⁴C-radioactivity on a chromatogram which represented unbound pentobarbital. The data show that a higher percentage of total pentobarbital and/or metabolites was present as unbound pentobarbital in fetal blood plasma than in maternal blood plasma. The relationship was true for both dose levels. The data indicate that unbound pentobarbital transfers through placental membranes more readily than bound pentobarbital and/or metabolites.

There was a significant increase in the percentage of unbound pentobarbital in the maternal and fetal blood when the dose was increased from 5 to 25 mg./kg. As was already shown, an increase in the pentobarbital dose administered to the pregnant rat increased the total pentobarbital and/or metabolites that transferred across the placenta. Of the total compound that transferred, a higher percentage of unbound pentobarbital was present in the fetal blood plasma at the higher dose level than was present at the lower dose level.

Effect of Pretreatment during Pregnancy on the Sleep Time and Pentobarbital Blood Level Required for Sleeping in the Newborn—As may be observed from the results presented in Table IV, there was a significant decrease in sleep time of 5-day-old newborn rats from pretreated mothers compared to 5-day-old newborn rats from control mothers. These results agree with the findings of Hart *et al.* (10) in a study of the stimulation of hepatic microsomal drug metabolism in the newborn and fetal rabbit. The data in Table IV show that a higher blood level of bound and/or unbound pentobarbital was required to induce sleep in the 5-day-old newborn rats from pretreated mothers, which indicated a decreased sensi-

Pretreated	6	94.50 ± 2.37	12.19 ± 0.23

^a Sleep time is expressed as the duration of the loss of the righting reflex. Pentobarbital blood level required for sleep is expressed as the level of bound and/or unbound pentobarbital in the blood, which was necessary for the loss of the righting reflex. ^b Day after birth at which sleep study was conducted. ^c Newborn from mothers treated with saline solution during gestation. ^d Mean ± standard error. ^e Newborn from mothers receiving pentobarbital during gestation.

tivity to the pharmacologic effect of the drug. The 30-day-old pretreated rats exhibited neither a lower sleeping time nor a higher dose required for sleep when compared to 30-day-old rats from control mothers, indicating that in the intervening time interval the effects of pretreatment were not permanent.

SUMMARY

Pentobarbital and/or metabolites reached an equilibrium between maternal and fetal circulation within 1 hr.

An increased dose of pentobarbital administered to the pregnant rat resulted in an increased level of pentobarbital and/or metabolites in all tissues studied. The level of pentobarbital and/or metabo-

lites in fetal blood was greatly influenced by the circulating level of pentobarbital and/or metabolites in the mother. Of the total compound transferred, a higher percentage of unbound pentobarbital was present in the fetal blood plasma at the higher dose level than was observed in animals receiving a lower dose of pentobarbital. A higher percentage of total pentobarbital and/or metabolites was present as unbound pentobarbital in fetal blood plasma than in maternal blood plasma.

The placental transfer of pentobarbital during chronic administration to pregnant rats caused a decreased sensitivity to the pharmacological effects of further drug administration to the newborn. Five-day-old newborn rats from pentobarbital pretreated mothers exhibited a decrease in sleep time, with a higher bound and/or unbound pentobarbital blood level being required for sleep. The changes induced by pretreatment were not permanent and did not exist by the time the rat was 30 days old.

Kinetics of Urinary Excretion of D-(–)-Mandelic Acid and Its Homologs I: Mutual Inhibitory Effect of D-(–)-Mandelic Acid and Its Certain Homologs on Their Renal Tubular Secretion in Rats

EDWARD J. RANDINITIS*, MARTIN BARR, HENRY C. WORMSER, and JANARDAN B. NAGWEKAR†

Abstract □ It has been shown from the apparent first-order urinary excretion studies of D-(–)-mandelic acid and certain of its homologs, DL-tropic acid, D-(–)-4-hydroxy-4-phenylbutanoic acid, DL-phenyllactic acid, and D-(–)-benzylactic acid, that the biological half-lives of the homologs are significantly shorter than that of D-(–)-mandelic acid in rats. Since these compounds, which differ from each other in their content of methylene groups around the carboxyl group, exhibit negligible metabolism and protein binding, low pKa values (3.3–4.7), and low lipid solubility at the physiological pH, and are primarily recovered in the urine in the intact form, they are utilized in these studies as model compounds to study the effect of hydrophobic group(s) on the rate of secretion. These compounds are shown to exert a mutual inhibitory effect on their renal tubular secretion, indicating a common "carrier" mechanism for their secretion. The utilization of these compounds indicated that the addition of methylene group(s) in the vicinity of the carboxyl group of the mandelic acid molecule increased its affinity for the carrier molecules of the renal tubular secretion system in rats.

Keyphrases □ D-(–)-Mandelic acid and homologs—mutual inhibition of urinary excretion □ Urinary excretion—D-(–)-mandelic acid and homologs □ Excretion rates, apparent—D-(–)-mandelic acid and homologs □ ORD—identity □ Polarimetry—identity □ GLC—analysis

Although considerable work has been reported showing the effect of variation of hydrophobic groups within a weakly acidic drug molecule on its rate of transport through kidney slices (1–3), little such work has been carried out *in vivo*. Furthermore, in *in vivo* work, the determination of the effect of hydrophobic variations in the molecule on the rate of urinary excretion and kidney tubular secretion has been shown to be complicated due to the differences of the homologs in their extent of binding to plasma proteins, pKa values, and partition coefficients between a lipid phase and water. The objectives of such studies were to investigate the physicochemical nature of the transport system involved in the kidney tubular secretion of drugs and other chemicals and to gain some insight into the structural specificity of a drug molecule for the transport system. The compounds commonly employed in such studies are *p*-aminohippurate (4), phenylbutazone (5), *p*-aminosalicylic acid (6), salicylic acid (2), and chlorothiazide (7).

From the studies of renal excretion of phenylbutazone analogs (5) and sulfonamide analogs (8), it has been shown that the rate of excretion of most of these compounds is inversely related to their pKa values at the normal slightly acidic urine pH. However, in their inhibitory studies of hippurate transport by phenylbutazone analogs in the kidney slices of dogs and rabbits, Despopoulos *et al.* (9) found a lack of a clearcut relationship between the inhibitory capacity of the phenylbuta-

zone analogs and their pKa values and lipid solubility. Despopoulos and Callahan (10) observed that the reabsorption of certain sulfonamides with pKa values greater than the normal urine pH of 6 to 7 occurs from the renal tubules, and it makes difficult the interpretation of data to correlate the chemical affinity of drug analogs to the renal transport system. This problem becomes further complicated if a drug is largely metabolized and the metabolites interfere with the secretion of the parent compound, as observed with substituted benzoic acids (11).

Rammelkamp and Bradley (12) and Beyer *et al.* (13) were among the first to demonstrate that iodo-pyracet¹ and *p*-aminohippurate cause an increase in the blood levels of penicillin due to the competition of the inhibitors with penicillin for the carrier of secretory process in the renal tubular membrane. Similar inhibitory effects of probenecid on the urinary excretion of the optical isomers of mandelic acid have been demonstrated in humans by Nagwekar and Kostenbauder (14). Kamienny *et al.* (15) have also shown that, in humans, sulfadiazine, sulfamerazine, sulfamethazine, and (–)-mandelic acid probably share the same renal tubular transport mechanism for secretion. Various possible mechanisms suggested for the inhibition of transport of compounds through renal tubular membranes have been shown to depend on the chemical nature of the substrate and the inhibitor (16). The type of inhibition which is widely studied for the transport of substances across the renal tubular membrane is that in which the substrate and inhibitor probably share the same transport carrier.

The purposes of this project were to study the kinetics of urinary excretion of a model acidic compound and its homologs, which differ from each other in the content of their hydrophobic groups, such as methylene groups, and to determine their biological half-lives and initial excretion rates in the absence and presence of each other in rats. If such compounds are secreted by the same pathway, it may then be expected that they would mutually inhibit the secretion of each other. For reasons described later, D-(–)-mandelic acid is considered as a model compound and is used in the present studies. The compounds used in these studies are listed in Table III. The differences in the initial urinary excretion rates or the biological half-lives that these compounds show are attributed to the differences in the hydrophobic interactions which take place between the compounds and a carrier or carrier system. As described in the next paper

¹ Diodrast, Winthrop Laboratories, New York, N. Y.

in this series (17), an additional objective of this project was to gain some insight into the structural and chemical specificity that the carrier transport system of the renal tubule shows toward anionic drugs by studying the Michaelis-Menten-type kinetics of secretion of these compounds.

EXPERIMENTAL

Materials—D-(−)-Mandelic acid,² m.p. 132–133°, $[\alpha]_{25}^D$ −154.2° (c, 1.94, H₂O); DL-tropic acid,² m.p. 118–119°; D-(−)-tropic acid, m.p. 123–124°, $[\alpha]_{25}^D$ −75° (c, 1.60, H₂O); and L-(+)-tropic acid, m.p. 126–127°, $[\alpha]_{25}^D$ +77.4° (c, 1.94, H₂O), were obtained by the resolution of DL-tropic acid by the method of King (18); DL-phenyllactic acid, m.p. 96–97°, $[\alpha]_{25}^D$ −20.0° (c, 1.89, H₂O); and D-(+)-phenyllactic acid, m.p. 121–122°, $[\alpha]_{25}^D$ +21.2° (c, 2.05, H₂O), were synthesized by the method of Eiduson *et al.* (19) from the corresponding isomers of phenylalanine. D-(−)-Benzylactic acid, m.p. 113–115°, $[\alpha]_{25}^D$ −10.0° (c, 1.50, ethanol), and the sodium salt of D-(−)-4-hydroxy-4-phenylbutanoic acid, $[\alpha]_{25}^D$ −12.9° (c, 1.55, H₂O), were obtained on resolving (20, 21) the corresponding racemic acids synthesized by the known procedures (22).

Apparatus—The compounds appearing in the urine of rats were quantitatively analyzed with the aid of an F & M model 810R-19 gas chromatograph equipped with a hydrogen-flame detector. The column employed was a 1.21-m. (4-ft.) long and 0.63-cm. (0.25-in.) o.d. copper tube packed with 80–100 mesh diatomite (Diatoport S) coated with 5% ethylene glycol succinate. Helium was employed as the carrier gas. A Beckman model 72 pH meter equipped with a combination electrode was used for the pH determinations. The specific rotation of the optically active compounds were determined at 25° with the aid of a J & J Fric model 2706 polarimeter using a sodium lamp as the source of light. The optical rotatory dispersion (ORD) curves of the compounds were obtained with the aid of a Cary model 60 recording spectropolarimeter.

Methodology—During the course of these studies, about 30 Sprague-Dawley male rats weighing between 165 and 210 g. were repeatedly used. None of the rats was used more than five times in these studies, and the rest period allowed between the successive use of a rat was at least 1 week. Food was withheld from the animals for 12–18 hr. prior to the administration of the compounds and during urine collection; water was allowed *ad libitum* throughout this period. To induce prompt urination, 5 ml. of water was administered intraperitoneally to each rat 15–20 min. prior to the intravenous administration of the compounds.

The compounds were administered in the dosage range of 150–700 μ mole/kg. (5–20 mg./rat) by the intravenous route *via* the tail vein. The compounds were administered as aqueous isotonic solutions of their sodium salts, prepared by the addition of an equivalent amount of sodium hydroxide to an aqueous solution of the acid. In inhibitory urinary excretion studies involving equivalent doses of each compound, an isotonic solution was prepared containing the appropriate dose of the sodium salt of each of the compounds and administered by the i.v. route to the rats. However, in the inhibitory studies involving a larger dose of the inhibitor, the i.p. administration of $1.0\text{--}1.7 \times 10^4$ μ mole/kg. (300–500 mg./rat) dose of inhibitor was found necessary. A solution containing an appropriate dose of the sodium salt of the inhibitor dissolved in 5 ml. of water was prepared and administered by the i.p. route 15–20 min. prior to the i.v. administration of the substrate compound.

Each rat was placed into a urine-collection cage immediately after the administration of the substrate compound. The urine-collection cage consisted of a 20.32-cm. (8-in.) plastic funnel, two chrome-plated wire baskets, and a 50-ml. graduated cylinder as shown in Fig. 1. A fine wire-mesh screen was fitted at the inner opening of the funnel to prevent rat feces from contaminating the urine. However, the rats rarely defecated during the first 3 hr. of urine collection, during which time most of the compound was recovered. Also, it was demonstrated in the preliminary studies that the excretion of the compounds in the feces was negligible. An animal drinking tube was forced through the wire basket to allow the animal water during the study.

Table I—Conditions Employed for Gas Chromatographic Analysis and Retention Times Observed for the Compounds

Compound	Oven Temp. ^a	He Flow Rate, ml./min.	Retention Time, min.
Methyl mandelate	165°	60	5.8
Methyl tropate	180°	40	8.2
Methyl phenyllactate	180°	40	5.4
Methyl benzylactate	180°	40	7.4
Phenylbutyrolactone	175°	60	17.0

^a The injection port and detector temperatures were maintained at 210°.

After the administration of the compound, the rat was observed for 2 hr. in which four to seven urine samples were carefully collected at intervals of 10–30 min. After each passage of urine, the genitalia of the rat were washed with a stream of water from a wash bottle, and the rat was transferred to another urine-collection cage. The cage was thoroughly washed with water, and the urine and washings were brought up to a suitable volume with water. The subsequent urine samples collected over a period of 2–24 hr. were pooled into one sample prior to analysis. The urine samples were analyzed on the same day of collection for the compounds.

Analysis of the Compounds—The urine samples were quantitatively analyzed for intact compounds appearing in the urine by a gas chromatographic method described by Kamienny *et al.* (15) after converting the acids to their methyl esters upon treating with diazomethane. This procedure was employed for the analysis of all the compounds except 4-hydroxy-4-phenylbutanoic acid, which was converted to the corresponding lactone by the addition of enough 5 N hydrochloric acid solution to adjust the pH of the urine sample to approximately 2 prior to its ether extraction and gas chromatographic analysis. This was necessary because 4-hydroxy-4-phenylbutanoic acid readily forms a lactone in the strongly acidic medium, and the lactone thus formed can be quantitatively analyzed by gas chromatography. The lactone is readily reconverted to the 4-hydroxy-4-phenylbutanoate ion at pH 6 and above, which usually is the pH range of rat urine. The conditions employed for the gas chromatographic analysis and the retention times observed for the methyl esters of the compounds are described in Table I.

Dissociation Constants, Apparent Partition Coefficients, and Binding of Compounds to Whole Blood (Rat)—The dissociation constants of the compounds were determined using a titrimetric procedure. A 20-mg. quantity of each acid dissolved in 10 ml. of

Figure 1—Urine collection cage employed in the studies.

Table II—Values of pKa and Partition Coefficient Determined for the Compounds

Compound ^a	pKa (Observed)	Apparent Partition Coefficient	
		$C_{\text{chloroform}}$ C_{water}	C_{ether} C_{water}
D-(–)-Mandelic acid	3.35 (3.36) ^b	c	d
DL-Tropic acid	4.20 (4.12) ^b	c	d
DL-Phenyllactic acid	3.80	c	d
D-(–)-Benzylactic acid	3.85	<0.01	<0.01
D-(–)-4-Hydroxy-4-phenylbutanoic acid	4.70	0.32	0.35

^a The assignment of the absolute configuration of the compounds was based on their optical rotatory dispersion curves as explained in the text. ^b Values reported in the literature. ^c The compound was absent in the chloroform layer. ^d The compound was absent in the ether layer.

water was titrated with 0.01 *N* sodium hydroxide solution; the pKa, which is equivalent to the pH at one-half neutralization, was determined.

An apparent partition coefficient was determined between a phosphate buffer at pH 7.0 and ether or chloroform representing the lipid phase. In each case, 5 mg. of the acid was dissolved in 10 ml. of the buffer and shaken with an equal volume of either chloroform or ether. Each phase was analyzed for acid content by the gas chromatographic procedure.

The studies to determine the binding of D-(–)-mandelic acid and each of its homologs by whole blood (rat) were carried out by the equilibrium dialysis procedure. Whole blood (rat) was obtained by decapitation, collecting the blood in a 150-ml. beaker previously coated with 2 ml. of heparin sodium.³ Four milliliters of freshly collected whole blood was placed into a Visking dialysis bag, sealed, and placed into a 4–5-dr. (15–20 ml.) bottle with a screw cap. Then, 4.0 ml. of an isotonic phosphate buffered (pH 7.4) solution, containing 1.0 mg. of D-(–)-mandelic acid or its homolog, was placed into the bottle; the bottle was sealed and shaken at $37 \pm 0.5^\circ$ for 6 hr. during which the equilibrium for the system was attained. The bottles were removed from the shaker and immediately the liquid outside of the bag was transferred to a 10-ml. beaker and allowed to attain room temperature. These solutions were then analyzed for mandelic acid or its homolog by the gas chromatographic method. Control studies were carried out in which 4 ml. of the phosphate buffer solution was used in place of 4 ml. of blood. Neither D-(–)-mandelic acid nor any of its homologs used in the present study was found to bind to the dialysis membrane.

RESULTS AND DISCUSSION

Selection of a Model Compound and Its Homologs—Recent studies dealing with the transport of ionic and polar substances through biological membranes have pointed to the existence of a carrier system in the membrane which facilitates such transport. According to current theory, there exists in the membrane separate carrier systems responsible for the transport of organic anions and cations through the renal tubular membrane (2, 11, 16, 23, 24). Evidence for the presence of a common carrier system for the active transport of organic anions has been reported (1, 11). Although the carrier system has not yet been isolated, its constituents are suggested to be protein and/or phospholipid in nature. It is also proposed that while the primary linkage between the carrier and substrate compound to be transported occurs through ionic bonds, the secondary linkages result from hydrophobic bonding between the nonpolar portions of the carrier and substrate molecules or from hydrogen bonding between the appropriate portions of the substrate and carrier molecules (1–3). Such secondary bonding forces are expected to become important in relating the affinity of the molecules to the carrier. Therefore, it is considered of interest to determine the initial rate of secretion of compounds which vary slightly in their content of methylene groups around their anionic sites and to relate the differences in their initial secretion rates to the differences in their hydrophobicity in the molecule.

³ Heparin sodium USP, 1000 units/ml., Testagar and Co., Inc., Detroit, Mich.

The selection of a model compound and its homologs was based on several important properties considered desirable for this study. Among these properties, the most important was that the compounds should be involved in the renal tubular secretory process and be recovered primarily in the urine in the intact form, since this will preclude the possible inhibitory effect of the metabolites on the secretion of the parent compound. The compounds should possess sufficiently low pKa values, so that they will remain in the urine mainly in the ionized form and their passive reabsorption from the renal distal tubule will be minimized. The partition coefficient of the compounds between a lipid phase and water (pH 6–8) should also be as low as possible to prevent their tubular reabsorption. The compounds should exhibit little or no tendency to bind to plasma proteins, since the urinary excretion rate depends on the concentration of the free form of the compound in the blood.

The literature survey indicated that D-(–)-mandelic acid (14, 15) is not metabolized significantly by humans and that DL-tropic acid (25) is not metabolized by rats. Therefore, appropriate preliminary studies carried out in rats indicated that D-(–)-mandelic acid and its homologs (listed in Table II) possess most of the properties described. The recovery of each compound in the unchanged form in the rat urine was found to be 90–100% of the administered i.v. dose. These compounds differ from mandelic acid by the addition of methylene groups in specified positions, in some cases (phenyllactic acid and benzylactic acid) maintaining the hydroxyl group adjacent to the carboxyl groups as in the mandelic acid molecule, and in others (tropic acid and 4-hydroxy-4-phenylbutanoic acid) separating these groups by the additional methylene groups.

The overall metabolism studies of 3-hydroxy-3-phenylpropanoic, 5-hydroxy-5-phenylpentanoic, 6-hydroxy-6-phenylhexanoic, and 2-hydroxy-5-phenylpentanoic acids, carried out in this laboratory, indicated that these compounds are metabolized by rats to the extent of 30–100% of the administered dose. Therefore, these compounds were considered unsuitable for the proposed studies.

Determination of the Dissociation Constants, Apparent Partition Coefficients of the Compounds, and Their Binding to Whole Blood (Rat)—Values of pKa determined for the compounds used in

Figure 2—Apparent first-order urinary excretion of D-(–)-mandelic acid following its i.v. administration of 367-μmole/kg. dose in the absence (●) and 346-μmole/kg. dose in the presence (○) of a 1.2×10^4 μmole/kg. dose of DL-tropic acid to rats.

Figure 3—Apparent first-order urinary excretion of DL-tropic acid following its i.v. administration of 410-μmole/kg. dose in the absence (●) and 344-μmole/kg. dose in the presence (○) of a 1.3×10^4 μmole/kg. i.p. dose of D-(-)-mandelic acid to rats.

the present studies are listed in Table II. These values are found to be in the range of 3.3 to 4.7. Since this range of pKa values is appreciably lower than the range of pH values (6.5–7.5) of the urine of the control rats used in all of the studies, it suggests that these compounds exist in the urine primarily in the ionized form and, therefore, are not likely to be significantly reabsorbed from the urine at the distal renal tubules. It is also evident from the results of the partition studies (Table II) that, except for the slight solubility of 4-hydroxy-4-phenylbutanoic acid, none of the compounds used in these studies is soluble in the lipidlike phase. Therefore, it may be assumed that none of these compounds is subject to significant renal tubular reabsorption from the urine at pH 6.5–7.5.

The results of the binding studies indicated that D-(-)-mandelic acid or any of its homologs used in the present studies is negligibly bound by the whole blood. This was deduced from the fact that, at equilibrium, the concentration of D-(-)-mandelic acid or its homolog in the solution outside of the dialysis bag containing the blood was the same as in the solution outside the dialysis bag of the control dialysis setup. The concentration of 1 mg. of D-(-)-mandelic acid or its homolog per dialysis setup used in the binding studies was based on the expected concentration of the acid in the volume of distribution of a rat weighing 200 g., following the intravenous administration of a 10-mg. dose of the acid. As suggested for humans (26), about 20% of the body weight was assumed to be the volume of distribution for rats. It was further assumed that the concentration of the compound in the blood and in the other possible volumes of distribution in rats is the same. The binding of D-(-)-mandelic acid by rat plasma in this concentration range has been studied and shown to be negligible (27).

Determination of the Biological Half-Life of the Compounds—It has been shown that, in humans, the metabolism and excretion of most drugs follow an apparent first-order process (28). Bray *et al.* (29) have demonstrated that the metabolism of benzaldehyde and toluene to benzoic acid and the urinary excretion of benzoic acid proceed by a pseudo-first-order process in rabbits. The uri-

nary excretion of DL-tropic acid has also been shown to follow pseudo-first-order kinetics in rats (25). Although the urinary excretion of D-(-)-mandelic acid (14, 15) and L-(+)-mandelic acid (14) has been shown to occur by a pseudo-first-order process in humans, such studies have not been reported in rats for D-(-)-mandelic acid; D-(-)-4-hydroxy-4-phenylbutanoic acid; D-, L- or DL-phenyllactic acid; and D-(-)-benzylactic acid. Therefore, it was necessary to determine if the excretion of D-(-)-mandelic acid and its homologs employed in the present studies follows pseudo-first-order kinetics. After establishing the proper procedures for rat urine collection and quantitative determination of these compounds excreted in the urine, the kinetics of urinary excretion of each compound were studied in rats. Preliminary data obtained in these studies indicated that the urinary excretion of these compounds occurred by a pseudo-first-order process.

Since the compounds used in the kinetic studies were those excreted unchanged in the urine of rats, the elimination of the compounds can be described by the following model:

where A is the amount of intact compound in the body at any time, Ae is the amount of intact compound excreted in the urine at any time, and k is the apparent first-order rate constant of excretion of the compound. The urinary excretion data obtained for the compound can then be treated according to the following equation (15):

$$\log \frac{\Delta Ae}{\Delta t} = \log kA_0 - \frac{kt}{2.303} \quad (\text{Eq. 1})$$

where $\Delta Ae/\Delta t$ is the rate of excretion of the compound at time t , and A_0 is the amount of the compound at zero time.

The $\log \Delta Ae/\Delta t$ is plotted against t ; from the slope of the straight line, obtained by the method of least squares, the biological half-

Figure 4—Apparent first-order urinary excretion of D-(-)-4-hydroxy-4-phenylbutanoic acid following its i.v. administration of 277-μmole/kg. dose in the absence (●) and 277-μmole/kg. dose in the presence (○) of a 1.3×10^4 μmole/kg. i.p. dose of D-(-)-mandelic acid to rats.

Figure 5—Apparent first-order urinary excretion of DL-phenyllactic acid following its i.v. administration of 486- μ mole/kg. dose in the absence (●) and 365- μ mole/kg. dose in the presence (○) of a 1.3×10^4 μ mole/kg. i.p. dose of D-(–)-mandelic acid to rats.

life of the compound is calculated. The time, t , in such plots represents the midpoints of the urinary collection intervals.

One factor that should be considered in evaluating the excretion rate and biological half-life of compounds is the dose administered to the subject. This is important because the biological half-life of compounds involved in tubular secretion is expected to be longer at the dosage level that saturates the secretory process than at the dosage level that does not saturate this process. Therefore, for the determination of the biological half-life of a compound excreted by an apparent first-order process, its excretion should be studied following the administration of a dose that does not saturate the tubular secretory process. Consequently, the kinetics of urinary excretion of D-(–)-mandelic acid, DL-tropic acid and its optical isomers, D-(–)-4-hydroxy-4-phenylbutanoic acid, DL-phenyllactic acid and its optical isomers, and D-(–)-benzylactic acid were studied following the intravenous administration of 150–700 μ mole/kg. of each compound. The plots of $\log \Delta Ae/\Delta t$ versus t for these studies were constructed, and from each straight-line plot the biological half-life of the corresponding compound was determined (Table III). The representative plots of $\log \Delta Ae/\Delta t$ versus t obtained for each of these compounds are shown in Figs. 2–6.

It may be noted from Table III that the values of the biological half-life for DL-tropic acid and each of its optical isomers are similar to each other. Likewise, the values of the biological half-life obtained for DL-phenyllactic acid and each of its optical isomers are similar to each other. This indicated that the renal tubular transport of these compounds by the carrier mechanism is not stereospecific. Therefore, DL-tropic acid and DL-phenyllactic acid,

instead of their individual optical isomers, were employed in the subsequent studies. The assignment of the absolute configuration of the compounds used in the study was based on their plain optical rotatory dispersion (ORD) curves as follows. Since the absolute configuration of (–)-mandelic acid is shown to be D-(–)-mandelic acid (30), the ORD curves for the homologs of mandelic acid were obtained over the wavelength range of 600–220 λ , and each curve was compared with that for D-(–)-mandelic acid. It was observed that, except for (–)-phenyllactic acid, the sign and shape of the ORD curves of the levorotatory homologs of mandelic acid were similar to that of D-(–)-mandelic acid. Thus, L-configuration was assigned to (–)-phenyllactic acid and D-configurations to the other levorotatory homologs of mandelic acid. This approach is in accordance with that described by Djerassi (31).

Among the compounds studied, the average biological half-life of D-(–)-mandelic acid is the longest (30 min.) and that of D-(–)-4-hydroxy-4-phenylbutanoic acid is the shortest (16 min.). The average half-life values for DL-phenyllactic acid and D-(–)-benzylactic acid are not found to be significantly different from each other (20–21 min.). The average half-life for DL-tropic acid was found to be 23 min. (Table III). It is evident that the biological half-lives of the homologs of mandelic acid employed in these studies are significantly shorter than that of D-(–)-mandelic acid. Since the pKa values and the lipid solubility at the physiological pH determined for D-(–)-mandelic acid and its homologs are not significantly different, the differences observed in the values of their biological half-lives may be attributed to the increased hydrophobic interaction between the methylene group(s) of the mandelic acid homolog and a certain hydrophobic portion of the carrier for renal tubular secretion. Such hydrophobic interaction is likely to result in the increased affinity of the homolog for the carrier. In view of the fact that the initial excretion rate is composed of two terms, the initial glomerular filtration rate and the initial secretion rate, this interpretation of the biological half-life data would be acceptable

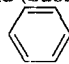

Figure 6—Apparent first-order urinary excretion of D-(–)-benzylactic acid following its i.v. administration of 346- μ mole/kg. dose in the absence (●) and 298- μ mole/kg. dose in the presence (○) of a 1.3×10^4 μ mole/kg. dose of D-(–)-mandelic acid to rats.

Table III—Summary of the Biological Half-Lives Observed in Rats for D-(–)-Mandelic Acid and Its Homologs^a in the Absence and Presence of Inhibitor

Compound (Substrate) R = 		Biological Half-Life, min.			
		Inhibitor Absent ^b	Inhibitor Present ^c 10–15 × 10 ³ μmole/kg. i.p. Dose		Inhibitor
			Equivalent ^e i.v. Dose		
D-(–)-Mandelic acid	R—CH(OH)—COOH	30 ± 4 ^d	30 ± 4 ^{d,e}	46 ± 8	DL-Tropic acid
DL-Tropic acid	$\begin{array}{c} \text{CH}_2(\text{OH}) \\ \\ \text{R}-\text{CH}-\text{COOH} \end{array}$	23 ± 4	28 ± 5	50 ± 10	D-(–)-Mandelic acid
D-(–)-Tropic acid		24 (2) ^f			
L-(+)-Tropic acid		25 (4)			
DL-Phenyllactic acid	R—CH ₂ —CH(OH)—COOH	20 ± 3	26 ± 4	42 ± 5	D-(–)-Mandelic acid
L-(–)-Phenyllactic acid		21 (2)			
D-(+)-Phenyllactic acid		20 (2)			
D-(–)-Benzylactic acid	R—(CH ₂) ₂ —CH(OH)—COOH	21 ± 3	18 ± 2	36 ± 4	D-(–)-Mandelic acid
D-(–)-Hydroxy-4-phenylbutanoic acid	R—CH(OH)—(CH ₂) ₂ —COOH	16 ± 2	22 ± 5	26 ± 5	D-(–)-Mandelic acid

^a I.v. dosage range 150–700 μmole/kg. ^b The biological half-lives of the homologs of D-(–)-mandelic acid are significantly ($p < 0.01$) shorter than that of D-(–)-mandelic acid. The biological half-life of D-(–)-4-hydroxy-4-phenylbutanoic acid is significantly shorter than that of DL-tropic acid ($p < 0.01$), DL-phenyllactic acid, and D-(–)-benzylactic acid ($p < 0.05$). The biological half-lives of DL-phenyllactic acid and D-(–)-benzylactic acid are not significantly shorter than that of DL-tropic acid. ^c The dose of inhibitor equivalent to the i.v. dose of the substrate compound. ^d Standard deviation was determined from six to eight rat studies. ^e The biological half-life of D-(–)-mandelic acid varied from 30 ± 3 to 33 ± 3 min. in the presence of equivalent i.v. doses of the other homologs of D-(–)-mandelic acid as inhibitors. ^f The values of average biological half-life of the individual optical isomers of tropic acid and phenyllactic acid based on the number of studies indicated in parentheses.

if the initial glomerular filtration rates of D-(–)-mandelic acid and its homologs are shown to be similar at the equimolar dosage levels. The data in support of this interpretation are presented in the subsequent discussion as well as in the next paper of this series (17).

Determination of the Apparent Initial Rate of Excretion—As in the case of biological half-life, a comparison was considered desirable between the apparent initial urinary excretion rates observed for compounds employed in the studies in terms of μmole/kg./min. However, it was realized that, since it is difficult to obtain urine from rats at such short intervals as 1 min. following the intravenous administration of the compound, the determination of the apparent excretion rate of substrate in terms of μmole/kg./min. was not feasible. Therefore, it was decided to determine the apparent initial urinary excretion rate in the above terms from an extrapolation of the straight-line plot of $\log \Delta Ae/\Delta t$ versus time to zero time. Actually the initial urinary excretion rate should be obtained by an extrapolation of the straight line to the time of 0.5 min., because this would represent the midpoint of the urine collection interval. But this value of the excretion rate was very close to that obtained by an extrapolation to zero time, and the value of the intercept deter-

mined upon extrapolation of the straight-line plot to zero time was designated as the apparent initial urinary excretion rate. The apparent initial excretion rates determined in this manner for these compounds are listed in Table IV. It is noted that, in this dosage range, the apparent initial excretion rate of D-(–)-mandelic acid is considerably lower than the apparent initial excretion rate of any of its homologs used in this study. However, the differences in the apparent initial excretion rates of the homologs of D-(–)-mandelic acid are not readily seen in this dosage range (300–400 μmole/kg.) of the compounds.

Mutual Inhibitory Urinary Excretion Studies—To determine if the compounds under study are secreted by the same renal tubular transport mechanism, mutual inhibitory urinary excretion studies were carried out for DL-tropic acid, D-(–)-4-hydroxy-4-phenylbutanoic acid, DL-phenyllactic acid, and D-(–)-benzylactic acid in the presence of D-(–)-mandelic acid. An isotonic solution containing a dose of 330–500 μmole/kg. of an appropriate homolog of mandelic acid and an equivalent amount of D-(–)-mandelic acid was administered intravenously to the rat; from the apparent first-order urinary excretion data obtained in each study, the biological half-lives of each homolog of mandelic acid and that of D-(–)-mandelic acid were determined (Table III). It is observed

Figure 7—Urinary excretion of D-(–)-mandelic acid observed following its i.p. administration of 1.0×10^4 μmole/kg. dose to rats, indicating that the maximum absorption of the compound occurred in 20 min.

Table IV—Comparison of Apparent Initial Urinary Excretion Rates Obtained in Rats for D-(–)-Mandelic Acid and Its Homologs^a in the Absence and Presence of Inhibitor

Compound (Substrate)	Initial Excretion Rate, μmole/kg./min.		
	Inhibitor Absent	Inhibitor Present ^b (i.v. Equivalent ^c Dose per Rat)	Inhibitor Present ^b (i.p. 10–15 × 10 ³ μmole/kg.)
D-(–)-Mandelic acid	5.0–8.5	6.1–7.9	3.8–5.8
DL-Tropic acid	11.8–16.4	6.9–9.0	3.5–4.3
DL-Phenyllactic acid	9.2–13.5	7.3–10.7	4.7–5.6
D-(–)-Benzylactic acid	8.7–15.2	11.9–14.3	3.5–4.5
D-(–)-4-Hydroxy-4-phenylbutanoic acid	10.6–11.9	6.6–11.4	3.9–5.5

^a I.v. dosage range of 300–400 μmole/kg. ^b DL-Tropic acid was employed as the inhibitor for D-(–)-mandelic acid, and D-(–)-mandelic acid was employed as the inhibitor for the remainder of the compounds. ^c Dose equivalent to that of the i.v. dose of the substrate compound.

from these data that, while the biological half-life of D-(–)-mandelic acid remained unchanged in the presence of each of its homologs, the biological half-life of each homolog, with the exception of D-(–)-benzylactic acid, increased slightly in the presence of D-(–)-mandelic acid. Consequently, it was expected that there should be a corresponding slight decrease in the apparent initial rate of excretion of each homolog in the presence of D-(–)-mandelic acid. But because of the unavailability of data regarding the initial excretion rate of the compounds at identical doses ($\mu\text{mole/kg.}$), such a comparison was not possible. However, an attempt is made to compare the range of apparent initial excretion rates observed for the compounds over a dosage range of 300–400 $\mu\text{mole/kg.}$ (Table IV). It can be seen from Table IV that, although there is a slight decrease in the apparent initial rate of excretion of DL-tropic acid and DL-phenylactic acid, such a decrease in the rate is not observed for D-(–)-4-hydroxy-4-phenylbutanoic acid. Therefore, studies were carried out to determine the effect of higher doses of D-(–)-mandelic acid on the biological half-life and the apparent initial rate of excretion of each of its homologs following the administration of 300–400 $\mu\text{mole/kg.}$ The dose of D-(–)-mandelic acid employed as an inhibitor in the studies was $1.3 \times 10^4 \mu\text{mole/kg.}$, and it was administered intraperitoneally 15–20 min. prior to the intravenous administration of the substrate homolog. To determine the effect of a large dose of one of the homologs on the biological half-life of D-(–)-mandelic acid, similar studies were performed using DL-tropic acid as the inhibitor. The dose of DL-tropic acid used was $1.5 \times 10^4 \mu\text{mole/kg.}$ and that of D-(–)-mandelic acid was 330 $\mu\text{mole/kg.}$ The biological half-lives and apparent initial excretion rates determined for these compounds from the apparent first-order urinary excretion data are presented in Tables I and IV, respectively. The typical apparent first-order plots obtained for the compounds are shown in Figs. 2–6. The intraperitoneal administration of the high doses of DL-tropic acid and D-(–)-mandelic acid used as the inhibitor did not produce apparent toxic effects in rats. The rats behaved normally during the experiments as well as a week later when reused in the studies.

The pH of the urine of the rats following the administration of large doses of the inhibitor compounds was found to be in the range of 6.5 to 7.5, which was comparable to the urine pH of the control rats. The 15–20-min. interval between the administration of the inhibitor and the substrate was allowed to permit maximum absorption of the inhibitor, as shown by the studies on the urinary excretion of D-(–)-mandelic acid and DL-tropic acid after their intraperitoneal administration of $1.0\text{--}1.5 \times 10^4 \mu\text{mole/kg.}$ (Fig. 7).

It is evident from the data presented in Tables I and IV that in the presence of a large dose of the inhibitor, there is a significant increase in the biological half-life and a corresponding decrease in the apparent initial excretion rate of each of the compounds employed in these studies. Therefore, it may be concluded that D-(–)-mandelic acid and its homologs, DL-tropic acid, D-(–)-4-hydroxy-4-phenylbutanoic acid, DL-phenylactic acid, and D-(–)-benzylactic acid, are involved in kidney tubular secretion and that they most probably share the same transport system for their secretion.

SUMMARY AND CONCLUSIONS

Studies were carried out in rats to gain some insight into the structural and chemical specificity that the "carrier" molecules of renal tubular transport show toward anionic drugs. D-(–)-Mandelic acid and certain of its homologs, DL-tropic acid, DL-phenylactic acid, D-(–)-benzylactic acid, and D-(–)-4-hydroxy-4-phenylbutanoic acid, were selected as the model compounds since they exhibit negligible metabolism and protein binding, low pKa values, and low lipid solubility at the physiological pH, and are primarily recovered in the urine in the unchanged form.

From the apparent first-order urinary excretion studies of these compounds, it was found that the biological half-life of each homolog is significantly shorter than that of D-(–)-mandelic acid in rats.

These compounds are shown to exert a mutual inhibitory effect on their renal tubular secretion in rats, indicating that they share the same carrier mechanism for their secretion.

The utilization of these compounds has demonstrated that the addition of methylene group(s) in the vicinity of the carboxyl

group of the mandelic acid molecule increases its affinity for the carrier molecules of the renal transport system in rats.

Kinetics of Urinary Excretion of D-(–)-Mandelic Acid and Its Homologs II: Competitive Inhibitory Effect of D-(–)-Mandelic Acid and DL-Tropic Acid on Their Renal Tubular Secretion in Rats

EDWARD J. RANDINITIS*, MARTIN BARR, and JANARDAN B. NAGWEKAR†

Abstract □ From the pseudo-first-order urinary excretion studies of D-(–)-mandelic acid and DL-tropic acid in rats, data regarding the apparent initial secretion rate *versus* dose (i.v.) are obtained for these compounds and treated according to the Michaelis-Menten kinetics. While the values of maximum apparent initial secretion rate (V_m) determined for these compounds are similar, the value of the dose of the substrate required to produce one-half of the maximum apparent initial secretion rate (K_m) determined for D-(–)-mandelic acid is found to be about twice that determined for DL-tropic acid. Data have been obtained to demonstrate that these compounds competitively inhibit the renal tubular secretion of each other, thereby strongly indicating that these compounds share a common carrier transport system for their secretion. Data obtained in the present studies and those described earlier are utilized to distinguish a certain structural characteristic around the cationic site of the "carrier" molecules of the renal tubular secretion system in rats.

Keyphrases □ D-(–)-Mandelic acid, homologs—urinary excretion □ DL-Tropic acid, D-(–)-mandelic acid—competitive inhibition, urinary excretion □ Structure—excretion rate relationship—D-(–)-mandelic, DL-tropic acids □ Transport system—D-(–)-mandelic acid, DL-tropic acid excretion

The authors (1) have shown that the biological half-lives of DL-tropic acid, DL-phenyllactic acid, D-(–)-benzylactic acid, and D-(–)-4-hydroxy-4-phenylbutanoic acid, which are homologs of mandelic acid, increased in the presence of D-(–)-mandelic acid in rats. The corresponding decrease in the apparent initial urinary excretion rates of these homologs was also shown to occur in rats in the presence of D-(–)-mandelic acid. The influence of DL-tropic acid on the urinary excretion rate of D-(–)-mandelic acid was also studied. It was demonstrated that the biological half-life of D-(–)-mandelic acid increased and its initial excretion rate decreased in the presence of DL-tropic acid. It was, therefore, suggested that D-(–)-mandelic acid and its previously mentioned homologs share the same transport mechanism for their renal tubular secretion in rats. Since these compounds, which are not significantly metabolized nor bound to the plasma proteins and are excreted entirely in the urine, were found to have different biological half-lives and, at a specific dose, different initial excretion rates, it was further suggested that the common carrier system for renal tubular secretion in rats shows different affinity for these compounds.

Because it is well known that the urinary excretion of most compounds results from a combination of glomerular filtration and tubular secretion, it is conceivable that the compounds used in these studies probably have the same maximum initial secretion rate and initial glomerular filtration rate, if the assumption is correct that these compounds are secreted by the renal tubules of

rats by the same carrier mechanism. Therefore, the purposes of the work presented here were to determine the apparent initial glomerular filtration rates and the apparent initial secretion rates of DL-tropic acid and D-(–)-mandelic acid in rats and to analyze the secretion rate data according to Michaelis-Menten kinetics. The additional purpose of the work was to determine if the mutual inhibition caused by these compounds in their renal secretion in rats is competitive or noncompetitive in nature. Since both D-(–)-tropic acid and L-(+)-tropic acid are completely recovered unchanged in the urine of rats and, furthermore, since the biological half-lives of these isomers are found to be similar to each other (1), DL-tropic acid was not resolved into its optical isomers but was used in the racemic form.

EXPERIMENTAL

Materials—D-(–)-Mandelic acid,¹ m.p. 132–133°, $[\alpha]_D^{25} - 154.2^\circ$ (c, 1.94, H₂O); and DL-tropic acid,¹ m.p. 118–119°.

Apparatus—The quantitative analysis of mandelic acid and tropic acid appearing in the urine was carried out using an F & M model 810R-19 gas chromatograph by the method described previously (1). A Beckman model 72 pH meter equipped with a combination electrode was used for rat urine pH determinations. The specific rotation of the optically active compound was determined with the aid of J & J Fric model 2706 polarimeter using a sodium lamp as the source of light.

Methodology—The procedure employed for the preparation of the rats and urine collection following the i.v. administration of the compounds was the same as described previously (1). During the course of these studies, approximately 35 Sprague-Dawley male rats weighing between 165 and 215 g. were repeatedly used. None of the rats was used more than five times in these studies; the rest period allowed between the successive use of a rat was at least a week.

To determine the apparent glomerular filtration rate of D-(–)-mandelic acid at dosage levels of 165–330 $\mu\text{mole/kg.}$ (5–10 mg./rat), the appropriate amount of the sodium salt of D-(–)-mandelic acid contained in 0.5 ml. was injected by the i.v. route 15–20 min. after i.p. administration of $15\text{--}120 \times 10^3 \mu\text{mole/kg.}$ (50–400 mg./rat) of DL-tropic acid as the sodium salt contained in 5 ml. of water at a pH of 7.0. A similar procedure was followed to determine the apparent glomerular filtration rate of DL-tropic acid at the dosage levels of 150–300 $\mu\text{mole/kg.}$ in the presence of $16\text{--}130 \times 10^3 \mu\text{mole/kg.}$ of i.p. administered D-(–)-mandelic acid per rat.

In the studies designed to determine the maximum initial secretion rate (V_m) of D-(–)-mandelic acid and its dose required to produce one-half of the maximum initial secretion rate (K_m), the doses of the sodium salt of D-(–)-mandelic acid in the range of $1.8\text{--}21.9 \times 10^3 \mu\text{mole/kg.}$ were dissolved in water (0.5–1.5 ml.) and administered to the rat by the intravenous route. Similar studies were also carried out for DL-tropic acid using the doses of its sodium salt in the range of $1.7\text{--}20.0 \times 10^3 \mu\text{mole/kg.}$

To determine the nature of inhibition of renal tubular secretion of D-(–)-mandelic acid by DL-tropic acid, the initial secretion rates of

$7.2 \times 10^2 \mu\text{mole/kg.}$ (20 mg./rat), $12\text{--}14 \times 10^2 \mu\text{mole/kg.}$ (40 mg./rat), and $24\text{--}28 \times 10^2 \mu\text{mole/kg.}$ (80 mg./rat) of D-(-)-mandelic acid. In these studies, DL-tropic acid and D-(-)-mandelic acid were administered by the i.v. route as their sodium salts, and both the substrate and inhibitor compounds were contained in the same i.v. solution.

RESULTS AND DISCUSSION

Determination of the Initial Glomerular Filtration Rate of the Compounds—As mentioned previously, the urinary excretion of most compounds results from a combination of glomerular filtration and renal tubular secretion. Since renal tubular secretion is a saturable process, the reduction can be caused in the excretion rate of a substrate in the presence of an inhibitor that competes for the secretory process. Therefore, it should be possible to inhibit completely the renal tubular secretion of a substrate compound in rats by a simultaneous administration of a large excess of a suitable inhibitor compound. In this event, the initial rate of excretion of the substrate would represent its initial rate of glomerular filtration. It is thus possible to determine the initial rate of glomerular filtration and the initial rate of secretion of a compound at a particular dosage level. Consequently, the initial excretion rates of D-(-)-mandelic acid following i.v. doses of $165\text{--}330 \mu\text{mole/kg.}$ were determined in the presence of increasingly higher doses of DL-tropic acid. The dose of DL-tropic acid, in the range of $12\text{--}150 \times 10^2 \mu\text{mole/kg.}$, was administered i.p. about 20 min. prior to the i.v. administration of D-(-)-mandelic acid. In a similar manner, the initial excretion rates of DL-tropic acid following its i.v. doses of $150\text{--}300 \mu\text{mole/kg.}$ were determined in the presence of increasingly higher doses of D-(-)-mandelic acid. The dose of D-(-)-mandelic acid, in the range of $16\text{--}130 \times 10^2 \mu\text{mole/kg.}$, was administered i.p. about 20 min. prior to the i.v. administration of DL-tropic acid.

It may be estimated from the urinary excretion data obtained following i.p. administration of $1 \times 10^4 \mu\text{mole/kg.}$ of D-(-)-mandelic acid (Fig. 7, Reference 1) that, at the $1.65 \times 10^4 \mu\text{mole/kg.}$ dosage level of D-(-)-mandelic acid, the amount of mandelic acid present in the volume of distribution of the rat is approximately 30 times greater than that at the $300 \mu\text{mole/kg.}$ dosage level of DL-tropic acid and approximately 60 times greater than that at the $150 \mu\text{mole/kg.}$ dosage level of the acid. At similar large i.p. doses of DL-tropic acid used as the inhibitor of D-(-)-mandelic acid administered at the dosage levels of $165\text{--}330 \mu\text{mole/kg.}$, the amount of DL-tropic acid present in the volume of distribution of the rat would be expected to be in the range described for D-(-)-mandelic acid as the inhibitor. As described previously (1), the apparent initial urinary excretion rates of the compounds were determined by extrapolating the pseudo-first-order plots to zero time. The apparent initial excretion rates obtained from these studies were then plotted against the i.p. dose of the inhibitor as shown in Figs. 1 and 2. It is noted from these plots that an apparently limiting initial excretion rate for each substrate compound is obtained in rats in the presence of $0.9\text{--}1.0 \times 10^4 \mu\text{mole/kg.}$ i.p. dose of inhibitor. Since a further decrease in the initial excretion rate was not observed even at higher inhibitor dosage levels, it was evident that at this i.p. dose of inhibitor an apparent saturation of tubular secretion process occurred and the initial excretion rate observed for the substrate was due to the apparent initial glomerular filtration rate. A reasonable linear relationship observed between the apparent initial glomerular filtration rate and the i.v. dose of DL-tropic acid is shown in Fig. 3. It may be seen from the data presented in Fig. 2 that a limiting initial excretion rate ($3.4 \mu\text{mole/kg./min.}$) obtained for D-(-)-mandelic acid at the dose of $165 \mu\text{mole/kg.}$ is substantially higher than that expected on the basis of the limiting initial excretion rate ($4.5 \mu\text{mole/kg./min.}$) obtained at the dose of $330 \mu\text{mole/kg.}$. Therefore, the initial excretion rate of D-(-)-mandelic acid at the dosage level of $180 \mu\text{mole/kg.}$ was determined in rats in the presence of a simultaneously administered 3

Figure 4—Relationship between the apparent initial glomerular filtration rate and the i.v. dose for D-(–)-mandelic acid in rats.

$\times 10^3$ $\mu\text{mole/kg. i.v. dose of DL-tropic acid}$. Both D-(–)-mandelic acid and DL-tropic acid were administered as their sodium salts. The initial excretion rate (2.4 $\mu\text{mole/kg./min.}$) noted for D-(–)-mandelic acid in this study was of the magnitude expected on the basis of the limiting initial excretion rate obtained at the dose of 330 $\mu\text{mole/kg.}$ Therefore, 2.2 $\mu\text{mole/kg./min.}$ was considered as the apparent glomerular filtration rate at the dose of 165 $\mu\text{mole/kg.}$ of the acid instead of the limiting initial excretion rate noted in Fig. 2. Thus, when these apparent glomerular excretion rates were plotted against the i.v. doses of D-(–)-mandelic acid, a reasonable linear relationship was observed (Fig. 4). These apparent initial glomerular filtration rates observed for D-(–)-mandelic acid are found to be in agreement with those obtained by Khambati and Nagwekar (2) for the acid in the presence of the simultaneously administered 3×10^3 $\mu\text{mole/kg. i.v. dose of DL-tropic acid}$ in rats. Khambati and Nagwekar determined the initial glomerular filtration rates of D-(–)-mandelic acid in the course of determining those for D-(–)-*p*-isopropyl mandelic acid. It seems that the limiting initial excretion rate obtained for D-(–)-mandelic acid at the 165- $\mu\text{mole/kg.}$ dose in Fig. 2 was an experimental artifact. Therefore, the use of the value of the apparent glomerular filtration rate (2.2 $\mu\text{mole/kg./min.}$) obtained for the acid at the i.v. dosage level of 165 $\mu\text{mole/kg.}$ in the presence of the simultaneously administered 3×10^3 $\mu\text{mole/kg. i.v. dose of DL-tropic acid}$ may be justified in constructing the plot in Fig. 4. It is then theoretically possible to estimate the apparent initial glomerular filtration rate of these acids at higher i.v. doses by the extrapolation of the straight lines shown in Figs. 3 and 4.

Incidentally, since D-(–)-mandelic acid is able to saturate the tubular secretory system upon the administration of an i.p. dose of 1.3×10^4 $\mu\text{mole/kg.}$ in a rat, initial excretion rates reported previously (1) for D-(–)-4-hydroxy-4-phenylbutanoic acid, DL-phenyllactic acid, and D-(–)-benzylactic acid in the presence of an i.p. dose of 1.3×10^4 $\mu\text{mole/kg.}$ of D-(–)-mandelic acid represent their respective apparent initial glomerular filtration rates, as evidenced by a linear relationship observed in Fig. 5 upon plotting these rates against their i.v. doses. This supports the observation that an i.p. dose of 1.3×10^4 $\mu\text{mole/kg.}$ of D-(–)-mandelic acid serves as an inhibitor of secretion of its homologs and, likewise, an i.p. dose of 1.2×10^4 $\mu\text{mole/kg.}$ of DL-tropic acid serves as an inhibitor of secretion of D-(–)-mandelic acid. The data presented in Fig. 5 also indicate that, in rats, the volume of distribution for all of the compounds used in the study is similar.

Determination of Michaelis-Menten Kinetic Parameters—Since renal tubular secretion represents a saturable system, the transport of molecules through the renal tubular membrane has been described by Michaelis-Menten kinetics (3), and the nature of inhibition of this transport by other compounds has been identified utilizing a Lineweaver-Burk plot technique (4). As in the study of enzyme kinetics, the maximum rate of tubular secretion or transport is generally designated as V_m or T_m , and the concentration of substrate required to produce one-half of the maximum rate of secretion as K_m . It is generally expected that for compounds of a homologous series, which are secreted by the same carrier mechanism, the value of V_m is the same, but, due to their differences in affinities for the carrier, the value of K_m for each compound is different. Homologs with a greater affinity for the carrier would be expected to possess a lower value of K_m (3). In an *in vitro* study of inhibition of uptake of *N*-methylnicotinamide by kidney slices, Farah *et al.* (4) have applied the Lineweaver-Burk plot technique to demonstrate that organic bases, such as tetraethylammonium, choline, and guanidine, competitively inhibit the uptake of the compound. Cho *et al.* (5) studied the tubular secretion of iodopyracet² and *p*-aminohip-

Figure 5—A plot of the limiting initial excretion rates obtained in rats for D-(–)-mandelic acid, ●; DL-tropic acid, ○; D-(–)-4-hydroxy-4-phenylbutanoic acid, ▲; DL-phenyllactic acid, □; and D-(–)-benzylactic acid, ▲; following their i.v. administration in the presence of $1.0\text{--}1.5 \times 10^4$ $\mu\text{mole/kg.}$ of inhibitor. (These data are obtained from Table IV of Reference 1.)

purate by the renal clearance method in dogs and showed that these compounds competitively inhibit the secretion of each other. To determine the tubular secretion rate, these workers assumed the values of filterability of *p*-aminohippurate and iodopyracet to be 0.92 and 1.00, respectively. The V_m value obtained for iodopyracet was 1.6 $\mu\text{mole/kg./min.}$ and that determined for *p*-aminohippurate was 5.0 $\mu\text{mole/kg./min.}$

As applied to secretion kinetics of the present study, the various terms appearing in the following Michaelis-Menten equation (6)

$$v = \frac{V_m (S)}{K_m + (S)} \quad (\text{Eq. 1})$$

are defined as follows. In this equation, v represents the apparent initial secretion rate ($\mu\text{mole/kg./min.}$), V_m the maximum apparent initial secretion rate ($\mu\text{mole/kg./min.}$), (S) the intravenous dose of the substrate ($\mu\text{mole/kg.}$), and K_m the dose of the substrate required to produce one-half of the maximum apparent initial secretion rate ($\mu\text{mole/kg.}$). From the following Lineweaver-Burk form (7) of Eq. 1,

$$\frac{1}{v} = \frac{K_m}{V_m (S)} + \frac{1}{V_m} \quad (\text{Eq. 2})$$

the values of V_m and K_m are determined from the slope and intercept of the straight line obtained by plotting $1/v$ versus $1/(S)$.

Figure 6—Urinary excretion data obtained for D-(–)-mandelic acid following the i.v. administration of a 3.37×10^3 $\mu\text{mole/kg.}$ dose to a rat (indicating the longer biological half-life of the compound during the earlier period being mainly due to an apparent saturation of the secretory process for the compound in the rat).

excretion data obtained in the present studies, it was necessary to determine the initial secretion rate of compounds over an appropriate range of dosage levels. The range of doses considered appropriate for a substrate compound in these studies is the range over which not only the urinary excretion of the compounds takes place by a first-order process but also the biological half-life of the substrate remains practically constant. Therefore, the kinetics of urinary excretion of D-(-)-mandelic acid was studied at doses $1.65\text{--}4 \times 10^2 \mu\text{mole/kg.}$ It is noted that the biological half-life of D-(-)-mandelic acid remains practically constant (33 min.) over the i.v. dosage range of $1.65\text{--}20 \times 10^2 \mu\text{mole/kg.}$ and possibly up to $33 \times 10^2 \mu\text{mole/kg.}$ But at the dosage levels of $33\text{--}40 \times 10^2 \mu\text{mole/kg.}$, a slower excretion rate (increased biological half-life) was observed for an hour following the i.v. administration of D-(-)-mandelic acid, which may mainly be due to an apparent saturation of the secretory process of the compound (Fig. 6). Therefore, the dosage range of this acid considered appropriate in this study was $1.65\text{--}20 \times 10^2 \mu\text{mole/kg.}$ The results obtained for DL-tropic acid were found to be similar to those obtained for D-(-)-mandelic acid and, therefore, the dosage range of this acid considered suitable was $1.5\text{--}20 \times 10^2 \mu\text{mole/kg.}$ The data obtained for the urinary excretion of D-(-)-mandelic acid following the i.v. administration of various doses are presented in Fig. 7. Similarly, the data obtained for the urinary excretion of DL-tropic acid are presented in Fig. 8.

The apparent initial renal tubular secretion rates were determined from the total initial excretion rates at each i.v. dosage level of DL-tropic acid, as well as D-(-)-mandelic acid, by subtracting the apparent initial glomerular filtration rates noted for these compounds from Figs. 3 and 4 at the corresponding dosage levels. The plot of the observed apparent initial excretion rate *versus* dose (i.v.) and the plot of the initial secretion rate *versus* dose (i.v.) are also constructed for these compounds, as shown in Figs. 9 and 10. The extrapolated lines due to the apparent initial glomerular filtration rate *versus* dose for these compounds are included in Figs. 9 and 10. The curvilinear plots obtained for the initial excretion rate data are in accordance with the expectation for compounds which are excreted by both glomerular filtration and tubular secretion (8).

To determine the Michaelis-Menten kinetic parameters, the reciprocal of the initial secretion rate was plotted against the reciprocal of the i.v. dose for both D-(-)-mandelic acid and DL-tropic acid (Fig. 11). From the slope of the straight line obtained by the method

Figure 10—Apparent initial excretion rates, ○; initial glomerular filtration rates, ---; and initial secretion rates, △; observed for DL-tropic acid following the i.v. administration of appropriate doses to rats.

Figure 11—Lineweaver-Burk plots of the reciprocal of the i.v. dose of D-(-)-mandelic acid, O; and DL-tropic acid, Δ; against their corresponding reciprocal of the apparent initial secretion rates.

of least squares and from the y-intercept obtained by extrapolation of the straight line, the respective values of K_m and V_m were determined for D-(-)-mandelic acid and for DL-tropic acid. These values are listed in Table I. Values for the maximum secretion rate (V_m) obtained for *p*-aminohippurate in rats by the renal clearance method have been reported by several workers (9-11). For the sake of comparison, when these V_m values are converted to units of $\mu\text{mole/kg./min.}$, they are found to be 9.27, 14.93, and 18.02 $\mu\text{mole/kg./min.}$ Therefore, in light of such a wide variation observed by other workers in the V_m values for *p*-aminohippurate, the V_m value of 18.8 $\mu\text{mole/kg./min.}$ obtained for D-(-)-mandelic acid may be considered comparable to the V_m value of 20.8 $\mu\text{mole/kg./min.}$ obtained for DL-tropic acid, thus strongly suggesting that the two acids are secreted by the same carrier mechanism present in the renal tubule of the rat. The values of K_m obtained in these studies for DL-tropic acid ($5.2 \times 10^3 \mu\text{mole/kg.}$) and D-(-)-mandelic acid ($11.1 \times 10^3 \mu\text{mole/kg.}$) strongly indicate that the affinity of DL-tropic acid for the renal tubular transport carrier is about twice that of D-(-)-mandelic acid.

Determination of the Nature of Inhibition—To determine whether the mutual inhibition observed for DL-tropic acid and D-(-)-mandelic acid is competitive or noncompetitive in nature, the apparent initial secretion rates of DL-tropic acid at various intravenous dosage levels were determined in the presence of a fixed dose of D-(-)-mandelic acid, and those of D-(-)-mandelic acid at various intravenous dosage levels were determined in the presence of a fixed dose of DL-tropic acid, and analyzed by the Lineweaver-Burk plot method. Accordingly, following the administration of $1.65\text{--}26 \times 10^3 \mu\text{mole/kg.}$ doses, apparent initial excretion rates of D-(-)-mandelic acid were determined in the presence of $21\text{--}26 \times 10^3 \mu\text{mole/kg.}$ (80 mg./rat) of DL-tropic acid. Similarly, initial excretion rates for DL-tropic acid at dosage levels of $3\text{--}24 \times 10^3 \mu\text{moles/kg.}$ were determined in the presence of $6.0\text{--}7.2 \times 10^3 \mu\text{mole/kg.}$ (20 mg./rat), $12\text{--}14 \times 10^3 \mu\text{mole/kg.}$ (40 mg./rat), and $24\text{--}28 \times 10^3 \mu\text{mole/kg.}$ (80 mg./rat) doses of D-(-)-mandelic acid. From these data, initial secretion rates for the substrates were calculated in the manner described earlier. The reciprocals of the substrate dose were then plotted against the reciprocals of the initial excretion rate of the substrate, as shown in Figs. 12 and 13. The straight-line plots shown for the inhibitory studies involving 20, 40, and 80 mg. of inhibitor were constructed by visual inspection. It becomes evident from the apparent common y-intercept in Figs. 12 and 13 that these acids competitively inhibit the renal tubular secretion of each other in rats.

Possible Implications of the Results Obtained in the Studies—Although the V_m and K_m values have not been determined for DL-phenyllactic acid, D-(-)-benzylactic acid, and D-(-)-4-

Table I—The Michaelis-Menten Kinetic Parameters of Secretion for D-(-)-Mandelic Acid and DL-Tropic Acid in Rats

Compound	Apparent V_m , ^a $\mu\text{mole/kg./min.}$	Apparent K_m , ^a $\mu\text{mole/kg.} \times 10^{-3}$
D-(-)-Mandelic acid	18.8 ± 3.1^b	11.1 ± 2.5^b
DL-Tropic acid	20.8 ± 2.5	5.2 ± 1.8

^a The values of the apparent V_m obtained for the compounds are not significantly different from each other, while the values of the apparent K_m determined for the compounds are significantly different from each other ($p < 0.01$). ^b Standard deviation for each compound was determined from 11-15 rat studies described in Fig. 11.

Figure 12—Lineweaver-Burk plots indicating competitive inhibition of secretion of D-(-)-mandelic acid by DL-tropic acid in the i.v. dose of 80 mg./rat ($21\text{--}26 \times 10^3 \mu\text{mole/kg.}$).

hydroxy-4-phenylbutanoic acid, it is observed from the inhibitory effect of D-(-)-mandelic acid on the urinary excretion of these compounds that their apparent glomerular filtration rates are similar to those of D-(-)-mandelic acid and DL-tropic acid (Fig. 5). Therefore, it is not unreasonable to conclude that there exists a common carrier system in the renal tubule membrane of rats for the transport of the acids employed in the present study.

The additional purpose of this project was to determine the effect of the incorporation of methylene groups in the side chain of the mandelic acid molecules on the rate of secretion, and thereby to gain some insight into the possible chemical nature of the carrier molecule in the vicinity of its positively charged primary binding site. Based on the data obtained in these studies, it seems possible to distinguish certain characteristics of the carrier molecule.

It has been illustrated in the present studies that the incorporation of methylene group(s) in the side chain of the mandelic acid molecule results in a significant decrease (1) in the biological half-life of the compounds due to an increase in the rate of renal tubular secretion. DL-Tropic acid ($t_{1/2}$, $23 \pm 4 \text{ min.}$) and DL-phenyllactic acid ($t_{1/2}$, $20 \pm 3 \text{ min.}$), each possessing one more methylene group than does mandelic acid, are found to have significantly shorter biological half-lives than that of D-(-)-mandelic acid ($t_{1/2}$, $30 \pm 4 \text{ min.}$). Although the D-(-)-4-hydroxy-4-phenylbutanoic acid and D-(-)-benzylactic acid molecules contain two more methylene groups than does the molecule of mandelic acid, the biological half-life of D-(-)-4-hydroxy-4-phenylbutanoic acid ($t_{1/2}$, $16 \pm 2 \text{ min.}$) is significantly shorter than that observed for D-(-)-benzylactic acid ($t_{1/2}$, 21 ± 3). It was also observed that the biological half-lives obtained for DL-phenyllactic acid and D-(-)-benzylactic acid are practically the same. These observations indicate that the presence of methylene groups next to the carboxyl group contribute significantly to the affinity of the mandelic acid homolog to the carrier molecule. Since the primary interaction of the substrate molecule with the carrier molecule is expected to be due to electrostatic forces, the further affinity of the homologs of mandelic acid may be attributed to the secondary interaction (12-14) between the hydrophobic groups of the carrier molecule and the homolog. Therefore, it is suggested that the hydrophobic groups, such as methylene groups, should be pres-

Figure 13—Lineweaver-Burk plots indicating competitive inhibition of secretion of DL-tropic acid by D-(-)-mandelic acid in the i.v. doses of Δ, 80 mg./rat ($36\text{--}44 \times 10^3 \mu\text{mole/kg.}$); □, 40 mg./rat ($12\text{--}14 \times 10^3 \mu\text{mole/kg.}$); and O, 20 mg./rat ($6.0\text{--}7.2 \times 10^3 \mu\text{mole/kg.}$).

ent next to the positively charged group or site on the carrier molecule.

An examination of the chemical structures of D-(–)-benzylactic acid and D-(–)-4-hydroxy-4-phenylbutanoic acid (1) may shed some light on the extent of the hydrophobic group in the vicinity of the cationic site of the carrier molecule. Both of these compounds have the same molecular weight, chemical composition, and absolute configuration. The only respect in which these molecules differ from each other is the position of the methylene groups in relation to the carboxyl group. In a D-(–)-4-hydroxy-4-phenylbutanoic acid molecule, the two methylene groups are present next to the carboxyl group; in a D-(–)-benzylactic acid molecule, the two methylene groups are separated from the carboxyl group by the carbon containing the hydroxyl group. Since the biological half-life for D-(–)-4-hydroxy-4-phenylbutanoic acid is significantly shorter than that for D-(–)-benzylactic acid, it suggests that the hydrophobic region in close proximity to the cationic groups of the carrier molecule probably does not extend uninterrupted beyond the hydrophobic region present in close proximity to the carboxyl group of the D-(–)-4-hydroxy-4-phenylbutanoic acid molecule. This inference seems to be supported by the fact that the biological half-lives of D-(–)-benzylactic acid and DL-phenyllactic acid are practically the same, in spite of the facts that the benzylactic acid molecule contains one more methylene group than does the phenyllactic acid molecule and the position of the hydroxyl group in relation to the carboxyl group in these molecules is the same.

The comparison of the biological half-life data obtained for D-(–)-mandelic acid, DL-tropic acid, and DL-phenyllactic acid also seems to support this view regarding the hydrophobic region in close proximity to the positively charged site on the carrier molecule. Perhaps the use of 5-hydroxy-5-phenylpentanoic acid would have offered some additional information in this regard, but its extensive metabolism by rats precluded its use in the present studies. However, studies similar to those described here are being carried out with other homologs of D-(–)-mandelic acid to distinguish further characteristics of the carrier molecule.

SUMMARY AND CONCLUSIONS

Using DL-tropic acid and D-(–)-mandelic acid as the mutual competitive inhibitors of their renal tubular secretion, urinary excretion kinetic studies were carried out in rats to determine their initial glomerular filtration rates at various doses without involving a surgical procedure. The initial rate-i.v. dose profiles were obtained for urinary excretion, renal secretion, and glomerular filtration of these compounds.

The Michaelis-Menten kinetic parameters (V_m and K_m) of secretion were determined for each of the two compounds. The values of V_m determined for these compounds are found to be similar, but the value of K_m obtained for D-(–)-mandelic acid is approximately twice that obtained for DL-tropic acid, indicating that the affinity of the former for the renal tubular transport carrier is about one-half that of the latter.

Based on the initial glomerular filtration rate data obtained for D-(–)-mandelic acid and DL-tropic acid in this study and those obtained for DL-phenyllactic acid, D-(–)-benzylactic acid, and D-(–)-4-hydroxy-4-phenylbutanoic acid in the previous study, it was concluded that the volume of distribution of D-(–)-mandelic acid and its above homologs is similar in rats.

The results of these studies have been utilized to attempt to distinguish certain structural characteristics around the positively charged site of the carrier molecules for renal tubular secretion in rats.

Effect of Chemical Modification on the Surface Activity of Some Phenothiazine Derivatives

GEORGE ZOGRAFI and MAYANK V. MUNSHI

Abstract □ The ability of some substituted phenothiazines to reduce the surface tension of aqueous solutions has been studied in order to evaluate their hydrophobic behavior. Particular emphasis was placed on utilizing conditions that would allow specific structural effects to be isolated quantitatively and to point out situations where this may be difficult to do. Substitution on the phenothiazine ring enhances surface activity in the order $\text{CF}_3 \gg \text{Cl} > \text{H}$. Changing the position of the chloro group on the ring significantly influences surface activity, the order being $3\text{Cl} > 2\text{Cl} > 1\text{Cl}$. The effect on surface activity due to changes in the number of alkyl groups, the degree of branching, and the number of dissociable groups on the alkylamino portion of the molecule also has been evaluated.

Keyphrases □ Phenothiazine derivatives—surface activity □ Surface activity, phenothiazines—chemical modification effect □ Structure, phenothiazines—surface activity relationship □ Concentration, phenothiazines—surface activity

The fact that many drugs exhibit surface-active properties has led to numerous studies concerned with their relative surface and biological activity (1). In particular, for many drugs exhibiting an apparent action at biological membrane surfaces, *e.g.*, local anesthetics (2) and the substituted phenothiazines (3, 4), significant surface activity at a variety of interfaces has been reported. This is not to say that surface activity is solely responsible for pharmacological activity, but rather that it reflects hydrophobic characteristics of a drug molecule, known to influence availability as well as reactivity at a site of action.

In previous reports from this laboratory (5, 6), it has been suggested that measurement of surface-tension change at the air-solution interface is a convenient means of observing the hydrophobic behavior of chlorpromazine without the necessity of introducing more complex hydrophobic phases such as oils, solids, or specific reactants. Such studies have shown that factors tending to promote hydrophobic character, *e.g.*, decreasing the degree of ionization, increasing ionic strength, and the presence of counterions exhibiting some tendency to ion-pair, all increase surface activity, while substances tending to reduce hydrophobic behavior, such as urea and the tetraalkylammonium salts, decrease surface activity.

The present study was designed to evaluate the effect of chemical modification on the surface activity and, hence, hydrophobicity of several phenothiazine derivatives. Consideration was given to a means of choosing solution conditions and a point of reference that could be used for more meaningful quantitative comparisons.

EXPERIMENTAL

Materials—The chemical structure of each phenothiazine studied is given in Table I along with reported pK_a values for the protonated species. Chlorpromazine, its 1-chloro, 3-chloro, ethyl-

amino, and butylamino analogs, as well as trimeprazine, prochlorperazine, and trifluoperazine (Smith Kline & French Laboratories), triflupromazine (E. R. Squibb & Sons), and promazine and promethazine (Wyeth Laboratories) were used. All buffer ingredients and inorganic compounds were of reagent grade, while the water used was double distilled.

Surface-Tension Measurement—Surface tension was measured by means of the drop volume method using equipment and procedures described previously (7). All studies were conducted at $25 \pm 0.1^\circ$. Great care was taken to avoid contact with light because of possible photodecomposition exhibited by the phenothiazines (8). All surface-tension data are expressed in terms of surface pressure, π , which is the difference between the surface tension of the solvent and that of a given solution being measured. Thus as surface tension is reduced, the surface pressure increases.

RESULTS AND DISCUSSION

Considerations in Evaluating Relative Surface Activity—In order to make meaningful comparisons of various drugs, an appropriate set of conditions and a point of reference must be chosen. Two conditions which must be chosen with care are the pH and ionic strength of the solution. Since the phenothiazines can exist as protonated and nonprotonated species, comparisons should be made where only one species is present or where the ratio of one species to the other is constant. Studies with the nonprotonated form of the phenothiazines are extremely difficult because of their very great water insolubility, as well as their tendency to adsorb on all materials with which they come in contact (9). Comparison at a constant ratio of protonated to nonprotonated species also is difficult because there is no assurance that the two species of a phenothiazine, both of which adsorb, will exhibit the same ratio of relative surface activity as that for another derivative. Uncertainties in exact pK_a values (Table I) also make this approach difficult. Thus, for comparing such systems, probably it is best to choose a pH value where all drugs studied exist only in the protonated form. Figure 1 demonstrates that one should be at a pH of 5.0 or less to obtain pH independence for phenothiazines having pK_a values close to that of chlorpromazine. In the present study, therefore, all experiments were carried out at a pH of 5.0 or less, depending on the pK_a of the drugs in question.¹

The use of a protonated species introduces an electrical contribution to the free energy of adsorption since work is required to overcome the electrical repulsion of those molecules already adsorbed. Increasing the ionic strength would be expected to increase surface activity significantly since these repulsive forces would be screened out by the higher concentration of ions in the vicinity of the surface. Figure 2 shows that such effects for chlorpromazine are significant; and since this was observed for all compounds, ionic strength was maintained at one value throughout the study.

Once standard conditions of pH and ionic strength are chosen for comparing the surface activity of drugs, it is desirable to choose some means of expressing the relative surface activity of each drug. Ideally, comparing the bulk concentration required to produce a given number of adsorbed molecules per unit area would be of value. Ordinarily the number of adsorbed molecules per unit area can be determined by measuring the change in surface tension or surface pressure with bulk solution activity and then applying the Gibbs adsorption equation (16). The major difficulty with this approach is not knowing the thermodynamic activity of the drug in solution.

¹ Previous studies have indicated buffer effects to be possible, presumably due to counterion binding (9). In such studies, however, acetate buffers at concentrations used in the present study were found to have no effect on surface activity so buffer effects were not considered as a variable in this study.

Figure 1—Plot of surface pressure versus molar concentration for chlorpromazine at pH: 4.0 (○), 5.0 (Δ), 5.6 (●), and 7.1 (▲) at 25° and an ionic strength of 0.1.

This is particularly applicable for the phenothiazines, where complex salt effects and aggregation have been noted (6, 9, 10).

In view of this and the need only to obtain relative surface activity under conditions which are identical except for the structural changes being considered, a much simpler approach can be used. What is done is to compare the bulk concentration of each drug required to produce a given surface pressure and to express this relative to one of the drugs. Solution concentration is kept as low

as possible to minimize solution activity effects and, as stated earlier, all other conditions are maintained constant. Such a comparison, therefore, leads to a measure of the free energy change for adsorption relative to the drug chosen as the standard. If the π versus concentration plot for the series of drugs is similar in curvature with about the same intercept, one can expect that the ratio of concentrations and hence the free energy change will be independent of the π chosen for comparison. If, however, one merely chooses one arbitrary value without checking the complete curve or at least another surface pressure, results may be quite misleading (11, 12). As an extreme example, it is quite possible that some plots may intersect and give different relative values depending on where comparisons are made. To demonstrate this point, plots up to 5 or 6 dynes/cm. are presented and ratios are calculated at 3 and 5 dynes/cm.

Comparison of the Various Phenothiazine Derivatives—Figures 3 through 7 are presented to compare the surface activity of the various derivatives, each plot demonstrating the effect of one type of structural change. Based upon these results, the ratio of drug concentration required to produce 3 and 5 dynes/cm. surface pressure to the chlorpromazine concentration required to do this has been calculated and is presented in Table I. Values greater than one indicate less surface activity than chlorpromazine, while values less than one indicate a greater surface activity than chlorpromazine. The general agreement at 3 and 5 dynes/cm. seems to suggest that the free energy change for adsorption relative to chlorpromazine is independent of the surface pressure chosen at lower values of surface pressure.

Figures 3 and 7 and the ratios given in Table I illustrate the significant effect of changing the substituent on Position 2 of the

phenothiazine ring while holding other factors constant. Both compounds containing a $-\text{CF}_3$ group are many times more surface active than those containing a $-\text{Cl}$ group, which in turn are more surface active than those containing only $-\text{H}$ at that position. Picturing the phenothiazine molecules oriented at the interface with the ring toward the air and the alkylamino group directed toward the bulk aqueous phase, it is not surprising that changes in ring structure change surface activity so significantly. The strong contribution of the ring to the surface activity of the molecule, and hence its hydrophobic properties, is made apparent also by an earlier observation with chlorpromazine sulfoxide (5). Here, the addition of oxygen to the sulfur produces a hydrophilic species with a ratio of surface activity relative to chlorpromazine of about 100. Thus a polar group in the ring essentially eliminates any surface activity. The significant hydrophobic effect of adding the $-\text{CF}_3$ and $-\text{Cl}$ group is made apparent further when one sees (Fig. 6) that trimeprazine, with four carbons in the alkylamino portion of the molecule but only $-\text{H}$ on the ring, is significantly less surface active than any of the substituted propylamino derivatives which, of course, have only three carbons at that position.

Since the phenothiazine ring is the primary hydrophobic portion of the molecule, the ring position of substituent groups might be expected to have an effect on surface activity. Figure 4 compares chlorpromazine (2-chloro) with its 1-chloro and 3-chloro analogs. This figure and the ratios given in Table I indicate a fairly significant increase in surface activity as the chloro group is moved away from the vicinity of Position 10. It can be shown with molecular models that substitution at Position 1 definitely alters the orientation of the alkylamino group relative to the ring, restricting movement and limiting the number of possible orientations. No such effects are likely with the 2- and 3-chloro derivatives. In addition, intermolecular steric effects which also influence packing in the surface film may contribute to the difference between these compounds, although again little difference between the 2- and 3-chloro derivatives is noted with molecular models. In view of this, the significant increase in surface activity of the 3-chloro derivative may be more related to a change in the electronic structure of the phenothiazine ring. Evaluation with a wider variety of chemical structures would be

Figure 3—Plot of surface pressure versus log molar concentration at pH 5.0, ionic strength 0.10, and 25° for: triflupromazine (○), chlorpromazine (Δ), and promazine (●).

Figure 4—Plot of surface pressure versus molar concentration at pH 5.0, ionic strength 0.1, and 25° for: 1-chlorpromazine (○), 2-chlorpromazine (Δ), and 3-chlorpromazine (●).

extremely valuable in elucidating possible steric and electronic effects, but unfortunately the availability of just the right compounds is limited at the present time.

Figures 5–7 illustrate the effect of altering the nature of the alkyl-amino group at Position 10 of the ring. Comparing the ethyl, propyl, and butyl derivatives illustrates the well-known effect of increasing alkyl chain length on surface activity, an increase of one $-\text{CH}_2-$ group giving about a twofold increase in activity. Comparison of the isomers, promazine and promethazine, indicates that the presence of a branched chain reduces surface activity relative to a compound with the same number of carbons. This agrees with the fact that branched chain hydrocarbons generally are less hydrophobic than their straight chain isomers. Examination of Fig. 7 illustrates the influence of adding a piperazine ring onto the propylamino group, namely, an increase in surface activity, presumably due to the extra carbons introduced into the molecule.

A closer analysis of the results with compounds differing at Position 10 demonstrates that great care must be taken in making simple correlations. It is apparent from Table I, for example, that the dissociation constant for the amino group is more sensitive to structural changes at this position. Thus it is especially important to compare these molecules at pH values much lower than the pK_a value of the drug having the lowest pK_a . Sometimes, as in the case of the piperazine compounds with two dissociable groups, this is not possible and quantitative correlation is made difficult. For example, as seen in Table I, the addition of only one $-\text{CH}_2-$ group to chlorpromazine, giving the butyl derivative, produces a more surface-active molecule than prochlorperazine, with more CH_2 groups, because of the second ionized portion of the latter compound. Another situation where this factor apparently is important is when one compares the ratio of trifluoperazine to triflupromazine and that of prochlorperazine to chlorpromazine. If differences in surface activity are due only to the introduction of the same substituent, *i.e.*, the

Figure 5—Plot of surface pressure versus molar concentration at pH 5.0, ionic strength 0.1, and 25° for: ethyl chlorpromazine (○), propyl chlorpromazine (Δ), and butyl chlorpromazine (●).

piperazine ring, these ratios should be the same; however, the value for the CF_3 compounds is 0.50 and that for the Cl compounds is 0.59. What is happening, of course, is that at pH 4.0 all of these compounds are essentially completely protonated at one amino group, but the two piperazine derivatives have different second dissociation constants. Trifluoperazine has a dissociation constant of 3.9 while the value for prochlorperazine is 3.6. Hence at pH 4.0 the piperazine of trifluoperazine probably contributes more to the surface activity because it has introduced a lower degree of ionization to the molecule.

Figure 7—Plot of surface pressure versus log molar concentration at pH 4.0, ionic strength 0.1, and 25° for: trifluoperazine (○), prochlorperazine (●), and chlorpromazine (△).

SUMMARY

The relative surface activity of various phenothiazine derivatives has been measured under solution conditions which for the first time allow meaningful comparison of structural effects.

Estimation of the concentration required to produce given changes in surface tension, relative to that produced by chlorpromazine, reveals significant effects due to substitution of H, Cl, and CF_3 groups on the phenothiazine ring. The position of a substituent on the ring has been shown to be another important factor.

The influence of changing the alkylamino group at Position 10 has been discussed in terms of changes in hydrophobicity due to the number and arrangement of alkyl groups. A primary factor to consider also is how substitution influences the dissociation constant(s) of the amino group(s) and hence the degree of ionization at the pH being utilized for comparison.

Centrally Acting Emetic Agents IV: Synthesis and Chromatographic Methods for Certain Nornuciferine Derivatives

RAYMOND J. VAVREK, JOSEPH G. CANNON*, and ROBERT V. SMITH

Abstract □ *dl*-Nornuciferine has been synthesized by a literature procedure; alkyl groups were introduced on the nitrogen by direct alkylation, reductive alkylation, or by acylation followed by reduction to afford eight *N*-alkylnornuciferine derivatives. Selective cleavage of the ether function at Position 1 of the 1,2-dimethoxyaporphine systems was achieved by use of hydriodic acid in acetic anhydride. As a preliminary to metabolic studies on the products, thin-layer and gas chromatographic methods were devised for qualitative and quantitative analysis of them.

Keyphrases □ Emetic agents—centrally acting □ Nornuciferine derivatives—synthesis □ IR spectrophotometry—identity □ NMR spectroscopy—identity □ TLC—analysis □ GLC—analysis

In a continuing study of aporphine derivatives, which are potential emetic agents (1), a series of 1,2-dimethoxylated aporphine (nornuciferine) derivatives was investigated. Compounds I–XVI (Table I) were prepared for biological evaluation of their emetic effects and for initiation of a study of the metabolic fate of dioxygenated aporphine systems in mammals.

The literature reveals a paucity of information on metabolism or biological fate of aporphine systems in general; Compounds I–VIII have been selected for initial metabolic investigation. In considering possible biotransformations of *N*-substituted nornuciferines, *N*- and/or *O*-dealkylation seem to be plausible reactions (2). Thus, for Compounds II–VIII, three possible metabolite types are available for study: I, an *N*-dealkylated product; IX, an *N*- and *O*-dealkylated system; and X–XVI, *O*-dealkylated products of the parent compounds. Analytical systems were required for separation, identification, and quantitation of each of these substances as a prelude to the proposed metabolic studies.

TLC was envisioned as the qualitative method of choice. Solvents and techniques employed in the separation of closely related alkaloids (3) served as a reference point for the development of systems in this investigation. For quantitative analysis, gas chromatography was considered. Arndt *et al.* (4) chromatographed nornuciferine (I) and nuciferine (II) with an SE-30 column. Since the nuciferine analogs in the present study represent wider structural variation and were expected to possess poorer volatility, a similar but more thermally stable internal phase was sought. OV-17, a silicone polymer with 50% phenyl substitution and a temperature limit of approximately 350°, was used.

RESULTS AND DISCUSSION

dl-Nornuciferine (I), prepared by the method of Weisbach and Douglas (5), was *N*-alkylated directly with an alkyl halide or was *N*-acylated and then reduced with lithium aluminum hydride. *dl*-

Nuciferine (II) was prepared by Eschweiler-Clarke methylation of I.

It is noteworthy that the Pschorr cyclization of 1-(2'-amino-benzyl)-6,7-dimethoxy-1,2,3,4-tetrahydroisoquinoline to an aporphine system proceeded in approximately twice the percent yield reported for this step in the literature (5). Initial low recovery of products in the lithium aluminum hydride reductions increased significantly by use of a procedure (6, 7) in which the reduction mixture, after quenching with water, was stirred with an ammonium tartrate solution which presumably aids in breaking the aluminum complexes of the amino product.

Attempts were made to cleave the ether links of Compounds I–VII to form 1,2-dihydroxyaporphine systems; hydriodic acid in acetic anhydride (8) was selected as the most promising reagent. Elemental analysis of the ether-cleaved products of I–VIII indicated an incomplete cleavage and suggested that the products were monohydroxy- and monomethoxyaporphines. NMR spectra of all of the ether-cleaved materials demonstrated a singlet (3H) at 3.85–3.89 δ , while the parent dimethoxylated aporphines exhibited signals at 3.82–3.86 δ (3H) and at 3.60–3.62 δ (3H). The higher field shift has been assigned to the methoxyl group at Position 1 (9, 10), on the basis of steric interactions of the 1-methoxyl group with the *peri*-hydrogen at Position 11 and with the methoxyl group at Position 2. These interactions force the methyl portion of the Number 1 methoxyl out of the plane of the aromatic ring and make it more susceptible to the shielding effects of both aromatic rings. This assignment has been corroborated in the nuciferine system itself (11). Kametani and Noguchi (12) have prepared *dl*-*N*-methyl-caaverine (1-hydroxy-2-methoxy-*N*-methylaporphine) by an unequivocal route. This compound, which is the free base form of Compound X (Table I), exhibited an NMR signal at 3.86 δ (3H) which was assigned to the protons of the 2-methoxy group. Therefore, the cleavage procedure employed in the present study was selective for the ether function at Position 1 of the 1,2-dimethoxyaporphines, giving a series of 1-hydroxy-2-methoxyaporphines (IX–XVI). There was no indication that isomeric 1-methoxy-2-hydroxyaporphines were formed in any of the cleavage reactions.

The literature contains numerous accounts of selective cleavage of polymethoxy aromatic ethers with sulfuric acid (13, 14) and with hydrohalic acids (15). Bruderer and Brossi's proposal (15) that selective ether cleavage in certain polymethoxylated heterocyclic systems is a function of differences in basicity of the ether oxygens due to electrostatic substituent effects has been rejected by Wilcox and Seager (16) following their kinetic study of similar systems, on the basis that this explanation requires postulating "unprecedentedly negative *ortho* σ (OCH_3) constants." These latter workers rationalized the greatly enhanced cleavage rates of the central methoxyl group of 1,2,3-trimethoxybenzene derivatives by hydrobromic acid in acetic acid as being due to steric acceleration factors; the greater basicity of the central methoxyl group is due to its being twisted out of the plane of the aromatic ring. In the present case of the apparently exclusive cleavage of the Number 1 methoxyl of 1,2-dimethoxyaporphines, the explanation of Wilcox and Seager (16) may be invoked as a reasonable one. The NMR data cited previously corroborated this type of steric disposition of the Number 1 methoxyl. Catalin models indicate serious nonbonded interactions of the Number 1 methoxyl with the Number 2 methoxyl and with the Number 11 hydrogen, when the Number 1 methoxyl is coplanar with the benzene ring to which it is attached.

X-ray crystallographic studies (17) indicate that the biphenyl portion of aporphine systems is appreciably strained, the angle of twist being 29.9°. This strain increases in aporphines bearing substituents at Positions 1 and/or 11. Based upon the premise that the release of steric strain in the course of a reaction can be a driving force, and upon the proposal (18) that the "packing strain" in di-

Table I—Nornuciferine Derivatives

^a M = methanol; EEt = ethanol-ether; E = ethanol; W = water; EWet = ethanol-water-ether; EW = ethanol-water; MEt = methanol-ether. ^b Weisbach and Douglas (5) give m.p. 262° (dec.). ^c Hydrochloride. ^d Baarschers *et al.* (11) give NMR data for this compound but do not otherwise characterize it or describe its preparation. ^e Hydroiodide.

tert-butyl ether accounts for its ease of cleavage under remarkably mild conditions, it seems reasonable that cleavage of the more strained ether function at Position 1 in the 1,2-dimethoxylated aporphine systems would relieve sufficient strain to account in part for the selectivity encountered. This proposal complements the hypothesis of steric inhibition of coplanarity of the Number 1 methoxyl.

No attempt was made to force the cleavage of the 1-hydroxy-2-methoxyaporphines to the diphenolic systems.

Thin-Layer Chromatography—Separation of the *N*-substituted nornuciferines (II–VIII) from their possible metabolites was attempted with 36 solvent systems; Table II lists the *R_f* values and

detection characteristics of Compounds I–XVI in four solvent systems found suitable [*i.e.*, solvent systems yielding separation of each of the *N*-alkylated nornuciferines (II–VIII) from their *O*- and *N*-dealkylated congeners (I and IX–XVI)]. An advantage of the piperidine-containing systems (Systems 2–4) was that either the hydrohalide salts or free bases could be spotted and after development would reveal the same *R_f* values. Using Solvent System 1, comparable development without tailing was observed only with the free bases.

Detection was achieved with Dragendorff's reagent (3) and by fluorescence in 254-mμ radiation. With the latter immediately

^a Average of 6 to 15 determinations; average of the percent standard deviation of R_f 's of all compounds in Solvent Systems 1–4 = 4.4%.

^b With silica gel G plates, solvent systems employed were: 1, chloroform–methanol (93:7); 2, benzene–piperidine (9:1); 3, cyclohexane–chloroform–piperidine (8:1:1); 4, benzene–ethyl acetate–piperidine (6:3:1). ^c In 254-m μ radiation, after heating at 110° for 30 min.

after development, all compounds appeared as blue-fluorescing spots; with heating, characteristic and more intense orange, yellow, or blue spots were observed. Sensitivities using this technique were improved over Dragendorff's reagent, and the limit of detection was estimated to be less than 1 mcg. for most of the compounds.

Gas Chromatography (GC)—Initial GC attempts with nuciferine (II) utilizing copper columns revealed significant decomposition which was apparently metal-catalyzed and could be obviated by employing a glass column and glass-lined injection port. Good development of all compounds was attained, except for XV which appeared to decompose at all temperatures studied. Retention times, relative to nornuciferine (I), are indicated in Table III. Separation of all *N*-substituted nornuciferines (II–VIII) from their possible *N*- and *O*-dealkylated metabolites (I, IX–XIV, and XVI) was excellent, except in the *N*-ethyl series where *N*-ethyl-nornuciferine (III) could not be completely resolved from nornuciferine (I).

The satisfactory GC of the nornuciferine derivatives in general and the free phenolic systems (IX–XVI) in particular was somewhat unexpected, because these compounds readily decompose on heating. The successful GC of most of the phenolic aporphines may be due to intramolecular hydrogen bonding between the phenolic hydrogen and the oxygen of the vicinal methoxyl group (19, 20). Quantities analyzed were between 0.5 and 3.0 mcg., and curves of peak height *versus* amount chromatographed were linear for Compounds I–XIV and XVI.

EXPERIMENTAL¹

N-[2-(3,4-Dimethoxyphenyl)ethyl]-*o*-nitrophenylacetamide—

Method A—This was a modification of the method of Gulland and Haworth (21). A mixture of *o*-nitrophenylacetic acid (100 g.), 400 ml. of thionyl chloride, and 600 ml. of chloroform was refluxed for 3 hr.; then volatile materials were removed under reduced pressure at room temperature. The resulting red oil was added dropwise to a well-stirred and chilled mixture of 50 g. of 3,4-dimethoxyphenethylamine in 200 ml. of ether and a solution of 70 g. of sodium hydroxide in 1 l. of water; the resulting mixture was stirred at room temperature for 1 hr. The solid which separated was collected on a filter and washed several times with water. It was then dissolved in chloroform; this solution was washed with saturated sodium chloride solution, dried over sodium sulfate, and filtered. Removal of

solvent from the filtrate gave a brown solid which was taken up in hot chloroform, treated with charcoal, filtered, and concentrated to 250 ml. Upon cooling, 113 g. (79%) of buff-colored crystals was deposited, m.p. 112° [lit. (21) m.p. 109–111°]. An IR spectrum (10% in chloroform) showed a peak at 1665 cm⁻¹ (amide).

Method B—An excess of an ethereal solution of diazomethane was added to a solution of 37 g. of *o*-nitrophenylacetic acid in 200 ml. of ether, and the resulting solution was stirred overnight at room temperature. Removal of the ether left a brown oil which was added to a solution of 73 g. of 3,4-dimethoxyphenethylamine in 300 ml. of benzene, and the resulting mixture was refluxed for 10 hr. The benzene was removed under reduced pressure, and the residual brown solid was recrystallized from methanol to yield 59 g. (78%) of product, m.p. 112°.

dl-Nornuciferine (I)—**Method C**—This was prepared by the method of Weisbach and Douglas (5) and was recrystallized, m.p. 121–125° [lit. (21), (–)-nornuciferine, m.p. 124–125°]. A polymorphic form crystallized from 2-propanol, m.p. 165–166°.

dl-Nuciferine Hydrochloride (II)—**Method D**—Conversion of I to *dl*-nuciferine hydrochloride was by application of the method of Icke and Wisegarver (22). A solution of 3 g. of I, 40 ml. of 88% formic acid, and 40 ml. of 37% aqueous formaldehyde solution was refluxed for 5 hr.; then volatile materials were removed under reduced pressure. The final residue was taken up in 250 ml. of 2% sulfuric acid, the solution was filtered, and the filtrate was treated with an excess of 14% ammonium hydroxide. The resulting mixture was extracted with ether; this extract was washed with saturated sodium chloride solution, dried with sodium sulfate, filtered, and treated with anhydrous hydrogen chloride. The white precipitate which separated was recrystallized (Table I). A portion of the hydrochloride salt of II was treated with sodium hydroxide solution, and the gummy solid resulting was extracted with ether. This extract was washed with saturated sodium chloride solution, dried with sodium sulfate, filtered, and concentrated to deposit large, slightly yellow prisms, m.p. 137–140° [lit. (21) m.p. 136–137°].

***N*-Acylated Nornuciferines**—**Method E**—A solution of a twofold excess of the appropriate acid chloride and 5 g. of nornuciferine (I) in 100 ml. of dry pyridine and 200 ml. of anhydrous benzene was refluxed and stirred for 2 hr. After cooling and filtering, the reaction solution was washed with 200 ml. of water; the water was extracted with benzene which was added to the original organic phase, and the combined organic solutions were washed with water, dried with sodium sulfate, and filtered. The solvent was removed from the filtrate under reduced pressure. The solid residue was recrystallized (Table I).

***N*-Alkyl nornuciferines (III–V)**—**Method F**—A suspension of 15.5 mmoles of the appropriate *N*-acyl nornuciferine in 250 ml. of purified tetrahydrofuran (distilled from lithium aluminum hydride) was added to a suspension of 5.2 g. of lithium aluminum hydride

^a Average of 4 to 15 determinations. ^b See *Experimental*. ^c Retention time of nornuciferine (I), 7.8 min. (22 determinations). ^d Retention time of nornuciferine (I), 3.0 min. (4 determinations). * Decomposes at all temperatures employed.

¹ Melting points are corrected. IR spectra were recorded on Beckman IR-5A and IR-10 instruments. NMR spectra were obtained with a Varian A-60 instrument; samples were prepared as 10% solutions in DMSO-*d*₆ using tetramethylsilane as internal standard. GC was performed with a Hewlett-Packard 5750B gas chromatograph equipped with dual-flame ionization detectors.

in 250 ml. of purified tetrahydrofuran, and the resulting mixture was refluxed for 6 hr. Water (10.4 ml.) was carefully added; then 200 ml. of saturated ammonium tartrate solution was added and the mixture was stirred for 1 hr. at room temperature. The layers were separated and the aqueous layer was extracted repeatedly with ether. The combined organic phases were washed with saturated sodium chloride solution, dried with sodium sulfate, and filtered; the filtrate was evaporated under reduced pressure. The residual brown oil was dissolved in dry ether, and this solution was treated with anhydrous hydrogen chloride to yield a white precipitate which was recrystallized (Table I).

N-Alkylnormuciferines (VI and VII)—Method G—A mixture of 2 g. of normuciferine (I), a 0.1 molar excess of the appropriate alkyl bromide, a 0.5 molar excess of sodium bicarbonate, and 25 ml. of anhydrous ethanol was refluxed for 10 hr. The resulting mixture was filtered while hot, and the filtrate was concentrated under reduced pressure to give a brown oil. Treatment of an anhydrous ether solution of this oil with anhydrous hydrogen chloride gave a white precipitate which was recrystallized (Table I).

dl-N-Benzylnormuciferine (VIII)—Method H—This was prepared from *N*-[2-(3,4-dimethoxyphenyl)ethyl]-*o*-nitrophenylacetamide by the method of Weisbach and Douglas (5) and was recrystallized, m.p. 98–99° [lit. (5) 98–99.5°].

Hydriodides of 1-Hydroxy-2-methoxynoraporphine (IX) and N-Alkylated Derivatives (X–XVI)—Method I—These were prepared by a modification of the method of Howell and Robertson (24). Nitrogen was passed through a suspension of 3 mmoles of the appropriate 1,2-dimethoxynoraporphine (I–VIII) in 7 ml. of acetic anhydride. To this suspension, 4.8 ml. of 57% hydriodic acid (stabilized with 1.4% hypophosphorous acid) was carefully added. The reaction mixture was refluxed in an oil bath of 150° under a stream of nitrogen for 0.5 hr.; then it was permitted to cool to room temperature in a stream of nitrogen. Excess volatile material was removed under reduced pressure, and the solid residue was recrystallized (Table I).

Thin-Layer Chromatography—Silica gel G plates (20 × 20 cm.) were prepared from a slurry containing 3 g. of silica gel G² and 7 ml. of water per plate. After air drying, plates were activated at 110° for 1 hr. and kept in a desiccator until used. Developing distance throughout was 10 cm. with the solvent systems listed in Table II. All solvents were reagent grade. Detection was accomplished with Dragendorff's reagent (Thies, Reuther, modified by Vagufalvi) (3) and by fluorescence under 254-mμ radiation, either immediately after development or following heating at 110° for 30 min.

Gas Chromatography—Glass columns [182.9 cm. (6 ft.) × 4 mm. i.d.] were packed with 3% OV-17 on diatomaceous earth,³ 100/120 mesh. Operating temperatures were: (a) injection port, 260°; column, 260°; and detector, 300°; (b) injection port, 290°; column, 290°; and detector, 320°. Conditions held constant were: carrier gas (helium), 120 ml./min. (50 psig); hydrogen, 40 ml./min. (13 psig); air, 440 ml./min. (30 psig); attenuation, 8; and range, 10². For GC, aqueous solutions of hydrohalide salts were treated with equal volumes of pH 8.0 *tris*-hydrochloric acid buffer (0.2 *M*); free bases were extracted into 1% isoamyl alcohol in *n*-heptane. All compounds except IX could be recovered as the free base by this procedure; extraction of IX required 25% isoamyl alcohol in *n*-heptane. Quantities analyzed were between 0.5–3.0 mcg.; curves of peak height *versus* amount chromatographed were plotted.

Oral Dosage Form Design and Its Influence on Dissolution Rates for a Series of Drugs

FOO SONG HOM and JOHN J. MISKEL

Abstract □ The study illustrates the influence oral dosage form design has on dissolution rates for drugs from different chemical and pharmacological classes. Comparative data demonstrate that relatively insoluble drugs, when formulated in soft elastic capsules, are released faster than from commercially available tablets. Faster dissolution from soft elastic capsules is believed to be due to the more rapid dispersion of the active ingredients. Rapid dispersion of medicaments is enhanced by the use of solubilizers and/or surfactants in the formulation design. Soft elastic capsules are recommended for the formulation of low-dose medications, of relatively insoluble drugs, and of drugs where early high-blood level of the drug is indicated.

Keyphrases □ Oral dosage form design effect—dissolution rates □ Capsules, soft elastic, tablets—drug release-rate comparison □ Rotating-bottle apparatus—dissolution testing □ UV spectrophotometry—analysis

In recent years, numerous scientists have demonstrated the direct relationship between proper formulation of a dosage form and the production of a clinically effective drug product. Many correlations have been established between formulation design and therapeutic activity, reporting the interrelation of particle size, dissolution, and absorption. In a review, Nelson (1) indicated that the rate of gastrointestinal absorption of a drug is often a function of the time needed for the drug to dissolve in the fluid at the site of absorption. He pointed out that, in general, the availability for absorption decreases in the order: solution > suspension > powder-filled capsule > compressed tablet > coated tablet. However, changes in this order may occur for various reasons, but they are exceptions. Tannenbaum *et al.* (2) demonstrated that in some cases, through the use of modern pharmaceutical techniques, it is possible to produce a tablet that results in greater drug absorption than a powder-filled capsule. Wagner *et al.* (3), in their study on the effect of dosage form on serum levels of indoxole, observed that the serum level response de-

Figure 1—Dissolution rates of hydrocortisone capsule and tablet in simulated gastric fluid T.S. Key: ●, soft elastic capsule; and ○, Tablet A.

Figure 2—Dissolution rates of ethinyl estradiol capsule and tablets in simulated gastric fluid T.S. Key: ●, soft elastic capsule; ○, Tablet A; and ◐, Tablet B.

creases in the order: emulsion (Lipomul-Oral) \approx soft gelatin capsule > aqueous suspension > powder-filled capsule. Aguiar *et al.* (4) studied and correlated the effects of deaggregation or dispersion, dissolution, and *in vitro* gut-permeation rates on the chloramphenicol availability from four commercial lots of capsules. Glazko *et al.* (5) observed different absorption rates from capsules containing identical amounts of chloramphenicol from different manufacturers. Similarly, Brice and Hammer (6) observed significant differences in serum antibiotic levels obtained from 16 commercially available lots of oxytetracycline capsules distributed by 13 different suppliers.

The present work is a study of the influence of soft elastic capsule and tablet dosage forms on dissolution rates for a series of chemically and pharmacologically different drugs. While it will be agreed that *in vitro* dissolution rate data do not necessarily reflect *in vivo* absorption and availability, sufficient correlation exists to justify the use of this technique to measure potential dosage form efficiency (7–12). The rotating-bottle method (13–15) is used to compare the dissolution rates of soft elastic capsules and tablets.

EXPERIMENTAL

A drug must be formulated in one of several dosage forms, depending on its intended use. In general, a dosage form is designed for rapid and complete absorption of the drug. In some cases a dosage form may be developed for delayed action or for combined effects of quick onset and prolonged action. For rapid and complete absorption of a drug, it is best to formulate in solution. However, this is not always practical, as with very insoluble drugs. In this case the next best form is the suspension dosage form. Modern pharmaceutical technology embraces the use of surfactants and/or solubilizers to enhance the rapidity and maximum absorption of a drug. By nature, many surfactants and solubilizers are liquids at room temperature. Hence, these agents may play multifaceted roles in liquid formulations: as vehicles and interface modifiers. Formulations of a drug containing surfactants and/or solubilizers may be encapsulated conveniently in soft elastic capsules, as demonstrated in the present work which includes examples of relatively insoluble drugs.

Figure 6—Dissolution rates of digitoxin capsule and tablets in simulated gastric fluid T.S. Key: ●, soft elastic capsule; ○, Tablet A; and ◐, Tablet B.

Figure 7—Dissolution rates of bishydroxycoumarin capsule and tablet in simulated gastric fluid T.S. Key: ●, soft elastic capsule; and ○, Tablet A.

Products Tested—For the purpose of this study the drugs chosen represent a number of chemical and pharmacological classes. The soft elastic capsules were manufactured using the continuous rotary die process. The drugs, where possible, were dissolved in polyethylene glycol 400 USP or suspended in various polyols with 1–3% of a nonionic surfactant. In some cases the dispersion vehicle was a nonionic surfactant or mixture of nonionic surfactants. Commercial capsules and tablets were purchased on the open market. These include “brand name” drugs and their generic counterparts.

Method—The rotating-bottle apparatus (13–15) was used for the dissolution tests in the following manner. Into each of the bottles was placed 50 ml. of simulated gastric fluid T.S. (without pepsin), and the bottles were allowed to come to temperature equilibrium in a water bath at $37.5 \pm 0.1^\circ$. One tablet or capsule was added to each bottle and rotation begun at about 40 r.p.m. At suitable time intervals, a bottle was removed and the contents filtered immediately through a $0.22\text{-}\mu$ Millipore filter in a microsyringe filter holder.¹ An aliquot of the clear filtrate was diluted and analyzed by appropriate USP (16) methods of colorimetry or spectrophotometry. Ethinyl estradiol was analyzed by a special colorimetric method (17). A technique similar to the one published by Burns *et al.* (18) was used to analyze phenylbutazone ($\lambda = 265\text{ m}\mu$, 0.1 N NaOH). Similarly the method of UV spectrophotometry was used to analyze sulfadiazine ($\lambda = 309\text{ m}\mu$, 0.1 N HCl) and propylthiouracil ($\lambda = 275\text{ m}\mu$, H_2O).

RESULTS AND DISCUSSION

Results, where possible, were plotted as percent of the amount ultimately dissolved so as to remove differences of overages occur-

ring in different products. With practically insoluble drugs, where only a fraction of the dose is dissolved, the amount of drug dissolved in 1 ml. of fluid was plotted *versus* dissolution time. Completion of dissolution, the saturation point in the case of poorly soluble drugs, was taken as the time on the graph when a smooth curve through the points reached a maximum. Typical curves are shown in Figs. 1–10. Figures 1–6 are plots of percent drug dissolved *versus* time from tablets and from solutions encapsulated in soft elastic capsules. Figures 7–10 are plots of milligrams or micrograms of drug dissolved per milliliter of fluid *versus* time for commercial tablets and for suspensions encapsulated in soft elastic capsules. A cursory observation of Figs. 1–10 is sufficient to conclude that dissolution of the drug from soft elastic capsules is faster than from tablets in simulated gastric fluid T.S. (without pepsin) at 37.5°. However, a quantitative comparison may be made by observing the average time from duplicate runs for dissolution of 90% of the drug, as shown in Table I. Table II lists the average amount in micrograms from duplicate runs of relatively insoluble drugs dissolved per milliliter of fluid after 5 min. of dissolution. An examination of Table I reveals that a drug, when formulated in soft elastic capsules, will have a dissolution rate from 3 to 30 times faster than tablets. It is apparent that the increase in dissolution rate is due to the rapid dispersion of the drug when the capsule splits open. Also, the use of a proper vehicle, solubilizer, and surfactant apparently helps to enhance the dispersion of a relatively insoluble drug. Table II details the average increase, provided by the soft elastic capsule, in the ap-

parent solubility of the drug ranging from 1.1 to 67 times that of tablets reflecting the effects of the vehicle, solubilizer, and surfactant.

The data indicate that it is possible to solubilize many low-dose, relatively insoluble drugs and to encapsulate them in soft elastic capsules of appropriate sizes. For high-dose and very insoluble drugs, it is preferable to encapsulate them as suspensions. With the applications of these two techniques in encapsulation, conceivably one can either singly or collectively use solubilizers and/or surfactants as specially designed vehicles for each drug. The soft elastic capsule is an ideal dosage form for drugs such as the oral contraceptives where submilligram unit doses are common.

An appreciation of the profound influence dosage form design has on dissolution, absorption, and efficacy (1–12) should preclude sole reliance on conventional tablet and powder-filled capsule technology in the development of "new drug" dosage forms. The costs of carrying new drug dosage forms through toxicity studies, clinical trials, and a new drug application procedure make errors in this area disastrous. Solutions and suspensions in soft elastic capsules, as well as tablets and dry-filled capsules, should be investigated in early stages of development employing *in vitro* dissolution studies. Availability as provided by the more promising dosage forms should then be appraised by *in vivo* animal studies.

CONCLUSIONS

The study illustrates the influence of oral dosage form design on dissolution rates for drugs from different chemical and pharma-

Figure 9—Dissolution rates of phenylbutazone capsule and tablet in simulated gastric fluid T.S. Key: ●, soft elastic capsule; and ○, Tablet A.

cological classes. It also suggests avenues that should not be overlooked when investigating new drugs or improving older medications. The results demonstrate that many relatively insoluble drugs may be readily formulated in soft elastic capsules and have faster dissolution rates than tablets in that solutions or suspensions of a drug can be readily encapsulated. Furthermore, surfactants or other compounds may be encapsulated along with the drug so as to enhance its solubility and potential absorption rate. Soft elastic capsules are recommended in the formulations of low-dose medication, of relatively insoluble drugs, and of drugs where early high-blood level of the drug is indicated.

DRUG STANDARDS

Chemical Standardization and Quality Assurance of Whole Crude Coal Tar USP Utilizing GLC Procedures

M. GRUBER, R. KLEIN, and M. FOXX

Abstract ☐ A procedure has been developed which utilizes gas-liquid chromatographic (GLC) analysis for the chemical standardization of medicinal crude coal tar USP. A similar method is recommended for the determination of coal tar fractions in Liquor Carbonis Detergens (LCD) (coal tar solution USP). Data confirming that LCD and similar "extracts," "fractionates," and "synthetics" cannot be considered as generic, pharmaceutical, or medicinal equivalents of a properly standardized whole crude coal tar are presented.

Keyphrases ☐ Crude coal tar—analysis ☐ Coal tar solution—analysis ☐ Ethanol content, coal tar solution—determination ☐ GLC—analysis.

Dioscorides, a Greek physician, described nearly 2000 years ago the merits of asphaltic tar in the "Materia Medica" as a treatment for cutaneous disorders (1). The advantages of the empirical use of "tars" were subsequently emphasized by numerous investigators including Brocq (2), White (3), and Goeckerman (4, 5).

In modern times, this medication is widely prescribed for various skin diseases, such as psoriasis and eczema, which are frequently severe and occasionally disabling.

In addition, this modality is routinely prescribed for seborrheic dermatitis, occupational and contact dermatitis, dermatophytosis, varicose eczema, chronic and exudative and lichenoid dermatitis, pruritis ani, and various other chronic skin disorders.

Although therapeutic response is often dramatic, the known variability of coal tar composition and consequent inconsistency of clinical results has made this medication the subject of complaint and controversy among dermatologists.

This ancient but fundamental topical drug is virtually devoid of any guardian standards of chemical composition. Consequently, almost any coal tar, regardless of its composition, may satisfy the requirements of current official compendia for crude coal tar. Practically no controls have been established to assure uniformity, potency, safety, and efficacy. It is, therefore, quite evident that the scientific development of far more definitive drug reference standards and methods of analysis for this valuable, but variable, therapeutic agent is mandatory. No proficient effort has been initiated to create an effective method to control the physical and

cological classes. It also suggests avenues that should not be overlooked when investigating new drugs or improving older medications. The results demonstrate that many relatively insoluble drugs may be readily formulated in soft elastic capsules and have faster dissolution rates than tablets in that solutions or suspensions of a drug can be readily encapsulated. Furthermore, surfactants or other compounds may be encapsulated along with the drug so as to enhance its solubility and potential absorption rate. Soft elastic capsules are recommended in the formulations of low-dose medication, of relatively insoluble drugs, and of drugs where early high-blood level of the drug is indicated.

DRUG STANDARDS

Chemical Standardization and Quality Assurance of Whole Crude Coal Tar USP Utilizing GLC Procedures

M. GRUBER, R. KLEIN, and M. FOXX

Abstract ☐ A procedure has been developed which utilizes gas-liquid chromatographic (GLC) analysis for the chemical standardization of medicinal crude coal tar USP. A similar method is recommended for the determination of coal tar fractions in Liquor Carbonis Detergens (LCD) (coal tar solution USP). Data confirming that LCD and similar "extracts," "fractionates," and "synthetics" cannot be considered as generic, pharmaceutical, or medicinal equivalents of a properly standardized whole crude coal tar are presented.

Keyphrases ☐ Crude coal tar—analysis ☐ Coal tar solution—analysis ☐ Ethanol content, coal tar solution—determination ☐ GLC—analysis.

Dioscorides, a Greek physician, described nearly 2000 years ago the merits of asphaltic tar in the "Materia Medica" as a treatment for cutaneous disorders (1). The advantages of the empirical use of "tars" were subsequently emphasized by numerous investigators including Brocq (2), White (3), and Goeckerman (4, 5).

In modern times, this medication is widely prescribed for various skin diseases, such as psoriasis and eczema, which are frequently severe and occasionally disabling.

In addition, this modality is routinely prescribed for seborrheic dermatitis, occupational and contact dermatitis, dermatophytosis, varicose eczema, chronic and exudative and lichenoid dermatitis, pruritis ani, and various other chronic skin disorders.

Although therapeutic response is often dramatic, the known variability of coal tar composition and consequent inconsistency of clinical results has made this medication the subject of complaint and controversy among dermatologists.

This ancient but fundamental topical drug is virtually devoid of any guardian standards of chemical composition. Consequently, almost any coal tar, regardless of its composition, may satisfy the requirements of current official compendia for crude coal tar. Practically no controls have been established to assure uniformity, potency, safety, and efficacy. It is, therefore, quite evident that the scientific development of far more definitive drug reference standards and methods of analysis for this valuable, but variable, therapeutic agent is mandatory. No proficient effort has been initiated to create an effective method to control the physical and

chemical properties of this medicinal substance with the exception of an exploratory investigation by de Martin and Cyr in 1953 (6).

GENERAL CHARACTERISTICS

Crude coal tar is an extremely complex by-product of the destructive distillation of coal. There are uncontrolled qualitative and quantitative chemical and pharmacological differences, dependent upon the source of raw material, method, and temperature of distillation, shape and size of retorts, and other factors (7). Accordingly, since the medicinal qualities of this material are dependent upon the aggregate effect of its hundreds of discrete components, many of which have never been identified, considerable variations in clinical results are apparently unavoidable. A lack of uniformity and the variations in therapeutic effect of different coal tars have caused concern (8).

All attempts to retain the therapeutic effects, while simultaneously removing the objectionable black color, odor, and staining properties of coal tar, have been futile, although it has been "fractionated," "separated," "extracted," "filtered" and "synthesized" to improve its esthetic appearance. The relatively clear substances which have emerged possess one common deficiency, namely a considerable reduction of pharmacological activity caused by the removal of the "objectionable" tar fractions including pitch, carbon, and asphaltic compounds (9).

Even its mode of action has not been satisfactorily defined, having been variously described as "reducing," "photosensitizing," "irritant," "antiseptic," "antipruritic," "keratoplastic," "anti-acanthotic," "vasoconstrictive," "antiparasitic," "antifungal," and "antibacterial."

Coal tar is described in the USP XVII as a "nearly black, viscous liquid, heavier than water, having a characteristic, naphthalene-like odor and a sharp, burning taste" (10). These vague descriptions have only compounded the physician's problem of attempting to obtain consistent and uniform clinical results.

The monograph on LCD (coal tar solution USP) is equally obscure (11). The only quantitative specification is for alcohol concentration. This permits enormous variation in the tar-extract content and the incorporation of such dissimilar constituents as to make this qualification virtually meaningless.

For the past 15 years, the authors' control laboratory has employed, with some success, the methods introduced by de Martin and Cyr (6). These techniques considerably improved quality and uniformity, but were inadequate for assuring a specific, chemically standardized, medicinal "whole" coal tar. During the past 2 years, the authors have utilized GLC to achieve this goal.¹

Other attempts have been made to standardize the therapeutic response which physicians could reasonably anticipate from tar by comparing relative bioassays or measurements of the photodynamic action of tar on normal guinea pig skin (12). Photobiological activity as the quality control determinant of tar, manifested by sensitization effects on human, rabbit, guinea pig, or other mammalian skin, is deceiving since this attribute of coal tar is related primarily to its anthracene-acridine content (9). The fluorescence under longwave UV light is easily induced or modified by the mere presence of anthracene and/or acridine in sufficient amounts. Accordingly, UV photosensitization cannot assure a medically acceptable grade of raw material since this characteristic bears only a singular relationship to the total properties of coal tar.

Some manufacturers have incorporated surface-active agents with coal tar and equated their antifungal release activities as a measure of their biological effect (13). Anticipated therapeutic performance, as measured by the reference standard of antiseptic properties, is also unpredictable. Coal tars, regardless of composition, demonstrate considerable fungistatic and bacteriostatic activity. These properties, while of value, have never been demonstrated to be primarily responsible for the clinical efficacy of tar. They are simply additional chemical and therapeutic attributes.

A gas chromatographic procedure is presented for the quality control of crude coal tar, as well as LCD (coal tar solution USP).

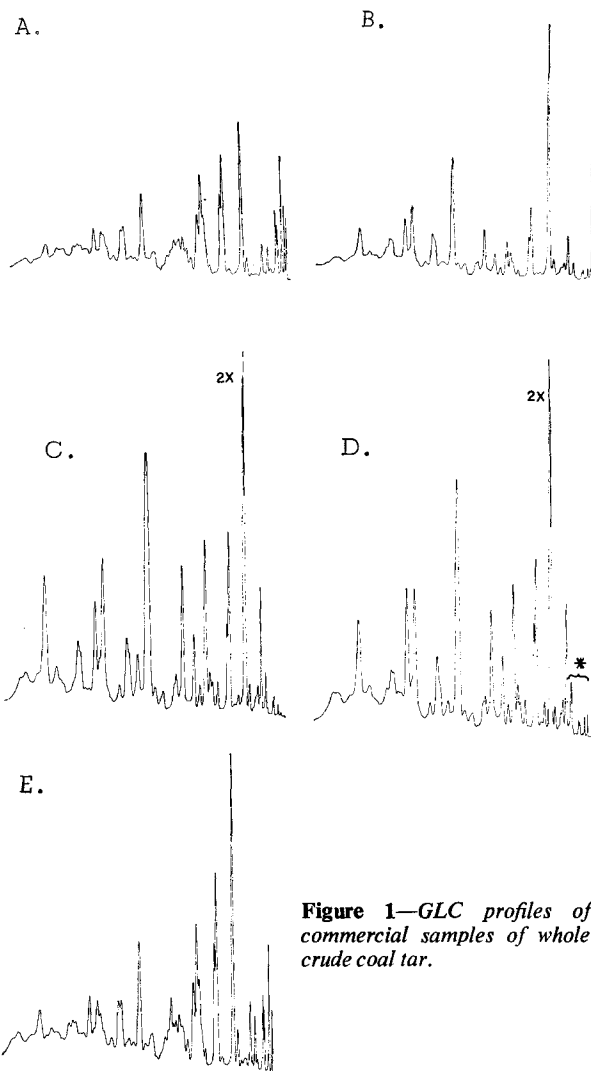

Figure 1—GLC profiles of commercial samples of whole crude coal tar.

Comparison of the various samples of each indicates the wide and uncontrolled range of presently admissible materials and demonstrates why consistent clinical results are not possible under the present official specifications defining this important topical drug.

The scientific data and information developed would enable the preparation of a monograph, which would exclude from official recognition any coal tar that does not possess comparable physical characteristics and chemical composition.

EXPERIMENTAL

In order to provide a more selective and specific tar analysis, it was necessary to analyze a number of market samples. These were obtained from various commercial sources and pharmacies, selected at random throughout the U. S. Although all of the samples secured were labeled USP and met present monograph specifications for coal tar and coal tar solution, they did nevertheless demonstrate marked physical differences and profound chemical variations both qualitatively and quantitatively.

Apparatus—A dual column Varian Aerograph model 204B chromatograph equipped with dual flame-ionization detectors was employed for all GLC work. Injection port and detector temperatures were 275 and 280°, respectively. Flow rates of 40 ml. He/min., 30 ml. H₂/min., and 300-ml. filtered air/min. (supplied by two Oscar's Vibrator Air Pumps) were maintained. Specific parameters are listed for each type of sample and analysis in the sections following.

Methods and Procedures—Crude Coal Tar—GLC sample size was 0.3 μ l. supplied from a Hamilton No. 7101 1- μ l. syringe. These

¹Zetar (colloidal whole crude coal tar USP), manufactured by Dermik Laboratories, Inc., Syosset, N. Y.

Table I—Solubility and Specific Gravity Data for Illustrated Crude Coal Tar Samples

Sample	CS ₂ , % Insoluble	CCl ₄ , % Insoluble	Carbenes, %	Benzol, % Insoluble	Sp. Gr. _{25°}
A	12.42	28.42	16.00	17.41	1.2011
B	9.64	16.89	7.25	14.22	1.2131
C	3.42	9.64	6.24	6.42	1.4232
D	3.39	10.40	7.01	8.21	1.4309
E	6.71	14.02	7.31	12.19	1.2247

samples were programmed on a 1.52-m. × 0.32-cm. (5-ft. × 0.125-in.) o.d. stainless steel column packed with 5% SE 30 on 80–100 mesh (chromasorb W, acid washed) from 110 to 255° at 10°/min., and held at the upper limit until no further peaks were recorded.

The variability of the chromatographic portion of crude coal tar was verified using a liquid-solid chromatographic technique on the samples, which involved filling a 22-mm. o.d. chromatographic tube equipped with a stopcock to a depth of 150 mm. with alumina (Grade F-20, Aluminum Corp. of America), and washing with 200 ml. of reagent grade petroleum ether. An accurately weighed 1-g. sample of the crude coal tar was macerated with 5 g. of alumina (prewashed with petroleum ether) and quantitatively transferred to the tube with the aid of 25 ml. of petroleum ether. The sample was eluted using 350 ml. of petroleum ether and the eluate collected at a rate of 4 ml./min. in a tared 400-ml. beaker, evaporated to near dryness on a steam bath under nitrogen, and the remainder of the solvent spontaneously evaporated at room temperature under a stream of nitrogen. The sample was desiccated for 15 min. and weighed. The column was further eluted with 350 ml. of reagent grade ethyl acetate in the same fashion. The residues were in turn run *via* GLC to determine if any significant portion of the petroleum ether eluate was lost in evaporation or any significant amounts of chromatographable material were present in the ethyl acetate fraction.

All other wet tests were performed according to the methods described by de Martin and Cyr (6).

LCD (Coal Tar Solution USP)—Tar Determination—GLC samples were 2.50 μ l. using a Hamilton No. 7105, 5- μ l. syringe for injection, programmed from 100 to 255° at 10°/min., and held at the upper limit using the same column as for coal tar. The initial temperature was decreased to allow for better separation of ethanol from the tar constituents. The percent tar was calculated by comparison of peak heights of naphthalene, methyl naphthalene, and phenanthrene *versus* those obtained from a standard using the same crude coal tar diluted to exactly 20.00% w/v in carbon disulfide A.R., according to the calculation:

$$\% \text{ coal tar} = \frac{J_i}{J_s} \times \frac{V_s}{V_i} \times C_s \quad (\text{Eq. 1})$$

where J_i is the height of peak i in the sample; J_s is the height of peak j in the standard; V_s is the injected volume (μ l.) of standard; V_i is the injected volume (μ l.) of sample; and C_s is the concentration (% w/v) of tar in CS₂ used as standard.

Ethanol Determination—The column used is 1.52-m. × 0.32-cm. (5-ft. × 0.125-in.) o.d. stainless steel filled with 10% polyethylene glycol² on chromasorb W (acid washed) isothermally at 70° with all other parameters as cited previously. The technique involves the use of 20.00% (v/v) acetone A.R./methanol A.R. as internal standard. The height responses were found to be linear between 0.2 μ l. and 2.5 μ l. of standard. Each analysis is performed using three injections of various volumes between 0.5 and 1.5 μ l., both for standard and sample. The ethanol response was plotted *versus* acetone response. Percentage of ethanol is found by determining the appropriate responses for ethanol from the graph in both sample and standard at the same acetone response and employing the following equation:

$$\% \text{ ethanol} = \frac{R_u}{R_s} \times \frac{\text{sp.gr.}_s \times \% Es}{\text{sp.gr.}_u} \quad (\text{Eq. 2})$$

where R_u is the response of sample from graph; R_s is the response of standard from graph; sp. gr._s is the specific gravity of standard

Table II—Comparison of Liquid *vs.* Gas Chromatography for the Determination of Chromatographic Portion of Crude Coal Tar

Sample	% Chromatographic		
	<i>via</i> GLC		<i>via</i> Liquid Chromatography
	<i>vs.</i> Phenanthrene	<i>vs.</i> Naphthalene	
A	12.1	12.4	13.2
B	17.4	17.0	15.9
C	26.2	26.9	25.8
D	27.1	27.0	27.4
E	21.1	20.8	20.2

ethanol at temperature T ; sp. gr._u is the specific gravity of sample at temperature T ; % Es is the percentage of ethanol w/w in standard; i.e., % Es of 95% ethanol = 92.3. The results were checked according to the USP determination for ethanol as stated in the monograph.

Thirty-five random samples, labeled "crude coal tar USP" of exactly 0.3 μ l. each were chromatographed under these conditions; five are presented in Fig. 1 for the purpose of illustration. Samples A and B were obtained from pharmacies, C is representative of material used by these laboratories, and D and E are samples from different batches obtained from another pharmaceutical manufacturer.

RESULTS AND DISCUSSION

The discrepancies found among the random samples of coal tar USP, both qualitatively and quantitatively, are enormous. The solubility and specific gravity data presented in Table I corroborate the observations of de Martin and Cyr (6); although in the case of Samples D and E, no positive prediction as to formulation compatibility could be made from the data obtained in wet tests. Predictions based on chromatographic evidence were subsequently substantiated by experimental incorporation into washable and greasy bases.

Crude coal tars A, B, and E yielded coarsely dispersed, inelegant pharmaceuticals. Even crude tar received from the same supplier may vary markedly from lot to lot, yielding different GLC profiles and producing visible physical variations in finished products while conforming to USP specifications. The preparations containing material from Samples A through E were not evaluated clinically. However, clinical trials previously conducted demonstrated that different tars produce significantly different patient responses on treatment of various dermatological conditions.

The evident chromatographic differences were checked on a weight basis by GLC and column chromatography to determine the validity of the measurement technique employed. These results are presented in Table II.

The petroleum ether fraction obtained by column chromatography indicated significant losses of benzene, toluene, xylenes, and pyridine. These, however, comprise less than 5% of the chromatographable portion taken on an area response basis; the overall net loss was considered insignificant. More important, excluding the peaks for xylenes, pyridine, benzene, and toluene (starred peaks in Fig. 1), the chromatographic traces were virtually identical to those obtained from the original samples of crude tar. Quantitative measurements based on naphthalene and phenanthrene responses, when compared to the original, yielded results which approximated those found on a weight basis (Table II). No significant amounts of chromatographable material were evident in the trace of the ethyl acetate fractions. Modifications of this technique are being used in this laboratory as a separation procedure for estimating the quality and quantity of coal tar in various preparations. It is obvious that additional separations must be performed if significant amounts of nonpolar materials, such as mineral oil, are present in the finished formulation. However, for this investigation, it did serve to provide additional quantitative evidence of the extent of composite differences which might be expected.

LCD—Exactly 2.50 μ l. of each of the five samples of coal tar solution (Fig. 2) were chromatographed under the conditions described. Because of the large amount of ethanol present, it was anticipated that the sample size would be inconsistent. Included in

Table III—Reproducibility of Peak Heights for LCD Samples (Sample C, Fig. 2)

Peak	Height, mm.		Reproducibility ^a
	Run 1	Run 2	
a	110.0	109.0	±0.5%
b	29.8	33.5	±5.5%
c	33.0	34.5	±1.4%
d	31.0	32.0	±1.6%
e	163.2	165.5	±0.6%
f	67.0	65.5	±1.1%
g	45.8	44.8	±1.2%
h	35.0	38.6	±4.4%

^a $\bar{X} = \pm 1.6\%$.

Fig. 2 are replicate runs of Sample C with peaks labeled "a" through "h." Height ratios were taken as a function of Run 2 *versus* Run 1. These data are presented in Table III and indicate an average error of $\pm 1.6\%$, which was found to be typical and acceptable.

Each of these samples fulfilled the requirement for coal tar solution as directed in USP XVII (*i.e.*, ethanol content between 81% and 86%). Although no quantitation of the coal tar content of these solutions was attempted, inasmuch as the original tar samples were not available, two coal tar solutions were prepared in the laboratory according to the USP procedure using one randomly selected tar sample. Analyses were performed *versus* the original tar diluted to exactly 20.00% w/v in CS₂ *via* GLC using the conditions noted previously. Peaks A, B, and C (naphthalene, methyl naphthalene, and phenanthrene) were used for calculation. The chromatograms are shown in Fig. 3 and the data presented in Table IV. Sample I was estimated to contain 20.29% w/v chromatographable tar and Sample II, 20.46% w/v tar.

Some variations were noted, particularly that the results derived from the phenanthrene peak produced lower, although acceptable, results than either of the other two employed. The authors' suspect that some sorption of phenanthrene occurs on the sand and, from the data, it appears to be approximately 6.5% of the amount present. Since a detailed investigation was not performed regarding this possibility, the authors chose to include no correction and the results are presented as a mean of the determinations from each of the three selected peaks. On an overall basis, no significant sorption of the chromatographable portion of the tar is apparent, thereby presenting a much more valid assay procedure for coal tar solution USP (LCD).

It is important to emphasize that *none of the LCD and "extract" samples actually contain the labeled amount of coal tar (20%)*. This figure (20%) is based on the amount of crude coal tar initially added to the ethanol, sand, and polysorbate 80, and not the amount of coal tar remaining in the extract after filtration. For example, Sample I of LCD was analyzed for water content *via* the classical Karl Fischer method and found to contain 6.5%. Combined with the ethanol data (81.39% per USP analysis), this leaves a material balance of 12.1% of which 5.0% is polysorbate 80. (The polysorbate 80 does not, for all practical purposes, ab(ad)sorb on the sand used in the laboratory preparation of LCD.) This leaves *approximately 7% tar "fractions" in the LCD solution*, the bulk of which is chromatographable.

Previous clinical research by Obermayer (9) has demonstrated that no particular fraction or fractions derived from whole crude coal tar yield total clinical results comparable to whole crude coal tar. In fact, certain of the fractions he tested had little or no medicinal value. It is quite evident, therefore, that even a "standardized" LCD constitutes only a fraction of the total composition of crude coal tar and cannot be considered a 20% solution. It similarly cannot be expected to produce comparable and reproducible therapeutic results.

Finally, a check of a simple GLC technique for the determination of ethanol was performed to assure the validity of the findings. Each of the samples was analyzed in duplicate and confirmed by the USP distillation procedure. These data were presented in Table V. All were found to conform, as stated previously, to the USP monograph for coal tar solution (LCD).

As an alternate to polyethylene glycols,² the authors have used a column of 1.52-m. \times 0.32-cm. (5-ft. \times 0.125-in.) o.d. stainless steel, filled with Poropak Q, isothermally at 150° with some success. However, this column becomes inconvenient when several samples of coal tar solution are to be analyzed since the elution of portions of the tar interferes with subsequent injections. Clearing of the column overnight at elevated temperatures was not always sufficient. Since no problem of this type was found with the polyethylene glycols² column (overnight purging at 195° was sufficient to clear it of retained chromatographable tar components), this is the column of choice for this procedure.

CONCLUSIONS AND SUMMARY

From the data reported in the literature regarding whole crude coal tar and LCD, certain differences were expected due to the variability of source, conditions of distillation, and modes of collection used in the manufacture of coal tar. This investigation has demonstrated that the situation is far more critical than originally suspected. The combination of previously discussed factors has resulted in an incompletely controlled drug and the indiscriminate manufacture of crude coal tar substitutes which include fractionated

Figure 2—GLC profiles of commercial samples of LCD.

Figure 3—GLC profiles of laboratory prepared "standardized" LCD. Key: A, LCD-I; B, Standard; and C, LCD-II.

extracted, filtered, and synthesized liquids, which bear little physical and chemical resemblance or correlation to a therapeutically acceptable grade of crude coal tar.

The authors have presented a new approach to the chemical standardization and analysis of this drug. In addition, an alternate method for determining the ethanol content of coal tar solution USP (LCD) is presented, which is equivalent to, and more rapid than, the procedure specified in the pharmacopeia.

It is reasonable to conclude that by designation of starting raw material, shape and size of retort, destructive distillation temperature, temperature during tar collection, and various other factors, in conjunction with laboratory specifications (including 15% maximum permissible variation in any one of the selected major constituents of the chromatographable portion of the tar, with differential solubility and specific gravity data), one would produce a tar demonstrating little or no inconsistencies in composition from batch to batch. In fact, this GLC technique has been routinely and successfully employed in the authors' laboratory for the past 2 years. It is equally obvious that while GLC standardized crude coal tar may yield a "standardized" LCD, the activity of this or any other "extract" cannot be expected to approach the efficacy obtained from the original whole substance.

This investigation is intended as a beginning, and further research pertaining to a nonchromatographable fraction of crude coal tar, as well as the sorption phenomena which occur in the manufacture of coal tar solutions, is being conducted. Additional analytical methods such as wet analyses and differential solubilities are being explored. These further investigations present interesting possibilities for future reports.

Since whole crude coal tar is not a chemical entity and its total therapeutic effect is dependent upon a myriad of carbonized and volatile constituents, achievement of complete and absolute uniformity of clinical results is improbable. It is apparent, however, that modern, precise analytical instrumentation can be utilized to revise the inadequate USP monograph on coal tar. A GLC tar profile, together with adequate chemical and physical specifications, will assure pharmacists of minimum rather than maximum variations in composition. Consequently, physicians may anticipate greater consistency and uniformity of therapeutic results.

Quantitative Chromatographic Analysis of Methallibure in Animal Feed Mixtures

G. J. KROL, J. F. CARNEY, and B. T. KHO

Abstract □ Methallibure [1-methyl-6-(1-methylallyl)-2,5-dithiobiurea] was separated from the constituents of feed extracts by partition column chromatography. The separation utilized polydextran gel as a stationary phase and a composite organic solvent as a mobile phase. The method requires no special treatment of the solid support and the column can be used for an indeterminate number of elutions. The observed interference of metal ions in the extraction and chromatography step was eliminated by the addition of dithizone to the extracting solvent. The procedure is quantitative and applicable to routine analysis of different commercial field samples. The chromatographic separation was tested for specificity with a thiadiazole derivative, which was prepared from methallibure, and complete separation between the two related structures was observed. The chromatographic column, used in the analysis, yielded approximately 900 theoretical plates.

Keyphrases □ Methallibure—determination □ Animal feed mixtures—methallibure determination □ Column chromatography—separation □ Dithizone—metal-ion interference elimination □ UV spectrophotometry—analysis

A partition chromatographic method for analysis of methallibure, an oestrus regulator for veterinary applications, in the presence of certain animal feed mixtures was reported by Hudson and Pearson (1). The method used diatomaceous earth¹ as a solid support and chloroform, formamide, and *n*-hexane as a two-phase solvent system. However, this procedure is relatively time consuming, since it requires preparation of a new column for every elution and involves relatively large volumes of eluent.

In view of these limitations, an alternative chromatographic method was developed. The method is based on an alkylated polydextran gel² solid support and an eluent composed of a mixed organic solvent. The preferential solvation of the gel by the more polar components of the solvent mixture yields a partition effect similar to that observed by Nystrom and Sjovall (2). In contrast to the diatomaceous earth method (1), the liquid partition effect obtained in this method requires no special treatment of the solid support, since the solvation of the gel and elution are carried out with the same mixed solvent system. Furthermore, once the column is packed, it can be used for an indeterminate number of elutions.

During the development phase of this method, a complication was encountered since some feed samples contained significant amounts of metal salts and the dithiobiurea structure of methallibure is a relatively efficient metal-ion complexing group (3, 4). In a number of instances, this situation led to a significant apparent

Figure 1—Separation of methallibure from diphenylthiocarbazon and Feed Mixture B extract (Drago) on polydextran gel (1.2 × 44-cm. column) with isopropanol-chloroform-cyclohexane-acetic acid-water (100:100:130:8:2) solvent. Key: M, methallibure; D, diphenylthiocarbazon; DC, diphenylthiocarbazon complex; and FE, feed extractives.

loss in the percent recovery of the methallibure, since a significant fraction of methallibure was complexed by metal ions and eluted in different volume. To avoid this complication, the extraction was carried out in the presence of an excess amount of diphenylthiocarbazon (dithizone), which competes effectively for metal ions with methallibure. Initially, 8-hydroxyquinoline was utilized for this purpose; however, it was subsequently observed that some metal-ion complexes of 8-hydroxyquinoline were eluted in the same volume as methallibure. A complete separation between the methallibure, dithizone, and dithizone metal-ion complexes was obtained.

EXPERIMENTAL

Equipment—Kontes glass chromaflex columns (or equivalent), 50 × 1.2 cm. (i.d.) and 50 × 5 cm., were used (Kontes, Vineland, N. J.). To prevent introduction of UV-absorbing extractives from the O-ring which is provided with the above columns, the O-rings have been replaced with O-rings improvised from 0.32-cm. (0.125-in.) (o.d.) organic solvent resistant tubing.³ The sintered-glass disk, which is present in the column, was covered with a nylon mesh (Pharmacia Fine Chemicals Inc., New Market, N. J.). The smaller column was fitted with a 500-ml. separator, the larger with a 2-l. funnel. Each separator had an airtight connection to the column. A Cary model 14 was used for the UV determinations, while Beckman DB was used in the method development to determine the optimum chromatographic solvent and the elution volumes. UV flow cell (1-cm. light path) was obtained from A. H. Thomas Co.

Solvents and Chemicals—Redistilled isopropanol (analytical reagent grade, Mallinckrodt), chloroform, glacial acetic acid, and spectro grade cyclohexane were used. The chromatographic solvent consisted of isopropanol, chloroform, cyclohexane, glacial acetic acid, and water (1.0:1.0:1.3:0.08:0.02 by volume, respectively).

Figure 2—Separation of methallibure from diphenylthiocarbazone and Feed Mixture C (Kent) on polydextran gel (1.2×44 -cm. column) with isopropanol-chloroform-cyclohexane-acetic acid-water (100:100:130:8:2) solvent. Key: M, methallibure; D, diphenylthiocarbazone; DC, diphenylthiocarbazone complex; and FE, feed extractives.

Methallibure was obtained from I.C.I., Pharmaceutical Division, Macclesfield, Cheshire, England.

Since the commercially available dithizone (obtained from either Eastman Organic Chemicals or Fisher Scientific Co.) was found to be insufficiently pure for purposes of this study, it was purified by the following procedure: 250 mg. of dithizone was dissolved in 50 ml. of the chromatographic solvent. The solution was filtered, applied to the larger column (23-cm. bed height), and eluted with 460 ml. of the chromatographic solvent. The preparation of the large column is analogous to the procedure described for the preparation of 50×1.2 -cm. columns. However, the solvent used for both preparation and elution may be composed of undistilled reagent grade solvents. The purified dithizone fraction, which was contained in the major blue band, was eluted in the 350- to 460-ml. fraction and used without further treatment. The solution prepared previously was stored in the dark at 4° and may be used for several days. The chromatographic column may be used repeatedly for the preparation of more dithizone after washing the column with additional 300 ml. of the solvent between sample applications.

Procedure—During the development phase and the subsequent testing of the method with different commercial feeds, the authors have utilized a Beckman DB flow cell-log recorder system. The spectrophotometer was set at the wavelength of the absorption maximum of methallibure (249 $m\mu$), and the area of the methallibure peak on the recorder scan was found to be proportional to the amount of methallibure. Representative elution patterns are illustrated by Figs. 1-3. However, since the volume which contained the methallibure fraction was found to be quite reproducible, the procedure was modified to a more suitable routine analysis which does not require a spectrophotometer-flow cell system. The following description outlines the procedure for routine analysis.

Figure 3—Separation of methallibure from diphenylthiocarbazone and Feed Mixture A extract (Felco) on polydextran gel (1.2×44 -cm. column) with isopropanol-chloroform-cyclohexane-acetic acid-water (100:100:130:8:2) solvent. Key: M, methallibure; D, diphenylthiocarbazone; DC, diphenylthiocarbazone complex; and FE, feed extractives.

Figure 4—UV scan of the 25-ml. methallibure and the 4-ml. blank fraction. Origin of the fraction: Feed Mixture B extract (Drago).

Preparation of Column—Polydextran gel was suspended in the chromatographic solvent (200 ml. of solvent/10 g. of polydextran gel) and the slurry equilibrated by shaking for 2 hr. The gel was allowed to settle, excess solvent decanted, and a fresh portion of solvent added. This procedure was repeated three times. The final slurry was transferred to the column by gravity feed. The column height was 44 cm.

Extraction of Methallibure from Feed—A 40-g. feed sample, containing approximately 2.2 mg. of methallibure, was transferred into a 250-ml. bottle and extracted with 10 ml. of the dithizone solution and 150 ml. of the chromatographic solvent. The extraction was aided by continuous shaking for 5 min. This procedure is applicable to a methallibure premix, such as polyethylene glycol (PEG), which is readily soluble in the chromatographic solvent. If methallibure is present in a methylcellulose premix, which is not soluble in the chromatographic solvent, the extraction could be carried out with a high speed homogenizer (for 15 min. at 40,000 r.p.m.). A VirTis "45" homogenizer is suitable for this purpose. Alternatively, the extraction could also be carried out by shaking with the more polar components of chromatographic solvent (omit cyclohexane). A portion of the extracted feed slurry was filtered through a fine- or medium-porosity sintered-glass funnel to provide a 4-ml. aliquot of clear filtrate. In order to avoid evaporation, the filtration was carried out under positive pressure with the aid of a

rubber bulb. A 4-ml. aliquot of the filtrate was transferred into a 5-ml. volumetric flask and diluted to 5 ml. with 1 ml. of dithizone solution.

Chromatography—A 3-ml. aliquot of the prepared solution was applied quantitatively to the column. The column was eluted with 102 ml. of the chromatographic solvent at a flow rate of approximately 0.5 ± 0.1 ml./min. (A pressure head was provided by a 300-ml. solvent reservoir in the separator above the column.)

The first 73-ml. fraction, which contained the feed extractives and dithizone (free and chelated by metal ions), was discarded and the next two fractions containing 25 and 4 ml. were collected and retained for quantitation by UV absorption. Both fractions were scanned in the 350–240-m μ range against the chromatographic solvent. Figures 4 and 5 illustrate typical UV scans of the 25- and 4-ml. fractions.

Quantitation—If the UV absorption of the 25-ml. fraction matched (within ± 0.005) the UV absorption of the 4-ml. fraction in the 350–290-m μ range, the absorbance (at 249 m μ) of the 4-ml. fraction was subtracted from the absorbance of the 25-ml. fraction and the difference in absorption (A_c) used to calculate the amount of methallibure in the sample. The following formula was used to calculate the amount of methallibure in the 25-ml. fraction.

$$\text{mcg. (of methallibure recovered after chromatography)} = \frac{(A_c) \times \text{vol.}_f}{0.129} \quad (\text{Eq. 1})$$

$$\text{mcg. (of methallibure per g. of feed)} = (A_c) \times 194 \times \frac{1}{\%} \quad (\text{Eq. 2})$$

where (A_c) is ($A_{25} - A_4$), absorbance of the 25-ml. fraction which contains methallibure corrected for background absorbance as reflected by the 4-ml. fraction; vol._f is the volume of the fraction which contains the methallibure; 0.129 is the extinction factor of

methallibure in the chromatographic solvent expressed in ml./mcg. units; and $\frac{1}{\%}$ is the dilution factor of the feed extract.

If the absorbance of the 25-ml. fraction in the 350–290-m μ range does not match the absorbance of the 4-ml. fraction, one may determine the amount of methallibure in the 25-ml. fraction by the curvature inversion technique (5, 6). This procedure involves scanning the methallibure fraction (25 ml.) against several reference solutions of methallibure at different concentrations but in the concentration range of the unknown sample. From the curvature at the inflection point (249 m μ , absorption maximum of methallibure), one can determine the concentration of the unknown sample. However, essentially all feed mixtures the authors encountered were analyzed without resorting to the curvature inversion technique. Usually, the magnitude of background absorbance was predictable and equivalent to 10–15% of the total absorbance of the methallibure fraction. The estimation of the background absorbance did not introduce more than a 3% error in calculation of the amount of methallibure.

RESULTS AND DISCUSSION

Three different commercial feed mixtures were spiked with known amounts of PEG and methylcellulose premixes. The samples were analyzed by direct UV determination without the aid of the curvature inversion technique. Tables I and II present the observed recoveries and the statistical analysis of the observed data. It is apparent from Tables I and II that although the standard deviations are relatively large, the observed recovery is essentially complete and independent of the nature of the feed mixture.

The chromatographic separation utilized in this study has also been tested for specificity. A complete separation between methallibure and its oxidation product, thiadiazole, has been observed (Fig. 6). On the basis of the elution volume and peak width, the chromatographic column used in this analysis yielded approximately 900 theoretical plates. This is equivalent to 20 theoretical plates/cm.

A similar partition chromatographic system was applied to the separation of the coccidiostat, nequinat (oxyquinoline structure), from feed mixtures (7). Although the chemical structure of methallibure is unrelated to the structure of nequinat, the chromatographic system is specific for both compounds; each compound was separated from closely related structures. This chromatographic approach was also extended to the quantitative separation of structurally related steroid compounds (8).

Improved Colorimetric Determination of Primary Aromatic Amines with 9-Chloroacridine: Application to Some Local Anesthetics

J. T. STEWART and D. M. LOTTI

Abstract □ Improvement in the stability of the 9-chloroacridine stock solution has been made in the colorimetric method for primary aromatic amines based on the reaction between the acridine and an amine. The improved procedure has been applied to some local anesthetics and local anesthetic mixtures. It has been found to be comparable in sensitivity to other local anesthetic determinations, particularly the popular diazotization-coupling procedures. Quantitative data from several systems reveal that use of this procedure permits the determination of local anesthetics in the presence of various drugs and other local anesthetics. Comparative analyses were performed with the method of Bratton and Marshall on procaine, metabutethamine, and nesacaine hydrochlorides.

Keyphrases □ Amines, primary aromatic—improved analysis □ 9-Chloroacridine solution—stabilization □ Tetrahydrofuran—9-chloroacridine solvent □ Colorimetric analysis—spectrophotometry

A colorimetric method for the determination of small quantities of primary aromatic amines with 9-chloroacridine and its use in the analysis of some sulfonamides have been previously reported by this laboratory (1, 2). Data presented in these papers showed that the sensitivity of the method rivals that of the commonly used diazotization-coupling procedures for primary aromatic amines and sulfonamides. It is necessary for the ethanolic 9-chloroacridine stock solution to be prepared immediately before use since the acridine undergoes rapid ethanolysis in ethanol (3). This fresh solution is permissible to use for approximately 0.5 hr. after preparation.

The objective of this paper is to report an improvement in the existing method by stabilization of the 9-chloroacridine stock solution, and application of the method to the analysis of several local anesthetics and local anesthetic mixtures. A comparative study of this improved technique was made with the procedure of Bratton and Marshall (4).

EXPERIMENTAL

Apparatus—Spectra and absorbance measurements were made with spectrophotometers (Perkin-Elmer, model 202, and Beckman, model DU). Matched cells with a 1-cm. optical path were used.

Reagents and Chemicals—9-Chloroacridine¹ was used as the chromogenic reagent. Powdered samples of propoxycaine hydrochloride,² butacaine sulfate,³ butesin,³ butethamine hydrochloride,⁴ metabutethamine hydrochloride,⁴ nesacaine hydrochloride,⁵ benzocaine,¹ and procaine hydrochloride⁶ were used in the analytical procedure for preparation of standard curves. Piperocaine,⁷ lidocaine,⁸ and tetracaine⁹ hydrochlorides were also used in the analysis. All other chemicals used were the highest grade of the commercially available materials.

Solutions (4×10^{-4} M) were prepared by dissolving weighed amounts of benzocaine and butesin in ethanol and the remaining local anesthetics in water. The reagent solution of 9-chloroacridine (4×10^{-4} M) was prepared by dissolving a weighed amount in tetrahydrofuran¹⁰ and storing in a light-resistant volumetric flask.¹¹

Procedure—One milliliter of an ethanolic or aqueous solution of a local anesthetic (4×10^{-4} M) was placed in a 10-ml. volumetric flask. To this was added 1 ml. of a tetrahydrofuran solution of 9-chloroacridine (4×10^{-4} M). Then the pH was adjusted to approximately 4 with 10% v/v aqueous hydrochloric acid. The solution was shaken and allowed to sit for 15 min. at room temperature, followed by the addition of ethanol to volume, and absorbance was measured at 435 mμ. Absorbance measurements were corrected for reagent blanks in the procedure.

RESULTS AND DISCUSSION

The colorimetric method for primary aromatic amines using 9-chloroacridine has been improved by using tetrahydrofuran in place of ethanol as solvent to make the acridine stock solution. Data shown in Table I for some local anesthetics reveal that the addition of small amounts of tetrahydrofuran to the analytical procedure does not cause any significant change in the sensitivity. The ethanolic solution was only useful for about 0.5 hr. due to reaction between the acridine and ethanol, and it was a disadvantage to prepare new acridine stock solutions that often. There was a need for a solvent in which dissolution, but no reaction between the acridine and solvent, would occur. Miscellaneous solvents were investigated, but only tetrahydrofuran proved successful in meeting these requirements.

Improved Colorimetric Determination of Primary Aromatic Amines with 9-Chloroacridine: Application to Some Local Anesthetics

J. T. STEWART and D. M. LOTTI

Abstract □ Improvement in the stability of the 9-chloroacridine stock solution has been made in the colorimetric method for primary aromatic amines based on the reaction between the acridine and an amine. The improved procedure has been applied to some local anesthetics and local anesthetic mixtures. It has been found to be comparable in sensitivity to other local anesthetic determinations, particularly the popular diazotization-coupling procedures. Quantitative data from several systems reveal that use of this procedure permits the determination of local anesthetics in the presence of various drugs and other local anesthetics. Comparative analyses were performed with the method of Bratton and Marshall on procaine, metabutethamine, and nesacaine hydrochlorides.

Keyphrases □ Amines, primary aromatic—improved analysis □ 9-Chloroacridine solution—stabilization □ Tetrahydrofuran—9-chloroacridine solvent □ Colorimetric analysis—spectrophotometry

Table I—Comparison of Absorbance Readings of Reaction Products Formed During the Analytical Procedure, with Ethanol and/or Tetrahydrofuran (THF) as Solvent for 9-Chloroacridine

Local Anesthetic	Concn., $M \times 10^{-6}$	Absorbance	
		Analytical Reaction With Ethanol	With THF
Propoxycaine hydrochloride	4.00	0.305	0.310
Butacaine sulfate	4.00	0.325	0.320
Butethamine hydrochloride	4.00	0.305	0.305

There was, however, limited success with *tert*-butyl alcohol. The tetrahydrofuran solution should be stored in a light-resistant volumetric flask, since it has been observed in this laboratory that light caused some decomposition of the 9-chloroacridine, possibly through a free radical reaction (5). Stock solutions of the acridine in tetrahydrofuran have been stable up to 1 month after preparation when properly stored.

tert-Butyl alcohol has some limitations in its employment as a solvent for 9-chloroacridine. The alcohol is very difficult to handle since it freezes at 25.5° (6). The observed reaction time for the analytical procedure is 30–45 min. longer with *tert*-butyl alcohol present than with tetrahydrofuran, and the stock solution of the acridine is stable for only 1 week. It has been possible in this laboratory to overcome the disadvantage of handling due to freezing by insulating the volumetric flask containing the acridine stock solution, but the observed slower reaction time for the analysis and instability of the reagent solution for periods longer than 1 week make tetrahydrofuran the preferred solvent for the acridine.

The improved method using the tetrahydrofuran–acridine solution was then applied to the analysis of some local anesthetics and local anesthetic mixtures. The results indicated that the reaction between local anesthetics containing a primary aromatic amino group and 9-chloroacridine to yield highly colored aminoacridine hydrochlorides can be utilized as a suitable assay procedure for local anesthetics. The absorption curve in the visible spectrum for a typical sample of benzocaine is shown in Fig. 1; the absorption maximum occurs at 435 $m\mu$. Reagent blank readings at this wavelength are very low.

In comparing absorption curves of the colored solutions obtained with equimolar concentrations of the various local anesthetics containing primary aromatic amino groups, it was noted that the curves were almost identical. Compounds such as propoxycaine, butacaine, butesin, butethamine, metabutethamine, and procaine all produce color that absorbs at the same wavelength and with essentially the same intensity as does benzocaine. Absorbance values for these anesthetics were between 0.30–0.35 absorbance units at 435 $m\mu$ as exemplified by benzocaine and metabutethamine (Fig. 1).

Figure 1—Visible absorbance curves of aminoacridine derivatives of local anesthetics. Key: X, benzocaine; □, metabutethamine hydrochloride; ○, nesacaine hydrochloride; and Δ, reagent blank.

Table II—Analysis of Known Local Anesthetic Mixtures for Local Anesthetic

Mixture	Components, Concn. of $4.00 \times 10^{-5} M$	Local Anesthetic	
		Found, $M \times 10^{-5}$	Yield, %
I ^a	Procaine hydrochloride Tetracaine hydrochloride	3.976	99.4
II ^b	Propoxycaine hydrochloride Piperocaine hydrochloride	3.960	99.0
III ^c	Butacaine sulfate Lidocaine hydrochloride	3.988	99.7
IV	Benzocaine Benzyl alcohol 8-Hydroxyquinoline	3.992	99.8
V	Butethamine hydrochloride Pentobarbital sodium Aminophylline	3.972	99.3
VI	Butesin Menthol Camphor Isopropyl alcohol	3.988	99.7

^a Mixture analyzed for procaine content. ^b Mixture analyzed for propoxycaine content. ^c Mixture analyzed for butacaine content.

Structurally all of these compounds have a primary aromatic amino group in the position *para* to the ester linkage except metabutethamine, in which the amino function is *meta* to the ester linkage. Nesacaine shows somewhat diminished intensity values at the same wavelength (Fig. 1), due presumably to a less-than-quantitative yield of reaction with 9-chloroacridine caused by the inductive effect of the chloro group *meta* to the primary amino group in the local anesthetic.

The local anesthetics, piperocaine, lidocaine, and tetracaine, which do not contain a primary aromatic amino group, give no color formation with this procedure.

Standard curves can be prepared by plotting observed absorbance readings *versus* the volumes taken of equimolar concentrations of various local anesthetics. In all cases, Beer's law holds for this system.

Quantitative data from several systems shown in Table II reveal that use of this improved procedure permits the determination of local anesthetics containing a primary aromatic amino group in the presence of other local anesthetic derivatives, such as piperocaine, lidocaine, and tetracaine, and in the presence of other compounds which are found in various combinations with local anesthetics in commercially available products. It was shown from earlier studies that primary, secondary, and tertiary aliphatic amines; secondary and tertiary aromatic amines; heterocycles; and carbonyl-containing compounds also do not interfere with this method (1).

The analytical method is essentially a microprocedure, and sensitivity is in the range of $10^{-5} M$ of local anesthetic, which makes it comparable to other local anesthetic determinations, particularly the popular diazotization-coupling procedures.

Table III—Determination of $2.00 \times 10^{-5} M$ Solutions of Procaine, Nesacaine, and Metabutethamine Hydrochlorides by the 9-Chloroacridine Method and the Method of Bratton and Marshall

	9-Chloroacridine —Method—		Bratton-Marshall —Method—	
	Mean % of Concn. Em- ployed	SD of Mean, %	Mean % of Concn. Em- ployed	SD of Mean, %
Procaine hydrochloride	99.30	0.29	99.43	0.28
Nesacaine hydrochloride	99.60	0.17	99.75	0.23
Metabutethamine hydrochloride	99.55	0.23	99.20	0.29

A favorable characteristic of the analysis is that the absorbance of the product formed is stable and does not fade over a 24-hr. period. This is an advantage over the colorimetric method of Bratton and Marshall. In the latter method, absorbance readings must be made within 15 min. after color development, due to precipitation of the azo dyes in the method (7). The 9-chloroacridine method also does not involve diazotization. Thus, it eliminates the need for freshly prepared sodium nitrite and ammonium sulfamate solutions required with the Bratton-Marshall technique. Control of pH is required in both methods.

The improved method of analysis for local anesthetics by the 9-chloroacridine approach was carried out for some representative local anesthetics, and comparative analysis were performed using the colorimetric procedure of Bratton and Marshall. Assays were performed on procaine, nesacaine, and metabutethamine hydrochlorides.

The procedure outlined by Connors was used for the analysis by the Bratton-Marshall method (8).

Four determinations by each method were performed for each local anesthetic. The mean percent of concentration employed and the percent standard deviation of the mean for each local anesthetic are shown in Table III for both methods (9).

Qualitative and Quantitative Determination of 1,2- and 1,3-Diglycerides by Nuclear Magnetic Resonance Spectroscopy

R. J. WARREN and J. E. ZAREMBO

Abstract □ An NMR procedure is presented for the qualitative and quantitative analysis of 1,2- and 1,3-diglycerides alone or in combination. The method provides a rapid, accurate quantitative analysis, as well as serving as a specific identification of the two isomers. The determination can be carried out on sample sizes in the range 20–50 mg.

Keyphrases □ 1,2- and 1,3-Diglycerides—determination □ NMR spectroscopy—analysis

One of the more difficult problems in glyceride analysis is the differentiation and quantitative determination of 1,2- and 1,3-diglycerides in the presence of one another. Chemical methods are tedious and time consuming. IR spectra are of little value when trying to determine low percentages of one isomer in a mixture of the two. Near-IR spectroscopy (1) has been used to differentiate the 1,2- and 1,3-diglycerides and might have some value. The major drawbacks to using this technique are the large amounts of sample required for a determination, overlap of absorption bands, and relatively small differences in absorptivity values.

The purpose of this study was to establish the feasibility of using NMR for differentiating between the

two isomers and for quantitative analysis of the two isomers.

EXPERIMENTAL

All spectra were recorded on a JEOLCO C60H spectrometer. Deuterated chloroform with 3% CHCl₃ added was used as solvent. The spectra were recorded at room temperature at a concentration of 80 mg./ml. Chemical shifts were measured relative to trimethylsilane (TMS).

The 1,2- and 1,3-diglycerides used were 1,2- and 1,3-distearins of reference standard quality.¹

RESULTS AND DISCUSSION

1,2-diglyceride

1,3-diglyceride

The NMR spectra of the 1,2- and 1,3-diglyceride isomers differ markedly in the region 220–260 c.p.s. (3.6–4.4 p.p.m.) (Fig. 1). The 1,3-isomer has a singlet absorption at 249 c.p.s. due to the

¹ Supelco and Applied Science Laboratories, State College, PA 16801

A favorable characteristic of the analysis is that the absorbance of the product formed is stable and does not fade over a 24-hr. period. This is an advantage over the colorimetric method of Bratton and Marshall. In the latter method, absorbance readings must be made within 15 min. after color development, due to precipitation of the azo dyes in the method (7). RESULTS AND DISCUSSION

1,2-diglyceride

1,3-diglyceride

The NMR spectra of the 1,2- and 1,3-diglyceride isomers differ markedly in the region 220–260 c.p.s. (3.6–4.4 p.p.m.) (Fig. 1). The 1,3-isomer has a singlet absorption at 249 c.p.s. due to the

¹ Supelco and Applied Science Laboratories, State College, PA 16801

Figure 1—A, NMR spectra of the 1,2-diglyceride isomer. B, NMR spectra of the 1,3-diglyceride isomer. TMS was used as the internal reference standard.

five glyceryl protons. The 1,2-isomer has a more complex spectrum consisting of a quartet at 259 c.p.s. from the two mutually non-equivalent 1-protons and a doublet at 225 c.p.s. from the two 3-protons. The quintet of the 2-proton is not used in this analysis. There is no interference from the 1,3-isomer at the first doublet, and this enables one to determine the 1,2-content in a mixture of the two isomers. A series of standards was prepared containing approximately 5, 7.5, 10, and 13 mg. of the 1,2-isomer in 25 mg. of the 1,3-isomer. The materials used for the mixture were reference standard samples. The mixtures were dissolved in CDCl_3 containing 3% (v/v) of CHCl_3 . The single absorption of the CHCl_3 at 436 c.p.s.

was used as an internal standard in determining the amount of 1,2-isomer present. The NMR spectra of the mixtures were obtained and integrated. Figure 2 shows a spectrum of a representative mixture. The integrated intensity of the 1,2-absorption relative to the internal standard was recorded. The value $A_{1,2}/A_{\text{CHCl}_3}$ was then plotted *versus* percent of 1,2-diglyceride (Fig. 3). ($A_{1,2}$ = integral value of signal at 225 c.p.s. A_{CHCl_3} = integral value of signal at 436 c.p.s.)

Subsequent samples were prepared and run in the same way. By comparison of standards and samples, it was possible to determine the amount of 1,2-isomer present.

Figure 2—NMR spectra of a mixture of 1,2- and 1,3-distearin.

Figure 3—The value of $A_{1,2}/A_{CHCl_3}$ plotted against the percent of 1,2-diglyceride, with $A_{1,2}$ = integral value of signal at 225 c.p.s. and A_{CHCl_3} = integral value of signal at 436 c.p.s.

Some interference could be expected if large amounts of triglycerides were present, but this is an unlikely circumstance. Unsaturated acid moieties would not interfere since they would absorb in the region beyond 275 c.p.s.

The determination can be carried out on samples in the 10–20-mg. range, but the results are best obtained with samples of approximately 50 mg. In addition to the quantitative aspect of the method, the NMR spectra also provide a specific qualitative identification of the isomers.

SUMMARY

A quantitative and qualitative method of analysis for 1,3- and 1,2-diglyceride isomers has been presented. The method can be carried out on sample sizes at the order of 50 mg. The method is fast, accurate, and specific for the two isomers.

Adsorption of Organic Compounds by Commercial Filter Papers and Its Implication on Quantitative-Qualitative Chemical Analysis

WIN LOUNG CHIOU and LLOYD D. SMITH

Abstract □ Eighteen acidic and neutral organic compounds were studied for adsorption onto Filter I (MF-Millipore filter) with a diameter of 17.5 mm. The adsorption after filtration of 3 ml. of solution ranged from zero to almost 100%. The adsorption to Filter II (Whatman filter), however, was much lower and in some cases negligible. The water-soluble or ionic forms of compounds are less adsorbed. The extent of adsorption for each compound might depend on its concentration, filtration rate, volume of solution filtered, and Filter I size used. The adsorption was found to be reversible and could be represented by the Freundlich adsorption isotherm equation. The water-soluble impurities from both types of filters were also studied. Their absorbances below 230 m μ were considerably high. The implication of adsorption and impurities from filters on quantitative-qualitative chemical analysis was discussed.

Keyphrases □ Filter paper adsorption—organic compounds □ Adsorption—organic compounds on filters □ Impurities—filters □ Solubility, organic compounds—filter adsorption □ Filtration rate effect—filter adsorption

The phenomenon of the possible adsorption of organic or inorganic compounds onto polymeric materials such as nylon (1), polyethylene (2), cellulose dialysis membrane, and regular filter paper has been well recognized in the past. Filter pads,¹ made from cellulose esters or similar polymeric materials, have been widely used in both analytical and biological work (3–14). However, the possible adsorption of chemicals to these filters has been generally underestimated or not noticed by research workers using these products. Some of the reasons for unawareness may stem from a statement by the manufacturer in their brochure (15) that the filters will not generally adsorb components from liquid solutions.

The systematic investigation, reported in this article, of the potential effect of these filters on both quantitative and qualitative chemical analysis was begun after an accidental discovery of the surprisingly high adsorption of a water-soluble organic compound after filtration. It was also stimulated by a report of Saad and Higuchi (5) that a discrepancy of 150 to 200% in the solubility of cholesterol was observed after filtering a saturated aqueous suspension through different pore size of the filters. The authors, however, gave no explanation about the possible cause of this difference. Although there are many types of these filters, only Filter I² was selected for thorough studies due to its wide

use. The adsorption to the Filter II³ was also studied to a lesser extent for the purpose of comparison.

EXPERIMENTAL

Materials—Eighteen acidic or neutral organic compounds were chosen for adsorption studies: *m*-nitrobenzoic acid (Eastman Organic Chemicals); iopanoic acid (Sterling Drug Inc.); hydrocortisone, hydrocortisone acetate, and ethinyl estradiol (The Upjohn Co.); chloramphenicol (Parke, Davis & Co.); benzoic acid (Merck & Co.); phenobarbital (Smith Kline & French Labs.); sodium phenobarbital (Merck & Co.); hexachlorophene (Robinson Laboratory Inc.); salicylic acid (Mallinckrodt Chemical Works); *p*-nitrobenzoic acid (Eastman Organic Chemicals); griseofulvin (McNeil Laboratories, Inc.); warfarin (S. B. Penick & Co.); sodium warfarin (Abbott Laboratories); digitoxin (Eli Lilly & Co.); naphthalene (Matheson Co. Inc.); and spironolactone (Searle & Co.). All the chemicals were reagent grade and were not further purified prior to experiments.

Filter I disks⁴ had a prefilter diameter of 17.5 mm. and various pore sizes: 0.025 μ (VS type), 0.22 μ (GS type), and 1.2 μ (RA type). Pyrex microanalysis filter holder (Cat. No. XX10 025 00 from the Millipore Corp.) was used for the support of filtration throughout the experiments. Filter II (W. R. Balston, Ltd., England) employed a round form of disk with the same diameter as Filter I, cut with a pair of scissors and placed into the Millipore filter holder for the filtration study.

Preparation of Solutions—Solutions of relatively water-soluble compounds such as *m*-nitrobenzoic acid, benzoic acid, phenobarbital, sodium phenobarbital, salicylic acid, *p*-nitrobenzoic acid, sodium warfarin, and naphthalene were prepared by dissolving them directly in distilled water or diluted aqueous hydrochloric acid solution. Solutions of relatively water-insoluble compounds such as iopanoic acid, hydrocortisone, chloramphenicol, hydrocortisone acetate, hexachlorophene, griseofulvin, ethinyl estradiol, digitoxin, and spironolactone were prepared by dilution of the concentrated stock solution in 95% ethanol with distilled water. These solutions contained, however, less than 1% ethanol (v/v).

Adsorption Studies—Before carrying out adsorption studies, the filter apparatus without the placement of filter disks was thoroughly cleaned with distilled water. Three milliliters of the distilled water or aqueous hydrochloric acid solution was then passed through the apparatus by the suction of a water aspirator. Possible contamination in the filtrate was checked spectrophotometrically by using a Cary 15 spectrophotometer.

The effect of both single and multiple filtrations on adsorption to the filters was studied. In the single-filtration studies, 3 ml. of aqueous solutions of organic substances was filtered through either the Filter I or II disk. The time of the filtration was kept as constant as possible: about 30 sec. for 0.22- μ Filter I and 1.2- μ Filter I and Filter II, and about 2.5 min. for the 0.025- μ Millipore. The absorbance of the solution, usually at the peak absorption wavelength of each

compound, was measured before and after the filtration using a Cary 15 spectrophotometer. Within the concentration range studied, it was found that the absorbances of the solutions of all the compounds followed Beer's law.

In the multiple-filtration studies, four aliquots of 3 ml. each of the aqueous solutions were passed successively through the same 0.22- μ Filter I pad; the absorbance of each 3-ml. filtrate was then determined. The effect of the rate of filtration on adsorption was also studied by the single-filtration method filtered over 30 and 300 sec.

It was found that both Filters I and II contain a fairly large amount of water-soluble impurities which can be extracted into the filtrate during the filtration process and show optical absorption at various wavelengths. Therefore, control experiments were performed by passing distilled water or appropriate aqueous vehicles through filter disks for all adsorption studies reported in this communication. The extent of adsorption was estimated after making such blank corrections. All experiments were run at least in duplicate. It must be noted the variation of adsorption from different runs was generally very small and insignificant.

Desorption Studies—In desorption studies, 3 ml. of aqueous solution was passed through 0.22- μ Filter I, the absorbance of the filtrate was measured, and the percent adsorbed was determined. The filter pad was then removed, the apparatus was thoroughly cleaned, and a blank check was run to ensure no contamination. The same pad was replaced in the apparatus, and 3 ml. of distilled water or 0.01 *N* HCl (as in the case of warfarin) passed through the pad. The absorbance of the filtrate was measured and the percent of chemical

washed from the filter pad was determined. Additional two or three similar washings were carried out on the same pad, and the extent of desorption was determined each time.

Adsorption Equilibrium Studies—Two 0.22- μ Filter I disks were placed in 15-ml. screw-top culture tubes. Five milliliters of various concentrations of griseofulvin or warfarin was added. The tubes were stirred at 100 strokes/min. in a constant-temperature (29 \pm 0.5°) water bath shaker (Eberbach Corp.) for 24 hr. The solutions were drained off the pads and the absorbance at suitable wavelengths was measured. It was found the adsorption equilibrium was reached after 24 hr. of shaking.

RESULTS AND DISCUSSION

Impurities from Filters—As previously noted (5), a significant amount of UV-absorbing impurities could be extracted from Filter I and these interfered with the spectrophotometric assay of the filtrate at 205 m μ during the study of the water solubility of cholesterol. However, it seems, to date, that no quantitative analysis of the impurities has been reported in the literature. The water-soluble impurities from Filter II also appear to be generally ignored.

Table I shows the absorbances from 205 to 320 m μ of the filtrates after passing 3 ml. of distilled water through different filters. It is obvious that the absorbance of extracted contaminants increases with the decrease of the wavelength except for the 1.2- μ Filter I disk which shows a minimum absorbance at 240 m μ . The absorbance of the impurities below 230 m μ is so high that it can result in a serious error in the quantitative-qualitative analysis if not taken into consideration. It must be noted the absorbance of filtrates decreased as the volume of the distilled water filtered increased. This is expected because there is only a maximum amount of impurities present. Therefore, the effect of the contaminants on the spectrophotometric measurements will be greater when working with smaller volumes of solutions. It should also be emphasized that the filtering area used in these studies is only about 2.5 cm.². Since much larger filter paper, especially Filter II type, is usually employed for the filtration purpose, the amount of extracted impurities will be considerable. This investigation does not attempt to determine the exact chemical nature of the impurities, although it has been reported in the past that Filter I might contain 2-3% of its dry weight as a detergent (16). It should be noted that the different spectra of the impurities from various pore sizes of Filter I might indicate that they contained different water-extracted contaminants and/or different quantities of such contaminant.

Adsorption from Single Filtration through Filter I—Table II lists the wavelength used for each compound, their initial concentrations and absorbances, and the percent adsorbed from the first 3 ml. of the filtering solutions by the 0.22- and 0.025- μ Filter I pads. It is quite surprising to find all 18 compounds with a wide range of solubility

^a Values obtained after analysis of a 3-ml. filtrate. ^b Approximate value.

Figure 1—Percent of griseofulvin adsorbed after passing 3 ml. of solutions through different filter paper. Key: ○, 0.025-μ Filter I; □, 0.22-μ Filter I; ◇, 1.20-μ Filter I; and △, Filter II.

and chemical structure were adsorbed by the 0.22-μ Filter I, ranging from 3.2 to 99.4%. This is contrary to the statement given by the manufacturer. A range of zero to almost 100% adsorption was found for the 0.025-μ Filter I.

From Table II several interesting points seem worth discussing.

1. Adsorption by Filter I probably exists for every organic compound. Hence, one should check this possibility whenever they are intended to be used for quantitative separation. A warning of the possible adsorption should be stated in the brochure by the manufacturer.

2. It is recommended that the adsorption problem should be checked when using other types of Millipore filters (Duralon and Mitex). They were not studied in this investigation.

3. As will be further discussed later, the extent of adsorption seems to relate to the pore size of filters: the smaller the pore size, the more the adsorption. This might be due to the higher specific surface area available for adsorption in the smaller pore size filters. This is demonstrated in the table, where a majority of compounds show higher adsorption by the 0.025-μ Filter I. It is, however, possible that the presence of different amounts or nature of the water-extractable impurities may also affect the degree of adsorption. The effect of the removal of these impurities on adsorption seems worth further study.

4. The water solubility of compounds also appears to relate to the adsorption: the lower the solubility, the stronger the adsorption. This is illustrated by the generally lower adsorption of the more soluble compounds listed at the top of the table (iopanoic acid is an exception). One interesting example is hydrocortisone and hydro-

Figure 2—Percent of spironolactone adsorbed after passing 3 ml. of solutions through different filter paper. Key: □, 0.025-μ Filter I; ○, 0.22-μ Filter I; ◇, 1.20-μ Filter I; and △, Filter II.

Figure 3—Percent of warfarin adsorbed after passing 3 ml. of solutions through different filter paper. Key: ○, 0.025-μ Filter I; □, 0.22-μ Filter I; ◇, 1.20-μ Filter I; and △, Filter II.

cortisone acetate. Both have similar chemical structures. However, hydrocortisone acetate, with much less water solubility, shows greater adsorption.

5. The ionic forms are generally much less adsorbed than their nonionic forms. This is clearly shown by warfarin, phenobarbital, benzoic acid, and salicylic acid. It indicates that the ionic bonding between organic adsorbates and filter adsorbents is not significant in contributing to adsorption. The adsorption between them may mainly be due to hydrophobic and hydrogen bonds.

6. The importance of the van der Waals force in causing adsorption is demonstrated by the high adsorption of naphthalene, a fully conjugated flat hydrocarbon.

7. It should be pointed out that the concentrations of several compounds listed in Table II such as hydrocortisone acetate (17), ethinyl estradiol (17), digitoxin (18), griseofulvin (6), and spironolactone (the authors' preliminary study) are approximately equal to their water solubility. A serious error in the solubility value may be made if one uses these filters and ignores their adsorption problem. It is also possible the discrepancy of the reported solubilities of many compounds in the literature (5, 17) might be attributed to the impurity, contamination and adsorption by the filters. Cholesterol might represent a good example. It is quite startling to find from the literature that this biologically important steroid has an extremely wide range of reported water-solubility values: 0.025 mcg./ml. at 30° from Saad and Higuchi (5); about 2.0 mcg./ml. from the Merck Index (18) and Gemant (19); 52 mcg./ml. from Lange and Amund-

Figure 4—Adsorption of four chemicals by 0.22-μ Filter I pads after repetitive filtration of 3 ml. aqueous solution. Table III—Effect of Filtration Rate on Adsorption by Filter I Pad, 0.22- μ Pore Size

Chemicals	% Adsorbed	
	30 sec. ^a	300 sec. ^a
Salicylic acid (0.1 N HCl; 25 mcg./ml.)	21.2	27.3
<i>p</i> -Nitrobenzoic acid (0.1 N HCl; 10 mcg./ml.)	25.8	46.6
Griseofulvin (distd. H ₂ O; 10 mcg./ml.)	28.9	29.1
Warfarin (0.01 N HCl; 30 mcg./ml.)	33.7	36.6

^a Filtration time of 3 ml. aqueous solution.

son (20); and 2600 mcg./ml. from the "Handbook of Chemistry and Physics" (21) which cites the value from Dehn (22). Although the solubility of a compound may vary with its particle size, crystalline form, and electric charge of particles (23), it is believed these factors could not explain a 10,000-fold difference.

Adsorption by Filters I and II versus Concentrations—The percent of adsorption at different concentrations of three compounds, griseofulvin, spironolactone, and warfarin, by Filter II and three different pore sizes of Filter I is shown in Figs. 1–3. The percent adsorbed was found to vary with the type of filters, Filter I versus Filter II, the pore size of Filter I, and finally the concentration of each compound. The decreasing degree of adsorption by the four different filters is generally in the following order: 0.025- μ Filter I > 0.22- μ Filter I > 1.2- μ Filter I > Filter II.

Adsorption from Multiple Filtration through Filter I—The percent of adsorption from the multiple filtration of five compounds, *i.e.*, spironolactone, griseofulvin, ethinyl estradiol, warfarin, and naphthalene, through the 0.22- μ Filter I is shown in Fig. 4. The extent of adsorption of all compounds studied decreased as the volume of filtering solutions increased. This is not unexpected because the adsorption site is usually saturable. The adsorption capacity of Filter I toward the naphthalene molecule is, however, surprisingly high, as evidenced by the least steepness of the slope in Fig. 4, and 85% of naphthalene was still adsorbed in the fourth filtration through the same filter.

Effect of Filtration Rate on Adsorption—From the practical point of view, it is also interesting and important to know whether the filtration rate will affect the adsorption, since different rates may be employed at different occasions by the same or different workers. The results obtained from four compounds after filtering through 0.22- μ Filter I are shown in Table III. A 10-fold difference in the filtration rate did indeed result in a change in the degree of adsorption. The slower the filtration rate, the more was

Figure 5—Cumulative desorption of four chemicals from 0.22- μ Filter I pads after previous filtration of 3 ml. aqueous solution. Key: ○, spironolactone (initial filtered concentration, 10 mcg./ml.); △, naphthalene (7.6 mcg./ml.); □, salicylic acid (H₂O; 25 mcg./ml.); and ◇, warfarin (0.01 N HCl; 20 mcg./ml.).

Figure 6—Freundlich adsorption isotherm of griseofulvin (0.22- μ Filter I).

the adsorption. Some compounds like *p*-nitrobenzoic acid and salicylic acid are sensitive to the rate while some are not.

Desorption Studies—Desorption experiments on four compounds, *i.e.*, spironolactone, naphthalene, salicylic acid, and warfarin, were run to study further the binding nature of adsorption on Filter I. The results are shown in Fig. 5. The fact that the adsorbed compounds could be washed from the filter indicates a reversible characteristic of the adsorption. The strong van der Waals bonding between the naphthalene and Filter I is once again demonstrated by the least desorption of naphthalene. Only 6% of the adsorbed naphthalene was washed away by 12 ml. of distilled water.

Adsorption Equilibrium—Table IV represents equilibrium adsorption data for griseofulvin and warfarin. The percent adsorbed was found to be almost independent of initial concentration. The plots of Freundlich adsorption isotherms are shown in Figs. 6 and 7 in which *q* represents micrograms of compounds adsorbed by the two filter disks used for each study, and *c*, in micrograms per milliliter, is the concentration of the solutions at equilibrium.

SUMMARY

1. Eighteen acidic and neutral organic compounds with a wide range of water solubility and chemical structure were studied for their adsorption to Filters I and II. The adsorption on the 0.22- and 0.025- μ Filter I varied from zero to almost 100% during the single-filtration studies. The adsorption on Filter II was low or negligible.
2. Water-soluble compounds generally showed a lower tendency for adsorption.

Table IV—Data Showing Equilibrium Adsorption of Griseofulvin and Warfarin by 0.22- μ Pore Size Filter I

Chemicals	Initial Concn., mcg./ml.	% Adsorbed
Griseofulvin	4.0	81.2
	6.0	80.7
	8.0	83.5
	10.0	82.5
Warfarin	5.0	99.4
	10.0	98.8
	20.0	98.4
	30.0	98.4

Figure 7—Freundlich adsorption isotherm of warfarin (0.22- μ Filter I).

3. Ionic salts were less adsorbed than their neutral forms.
4. The adsorption of a compound might vary with its concentration, volume of the solution filtered, filtration rate, and the pore size.
5. The adsorption was found to be reversible. The adsorption at equilibrium could be represented by Freundlich adsorption isotherm plots.
6. Water-soluble impurities from Filters I and II were studied spectrophotometrically. Their absorbances below 230 $m\mu$ were found to be considerably high.
7. The possible effects of adsorption and impurities from filters on the quantitative-qualitative chemical analysis were discussed.

Polytetrafluoroethylene Coating as a Suppository Mold Releasing Agent

H. W. PUFFER and PAMELA A. BARNETT

Abstract □ The release quality of suppository molds with either smooth or damaged polytetrafluoroethylene coated or uncoated cavity surfaces was compared using four different suppository bases. The release of suppositories from damaged molds was improved by coating the damaged cavity surfaces with polytetrafluoroethylene. Such a coating did not appreciably improve the release characteristics of new molds.

Keyphrases □ Polytetrafluoroethylene coating—suppository mold
□ Suppository molds—suppository releasing agent

The fusion or melting-casting process is a popular method in the preparation of suppositories (1). However, sticking of the suppositories to the cavity surface can become a problem, particularly with worn or damaged molds. To obviate this problem, some authorities (2, 3) recommend coating the cavity surfaces of the mold with a lubricant such as mineral oil or green soap tincture. Obviously such a step requires time and is inconvenient. Lubricants used in this manner may also be deposited as a thin film on the surface of the suppository. It would seem best to avoid the use of lubricants entirely.

Similar problems of sticking in industrial molds have been prevented or reduced by using polytetrafluoroethylene¹ (4, 5), an inert plastic homopolymer. Polytetrafluoroethylene has the advantage of imparting a non-stick finish to the mold. This study, therefore, was undertaken to evaluate polytetrafluoroethylene as a mold releasing agent in the fusion method of molding suppositories.

EXPERIMENTAL

Materials—The four molds used in this study were constructed of nickel-plated brass, having outside dimensions of 14.7 × 3 × 3.7 cm. and weighing 1261 g. each. They were of the divided type, aligned by two affixed pins and secured by two thumbscrews. Each mold contained six Wellcome-shaped cavities having a capacity of 2 g. each. Two of the molds were new and their surfaces were smooth and polished. Two of the molds were badly damaged by severe scratches and chemical erosion. One new mold and one damaged mold were custom coated² with polytetrafluoroethylene.

The following suppository bases were used: (a) theobroma oil BP,³ (b) suppository base II,⁴ (c) glycerinated gelatin USP,⁵ and (d) polyethylene glycol containing polyethylene glycol 1000,⁶ 50%, and polyethylene glycol 4000,⁶ 50%.

Procedure—The theobroma oil and suppository base II were melted and maintained molten, using a constant-temperature

^a Key: N, new mold with smooth polished cavity surfaces; NP, new mold with polytetrafluoroethylene-coated cavity surfaces; DP, damaged mold with polytetrafluoroethylene-coated cavity surfaces; D, damaged mold with scratched and eroded cavity surfaces. ^b For each time period, 10 lots containing six suppositories were formed for each of the possible suppository base-mold surface combinations. Each figure represents the quantity of perfectly formed suppositories released from the mold (60 suppositories maximum possible for each figure).

water bath,⁷ at a temperature of 36.5 ± 0.5°. The polyethylene glycol base was similarly prepared and used at a temperature of 54.5 ± 0.5°. Glycerinated gelatin base was prepared according to the USP (6) method and maintained molten with the water bath at a temperature of 46.5 ± 0.5°. Each base was prepared and used as a single batch throughout the study.

For each time period (Table I), 10 lots containing six suppositories were formed for each of the possible suppository base mold surface combinations. The molten base was removed from the water bath and poured continuously to form each lot. After pouring, each lot of suppositories was allowed to solidify at room temperature, 17 ± 3°, for the designated time. At the end of the time period, the suppositories were removed from the mold, and the quantity of perfectly formed suppositories released from the mold was counted. After use, the molds were allowed to stand and equilibrate with room temperature before being used again.

% of maximum possible yield ^a	68.0	66.6	67.0	51.4

^a Maximum possible yield was 1920 suppositories.

RESULTS AND DISCUSSION

Polytetrafluoroethylene was most effective in improving the release of suppositories composed of a fatty base and had little effect on the release of polyethylene glycol suppositories after the first 6 min. (Table I). Coating the molds with polytetrafluoroethylene did not decrease appreciably the time required for the molds to stand before removing the suppositories (Table I). As indicated in Table II, there was little difference in the number of suppositories released from polytetrafluoroethylene-coated molds *versus* the new mold with smooth cavity surfaces. However, the release qualities of the damaged mold that had been coated with polytetrafluoroethylene appeared to be very much improved and approximated that of the new molds (Table II). With the assumption that 12 min. is adequate for complete solidification of the four bases tested, the experimental results indicate an increase of approximately 20%⁸ in the yield of suppositories from damaged molds that were polytetrafluoroethylene coated. According to these results, badly damaged molds could be restored by coating their surfaces with polytetrafluoroethylene. However, there would be little advantage in poly-

tetrafluoroethylene coating new molds. The cost of the coating is relatively inexpensive and substantially less than buying a new mold. The coating is easily damaged and, as with new molds, the surfaces should be handled carefully.

⁸ Calculated using data from the 12-min. time period, Table I, as follows: damaged molds (D) yield $42+48+43+56 = 189$ suppositories, damaged molds polytetrafluoroethylene coated (DP) yield $59+60+60+60 = 239$; $239-189 = 50$ suppositories; $50/239 = 20.5\%$.

Gas Chromatographic Determination of *N*- γ -Phenylpropyl-*N*-benzyloxy Acetamide (W-1372) in Blood

J. F. DOUGLAS and J. A. STOCKAGE*

Abstract □ A procedure is described for the determination of *N*- γ -phenylpropyl-*N*-benzyloxy acetamide (W-1372) in plasma or whole blood. W-1372 is extracted from plasma with hexane and measured quantitatively by gas chromatography. The technique is simple, reproducible, and accurate in the range of 1–10 mcg./ml. Dibutyl phthalate is used as the internal standard for quantitation by the relative peak area method.

Keyphrases □ *N*- γ -Phenylpropyl-*N*-benzyloxy acetamide (W-1372)—determination, blood □ Blood—W-1372 drug determination □ GLC—analysis

W-1372 is a new hypolipidemic agent which has been shown by Berger *et al.* (1, 2) to retard atherosclerotic lesions and reduce blood cholesterol in animals maintained on a hypercholesteremic diet. This manuscript describes a procedure for the quantitative determination of W-1372 in blood.

EXPERIMENTAL

Equipment and Reagents—An F and M model 402 dual-column gas chromatograph, equipped with a hydrogen-flame

Figure 1—Gas chromatograms of human plasma treated as described. Left: Chromatogram from normal plasma. Right: Chromatogram from normal plasma with 10 mcg./ml. of W-1372 added.

Table I—Recovery of W-1372 Added to Human Plasma

mcg./ml. Added	Recovery, % ^a
2.0	99.2 \pm 1.0
5.0	98.0 \pm 1.1
10.0	98.3 \pm 0.6

^a Values are the mean of quadruplicate determinations and are given with their standard error.

ionization detector and a 1-mv. Minneapolis-Honeywell recorder, was employed. The chromatographic columns used were 1.23-m. \times 0.63-cm. (4-ft. \times 0.25-in.) glass tubes packed with 3.8% methylvinyl silicone gum rubber (W98) on 80–100 mesh Diataport S. The temperatures used were: column, 200°; injection port, 275°; and detector block, 225°. Carrier gas (helium) flow was 60 ml./min.

Sensitivity settings were range 10 with an attenuation factor of 4 \times . The reagents were redistilled hexane, redistilled chloroform, and dibutyl phthalate (Eastman). The retention times under these conditions are 4.8 min. for W-1372 and 1.6 min. for dibutyl phthalate (Fig. 1).

Procedure—Plasma or whole blood, 1.0 ml., was extracted with 10 ml. of hexane, and 8.0 ml. of the organic solvent was removed and evaporated to dryness in a stream of nitrogen. For drug concentration greater than 10 mcg./ml., the specimen was diluted with physiological saline to an appropriate volume prior to extraction. The dried sample was dissolved in 0.1 ml. of chloroform containing 1.0 mcg. of dibutyl phthalate, and 2.6 μ l. of this solution was injected into the gas chromatograph. The concentration of W-1372

Figure 2—Relationship between relative peak area and W-1372 concentration in plasma.

was determined by the relative peak area method, using dibutyl phthalate as the internal standard.

RESULTS AND DISCUSSION

W-1372 can be quantitated gas chromatographically when the relative peak area is used as an index of concentration. The relationship between relative peak area and drug concentration in the range of 1–10 mcg./ml. of plasma is illustrated in Fig. 2. The reproducibility of the procedure, as indicated by the standard error

of quintuplicate determinations, is also shown in Fig. 2. The recovery of W-1372 was 98–99%, as shown in Table I.

The extraction procedure effectively separates W-1372 from normal interfering plasma constituents, since determinations in normal plasma of humans (Fig. 1), dogs, or monkeys give little or no blank (<0.1 mcg./ml.). The known major metabolites of W-1372—benzoic acid, hippuric acid, and *N*- γ -phenylpropyl-*N*-benzyl-oxyamine (3)—do not interfere.

The blood-depletion pattern of W-1372 following intravenous administration was studied in the dog, squirrel monkey, and Cebus monkey. The results (Table II) indicate that the drug is rapidly removed from the blood, with only trace amounts present after 30 min. in the dog and Cebus monkey and a low level present at this time in the squirrel monkey. A previous study (3) has shown that the plasma half-life of radioactivity following oral administration of W-1372-benzyl-¹⁴C is 4 hr. in the squirrel monkey and 12 hr. in the dog.

Mechanism of Action of Retinyl Compounds on Wound Healing I: Structural Relationship of Retinyl Compounds and Wound Healing

K. H. LEE and THEODORE G. TONG

Abstract □ Retinol, retinyl acetate, and retinoic acid promote wound healing. Retinoic acid is most active. Beta-carotene is active, while lycopene is inactive; β -ionone is active and α -ionone is inactive. For full activity, the compound should contain a β -ionone ring, a conjugated double-bond side chain, and a terminal carboxylic acid side chain.

Keyphrases □ Retinyl compounds, activity—structural relationship □ Wound healing—retinyl compound effect □ GLC—separation □ NMR spectroscopy—identity

In a previous report, it was shown that local application of retinol, retinyl acetate, or retinoic acid, dissolved in a nonionic base (NIB), promotes skin wound healing (1). Retinoic acid is relatively more effective than retinol or retinyl acetate. The fact that retinol, retinyl acetate, and retinoic acid are all effective when applied locally on the skin wound indicates that the primary alcohol

group is not essential in promoting wound healing. It is of interest, therefore, to study the structural relationship of the other part of the retinol molecule for wound-healing activity. The compounds evaluated in this investigation are β -carotene, lycopene, β -ionone, and α -ionone.

Beta-carotene has the same ring structure and conjugated double-bond hydrocarbon side chain as retinol. It should show activity on wound healing as retinol. Lycopene has essentially the same structure as β -carotene but differs from the latter in not having the closed ring structure at either end of the molecule. Beta-ionone, on the other hand, has the same cyclohexene ring but does not have the same length of hydrocarbon side chain as retinol or β -carotene. Alpha-ionone differs from β -ionone by the position of the double bond in the cyclohexene ring and does not conjugate with the side chain. The structure-activity relationships of these compounds to wound healing are discussed.

Mechanism of Action of Retinyl Compounds on Wound Healing I: Structural Relationship of Retinyl Compounds and Wound Healing

K. H. LEE and THEODORE G. TONG

Abstract □ Retinol, retinyl acetate, and retinoic acid promote wound healing. Retinoic acid is most active. Beta-carotene is active, while lycopene is inactive; β -ionone is active and α -ionone is inactive. For full activity, the compound should contain a β -ionone ring, a conjugated double-bond side chain, and a terminal carboxylic acid side chain.

Keyphrases □ Retinyl compounds, activity—structural relationship □ Wound healing—retinyl compound effect □ GLC—separation □ NMR spectroscopy—identity

In a previous report, it was shown that local application of retinol, retinyl acetate, or retinoic acid, dissolved in a nonionic base (NIB), promotes skin wound healing (1). Retinoic acid is relatively more effective than retinol or retinyl acetate. The fact that retinol, retinyl acetate, and retinoic acid are all effective when applied locally on the skin wound indicates that the primary alcohol

group is not essential in promoting wound healing. It is of interest, therefore, to study the structural relationship of the other part of the retinol molecule for wound-healing activity. The compounds evaluated in this investigation are β -carotene, lycopene, β -ionone, and α -ionone.

Beta-carotene has the same ring structure and conjugated double-bond hydrocarbon side chain as retinol. It should show activity on wound healing as retinol. Lycopene has essentially the same structure as β -carotene but differs from the latter in not having the closed ring structure at either end of the molecule. Beta-ionone, on the other hand, has the same cyclohexene ring but does not have the same length of hydrocarbon side chain as retinol or β -carotene. Alpha-ionone differs from β -ionone by the position of the double bond in the cyclohexene ring and does not conjugate with the side chain. The structure-activity relationships of these compounds to wound healing are discussed.

Figure 1—NMR spectra of α - and β -ionones.

EXPERIMENTAL

Materials and Chemicals—Synthetic crystalline, β -carotene, Sigma grade, Type 1, and crystalline lycopene, Blakeslea trispora origin, were obtained from Sigma Chemical Co., St. Louis, Mo. Sodium salicylate and salicylic acid, reagent grade, were obtained from J. T. Baker Chemical Co., Phillipsburg, N. J. The prednisone used was a product of The Upjohn Co., Kalamazoo, Mich. Non-ionic base and 1% hydrocortisone in NIB were prepared by the Pharmaceutical Technology Laboratory, San Francisco Medical Center, San Francisco, Calif. Beta-ionone (n_D^{20} 1.584) and α -ionone (n_D^{20} 1.5030), 77%, were obtained from Aldrich Chemical Co., Inc., Milwaukee, Wis.

Purification of α -Ionone—The purities of the ionones were measured by their spectra (Analytical NMR Spectrometer, model A-60A, Varian Associates, Palo Alto, Calif.). Beta-ionone, as purchased, was a pure preparation, while α -ionone contained 31% of the β -isomer. The isomers were separated by using a preparative gas chromatograph (Varian Aerograph, model 700, Walnut Creek, Calif.). A FFAP column, 3.04 m. \times 0.95 cm. (10 ft. \times 0.37 in.), at 190° was used. The separation was complete and satisfactory. Both fractions collected were pure as measured by an NMR spectrometer. The NMR spectra are shown in Fig. 1.

Application of NIB Preparations—NIB preparations were applied, with gentle rubbing, directly on the sutured wound right after wounding. The application was repeated, once a day, on the 1st and 2nd days after wounding. For the control, only NIB was applied.

Administration of Drugs—Sodium salicylate, dissolved in a small amount of water and prednisone suspended in corn syrup, was fed to the rats daily for 4 days through a short stomach tube connected to a blunt hypodermic needle attached to a 50-ml.

syringe, starting 1 day before operation. The dosage levels for sodium salicylate and prednisone were 50 and 2.5 mg. per rat per day, respectively.

Wound Procedure—Sprague-Dawley male rats, weighing 230–240 g., were anesthetized with ethyl ether in an open mask. The hair on the back was depilated with an electric clipper. One incision, 6 cm. in length, was made through the skin and underlying musculature at a distance about 1.5 cm. from the midline on each side; no ligatures were used. Bleeding usually ceased after a few minutes. The incisions were closed with continuous through-and-through sutures with stitches 0.5 cm. apart. Black silk surgical thread and a curved needle were used. The continuous suture was pulled tight enough to secure good adaptation of the wound edges. The wounds were left undressed.

Measurement of Healing—Tensile strength, the force required to open a healing skin wound, was used to measure healing (2). On the 7th day after wounding, the tensile strength of the wound was measured with a simple laboratory-made tensiometer. The tensiometer consisted of a 15.24 \times 30.48-cm. (6 \times 12-in.) board with one post, 10.16 cm. (4 in.) long, fixed on each side of the long ends. The board was placed at the end of a table. A pulley, with bearing, was mounted on the top of one post. A battery clamp, with 1-cm. clamp width, was tied to the tip of the post without a pulley by a piece of 20-lb. test monofilament fishing line so that the clamp could reach the middle of the board. Another battery clamp was tied to a long piece of fishing line with a 1-l. polyethylene bottle tied to the other end. Before testing, the animal was anesthetized with ethyl ether in an open mask. The sutures of the wound were cut out with a pair of scissors. The animal was then placed on a stack of paper towels on the middle of the board. The amount of the towels could be adjusted so that the wound was on the same level as the tips of the posts. The clamps were then carefully clamped on the skin at the

Table I—Structural Formulas of the Retinyl Compounds Studied

II. Retinyl acetate	
III. Retinoic acid	
IV. β -Carotene	
V. Lycopene	
VI. β -Ionone	
VII. α -Ionone	

opposite sides of the wound at a distance 0.5 cm. from the wound. The longer piece of fishing line was placed on the pulley, and the position of the board was adjusted so that the polyethylene bottle was freely hanging in the air. Water was added to the polyethylene bottle at a rapid but constant rate from a large reservoir (20-l. bottle) until the wound began to open. The amount of water in the polyethylene bottle was weighed and considered as the tensile strength of the wound. Two to three determinations were made on each wound. The mean of the determinations made on wounds on both sides of the animal was taken as the tensile strength of the wound.

RESULTS AND DISCUSSION

The structural formulas for the compounds are shown in Table I.

The fact that retinol, retinyl acetate, and retinoic acid are all active in promoting wound healing indicates that the primary alcohol group is not essential (1). Beta-carotene, the natural precursor of retinol, has essentially the same trimethylcyclohexene ring and conjugated double-bond hydrocarbon side chain as retinol (Compound IV, Table I). The results of the effect of β -carotene on skin wound healing in rats are summarized in Table II. The mean tensile strength of the NIB control is 451 ± 9 g. (Group I). The mean tensile strength of Group II animals to which β -carotene in NIB was applied is 514 ± 7 g. The increase in tensile strength as compared with the control is 14%. The mean tensile strength of Group III animals receiving β -carotene in isopropyl myristate (IPM) is 515 ± 9

g., which is 14% higher than that of the control and is essentially the same as that of Group II animals. This also indicates that neither NIB nor IPM affects healing. The results from Group V and Group VII animals have definitely shown that topical application of β -carotene, like retinoic acid, reverses the healing-inhibitory action caused by oral administration of sodium salicylate or prednisone, as shown in Group IV and Group VI (1).

The effects of lycopene and ionones on wound healing are shown in Table III. Lycopene has essentially the same structure as β -carotene, except that it does not have the closed ring structure at either end of the molecule (Compound V, Table I). The mean tensile strength of Group II animals receiving 1% lycopene in NIB topically is 418 ± 5 g. It is clear that lycopene does not promote healing and, instead, it has a mild inhibitory effect.

Beta-ionone has essentially the same trimethyl cyclohexene ring structure as retinol or β -carotene, except that it does not have the same side chain (Compound VI, Table I). The mean tensile strength of the healing wound of animals receiving topical application of 1% β -ionone in NIB is 497 ± 11 g., which is 110% of the control (Group III). Beta-ionone is less active than β -carotene.

On the other hand, α -ionone, the isomer of β -ionone (the only difference being the position of the double bond in the trimethyl cyclohexene ring) does not have any activity in promoting healing. The mean tensile strength of the rats receiving 1% of α -ionone in NIB is 453 ± 6 g. (Group IV). It is interesting to point out the well-known fact that the α -isomer of retinol also does not have any vitamin A activity. The results from the foregoing structural relationship and

Tetrameric Structure and Conformation of Heat-Microaggregated Human Serum Albumin

JOEL KIRSCHBAUM

Abstract \square ^{131}I -labeled heat-microaggregated human serum albumin is a colloid used in a method that measures liver blood flow through a determination of the rate of removal of microaggregates from the circulation. The heat-microaggregated material, either labeled or unlabeled, has a molecular weight (mol. wt.) of 273,000 daltons and a sedimentation coefficient of 8.6 S. Since the precursor, human serum albumin, has a molecular weight of 67,000 daltons and a sedimentation coefficient of 4.6 S, the microaggregate is a tetramer. The tetramer may be converted to subunits with a molecular weight of 72,000–76,000 daltons and a sedimentation coefficient of 4.7 S by the addition of buffered urea, guanidinium chloride, or formamide or by decreasing the pH to 2.2. Immunological studies indicate that this subunit has a different conformation from that of native human serum albumin. Hydrodynamic calculations indicate that the colloid has a particle size between $50 \times 50 \times 200 \text{ \AA}$ and $50 \times 100 \times 100 \text{ \AA}$.

Keyphrases \square Albumin, human serum, heat-microaggregated—tetrameric structure, conformation, physical constants \square Human serum albumin, heat-microaggregated—structure, physical constants \square Ultracentrifugation—sedimentation coefficients \square Conformational studies—heat-microaggregated human serum albumin

Heating human serum albumin results, under certain conditions, in the formation of two protein aggregates (1, 2), made clinically useful by subsequent labeling with ^{131}I . One preparation, particulate in nature (2), is known as heat-macroaggregated human serum albumin. The other preparation is known as heat-microaggregated human serum albumin (3). The rate of disappearance of injected colloidal microaggregated particles from the circulation of mammals permits an estimation of the phagocytic capacity of the reticuloendothelial system, because this removal involves principally the Kupffer cells of the liver. Knowledge of phagocytic capacity appears to be useful in determining the extent of such diseases as pneumococcal pneumonia, typhoid

fever, and Hodgkin's disease. This paper describes some physical properties of the metabolizable microaggregate, either unlabeled or labeled with ^{131}I .

EXPERIMENTAL

Source of Heat-Microaggregated Human Serum Albumin—The aggregation of human serum albumin (HSA) was performed according to the method of Iio and Wagner (3), as modified from the method of Benacerraf *et al.* (1). HSA at a concentration of 3% protein in 0.9% NaCl adjusted to pH 10 with NaOH was shaken vigorously for 20 min. at 70° and then for 15 min. at 79°. After rapid cooling, the precipitate that formed from the solution was resuspended in 0.1 M NaHCO_3 . After storage, the precipitate dissolved and the solution of heat-microaggregated HSA was diluted to 10 mg./ml.

Sedimentation Coefficients—By the use of a Spinco model E analytical ultracentrifuge, the sedimentation coefficients of ^{131}I -labeled and unlabeled heat-microaggregated HSA at 20° and the viscosity and density of water, $\rho_{20,w}^0$ (4), were calculated at 29,500, 42,040, and 50,740 r.p.m. with 0.2 M NaCl–0.02 M sodium phosphate buffer (pH 6.85) as diluent. The viscosity was measured with the aid of either capillary or rotating (5) viscometers. A 10-ml. pycnometer at $20 \pm 0.002^\circ$ (Fisher Isotemp water bath) was used for density measurements. Viscosity and density corrections for aqueous solutions of urea and guanidinium chloride were also obtained from the data of Kawahara and Tanford (6).

Molecular Weights—The molecular weight was determined by two methods. The Archibald approach-to-sedimentation equilibrium method (7) was used with the modification of Engelberg (8) to evaluate the integral of the concentration gradient. The Yphantis meniscus-depletion (9) analyses were performed in a capillary-type double-sector cell at 20° at a speed of 20,410 r.p.m. The cell bottom was layered with FC-43 fluorochemical oil (Beckman Instruments), and 0.03 ml. of 0.1% dialyzed solution was layered over the oil. The solvent was the last dialysate.

Immunological studies utilized rabbit and horse antihuman serum albumin (Hyland Laboratories, Los Angeles, Calif.).

Polyacrylamide gel electrophoresis was performed with the Canalco model 6 apparatus (Canal Industrial Corp., Rockville, Md.).

Tetrameric Structure and Conformation of Heat-Microaggregated Human Serum Albumin

JOEL KIRSCHBAUM

Abstract \square ^{131}I -labeled heat-microaggregated human serum albumin is a colloid used in a method that measures liver blood flow through a determination of the rate of removal of microaggregates from the circulation. The heat-microaggregated material, either labeled or unlabeled, has a molecular weight (mol. wt.) of 273,000 daltons and a sedimentation coefficient of 8.6 S. Since the precursor, human serum albumin, has a molecular weight of 67,000 daltons and a sedimentation coefficient of 4.6 S, the microaggregate is a tetramer. The tetramer may be converted to subunits with a molecular weight of 72,000–76,000 daltons and a sedimentation coefficient of 4.7 S by the addition of buffered urea, guanidinium chloride, or formamide or by decreasing the pH to 2.2. Immunological studies indicate that this subunit has a different conformation from that of native human serum albumin. Hydrodynamic calculations indicate that the colloid has a particle size between $50 \times 50 \times 200 \text{ \AA}$ and $50 \times 100 \times 100 \text{ \AA}$.

Keyphrases \square Albumin, human serum, heat-microaggregated—tetrameric structure, conformation, physical constants \square Human serum albumin, heat-microaggregated—structure, physical constants \square Ultracentrifugation—sedimentation coefficients \square Conformational studies—heat-microaggregated human serum albumin

Heating human serum albumin results, under certain conditions, in the formation of two protein aggregates (1, 2), made clinically useful by subsequent labeling with ^{131}I . One preparation, particulate in nature (2), is known as heat-macroaggregated human serum albumin. The other preparation is known as heat-microaggregated human serum albumin (3). The rate of disappearance of injected colloidal microaggregated particles from the circulation of mammals permits an estimation of the phagocytic capacity of the reticuloendothelial system, because this removal involves principally the Kupffer cells of the liver. Knowledge of phagocytic capacity appears to be useful in determining the extent of such diseases as pneumococcal pneumonia, typhoid

fever, and Hodgkin's disease. This paper describes some physical properties of the metabolizable microaggregate, either unlabeled or labeled with ^{131}I .

EXPERIMENTAL

Source of Heat-Microaggregated Human Serum Albumin—The aggregation of human serum albumin (HSA) was performed according to the method of Iio and Wagner (3), as modified from the method of Benacerraf *et al.* (1). HSA at a concentration of 3% protein in 0.9% NaCl adjusted to pH 10 with NaOH was shaken vigorously for 20 min. at 70° and then for 15 min. at 79°. After rapid cooling, the precipitate that formed from the solution was resuspended in 0.1 M NaHCO_3 . After storage, the precipitate dissolved and the solution of heat-microaggregated HSA was diluted to 10 mg./ml.

Sedimentation Coefficients—By the use of a Spinco model E analytical ultracentrifuge, the sedimentation coefficients of ^{131}I -labeled and unlabeled heat-microaggregated HSA at 20° and the viscosity and density of water, $\rho_{20,w}^0$ (4), were calculated at 29,500, 42,040, and 50,740 r.p.m. with 0.2 M NaCl–0.02 M sodium phosphate buffer (pH 6.85) as diluent. The viscosity was measured with the aid of either capillary or rotating (5) viscometers. A 10-ml. pycnometer at $20 \pm 0.002^\circ$ (Fisher Isotemp water bath) was used for density measurements. Viscosity and density corrections for aqueous solutions of urea and guanidinium chloride were also obtained from the data of Kawahara and Tanford (6).

Molecular Weights—The molecular weight was determined by two methods. The Archibald approach-to-sedimentation equilibrium method (7) was used with the modification of Engelberg (8) to evaluate the integral of the concentration gradient. The Yphantis meniscus-depletion (9) analyses were performed in a capillary-type double-sector cell at 20° at a speed of 20,410 r.p.m. The cell bottom was layered with FC-43 fluorochemical oil (Beckman Instruments), and 0.03 ml. of 0.1% dialyzed solution was layered over the oil. The solvent was the last dialysate.

Immunological studies utilized rabbit and horse antihuman serum albumin (Hyland Laboratories, Los Angeles, Calif.).

Polyacrylamide gel electrophoresis was performed with the Canalco model 6 apparatus (Canal Industrial Corp., Rockville, Md.).

RESULTS AND DISCUSSION

Hydrodynamic Properties of the Heat-Microaggregated Human Serum Albumin Molecule—The heat-microaggregated HSA was considered sufficiently pure for hydrodynamic studies, because polyacrylamide gel electrophoresis indicated that approximately 95% of the heat-microaggregated HSA migrated as one component and the sedimentation velocity studies showed only one peak with almost no asymmetry. The sedimentation coefficient of unlabeled heat-microaggregated HSA at 20°, corrected to the viscosity of water and extrapolated to zero concentration, was $8.56 \pm 0.04 S$ ($S = 10^{-13} \text{ sec.}$) between pH 4.7 and 10.2 (Table I). The sedimentation coefficient of the heat-microaggregated ^{131}I -labeled HSA was $8.45 \pm 0.08 S$. The heat-microaggregated preparation was sensitive to small changes in duration of heating; an increase of 5 min. in the heating time at 79° led to the formation of a particle with a molecular weight of 880,000 daltons.

The partial specific volume of heat-microaggregated HSA was experimentally determined (10) to be $0.737 \text{ cm.}^3/\text{g.}$, compared with $0.733\text{--}0.736 \text{ cm.}^3/\text{g.}$ for native HSA (11, 12).

According to the Archibald method, approximately 95% of the sedimenting material had a molecular weight of $279,000 \pm 10,000$ daltons at the meniscus and cell bottom; the remaining 5% possessed an approximate molecular weight of $132,000 \pm 9000$ daltons, which corresponds to the naturally occurring dimer of HSA found in serum albumin at similar concentrations of 5–8% (12). The molecular weight found by the Yphantis method at 20,410 r.p.m. was $267,000 \pm 8000$ daltons. Since the molecular weight of HSA is 67,000 (12, 13), four molecules of HSA must have combined to give one molecule of microaggregated HSA. The addition of ^{131}I has no apparent effect on molecular weight or sedimentation coefficient.

The diffusion constant, $D_{20,w}$, was calculated to be $2.84 \times 10^{-7} \text{ cm.}^2 \text{ sec.}^{-1}$ from the Svedberg equation (14), $D_{20,w} = RTs/M(1 - \bar{v}\rho)$, where R is the gas constant, T is the temperature in °K., s is the sedimentation coefficient, M is the molecular weight, \bar{v} is the partial specific volume, and ρ is the density. Using this value for $D_{20,w}$, $f/f_{\text{min.}}$ was calculated (15) to be 1.7, where $f = kT/D$ (k is Boltzmann's constant) and $f_{\text{min.}} = 6\pi\eta(3M\bar{v}/4\pi N)^{1/3}$ (η is the viscosity of solvent and N is Avogadro's number). This indicates that the heat-microaggregated HSA molecule is slightly asymmetric, since HSA is globular with a calculated $f/f_{\text{min.}}$ value of 1.3–1.4 (15, 16).

Dissociation of the Aggregate—The apparently mild conditions required for aggregation suggested that dissociation of the aggregate to monomers of HSA was possible. As will be shown later, it was found that although the monomeric molecular weight of the dissociated microaggregate was similar to that of the monomer, the conformation changed. As seen in Table I, the sedimentation coefficients of microaggregated HSA and monomeric HSA dissolved in buffered 8 M urea, 9 M formamide, or 5 M guanidinium chloride were identical within the limits of experimental error (17). These values indicated that heat-microaggregated HSA (mol. wt. 273,000) had dissociated to monomeric HSA. The molecular weight in 8 M urea, 9 M formamide, and 5 M guanidinium chloride was between 72,000 and 76,000 daltons. Ten milligrams microaggregated HSA/milliliter 0.2 M glycine-HCl buffer (pH 2.2) showed two components. The $s_{20,w}^0$ values of 4.5 and 9 S indicated some breakdown of the aggregate. Aggregated HSA, HSA, or mixtures of both HSA and aggregated HSA all produced schlieren images

with one broad peak, indicating not only breakdown of the aggregate but also some denaturation of the monomeric HSA (18). After removal of urea by dialysis, the schlieren peaks still appeared broad, indicating that denaturation of HSA is only partially reversible.

Conformation of Heat-Microaggregated Human Serum Albumin—Although both monomeric HSA and monomeric HSA first dissolved in buffered 8 M urea and then dialyzed against H_2O yield strong precipitin bands, both aggregated HSA and urea-dissociated, aggregated HSA (dialyzed subsequently against H_2O and buffer to remove urea) fail to form precipitin bands with rabbit or horse antihuman serum albumin. This failure indicates that the HSA monomer formed from dissociated tetrameric microaggregated HSA has a different conformation from that of human serum albumin.

Since: (a) the HSA molecules are globular (15) with a diameter of approximately 50 Å [radius = $(3M\bar{v}/4\pi N)^{1/3}$]; (b) the conformation of each of the HSA molecules after heating is still generally spherical, as seen by the sedimentation coefficient of 4.5 S found after the addition of urea and subsequent dialysis (Table I); and (c) the aggregate is asymmetric, then the aggregate may consist of either: (a) a chain 4 subunits long ($200 \times 50 \times 50 \text{ Å}$); (b) a tetragon, two subunits wide and 2 subunits long ($100 \times 100 \times 50 \text{ Å}$), or an intermediate conformation. One forbidden conformation is the symmetrical tetrahedral pyramid.

Binding Forces of the Aggregate—The disaggregation of the tetramer caused by buffered urea, guanidinium chloride, formamide, or low pH indicates that the denaturing agent may be interacting with peptide groups through hydrogen and hydrophobic bonds (19). The aggregate may have been formed by the reverse process, with heat causing the cleavage ("melting") of some interpeptide bonds and the subsequent cooling of the mixture resulting in the partial intertwining of the protein chains from four molecules.

Phospholipid Spherules as a Model to Assess Photosensitizing Properties of Drugs

ALVIN FELMEISTER and SHRILEKHA V. TOLAT

Abstract □ The effect of a series of UV irradiated and nonirradiated phenothiazine drugs on the chromate leakage from lipid spherules has been determined. All of the drugs studied increased chromate leakage to varying degrees prior to irradiation. However, only chlorpromazine and prochlorperazine exhibited a marked increase in chromate leakage after irradiation. These effects are discussed in terms of the *in vivo* photosensitizing properties of the drugs.

Keyphrases □ Photosensitizing properties—phenothiazines □ Lipid spherules, chromate leakage—photosensitizing properties, phenothiazines □ Phenothiazines—photosensitizing properties □ Spectrophotometry—analysis

Nonphysiologic photosensitized reactions have been studied extensively since Raab first observed the photosensitized activity of acridine toward paramecium almost 70 years ago (1). During the intervening time, much has been learned about such reactions, although their exact mechanism of action has not been completely elucidated. However, it has been reasonably well established that changes in the permeability of the membrane of cells or cell organelles are often induced by light-irradiated photosensitizing agents (2).

It was the purpose of this investigation, therefore, to develop a physical model that might be used to assess photosensitizing agents by measuring their influence on membrane permeability. The phospholipid spherule model developed by Bangham *et al.* (3) was selected for this purpose. These workers have shown that phospholipids, when permitted to swell in an aqueous salt solution, form salt-containing compartments bounded by bimolecular membranes. These structures (spherules) exhibit permeability characteristics that are quite

similar to those of biological membranes. Furthermore, these spherules have been shown by numerous researchers to be useful tools for studying membrane-drug interactions, particularly when changes in permeability are involved (4). Therefore, changes in permeability of these spherules induced by light-irradiated drugs should be a measure of the photosensitizing property of these drugs.

Five phenothiazine derivatives were selected for this initial study. Two of these compounds, chlorpromazine and prochlorperazine, have been shown unequivocally to be photosensitizers (5). The other three compounds, promazine, trifluorpromazine, and fluphenazine, rarely if ever produce photosensitization (5-7).

MATERIALS AND METHODS

The phenothiazine derivatives were used without further purification. These were chlorpromazine hydrochloride and prochlorperazine hydrochloride (Smith Kline & French Laboratories); promazine hydrochloride (Wyeth Laboratories); and trifluorpromazine hydrochloride and fluphenazine dihydrochloride (The Squibb Institute for Medical Research).

The lipid spherules were prepared by the method of Bangham *et al.* (3) with slight modification. Briefly, egg lecithin and dicetylphosphate (90 and 10 μmoles , respectively) were dissolved in chloroform and placed in a 50-ml. round-bottom flask. The solvent was removed under reduced pressure using a flash evaporator. Six milliliters of a 0.145 *M* potassium chromate solution was then added to the flask, and the lipid material was permitted to swell for 4 hr. at room temperature. At the end of 4 hr., any chromate ion not trapped within the spherules was removed by dialyzing the dispersion against a 0.145 *M* KCl solution for 18-20 hr. One milliliter of the dialyzed suspension of chromate-containing spherules was transferred to each of five cells. By use of a micrometer syringe, 0.05 ml. of a 1×10^{-2} *M* solution in 0.145 *M* KCl of the

Phospholipid Spherules as a Model to Assess Photosensitizing Properties of Drugs

ALVIN FELMEISTER and SHRILEKHA V. TOLAT

Abstract □ The effect of a series of UV irradiated and nonirradiated phenothiazine drugs on the chromate leakage from lipid spherules has been determined. All of the drugs studied increased chromate leakage to varying degrees prior to irradiation. However, only chlorpromazine and prochlorperazine exhibited a marked increase in chromate leakage after irradiation. These effects are discussed in terms of the *in vivo* photosensitizing properties of the drugs.

Keyphrases □ Photosensitizing properties—phenothiazines □ Lipid spherules, chromate leakage—photosensitizing properties, phenothiazines □ Phenothiazines—photosensitizing properties □ Spectrophotometry—analysis

Nonphysiologic photosensitized reactions have been studied extensively since Raab first observed the photosensitized activity of acridine toward paramecium almost 70 years ago (1). During the intervening time, much has been learned about such reactions, although their exact mechanism of action has not been completely elucidated. However, it has been reasonably well established that changes in the permeability of the membrane of cells or cell organelles are often induced by light-irradiated photosensitizing agents (2).

It was the purpose of this investigation, therefore, to develop a physical model that might be used to assess photosensitizing agents by measuring their influence on membrane permeability. The phospholipid spherule model developed by Bangham *et al.* (3) was selected for this purpose. These workers have shown that phospholipids, when permitted to swell in an aqueous salt solution, form salt-containing compartments bounded by bimolecular membranes. These structures (spherules) exhibit permeability characteristics that are quite

similar to those of biological membranes. Furthermore, these spherules have been shown by numerous researchers to be useful tools for studying membrane-drug interactions, particularly when changes in permeability are involved (4). Therefore, changes in permeability of these spherules induced by light-irradiated drugs should be a measure of the photosensitizing property of these drugs.

Five phenothiazine derivatives were selected for this initial study. Two of these compounds, chlorpromazine and prochlorperazine, have been shown unequivocally to be photosensitizers (5). The other three compounds, promazine, trifluorpromazine, and fluphenazine, rarely if ever produce photosensitization (5-7).

MATERIALS AND METHODS

The phenothiazine derivatives were used without further purification. These were chlorpromazine hydrochloride and prochlorperazine hydrochloride (Smith Kline & French Laboratories); promazine hydrochloride (Wyeth Laboratories); and trifluorpromazine hydrochloride and fluphenazine dihydrochloride (The Squibb Institute for Medical Research).

The lipid spherules were prepared by the method of Bangham *et al.* (3) with slight modification. Briefly, egg lecithin and dicetylphosphate (90 and 10 μmoles , respectively) were dissolved in chloroform and placed in a 50-ml. round-bottom flask. The solvent was removed under reduced pressure using a flash evaporator. Six milliliters of a 0.145 *M* potassium chromate solution was then added to the flask, and the lipid material was permitted to swell for 4 hr. at room temperature. At the end of 4 hr., any chromate ion not trapped within the spherules was removed by dialyzing the dispersion against a 0.145 *M* KCl solution for 18-20 hr. One milliliter of the dialyzed suspension of chromate-containing spherules was transferred to each of five cells. By use of a micrometer syringe, 0.05 ml. of a 1×10^{-2} *M* solution in 0.145 *M* KCl of the

drug under investigation was added to each of two of these cells (final drug concentration $\approx 5 \times 10^{-4} M$). The same volume of an UV-irradiated solution of the drug was added to two of the remaining cells. An equal volume of 0.145 M KCl was added to the remaining cell, which served as the control. After mixing the material in each cell, 1 ml. of the dispersion was transferred from each cell to a corresponding dialyzing sac. The sacs were sealed and then placed in separate test tubes containing 5 ml. of 0.145 M KCl. The test tubes were maintained at 37° in a water bath for 30 min. At the end of this time the sacs were removed and the concentration of chromate ion present in the KCl solution was determined spectrophotometrically (absorbance at 380 m μ). The absorbance, which is proportional to the chromate-ion concentration, was used as a measure of leakage of this ion from the spherule (*i.e.*, lipid membrane permeability).

Known concentrations of chromate ion were determined by this procedure in the presence of the irradiated and nonirradiated phenothiazines ($5 \times 10^{-4} M$) to determine whether either the drug itself or any of its photoproducts interfered with the spectrophotometric analysis. The results obtained were not significantly different from those obtained in the absence of the phenothiazines.

Irradiation of Drug Solution—Three milliliters of a $1 \times 10^{-2} M$ solution of the drug was placed in a standard 1-cm. quartz cell. The cell was positioned 4 in. from the center of a "black light" UV lamp, model 16, Eastern Corp., and exposed for 90 min. The wavelengths emitted by this lamp fall between 290 and 400 m μ . The irradiated solution was then transferred, as previously described, to cells containing the spherules.

RESULTS AND DISCUSSION

The effect of both the irradiated and nonirradiated phenothiazine derivatives on the release of chromate ion from the spherules is summarized in Table I.

Preirradiation—All the nonirradiated drugs tested induced considerably more leakage than that observed with the control. This probably is a measure of the ability of these compounds to interact at a lipid-water interface. Similar effects have been observed with these drugs on other model systems such as erythrocytes, platelets (8), and monomolecular films (9). In fact, phenothiazine-membrane interaction has been proposed as one mechanism of the pharmacologic activity of these drugs (10). The greater leakage induced by chlorpromazine and prochlorperazine apparently is a measure of a greater drug-spherule interaction.

Postirradiation—Of the five drugs studied, only chlorpromazine and prochlorperazine showed any significant change in chromate leakage after irradiation. With both of these phenothiazines, the increase in leakage is considerable. The difference between these two compounds, however, is not significant, indicating that on an equal concentration basis, both of these drugs, when irradiated, induce about the same degree of leakage.

The large increase in leakage induced by the UV irradiation of chlorpromazine and prochlorperazine suggests that such irradiation results in the formation of species that are considerably more membrane active than the parent compounds.

It has been reported that chlorpromazine photopolymerizes *via* a free radical formed by the elimination of the chlorine from the 2-position (11). It is reasonable to postulate that prochlorperazine, which also has a chlorine at the 2-position, will polymerize *via* a similar mechanism. The fact that only these chlorine-containing compounds resulted in increased chromate leakage, coupled with the likelihood that only these compounds will polymerize on exposure to UV radiation, suggests that a photopolymer may be the membrane-active species.

Huang *et al.* (11) postulated that the formation of a photopolymer of chlorpromazine could be responsible for some photosensitized reactions observed in individuals maintained on large doses of this drug.

However, the possibility cannot be eliminated that the *N*-oxide and hydroxy derivatives of chlorpromazine, which were also identified by Huang and Sands (12) as photoproducts, may be responsible to some degree for the observed effects. These products, resulting from the UV irradiation of chlorpromazine, have been shown to be more surface active than chlorpromazine itself (13) and thus more likely to penetrate and disrupt phospholipid membranes.

Table I—Release of Chromate from Phospholipid Spherules Induced by UV-Irradiated and Nonirradiated Phenothiazines

Drug Added	—% of Chromate Released ^a —		Increase due to Irradiation, % ^a
	Nonirradiated Mean ^b \pm SEM	Irradiated Mean ^b \pm SEM	
Chlorpromazine	370 \pm 17	2790 \pm 570	86
Prochlorperazine	428 \pm 25	2400 \pm 220	82
Promazine	180 \pm 30	170 \pm 22	—
Trifluorpromazine	220 \pm 50	230 \pm 55	—
Fluphenazine	220 \pm 40	190 \pm 40	—

^a As compared to that released by the control. ^b Calculated from three to five independently obtained values.

CONCLUSION

Weissman *et al.* (14) have pointed out that artificial lipid spherules appear to resemble natural structures (lysosomes, mitochondria, and erythrocytes) in their release of ions after exposure to lytic agents such as lysolecithin, streptolysin S, a nonionic surfactant (Triton X-100), and steroids. Apparently, these effects, in both natural and artificial systems, are the results of changes in permeability induced by the interaction and subsequent rearrangement of the lipid layers by the lytic agents.

It would appear then that the five phenothiazines are lytic at the concentration used in this study ($5 \times 10^{-4} M$), since they all produced a significant increase in chromate leakage. Such a lytic effect was observed by Ahtee and Paasonen (8) with a series of phenothiazine drugs using erythrocytes, although these authors noted that at lower drug concentration, erythrocyte membrane stabilization occurred rather than lysis. Furthermore, irradiated chlorpromazine and prochlorperazine appear to be much more potent lytic agents than any of the nonirradiated compounds, suggesting the formation of new, more membrane-active species by the irradiation.

Thus, the results of this investigation suggest that if either of these latter two drugs accumulate in membranes of cells or cell organelles, even at levels below that required to produce lysis, irradiation could convert them to species with significant lytic activity. Such lytic species in turn could lead to increased cell membrane permeability and subsequent edema and inflammation. In contrast, the lytic potential of the other drugs studied would be expected to remain relatively unchanged after exposure to UV irradiation. Based on this finding, it appears that of these five phenothiazines, only chlorpromazine and prochlorperazine should produce direct photosensitized cutaneous reactions.

The available clinical data generally support this postulation. Both chlorpromazine and prochlorperazine are consistently reported to produce photosensitization (5). In addition, both also are capable of producing this effect in all exposed individuals if a sufficient drug concentration level is achieved. In contrast, based on the available clinical reports, trifluorpromazine and fluphenazine are essentially nonphotosensitizing (5, 6), and promazine has been reported as a photosensitizer in only one early study (7).

This preliminary study does indicate that lipid spherules are useful models to assess photosensitizing properties of the phenothiazine drugs. Studies with additional known and potential photosensitizers are currently underway to validate the usefulness of this model for other groups of compounds.

Dermatitic Effect of Nonionic Surfactants IV: Phospholipid Composition of Normal and Surfactant-Treated Rabbit Skin

MICHAEL MEZEI and AMBROSE K. Y. LEE

Abstract □ Results of the authors' previous experiment indicated that the primary site of action of topically applied surfactants (polysorbate 85 and polyoxyethylene ether 96) is in the epidermal membranes. To elucidate the interaction of surfactants with biological membranes, the composition of epidermal phospholipids and the rate of biosynthesis of major phospholipid components were determined by utilizing thin-layer chromatographic, spectrophotometric, and radiotracer techniques. Results indicated that the major lipid components are cholesterol, lecithin, lysolecithin, phosphatidyl ethanolamine, and sphingomyelin. The treatment with surfactant did not induce any significant change in the phospholipid composition. The biosynthetic and turnover rates of all identified phospholipids, however, were greatly increased (two to four times) in the surfactant-treated skin. Available data suggest that the tested surfactants damaged the epidermal membranes. A role of surfactants in increasing the absorption of medicinal substances was also proposed in view of these results and other reports regarding the effect of surfactants on biological membranes.

Keyphrases □ Phospholipid composition, rabbits—normal, surfactant-treated skin □ Nonionic surfactants—dermatitic effect, rabbits □ TLC—analysis □ Scintillometry—analysis, ³²P-incorporation □ Spectrophotometry—analysis

In a multiphase system the molecules of a surface-active agent align and orient themselves at the interface. In a biological system the membranes provide the interface. The concentration of a surfactant in a tissue because of its hydrophilic-lipophilic character is the highest at, or in, the biological membranes; therefore, the site of action of a topically applied surfactant is very likely in the epidermal membranes.

Unfortunately, it is difficult to design experiments to test the action of surfactants on biological membranes. At present, the exact structural configuration of membranes is not defined because of the lack of reliable techniques to study membranes at cellular or molecular level. Recent reviews describe most of the presently accepted theories relating to the structure and function of biological membranes (1-5). Changes in membranes induced by surfactants or any other agents can be stud-

ied only by indirect methods. On the basis of the presently accepted concepts of biological membranes, a qualitative and/or quantitative change in lipid composition of a tissue may indicate structural changes and, consequently, functional changes in the membranes. Results of previous investigations (6-8) indicated that the treatment with surfactant preparations induced an increase both in the content and in the biosynthetic rate of epidermal phospholipids, nucleic acids, and acid-soluble material. This increase was explained by the assumption that the surfactants damaged the biological membranes by either rupturing the membranes or replacing certain phospholipid molecules in the continuous phospholipid micelles present in the membranes. Phospholipid molecules present in ruptured membranes and those that are possibly replaced by surfactants were measured along with newly formed molecules during the analysis of skin tissue.

The higher rate of biosynthesis of epidermal phospholipids was explained by the reasoning that it was expected in order to repair the surfactant-damaged membranes or to regenerate membranes. A further step in this project was to find out whether the surface-active agents interact with the membrane as a whole or with only certain components of the membrane. If the surfactants disrupt or damage the membrane as a result of hydrophobic or micellar interactions or by hydrogen bonding and a completely new membrane is regenerated, then the content and the rate of biosynthesis of all phospholipid membrane components will be increased. On the other hand, if the surfactant interacts with certain phospholipid molecules participating in the membrane, i.e., a molecule can replace one phospholipid molecule present in the lipid micelles, one should find that the content and the rate of biosynthesis of those particular phospholipids would be increased more than that of other phospholipid components. The determination of phospholipid composition and the rate of biosynthesis of each phospholipid component in the control and sur-

Table I—Relative Percent Composition of Epidermal Phospholipids

Phospholipids	Untreated, mean \pm SD	Relative Percent ^a		
		Petrolatum, mean \pm SD	Polysorbate 85, mean \pm SD	Polyoxyethylene Ether 96, mean \pm SD
Lecithin	41.6 \pm 5.0	41.6 \pm 5.2	43.3 \pm 4.8	40.2 \pm 4.6
Lysolecithin	10.9 \pm 4.3	10.4 \pm 3.9	10.3 \pm 4.6	10.4 \pm 4.8
Phosphatidyl ethanolamine	27.1 \pm 4.0	27.7 \pm 4.6	27.5 \pm 3.4	29.2 \pm 3.6
Sphingomyelin	20.3 \pm 5.1	20.4 \pm 2.0	18.8 \pm 5.5	20.1 \pm 5.4

^a Results indicated represent the mean value of percentage composition, on the basis of lipid phosphorus, with standard deviation (\pm SD, N = 31). The percentage composition was calculated, in case of each rabbit, from the sum of phosphorus recovered from spots on the thin-layer plate corresponding to the four phospholipids which was accepted as 100%. Epidermal samples were obtained from three groups of rabbits: 21 rabbits were treated for 4 days, five for 2 days, and five for 7 days.

factant-treated skin, as described in this report, was another attempt to test, although indirectly, the site of action of the selected surfactant at the molecular level.

MATERIALS AND METHODS

The selection and the treatment of the experimental animals and the isolation of epidermis and epidermal lipids have been described in the authors' previous reports (6-8). Aliquots of the lipid extract were used for the separation of phospholipids by TLC.

Thin-Layer Chromatography—Thirty grams of silica gel G (E. Merck, A. G., Darmstadt, Germany) was mixed with 63 ml. of 0.01 M Na₂CO₃ solution and spread on 20 \times 20-cm. glass plates in 0.25-mm. thickness. The plates were dried at room temperature and were activated for 1 hr. at 105° just before use. Aliquots of lipid extracts were applied along with standard solutions of known phospholipids with a microliter syringe as narrow streaks on 2-cm. wide lanes, 1.5 cm. from the bottom of the plate. The plates were subjected to ascending chromatography in a closed glass developing tank, which contained 100 ml. of chloroform-methanol-distilled water, 65:30:5. This solvent was allowed to rise to 15 cm. from the starting line.

The developed chromatograms were examined by various detection methods, such as exposure to iodine vapor, spraying with ammonium molybdate-perchloric acid, rhodamine B, and Dragendorff reagents (9). Individual lipids were identified by comparison with standard lipid applied on the same thin-layer plate. Additional evidence of identity of the various phospholipids was obtained by recent experiment using the Zeiss chromatogram spectrophotometer (10). The identified components, as well as standard known lipids and blank areas, were scraped into glass-stoppered test tubes, and the phospholipids were digested with sulfuric acid and hydrogen peroxide and the phosphorus was determined as described by Keenan *et al.* (11).

Radiotracer Technique—Recent experiments were extended to measure the rate of *in vivo* incorporation of ³²P into the epidermal phospholipid components. In this part of the project, rabbits (five in a group) were treated for 2, 4, and 7 days. Twenty-four hours before the end of treatment, approximately 5 mc. inorganic ³²P (Na₂HPO₄) was injected intravenously through the ear veins. The experimental procedure for extracting the epidermal lipids was the same as with other rabbits treated for 4 days without the use of an isotope (7). To minimize the error introduced by the TLC technique, the same

sample that was obtained from the identified and marked spots was used for both spectrophotometric determination of phosphorus (11) and for the measurement of ³²P incorporation. In this way a more reliable specific radioactivity (c.p.m./mcg. lipid-P) could be calculated. Aliquots (3.0 ml.) of the isobutanol layer, which was used for the spectrophotometric determination of phosphorus, were mixed with scintillator solvent (7.0 ml. Bray's solution) composed of 60 g. naphthalene, 20 ml. ethylene glycol, 100 ml. methanol, 4 g. PPO, and 0.2 g. POPOP, and dioxane made up the volume to 1.0 l. The radioactivity was measured by Unilux I liquid scintillation counter (Nuclear Chicago).

RESULTS AND DISCUSSION

Thin-layer chromatographic analyses of epidermal lipid extracts indicated that there are four phospholipids—lecithin, lysolecithin, phosphatidyl ethanolamine, and sphingomyelin—present in rabbit skin in amounts that could be measured and identified. Besides these four components, three other phospholipids were detected but not identified, mainly because of the minute amount present. Table I demonstrates the relative percent composition of the four major epidermal phospholipids of untreated and surfactant-treated rabbit skin. The relative percent composition was calculated from the sum of phosphorus recovered from spots containing these four phospholipids. The unidentified phospholipids, which probably compose 10-20% of the total phospholipid content, were disregarded.

According to the data shown by Table I, there is no statistically significant change in the percent composition of these phospholipids after the treatment with the tested surfactant preparations (10% in white petrolatum). There is, however, a slight increase in lecithin content as well as a slight decrease in sphingomyelin content of samples treated with polysorbate 85 compared with that of untreated skin samples. The distribution of incorporated radioactivity in epidermal phospholipids is shown by Table II. Due to the treatment with polysorbate 85, the content of lecithin seemed to be increased (Table I) but the reverse is true regarding the radioactivity (Table II). The same treatment resulted in a decrease in the content (Table I) and an increase in the radioactivity (Table II) of sphingomyelin. That the treatment with surfactants has an effect, however slight, on the content but more on the rate of biosynthesis of these four phospholipids becomes evident if the results shown in Table III are considered. Table III demonstrates the effect

Table II—Distribution of Incorporated Radioactivity in Epidermal Phospholipids

Phospholipids	Untreated, mean \pm SD	Relative Percent ^a		
		Petrolatum, mean \pm SD	Polysorbate 85, mean \pm SD	Polyoxyethylene Ether 96, mean \pm SD
Lecithin	50.0 \pm 4.7	48.5 \pm 5.2	46.9 \pm 5.8	43.2 \pm 5.8
Lysolecithin	7.5 \pm 2.9	7.6 \pm 2.1	6.6 \pm 1.7	8.6 \pm 2.8
Phosphatidyl ethanolamine	28.9 \pm 3.2	31.2 \pm 3.7	27.6 \pm 5.7	29.6 \pm 2.8
Sphingomyelin	13.5 \pm 4.4	12.8 \pm 5.3	18.8 \pm 7.2	18.7 \pm 5.3

^a Values represent the mean percentage of counts measured in the four phospholipids recovered from the thin-layer plates. The percentage of radioactivity was calculated, in case of each rabbit, from the sum of counts in the four phospholipids recovered which was accepted as 100%. The mean of these percentages were calculated, in case of each phospholipid component, with standard deviations (\pm SD, N = 15). Epidermal samples were obtained from three groups of rabbits (five in each group) treated for 2, 4, and 7 days, respectively.

Table III—Incorporation of ^{32}P into Epidermal Phospholipids

Phospholipids	Length of Treatment, days	Specific Activity as Percent of Control ^a		
		Petrolatum, mean \pm SD	Polysorbate 85, mean \pm SD	Polyoxyethylene Ether 96, mean \pm SD
Lecithin	2	128 \pm 35	194 \pm 52	179 \pm 52
	4	118 \pm 15	202 \pm 12	151 \pm 6
	7	113 \pm 14	196 \pm 85	194 \pm 60
Lysolecithin	2	142 \pm 33	159 \pm 29	117 \pm 19
	4	104 \pm 6	466 \pm 69	221 \pm 40
	7	103 \pm 37	145 \pm 22	209 \pm 78
Phosphatidyl ethanolamine	2	120 \pm 32	155 \pm 19	129 \pm 23
	4	120 \pm 25	211 \pm 45	197 \pm 27
	7	142 \pm 33	222 \pm 84	216 \pm 27
Sphingomyelin	2	112 \pm 8	290 \pm 148	226 \pm 20
	4	133 \pm 30	410 \pm 55	341 \pm 50
	7	103 \pm 16	283 \pm 132	269 \pm 87

^a The results are expressed as percent differences of specific activity (c.p.m./mcg. lipid-P) of skin samples treated with the ointment base: white petrolatum, and nonionic surfactants: polysorbate 85 and polyoxyethylene ether 96, as compared with that of the untreated skin, which is accepted as 100%. Values show the mean \pm standard deviation (\pm SD, N = 5).

of treatment with surfactant preparations on the rate of incorporation of ^{32}P into epidermal lipid components.

To assess statistical significance of the data, the percentage stimulations of ^{32}P incorporation into the epidermal phospholipid component of each individual rabbit were calculated. These percentage increases were averaged, and then the mean values were calculated with standard deviations. This was necessitated by the variation in the absolute incorporation of ^{32}P into the various epidermal phospholipids of different rabbits. This variation was due not only to individual biological variation but, to a greater extent, to the fact that it was almost impossible to inject intravenously exactly 5.0 mc. ^{32}P . Since the amount of ^{32}P in the circulatory blood and, consequently, at the site of the designated epidermal tissue varied with each rabbit, the variation in the rate of incorporation of ^{32}P into phospholipid components was very large, even within one type of skin. This variation would tend to decrease the statistical significance of any differences that might be observed between the specific activity of a particular phospholipid extracted from the untreated and surfactant-treated skin of one rabbit. The rate of ^{32}P incorporation was expressed as specific activity in counts per minute per phosphorus (c.p.m./mcg.-P) present in the particular phospholipid recovered from the thin-layer plate.

In all cases the incorporation of ^{32}P into phospholipids of the surfactant-treated skin was much greater than that of the untreated skin samples. The treatment with petrolatum also seems to stimulate the incorporation of ^{32}P , but this stimulation is not significant. The highest increase in the rate of ^{32}P incorporation is observed in skin samples treated with polysorbate 85 preparation for 4 days. This increase is more than fourfold in the case of lysolecithin and sphingomyelin and somewhat more than twofold with lecithin and phosphatidyl ethanolamine. Treatment with polysorbate 85 for 2 and 7 days induced a less dramatic increase in the specific activity of each of the four phospholipids. The explanation for the relationship between the length of time of treatment and the extent of increase in the specific activity of the phospholipids is rather complex. Speculations for possible mechanisms of reaction to injury caused by the surfactant at various stages of the treatment are presented elsewhere (8). The treatment with polyoxyethylene ether 96 also induced a considerable increase in the rate of incorporation of ^{32}P into each of the phospholipids. These increases, however, were almost independent of the length of time of treatment.

In most cases the standard deviation is rather large, mainly because of the thin-layer chromatographic technique and partly because of other numerous steps in the experimental procedure. The quantitative recovery of phospholipids from the corresponding spots on the thin-layer plates and the spectrophotometric and radioactive measurement of the phospholipid components in the presence of silica gel are the major factors in the spread of results. In spite of these problems, the effect of the tested surfactants on the rate of biosynthesis of the major epidermal phospholipids is apparent.

Results reported previously (6-8) and data presented herein are clear, although indirect, indications for changes in epidermal membranes as a result of treatment with surfactants. Many investigators (12-20) reported that surfactants in a variety of dosage forms

increase the absorption of medicinal substances. In most of these reports (12-20) the role of surfactants in enhancing absorption was explained by the physicochemical properties of the tested surfactants; a surfactant may reduce the disintegration time of a tablet or may enhance the dissolution or diffusion of an active ingredient by various physicochemical phenomena, thereby influencing the rate of absorption of agents administered along with a surface-active agent. These are sound explanations, and no doubt a surfactant can influence absorption on these bases due to its physicochemical properties. The authors would like to propose, on the bases of previous studies (6-8), that the role of a surfactant in enhancing absorption of other agents present in the same product is also due to its physiological properties. As the authors postulated (21), the surfactants may act on the membranes by various possible mechanisms, and this is also a contributing factor for the reported increased rate of absorption. A damaged or regenerating membrane is less of a barrier to penetrating substances than are intact membranes. The question now is whether it is wise to increase the absorption of a substance by damaging the membranes, especially in the case of chronic treatment. The surfactants increase the permeability of membranes, which may lead not only to higher penetration of medicinal substances but, by disturbing the balance of a cell system, also to metabolic disorder.

1,3,2-Dioxaphosphorinane 2-Oxides IV: Preparation of Some 2-Substituted-5-carbomethoxy-5-methyl-1,3,2-dioxaphosphorinane 2-Oxides as Potential Antitumor Agents

JOHN H. BILLMAN and GERALD R. ROEHRIG

Abstract □ Twenty-two of the title compounds, in which the substituents are chloro, alkylamino, dialkylamino, arylamino, hydroxy, and amine salts, as well as the pyrophosphate, have been synthesized and submitted for antitumor evaluation.

Keyphrases □ 1,3,2-Dioxaphosphorinane 2-oxides—synthesis □ Antitumor agents—synthesis, 1,3,2-dioxaphosphorinane 2-oxides □ IR spectrophotometry—structure, analysis

Previous work in the authors' laboratory (1) has led to consideration of the dioxaphosphorinane 2-oxides as potential antitumor agents. Synthesis and evaluation of compounds of Type I are described at this time.

Y = —Cl, —NHR, —NR₂, —NHAr, —OH, -amine salts and the pyrophosphate

The starting point for the preparation of these compounds was the phosphochloridic acid II, which was prepared according to Scheme I. Compound II can formally be considered as an acid chloride analogous to the more commonly encountered carboxylic acid chlorides; as such, one would expect that it might exhibit many of the same types of reactions as the acyl chlorides. Indeed, many of those reactions have been observed and used to advantage. Schemes II–IV are representative of those used for the preparation of the compounds cited in this paper.

The salts of the acid were prepared for two basic reasons. Since the majority of these compounds are relatively water insoluble, it was thought that a compound with considerably greater water solubility might exhibit a greater degree of antitumor activity. Also, by incorporating amines that exhibit biological activity, one could compare the activity of the salt with that of

Scheme I

Scheme II

R = alkyl, aryl, or hydrogen

Scheme III

the free amine. At this point, insufficient data have been returned to clarify either of these points.

Tables I and II contain the data pertinent to the structures of the compounds under consideration.

1,3,2-Dioxaphosphorinane 2-Oxides IV: Preparation of Some 2-Substituted-5-carbomethoxy-5-methyl-1,3,2-dioxaphosphorinane 2-Oxides as Potential Antitumor Agents

JOHN H. BILLMAN and GERALD R. ROEHRIG

Abstract □ Twenty-two of the title compounds, in which the substituents are chloro, alkylamino, dialkylamino, arylamino, hydroxy, and amine salts, as well as the pyrophosphate, have been synthesized and submitted for antitumor evaluation.

Keyphrases □ 1,3,2-Dioxaphosphorinane 2-oxides—synthesis □ Antitumor agents—synthesis, 1,3,2-dioxaphosphorinane 2-oxides □ IR spectrophotometry—structure, analysis

Previous work in the authors' laboratory (1) has led to consideration of the dioxaphosphorinane 2-oxides as potential antitumor agents. Synthesis and evaluation of compounds of Type I are described at this time.

Y = —Cl, —NHR, —NR₂, —NHAr, —OH, -amine salts and the pyrophosphate

The starting point for the preparation of these compounds was the phosphochloridic acid II, which was prepared according to Scheme I. Compound II can formally be considered as an acid chloride analogous to the more commonly encountered carboxylic acid chlorides; as such, one would expect that it might exhibit many of the same types of reactions as the acyl chlorides. Indeed, many of those reactions have been observed and used to advantage. Schemes II–IV are representative of those used for the preparation of the compounds cited in this paper.

The salts of the acid were prepared for two basic reasons. Since the majority of these compounds are relatively water insoluble, it was thought that a compound with considerably greater water solubility might exhibit a greater degree of antitumor activity. Also, by incorporating amines that exhibit biological activity, one could compare the activity of the salt with that of

BIOLOGICAL RESULTS

All biological testing was carried out by the Cancer Chemotherapy National Service Center (CCNSC), Bethesda, Md. Compounds I–VI, VIII–X, XII–XIX, XXI, and XXII were tested against L1210 lymphoma over a total dose range of 40–400 mg./kg. and found to be inactive. Compounds II, III, V, VI, X, XIII, and XV–XVIII were tested against Walker 256 carcinosarcoma over a total dose range of 100–400 mg./kg. and found to be inactive.

EXPERIMENTAL¹

2-Chloro-5-carbomethoxy-5-methyl-1,3,2-dioxaphosphorinane 2-Oxide (II)—*Procedure A*—Phosphorus oxychloride (154.5 g.,

1.01 moles) was added in small portions to stirring 2-carbomethoxy-2-methyl-1,3-propanediol (50.0 g., 0.337 mole) in a conical flask fitted with a drying tube. After the exothermic reaction had subsided, the stirring reaction mixture was heated to 90° for 4 hr. The reaction mixture was poured with stirring into 600 ml. of petroleum ether (90–120° b.p.) which had been cooled to 0° in an ice bath. White crystals of the phosphochloridic acid precipitated; they were filtered and washed with anhydrous ether, yielding 31.3 g. or 41.3%.

Anal.—Calcd. for C₆H₁₀ClO₅P: C, 31.52; H, 4.41. Found: C, 31.35; H, 4.35.

2-Hydroxy-5-carbomethoxy-5-methyl-1,3,2-dioxaphosphorinane 2-Oxide (III)—*Procedure B*—A stirring solution of II (42.50 g., 0.186 mole) in 100 ml. of 95:5 acetone–water was refluxed for 3.5 hr. and the reaction mixture was cooled overnight. The resulting white crystals of III were recrystallized from acetone, yielding 20.6 g. or 52.7%.

Anal.—Calcd. for C₆H₁₁O₆P: C, 34.25; H, 5.28. Found: C, 34.30; H, 5.41.

¹ All melting points were determined on a Thomas-Hoover capillary apparatus and are corrected. IR spectra were obtained from a Perkin-Elmer 137 infrared spectrophotometer. Analyses were carried out by Midwest Microlab, Inc., Indianapolis, Ind.

2-Hydroxy-5-carbomethoxy-5-methyl-1,3,2-dioxaphosphorinane 2-Oxide, 4-Methylmercaptoaniline Salt—*Procedure C*—This procedure is representative of those used in preparation of the salts. A solution of 4-methylmercaptoaniline (3.31 g., 23.8 mmoles) in 50 ml. of acetone was added dropwise to a stirring solution of III (5.00 g., 23.8 mmoles) in 25 ml. of acetone, and the resulting mixture was stirred for 1 hr. at room temperature. White crystals of the salt precipitated; they were washed with acetone and dried, yielding 6.60 g. or 79.4%.

Anal.—Calcd. for C₁₃N₂O₆NO₂PS: N, 4.01. Found: N, 3.99.

Bis(5-carbomethoxy-5-methyl-2-oxo-1,3,2-dioxaphosphorinanyl)-pyrophosphate (V)—*Procedure D*—A solution of III (4.60 g., 21.9 mmoles) in 25 ml. of acetone was added dropwise to a stirring solution of II (5.00 g., 21.9 mmoles) in 25 ml. of acetone at room temperature. An excess of triethylamine in acetone was added to the reaction mixture, which was then stirred for 2 hr. at room temperature. Triethylamine hydrochloride precipitated; the reaction mixture was chilled and filtered. The solvent was removed from the filtrate *in vacuo*; the resulting white crystals of V were

recrystallized from ethyl acetate–acetonitrile, yielding 1.75 g. or 20.0%.

Anal.—Calcd. for C₁₂H₂₀O₁₂P₂: C, 35.83; H, 5.01. Found: C, 35.91; H, 5.16.

2-Aziridino-5-carbomethoxy-5-methyl-1,3,2-dioxaphosphorinane 2-Oxide—*Procedure E*—This procedure is representative of those used in the preparation of the alkylamides of Type IV. A solution of aziridine (0.94 g., 21.7 mmoles) and an excess of triethylamine in 50 ml. of acetone was added dropwise to a stirring solution of II (5.00 g., 21.9 mmoles) in 25 ml. of acetone at 0°. Triethylamine hydrochloride precipitated immediately. The reaction mixture was filtered after precipitation was complete, and the solvent was evaporated from the filtrate *in vacuo*. The resulting white crystals of the amide were recrystallized from ether, yielding 1.70 g. or 33.3%.

Anal.—Calcd. for C₈H₁₄NO₅P: N, 5.96. Found: N, 6.04.

2-(4-Bromoanilino)-5-carbomethoxy-5-methyl-1,3,2-dioxaphosphorinane 2-Oxide—*Procedure F*—This procedure is representative of those used in the preparation of the arylamides of Type IV. A solution of 4-bromoaniline (15.04 g., 87.4 mmoles) in 50 ml. of benzene was refluxed with stirring for 1 hr. in an apparatus equipped with a Dean trap to remove moisture. A solution of II (10.00 g., 43.7 mmoles) in 50 ml. of benzene was added dropwise to the stirring reaction mixture, which was then refluxed for an additional 4 hr. 4-Bromoaniline hydrochloride precipitated; the reaction mixture was filtered while still hot and the filtrate was chilled. The resulting white crystals of the amide were recrystallized from benzene, yielding 9.1 g. or 57.2%.

Anal.—Calcd. for C₁₂H₁₅BrNO₅P: N, 3.85. Found: N, 3.86.

Presence of Diosgenin in Tissue Cultures of *Dioscorea composita* Hemsl. and Related Species

ATUL R. MEHTA* and E. JOHN STABA

Abstract □ Four species of *Dioscorea* were grown as callus and suspension tissue cultures on revised Murashige and Skoog's tobacco medium and contained diosgenin.

Keyphrases □ Diosgenin, presence—tissue cultures, determination □ *Dioscorea* tissue cultures—diosgenin determination □ TLC—separation □ GLC—determination

A number of *Dioscorea* species (family *Dioscoreaceae*) are cultivated commercially for their tubers which yield diosgenin, an important starting compound for the manufacture of corticosteroidal drugs. Of these, only *D. composita* and *D. deltoidea* have previously been established as tissue cultures. Diosgenin, however, was not detected in the tissue cultures of *D. composita* (1-4) while the presence of diosgenin in the callus and suspension cultures of *D. deltoidea* is reported. In this communication, the authors report the establishment of four species of *Dioscorea* as tissue cultures and their diosgenin content.

EXPERIMENTAL

Tissue Culture—Callus cultures of *D. composita*, *D. deltoidea*, *D. floribunda*, and *D. spiculiflora* were initiated from aseptically germinated seedlings placed in glass vials containing revised Murashige and Skoog's tobacco medium supplemented with 1-3 p.p.m. 2,4-dichlorophenoxyacetic acid (2,4-D). Details of the cultural procedures followed were described previously (5). Yellowish-white to pale-brown callus developed from the seedling within 3-4 weeks, and these were subcultured to fresh agar media every 4 weeks. On low 2,4-D medium (1 p.p.m.), root primordia differentiated from *D. floribunda* callus tissues; therefore, all callus cultures (except *D. deltoidea*) were maintained on a medium containing 3 p.p.m. 2,4-D.

In the present investigation: (a) callus tissues which had undergone four subcultures and (b) later grown as suspension culture on a reciprocal shaker for 3 weeks were assayed for the presence of diosgenin. Differentiated and undifferentiated tissue cultures of *D. floribunda* were assayed separately for diosgenin.

Analysis—The dried and acid-hydrolyzed tissues were extracted with benzene for TLC (qualitative) (6) or with chloroform for GLC (quantitative). Dried chloroform extracts and standards (diosgenin and cholesterol) were silylated with a Tri-Sil-pyridine mixture (Pierce Chemical Co., Rockford, Ill.) and assayed (Varian Aero-

graph model 1740 with flame-ionization detector). A 1.52-m. × 0.63-cm. (5-ft. × 0.25-in.) glass column containing 80-100-mesh Varaport 30 coated with 3% OV-17 was used at 275°.

RESULTS AND DISCUSSION

The quantitative assays for diosgenin from tissues and suspension cultures of different *Dioscorea* species are summarized in Tables I and II. Of the species examined, maximum diosgenin content was present in tissue cultures of *D. deltoidea* and then in decreasing order of diosgenin production by callus tissue cultures in *D. floribunda* (undifferentiated), *D. spiculiflora*, and *D. composita*. Progressive changes in diosgenin content in *D. deltoidea* cell suspensions during the course of culture for 10 weeks were studied (Table I). The diosgenin content is high initially, declines, and again rises to a high level at 8 weeks. Of all the cultural parameters examined, the pH of the medium follows a strikingly similar pattern. However, further experimentation is needed to confirm and explain this observation and why *D. composita* was not reported earlier to contain diosgenin.

It has been suggested (7, 8) that diosgenin is biosynthesized principally in the aerial parts of *Dioscorea* species and is then translocated to the tubers where it is stored. Earlier studies (5, 6) clearly indicated that undifferentiated *D. deltoidea* tissue cultures produced diosgenin, whereas root-differentiated tissue cultures produced very small amounts. In this study, root-differentiated cultures of *D. floribunda* produced significant amounts of diosgenin.

Role of Hydrophobic Interactions in Enzyme Inhibition by Drugs

ERIC J. LIEN, MEHDI HUSSAIN*, and GEORGE L. TONG†

Abstract □ The role of hydrophobic interactions in inhibiting the relatively specific enzymatic reactions of five enzyme systems by series of congeneric drugs has been illustrated by the use of substituent constants and regression analysis. The inhibition of lipoxxygenase by alcohols, the inhibition of D-amino acid oxidase by maleimides, and the inhibition of hydroxyindole-*o*-methyltransferase by *N*-acetyltryptamines are found to be linearly dependent on the lipohydrophilic character of the inhibitors ($\log P$ or π). The inhibition of carbonic anhydrase by sulfonamides is found to be linearly dependent on the $\log P$ and Hammett's σ constant. For monoamine oxidase inhibition by substituted β -carbolines, a parabolic equation of $\log P$ gives the most significant correlation. The ideal lipohydrophilic character ($\log P_0$) for maximum inhibition is found to be 2.74.

Keyphrases □ Enzyme inhibitory activity—hydrophobic interactions, drugs □ Hydrophobic interactions, drugs—enzyme inhibitory activity □ Physicochemical constants, enzyme inhibition—correlation

In recent years much effort has been focused on elucidation of weak intermolecular forces in biological systems (1), especially on the importance of hydrophobic interactions (2–6). Various experimental methods have been used to estimate the hydrophobic bonding tendency of drug molecules, such as partitioning and chromatographic methods (3, 7). Organic solvents capable of forming hydrogen bonds (e.g., alcohols and esters) appear to give better correlations than hydrocarbons (8). The purpose of this paper is to correlate quantitatively enzyme inhibitory activity with the tendency of hydrophobic interactions of series of drugs, as measured by the partition coefficient of 1-octanol–water. It is hoped that this work may shed some light on the intermolecular forces involved in enzyme inhibition and provide some clues in designing new enzyme inhibitors.

METHOD

The biological data given in Table I are taken from the literature (4, 9–12). The Hammett's sigma constants (σ) are from the compilation of Jaffé (13) unless otherwise stated. The $\log P$ values are either experimentally determined or calculated from the π constants

(14, 15) of Hansch. For example, the $\log P$ of *N*-acetyltryptamine is calculated as follows:

The steric constants, E_s , are taken from Leffler and Grunwald (16). The equations listed in Table II are derived *via* the method of least squares using an IBM 360/65 computer. The inhibition constant K_I , $k' = (k_i/K_I)$, or the concentration of an inhibitor giving 50% inhibition of the enzyme (I_{50}) is converted to the molar basis, and pK_I , $\log k'$, or $\log 1/I_{50}$ is used as a measure of the inhibitory activity.

RESULTS

The equations correlating enzyme inhibition with the physicochemical constants are summarized in Table II, where n is the number of data points used in the analysis, r is the correlation coefficient, and s is the standard deviation.

In the inhibition of lipoxxygenase by monohydric alcohols, the relative inhibitory activity is mainly determined by the lipohydrophilic character ($\log P$). More than 98% ($r^2 = 0.983$) of the variance in the data can be accounted for by the simple linear equation (Eq. 1a). Equation 1b, derived by Mitsuda *et al.* (4), gives a slightly lower correlation coefficient, presumably due to the slightly different $\log P$ values used.

For the carbonic anhydrase inhibition by sulfonamides, by comparing Eq. 2a with Eq. 2b one can see that the electronic term σ is slightly more important than the $\log P$ term. The positive coefficient associated with σ indicates that electron-withdrawing groups will increase the inhibitory activity. By using both terms simultaneously, a much better correlation is obtained (Eq. 2c). The $\log P$ term in Eq. 2c is significant at 97.5-percentile level, as indicated by an *F*-test ($F_{1,16} = 7.2$; $F_{1,15} 0.975 = 6.2$).

The π -constant alone gives almost perfect correlation for inhibition of D-amino acid oxidase by *N*-alkylmaleimides (Eqs. 3b and 3c). By using π and σ terms together, high correlation is obtained for the *N*-aryl as well as *N*-alkyl derivatives. The σ term in Eq. 3a is highly significant ($F_{1,5} = 111$; $F_{1,5} 0.995 = 63.6$).

For the inhibition of hydroxyindole-*o*-methyltransferase by *N*-acetyltryptamines, $\log P$ alone gives fairly good correlation (Eq. 4a). By deleting three molecules with deviation greater than $2s$, a better

The inhibition of carbonic anhydrase by sulfonamides is found to be linearly dependent on the $\log P$ and Hammett's σ constant. For monoamine oxidase inhibition by substituted β -carbolines, a parabolic equation of $\log P$ gives the most significant correlation. The ideal lipohydrophilic character ($\log P_0$) for maximum inhibition is found to be 2.74.

Keyphrases □ Enzyme inhibitory activity—hydrophobic interactions, drugs □ Hydrophobic interactions, drugs—enzyme inhibitory activity □ Physicochemical constants, enzyme inhibition—correlation

In recent years much effort has been focused on elucidation of weak intermolecular forces in biological systems (1), especially on the importance of hydrophobic interactions (2–6). Various experimental methods have been used to estimate the hydrophobic bonding tendency of drug molecules, such as partitioning and chromatographic methods (3, 7). Organic solvents capable of forming hydrogen bonds (e.g., alcohols and esters) appear to give better correlations than hydrocarbons (8). The purpose of this paper is to correlate quantitatively enzyme inhibitory activity with the tendency of hydrophobic interactions of series of drugs, as measured by the partition coefficient of 1-octanol–water. It is hoped that this work may shed some light on the intermolecular forces involved in enzyme inhibition and provide some clues in designing new enzyme inhibitors.

METHOD

The biological data given in Table I are taken from the literature (4, 9–12). The Hammett's sigma constants (σ) are from the compilation of Jaffé (13) unless otherwise stated. The $\log P$ values are either experimentally determined or calculated from the π constants

(14, 15) of Hansch. For example, the $\log P$ of *N*-acetyltryptamine is calculated as follows:

The steric constants, E_s , are taken from Leffler and Grunwald (16). The equations listed in Table II are derived *via* the method of least squares using an IBM 360/65 computer. The inhibition constant K_I , $k' = (k_i/K_I)$, or the concentration of an inhibitor giving 50% inhibition of the enzyme (I_{50}) is converted to the molar basis, and pK_I , $\log k'$, or $\log 1/I_{50}$ is used as a measure of the inhibitory activity.

RESULTS

The equations correlating enzyme inhibition with the physicochemical constants are summarized in Table II, where n is the number of data points used in the analysis, r is the correlation coefficient, and s is the standard deviation.

In the inhibition of lipoxxygenase by monohydric alcohols, the relative inhibitory activity is mainly determined by the lipohydrophilic character ($\log P$). More than 98% ($r^2 = 0.983$) of the variance in the data can be accounted for by the simple linear equation (Eq. 1a). Equation 1b, derived by Mitsuda *et al.* (4), gives a slightly lower correlation coefficient, presumably due to the slightly different $\log P$ values used.

For the carbonic anhydrase inhibition by sulfonamides, by comparing Eq. 2a with Eq. 2b one can see that the electronic term σ is slightly more important than the $\log P$ term. The positive coefficient associated with σ indicates that electron-withdrawing groups will increase the inhibitory activity. By using both terms simultaneously, a much better correlation is obtained (Eq. 2c). The $\log P$ term in Eq. 2c is significant at 97.5-percentile level, as indicated by an *F*-test ($F_{1,16} = 7.2$; $F_{1,15} 0.975 = 6.2$).

The π -constant alone gives almost perfect correlation for inhibition of D-amino acid oxidase by *N*-alkylmaleimides (Eqs. 3b and 3c). By using π and σ terms together, high correlation is obtained for the *N*-aryl as well as *N*-alkyl derivatives. The σ term in Eq. 3a is highly significant ($F_{1,5} = 111$; $F_{1,5} 0.995 = 63.6$).

For the inhibition of hydroxyindole-*o*-methyltransferase by *N*-acetyltryptamines, $\log P$ alone gives fairly good correlation (Eq. 4a). By deleting three molecules with deviation greater than $2s$, a better

^a From Reference 4.

correlation is obtained ($r = 0.948$ for Eq. 4b). The authors also explored the role of the electronic parameter. For the 15 molecules with X-Ar as R_2 (Table I), neither the σ of X nor the σ of R_1 gives significant improvement in correlation. Of the three poorly predicted molecules, two may be due to steric hindrance, one with the methyl group as R_3 , and the other with the 3,4,5-trimethoxybenzyl group as R_2 . The fact that the observed activities of these three compounds are lower than the predicted values supports this argument. The third molecule has the 3,5-dichlorophenyl group as R_2 . It is difficult to explain why this is poorly predicted since the one with the 3,4-dichlorophenyl group as R_2 is slightly more active than predicted.

For the inhibition of monoamine oxidase by 9-substituted β -carbolines, Taft's steric constant, E_s , gives somewhat better correlation than $\log P$ (Eq. 5a versus 5b). However, the correlation coefficients are too low to be considered significant. Even when a $(\log P)^2$ term is included, the correlation coefficient is still below 0.70 (Eqs. 5c and 5d). When three compounds with an alcoholic OH group are excluded, a parabolic equation of $\log P$ gives fairly good correlation (Eq. 5g). The $(\log P)^2$ term in Eq. 5g is significant at the 99-percentile level ($F_{1,5} = 18.2$; $F_{1,5, 0.99} = 16.3$). For the eight compounds without an OH group, neither the linear equation of E_s nor that of $\log P$ gives a good correlation (Eqs. 5e and 5f); the addition of the E_s term to the parabolic equation does not improve the correlation significantly (Eq. 5h versus 5g, $F_{1,4} = 0.21$). It is felt that an active function like an OH group may have its own *intrinsic activity* not possessed by the other inert substituents. For example, the H of the OH group might form a hydrogen bond with an atom having unshared electron pair(s). The fact that the activities of the compounds with the OH group are appreciably higher than what are predicted from Eq. 5g is in accordance with this explanation. The optimum lipohydrophilic character ($\log P_0$) for the maximum inhibition is derived by setting $(d \log 1/I_{50})/(d \log P) = 0$ (17–19). This is the apex of the parabolic curve. Once this $\log P_0$ is obtained, it may serve as a useful guidepost in designing new inhibitors.

The importance of the hydrophobic interactions for the enzyme inhibition is clearly shown by the good correlations obtained by using $\log P$ or π with or without a σ term.

DISCUSSION

From the correlations obtained, it is clear that in the five enzyme systems examined the lipohydrophilic character of the inhibitors plays a very important role in inhibition. The rather nonspecific hydrophobic interactions may be involved in two different ways: (a) adsorption and desorption on the macromolecule, since all proteins including enzymes contain 20–45% of amino acids with nonpolar side chains (20), and (b) inducing proper fit at the active site or the allosteric site (21) by the association of the nonpolar groups in the presence of water molecules. At present, not enough data are available to differentiate which of these two is more important.

It will be interesting to apply the method used in this study to other systems where drugs exert their activity by enzyme inhibition, such as choline esterase inhibitors and histidine decarboxylase inhibitors.

Cyclic Analog of Ethacrynic Acid

M. BRAWNER FLOYD and GEORGE R. ALLEN, Jr.

Abstract □ The α,β -unsaturated ketone (4,4-dimethyl-2-ethyl-1[4H]-naphthalenon-6-yl)oxyacetic acid (III), a cyclic analog of ethacrynic acid, has been prepared, and its diuretic activity on oral administration to rats and dogs has been evaluated. No significant activity was observed.

Keyphrases □ Ethacrynic acid cyclic analog—synthesis □ Diuretic activity—ethacrynic acid analog □ UV spectrophotometry—identity

In 1962, Schultz *et al.* (1) disclosed a new class of diuretic agents possessing general structure I. Among the more potent members of this series was ethacrynic acid (II), which has received wide acceptance as a pharmaceutical agent (2). The interesting activity associated with II prompted the authors of this study to explore the preparation of cyclic congeners to assess their effectiveness as diuretic agents; in the present note they describe the preparation of III. Independent of these efforts, Topliss and Konzelman (3) reported recently the preparation and biological properties of the related compounds IV ($n = 0, 2$).

The preparation of III from 4-*p*-anisyl-4-methylpentanoic acid (V) (4) is outlined in Scheme I. Lithium aluminum hydride reduction of V and treatment of the resulting alcohol with *p*-bromobenzenesulfonyl (Bs) chloride afforded the crude brosylate VI. Formolysis of VI has been reported to give the rearranged tetralin VII exclusively in 59% yield along with the formate derived from VI (5). In this study, pyrolysis of VI at 150° gave a 3:2 mixture of tetralins VII and VIII in 74% yield.

This result indicates the intervention of a normal ring closure in the absence of solvent. Mild chromic acid oxidation of the tetralin mixture resulted in preferential conversion of VII to tetralone IX. Treatment of IX with methyl magnesium carbonate (6, 7), and ethylation of the resulting magnesium enolate gave the crude 2-ethyltetralone X. Phenol XI was obtained by ether cleavage of the crude alkylation product and chromatographic separation from the phenols XII, derived from methylation of IX, and XIII, derived from unalkylated IX. The genesis of XII may be a consequence of the ability of methyl magnesium carbonate to function as an alkylating agent. Reaction of XI with ethyl bromoacetate and potassium carbonate in refluxing acetone gave the ethyl aryloxyacetate XIV. Finally, bromination of XIV and treatment of the resulting XV with dilute potassium hydroxide effected saponification and dehydrohalogenation to give III.

PHARMACOLOGY

When administered orally to rats at 25 mg./kg., the aryloxyacetic acid III had no significant effect on urinary volume or chloride, sodium, and potassium-ion excretion as determined by the method of Cummings *et al.* (8). Although urine volume was slightly elevated in dogs that had been dosed orally at 5 mg./kg., electrolyte excretion was not increased (9).

Scheme I

EXPERIMENTAL

General—Melting points are uncorrected and were determined in open capillary tubes on a Mel-Temp apparatus. UV spectra were determined with a Cary recording spectrophotometer in methanol solution.

4-(*p*-Anisyl-4-methylpent-1-yl)-*p*-bromobenzenesulfonate (VI)—To a stirred suspension of lithium aluminum hydride (8.0 g.) in 250 ml. of ether was added a solution of 4-*p*-anisyl-4-methylpentanoic acid (V, 31 g.) in 250 ml. of ether over 1.5 hr. with ice-bath cooling. Following the addition the mixture was refluxed with stirring for 1.5 hr. The crude alcohol (100%) was obtained by hydrolysis with dilute sulfuric acid and solvent removal.

To a stirred solution of the alcohol (27 g.) in 240 ml. of dry pyridine at -15° was added a solution of *p*-bromobenzenesulfonyl chloride (50 g.) in 130 ml. of pyridine over 5 min. The mixture was stirred at 0° for 30 min. and poured into water. The product was extracted with ether; the extracts were washed successively with water, cold 2 *N* HCl, water, saturated NaHCO_3 , and water. The extract was dried and evaporated to give 53 g. (95%) of crude VI, m.p. 48–55°.

4,4-Dimethyl-6-methoxy-1-tetralone (IX)—The brosylate (51 g.) was heated under argon at 150° for 110 min. The cooled product was treated with saturated NaHCO_3 and extracted with light petroleum ether. The solution was washed with water, dried, and evaporated to give an amber liquid which was chromatographed on an alumina column, eluting with hexane and 20:1 hexane-ether. The tetralin fraction so obtained (16.8 g.) analyzed as 60% 1,1-dimethyl-7-methoxytetralin (VII) and 40% isomer, presumably the 6-methoxyisomer VIII, on gas chromatography with a hydrocarbon oil (Apiezon L) column at 200° .

To a solution of the tetralin mixture (16.8 g.) in 85 ml. of glacial acetic acid was added a solution of chromium trioxide (20 g.) in 55 ml. of acetic acid and 10 ml. of water over 70 min. at $15-20^{\circ}$ (ice bath). After standing at room temperature for 16 hr., the bulk of the solvent was evaporated; the resulting residue was treated with 5% H_2SO_4 . Treatment with ether, filtration through diatomaceous earth (Celite), and further extraction with 1:1 ether-light petroleum ether gave an extract which was washed successively with water, saturated NaHCO_3 , and water. Distillation of the dried concentrate afforded IX (5.51 g.) as a pale-yellow liquid, b.p. $110-114^{\circ}$ (0.14 mm.), λ_{max} 225 $\text{m}\mu$ (ϵ 11,300); 278 $\text{m}\mu$ (ϵ 10,900).

Anal.—Calcd. for $\text{C}_{13}\text{H}_{16}\text{O}_2$: C, 76.44; H, 7.90. Found: C, 76.52; H, 7.78.

4,4-Dimethyl-2-ethyl-6-hydroxy-1-tetralone (XI)—A solution of VIII (5.5 g.) in 60 ml. of 2.5 *M* methyl magnesium carbonate in dimethylformamide (7) was heated at 125° for 80 min. After slight cooling, ethyl iodide (42 g.) was added; the resulting mixture was refluxed for 6 hr. The reaction mixture was acidified with 4 *N* HCl and heated on the steam bath for 15 min. The reaction mixture was diluted with water and extracted with ether. The extract was washed with water, dried, and evaporated to give the crude X (6.4 g.) as a dark liquid.

The crude alkylation product (5.6 g.) was added to fused pyridine hydrochloride at $190-200^{\circ}$ over 5 min. under argon, and the resulting mixture was stirred for 80 min. The cooled reaction mixture was treated with water and extracted with ether. The extract was washed successively with water, 2 *N* HCl, and water. Phenolic material was extracted into 0.5 *N* NaOH, and the extract was acidified with 4 *N* HCl. Ether extraction afforded a mixture of phenols which were separated by column chromatography on silica gel, eluting with hexane progressively enriched in ethyl acetate. The most mobile component was recrystallized from acetone-hexane, m.p. $128-130^{\circ}$, and consisted of XI (1.76 g.), λ_{max} 227 $\text{m}\mu$ (ϵ 11,600); 279 $\text{m}\mu$ (ϵ 13,400).

Anal.—Calcd. for $\text{C}_{14}\text{H}_{18}\text{O}_2$: C, 77.03; H, 8.31. Found: C, 77.39; H, 8.45.

The methyl derivative XII was recrystallized from acetone-hexane, m.p. $168-173^{\circ}$ (50 mg.), λ_{max} 227 $\text{m}\mu$ (ϵ 11,900); 276 $\text{m}\mu$ (ϵ 13,500).

Anal.—Calcd. for $\text{C}_{13}\text{H}_{16}\text{O}_2$: C, 76.44; H, 7.90. Found: C, 76.50; H, 7.99.

Finally, elution gave XIII which was recrystallized from acetone-hexane, m.p. $143-145^{\circ}$ (108 mg.), λ_{max} 228 $\text{m}\mu$ (ϵ 12,300); 279 $\text{m}\mu$ (ϵ 14,200).

Anal.—Calcd. for $\text{C}_{12}\text{H}_{14}\text{O}_2$: C, 75.76; H, 7.42. Found: C, 75.73; H, 7.52.

Intermediate fractions contained 800 mg. of an unresolved mixture of XI and XII.

Ethyl (4,4-Dimethyl-2-ethyl-1-tetralon-6-yl)oxyacetate (XIV)—A mixture containing XI (1.73 g.), potassium carbonate (1.22 g.), and ethyl bromoacetate (1.47 g.) in 20 ml. of acetone was refluxed with stirring for 3 hr. The reaction mixture was diluted with water, rendered alkaline with 2.5 *N* NaOH, and extracted with ether. The extract was washed with water, dried, and evaporated to give XIV (2.5 g.) as a pale-yellow oil.

(4,4-Dimethyl-2-ethyl-1-[4H]-naphthalenon-6-yl)oxyacetic Acid (III)—To a stirred solution of XIV (2.3 g.) in 35 ml. of chloroform was added a solution of bromine (1.36 g.) in 10 ml. of chloroform over 1.5 hr. at room temperature. After 1 hr. the solution was evaporated to give the crude bromoester XV as an orange oil. This material was dissolved in 300 ml. of methanol containing potassium hydroxide (1.67 g.) and allowed to stand in the dark for 120 hr. The bulk of the methanol was evaporated and the residue was treated with water. Acidification in the cold with 4 *N* HCl and extraction with ether gave a solution of the free acid which was washed with water and dried. Evaporation and recrystallization of the residue from methanol-water gave white crystals of III (1.60 g.), m.p. $149-151^{\circ}$. Another recrystallization gave the analytical sample, m.p. $150-152^{\circ}$, λ_{max} 238 $\text{m}\mu$ (ϵ 12,100); 298 $\text{m}\mu$ (ϵ 10,300).

Anal.—Calcd. for $\text{C}_{16}\text{H}_{18}\text{O}_4$: C, 70.06; H, 6.61. Found: C, 69.80; H, 6.50.

Preparation and Anticancer Activity of 2-Diethylaminoethyl-*cis*- and -*trans*-methylcyclohexanecarboxylates

ROBERT E. HARMON, PAUL A. MEULMAN, and S. K. GUPTA

Abstract □ Pure *cis*- and *trans*-methylcyclohexanecarboxylic acids and their 2-diethylaminoethyl esters have been prepared. The latter were isolated as crystalline hydrochloride salts. They were tested for possible anticancer activity.

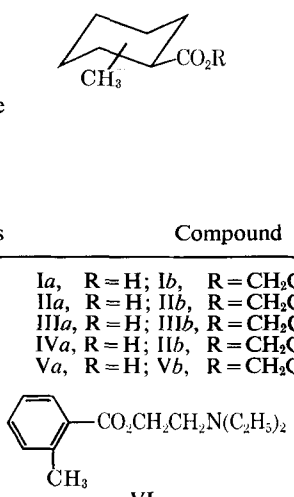

Keyphrases □ *cis*-, *trans*-Methylcyclohexanecarboxylic acids—synthesis □ 2-Diethylaminoethyl-*cis*-, *trans*-methylcyclohexanecarboxylic esters—synthesis, anticancer activity □ Pharmacological screening—2-diethylaminoethyl-*cis*-, *trans*-methylcyclohexanecarboxylic esters

Numerous carboxylic acid esters of tertiary amino alcohols have shown significant pharmacological activity. For instance, the esters of sterically hindered alkyl-substituted benzoic acids have shown anesthetic action (1–5). Similarly, the local anesthetic action of 2-diethylaminoethyl ester hydrochlorides of 1-phenyl and 1-cyclohexanecarboxylic acids is comparable to that of cocaine (6). Investigations of 2-dialkylaminoethyl ester hydrochlorides of various 1-methyl-3-alkyl-cyclohexanecarboxylic acids revealed that these compounds were effective cardiovascular depressants (7). In this paper, the authors report the preparation and anticancer activity of 2-diethylaminoethyl-*cis*- and -*trans*-methylcyclohexanecarboxylate hydrochlorides.

The *cis*- and *trans*-methylcyclohexanecarboxylic acids (Ia–Va) and their 2-diethylaminoethyl esters (Ib–Vb), prepared for this investigation, are given in Table I. The three *cis*-methylcyclohexanecarboxylic acids (Ia, IIIa, and IVa) were prepared by the catalytic hydrogenation of the corresponding toluic acids (8, 9). *trans*-2-Methylcyclohexanecarboxylic acid (IIa) was prepared by heating crotonic acid with 1,3-butadiene in a sealed tube at 175° (10). *trans*-4-Methylcyclohexanecarboxylic

acid (Va) was prepared by heating the corresponding *cis*-isomer IVa in the presence of anhydrous hydrogen chloride (11). However, all attempts to prepare pure *trans*-3-methylcyclohexanecarboxylic acid failed because these procedures gave mixtures of *cis*- and *trans*-isomers which were very difficult to separate. The purity of the acids Ia–Va was established by comparison of boiling points, refractive indexes, and IR spectra with the literature values. The 2-diethylaminoethyl esters of the acids IIa–Va were prepared by the method of Rabjohn (12). This involved heating the potassium salt of the carboxylic acid with 2-chlorotriethylamine in toluene. All attempts to esterify the *cis*-2-methylcyclohexanecarboxylic acid (Ia) by this method were unsuccessful. Therefore, the acid Ia was first converted into 2-diethylamino-*o*-toluate (VI). The latter, on catalytic hydrogenation using Adam's catalyst, afforded the 2-diethylaminoethyl-*cis*-2-methylcyclohexanecarboxylate (Ib). However, all these 2-diethylaminoethyl esters (Ib–Vb) were obtained only as oils. Therefore, they were converted into crystalline hydrochloride salts by treating the free esters with hydrogen chloride gas. The hydrochloride salts were characterized by satisfactory elemental analyses and IR and NMR spectroscopy.

ANTICANCER ACTIVITY

All the 2-diethylaminoethyl-methylcyclohexanecarboxylates described in this paper were evaluated in the routine mouse tumor

screening of the Cancer Chemotherapy National Service Center, Bethesda, Md. (13). The results are mentioned in Table II. None of the compounds prepared in this investigation showed confirmed anticancer activity. Hence, no correlation could be drawn between an equatorial–equatorial or an axial–equatorial arrangement of the methyl and the diethylaminoethoxycarbonyl groups on the cyclohexane ring of a compound and the anticancer activity of that compound.

EXPERIMENTAL

The melting points were determined with a Thomas-Hoover Unimelt apparatus and are uncorrected. Microanalyses were performed by Galbraith Laboratories Inc., Knoxville, Tenn. The IR spectra were recorded on a Beckman IR-8 spectrophotometer. The NMR spectra were obtained with a Varian A-60 spectrometer.

Preparation of Methylcyclohexanecarboxylic Acids Ia–Va—*cis*-2-Methylcyclohexanecarboxylic acid (Ia) was prepared by catalytic hydrogenation of *o*-toluic acid by the procedure of MacBeth *et al.* (9) and Cope *et al.* (8). It had b.p. 130–130.5° (10 mm.), *n*_D²⁵ 1.4631 [lit. (9) b.p. 119° (11 mm.), *n*_D²⁵ 1.4644].

trans-2-Methylcyclohexanecarboxylic acid (IIa) was prepared by heating crotonic acid with 1,3-butadiene in a pressure vessel by the procedure of Diels and Alder (10). It had m.p. 51–52.5° [lit. (14) m.p. 52°].

cis-3-Methylcyclohexanecarboxylic acid (IIIa) was prepared by the catalytic hydrogenation of *m*-toluic acid by the procedure of Darling *et al.* (15). It had b.p. 98–99° (1.3–1.8 mm.), *n*_D²⁵ 1.4561 [lit. (15) b.p. 98–99° (1.2 mm.), *n*_D²⁵ 1.4570].

cis-4-Methylcyclohexanecarboxylic acid (IVa) was prepared by the hydrogenation of *p*-toluic acid by the procedure of Delephine and Badoche (11). It had b.p. 96.5–98° (1.25–1.70 mm.), *n*_D²⁵ 1.4581 [lit. (11) b.p. 128–130° (13 mm.), *n*_D²⁵ 1.4605].

trans-4-Methylcyclohexanecarboxylic acid (Va) was prepared by heating IVa in the presence of hydrogen chloride gas by the procedure of Delephine and Badoche (11). It had m.p. 108–110° [lit. (11) m.p. 111°].

Preparation of 2-Diethylaminoethyl Esters—2-Diethylaminoethyl-*cis*-2-methylcyclohexanecarboxylate (Ib)—To a solution of *o*-toluoyl chloride (23.8 g., 0.153 mole) in anhydrous ether (50 ml.) was added in small portions, with shaking and cooling, freshly distilled 2-diethylaminoethanol (0.380 mole). The reaction mixture was allowed to stand at room temperature overnight. A saturated solution of sodium carbonate (100 ml.) and ether (50 ml.) was added to the solution. The ether layer was separated and the aqueous layer extracted with ether twice. The combined ether extracts were washed with water, dried (Na₂SO₄), and evaporated to yield an oil. Fractional distillation of the oil afforded 31.0 g. (75%) of 2-diethylaminoethyl-*o*-toluate (VI) as a colorless oil, b.p. 133–135.5° (1.9–2.1 mm.), *n*_D²⁵ 1.5021. A solution of VI (9.8 g., 0.042 mole) in glacial acetic acid (60 ml.) was mixed with platinum oxide (0.31 g.) and hydrogenated at 60 p.s.i. pressure of hydrogen gas. The temperature was maintained at 90° for 5 hr. and at room temperature for 16 hr. The catalyst was removed by filtration and the filtrate evaporated under reduced pressure (100 mm.) to get rid of all the acetic acid. Fractional distillation of the residual oil afforded 7.0 g. (70%) of 2-diethylaminoethyl-*cis*-2-methylcyclohexanecarboxylate (Ib) as a colorless oil, b.p. 116–118° (1 mm.), *n*_D²⁵ 1.4601.

For the sake of characterization, a small amount of Ib was converted into its crystalline hydrochloride salt by adding dropwise

an ethereal solution of hydrogen chloride to an ethereal solution of Ib until the solution became acidic. The precipitated hydrochloride salt was filtered and recrystallized from absolute ethanol–ether. It had m.p. 120–120.5°.

General Procedure for the Preparation of Esters IIb–Vb—Esterification of the methylcyclohexanecarboxylates IIa–Va was carried out by the method of Rabjohn (12). This procedure involved heating the potassium salt of the carboxylic acid with 2-chlorotriethylamine hydrochloride in toluene during 25–30 hr. Filtration (to remove the precipitated KCl), removal of toluene by evaporation under reduced pressure, and fractional distillation afforded the esters IIb–Vb in 70–90% yields. The boiling points, refractive indexes, and yields of the esters IIb–Vb are given in Table III. All the esters were converted into crystalline hydrochloride salts by bubbling anhydrous hydrogen chloride gas into an ethereal solution of the ester until the solution turned acidic. The precipitated hydrochloride salts were filtered and recrystallized from absolute ethanol–ether. The melting points and analyses are also given in Table III.

Absorption of Clindamycin from the Buccal Cavity

MILDRED J. TARASZKA

Abstract □ Clindamycin, which is known to be absorbed from the gastrointestinal tract, was absorbed extremely slowly, or possibly not at all, from the buccal cavity at various pH values. This finding indicates that buccal absorption alone cannot be used to predict the gastrointestinal absorption of a compound.

Keyphrases □ Clindamycin—buccal absorption □ Drug absorption, buccal—clindamycin □ GLC—analysis

Recently, several investigators (1–3) have proposed the method of buccal absorption as an example of an *in vivo* model of drug partitioning into, or passive drug transfer through, a lipid membrane. They also proposed the buccal absorption test for predicting the relative absorption and excretion of compounds in biological systems. Since clindamycin (I)¹ is well absorbed from the human gastrointestinal tract (4–6), it was of interest to determine the pH profile for buccal absorption of clindamycin. Clindamycin is an antibiotic which is synthetically derived from lincomycin (7, 8).

EXPERIMENTAL

Absorption Studies—The buccal absorption procedure was essentially the same as that used by Beckett and Triggs (1). The subjects were instructed to hold 25 ml. of buffer containing 1 mg. of the base form of the compound in their mouths for a given time interval. During this interval they kept the solution in constant movement with tongue-and-cheek action. At the end of the time interval, the solution was expelled into a 60-ml. Teflon-stoppered, separatory funnel. Immediately the mouth was given a 10-sec. rinse with 10 ml. of deionized water. The water rinse was combined with the previously expelled solution. The amount of compound unabsorbed was measured by extraction and GLC.

Standards were prepared by having the subjects hold plain buffer in their mouths. Various amounts of compound were then added to the expelled solution in the separatory funnels and used as standards.

To ensure that the buccal-absorption methodology was in agreement with that used in the literature, a 1-mg. sample of benzphetamine base in 25 ml. of pH 8.5 phosphate buffer was tested. In two separate experiments, 76 and 79% of the benzphetamine samples were buccally absorbed in 5 min.; these results are in agreement with the data presented by Beckett and Triggs (1).

Assay for Clindamycin—The pH of the buffer solution in the separatory funnel was adjusted to pH 11 with NaOH, and 2 ml. of a water-saturated chloroform solution containing 0.3 mg./ml. of

Table I—Standard Samples

Weight of Clindamycin, mg.	Peak Area Ratio Clindamycin—Internal Standard
1.0	1.080
0.9	0.898
0.6	0.606
0.4	0.395
0.2	0.224
0.1	0.092

cholesteryl acetate as an internal standard was added. The separatory funnel was shaken vigorously for 1.5 min., and the cloudy chloroform layer collected in a centrifuge tube. The tubes were centrifuged at 10° for 10–15 min. at 12,000 r.p.m. to break the suspension. Approximately 1 ml. of the chloroform layer was transferred to a 2-ml. volumetric flask and evaporated to dryness under a dry stream of air. Then 0.4 ml. of hexamethyldisilazane was added and the flask was shaken to dissolve the residue. One-tenth milliliter of trifluoroacetic acid was added, and the flask was allowed to stand for 1 hr. for complete reaction. Gas chromatography of clindamycin *tris*-trimethylsilyl ether was carried out using glass columns 50.80 cm. × 1.27 mm. (20 in. × 0.5 in.) packed with Gas Chrom Q, 80–100 mesh, and coated with 1% OV-1. The oven temperature was 210° and the carrier gas (He) flow was 60 ml./min.

Assay for Benzphetamine—The assay for benzphetamine is similar to that for clindamycin, except 3 ml. of chloroform solution containing 0.75 µl. nicotine as an internal standard was added to the separatory funnel. The collected chloroform layer was gas chromatographed using glass columns packed with Diaport S, 60–80 mesh, and coated with 6% LAC-728. The oven temperature was 180° and the carrier gas (He) flow was 50 ml./min.

Ionization Constant for Clindamycin—Twenty-milliliter samples of clindamycin (1.5×10^{-3} M) were titrated with 0.1 M KOH in a radiometer type SBR2/SBU1 titrator. A pKa of 7.72 ± 0.04 ($\bar{X} \pm \sigma$) was evaluated from the continuously recorded titration curves at 25°.

RESULTS AND DISCUSSION

A typical gas chromatogram of clindamycin from buffered saliva solutions is shown in Fig. 1. An impurity extracted from saliva is present (Peak 4 in Fig. 1) but does not interfere with the assay. The 4'-ethyl analog of lincomycin (Peak 2 in Fig. 1) is an antibiotic produced at about the 3% level in the microbiological synthesis of lincomycin (9). Since clindamycin is synthesized from lincomycin, the 4'-ethyl analog of clindamycin was present in small amounts in the clindamycin samples. The total area under Peaks 1, 2, and 3

Figure 1—Typical gas chromatogram of a silylated clindamycin buccal solution. Key: Peak 1, column-thermal degradation product of clindamycin; Peak 2, 4'-ethyl analog of clindamycin; Peak 3, clindamycin; Peak 4, saliva impurity; and Peak 5, internal standard cholesteryl acetate.

^a pH at end of absorption experiment.

was used to calculate clindamycin in the assay. Table I gives the peak area ratios of clindamycin-internal standard for various known amounts of clindamycin and is typical of the GLC quantitation.

The results of buccal absorption of clindamycin for two subjects are presented in Table II. One milligram of clindamycin base per 25 ml. solution was used for each experiment. Within experimental error, no clindamycin was absorbed buccally in 5 min. at pH 4, 7.5, or 8.5. A small amount of clindamycin may have been absorbed after 15 min. at pH 8.5, or this indicated absorption may have been due to the swallowing of a portion of the solution during the longer time interval. In contrast to the poor buccal absorption, clindamycin is well absorbed from the gastrointestinal tract (4-6).

The data of Bickel and Weder (3) indicated that at pH 7.4 the buccal absorption of imipramine and similar compounds could be related to lipid solubility as measured by partition values. At this pH, imipramine with an apparent partition coefficient (diethylether-water) of 140 was absorbed to the extent of approximately 60%. The true partition coefficient,² *k*, for clindamycin between diethylether and water is 9.8 at 25° (10). The apparent partition

² The true partition coefficient, *k*, equals the concentration of unionized species in the organic phase per the concentration of the unionized species in the aqueous phase.

coefficient of clindamycin at pH 7.4 was calculated (11) to be 3 from the above *k* and the p*K*_a. This indicates that the lower lipid solubility of clindamycin relative to imipramine could partially account for the poor buccal absorption of clindamycin. However, it does not explain the difference between the poor buccal absorption and the excellent gastrointestinal absorption of clindamycin. This difference in absorption may be due to the differences in surface area, transport mechanisms, and/or mucous membrane pH between the buccal cavity and the gastrointestinal tract.

Effect of Polysorbate 80 and Oleic Acid on Drug Absorption from the Rat Intestine

GERHARD LEVY and AINO PERÄLÄ*

Abstract □ Low concentrations of polysorbate 80 and oleic acid, which enhance drug absorption across the external membranes of goldfish, have no apparent effect on the absorption of salicylate, salicylamide, and 4-aminoantipyrine from the *in situ* rat small intestine.

Keyphrases □ Polysorbate 80, oleic acid—drug absorption rate, effects, rat intestine □ Absorption rate, rat intestine—polysorbate 80, oleic acid, effects □ Drugs, absorption—polysorbate 80, oleic acid, effects, rat intestine □ Oleic acid, polysorbate 80—drug absorption rate, rat intestine, effects

Polysorbate 80 and oleic acid enhance the rate of drug absorption by goldfish immersed in drug solutions containing low concentrations of one of these substances (1-4). The purpose of this study was to determine if

polysorbate 80 and oleic acid can also increase the absorption rate of certain drugs from the small intestine of the rat.

EXPERIMENTAL

Drug absorption was studied by the *in situ* rat gut technique of Doluisio *et al.* (5) with the following modifications: (a) Sprague-Dawley rats (weighing approximately 220 g.) were anesthetized with 1.5 mg. urethan/g. body weight (rather than 1 mg./g.); (b) the animals were hydrated immediately after urethan administration by an intraperitoneal injection of 5 ml. normal saline solution; (c) the gut was first rinsed with the perfusion solution (5) and then with the drug solution; and (d) 7 ml. (rather than 10 ml.) of the drug solution was placed in the intestine for the absorption experiment.

The drug solutions contained 200 or 400 mg.% salicylic acid, 150 or 300 mg.% salicylamide, or 50 or 100 mg.% 4-aminoantipyrine in Sorensen's buffer of pH 6.0. Solutions containing the low concentra-

tions of drug and 0.03% polysorbate 80 or 0.1% oleic acid were also prepared. The concentrations of salicylic acid and salicylamide were determined in suitably diluted and acidified samples by the method of Trinder (6). The concentration of 4-aminoantipyrine was determined by the method of Brun (7), as modified by Levy and Miller (8).

RESULTS AND DISCUSSION

The results of the absorption experiments are summarized in Table I. In agreement with Doluisio *et al.* (5), it was found that the concentration of salicylic acid in the intestinal solution decreased exponentially for at least two half-lives. The absorption half-life of salicylic acid was 8–9 min. in this study, compared to 8 min. reported by Doluisio *et al.* Contrary to the observations of those workers, the authors of this study noted considerable ($\approx 50\%$) net absorption of water, which was reduced somewhat by hydrating the animals and reducing the volume of the solution in the intestine from 10 to 7 ml.¹

The absorption of salicylamide from the rat intestine was somewhat slower than that of salicylate (even though the former was essentially nonionized while the latter was almost fully ionized), and the absorption of 4-aminoantipyrine was even slower. Polysorbate 80 and oleic acid had no apparent effect on the absorption of these three drugs, on water absorption, and on the gross appearance of the small intestine. The concentration of oleic acid used in this study was slightly in excess of solubility in order to maintain a reasonably constant concentration during the experiment.

The lack of effect of polysorbate 80 and oleic acid on drug absorption from the small intestine of the rat is in contrast to the pronounced absorption-enhancing effect of similar low concentrations of these substances in goldfish (1–4). The absorption and ex-

sorption rate constants of 4-aminoantipyrine in goldfish are increased almost twofold by 0.01% polysorbate 80 (3). The absorption of barbiturates by goldfish is enhanced appreciably by polysorbate 80 and oleic acid in low concentrations (1, 2, 4). However, while the external membranes of goldfish and the rat intestine have the characteristics of a lipid barrier and yield qualitatively similar (*i.e.*, the same rank order) results in their respective permeability to a series of drugs with different lipid–water partition coefficients (9), the two types of membranes do differ in their response to certain additives. Thus, the goldfish membranes are exquisitely sensitive to such substances as sodium lauryl sulfate and salicylic acid (unpublished observations), and become more permeable when exposed to polysorbate 80 and certain other surface-active substances (1–4). On the other hand, the *in situ* rat small intestine appears to be much more resistant to these substances.

ACKNOWLEDGMENTS AND ADDRESSES

Received December 22, 1969, from the Department of Pharmaceutics, School of Pharmacy, State University of New York at Buffalo, Buffalo, NY 14214

Accepted for publication January 19, 1970.

* Present address: School of Pharmacy, University of Helsinki, Finland.

¹ In more recent studies in this laboratory, the volume of intestinal solution is maintained essentially constant by adding drug-free solvent at each sampling time. Absorption rate constants obtained under these conditions are somewhat smaller than the rate constants obtained by the method used in this study.

New Compounds: Potential Antidiabetics IV: 1-(2,4-Dinitrophenyl)-3,5-diphenyl- 4-arylazopyrazoles and 1-Carbamoyl- 3,5-diphenyl-4-arylazopyrazoles

H. G. GARG and PREM PAL SINGH

Abstract □ A series of 1-(2,4-dinitrophenyl)-3,5-diphenyl-4-arylazopyrazoles and 1-carbamoyl-3,5-diphenyl-4-arylazopyrazoles have been synthesised by the condensation of the corresponding 1,3-diphenyl-2-arylhydrazono-1,2,3-propanetriones with 2,4-dinitrophenylhydrazine and semicarbazide hydrochloride, respectively.

Keyphrases □ Antidiabetics—synthesis, pyrazoles, isoxazoles □ 1-(2,4-Dinitrophenyl)-3,5-diphenyl-4-arylazopyrazoles—synthesis, potential hypoglycemics □ 1-Carbamoyl-3,5-diphenyl-4-arylazopyrazoles—synthesis, potential hypoglycemics

Numerous derivatives of pyrazoles and isoxazoles have been prepared for testing their antidiabetic activity (1–4). The compounds 1-phenyl-3-methyl-4-arylhydrazono-2-pyrazolin-5-ones have shown encouraging antidiabetic activity in experimental animals (5). To examine their hypoglycemic activity, a series of 1-(2,4-dinitrophenyl)-3,5-diphenyl-4-arylazopyrazoles and 1-carbamoyl-3,5-diphenyl-4-arylazopyrazoles have been prepared and are reported in the present communication.

R = substituted phenyl
DNP = 2,4-dinitrophenyl

Scheme I

Precursors 1,3-diphenyl-2-arylhydrazono-1,2,3-propanetriones (I) were obtained by coupling diazotized anilines with 1,3-diphenyl-1,3-propanedione (4). 2,4-Dinitrophenylhydrazine and semicarbazide hydrochloride

ACKNOWLEDGMENTS AND ADDRESSES

Received November 6, 1969, from the *Department of Chemistry, University of Roorkee, Roorkee, India*.

Accepted for publication January 13, 1970.

The authors thank Dr. Maxwell Gordon, Smith Kline & French Laboratories, Philadelphia, Pa.; Prof. W. U. Malik, Head of Chemistry Department, for providing the necessary facilities for work; and the C.S.I.R., New Delhi for the award of a Junior Research Fellowship (to P.P.S.)

Effect of Mesenteric Blood Flow on Intestinal Drug Absorption

Keyphrases □ Drug absorption, intestinal—mesenteric blood flow effect □ Mesenteric blood flow—drug absorption □ Sulfaethidole half-life—mesenteric blood flow

Sir:

A previously published report from our laboratory indicated that drug absorption rates in rats slowed for several drugs when the animals were fasted for periods beyond 20 hr. (1). These results suggested that some non-specific phenomenon was occurring during prolonged fasting which affected absorption rates about equally for each drug. Although a multitude of physiological and biochemical changes are known to occur during fasting (1), particular interest is the possibility that intestinal blood flow decreases during periods of inanition. In our previous studies, subjective observation of rat intestine, following prolonged periods of fasting, supported the view that the decreased drug absorption rate was, at least in part, the consequence of reduced intestinal blood perfusion. In the absence of prolonged fasting, the color of the intestines was reddish pink;

but after prolonged fasting, the intestines became blanched.

The possibility that the unusual drug absorption pattern, which was encountered in fasted animals, was the result of an alteration in intestinal blood perfusion led us to investigate the effects of changes in intestinal blood flow on the kinetics of drug absorption. Three mongrel dogs (8–19 kg.) were anesthetized with allobarbitol-urethane, and the small intestine was exposed by midline laparotomy. A segment of the jejunum was cannulated, and approximately 12 luminal samples were withdrawn over a 40-min. period using a double-syringe method for absorption determination (2). The cranial mesenteric artery was exposed from its origin at the aorta to the first branch, a blood flow probe was implanted on the artery, and blood flow was measured by means of an electromagnetic flowmeter (Medicon). Carotid arterial blood pressure, measured by means of a pressure transducer (E & M Linear Core), and cranial mesenteric blood flow were recorded simultaneously on a direct-writing polygraph. Intestinal solutions were buffered at pH 6.0 and warmed to 37° (2).

Initially, serial luminal samples were collected from animals with intestinal blood flow unaltered. The blood supply to the intestines was then gradually diminished by means of a hydraulic occluder located immediately distal to the flow probe. In this way, we determined the effect of reducing the rate of volume flow to approximately 65, 30, and 0% of control values on the absorption profile of sulfaethidole. Sulfaethidole concentrations were determined by the method of Bratton and Marshall (3).

Figure 1 shows the results of a typical experiment using the *in situ* dog intestinal preparation, in which the rate of disappearance of sulfaethidole from the jejunum was followed at several intestinal blood flow rates. Each line represents a separate gut segment, but all four determinations are from the same dog. Half-lives of 17, 37, 56, and 134 (approx.) min. were found for 100, 64, 26 and 0% of control blood flow rate, respectively. In these experiments, the absorption

process obeyed apparent first-order kinetics. The results obtained from three animals are shown in Table I.

Preliminary experimentation indicated that half-lives obtained from different jejunal segments in the same dog did not vary from one another by more than 15%. These results are thus suggestive of a meaningful relationship between intestinal blood perfusion and drug absorption rate. In most instances, a 40–60% reduction in mesenteric blood flow resulted in a dramatic increase in the absorption half-life for sulfaethiodole.

Mesenteric circulation is subject to alteration from a wide variety of sources, and some of these will be examined and discussed in a future publication. However, it is obvious that adequate precautions should be taken to assure that significant differences in intestinal blood perfusion rates do not exist among the different animals used in a particular absorption study. Unless such precautions are taken, comparisons of the drug absorption data obtained from the various animals should be viewed with a degree of caution.

Although the data reported herein do confirm that the intestinal drug absorption process is hindered by a decrease in vascular perfusion, additional studies must be designed to quantitate the effects of fasting on intestinal blood flow before ascribing a causative role to this factor in our previous experiments.

Spectrophotometric Analysis of Acetylcholine Levels in Plasma

Keyphrases ☐ Acetylcholine levels, plasma—determination ☐
Plasma—acetylcholine determination ☐ Colorimetric analysis—
spectrophotometer

Sir:

The interest in determining acetylcholine levels in biological media before and after angiotensin-II administration parenterally in turtles led to the search for an acceptable method of analysis. The bioassay of

isolated guinea pig ileum contractions against known acetylcholine concentrations was initially considered (1), but the sensitivity of the test was proven unacceptable. The bromocresol purple method of Woods (2) and the methyl orange method of Brodie (3, 4) are general methods for determining organic bases and are limited in their usefulness for biological media, which normally contain interfering organic bases.

The bromophenol blue method of Auerbach (5), modified by Mitchell and Clark (6), was chosen because it bypassed this difficulty of interfering bases and increased the sensitivity of the test 10-fold.

The interaction involves the formation of a color complex between anionic bromophenol blue and the quaternary cation, acetylcholine. The reaction occurs in an alkaline medium with the resulting color complex formed being quantitatively extracted, utilizing organic solvents. The advantage of this method is that organic bases and unreacted dye do not interfere with the extraction. Auerbach (5) also has tested 50 tertiary amines with negative results.

Procedure—Three map turtles heparinized with 100 USP units were utilized for the analysis. Each turtle was treated with 20 mg./kg. of physostigmine salicylate 5 min. prior to withdrawal of the blood sample. One milliliter of blood was removed from each turtle and added to 0.5 ml. of a 0.5% physostigmine solution. The resulting mixture was centrifuged for 15 min. at 2000 r.p.m., and a 0.5-ml. plasma sample was used for analysis. Following the addition of a buffer (0.3 g. of K_2HPO_4 and 0.3 g. of Na_2CO_3) to pH 9, the indicator, bromophenol blue, was added in a 0.5-ml. volume (0.08% in 30% K_2HPO_4). Fifteen minutes of shaking with organic solvents (washed ethylene dichloride and 4% isoamyl alcohol) completed the extraction of the dye-acetylcholine complex. The organic phase was read at 600 $m\mu$ against an ethylene dichloride-isoamyl alcohol blank because none of the other reagents absorbs. It is mandatory that the analysis take place within a 1-hr. time span because of the rapid fading of the indicator after this period. All absorbances were read on the Coleman (Hitachi 124) double-beam spectrophotometer. The procedure was then repeated following angiotensin-II administration. The differences in absorbance are due to increased acetylcholine levels. This was again repeated, using turtles with both vagi surgically severed. In the turtles with intact vagi, the following values were read: plasma sample plus physostigmine, 0.040, 0.055, and 0.043—mean = 0.046 ± 0.008 SD; plasma sample plus physostigmine after administration of angiotensin, 0.395, 0.410, and 0.380—mean = 0.395 ± 0.014 SD. The difference in absorbance, 0.349 $m\mu$, is attributed to increased acetylcholine blood levels and corresponds to a concentration of 9.1 mcg./0.5 ml. on the standard curve. When this was repeated in vagotomized turtles, the following values for absorbance were read: plasma sample plus physostigmine, 0.050, 0.040, and 0.045—mean = 0.045 ± 0.004 SD; plasma sample plus physostigmine in angiotensin-treated turtles, 0.290, 0.285, and 0.305—mean = 0.293 ± 0.010 SD. The difference in absorbance between the two means, 0.248 $m\mu$, is attributed to increased acetylcholine blood levels and corresponds to

Spectrophotometric Analysis of Acetylcholine Levels in Plasma

Keyphrases ☐ Acetylcholine levels, plasma—determination ☐
Plasma—acetylcholine determination ☐ Colorimetric analysis—
spectrophotometer

Sir:

The interest in determining acetylcholine levels in biological media before and after angiotensin-II administration parenterally in turtles led to the search for an acceptable method of analysis. The bioassay of

isolated guinea pig ileum contractions against known acetylcholine concentrations was initially considered (1), but the sensitivity of the test was proven unacceptable. The bromocresol purple method of Woods (2) and the methyl orange method of Brodie (3, 4) are general methods for determining organic bases and are limited in their usefulness for biological media, which normally contain interfering organic bases.

The bromophenol blue method of Auerbach (5), modified by Mitchell and Clark (6), was chosen because it bypassed this difficulty of interfering bases and increased the sensitivity of the test 10-fold.

The interaction involves the formation of a color complex between anionic bromophenol blue and the quaternary cation, acetylcholine. The reaction occurs in an alkaline medium with the resulting color complex formed being quantitatively extracted, utilizing organic solvents. The advantage of this method is that organic bases and unreacted dye do not interfere with the extraction. Auerbach (5) also has tested 50 tertiary amines with negative results.

Procedure—Three map turtles heparinized with 100 USP units were utilized for the analysis. Each turtle was treated with 20 mg./kg. of physostigmine salicylate 5 min. prior to withdrawal of the blood sample. One milliliter of blood was removed from each turtle and added to 0.5 ml. of a 0.5% physostigmine solution. The resulting mixture was centrifuged for 15 min. at 2000 r.p.m., and a 0.5-ml. plasma sample was used for analysis. Following the addition of a buffer (0.3 g. of K_2HPO_4 and 0.3 g. of Na_2CO_3) to pH 9, the indicator, bromophenol blue, was added in a 0.5-ml. volume (0.08% in 30% K_2HPO_4). Fifteen minutes of shaking with organic solvents (washed ethylene dichloride and 4% isoamyl alcohol) completed the extraction of the dye-acetylcholine complex. The organic phase was read at 600 m μ against an ethylene dichloride-isoamyl alcohol blank because none of the other reagents absorbs. It is mandatory that the analysis take place within a 1-hr. time span because of the rapid fading of the indicator after this period. All absorbances were read on the Coleman (Hitachi 124) double-beam spectrophotometer. The procedure was then repeated following angiotensin-II administration. The differences in absorbance are due to increased acetylcholine levels. This was again repeated, using turtles with both vagi surgically severed. In the turtles with intact vagi, the following values were read: plasma sample plus physostigmine, 0.040, 0.055, and 0.043—mean = 0.046 ± 0.008 SD; plasma sample plus physostigmine after administration of angiotensin, 0.395, 0.410, and 0.380—mean = 0.395 ± 0.014 SD. The difference in absorbance, 0.349 m μ , is attributed to increased acetylcholine blood levels and corresponds to a concentration of 9.1 mcg./0.5 ml. on the standard curve. When this was repeated in vagotomized turtles, the following values for absorbance were read: plasma sample plus physostigmine, 0.050, 0.040, and 0.045—mean = 0.045 ± 0.004 SD; plasma sample plus physostigmine in angiotensin-treated turtles, 0.290, 0.285, and 0.305—mean = 0.293 ± 0.010 SD. The difference in absorbance between the two means, 0.248 m μ , is attributed to increased acetylcholine blood levels and corresponds to

a concentration of 6.0 mcg./0.5 ml. on the standard curve.

Standardization—The experimental values for acetylcholine were standardized against known concentrations of acetylcholine chloride by utilizing a standard curve prepared from the following. A concentration of 20.0 mcg./0.5 ml. gave the following values in three samples: 0.750, 0.760, and 0.769 m μ with a mean of 0.759 m μ ; a concentration of 10.0 mcg./0.5 ml. gave the following values in three samples: 0.335, 0.343, and 0.352 with a mean of 0.343 m μ ; a concentration of 6.6 mcg./0.5 ml. gave the following: 0.230, 0.243, and 0.250 with a mean of 0.241 m μ ; a concentration of 5.0 mcg./0.5 ml. gave the following values: 0.175, 0.187, and 0.199 with a mean of 0.189 m μ ; a concentration of 4.0 mcg./0.5 ml. gave the following values: 0.134, 0.145, and 0.156 with a mean of 0.141 m μ .

The results of this analysis support the hypotheses that angiotensin-II administration causes the release of acetylcholine at neuroeffector sites in the turtle

plasma and that this release is not dependent upon the presence of intact vagus innervation (7).

BOOKS

REVIEWS

Pharmaceutical Enzymes and Their Assay. Edited by R. RUYSEN. Universitaire Pers afd. Uitgeverij van N. V. Universitaire Boekhandel 12. St.-Amandstraat, Ghent, Belgium, 1969. 151 pp. 15.7 \times 24.5 cm. Price \$11.00. (*French and English*)

In 1961, the Fédération Internationale Pharmaceutique created the Commission for the Standardization of Pharmaceutical Enzymes, the primary mission of which was the establishment of uniform international standards for enzymes having pharmaceutical applications.

The lack of uniformity in the methods used to express the catalytic activity of pharmaceutical enzymes prompted the Commission, as its first resolution, to adopt, insofar as is practicable, an international unit system which defines an enzyme unit as that amount which catalyzes the transformation of 1 micromole of substrate per minute (or where more than one bond of a more complex substrate is attacked, one microequivalent of the group concerned per minute) under well-defined, usually external, optimal conditions. Since a unit system of this kind requires that either new methods be developed or existing methods be modified for the assay of virtually

every enzyme, the attention of the Commission has thus far been devoted largely to assay methods and the many problems associated with them.

This book is a hard-cover publication of a symposium held by the Commission at the University of Ghent in May 1968. The selected topics, which are all expertly discussed in this series of seven papers, include: (1) reactions of organofluorophosphate-sensitive enzymes; (2) assay of proteinases; (3) determination of the components of the human plasma fibrinolytic system; (4) action of streptokinase on purified human plasminogen; (5) some aspects of the biochemistry of cellulases and hemicellulases; (6) microbial enzymes and their industrial applications, and (7) assay methods of the F.I.P. Commission on enzymes. Papers 4 and 5, previously mentioned, are written in French; the rest of the book is in English.

The long seventh paper contains an excellent review of the problems encountered and the progress made thus far by the Commission toward its goal. Also discussed are the many requirements which must be met by an assay method if it is to be accepted on an international level. Included herein is a detailed presentation of the Commission's proposed methods of assay for trypsin, chymotrypsin, papain, trypsin-inhibitor, pepsin, pancreatic amylase, pancreatic protease, enterokinase, and pancreatic lipase.

British Medical Bulletin: Control of Human Fertility. Vol. 26, No. 1. Edited by G. I. M. SWYER. Medical Department, The British Council, 97 & 99 Park St., London, England, 1970. i + 97 pp. 22 × 28.5 cm. Price \$6.50.

This issue contains papers on various aspects of human fertility contributed by a rather impressive list of investigators. This compilation takes a multidisciplinary approach with several papers discussing the relative health hazards of various kinds of contraceptive methods.

The papers are, for the most part, written to put the particular topic into a historical context, present the developments and status of the research, and provide some comments on the future directions to be taken. This particular issue should be of interest not only to scientists actively working within this field, but also to those who are interested in a technical state-of-the-art review.

Clinical Toxicology. Second Edition. Edited by C. J. POLSON and R. N. TATTERSALL. J. B. Lippincott Co., Philadelphia, PA 19105, 1969. x + 655 pp. 14.5 × 22.2 cm. Price \$18.50.

The growing interest in toxicology in colleges of pharmacy as well as by pharmacists as a whole will require greater attention being given to texts and references on the subject than presently available. Publication of the second edition of the British text "Clinical Toxicology," offers some help to the teacher and student. As a text for American students it suffers from the inclusion of repeated references to medical-legal rules and interpretations which are quite appropriate for British students but extraneous and perhaps confusing to our students. The authors, however, have made it clear that the book is intended primarily for physicians who are in need of general and specific information on the clinical manifestations, treatment, and prognosis of cases of poisoning. In this respect, it can also be valuable to the pharmacist as a source book of clinical toxicology. The book is extremely easy to read and gets directly to the practical aspects of toxicity of compounds and products. Further interest is generated by including illustrative cases of poisoning which helps orient the reader to the effect of a particular substance ingested by a person. The authors do not try to cram volumes of information on a specific compound but include sufficient information which may be of extreme importance in diagnosing and treating a poisoned patient.

"Clinical Toxicology" is divided into two parts. The first and the shorter portion of the book deals with the general considerations of poisoning while the second, and in essence, the bulk of the book, reviews the individual substances generally as separate short chapters. The book can be recommended for pharmacists and physicians but only as an added source of information. As with most texts on clinical toxicology, information on toxicity of newer

Review of Biochemistry. By NATHAN H. SLOANE and J. LYNDAL YORK. Macmillan Co., 866 Third Ave., New York, NY 10022, 1969. ix + 278 pp. 18 × 26 cm. Price: \$9.95, hardbound; \$6.95, paperbound.

This outline review of biochemistry prepared by Nathan H. Sloane, Professor of Biochemistry, University of Tennessee Medical Units, and J. Lyndal York, Associate Professor of Biochemistry, University of Arkansas School of Medicine, is aimed at presenting modern biochemistry in a concise, practical form covering fundamentals applicable to the health professions.

The authors emphasize in the Preface that this book "... is not a text; rather, it can be used to greatest advantage in conjunction with lecture material and assigned reading in textbooks and periodicals."

The outline form which is used throughout the book allows the reader to scan a great deal of information with minimum effort.

The book surveys biochemical methods and physiochemical principles as well as including chapters on the cell, amino acids and peptides, proteins, and enzymes. Three chapters deal with carbohydrate metabolism and chemistry. The metabolism of lipids, amino acids, and nucleic acids is covered. In the concluding chapters, aspects of genetics, hemoglobin, renal function, and vitamins are among the topics discussed.

Neurophysiological and Behavioral Aspects of Psychotropic Drugs.

Edited by A. G. KARCZMAR and W. P. KOELLA. Charles C Thomas, 301-327 East Lawrence Ave., Springfield, IL 62703, 1969. xviii + 199 pp. 17.5 × 25.5 cm. Price \$12.50.

This book is based on reports developed by several study groups of the American College of Neuropsychopharmacology in 1966. These reports were expanded and updated through 1968 before publication.

The work presented in this volume represents the efforts of two particular groups. The first one studied the biological effects of pharmaceutical agents—neurophysiological aspects, with five chapters being devoted to various aspects of that topic including several papers on LSD responses and behavioral changes.

The other major portion of the book contains the reports of the second group which focused on the effects of drugs on chemistry, learning, and memory.

The editors of this book have attempted to compile information from various disciplines and sources related to this topic into one volume which is relatively specific and current.

British Medical Bulletin: Control of Human Fertility. Vol. 26, No. 1. Edited by G. I. M. SWYER. Medical Department, The British Council, 97 & 99 Park St., London, England, 1970. i + 97 pp. 22 × 28.5 cm. Price \$6.50.

This issue contains papers on various aspects of human fertility contributed by a rather impressive list of investigators. This compilation takes a multidisciplinary approach with several papers discussing the relative health hazards of various kinds of contraceptive methods.

The papers are, for the most part, written to put the particular topic into a historical context, present the developments and status of the research, and provide some comments on the future directions to be taken. This particular issue should be of interest not only to scientists actively working within this field, but also to those who are interested in a technical state-of-the-art review.

Clinical Toxicology. Second Edition. Edited by C. J. POLSON and R. N. TATTERSALL. J. B. Lippincott Co., Philadelphia, PA 19105, 1969. x + 655 pp. 14.5 × 22.2 cm. Price \$18.50.

The growing interest in toxicology in colleges of pharmacy as well as by pharmacists as a whole will require greater attention being given to texts and references on the subject than presently available. Publication of the second edition of the British text "Clinical Toxicology," offers some help to the teacher and student. As a text for American students it suffers from the inclusion of repeated references to medical-legal rules and interpretations which are quite appropriate for British students but extraneous and perhaps confusing to our students. The authors, however, have made it clear that the book is intended primarily for physicians who are in need of general and specific information on the clinical manifestations, treatment, and prognosis of cases of poisoning. In this respect, it can also be valuable to the pharmacist as a source book of clinical toxicology. The book is extremely easy to read and gets directly to the practical aspects of toxicity of compounds and products. Further interest is generated by including illustrative cases of poisoning which helps orient the reader to the effect of a particular substance ingested by a person. The authors do not try to cram volumes of information on a specific compound but include sufficient information which may be of extreme importance in diagnosing and treating a poisoned patient.

"Clinical Toxicology" is divided into two parts. The first and the shorter portion of the book deals with the general considerations of poisoning while the second, and in essence, the bulk of the book, reviews the individual substances generally as separate short chapters. The book can be recommended for pharmacists and physicians but only as an added source of information. As with most texts on clinical toxicology, information on toxicity of newer

Review of Biochemistry. By NATHAN H. SLOANE and J. LYNDAL YORK. Macmillan Co., 866 Third Ave., New York, NY 10022, 1969. ix + 278 pp. 18 × 26 cm. Price: \$9.95, hardbound; \$6.95, paperbound.

This outline review of biochemistry prepared by Nathan H. Sloane, Professor of Biochemistry, University of Tennessee Medical Units, and J. Lyndal York, Associate Professor of Biochemistry, University of Arkansas School of Medicine, is aimed at presenting modern biochemistry in a concise, practical form covering fundamentals applicable to the health professions.

The authors emphasize in the Preface that this book "... is not a text; rather, it can be used to greatest advantage in conjunction with lecture material and assigned reading in textbooks and periodicals."

The outline form which is used throughout the book allows the reader to scan a great deal of information with minimum effort.

The book surveys biochemical methods and physiochemical principles as well as including chapters on the cell, amino acids and peptides, proteins, and enzymes. Three chapters deal with carbohydrate metabolism and chemistry. The metabolism of lipids, amino acids, and nucleic acids is covered. In the concluding chapters, aspects of genetics, hemoglobin, renal function, and vitamins are among the topics discussed.

Neurophysiological and Behavioral Aspects of Psychotropic Drugs.

Edited by A. G. KARCZMAR and W. P. KOELLA. Charles C Thomas, 301-327 East Lawrence Ave., Springfield, IL 62703, 1969. xviii + 199 pp. 17.5 × 25.5 cm. Price \$12.50.

This book is based on reports developed by several study groups of the American College of Neuropsychopharmacology in 1966. These reports were expanded and updated through 1968 before publication.

The work presented in this volume represents the efforts of two particular groups. The first one studied the biological effects of pharmaceutical agents—neurophysiological aspects, with five chapters being devoted to various aspects of that topic including several papers on LSD responses and behavioral changes.

The other major portion of the book contains the reports of the second group which focused on the effects of drugs on chemistry, learning, and memory.

The editors of this book have attempted to compile information from various disciplines and sources related to this topic into one volume which is relatively specific and current.

Staff Review ■

The book is replete with references. Also appended is a list of reference standards (six enzymes and three substrates) available from the Commission.

NEW JOURNALS

Current Index to Conference Papers in Life Sciences. By World Meetings Information Center, Harry Baum, Director. CCM Information Corp., 909 Third Ave., New York, NY 10022, 1969. iv + 188 pp. 17 × 25 cm. Price: Single copy, \$10; Subscription rate, \$90 per year.

This index is one of three recently published; the other two indexing the areas of chemistry and engineering. It is available monthly as a bound copy and weekly on magnetic tape to institutions with computer operated information systems. The index represents an attempt to bring to scientists information presented at professional conferences without waiting one to two years for the proceedings to be published. ■

Emergency Health Services Digest. By U. S. Dept. of Health, Education, and Welfare, Public Health Service, Health Services and Mental Health Administration, Div. of Emergency Health Services, 1969. v + 53 pp. 15 × 23 cm. Price: \$0.40 per issue.

As a planned semiannual journal published by the Department of Health, Education, and Welfare, this journal contains summaries of articles published elsewhere. Its purpose is to bring together from various sources information concerning emergency medical and health care procedures. ■

Journal of Texture Studies. An International Journal of Rheology, Psychorheology, Physical and Sensory Testing of Foods and Pharmaceuticals. Edited by P. SHERMAN and A. S. SZCZESNIAK, D. Reidel Publishing Co., P.O. Box 17, Dordrecht, The Netherlands, 1969. 9 + 129 pp. 16 × 24 cm. Price: Single copy, \$14; Subscription rate, \$45 per year. (*English*)

In the introduction, the editors state that because of the interdisciplinary nature of research in textures of foods and pharmaceuticals, they established this quarterly journal to fill the need of having research papers on texture studies published under one cover. In addition to original research communications, it will also contain abstracts of pertinent papers published elsewhere, book reviews, and notices of meetings. Review articles on different facets of texture studies are also planned. ■

Chemico-Biological Interactions. Edited by G. P. WARWICK, Published by Elsevier Publishing Co., P.O. Box 211, Amsterdam, The Netherlands, 1969. 1 + 126 pp. 18.5 × 26 cm. Price: Subscription rate, Dfl. 90 plus Dfl. 5.40 postage per year. (*English*)

The aim of this bimonthly periodical is to bring together papers concerned with the study of changes brought about by exogenous chemicals in biological systems. An important emphasis will be molecular mechanisms. In addition to research articles, short communications and related review articles will be published. ■

NOTICES

Electrometric Methods. Edited by D. R. BROWNING. McGraw-Hill Book Co., 330 West 42nd St., New York, NY 10036, 1969. viii + 131 pp. 13.5 × 22 cm. Price \$7.50.

One-Dimensional Two-Phase Flow. By GRAHAM B. WALLIS. McGraw-Hill Book Co., 330 West 42nd St., New York, NY 10036, 1969. xxi + 408 pp. 15.5 × 24 cm. Price \$16.50.

Health in a Bottle: Searching for the Drugs That Help. By L. EARLE ARNOW. J. B. Lippincott Co., East Washington Square, Philadelphia, PA 19105, 1970. ix + 272 pp. 14 × 21 cm. Price \$5.95.

Pharmaceutical Abstracts. Vol. X, No. 4. Edited by HENRY M. BURLAGE. College of Pharmacy, University of Texas, Austin, TX 78712, 1969. 21 × 28 cm. Price \$6.00. **FINAL ISSUE.**

Handbook of Experimental Pharmacology. Edited by O. EICHLER, A. FARAH, H. HERKEN, and A. D. WELCH. Springer-Verlag, Heidelberger Platz 3, West Berlin, Germany, 1969. ix + 308 pp. 17 × 25.5 cm. Price \$34.10. (*principally in German*)

Experimental Medicine and Surgery. Edited by WILLIAM J. SOUTHWELL and ISIDORE GREENBERG. Brooklyn Medical Press Inc., New York, NY 11216, 1969. i + 244 pp. 17 × 24.5 cm. Price \$8.00.

Pharmacological Facts and Figures. Vol. 9. By F. LEMBECK and K. F. SEWING. Translated from the German by H. HELLER and D. R. FERGUSON. Springer-Verlag, 175 Fifth Ave., New York, NY 10010, 1969. viii + 111 pp. 23 × 15 cm. Price \$3.00.

NEW JOURNALS

Current Index to Conference Papers in Life Sciences. By World Meetings Information Center, Harry Baum, Director. CCM Information Corp., 909 Third Ave., New York, NY 10022, 1969. iv + 188 pp. 17 × 25 cm. Price: Single copy, \$10; Subscription rate, \$90 per year.

This index is one of three recently published; the other two indexing the areas of chemistry and engineering. It is available monthly as a bound copy and weekly on magnetic tape to institutions with computer operated information systems. The index represents an attempt to bring to scientists information presented at professional conferences without waiting one to two years for the proceedings to be published. ■

Emergency Health Services Digest. By U. S. Dept. of Health, Education, and Welfare, Public Health Service, Health Services and Mental Health Administration, Div. of Emergency Health Services, 1969. v + 53 pp. 15 × 23 cm. Price: \$0.40 per issue.

As a planned semiannual journal published by the Department of Health, Education, and Welfare, this journal contains summaries of articles published elsewhere. Its purpose is to bring together from various sources information concerning emergency medical and health care procedures. ■

Journal of Texture Studies. An International Journal of Rheology, Psychorheology, Physical and Sensory Testing of Foods and Pharmaceuticals. Edited by P. SHERMAN and A. S. SZCZESNIAK, D. Reidel Publishing Co., P.O. Box 17, Dordrecht, The Netherlands, 1969. 9 + 129 pp. 16 × 24 cm. Price: Single copy, \$14; Subscription rate, \$45 per year. (*English*)

In the introduction, the editors state that because of the interdisciplinary nature of research in textures of foods and pharmaceuticals, they established this quarterly journal to fill the need of having research papers on texture studies published under one cover. In addition to original research communications, it will also contain abstracts of pertinent papers published elsewhere, book reviews, and notices of meetings. Review articles on different facets of texture studies are also planned. ■

Chemico-Biological Interactions. Edited by G. P. WARWICK, Published by Elsevier Publishing Co., P.O. Box 211, Amsterdam, The Netherlands, 1969. 1 + 126 pp. 18.5 × 26 cm. Price: Subscription rate, Dfl. 90 plus Dfl. 5.40 postage per year. (*English*)

The aim of this bimonthly periodical is to bring together papers concerned with the study of changes brought about by exogenous chemicals in biological systems. An important emphasis will be molecular mechanisms. In addition to research articles, short communications and related review articles will be published. ■

NOTICES

Electrometric Methods. Edited by D. R. BROWNING. McGraw-Hill Book Co., 330 West 42nd St., New York, NY 10036, 1969. viii + 131 pp. 13.5 × 22 cm. Price \$7.50.

Spectroscopy. Edited by D. R. BROWNING. McGraw-Hill Book Co., 330 West 42nd St., New York, NY 10036, 1970. vii + 183 pp. 13.5 × 22 cm. Price \$8.50.

Chromatography. Edited by D. R. BROWNING. McGraw-Hill Book Co., 330 West 42nd St., New York, NY 10036, 1969. vii + 151 pp. 13.5 × 22 cm. Price \$7.50.

REVIEW ARTICLE

Pharmaceutical Sciences—1969: Literature Review of Pharmaceutics

EMANUEL J. RUSSO and TERRY L. BENNEY

Keyphrases ☐ Pharmaceutical sciences—1969 literature review ☐ Pharmacy, general—dosage forms, stability, technology ☐ Physical aspects—pharmaceutics ☐ Biopharmaceutics—1969 literature review

This review of the literature represents a comprehensive cross section of the research and development efforts in various selected disciplines of the pharmaceutical sciences. It is the eighth annual survey of the series (1–7). To compile it, numerous periodicals and selected sections of *Chemical Abstracts* were abstracted.

The review was prepared with two purposes in mind. Primarily, it was to provide an opportunity of reviewing the research highlights of the past year in the field of pharmaceutical technology. Secondly, it was to supply a convenient source of references for anyone interested in the studies carried out in a specific area. The format was slightly altered from that of previous years; tables were included as a new approach to covering articles of preferred interest in specific areas.

GENERAL PHARMACY

A philosophical review article was published describing the effect of pharmaceutical research on science and society in general (8). Several review articles appeared on governmental control of the pharmaceutical

industry in various countries (9, 10). These included a description of the origin, development, and application of the National Drug Code in the United States, as well as the quality control procedures for sampling, stability, and packaging required for pharmaceutical products in Turkey. The Food and Drug Administration (FDA) outlined its viewpoint on microbiological control of topical and internal preparations where sterility is not a requirement (11). The primary sources of possible contamination were viewed as being the raw materials, water supply, processing operations, equipment and plant facilities, and employees. Microbiological tests on finished products, to be most meaningful, should include tests for *Salmonella*, *Pseudomonas*, and coliforms. Several other interesting papers described the factors responsible for microbiological contamination of cosmetics and proprietaries (12, 13). The authors believed the training of employees and equipment cleanliness to be the most important factors contributing to microbiological contamination. The articles also contained a brief discussion of the numerous known contaminating organisms, and they described methods to control or decrease their levels.

The optimum pH for many commonly used ophthalmic drugs was presented, along with a discussion of preservatives and buffers suitable for use in ophthalmic preparations (14). The use of macromolecules such as methylcellulose and polyvinyl alcohol in preparing artificial tears and lubricants for contact lenses was discussed in detail (15). Clinical tests indicated that these macromolecules are most effective on the corneal epithelium at a concentration of 1.5%. Another paper reported the formulation and method of preparation

Editor's Note: The scope of this article has been limited to a review of the literature in the area of pharmaceutics because reviews of the literature related to other areas of the pharmaceutical sciences are published elsewhere annually.

Table I—References for Some Relatively Nontechnical Discussions Related to Pharmaceuticals

Ref- erence	Topic
18	Review of local anesthetics
19	Review of antihistamines
20	Review of antiepileptic drugs
21	Review of phenothiazine tranquilizers
22	Review of diabetes and hypoglycemic agents
23	Review of antifertility agents
24	Review of over-the-counter (OTC) antacids
25	Review of sleep-aids and other OTC sedatives

of a stable sulfacetamide ophthalmic solution by avoiding heat sterilization or tyndallization during manufacture (16).

The physiology of the nose and the influence of physical and chemical factors on the penetration of medications through the nasal mucosa were outlined (17). The effect of vasoconstrictors, wetting agents, and pH on the duration of drug activity was investigated in guinea pigs.

Other papers of interest in general pharmacy are given in Table I.

Preservatives—The water-solubility and surface-tension-lowering properties of a series of homologous quaternary ammonium compounds were reported to be directly related to their antimicrobial effectiveness (26). Other investigators found no direct relationship between disinfectant effects and other properties of a series of amphoteric surfactants (27). Various alcohols were compared for *in vitro* antimicrobial effectiveness; *n*-propanol was the most effective when used alone, while *n*-butanol, *n*-propanol, and ethanol were very effective when combined (28). Dimethylsulfoxide (DMSO) was shown to inhibit completely the growth of *Escherichia coli*, *Pseudomonas aeruginosa*, and *Bacillus megaterium* when used in concentrations of 15% or greater (29). Polyethylene glycol 300 reduced the viability of certain spores with or without the presence of heat (30). The ability of certain organisms (mainly *Pseudomonas* species) to degrade parabens and limit their bacteriostatic effectiveness was demonstrated (31). The action of surfactants on the effectiveness of a wide variety of preservative agents was reported in several articles (32–35). In most cases, the effectiveness of the preservative was shown to decrease after a certain critical concentration of the surfactant was exceeded. The effectiveness of chlorobutanol, chlorohexidene, phenylmercuric nitrate, and polymyxin B sulfate appeared to decrease in the presence of methylcellulose and carboxymethylcellulose (36). In the presence of the latter gum, only phenylmercuric nitrate retained its bactericidal activity. A combination of phenylmercuric nitrate and phenylethyl alcohol was observed to be more effective in preserving fluorescein solutions against *Pseudomonas* contamination than either of the two agents used alone (37).

Several halogenated naphthol derivatives were tested at different levels in liquid pharmaceutical preparations for effectiveness against 20 different organisms (38). All derivatives were active at levels of 20–50 mcg./ml. against most organisms except *P. aeruginosa*, *Proteus vulgaris*, and *Micrococcus caseolyticus*. The loss of

phenylmercuric nitrate and phenylethyl alcohol from solution due to their adsorption by the dropper attachments of ophthalmic packages was described (39). The rubber, nylon, and plastic components tested in this study appeared to adsorb phenylmercuric nitrate more than phenylethyl alcohol. The effect of the electrical charge of a preservative on its bactericidal effect in atropine solutions was used to explain why cationic quaternary compounds are so much more effective than anionic preservatives (40).

Basic mathematical models were suggested for calculating the concentration of preservatives in the aqueous phase of emulsion systems (41). The total concentration of the preservative, the oil–water partition coefficient, the oil–water ratio, and the concentration of the emulsifier were all shown to affect the concentration of the preservative in the aqueous phase, which is the controlling factor. The use of phenylmercuric salts to preserve cosmetics and other ointments was the topic of several interesting papers (42–44). The sensitivity to various preservatives commonly used in cosmetics was also investigated (45). Less than 2% of contact allergies were caused by sorbic acid, but group reactivities were noted with various quaternary compounds and the parabens.

Other papers of interest on preservatives are described in Table II.

Flavor, Aroma, and Color—The effect of formulation and chemical modification on the flavor, odor, and color of drugs was reviewed by several authors (54, 55). The effect of the viscosity of pharmaceutical syrups on the bitter taste was studied using narcotine as the test drug (56). The results of this experiment, obtained organoleptically, indicated that the more viscous vehicles are better able to mask bitterness. The steric requirement of sweet-tasting compounds or molecules was described, based on the differences in sweetness observed between D- and L-sugars and amino acids (57). It was proposed that these steric requirements must be met at the chemoreceptor site if the compound is to have a sweet taste.

A method was devised for quantifying perfume formulations for use in a computer so that fragrances can be classified and reproduced (58). Two interesting papers described the stability of aldehyde-type fragrances and the effect of stabilizers on perfumes present in soaps (59, 60). The maximum rate of color change of a drug solution occurs when the solution is irradiated with light of a wavelength near that of the absorption peak

Table II—Additional References on Preservatives

Ref- erence	Topic
46	Review of disinfectants
47	Review of disinfectants
48	Test method for measuring disinfectant stability
49	Review of preservatives useful in cosmetics
50	Review of microbiological control of cosmetic products
51	Review of disinfectants used in soaps and detergents
52	Review of preservatives useful in ophthalmic preparations
53	Effect of heat and preservatives on spores of <i>B. stearothermophilus</i>

of the drug being tested (61). The amount of color change was shown to be independent of the volume of the solution and of the concentration of the drug under constant light intensity.

Stability—Changes in the anionic product of water, in polarity of nonaqueous solvents, and in pK were considered to be the three main factors affecting drug stability during antibacterial heat treatment (62). The effect of ultrasonics on the degradation of aspirin and other drugs in mixed solvent systems was investigated (63, 64). These studies indicated that the application of ultrasonic energy to a system undergoing degradation increases the rate of degradation but does not necessarily change the kinetic order of degradation. It was postulated that the rate changes are due to an increased number of molecular collisions as a result of the addition of ultrasonic energy. The effect of light, oxygen, and humidity on the stability of various oils and drug systems was outlined in a series of papers (65–73). Studies on the stability of phenylephrine in aqueous solution indicated that this compound deteriorates more rapidly at an alkaline pH because of the formation of free radicals, followed by chain-type reactions (74). The discoloration of the phenylephrine was found to depend on the pH and the temperature; it is due to the presence of 5-hydroxy-*N*-methylindoxyl formed by oxidative cyclization of the parent compound (75). The racemization of *l*-phenylephrine was shown to occur readily at a pH lower than 2 (76). This racemization is first order with respect to the phenylephrine concentration and is catalyzed by the hydrogen-ion concentration. The decomposition of pilocarpine in aqueous media was shown to occur in a reversible first-order reaction (77, 78). The decomposition is general, acid/base catalyzed, the products showing pH characteristics comparable to those of other lactones. The effects of sterilization and storage on the stability of aqueous solutions of pilocarpine, atropine, and scopolamine also received attention (79). No appreciable decomposition was noted as a result of the storage of solutions that were unbuffered or contained benzoic acid, while almost complete decomposition was noted in solutions containing phosphate buffers. The photolytic decomposition of sulfacetamide was shown to be of zero order and inhibited by the addition of sodium thiosulfate or by lowering the pH and dielectric constant of the vehicle (80).

The stability and mechanism of degradation of therapeutic methane sulfose derivatives were investigated using ¹⁴C-labeled materials (81–83). The addition of antioxidants was shown to retard the color formation resulting from the degradation of *p*-aminosalicylic acid solutions (84). Aqueous solutions of acetylsalicylic acid prepared by the addition of polysorbates were shown to be more stable than similar solutions solubilized by the addition of ethanol (85). Stored under varying conditions of heat, light, and moisture, aspirin tablets showed the least amount of decomposition when prepared with tricalcium phosphate and talc (86). Similar tablets prepared with sodium alginate or polyvinyl pyrrolidinone showed the greatest amount of decomposition after storage for 3 months. The stability of cycloserine, determined in solution as well as in tablet dosage forms stored in various containers, was shown to be very poor

in the presence of water or humidity (87–89). The stabilizing effect of antioxidants on procaine hydrochloride solutions was clearly demonstrated by Moraga *et al.* (90). In solutions buffered to pH 7.9, the specific rate constants for chlorothiazide decomposition were observed to decrease with increasing concentrations of organic solvents such as ethanol, propylene glycol, and acetone (91). The effect of micellar binding on the enzymatic hydrolysis of arylsulfate esters was demonstrated by Baxter and Kostenbauder (92); although acid-catalyzed hydrolysis of the aryl sulfate ester was enhanced when the substrate was bound to the surface of the micelle-forming surfactant, the enzyme-catalyzed hydrolysis of this substrate exhibited a marked overall inhibition when the substrate was bound to the same surfactant. Deviations from first-order kinetics were observed at temperatures below –9° for the hydroxyl ion-catalyzed decomposition of hexobarbital (93). Rate increases occurred in frozen solutions that were as much as 42 times the calculated rates in supercooled liquid solutions at the same temperatures. These increases were partially explained by the increased concentration of the reactants which takes place in the liquid regions of the partly frozen solutions. Similar increases in rate of degradation as a result of freezing have been reported for adrenocorticotrophic hormone (ACTH) in human plasma (94). The stability of various antibacterial agents in culture media was shown to affect their activity *in vitro* (95). To be effective against bacteria, these drugs, which are hydrazone derivatives, have to release isoniazid upon decomposing in the culture media. The effect of oxidation on the stability of lecithin, Erolan (wool alcohols DAB7), lemon oil, and methoxy mercurate oils was outlined in a series of papers (96–99).

The instability of benzocaine in throat lozenges was reported to be due to the reactivity of the primary amine group (100). Corn syrup, citric acid, and natural cherry flavors, three commonly used excipients of throat

lozenges, were observed to be incompatible with benzocaine. The stabilizing effect of the *ortho*-hydroxyl group on the acid and base hydrolysis of amides was shown in a comparison of salicylamide to benzamide and other *N*-substituted derivatives (101). Benzamide was even less stable in alkaline than in acid media. The stability of the phenolate ions may result from a resonance effect, with consequent resistance to nucleophilic attack by hydroxyl ions.

Studies carried out on dilute prostaglandin solutions indicated that the F series compounds are very stable in an alkaline pH, while those of the E series are rapidly inactivated. In an acid pH, however, the members of the E series are more stable than those of the F series (102). Contact with various types of rubber stoppers was shown to affect the stability of benzalkonium chloride solutions (103). Autoclaving of carbachol solutions buffered at a pH between 5 and 6 had no effect on drug stability, while a similar amount of heat applied to unbuffered solutions caused 5–10% decomposition (104).

Other papers of interest relating to the topic of stability are listed in Table III.

Stability Kinetics—An apparatus for determining the stability of drugs under nonisothermal conditions was described (123). Details were presented for devices that allow programmed automated control of temperature, light, and pressure within the apparatus. The employment of the stirred-flow technique to develop mathematical equations for complex kinetic runs was described by Taylor (124). A computer program for chemical kinetics was used to update kinetic experiments and to correct the laboratory procedure used in these experiments (125).

In a comparative study of three methods for predicting the stability of aspirin and ascorbic acid solutions, the direct application of chemical kinetics at accelerated temperatures and the use of the Arrhenius equation gave predicted shelflife values that coincided with those obtained experimentally after storage at 25° (126). Maulding *et al.* (127) were able to predict the compatibility of aspirin with various tablet excipients, based on the hydrolysis rates of aspirin observed in aqueous suspension of the excipients.

Hydrocortisone hemisuccinate degradation was observed to occur in consecutive first-order reactions, the ester hydrolysis being facilitated by way of an intramolecular attack. The formation of a species devoid of the 17-dihydroxy acetone side chain subsequent to the formation of the steroid alcohol was confirmed in the experiments (128).

The light-catalyzed oxidation rate of chlorpromazine was shown to depend on the pH of the solution (129). The rate of decomposition was observed to be much slower in vehicles whose pH is between 2 and 6 than in more alkaline vehicles. The pH profile for the degradation of hydrochlorothiazide solutions was determined by several investigators (130, 131). The pH of maximum stability for this compound was observed to occur at 2.5. The kinetics of dihydroergotamine methane-sulfonate were observed to be first order, the pH of maximum stability occurring at pH 2.5 (132). The heat of activation of this reaction was calculated to be 12–13

kcal./mole. The autoxidation of sorbic acid in citric acid-containing solutions was shown to be accelerated by very low concentrations of the ferric or cupric ions but inhibited by higher concentrations (133). The acid degradation of aldopentoses to furfural and the further degradation of furfural were observed to be first-order functions of the acid and pentose concentrations (134). Although the heat of activation was the same for all of the aldopentoses tested, the order of reactivities did vary. The steric positioning of the hydroxyls in the reactive forms was postulated to be the controlling factor in the rate of reaction. The rate of inversion of sucrose in aqueous solutions of some strongly dissociated acids was investigated by Pethybridge (135). GLC was used to study the kinetics and characterize the acid hydrolysis of acacia polysaccharides (136). The acid degradation products were shown to consist largely of galactopyranose units (present equally as end groups), 3–6 linked branch points, and chain units.

Alkaline hydrolysis was used by Sun and Connors (137) to identify low molecular weight aliphatic esters. They obtained rate constants characteristic of the entire ester molecule. The hydrolysis of monostearin in aqueous media was noted to follow first-order kinetics and to decrease as the pH decreased (138).

Hydrolysis caused by enzyme systems was the topic of several papers. The pH effects of trypsin catalysis of *N*-benzoyl L-alanine methyl ester were thoroughly investigated (139). The kinetic results in acidic pH's suggest that a group, presumably the imidazole function of a histidine residue, is involved in acylation and deacylation, while those in basic solutions suggest that another group, presumably the $-\text{NH}_3^+$ function of a terminal isoleucine, controls the activity of the enzyme at different stages of complex formation. Dittert *et al.* (140) found that pseudocholinesterases present in human plasma were primarily responsible for the enzymatic activity of the plasma on the hydrolysis of 4-acetamidophenyl-2,2,2-trichloroethyl carbonate.

The hydrolysis of acylcholines in both acidic and basic solutions was evaluated in the presence of borate buffers (141). In acidic solutions, acylcholines with longer hydrocarbon chains were considerably more stable than those with shorter chains. In basic solutions, acylcholines degraded in a first-order manner below the critical micelle concentration (CMC) but not above. This phenomenon was postulated to be due to the formation of an anionic fatty acid which complexed with the undegraded cationic acylcholine, thus repressing hydrolysis. The effects of pH and buffer concentration on derivation of rate equations for the hydrolysis of ethyl glucuronate in phosphate buffers received attention in a very interesting paper (142). The kinetics of *meso*-inositol hexanicotinate were investigated in acidic solution to determine the gastric stability of this substance as a possible explanation of its absorption from the gastrointestinal tract (143). The compound hydrolyzes 10 times faster than other nicotinic acid esters in acid solution. The kinetics and mechanism of the reaction between hydroxylamine and succinamide or ethyl acetate were thoroughly investigated by Notari (144–146) in a series of papers. The rate of formation of 2-dimethylaminoethanethiol propionate from propionic anhydride

and 2-dimethylaminoethanethiol was observed to exhibit a pH dependency which could be explained by assuming the thiol anion to be the attacking species (147). Differences observed in the kinetics of propionyl thiocholine iodide and 2-dimethylaminoethanethiol propionate were attributed to the stabilization of the hydrolysis transition state by a protonated nitrogen at a lower pH and by the quaternary nitrogen atom at a higher pH (148). The rapid stop-flow system was utilized to study the kinetics of the oxidation of cystine by 1,3-dihydro-1-hydroxy-3-oxo-1,2-benziodoxole (149). The rate constants were determined, and the mechanism of reaction was postulated for this system.

Other kinetic papers of interest are listed in Table IV.

Antibiotic Stability—The kinetics and mechanism of degradation of ampicillin were investigated by Hou and Poole (162). The pH rate profile in buffer solutions showed a minimum at a pH of 4.85, while at zero buffer concentrations the maximum stability was shifted to a pH of 5.85. Similar studies were carried out with regard to hetacillin decomposition (163). It is clear that hetacillin initially decomposes to ampicillin, the decomposition rate being greatest in the presence of phosphate ions and least in the presence of the citrate ion. The mechanisms and rates of catalysis of penicillins by the cupric ion and aminocatechols were investigated by various workers. The cupric ion–penicillin complexation was postulated to occur at a catalytic site which promotes the rapid degradation of the antibiotic in the presence of the metal (164). The catecholamines were observed to catalyze the hydrolysis of penicillin in neutral pH by a mechanism similar to that postulated for several hydrolytic enzymes (165). The antigen which causes penicillin allergy may be formed by aminolysis of the antibiotic *via* a mechanism involving its decomposition in the presence of poly-L-lysine and tris(hydroxymethyl)-aminomethane (166). Subsequent studies indicated that poly-L-lysine catalyzes the hydrolysis of penicillin to penicilloic acid as well as the aminolysis of the antibiotic by tromethamine (167). Differential thermal analysis was used to identify stearic acid as the inactivating component in tablets of sodium dicloxacillin (168). This method also indicated the incompatibility of stearic acid with penicillin G and sodium oxacillin but not with

ampicillin. The results were substantiated by chemical analysis after storage of the combinations at accelerated temperatures. Anionic surfactants were observed to increase the stability of penicillin in ophthalmic solutions and ointments, while cationic surfactants did not appear to have such an influence (169).

Chloramphenicol in solution was observed to decompose faster at pH's above 8, particularly when exposed to light (170). The effect of polysorbate 80 (Tween 80) on the acid hydrolysis and discoloration of chloramphenicol was reported in a series of interesting papers (171, 172). The mechanism of solubilization of chloramphenicol by polysorbate indicated that the palisade layers of micelles are responsible for the solubilization and will hinder the degradation of the antibiotic, especially at alkaline pH's. The addition of polysorbate 80, however, was observed to accelerate the color formation of chloramphenicol solutions, primarily because of contamination by trace metals found in the surfactant.

The kinetics of hydrolysis of antimycin A in solution was reported to follow classical consecutive first-order kinetics (173). The addition of ascorbic acid was demonstrated to prevent the oxidative decomposition of tetracycline due to air, light, and the presence of riboflavin (174). The rates and mechanism of catalysis of streptovitacin A were discussed in an interesting paper by Notari and Caida (175). The dehydration of this antibiotic gave rise to anhydrostreptovitacin A, with no evidence of the formation of the phenolic product.

Additional references on antibiotic stability are presented in Table V.

Vitamin Stability—The influence of various additives on the stability of vitamin A was considered in various papers. The aluminum salts of fatty acids were shown to stabilize vitamin A in mixtures with tocopherols and lecithin (180). Proteins, as found in gelatin, enzyme-hydrolyzed casein, and ground nut protein, displayed a protective action for vitamin A, even in the absence of antioxidants (181). Dextrose and sodium benzoate, however, increased the autooxidation of vitamin A under similar conditions. The influence of water on the stability of anhydrovitamin A in ethanol was investigated (182). The stability was shown to be universally proportional to the water content of the ethanolic solutions.

The addition of chelating agents and the purging of oxygen from the vehicle were shown to stabilize thiamine bromide solutions for use in ampuls (183). These ampuls, after sterilization and storage for 2 years at 20°, still met official potency limits. Thiamine hydrochloride tablets were observed to degrade in a pattern in which an apparent equilibrium was reached (184). The amount of thiamine at equilibrium depends on the

amount of moisture present and exhibits a minimum at a 5.5% moisture content. The model proposed for such a system presumes that the thiamine dissolved in the water adsorbs on the cellulose and that the thiamine present in the monolayer degrades totally, whereas the thiamine in layers beyond the monolayer does not degrade. The kinetics and mechanism of degradation of various thiamine derivatives were outlined in a series of very interesting papers (185–187). The stabilities of these different derivatives were compared with those of thiamine under similar conditions.

Various flavors present in vitamin B₁₂ solutions were found to exert a significant influence on their stability (188). Vitamin B₁₂ suppositories were reported to be stable when prepared by coating the microgranules containing the vitamin prior to their incorporation into the suppository mass (189).

The kinetics of cupric chloride-catalyzed autoxidation of L-ascorbic acid were found to be related to the polarity of the solvents employed (190). The ionization of ascorbic acid to the ascorbate ion, which is affected by the solvent polarity, was postulated as one of the factors controlling the rate of degradation of the vitamin in solvents of different polarities. The cupric-ion catalysis of ascorbic acid solutions was hindered by 2% sucrose or 0.1% citrate in the presence of commonly used preservatives (191). The action of Complexon III (ethylenediaminetetraacetic acid) on the stability of L-ascorbic acid solutions was demonstrated to be potentiated by the presence of acetic, citric, tartaric, metaphosphoric, oxalic, and hydrochloric acids (192, 193). Ascorbic acid monostearate was shown to have greater stability than free ascorbic acid, especially in alkaline solution (194). The thermal degradation of thiamine and ascorbic acid combinations in aqueous solutions was investigated (195). Thiamine exerts a protective action on ascorbic acid only in aqueous solutions and not in the presence of citrate or phosphate buffers.

The stability of vitamin D₂ in the solid state was the subject of a very thorough investigation by Takahashi and Yamamoto (196–202). In the presence of calcium phosphate and talc, the vitamin was shown to isomerize readily, yielding isocalciferol and isotachysterol. The isomerization was observed to be catalyzed by surface acid on the excipients. Storage of the powders under conditions of high humidity increased the stability of the vitamin, since the surface acidity was decreased by the absorption of moisture. Further investigations indicated that vitamins such as ascorbic acid, thiamine hydrochloride, and pyridoxine hydrochloride, which have a high surface acidity in the dry state, behave in a similar manner.

The effect of polysorbate 80 and sodium lauryl sulfate on the photolytic degradation of flavine mononucleotide was investigated through measurement of the electron-spin resonance of semiquinone, an intermediate degradation product (203). The degradation was observed to follow first-order kinetics in the dark, both additives accelerating the formation of the semiquinone derivative.

Other references pertaining to vitamin stability are given in Table VI.

PHARMACEUTICAL TECHNOLOGY

A series of review articles on the current aspects of pharmaceuticals discussed a wide number of topics, including drug release and absorption, drug solubility, preservatives, chemical stability, physical stability, and packaging (209–212). Other articles outlined the general concepts involved in the formulation of products containing corticosteroids or hormones having polypeptide structures (213, 214) and reviewed the possible incompatibilities of these hormones with the excipients present in various dosage forms. Schumacher (215) presented a very thorough review of the bulk-compounding technology utilized in the preparation of liquids, suspensions, emulsions, and ointments. The main trends in pharmaceutical research and development were also aptly reviewed (216).

Parenterals—Possible contamination of parenteral products by the packaging components was the topic of several interesting papers. Contamination with heavy metals from ampul glass as a result of washing was eliminated by an acid rinse followed by a wash with deionized water (217). Zinc ions eluted from rubber stoppers were shown to affect the stability of dextran solutions (218). White rubber stoppers were shown to elute more zinc than black butadiene acrylonitrile rubber stoppers (219). Atomic absorption spectrophotometry was used to detect amounts of silicone removed from disposable plastic syringes by distilled water washes (220).

The factors influencing the turbidity occurring in parenteral solutions containing polysorbate 80 and benzyl alcohol were pointed out (221). The turbidity was determined to be a function of the concentrations of the components and the temperatures to which they are exposed. The use of benzyl benzoate in preparing solutions of steroids in peach oil was described (222). Such oil solutions of hydroxyprogesterone capronate and androstenediol dipropionate did not show the presence of crystals after 1 year of storage at -26° .

A closed system of incorporating nitrogen into vials was found to be much more effective than conventional systems for preventing the degradation of the active agent by aerobic oxidation (223). The advantages and methods employed in the nitrogen flushing of products stored in metal containers were discussed (224).

A new stratified lyophilization technique and an example of the use of this technique in preparing ACTH preparations with prolonged action were described in two interesting papers (225, 226). The presence of isonicotinic acid hydrazide was shown to decrease significantly the potency of streptomycin and *p*-aminosalicylic acid.

cyclic acid after freeze-drying (227). Solutions prepared without the hydrazide but under otherwise similar conditions showed no losses in potency. Injectable solutions of sodium sulfathiazole in a 10% sorbitol solution stored under nitrogen were shown to be stable after storage for 14 months at 37° (228).

Other papers of interest in the category of parenterals are given in Table VII.

Sterility—A very complete review of the different techniques utilized for sterilization was presented by Doyle (233). The advantages of the continuous sterilization technique were presented in two excellent papers (234, 235). Such sterilization is accomplished in towers in which carrier-conveyor baskets filled with containers pass through a succession of zones where the temperature is regulated by water, steam, and air. This method was postulated to be superior to the classic autoclave method.

The efficiency of gaseous sterilization was described by several authors (236, 237). A nonexplosive mixture of ethylene oxide and methyl bromide was shown to be effective against a variety of spores (238). Sterility was achieved in 2–48 hr., depending on the object to be sterilized and the conditions applied. The adsorption and desorption of ethylene oxide on rubber, polyethylene, and polyvinyl chloride objects were investigated (239). It was shown that the adsorbed gas remains as a residual for prolonged periods of time unless desorption is accelerated by heating. Ethylene oxide-sterilized plastic medical devices showed no significant toxicities 24 hr. after sterilization (240). The disinfectant action of peracetic acid and formaldehyde on equipment was also demonstrated in a series of interesting papers (241–243). Complete sterilization of microbes was achieved with a 0.5% peracetic acid solution in 1–30 min.

The bacteriological aspects of sterilization by the use of γ -radiation were reviewed, with emphasis on the mechanism of action and the factors influencing the radiation resistance of bacteria and other microorganisms (244). The specific uses of radiosterilization in pharmaceuticals were reviewed by several authors (245, 246). A dose of between 2.5 and 4 mrad sterilized all solutions tested. Physical as well as chemical changes were observed in certain cases, especially when aqueous solutions were irradiated. Similar losses in potency were described after irradiation of aqueous solutions of atropine, morphine, and lidocaine (247). The amount of degradation was increased by an increase in the radiation and by a concentration of oxygen above the irradiated solution. Sterilization of hydrocortisone and chloramphenicol ophthalmic ointments by γ -radiation did not cause any change in the physical or chemical properties of the ointments but did increase the number of free radicals present (248). No changes in characteristics or properties of surgical appliances, especially those of biological origin, were observed after irradiating them with 2.5 mrad (249). This radiation level gave complete sterility of all products tested. Changes induced in fats and glucose solutions as a result of heat sterilization were described in two papers (250, 251). These changes were reportedly caused by the high temperatures required.

Table VII—Additional References on Parenterals

Ref- erence	Topic
229	Chemical resistance tests on Indonesian ampuls
230	Use of homemade detergents in cleaning ampuls
231	pH and resistance of liquids used in injectables
232	Review of incompatibilities of numerous injectable drugs

Methods of sterilizing objects by the use of steam as well as by dipping them into chemical preservative solutions were studied (252, 253). Although these techniques can be used to sterilize Plexiglas objects and polyethylene hypodermic syringes, none is capable of sterilizing rubber stoppers.

Various techniques for sterility testing of pharmaceutical products were described in two review articles (254, 255). The membrane filtration technique was considered the method of choice for determining the bacterial content of liquids. The significance of sample size and sample ratios in sterility testing of drug products was discussed in a very interesting paper (256). To eliminate preservative or drug effects in testing parenteral solutions, the optimum sample size is 10 ml. and the optimum dilution in the culture medium is 1:64. Thioglycollate was deemed an unsatisfactory medium for general sterility testing, especially when only a small amount of contamination is present (257). This medium was felt to be reliable only for the detection of *Proteus* species.

Tablets and Capsules—Some of the controls and testing methods used in tableting were outlined in an excellent article by Sinotte (258). Special consideration was given to the potential for automatic testing and the advantages and disadvantages of automating these processes.

The concepts of comminution and its effects on the properties of powders thus ground were briefly reviewed in several papers (259, 260). The factors affecting the efficiency of grinding during jet milling were studied for the grinding of calcite using a 20-mm. diameter jet mill (261). These experiments evaluated the effect of the feed rate of the solids, the injector nozzle pressure, and the grinding nozzle diameter on the particle-size distribution. Several new techniques for measuring particle size of powders were investigated. An average particle-size-measuring technique was developed, giving standard deviations of approximately 2.5%, based on the observation that the bulk volume of powders needed to form a single layer on an area of fixed size is proportional to the average particle size. This method requires the use of calibration curves for different types of solids and is less applicable to powders and very small non-spherical particles which do not pack reproducibly (262). The use of an attenuated light beam passing through a settling suspension of particles was utilized to develop theoretical curves for determining the size distribution and specific surface of the powder being investigated (263).

The effect of particle shape on the angle of repose, bulk density, and rate of flow through an orifice was investigated using sand (264). In all size ranges in which

there is an increasing departure from the spherical, the angle of repose increases while the bulk density and flowability decrease. The rate of flow of a powder through a circular orifice was reported to be a function of the particle size, bulk density, cohesiveness, tensile strength, and shear index of the powder. Different methods of measuring cohesiveness and the effect of glidants and particle size on cohesiveness of a series of powders were demonstrated (265). In the case of granular solids passing through a circular orifice, differences due to shape, density, porosity, and friction of particles could be eliminated by using the term for bulk density instead of particle density in the flow equation (266). The packing properties of powder particles in centrifugal fields were investigated using calcium carbonate and aluminum oxide powders (267, 268). The results supported the assumption that the bulkiness of a fine powder is the product of the forces of interparticle adhesion and the external forces acting on the individual particle. The use of a shear cell has been proposed to measure the cohesiveness and tensile strength of powder as well as the mechanistic behavior of such powder under shear (269, 270). Some of the processes considered are plastic deformation and structural changes such as consolidation or dilation, blockage to resist continuation of motion, and particle orientation, all of which occur in the powder bed. Utilizing this apparatus, a relative shear force and index of retention value can be defined.

The effect of lubricants and surface-active agents on the flow of powders was evaluated. Studies on a capillary vibroviscosimeter indicated that the addition of surface-active additives lowers the viscosity of a flowing powder. The magnitude of this effect, however, was decreased by increasing the vibration rate (271). The viscosity and the angle of repose increased and the packing density decreased with an increase in temperature above 100°, a level at which moisture has a negligible effect on the adhesiveness of powders (272). Lubricants were observed to reduce the angle of repose of powders and to improve their flow characteristics (273). With the addition of ultrafine solid additives, the adhesive forces of strongly adhesive materials were decreased and those of less adhesive powders were increased (274). These results were interpreted to mean that an ultrafine additive roughens the surface of a powder particle enough to increase its friction coefficient and to decrease its adhesion forces.

Based on a diffusion model, Hogg *et al.* (275) developed a quantitative theory to describe the mixing of particulate systems in which one component is present in trace quantities. The theoretical expressions derived to predict the rates of mixing of identical components, both as spherical and as angular particles, agreed with the data obtained. Three probability distributions were defined governing particle movement within a horizontal drum mixer (276). A relationship for the diffusion coefficient, based on the probability distributions, was derived from Fick's first law. The frequency of collisions resulting in particle movement was determined by the interaction between mixer speed and load. The average distance that a particle travels is affected by mixer load but not by speed. The convective

and surface mixing of tracer particles of a granular material over a horizontal blade moving relative to a bed was investigated (277). The horizontal movement is determined by the blade height and immersion and the relative velocity of bed to blade and gravity, while the vertical movement is also affected by the particle diameter. The relationship between sample weight and the coefficient of variation as a mixing index and mixing ratio was examined in a V-shaped mixer, utilizing different mixing ratios (278). In the case of adhesive ingredients such as salicylic acid, the charging point and the size of the diluent were found to have a marked effect on the mixing rate. Such phenomena were believed to be due to differences in adhesive force between the same and different kinds of particles or between the particles and the walls of the mixer.

The physical and mechanical factors affecting the compression of tablets were described in a wide range of papers. The powder segregation that occurs during die filling consists of the finer particles ("fines") filtering through to the bottom of the moving powder mass, where it builds an inner mound of fine rich material on the bottom of the die and an excess of coarser material at the periphery of the die cavity (279). This segregation is lessened when the amount of fines is decreased, the rate of die fill is increased, or the height from which the powder falls is increased. The pressure on the die wall was observed to increase with a decrease in the hardness value of the material being compressed (280). The maximum compression force required for tableting granules was dependent on the granule size, although the energy required for tableting was similar for all sizes (281). The smaller granules were observed to decrease the time of the first compression phase. Experiments with an automated tablet press showed that for the limited range of dimensions applicable to most pharmaceutical tablets, there exists a common linear relation between the applied compaction pressure and the force lost to the die wall per unit area of apparent die wall contact during compression (282). During tablet compression, pressure is believed to be transmitted in two directions: along the compression and along the die wall (283). A model was presented to show the phenomena which occur during repeated compressions; this model illuminates some facts about the internal structure of compression-molded substances and illustrates the need for lubricating agents (284).

The physical and mechanical factors utilized in preparing directly compressed tablets were discussed (285). Modification of the specific gravity of the compressed material was observed to modify its other characteristics. The tableting properties of directly compressible starch, STA Rx 1500 brand of starch, and a material derived from beets were also described (286–289). The fluidity and compressibility of these materials made them especially useful for direct compression. The effects of hydroxypropyl methylcellulose, carboxymethyl dextran, starch dextrans, xylitol, talc, and cyclamic acid on the properties of tablets were discussed by a great many authors (290–302). Polytetrafluoroethylene was successfully used as a lubricant in the compression of powders as well as being bonded to the tips of punches to reduce the adhesion between them and the

tablets (303). The properties of Aerosil (pyrogenic silica) and its use as a glidant were discussed. In some of these studies the addition of Aerosil increased the disintegration time of tablets prepared from inorganic salts (304–306). The crystalline form as well as the granular character of lactose was observed to affect the properties of tablet formulations (307). In a thorough investigation, dicalcium phosphate, calcium sulfate, and magnesium carbonate were compared with glucose and sucrose as diluents in the tableting process, the relative merits being judged by the quality of the finished tablets (308). The optimum tableting pressure for these materials was determined, and the effect of this pressure on the required ejection force and the tablet properties was discussed. Under the experimental conditions, the inorganic salts were clearly superior to glucose and sucrose as diluents. In tablets prepared with polyethylene glycol 4000 as a binder, not only the active ingredient used but also the granulation procedure and the moisture present in the powder mixture were observed to affect the hardness and porosity (309).

The effect of various materials on the disintegration times of tablets was well documented (310–318). In general, additives were placed into three classes: those acting as capillary-forming agents, as in the case of starch; surface-active agents such as Tween 80; and swelling agents such as ultraamylopectin. The latter two types were more effective than starch in lessening the disintegration time of certain hydrophobic materials. The mechanism of tablet disintegration was discussed on the basis of cohesive and adhesive properties of the particles. For a tablet to disintegrate, the dispersion of the particles caused by the penetration of water must overcome the forces binding the particles through cohesion and adhesion (319). The inhibitory effect of magnesium stearate on the penetration of liquids into tablets was found to be roughly proportional to its concentration in the tablets (320). With tablets of sulfamethazine, high-viscosity binders prolonged dissolution and hydrophilic binders shortened it, although both types of binders gave similar disintegration times (321). The dissolution rates in both cases were shown to be directly proportional to the amount of binder added. The particle size of aspirin after disintegration from tablets was shown to be different from that used in preparing the tablets, even in the presence of starch. Large particles were broken, while small particles were observed to be agglomerated and partially aggregated to larger particles, thereby negating the therapeutic advantage of finely divided aspirin (322). The effect of tablet form on physical properties was the subject of an interesting paper (323). It was noted that the disintegration time of tablets was dependent on the surface area, flat tablets disintegrating somewhat more rapidly than convex tablets. The breaking strength of convex tablets, however, was found to be greater than that of flat tablets. Taking all factors into consideration, the authors concluded that strongly convex tablets are often preferable.

The porosity, pore-size distribution, and water permeability of several different coating powders used for subcoating sulfathiazole tablets were evaluated (324). Powders consisting of acacia, sucrose, titanium dioxide,

talc, calcium carbonate, and Aerosil formed the coatings that were considered to have the best properties. Exclusion of Aerosil from this powder resulted in the formation of a more compact coat having fewer and smaller pores. Polyvinyl acetal diethylamino acetate was investigated for use in preparing a gastric-soluble protective coating for tablets (325). The effectiveness of this material, which is soluble in a wide variety of organic solvents and aqueous solutions of pH less than 5.8, was determined *in vivo* by obtaining blood levels following the administration of coated triacetyloleandomycin and barium sulfate coated tablets to dogs. Other coating materials evaluated with regard to their properties and physical stability on aging were those consisting of zein, polyvinylpyrrolidinone, sodium carboxymethylcellulose, cellulose acetate phthalate, Polyox WSR 205, and WRS 301 (water-soluble resins) (326–328).

The manufacture, filling, and coating of hard-gelatin capsules were very capably reviewed by Jones (329). The transfer of water vapor through capsules and the experimental equilibrium water constants were determined for encapsulated starch and microcrystalline

cellulose stored in closed containers (330). The equilibrium constants and the estimated values calculated from the sorption isotherms of these substances were observed to be in good agreement. Capsules were evaluated for filling characteristics after being filled with cornstarch or lactose, with or without Aerosil as a glidant, by a semiautomatic ring-filling method. On powders without Aerosil, the coefficient of variation of the dose showed that filling by a screw auger was more accurate than by a flat one. The powders containing Aerosil exhibited maximum deviations between 0.1–2% of the glidant (331). The use of a shellac coating on capsules of pancreatic enzymes to prevent dissolution in gastric fluids was evaluated both *in vitro* and *in vivo* (332). This coating inhibited release of the enzymes for at least 2 hr. in artificial gastric juice, yet the enzymes were released in less than 1 hr. when placed in synthetic duodenal fluid.

Further references of interest in the field of tablets and capsules are given in Table VIII.

Suspensions—The effects of the nature of the suspended solids, surface charge ζ -potential, and shear rate on the properties of dispersed systems were thoroughly reviewed in several excellent papers (362–364). A rotational viscosimeter was used to measure the apparent rheological properties of rapidly settling suspensions (365). Using this data, a generalized correlation between the viscosity of the medium and the viscosity of the suspension was developed to predict the apparent viscosity of such rapidly settling suspensions. Measurements were presented on kaolin suspensions, which confirmed that interaction between the suspended particles, macromolecules of the suspension media, and electrolytes influences the flow behavior and stability of the suspensions (366). The adsorption of ions on the surfaces of suspended particles, by changing their distribution in an electrical field, influences their coagulation, flocculation, and sedimentation characteristics through the formation of electrical double layers. The sedimentation and flocculation of dispersed phases were investigated utilizing suspensions of calcium carbonate (367). The volume of immobilized medium present on the particle surface varied, depending on the kind of suspending medium; the larger the volume of the immobilized medium, the greater was the effect on structural viscosity. In a review of the mechanism of flocculation and floccule sedimentation, it was pointed out that theories applicable to colloidal systems must be modified when paracoloidal particles are present (368). The existence of order in dilute colloidal suspensions due to long-range electrostatic forces was shown by the measurement of diffraction of light caused by such suspensions (369).

The effect of the concentration and the shape and size of the solid on the settling of a suspension was outlined in several papers (370–372). Numerical data obtained by utilizing such a model system compared well with the actual experimental data obtained using aluminum oxide suspended in salt solutions.

The rheology of kaolin suspensions was the topic of many interesting papers. The curves of yield stress *versus* pH were shown to exhibit a maximum for sodium kaolinite at pH 5.75, for aluminum kaolinite at pH

7.95, and for the acid form of kaolinite at pH 7. The maximum appeared to occur at the zero point of charge of the kaolinite edges, which is partly dependent on the ionic environment in which the clay is prepared (373). The kaolin–water system was used to illustrate techniques for determining the electrophoretic mobility of particles in suspension (374, 375). These data were used to show the relation between the salt flocculation value of a suspension and its electrophoretic mobility.

The viscosity of various kaolin suspensions was observed following the addition of a basic aluminum chloride complex (376). After addition of only small amounts of the complex, the clays still showed individual differences; but at higher concentrations, common trends could be distinguished, indicating that the adsorption of the complex masks the individual surface characteristics of the kaolin particles. The negative surface charge of kaolin was shown to increase during oven drying of suspensions of kaolin containing a soluble phosphate (377). The viscosity of certain kaolin–water systems was correlated with the montmorillonite content of kaolin (378). Transition from low viscosity to high viscosity occurred when the montmorillonite content exceeded 5%. Adsorption of hexadecyl sulfate by kaolinite crystals was postulated to occur on edges of the tabular kaolinite crystals, forming a bimolecular layer which causes the edges to become negative and deflocculation to occur (379). The rheological behavior of other clay systems was also extensively investigated. The electrical double-layer theory was used to analyze an idealized clay particle system, with the purpose of describing the mechanical stability in terms of attractive and repulsive forces (380). The general pattern of behavior of the model was shown to be compatible with the behavior of the clay mass. The chemical factors involved in the flocculation of clay slurries were pointed out by Slater *et al.* (381). For a polymer to act as an effective flocculant by the “bridging mechanism,” it must have a certain extended configuration in solution which is influenced by pH, ionic strength, and polyvalent counterions, and the polymer must be adsorbed on the mineral by multiple functional groups. In various systems, this attachment may occur by electrostatic attraction, hydrogen bonding, dipole interaction, or even covalent bonding. The use of polyacrylamine and polyvinyl alcohol in flocculating and increasing the structural strength of bentonite suspensions was pointed out (382, 383).

Factors affecting the long-term settling characteristics of clay suspensions were described in an interesting article (384). Temperature and concentration were shown to affect greatly the settling characteristics of the clays tested. Layering formed most readily in aqueous vehicles having a low viscosity and density. A mechanism was postulated for the deflocculation of clays in nonaqueous systems by the addition of amines and amino acetates (385). The partition of the amine between the clay and the organic liquid was measured, and this was considered an important factor in the deflocculating efficiency of the amine.

The effect of surfactants on the stability of suspensions of bentonite, polyethylene, carbon black, and kaolin was the subject of several papers (386–389). In most

cases, unstable hydrophilic particles can be stabilized by the addition of surface-active agents. The temperature for optimum stability of these systems, however, was shown to increase as the chain length of the surfactant used was increased. The relation between the extent of dilatancy and colloidal stability of suspensions was studied utilizing polysodium methacrylate as a dispersing agent (390). The colloidal stability of this system was varied by changing the degree of dissociation of the acid groups of the polymer. The extent of adsorption of the dispersant was found to correlate well with the viscosity measurements. The increase in viscosity could result from an increase in flocculation due to shear. The pH of maximum stability and the maximum ζ -potential were observed to occur between 7 and 10 for titanium dioxide suspensions (391). This system has an isoelectric point at pH 3, when surface hydroxyls on the titanium dioxide surface are completely neutralized. Above pH 10 the ζ -potential of this system once again drops, with a resultant decrease in stability. The stability of aluminum hydroxide in normal alcohols and toluene stabilized with surface-active agents was postulated to be due to the double-layer electrostatic repulsion forces on the gel (392). The effect of impurities on the charge of aluminum oxide in aqueous suspensions was also determined (393). The ζ -potential of the less pure oxide was greater, resulting in increased structural characteristics of the suspensions. The impurities on the surface of the aluminum oxide particles were postulated to increase the thickness of the firmly bound layer, consequently increasing the effective particle radius and lowering the amount of dispersive medium.

The effects of ultrasound on the properties of suspended solids were demonstrated in two interesting papers (394, 395). Ultrasonic energy was shown to have a greater effect on larger particles than on smaller particles. A logarithmic relation was demonstrated between the increase in solid surface and the concentration of suspended solids. Increasing the viscosity of the dispersing medium appears to reduce the increase of solid surface, while the addition of surfactant enhances it. The maximum increase occurs in the region of the CMC of the dispersed system. Ultrasonic energy may increase the solid surface by reducing the particle size of some materials and the agglomeration of others.

Other articles of interest relating to suspensions are described in Table IX.

Emulsions—Review articles were published on emulsion theory and practice, recent advances in emulsion processes, and critical factors affecting emulsion systems (414–417). A computer was utilized to solve the fundamental flocculation-rate equations, including the effects of polydispersity and the particle-particle potential energy barrier (418). These calculations were based on the assumption that the only rate-limiting process is the passage of particles over the primary electrical barrier to the flocculation of the suspension. The description of a Coulter counter technique for obtaining size distribution of oil-in-water emulsions was presented (419). Although this method compares well with other measuring techniques when certain precautions are taken, it has the same disadvantage of being rather laborious.

The flow characteristics of oil-in-water liquid petrolatum emulsions were investigated using a cylinder-type viscosimeter (420). The shear rate-shear stress curves showed a hysteresis loop which changed from a dilatant to a thixotropic form in accordance with change in distribution of particle size and state of aggregation of the emulsion. The increase in the fineness of particle size of the dispersed phase was shown to increase the viscosity of the emulsion (421).

The distribution of surfactant between the water and oil phases at the point of immersion was a contributing factor in the type of emulsion formed (422). Placing more surfactant in the aqueous phase was shown to favor the formation of an oil-in-water emulsion. No relation was observed between the rate of coalescence of oil droplets in an oil-in-water emulsion and the interfacial tension (423). Although the stability of the oil drops differs from the so-called "emulsion stability," the rate of coalescence of drops was observed to correlate with such stability. The effect of the hydrophilic-lipophilic balance (HLB) of the emulsifiers on emulsion stability was investigated by a number of workers (424–429). The size of the emulsion droplets changed remarkably with temperature and HLB of emulsifier. The droplets coalesced more readily when close to the phase-inversion temperature, and relatively stable oil-in-water emulsions were obtained when the phase-immersion temperature was 20–65° above the storage temperature of the emulsion. At optimum stability, emulsions are relatively insensitive to changes in HLB values but are quite sensitive to the phase-inversion temperature of the system being investigated.

The stabilization of oil-in-water emulsions by the use of nonionic detergents was investigated in a series of papers by Elworthy and Florence (430–432). The higher stability obtained by increasing the glycol chain length of the emulsifier was not due to a raised surface potential but was ascribed to entropic effects. The rate of coalescence of the emulsions was related to the ζ -potential, surface concentration, and polyoxyethylene chain length. In these systems, the adsorbed film was observed to increase the attractive forces between particles. The apparent CMC determined from the interfacial tension-concentration curves were higher than those obtained at the air-water interface. The effect of cationic detergents on emulsions stabilized by acacia and sodium alginate received attention (433). The ζ -potentials and particle sizes were obtained so that the interaction energies could be calculated for these systems. By utilizing the observed degrees of aggregation, the van der Waals constant was estimated and the binding parameters, numbers of binding sites available, and free energies of absorption were calculated. Emulsions prepared with Carbopol (water-soluble resin) neutralized with hexylamine and 2-ethylhexylamine were noted to give stable emulsions, while other shorter or longer chained amines yielded poorer emulsions (434). These results were rationalized on the basis of polymer confirmation and HLB. The use of lecithin, starch phosphate, gelatin, and other hydrophilic colloids as emulsifiers was evaluated in a series of papers (435–437). The viscosities, ζ -potentials, and stabilities of these emulsions were determined. The temperature effects and the effects of adding electrolytes or hydrophilic colloids to solid, stabilized, kerosene-water emulsions were studied (438). Large quantities of electrolytes were observed to have a deteriorating effect, which was ascribed to chemical changes taking place in the stabilizers. The addition of hydrophilic colloids led to better emulsification and finer dispersion. This behavior was attributed to the formation of a protective layer which hinders coalescence of the oil droplets. The use of mixtures of surfactant fatty alcohol emulsifiers to stabilize oil-in-water emulsions and alter their consistency from fluid to semisolid was described (439). A mechanism involving the formation of a viscoelastic network in the continuous phase was proposed to explain this self-bodying action.

Peterson (440) thoroughly reviewed factors affecting nonaqueous emulsion systems and their stability. Anionic emulsifiers are best suited for the preparation of

stable emulsions; glycerin appears best at low emulsifier concentrations. Measurement of particle size after long periods showed that such emulsions have good stability during aging. The factors affecting the formation of microemulsions and their resulting properties were outlined in an interesting paper (441). The presence of excess electrolyte in the aqueous phase was shown to inhibit microemulsification. Microemulsions in systems based on soaps are strongly cation dependent, while those prepared with dodecyl sulfate are independent of the nature of the cation. Changing of the water-emulsifier ratio was observed to have no effect on either the total interfacial area or interfacial stoichiometry of the microemulsion tested.

Other articles related to emulsions are presented in Table X.

Ointments and Creams—Ointment bases were classified according to their properties in several interesting review articles (449, 450). Lipophilic and hydrophilic ointments, the first two classes, were further subdivided according to the chemical composition of the bases. Diphilic ointments, the third class, were divided into those containing emulsifiers and emulsifier-type bases.

Rheological measurements were made on a number of ointment bases over a wide range of temperatures (451, 452). The addition of a small quantity of complex material to a paraffin ointment base was shown to change its behavior from elastic to viscoelastic. These viscoelastic materials were all assessed in creep testing, where fundamental parameters were provided and the rheological behavior was represented by mechanical models. There was a distinct difference between the behavior of creams prepared with ionic and nonionic soaps. Lipophilic emulsifiers, such as wool fat alcohols, were noted to reduce the yield value and thixotropy of petrolatum, but complex emulsifiers had the opposite effect (453, 454). The effect of soaps on the yield value and consistency of oil-in-water emulsion ointments was also carefully evaluated (455). The use of stearic acid-sodium lauryl sulfate combinations in these systems led to the formation of creams, which were actually fluids without a gel structure, while cetyl alcohol-sodium lauryl sulfate or cetyl alcohol-sodium stearate combinations formed ointments with a measurable rigidity. The internal structures of ointments prepared with bentonite, ichthyol ointment prepared from petrolatum and methylcellulose bases, sulfonamide ointments, and zinc paste were evaluated using various rheological testing methods (456–462). In most cases, a thixotropy was observed which changed markedly at higher temperatures, approaching the idealized state. Regeneration of the inner structure was usually observable by 24 hr., although the time varied, depending on the surfactant present in the ointment system.

The use of the newer surfactants and emulsifying agents in the preparation of emulsion ointments was thoroughly reviewed by Goldenberg (463). The effect of various emulsifiers on the emulsion system of creams was also studied (464). This paper described the preparation of an ambiphilic cream system, one that can be diluted with either water or oil and still give a stable emulsion. It also listed the properties of other creams prepared with different emulsion systems. The ad-

vantages of methylcellulose as a base in preparing various ointments was reviewed (465). Although active materials were observed to penetrate the skin to a greater extent in ointments prepared with methylcellulose than in those prepared from other commonly used bases, too great an amount of methylcellulose in an ointment should be avoided, because it may interfere with the healing of wounds by the formation of a film. The use of polyhydric alcohols, sodium lauryl sulfate, cetyl alcohol, decaglycerol esters, sugar esters, and other complex esters in preparing ointments of various types was also considered (466–470). The viscosity and some of the other properties of ointments prepared from these materials were measured and further described in these papers.

A method was demonstrated for measuring the particle size of solid pharmaceuticals present in ointments (471). This technique consists primarily of mixing the ointment with a solvent in which it is soluble and then filtering and measuring the size of the insoluble particles remaining behind. For meaningful results, however, the solvent utilized in this technique must not dissolve the solids present in the ointment. To compare the wettability of ointments by liquids of different surface tensions, the contact-angle kinetics of various ointments were investigated (472). The contact angle was observed to change characteristically with the properties of the ointments and the surface tensions of the liquids being evaluated. The water-absorptive properties of lipophilic bases and the dehydration kinetics of hydrogels were also investigated (473, 474). The absorptive properties of starch, talc, and zinc oxide dispersed in petrolatum were evaluated in terms of absorptive rate and capacity. The effect of sample area and air flow on the kinetics of dehydration of hydrogels was evaluated. The dehydration was observed to proceed in two separate steps, a zero-order followed by a one-third-order rate.

In vitro as well as *in vivo* methods for evaluating ointment bases were reviewed in an interesting article (475). The specific evaluation of drug release from ointment-type dosage forms was described by a number of authors. Skin penetration of methyl nicotinate was observed to occur rapidly from water solutions because of hydration of the skin, but was markedly slower from more viscous vehicles which reduced the hydration of the skin (476). The drug-releasing properties of ointments were demonstrated, using a diffusion membrane prepared from freshly removed skin of the rabbit (477). The ointment being tested was placed on the skin, which was carefully stretched over the opening of a diffusion cell, and the amount of drug that penetrated the membrane was determined in 3 hr. The results obtained by this technique for procaine and pentachlorophenol ointments were compared with those obtained using a cellophane membrane. The use of an agar plate technique to study drug release from ointments was also widely investigated (478–480). In general, the release of antibiotics from emulsion-type ointment bases containing surface-active agents or those of nonoleaginous consistency was greater than that observed from oleaginous bases. The interactions between hexachlorophene, polysorbate 20 (Tween 20), and polyethylene glycol

4000 were demonstrated by the hindered release of the antibacterial agent in the presence of the two surfactants.

The properties and usual components of transparent gels were carefully reviewed by Hynniman and Lamy (481). A special technique to observe the structural features of such gels utilizing the electron microscope following a freezing step to prevent changes in micelles was reported (482). Such techniques are necessary, since the components of such gels and emulsions are very difficult to observe microscopically. The use of polyvinyl alcohol in preparing transparent gels was discussed, as was the stability of various antibiotics in these gel systems (483–484).

The microbiological contamination of antibiotic ophthalmic ointments was examined (485). It was determined that 8 of the 114 batches tested were contaminated. The disadvantages of chlorohexidine as a preservative in nonstick ointments containing anionic surfactants was pointed out (486). The interaction of this preservative with stearic acid soaps and other anionic surfactants completely eliminates its antimicrobial activity. Further disadvantages of chlorohexidine are its inability to control certain *Pseudomonas* strains and its lack of fungistatic activity.

Other articles of interest relating to ointments and creams are described in Table XI.

Suppositories—The use of new suppository bases consisting of hydrogenated coconut oil and beef fat fractions was described (495). These bases compared favorably with cocoa butter and synthetic lauric acid glyceride bases and were shown to be nonirritating. The characterization of Witepsol, a new synthetic suppository base, was reported (496). This material was observed to contain di- and triglycerides, some monoglycerides, and an unidentifiable strong polar substance. A modified glycerin suppository was proposed, based on its different water absorption, solubility, hardness, and ability to release medication (497). The effects of varying the glycerin, gelatin, and sodium stearate contents of these suppositories were reported. The addition of saponins to oleaginous suppository bases was shown to increase greatly the liberation of triphthazine from them (498).

The release of medication from suppository bases received wide attention during the past year. In an excellent paper, Weiss and Sciarrone (499) described

the diffusion of salicylates across a hydrophobic membrane from cocoa butter to an aqueous layer. The release of the drug at the surface was observed to be controlled by diffusion. However, the transfer across the interface is a function of the partition coefficient; consequently, as the partition coefficient decreased, the release rate appeared to approach a limiting value. The release of chloramphenicol from suppositories prepared from different type bases was determined by an agar plate diffusion method (500). Although all of the bases tested gave similar antibiotic release after 2 hr., the suppositories prepared from polyethylene glycol bases showed a considerably better release after 8 hr. The water solubility of the drug was an important factor in the release from fatty-type suppository bases (501). The addition of viscosity-inducing agents such as Arlacel 161 or aluminum stearate or Aerosil had an inhibiting effect on the release of very soluble drugs but only a slight effect on difficult-to-release drugs. The addition of emulsifiers with increasing HLB values was observed to increase the release of soluble drugs from cocoa butter or Witepsol-type suppository bases (502). Optimum release occurred when the HLB value was greater than 10. The effect of the solubility and particle size of aminophenazone on its release from Witepsol suppositories was evaluated (503). As expected, release was most rapid when the drug was in solution and least when it was incorporated as large agglomerates. The effect of surfactants in increasing the absorption of triphthazine from fatty bases was ascribed to their surface tension-reducing properties (504, 505). Similar results were obtained with regard to the rectal absorption of oxytetracycline (506). Fatty-type suppository bases prepared with oil-water emulsifiers showed the greatest absorption, while similar bases prepared without the emulsifiers gave poor absorption of the antibiotic. Intermediate values were obtained with polyethylene glycol-type bases.

The complexation of anionic dyes with quaternary ammonium salts produces a material capable of coloring fatty base suppositories (507, 508). Such techniques must be utilized, because most common dyes are insoluble in the fatty acid glycerides and behave as pigments. The use of various carotenoid dyes, which are fat and oil soluble, to color fatty-type suppository bases was also presented (509).

Further articles of interest on suppositories are presented in Table XII.

Aerosols—Many papers published during the past year reviewed the principles and components of aerosol systems (516–527). These papers discussed operating principles of aerosols, components such as valves,

containers, dispensing mechanisms, typical aerosol formulations, filling techniques and equipment, propellants, and the many uses of aerosol products.

The kinetic theory of aerosols and droplet formation during coalescence were discussed in great detail in several papers (528–532). Equations were derived for the solution effect on droplet growth, generalizing this effect as a function of the mean ionic activity coefficient. Two processes were postulated to occur during liquid coalescence: drainage from the drop and Rayleigh disturbance. Interfacial tension and the viscosity of the dispersed phase were concluded to be contributing factors to drop coalescence.

The advantages of carbon dioxide as an aerosol propellant, especially for foods and cosmetics, were described (533, 534). Mixtures of branched-chain aliphatic hydrocarbons were proposed (535). These propellants, which are odorless, water resistant, non-corrosive, and physiologically inactive, may be used in a wide variety of sprays.

The effect of particle size, surfactants, and propellant on the depth of penetration of propylidone in dogs was studied (536). Greater depth of penetration into the lungs was obtained with powders in the 0.5–10- μ range, although concentration, ratio of propellants, and type of surfactants were also important factors. A cascade impactor was employed to measure the formulation factors influencing the particle size of dexamethasone phosphate aerosols (537). The aerosol particle was capable of being reduced in size by reducing the size of the drug particle, adding a surfactant, reducing the diameter of the spray orifice, increasing the propellant vapor pressure, and increasing the propellant temperature.

The effects of nonionic emulsifiers, buffers, and HLB values on the stability of emulsions used in aerosol foams were investigated (538). Factors affecting aerosol foam appearance were pointed out in an interesting paper (539). Prevention of aerosol propellant loss to the atmosphere will minimize foam wetness, while an increase in the amount of product ingredients in which the propellant is soluble and a lowering of the viscosity of the system will allow a rapid rise of bubbles and an improvement in the percentage of product that can be extruded as a suitable foam. Unusual aqueous aerosol foams and pearlescent aerosols were reported in other papers (540, 541). These new and unusual aerosol systems may find uses in the near future.

The incompatibilities of the components of the aerosol container with its contents were pointed out in several papers (542, 543). Some incompatibilities were those between the contents and the rubber or resin present in the valves and gaskets. The most serious consequence of such incompatibilities is the loss of propellant. A technique was described to test the swelling effects of aerosol contents on gaskets (544); this closed system equilibrates in 24 hr. and gives reliable results in 2 or 3 days.

Several authors evaluated techniques for sterilizing aerosols (545, 546). Sterile filling, bacterial filtration of the vehicle, γ -radiation, and incorporation of ethylene oxide into the gases were all tested for their effectiveness in producing sterile aerosols. Only the ethylene

oxide method was completely successful in producing a sterile product. The main disadvantage of this technique is its possible toxic effects if the aerosol is to be used in inhalation therapy. Other problems associated with the testing of aerosol products were discussed (547–549). The biggest problems were considered to be sterility of the product, corrosion of components, and chemical decomposition during storage. For determination of the propellants, a pressurized liquid-sampling technique and a gas chromatographic analytical method were proposed (550). Another paper described the use of cloud point titration to determine the propellant content of aerosols (551). As shown by tests on 10 commercially available aerosols, the dispensing efficiency of nonmetered topical spray aerosols is very low (552). The pickup efficiency of these aerosols was observed to decrease with an increase in the target distance or in the temperature of the aerosol and to increase with an increase in the nonvolatile content. The formulation, propellant systems, and storage conditions were shown to affect the uniformity of the dose dispensed by different metered valves, above and beyond the normal variation produced by the valves themselves (553).

The toxicological testing of aerosol products was reviewed from both the standpoint of skin and membrane reactions and the dangers of respiratory retention (554). Also discussed was a quantitative method of evaluating the chilling effect of topical aerosol sprays (555). The drop in temperature was observed to be a function of exposure time and to follow first-order kinetics. The chill index was determined and used to compare the chilling effects of commonly used aerosol propellant systems.

Further papers of interest relating to aerosols are presented in Table XIII.

Sustained Release—Several articles were published dealing with the terminology, the biopharmaceutical and technical aspects, and the advantages of sustained-release dosage forms (559–561). Equations for the kinetics of the liberation of drugs from sustained-release tablets were developed (562). These equations, which consisted of simplifications of Higuchi's equation for the case where a solid drug is incorporated in a solid matrix, were developed for low-solubility drugs. A method for measuring the permeability of water vapor through a polymer film by a radioisotope dilution technique was reported (563). This method was shown to be rapid, precise, and sensitive and also applicable to the investigation of other parameters which influence the permeability of water vapor.

The application of various epoxy resins in the preparation of pharmaceutical dosage forms was thoroughly investigated (564–566). The addition of basic and acidic curing agents was observed to influence the solubility of the resins in basic and acidic buffers. The type of resin, size of beads, and concentration of drug used were shown to affect the release of the drug. Hydrocortisone, pentobarbital, and papavarine were used as model drug substances in these experiments. Kornblum (567) reported a spray-drying technique which provides a free-flowing powder with decreased dissolution rate after compression into tablets. Since this technique gives good reproducibility of drug release after tableting,

558	Retention of Freon (fluorocarbon refrigerant) in poly-(N-cyanoacrylate)-sprayed films

it offers another method of preparing sustained-release products.

The chronology of development of a prolonged-action dosage form of proxiphylline was described in detail (568, 569). *In vivo* results indicated that tablets prepared by mixing the active ingredient with a synthetic lipid prior to tableting (embedded tablets) gave the best clinical results. The use of coated tablets did not give as suitable clinical results. *In vitro* comparison of these same formulations showed the liberation of the proxiphylline from the embedded tablet to be dependent on the particle size, the drug concentration, the pH, and the enzyme activity of the solvent system. The release from the coated tablet was much more rapid and was independent of pH and enzyme activity.

The ability of ethylene glycol monomethacrylate gel to hinder the release of drugs saturated in it was described (570). The *in vivo* plasma salicylate concentrations obtained following the administration of oral gels saturated with sodium salicylate confirmed this property of the gel. The effect of gel particle size on the release of the salicylate was shown. Poly vinyl acetate was used to coat micropearls of ascorbic acid to hinder their release (571). These coated granules slowly released ascorbic acid *in vitro* over 20 hr. in gastric and intestinal fluids. *In vivo*, ascorbic acid blood levels were obtained for periods of up to 20 hr. With tablets of ascorbic acid compressed with amyl sodium polyethylene, the release of the vitamin was shown to be inversely related to the degree of compression (572). This effect was postulated as being due to the differences in microstructure obtained by different forces of compression. In the case of *N,N'*-dibenzylethylenediamine ampicillin, the chemical modification was considered to prolong the release of the active drug (573). When administered intramuscularly once daily, this antibiotic had a bactericidal activity equivalent to orally administered ampicillin trihydrate given four times a day. Subcutaneous injection of zinc protamine glucagon gave a prolonged action compared with zinc glucagon suspensions administered to dogs under similar conditions (574). The differences in duration of action were believed to be caused by differences in the composition of the suspension media used.

Bolton (575) presented a method for calculating the release pattern of sustained-release products when more than 1-hr. release rates must be determined. This method is useful whenever hourly assays, as required by the Wiley method, are undesirable.

Other articles of interest related to sustained release are given in Table XIV.

Cosmetics—The trends in cosmetics and toiletries were well reviewed in several articles covering new cosmetic materials, testing methods, and types of prepa-

rations useful in cosmetics (583–586). The use of silicones in shampoos, hair sprays, hand lotions, aerosols, quick-breaking foams, toothpastes, and shaving creams was discussed (587, 588). Formulations were given for the types of silicone preparations used in these various products. The properties and uses of fatty acid lactylates were pointed out in a series of interesting articles (589, 590). The use of these materials in deodorant sprays, hair preparations, and shampoos was described. Brandau (591) discussed the various types of surfactants currently used in cosmetic preparations and presented formulations for shampoos, lotions, gels, and skin cleansers utilizing such surfactants. The foaming and surface-tension changes induced by several fatty acid sulfate ethers were described (592). Irritation studies of these materials in the rabbit eye indicated their lack of irritability and possible usefulness in shampoos. Materials which may be used as emollients were broken down into four general classes: hydrocarbons, vegetable fats, animal fats, and fatty alcohols. The properties and advantages of each group were discussed in an interesting review (593).

A series of articles pointed out the use of various materials, such as hexadecyl alcohol, metallic stearates, and vitamins in cosmetics (594–596). The properties of each of these materials, as well as typical cosmetic formulations, were described for each class of compounds. The use of zinc salts in cosmetics and as astringents was also discussed (597). The chemistry and biology of these compounds were thoroughly studied. Blake reviewed the application of radioisotopes in cosmetic research (598). The application and detection of such compounds were covered in detail. The use of tallow and coconut fatty acids to prepare soaps was discussed (599). The soaps were evaluated for their ability to dissolve, slush, lather, and swell. The effects of different ratios of these materials on the properties of the soaps were described.

In a series of articles (600–604), Gucklhorn fully outlined the advantages and disadvantages of the various preservatives used in cosmetic preparations. The bacteriologic spectra and reactions of the parabens, halogenated salicylonilides, organic mercurials, essential oils, sorbates, and other commonly used pre-

servatives were discussed. The antibacterial and antimycotic activities of undecylenic acid and mono- and diethanolamine were determined against a wide variety of organisms (605). Since all of these materials exhibit some antibacterial activity, formulations containing them were presented. In view of the nutritive properties of cosmetics, they are best prepared using bactericidal rather than bacteriostatic preservatives. The bactericidal levels of certain commonly used preservatives were described (606). UV light at 253 μ was utilized to purify water prior to its use in preparing cosmetics and pharmaceuticals (607). This UV method of sterilization was shown to be completely effective if carried out properly.

The use of the scanning electron microscope in cosmetic research was described (608). This instrument, which scans the topography of skin and nails, may be used to investigate the effects of cosmetics on skin. Various viscosimeters and their application in studying the rheology of cosmetics were also discussed (609).

Review articles on hair preparations and shampoos described typical formulations and laboratory techniques (610, 611). Amphoteric surfactants were described which give additional hair-conditioning properties to shampoos (612). The perfuming of soaps and a technique for determining the minimum odor intensity were discussed in several other interesting articles (613–615).

Packaging—During the year, many articles were published covering the use of plastics in pharmacy and pharmaceutical packaging. Varsano and Gilbert (616–618) had a series describing the effects of preservatives, pH, and temperature on plastic packaging materials. The biological effects of plastics and of drug-plastic interactions, along with newer packaging innovations involving plastics, were also reviewed. The properties of polystyrene, polypropylene, polyvinyl chloride, vinyl resins, and other general considerations relating to the use of these materials in pharmaceutical packaging were discussed (619–622). The interaction between silver nitrate solutions and polyethylene containers from various sources was investigated (623). Storage of these solutions in plastic containers resulted in the precipitation of silver particles and an increase in pH. Preservatives containing free hydroxyl groups were prone to adsorption by polyvinyl chloride containers (624). The solute composition and pH of the solute were also shown to be contributing factors. The stability of fatty oils in plastic containers, a measure of their oxygen permeability, was investigated (625). Hot, humid storage conditions were shown to cause clouding of neutral oils stored in plastic containers. Comparisons of various plastic and glass containers with regard to influence of pH, oxygen permeability, and catalytic action of the surface were ably made by Houta and Lenpin (626). The influence of plastic materials on the pH of water is nearly negligible compared with that of glass. The permeability of plastic material to oxygen has no substantial effect on the stability of easily oxidizable substances, although certain plastics are affected by strong oxidizing agents. The alkalinity of glass containers was the subject of several detailed articles (627–629). The importance of this alkalinity on liquid pharmaceuticals was pointed

out. The ions eluted from different types of glass following acidic or basic attack at 121° were also described.

The protective properties of packaging materials, the properties of rubber, its permeability to water, the permeability of glass to light, and the resistance of aluminum ointment tubes to corrosion were discussed (630).

The effects of sterilization on leaching from stoppers composed of natural rubber, IR-25, butyl rubber, POV-30, and polycarbonates were investigated (631). None of the material leached from these stoppers affected the medicinal or physicochemical properties of the solutions being sterilized. The use of polyethylene or cellophane liners over rubber closures of multiple-dose injection vials to protect the solutions was investigated (632). Although this technique was successful in protecting ascorbic acid or sodium sulfadiazine solutions, it was unsuccessful in protecting phenol solutions from the rubber stoppers.

EQUIPMENT

A thorough review of pharmaceutical engineering was presented in several articles (633–636). The engineering aspects and the equipment used in drying, analyzing particle size, and mixing of solids and liquids were described in these reviews. A comprehensive review of methods of mixing and of mixers utilized in the mixing of liquids was presented by Skidmore (637). The advantages and disadvantages of each system were pointed out in this excellent paper. An apparatus for adding suspensions or solids to reaction mixtures was evaluated (638). Wray (639) presented an excellent account of the uses of an instrumented rotary tablet machine. The effects of compression forces on tablet hardness, disintegration time, and tablet weight were given. The characteristics of good and bad formulations, as determined by the instrumented tablet machine, were described. The advantages and disadvantages of new tableting equipment were pointed out (640). The Industrial Pharmaceutical Technology Section (APHA Academy of Pharmaceutical Sciences) standards for tableting tools and the proposed inspection program for such tools were detailed (641).

A description of the concept of laminar flow and the equipment necessary for such systems was presented (642). The effectiveness and limitations of horizontal and vertical laminar flow systems were shown. The equipment used for color measuring and matching was described (643). The use of spectrophotometers for reflectance data and the tristimulus colorimeter to take into account the light source and color sensitivity of the eye was reviewed.

Filling equipment for tablets and ampuls was described in detail in two papers (644, 645). The ampul-filling equipment utilized an automatic magnetic logic setup which gave very reproducible filling volumes.

PHYSICAL PHARMACY

Yang (646), in studying polymorphism in sulfonamides, suggested that the *para*-amino group, the acidic *N*¹-hydrogen atom, and the oxygen of the sulfonamide

group are implicated in the various hydrogen-bonding arrangements that distinguish one polymorphic form from another. Functional groups attached to the *N*¹-position which serve as electron-withdrawing or electron-furnishing substituents apparently influence the strength of the hydrogen bonds formed and hence the tendency of compounds to exist in more than one crystal form. Through IR spectral studies, the physiological activity of the α -form of chloramphenicol palmitate was shown to be due to the weak intermolecular hydrogen bonding of the alcoholic hydroxyl groups. The β -form of this compound showed a very strong intermolecular hydrogen bonding of the alcoholic hydroxyl groups and is said to be physiologically inactive (647). Halebian and McCrone (648) reviewed the applications of polymorphism in the pharmaceutical industry. Their publication discussed the preparation of physically stable dosage forms, the possible differences in chemical stability with various polymorphs, the absorption of compounds exhibiting polymorphism, the tableting of polymorphic compounds, and methods of studying polymorphism. Rosenstein and Lamy (649) discussed the pharmaceutical aspects of polymorphism and suggested that the more energetic polymorphic form of a drug may be considered the form of choice in dosage form development.

Using an electrostatic model, Ladd and Lee (650) suggested that the process of hydrate formation takes place in two stages: (a) expansion of the anhydrous crystal and accommodation of gaseous water molecules, and (b) water-ion interaction. The maximum hydration of dimethylsulfoxide (DMSO) in aqueous solution at 25° was investigated by the deviation of experimental values of fluidity, dielectric constant, refractive index, density, and molar refraction from values calculated by linear interpolation between the values of the two pure liquids as a function of mole fraction. The maximum deviation in fluidity and dielectric constant occurred at the ratio of 3 water molecules per DMSO molecule, which was the maximum hydration (651).

The application of calorimetry to simultaneous determination of equilibrium constants and enthalpy changes for reactions in solution was discussed, and data were presented supporting a more optimistic evaluation of the calorimetric method (652). A calorimetric method was also employed to study proton ionization from aqueous solutions of protonated amines. Resulting enthalpy values were combined with pK values to calculate entropy values. The effect of hydrocarbon chain length and branching on entropy and enthalpy values for proton ionization from primary and secondary aliphatic protonated amines was described by a simple linear equation (653). Michaelis and Higuchi (654) demonstrated the influence of temperature on the distribution ratio of pharmaceutical ammonium species paired with various anions and between aqueous and organic phases, and they determined the thermodynamic parameters associated with these extractive processes. These authors concluded that, unlike transfer of uncharged solute molecules, ion-pair transfers involving inorganic anions appear to be largely entropically controlled. The process of movement from water to chloroform of dextromethorphanium halides, for

example, involved a material increase in ordering. Less polar organic phases tended to lead to less negative entropic changes.

Based on the principle of the higher kinetic energy of water particles in Brownian movement relative to the kinetic energy of particles dissolved in water, Wolkowski (655) presented a new hypothesis for the osmotic mechanism; it explains the principle of water penetration from lower pressures to the higher pressures which exist in solutions of higher concentration. Kostenbauder *et al.* (656) described the unique permeability characteristics of nylon film which make it a useful membrane for conducting dialysis studies or separations that are not readily accomplished with the semipermeable membranes more commonly employed for these purposes. The authors indicated that the permeability of nylon to drugs is not that exhibited by a porous membrane nor that of many nonporous membranes. Nylon is relatively impermeable to small molecules and ions such as water, urea, and sodium chloride; but many less polar, high-molecular weight nonionized species, as well as such ionic compounds as cetyl-, dodecyl-, and ethylpyridinium bromides and sodium naphthalene sulfonate, diffuse readily through nylon films (656). The diffusion rate of sennoside A through a cellulose membrane into water increased, irrespective of the temperature conditions under which diffusion took place, when the membrane was irradiated with ultrasound. These results were consistent with the hypothesis of boundary-layer disruption at the phase interface (657). Rushing discussed the osmotic properties of aqueous solutions of certain divalent salts of disulfonic acids (658).

Repta and Higuchi (659) described the preparation and chemistry of an unsymmetrical monomolecular crystalline anhydride of citric acid, and they suggested possible uses of this compound in pharmaceutical formulations.

Dissolution—Dissolution testing assumed increasing importance during the past year. Studies of three different lots of diazepam tablets revealed no correlation between the rate of disintegration and the rate of dissolution. Increased stirring rate and solvent volume, however, did accelerate the dissolution rate, as did the addition of polysorbate (Tween) (660). Tawashi (661) reviewed the current concepts of crystal dissolution and how dissolution rates and release patterns of drugs are related to such parameters as the cohesive forces in the crystal, which in turn are affected by crystal imperfections or defects. These defects explain some of the discrepancies between experimental and calculated yield strengths. Crystal defects included grain boundaries and cracks, lattice flaws, vacant sites, and foreign atoms outside the regular geometric pattern of the crystal. Other important factors noted in the review were crystal polymorphism, crystal impurities, dosage form additives, processing, and compaction, all of which may act to alter the dissolution rate of the dosage form.

In studying dissolution rates of high-energy polyvinyl pyrrolidone (PVP)–sulfathiazole coprecipitates, Simonelli *et al.* (662) demonstrated the apparent solubility and rate of solution of sulfathiazole from compressed tablets containing PVP to be greatly increased if sulfathiazole was previously coprecipitated with PVP.

683	Influence of polymer molecular weight and solvent pH on solvent penetration and polymer swelling in compressed disks of a series of polymer-free acids derived from ethylene maleic anhydride resins

The increase noted was found to be a function of the chain length of the PVP used as a coprecipitate and the sulfathiazole-to-PVP weight ratio of the coprecipitate powder mixture used to compress the tablet. Similarly, Bates (663) showed that a 1:6, reserpine–PVP, coprecipitate had a 200-fold increase in dissolution rate over that for pure reserpine. This was due to the reduced particle size and, consequently, to the increased surface area of the reserpine in the coprecipitate.

The relative rates of dissolution and solubilities of three polymorphic forms of chloramphenicol palmitate in a 35% tertiary butanol–water mixture and two polymorphs of mefenamic acid in dodecyl alcohol were measured. The thermodynamic relationships involving the transition of the metastable polymorphs to the stable one were examined; the significance of the energy differences between the polymorphs and their absorption, as reflected by blood levels in humans, were discussed (664).

An IR-attenuated total reflectance spectrophotometric technique was employed to demonstrate the surface reversion of methyl prednisolone Polymorph II to Polymorph I in the presence of water. The process was shown to occur rapidly enough to account for the slower than expected dissolution rates of nondisintegrating pellets of Form II in water. The unusual effects of agitation upon the dissolution rate of Form II pellets were thus explained (665).

A marked increase of dissolution rates and attainment of supersaturation of griseofulvin were found when the drug was dispersed by fusion or solvent methods in

matrices of polyethylene glycol (PEG) polymers, pentaerythritol, pentaerythrityl tetraacetate, or citric acid. Although the exact physical nature of the dispersion systems was not determined, it was suggested that some griseofulvin is molecularly and/or colloiddally dispersed in the PEG polymers due to their highly viscous and supercooling effect, which would retard the nucleation and growth of griseofulvin precipitation during the solidification process. Pentaerythritol and pentaerythrityl tetraacetate are believed to form limited or completely solid solutions with griseofulvin. The griseofulvin-citric acid mixture forms a glass, and the resultant glass solution may represent a new class or physical modification of drugs exhibiting a strikingly fast dissolution rate of griseofulvin (666).

A column-type method was described for the assessment of the dissolution behavior of solid dosage forms. The method, which is based on the mass transfer between solid and liquid phase in an exchange column, was shown to avoid certain disadvantages of the commonly used beaker methods employing fixed liquid volumes. Because of its reproducibility and the absence of arbitrary external parameters, the method appears to be useful for a meaningful study of dissolution kinetics (667).

Two samples of commercial aspirin with no crystallographic or solubility differences did, however, exhibit different thermodynamic activities, as determined by the effects of agitation and temperature on intrinsic dissolution rates. The metastable form was capable of rapid reversion to a more stable form, depending on the conditions of study (668).

Wagner (669) showed that, under sink conditions, the percent dissolved value at time t may simply be equivalent to the percent surface area generated to that time; if this is so, the percent dissolved-time data may best be described by a distribution function, and the parameters of the distribution may best be employed to describe the data. Simulated percent dissolved-time data, generated by means of the logarithmic normal distribution function, were shown to yield apparent first-order plots. Hence, apparent first-order kinetics, derived from *in vitro* dissolution tests on conventional tablets and capsules, may be artifacts in some cases. In the special case when surface area of drug available for dissolution decreases exponentially with time after some lag time, t_0 , first-order kinetics appear applicable to the dissolution data. The new method of examining dissolution-rate data is capable of providing characterizing parameters of greater potential utility than conventional treatments used previously. Gibaldi *et al.* (670) showed that dissolution from constant-surface pellets into micellar solutions followed first-order kinetics in agreement with theory. A method for determining the apparent zero-order rate constant for dissolution from constant-surface pellets, which does not require maintenance of sink conditions, was also suggested.

Low (premicellar) concentrations of polyoxyethylene lauryl ether and lysolecithin markedly enhanced the dissolution rate of salicylic acid powder, while pepsin and gastric mucin were without effect. The same surfactants enhanced the dissolution rate of aspirin from a tablet dosage form but were without effect on the dis-

solution rate of the drug from a capsule dosage form. Good correlation was observed between the surface tension of the polyoxyethylene lauryl ether solutions and the dissolution rates of aspirin from the tablet dosage form in these media. The authors discussed the relevance of these data to design of *in vitro* dissolution tests (671).

Additional studies on dissolution are provided in Table XV.

Table XVI describes references on the measurement of particle size.

Additional references on physical pharmacy are provided in Table XVII.

Solubility—Paruta (699) in determining the solubilities of methyl-, ethyl-, propyl-, and butylparabens in a series of normal alcohols, noted that these compounds have a dielectric requirement of about 14 with another postulated to exist at about 30. These compounds exhibited a good parallel solubility in the various alcohols, indicating a similarity of interactions in the dissolution

process. In aqueous solutions of dioxane, these same *n*-alkyl parabens had a dielectric requirement of about 8–10. Two-phase systems were found for certain of these paraben derivatives over a given composition range of the binary solvent mixture, suggesting the production of a solvate between the paraben and a fixed composition of the binary mixture, thus forming a biphasic system in equilibrium (700). Similar conclusions relative to solvate formation were drawn from an investigation of the solubilities of *n*-alkyl parabens in binary mixtures of ethanol and water. With the latter solvent system, a dielectric requirement of 29–32 was suggested for *n*-alkyl parabens (701).

Several interesting papers dealing with micellar solubilization were published in the past year. Oil-soluble surfactants were studied as solubilizing agents for water-soluble food dyes in the solvent perchloroethylene. In the absence of water, no solubilization of dye occurred; but above a minimum water-to-surfactant ratio, the dye was soluble to a measurable degree. The author concluded that the CMC decreases linearly with an increasing water-to-surfactant ratio (702). The solubility of testosterone, methyltestosterone, and testosterone propionate in aqueous solutions of ethoxylated

cholesterol was determined and found to be greatest for the propionate derivative. Based on the UV spectral characteristics of the three steroids in aqueous solutions of the surfactant, which were similar to those in various polyethylene glycols, the mechanism of solubilization was reported to involve association of the steroid with the polyoxyethylene portion of the surfactant (703). Wan and Hwang (704) showed that the solubilities of a series of alkyl gallates in water and in cetomacrogol solution increased with a decrease in alkyl chain length. The solubilities of the short-chain gallates in benzaldehyde increased, while those of the long-chain gallates decreased with chain length. The comparative antioxidant efficiency in solubilized systems appeared to be related to the distribution ratios, and that in emulsified systems to the solubility of the antioxidant in the aldehyde. Thakkar and Hall (705) attempted to explain the anomalous initial supersaturation observed in solubilized systems of testosterone and concluded that the behavior was related to conversion of the anhydrous crystal form to a hydrate crystal form. In studying the solution behavior of the anhydrous form, the authors noted that the peak solubility time in surfactant solution was either increased or decreased relative to water, depending on the concentration and type of surfactant used.

Using ultracentrifugation and viscometric techniques, the behavior and state of aggregation of barium dinonylnaphthalene sulfonate in toluene, toluene-methanol, and methanol were studied, and methanol was shown to diminish the size of sulfonate and carboxylate micelles in nonaqueous solutions (706).

Phenobarbital USP, when crystallized slowly at room temperature from 50% aqueous acetone, dissolved faster in single crystal as well as in powder and tablet form than did an anhydrous form of phenobarbital crystallized in a similar manner from a saturated solution of 85% ethanol. With heat or upon storage in a dry atmosphere, the hydrated crystal form was converted to the anhydrous crystal form (707).

Guess and Jones (708) showed that the degree of solubility of ethylene oxide in plasticizers is a function of the chain length of the plasticizer hydrocarbon moiety. They concluded that the degree of polarity of the plasticizer might, therefore, be a great factor in controlling the solubilization.

The solubility of free modified cellulose polymer films was found to be decreased in the presence of certain FD&C and D&C red dyes. These same dye-containing polymers, when employed as coatings on riboflavin tablets, retarded the tablet disintegration time and the riboflavin dissolution rate. Riboflavin urinary excretion studies confirmed that the dyes may adversely affect *in vivo* product performance (709).

Additional studies of solubility are listed in Table XVIII.

Complexation—Higuchi *et al.* (729) reported a study of some of the methods available for the experimental measurement of hydrogen-bonding interactions in the formation of complexes and the means of determining the association (equilibrium) constants from the experimental results. An attempt was made to develop suitable methods for the quantitative analysis of hydrogen-bond-

ing data so that useful estimates of association constants could be made *a priori*. The study also showed the effect of a nonaqueous solvent on the value of the association constant, and a method was provided whereby an estimate of solvent interaction could be calculated. A critical evaluation of the utility of thermal methods for the detection of possible interactions between the solid components of pharmaceuticals was reported. Phase diagrams were constructed for a number of binary systems. Using thermal methods, interactions were detected with deoxycholic acid–menadione, quinine–phenobarbital, theophylline–phenobarbital, and caffeine–phenobarbital systems (730). Evidence for the interaction of procaine and procaine amide with ATP in aqueous solution was found by means of optical rotation and NMR measurement. The aromatic components of drug and nucleotide molecules were shown to associate through hydrophobic bonding with vertical stack formation rather than through horizontal bonding (731). A simple and general procedure for calculating the statistical factors of mixed ligand complexes was presented. It was noted, for example, that the formation of a mixed complex, MAB, from a metal ion, M, in the presence of equal concentrations of Ligands A and B, is always favored, on a statistical basis, over the formation of MA₂ or MB₂. Thus, there is an enhanced probability of bringing together two different ligands, or a small substrate molecule and an enzyme, *via* a metal ion—a fact which may have great biological implications, particularly as regards the multimetal–multiligand systems in biological fluids (732). Spectroscopic studies on complexation between caffeine and benzoic acids were reported. The relation between the free energy change and the pK_a for benzoates suggested that direct electrostatic forces between the carboxyl group in the benzoate molecules and the nitrogen of the 7-position in the caffeine molecule play a dominant role in the complexations (733). The physical and chemical properties of complexes of mono-, di-, and triethanolamine with bentonite, kaolin, and other clays were reported. A triethanolamine–bentonite complex having optimum swelling characteristics at pH 7 gave good stabilization of aqueous suspension. Electrolyte concentrations greater than 1% decreased the stabilization effect of the complex (734). Polli and Frost (735) investigated the role of PVP as a stabilizer for hexylresorcinol in a compressed tablet. While the presence of PVP was shown to be responsible for the color stability of hexylresorcinol, the antimicrobial activity of hexylresorcinol was found to be reduced in the presence of PVP. This reduction in activity was apparently due to the molecular interaction between hexylresorcinol and PVP, and indicates the need for biological evaluation of complexes whenever their formation is suspected. The apparent stability constant of the salicylic acid–caffeine complex was studied in a medium of varying polarity. The salicylic acid and caffeine interacted very strongly in the nonpolar solvent, presumably by hydrogen bonding, but their interaction was minimal in the moderately polar solvents. Because the complexes differ in the organic and aqueous phases, they are not likely to penetrate the phase boundary when the caffeine and salicylic acid are allowed to partition between these phases (736). By this means, Krivis and Rabb (737) reevaluated the

Cu–isonicotinic hydrazide system and obtained evidence for the formation of a Cu (I) species rather than a Cu (II) species. The reduction of Cu (II) to Cu (I) and the subsequent formation of an isonicotinic hydrazide complex with the latter ion may be the critical reaction responsible for the therapeutic efficacy of isonicotinic hydrazide. The stability constants and the enthalpies of formation of complexes of caffeine and sodium salts of aromatic acids showed that the stability of the complex is the most important factor in the solubilization of caffeine by these salts (738). The interactions of ergotamine tartrate and caffeine between pH 1 and 6.65 demonstrated that there are marked changes in the solubility of the alkaloid with increased caffeine concentration. Caffeine enhanced the dissolution rate of ergotamine tartrate by a factor of 3 at gastric pH (739). The degree of sorption of chlorobutanol-¹⁴C by polyamide and polyethylene was determined using scintillation spectroscopy. The magnitude and rate of sorption were measured, as well as the standard chemical potentials, heats of sorption, and standard entropy values (740).

Additional references on complexation are provided in Table XIX.

Surface Phenomena—To aid the reader in locating areas of specific interest, the authors of this review have subdivided the various publications dealing with surface phenomena; however, because of the obvious overlap in subject matter, the reader who needs a thorough review is advised to consider the entire section.

Interface Studies—The absorption of cellulosic ethers at lipid–liquid/water interfaces was studied in order to clarify the role of polymers in depressing the rate of drug transfer. Carboxymethylcellulose lowered the interfacial tension only when the lipid was nonpolar and the aqueous phase was acidic. Hydroxypropylcellulose markedly depressed the interfacial tension regardless of the polarity of the lipid phase or the pH of the aqueous phase (777). Air–water interface adsorption studies were conducted using seven members of a homologous series of *N*-alkyl betaine zwitterionic amphiphiles. The standard free energies of adsorption were calculated and resolved into separate contributions from polar head groups and methylene groups in the alkyl chain. The data were compared with previously published data for the same compounds undergoing micellization (778). A similar study was made of the properties of monolayers of normal alkyl betaines at the air–water interface. Condensation of the films at pH 4.5–6 was ascribed to the formation of the zwitterions, but there was no indication that an anionic species is produced on alkaline substrates. The entropies and enthalpies of spreading suggest that there is intramolecular neutralization of charges between N⁺ and COO[−] groups in each molecule (779). The adsorption of cetyltrimethylammonium bromide at different concentrations of the liquid paraffin–water interface was measured by an interfacial tension-lowering technique as well as by an emulsion technique. The experimental data on adsorption appeared to fit both the Freundlich and Langmuir adsorption isotherms (780). On the basis of previous work on interface potentials in amino acid solutions, a structural scheme of interactions between nonpolar radicals and water molecules was sug-

gested. The aqueous molecules are spontaneously oriented at the interface, with nonpolar substances forming a maximally dense monomolecular layer. This layer forms a basis on which other layers can be formed by hydrogen bonding (781). An apparatus and technique to obtain accurate surface pressure measurements were described, and a single valid surface pressure area per molecule curve was constructed for an insoluble cationic film spread from pure water onto a substrate of sodium chloride solution. With this curve and the results obtained by a crystal spreading method, it was shown that the old criteria for assessing the reliability of the π times area results for an expanded film are invalid and that the spreading of solvents is a major source of error (782).

Additional studies on interface phenomena are described in Table XX.

Surface Tension Studies—Zettlemoyer and Rao (800) reported that the DuNuoy procedure for measurement of surface tension of anionic sodium α -sulfo fatty acid ester surfactants did not give reproducible values, thus indicating that the equilibrium surface tension is too variable for a given solution using this testing procedure. The surface thermodynamic properties of a series of alcohols (C₆–C₁₈), cellosolves, and carbitols were derived from surface tension measurements at various temperatures. A systematic variation of thermodynamic properties with respect to chain length and change in temperature was observed with the alcohols and cellosolves (801). The surface tension of pure liquids was shown to depend on the miscibility of the phases and the orientation of the molecules at the interface. As a function of temperature, the surface tension isobars were concave at elevated pressures but were straight lines at lower vapor pressures. The temperature coefficient of surface tension is affected by the decrease in surface tension resulting from an increase in the saturated vapor pressure and by

the increase in the mobility of the liquid phase molecules with increasing temperature (802). A method was described for substituting a dynamic measurement of surface tension in aqueous solution for the usual static measurements. The dynamic method shows a time-dependent accumulation of surfactants and a change in the surfaces prior to their reaching equilibrium (803). The influence of temperature and added electrolytes on the dynamic surface tension of sodium dodecyl sulfate solutions was examined by an oscillating jet method. An increase in temperature increased the initial rate of surface tension lowering but had little subsequent effect. Addition of electrolytes increased the subsequent rate but had little effect on the initial rate (804).

Additional references on surface tension studies are provided in Table XXI.

Wetting and Contact Angle Studies—The minimum depth of free energy corresponding to an equilibrium in thin liquid films was determined by measuring the contact angle between the film and the bulk solution. The significance of this angle and its relationship to conventional contact angles were discussed and an experimental method for measuring it was described. Results were also provided for solutions of sodium dodecyl sulfate containing sodium chloride (821). Shafrin and Zisman (822) reported on a new class of surfactant compounds designed to adsorb on solids to improve adhesion of liquids, resins, and protective coatings. Shortening the aliphatic chain from chlorophenyldodecanoic to chlorophenylacetic acid influenced the wettability properties

but also permitted use of solvents such as water. A technique was developed for measurement of contact angle in the transition zone between very thin and thick liquid films, based on the Wilhelmy plate technique for measuring surface tensions of liquids. Results were obtained at 25° for films stabilized with sodium dodecyl sulfate in varying amounts of sodium chloride (823). Equations were derived which described the thermocapillary flow of liquid films spread on hydrophilic surfaces and consisting of two layers having different rheological properties. The layer adhering to the solid surface was presumed to exhibit viscoelasticity and the top layer to exhibit Newtonian flow patterns. Dimensionless velocity gradients were established according to layer thickness (824). A theoretical formula was presented for the spreading of a spherical droplet on a smooth rigid surface, based on the assumption that spreading is impelled by surface tensions at the interface and retarded by viscous flow of the droplet. Equations were also derived to predict the rate of spreading and change of contact angle with time (825).

Additional references on wetting and contact angle studies are provided in Table XXII.

Micelle Studies—Frank and Zografi (832) stated that di-(2-ethylhexyl)sodium sulfosuccinate, when dissolved in various hydrocarbon solvents, was capable of solubilizing large amounts of water, whereas closely related compounds such as the di-*n*-octyl and di-*n*-hexyl derivatives exhibited negligible solubilizing capacity. Using light-scattering techniques, the authors measured the micelle size of these three compounds in *n*-octane and

found large differences in micelle weight between di-(2-ethylhexyl)sodium sulfosuccinate and the other compounds in *n*-octane and suggested a significant role for the 2-ethyl side chain. The active participation of water in the organization of these micelles was suggested by significant changes in micellar weight well in excess of that accounted for by the added amount of water. The influence of different hydrocarbon solvents on micelle weight was also found to be quite significant. The effects of a series of nonionic surfactants on micellization of an anionic surfactant was studied as a function of mole ratio and polyoxyethylene chain length. Changes in the degree of association of the anionic surfactant brought about by its incorporation in the mixed micelles was also studied. The degree of ionic dissociation of ionic surfactant in mixed micelles increases as the proportion of a nonionic material increases and as the polyoxyethylene chain is lengthened. At low concentrations, specific conductances are smaller for mixed solutions than for anionic solutions alone, whereas at higher concentrations, mixtures have greater conductance. These results are explained by the degree of ionic dissociation and the mobility of the mixed micelles (833). Micellar weights were determined from mixtures of nonionic and anionic surfactants. The degree of association was less than that calculated, showing the existence of mixed micelles. The increase in micellar weight with rising temperature, characteristic of nonionics, is suppressed by adding anionic surfactants. The micellar weight and the degree of association increased in the presence of sodium chloride (834). Schott (835) noted a remarkable resemblance in the shape, compactness, degree of hydration, and intrinsic viscosity of solutions of globular proteins near their isoelectric point and of nonionic detergent micelles. The polarographic micelle point values of nonionic surfactants were determined by a polarographic maximum suppression method in the presence of electrolytes. These values did not compare well with the CMC's obtained by other methods, which were always higher. These differences were explained as due to the presence of ions which influence the water structure, causing a lowering of the CMC value (836). The decrease in the CMC caused by electrolytes was interpreted in terms of a salting-out mechanism, and

evidence was offered in support of the contention that micelles of polyoxyethylated nonionic detergents have a weak positive charge. The effects of urea and formamide on CMC values indicate that hydrophobic bonding is lessened in their presence, with a resulting increase in the CMC (837). Sodium and potassium caprate, laurate, and myristate solutions, both below and above the CMC, were titrated with HCl. By simultaneous monitoring of hydrogen-ion and potassium-ion activity during the course of the titration of micellar laurate solutions, the authors were led to conclude that hydrogen ion competes with potassium ion at the negatively charged micelle-solution interface (838). Keymer (839) noted the unclear relationship that exists between CMC and molecular size or structure, pointing out that the CMC values of anionic substances decrease with an increasing ratio of hydrophilic to hydrophobic portions of the molecule, but that the CMC values of amphoteric, nonionic, and free acid molecules behave in a reverse manner. The author stated that as the aqueous solubility increases, the formation of micelles is reduced and the CMC increases, and if the solubility approaches infinity, no micelle formation is possible. Wan and Poon (840) studied the effect of salts on the surface interfacial tension and CMC of surfactants and noted that all the salts used produced shifts in the CMC to lower concentrations and reduced the surface interfacial tensions of air-surfactant solution and liquid paraffin-surfactant solution. No appreciable difference was observed when air was substituted for liquid paraffin as the upper phase, indicating that the hydrocarbon layer exerts no pressure effects. Shifts in the CMC were related to the valency of the gegenion, with a divalent gegenion producing a shift much greater than a monovalent gegenion. The CMC of cetomacrogol 1000 was practically unaffected by the addition of salt, and the extent of interfacial tension reduction was small with respect to salt concentration when compared with corresponding systems containing ionic surfactants.

Table XXIII provides additional references on micelle studies.

Adsorption Studies—The adsorption of cyanocobalamin on talc is remarkably repressed by polyvinylpyrrolidone (PVP); this phenomenon is due to the preferential adsorption of PVP by talc and not to any direct interaction between PVP and cyanocobalamin (874). Study of the sorption characteristics of cationic surface-active agents by a polyamide (nylon 6,6) showed that maximum sorption occurs in the region of the CMC of the surface-active agent. It was theorized that the hydrophobic moiety of benzalkonium chloride, a cation, interacts with the nonspecific sites in the hydrocarbon units of the polyamide (875). The surface behavior of aqueous dispersions of cholesterol was studied by microelectrophoresis and the adsorption of radiolabeled surface-active agents. Although bile salts were not greatly adsorbed on cholesterol, they did retard its crystal growth, apparently because their nuclear structure permits adsorption at those sites governing the rate of crystal growth but is too rigid to permit general adsorption at all sites and surfaces (876). The equation of state of an adsorbed film was used to derive both a more general equation of equilibrium and an analytical

expression for the heat of adsorption as a function of the amount adsorbed. The van der Waals equation was used to show that forces of molecular interaction on the surface of the adsorbent are generally repulsive and account for variation in the adsorption of heat with the amount adsorbed (877). Adsorption isotherms were obtained from the adsorption of methylene blue by carbon black, indicating that dye adsorption increases with increasing pH until the amount of dye adsorbed becomes constant between pH 7 and 9 (878). Based on simplified models of an adsorption system, equations were derived for estimating the role of various factors in adsorption. The relative surface activity of adsorbates which adsorb at a smooth adsorbent-liquid interface was estimated as a function of the state of distribution of molecules before adsorption, the structure of adsorption layers, the size and shape of adsorbate molecules, the orientation of adsorbate molecules in the adsorption layer, the interaction energy of adsorbate with solvent and adsorbent, and the interaction energy between adsorbate molecules (879). When large organic molecules diffuse through a multiphase matrix containing water, dispersed water-insoluble solvents, proteins, etc., they become partially immobilized by adsorption, the overall effect being a decrease in the apparent coefficient of diffusion. To differentiate the effects of sorption and free diffusion, a model was proposed which assumes a rapid, dynamic equilibrium between the diffusible and sorbed species. Fick's law is assumed to apply for the diffusing species, while the sorbed species is assumed to be immobile. Results show good agreement between the measured rate and that predicted by the model (880).

Surface Area and Porosity Studies—Giles and Trivedi (923) described a rapid semimicro method for the determination of the specific surface of solids by dye adsorption. The method utilizes known volumes of solutions of rated concentrations, with which the solid is shaken and the adsorbed weight determined by analysis. From these data the adsorption isotherm is plotted, the level of the plateau representing the amount of dye in a complete monolayer on the surface. The authors have successfully used microporous silica, alumina, and graphite as solid adsorbents. The theory of multilayer adsorption on solid adsorbents was statistically and mechanically formulated by taking into account the lateral attractions between adsorbate models. The theory was generalized to a mobile adsorption on flat, homogeneous surfaces (924). Henson and Hunter (925) presented criteria for determining the best setting of relative pressures at which to conduct adsorption determinations so that a good estimation of the capacity and surface area of the monolayer can be obtained. Experiments were selected by maximizing a function of partial derivatives of equations at specific values of the parameters. *p*-Nitrophenol in water or in benzene solution and several dyes were used to measure the apparent specific surface of porous charcoals, silicas, and alumina by adsorption. The results reveal a relation between the apparent surface and pore size distribution (926). An apparatus was developed for B.E.T.-type adsorption measurements for surface area determinations. The apparatus is purported to expedite the measuring process and the evaluation of the resulting data (927). An air-permeability method compared favorably with the B.E.T. method for determining specific surface areas, owing to the smaller surface microporosity, but the calculated average particle diameters only

roughly coincided with those from microscopic measurements (928). Conductometric titration of clay suspensions with dodecylamine hydrochloride solutions was presented as a rapid method for the determination of surface area of clay particles suspended in aqueous media (929). A critical examination of the different methods proposed for the measurement of surface area of solids led to the development of a differential volumetric measurement technique (930).

Diffuse (Electrical) Double-Layer Studies—Jones (931) reported on the relation between surface charge density and the double-layer potential of soap films. With the aid of the Gouy-Chapman theory of double-layer potential, surface charge density, and electrolyte concentration in liquid films, it was shown to be more realistic for systems to behave as though characterized by constant surface charge density than by constant potential. Conway and Gordon (932) directed attention to some of the problems arising in the treatment of the double layer which can usefully be considered in light of similar or related problems regarding ionic solutions. They provided a table which compares the problems observed under conditions of ionic equilibrium with those observed in double-layer systems. Becher (933) published an excellent review on the theory of the electrical double layer, including a complete solution of the case of the diffuse double layer for an infinite flat plane. The effect of adsorption, ionic strength, and pH on the potential of the diffuse electric layer was described (934), along with an evaluation of the electrical double layer on silica in the presence of bivalent counterions such as magnesium, calcium, and barium (935). Electrophoretic measurements were made of micelles of dimethyldodecylamine oxide and betadodecylaminopropionic acid in 0.1 *M* sodium chloride solutions of varying pH. The electrical double layer around the micelle at different pH values was then constructed according to the Stern theory (936).

Foam Studies—The effect of electrolytes on the foam stability of aqueous solutions of nonionic surfactants was discussed (937). A study was made of the relation between the initial foam height, as measured by the Ross-Miles test, and such factors as concentration of the surfactant, CMC of the solute, surface tension of the solution, surface area of the foam, and the work involved in the production of the foam surface (938). Ranny (939) reported that optimum foam volume and stability were achieved with surfactants having long, straight carbon chains with the hydrophilic groups at one end. Shifting of the hydrophilic groups toward the middle of the chain decreased the stability of the foam.

General Studies on Colloids, Gels, and Sols—A silver iodide sol, when coagulated by aluminum sulfate in solutions acidified with sulfuric acid, showed an increase in the critical coagulation concentration with a decrease in the pH. This result, which was attributed to the formation of an AlSO_4^+ complex, indicated that the antagonistic effect observed when coagulation is carried out with pairs of electrolytes may be entirely due to counterion complexing (940). Napper (941) considered the stabilization of colloids by nonionic hydrophilic macromolecules to be steric. The stability of ion-stabilized colloids in the presence of surfactants was

reported; according to this concept, the stability of the sol depends on the recession of the electrical double layer and the thickening of the adsorbed film of soap on the particles, a process which lowers the molecular forces between them (942). Dukhin and Stoilov (943) critically reviewed the three most frequently used methods for determining the permanent dipole moment of anisodiametric colloid particles. A method was reported for modifying the texture of aluminum phosphate gel by thermal treatment (944), and a description was given of a procedure for incorporating oils into transparent gels without the development of haze during storage (945). By studying the colloidal stability of silver iodide at levels far above the coagulation concentration, it was shown that sols do not restabilize at salt concentrations up to 3 *M*, even though a repulsive force can exist at such levels (946). Current views on the stability of colloidal solutions were discussed, along with approaches to stabilizing these systems (947).

Studies on General Properties of Surface-Active Agents—A comparison of HLB values according to two prevailing systems was made for two classes of nonionic surfactants, namely, the ethylene oxide adducts of *n*-dodecanol and of branched nonylphenol with increasing degrees of polyoxyethylation. The two systems were shown to differ fundamentally in that only one treats the HLB value as constitutive and additive. For both HLB systems, simple relationships were found between the HLB values of each class of surfactants and their critical micelle concentrations. These relationships have different forms for the two systems and, within the same system, different numerical values for the two classes of surfactants (948). Schott (949) compared the cloud points of 165 nonionic surfactants, based on their calculated HLB values. Increasing length of the polyoxyethylene moiety increased the HLB and cloud points. The equations for calculating the HLB, which had been derived from emulsification experiments, contained the weight-percentage of polyoxyethylene as the sole variable characterizing the surfactant. Therefore, the calculated HLB was not affected by the surfactant characteristics, which largely govern the values of cloud point, CMC, and interfacial tension. Additional HLB measurements would be needed to determine whether all experimental HLB values are really independent of the structure of the surfactant molecules, as proposed. The properties of sodium alkane (C_{13} to C_{19}) sulfonates were determined and shown to be highly dependent on their molecular weight (950). While studying the turbidity point of nonionic surfactants, it was noted that the length of the hydrophobic alkyl group influences the cloud point, contrary to the dehydration theory, which assumes clouding to be due to the hydrated ether groups of the surfactant (951). A change was observed in the physical and chemical properties of surface-active semicolloid solutions after magnetic field treatment. Concentration of surfactant above the CMC, by destroying micelles, caused an increase in the amount of the ionic form of the surfactant and, consequently, an increase in conductance and decrease in surface tension (952). Felmeister and Schaubman (953) reported on studies in which a monomolecular film of dipalmitoyl lecithin was spread on an aqueous phase into which a

photosensitive phenothiazine drug was dissolved. The system was then exposed to UV radiation, and the resultant changes indicated that substitution in the 2-position of the phenothiazine nucleus is critical in the photosensitized interaction. In a similar study, the same authors proposed a relationship between the increase in surface activity induced by irradiating a drug and its *in vivo* photosensitizing properties (954). ζ -Potential measurements were made of plasma, bile, and solutions of albumin, calcium, and sodium chloride in order to evaluate their effect on the net surface charge of suspended particles (955). To test the validity of ζ -potential as a determining factor in the stability of colloidal systems, and the possibility that electrolytes might change the electrophoretic properties of colloid particles by their influence on ζ -potential and solution ionic strength, the electrophoretic mobility of suspensions of solid emulsion particles of paraffin with stearic acid, using petroleum spirit as a spreading solvent, was studied as a function of salt concentration. The electrophoretic mobilities were strongly influenced by the nature of the counterion, making it necessary to modify the equations expressing the effect of decrease of repulsion potential attributed to a hydration barrier (956).

Additional studies on general properties of surface-active agents are provided in Table XXV.

Crystallization—Lin and Lachman (973) reported that different crystal forms were obtained on dissolution and recrystallization of a new antihypertensive agent, as determined by X-ray diffraction, IR, and photomicrographs. A method was developed, based on dissolution rates, for estimating the ratio of crystalline drug to that dispersed at the molecular level within a carrier. Under appropriately chosen conditions in the two diverse systems, the dissolution rate of the drug was linearly related to its degree of crystallinity (974). Methods of preparation and characterization of two crystal forms of sulfathiazole, using differential scanning calorimetry and IR spectroscopy, were presented. The transition temperature depended on the rate of heating and the sample source. Interconversion of the crystal forms under different conditions, such as heating and suspension in water, was described. An assay procedure was devised, based on the area of the thermal transition peak of Form I, and results of analysis of synthetic mixtures of Forms I and II were given (975). To obtain basic data on crystallization of the molecular compound of aminopyrine and baribital from aqueous solution, the diagram of the ternary system aminopyrine-baribital-water was studied in the temperature range 0–98°. The molecular compound was best obtained by using an excess of aminopyrine and by crystallizing from concentrated solution at high temperature (976). Marshall and Nancollas (977) investigated the kinetics of crystal growth of dicalcium phosphate dihydrate and showed that, after a brief initial surge, the rate of growth of crystals follows a second-order rate, with respect to calcium and biphosphate concentration, over a wide range of calcium and phosphate concentration, suggesting a predominantly surface-reaction controlled process.

Similarly, the kinetics of calcium sulfate precipitation from aqueous supersaturated solutions containing gelatin or sodium carboxymethylcellulose were studied. The rate of precipitation was shown to depend upon the rate of conglomeration of the calcium sulfate colloidal particles present in the system. Gelatin and sodium carboxymethylcellulose concentration and pH all affect the kinetics. Above the isoelectric point, gelatin slows down precipitation, but below this point the precipitation is accelerated. The negatively charged carboxymethylcellulose stabilized the system and was more effective than gelatin in this regard (978). Phenobarbital can be freed of impurities, especially occluded mother liquor, by controlled crystallization (979). The aging of an aqueous suspension of amorphous aluminum hydroxide was followed in a simple dilatometer. Initially, an increase in volume was observed, and the simultaneous development of pseudoboehmite was revealed by X-ray diffraction. The subsequent formation of a trihydroxide was accompanied by a decrease in volume. Rheological measurements showed that the formation of pseudoboehmite through a condensation polymerization process was accompanied by gelation. The gel structure could eventually hinder the growth of pseudoboehmite particles, with a consequent discontinuity in the kinetics of the process (980).

Rheology—Rheological studies of triethanolamine-bentonite gels revealed their typical thixotropic characteristics (981). By postulating that thermodynamic transportation coefficients may be related to the friction that occurs in viscous flow, a relation between the viscosity and the intradiffusion coefficient was obtained for multicomponent systems (982). Several proposed mechanisms of thixotropic behavior of montmorillonite-water systems were evaluated and the effects of temperature, reshearing, concentration, and storage time on these systems were studied by NMR and rheological measurements. The specific parameters used were the change in line width of the NMR spectrum and the static yield values obtained from the rheograms. The results were in complete agreement with the theory that the colloidal particles, upon contact, adhere to form a spacious matrix resembling a house of cards (983).

Additional studies on rheology are provided in Table XXVI.

PHARMACEUTICAL ASPECTS

Radiopharmaceuticals—Spencer *et al.* (996) demonstrated that, in man, aluminum phosphate gel reduces the absorption of radiostrontium by 85% and the absorption of radiocalcium by only 38%. Vertua (997) reviewed the theoretical concepts and applications of radioisotopes in pharmacology. Another article reviewed the compounds which protect against radiation and discussed possible mechanisms (998). Another described radioactive medicinal substances (999).

Antibiotics—In reviewing the chemical aspects of penicillin allergy, Schwartz (1000) discussed the biochemical basis of drug allergy and the antigenic determinants of penicillin allergy and penicillin metabolism. He concluded that more work should be directed toward defining degradation products, their rate of formation, and their ability to react with protein. Benzyl penicillin and 6-APA were shown to contain small but significant amounts of high molecular weight protein impurities attached to penicilloyl groups. These impurities stimulate formation of the antibodies with penicilloyl specificity that may be responsible for penicillin allergies (1001). The amphoteric penicillins, ampicillin and cyclacillin, possess properties similar to the alicyclacillinphatic amino acids. At a pH equal to the isoelectric point, they exist essentially as zwitterions, and in this form are most stable and least soluble in water. The aqueous solubility of ampicillin changes only slightly with a change in ionic strength, unless a nonpolar solvent is added. In water at 25° the carboxyl groups of all penicillins appear to have the same pK_1 , while the amino groups of the amphoteric penicillins vary in the pK_2 values over a wide range, probably being influenced by the adjacent side-chain groups. A change in the dielectric constant affects the pK_1 more than the pK_2 , while a change in temperature does the opposite (1002). Cyclacillin (WY-4508) was shown to have more selective *in vitro* activity than ampicillin against a variety of Gram-positive and Gram-negative organisms. Rapid absorption follows oral administration of this new antibiotic, with 44% renal excretion in 24 hr.

(1003). Lincomycin-2-phosphate was inactive in a plate antibacterial assay using *Sarcina lutea*, although *in vivo* the phosphate ester is as active as the parent compound, lincomycin, in mice infected with *Staphylococcus aureus*. The ester gave slightly higher blood levels than the parent compound upon oral administration to dogs. In addition, the ester has a less bitter taste than the parent compound (1004). Compared with tetracycline, doxycycline has equal or better *in vitro* activity against a wide range of organisms. A greater lipid solubility and a greater degree of binding to serum protein was also noted for doxycycline (1005). The bactericidal activity of various deoxystreptamine antibiotics was tested against a large number of organisms *in vitro* and in mice. Good correlation was seen between the *in vivo* and *in vitro* activity (1006). Fifteen salts of erythromycin were prepared and their relative water solubilities and bitterness levels measured. The water solubilities were found to be related to the size of the alkyl group attached to the acid. The level of bitterness, however, was related not only to the size of the alkyl group but also to the stability of the salt, which was shown to be a function of the strength of the acid used to prepare it. The least bitter salt was the stearyl sulfate (1007). As shown by experiments using two antibiotics against *Escherichia coli* in the guinea pig, bacterial kinetics can be divided into a bacteriostatic phase, a rapid bactericidal phase, and a slow bactericidal phase. At high antibiotic levels the first phase slows, while the second phase intensifies. The same results were obtained *in vivo* and *in vitro* (1008). Cephalixin and cephaloglycine were tested for activity against a large number of pathogens *in vitro*. Both antibiotics were rapidly ab-

sorbed and excreted in the urine, with the absorption being delayed by food. Serum levels were shown to be higher when the agents were administered with probenecid (1009). The bactericidal action of chloramphenicol and streptomycin was tested on sensitive strains of *E. coli* and *S. aureus*. With a short contact time, chloramphenicol was completely inactive, but as the contact time increased so did its bactericidal activity. Streptomycin had a strong bactericidal action (1010). The plasma concentration curve for bamifylline after oral administration was similar to that obtained after i.v. administration of the same dose. The drug is rapidly excreted in the urine and follows two metabolic routes of degradation (1011). Koyama *et al.* (1012) described the configuration of viomycin, as determined by X-ray diffraction. A review of various tetracyclines was published, including their absorption, excretion, distribution in the body, and daily dosage (1013). The apparent partition coefficients between *n*-octyl alcohol and aqueous buffers were determined for several tetracyclines. Using microscopic dissociation constants for tetracycline, the relative amounts of each microscopic ionic form of tetracycline theoretically present at each pH were calculated. The zwitterionic form, which was present in the highest concentration in the pH range from 4 to 7, appeared to be the most lipid-soluble form, its reduced polarity possibly resulting from an intramolecular type of ion-pair formation. The possible relationships between the biological activity of the various tetracycline analogs and their pH-octanol solubility profiles were discussed (1014). Carbenicillin-resistant variants obtained from each of eight strains of *Pseudomonas aeruginosa* were tested by growing inoculum on agar plates containing carbenicillin. The resistant variants resembled the parent strains in cultural appearance, pigment production, and virulence for mice (1015). The surface tension of 21 antibiotic compounds was correlated with their antibacterial activity *in vitro*. It was noted that the compounds with the lowest surface tension had the highest antibacterial activity (1016).

Additional studies on antibiotics are listed in Table XXVII.

BIOPHARMACEUTICS

A thorough review of biopharmaceutics was presented by Garrett and Araujo (1053). Also published during the year were reviews on drug-response evaluations, empirical equations for correlating the biological efficiency of organic compounds, and test models for

evaluating the chemotherapeutic effectiveness of drugs (1054–1056). Drug absorption, distribution, and excretion were reviewed, and, in particular, the metabolic fate of chlorpropamide, diphenylhydantoin, and hetacillin (1057–1061). The clinical effectiveness of hetacillin was shown to be due to its conversion to ampicillin (1062).

Reports were given describing the species differences in the metabolism of diazepam, apomorphine, sulfisomidine and sulfamethomidine, sulfadimethoxine, and phenacetylurea, and pharmacological response in general was discussed (1063–1071). Also studied were the effects of species differences on the binding of drugs to plasma protein (1072–1074). The effects of age and sex on drug metabolism were reported (1075–1077).

Effects of Physicochemical Properties—The various physical and chemical factors affecting drug absorption, availability, and therapeutic response in general were reviewed (1078–1083).

Two polymorphic forms of aspirin were prepared by Tawashi (1084) and shown to be thermodynamically different, based on their differential thermal analysis, thermogravimetric analysis, and dissolution rates. Form II, the most thermodynamically unstable, gave blood serum salicylate levels 70% higher than Form I for the same time period. The urinary excretion of ethylamphetamine and its metabolite, amphetamine, was studied in man after oral administration of the (+), (–), and (±) isomers of ethylamphetamine hydrochloride. The rate of excretion of these amines is dependent on the pH of the urine. At acid values, the (+) isomer is metabolized faster and to a greater extent than the (–) isomer, which is excreted mostly unchanged (1085). Similar results were shown for the influence of urinary pH on the rate of excretion of *l*-adamantanamine (1086). Partition coefficients in *n*-heptane–sodium hydroxide or HCl were determined for a series of amines and acids, and a linear relation was found between the chain length and the log of the partition coefficient. Alkyl chain length was linear with buccal absorption of certain amphetamines and fenfluramines when they were 1% nonionized. Similarly, there was a linear relation between the logs of the partition coefficients and buccal absorption of the amines and acids when these compounds were 1 and 10% nonionized. When the amines and the acids had similar partition coefficients, their buccal absorption was similar over a pH range of 4 to 9. *n*-Heptane was considered equivalent in solvent properties to the buccal lipid membrane for the compounds used in the test (1087).

The phenomenon of displacing one drug from a plasma-binding site with another drug continues to be of interest. Solomon (1088) advised that concurrent therapy with two compounds which bind to protein should always be undertaken with caution, since many drugs appear to compete for a common binding site. Data on the extent of binding of a drug to albumin and its rate of metabolism in man are of great value in predicting whether it will displace other compounds from binding sites on albumin. The effect of caffeine on the gastric absorption of nonabsorbable drugs such as sulfathiazole and *p*-aminobenzoic acid was studied in rabbits. While caffeine enhanced the gastric absorp-

tion of *p*-aminobenzoic acid, it had no effect on the rate of absorption of sulfathiazole, probably because of the negligible complex this compound forms with it at gastric pH (1089). Similar studies involving the competition between digitoxin and other drugs in their interaction with serum proteins were published (1090–1092).

The affinity of certain drugs for plasma protein and the resulting effect of this binding on drug absorption were extensively studied. Jusko and Levy (1093) indicated that the interaction between riboflavin and albumin is nonionic, but that electrostatic forces contribute appreciably to the binding of riboflavin-5-phosphate to albumin. Salicylates, when added to saliva, are bound to the saliva proteins to the extent of 35–50% after a contact time of 0.5–2 hr. at 37° (1094). The partitioning of bishydroxycoumarin from rat plasma to an organic solvent phase was found to decrease with increasing drug concentration to a minimum value and then to increase as the concentration was further increased. The same type of profile was observed in the partitioning of the drug from rat plasma to the liver, both *in vitro* and *in vivo*. These results demonstrate the unusual concentration dependence of the plasma protein binding of bishydroxycoumarin, the pronounced effect of the binding on the distribution of the drug, and the effect of the distribution on elimination (1095). The markedly greater affinity of digitoxin than digoxin for serum albumin is reflected in the higher plasma concentrations, lower rate of urinary excretion, and longer half-time of digitoxin when the compounds are administered to man (1096).

Additional studies describing the influence of physicochemical properties on drug absorption are provided in Table XXVIII.

Effects of Formulation—Schneller (1144), in describing the hazard of therapeutic nonequivalency of drug products, cited published examples whereby a given chemical entity showed different blood levels depending on the dosage formulation. He concluded that every manufacturer, before distributing any new or modified product, should be obligated to perform tests which are appropriate and sufficient to demonstrate the clinical safety and efficacy claimed for it. In the absence of such tests, it cannot be assumed that the product will prove clinically acceptable simply because an apparently identical product has already been marketed. Schamberg's (1145) review indicated that different drug formulations containing the same kinds and amounts of active ingredients may differ appreciably in their effect and cannot be considered therapeutically equivalent. In a similar vein, it was suggested that attempts be made to establish the therapeutic availability of dosage forms used in clinical trials and that outlined details of the formulations utilized be included in published reports of clinical comparisons of drugs (1146). Another review article described the importance of dissolution rates and the pitfalls of dissolution methods for chemical substances as well as drug products (1147). The solubilities and absorption rates of the active compounds in pharmaceuticals are known to be affected by the technological factors of manufacturing (1148). The fast, medium, and slow *in vitro* dissolution rates of three

sulfamethazine tablet formulations were correlated with the *in vivo* blood level data. A significant statistical difference existed for areas under the blood level curves and for maximum blood concentration of sulfamethazine when the fast-dissolving formulation was compared with the slow-dissolving formulation (1149). Using *in vitro* techniques, the penetration of ¹⁴C-labeled fluocinolone acetonide and its acetate ester through human skin at 37° was examined with vehicle mixtures of isopropanol and isopropyl myristate or propylene glycol. Little penetration was found with either of the nonvolatile solvents. As the formulation was changed to include increasing amounts of a volatile component, however, the penetration was increased up to 8 to 10 times. Precipitation of steroid prevented greater increases (1150). Results were presented which showed that two oral dosage forms of nitrofurantoin, microcrystalline drug in a tablet and macrocrystalline drug in

1186	Factors affecting drug transfer in the presence of macromolecules: viscosity as the principal factor in transfer of sodium carboxymethylcellulose and hydroxypropylcellulose, except in the presence of mucin, when drug interaction and interfacial tension also appear to be involved
1187	Effect of antacids on the <i>in vitro</i> and <i>in vivo</i> absorption of ethionamide and prothionamide in various tablet and capsule dosage forms

a capsule, were both well absorbed. However, differences were observed in the urinary recoveries and in the urinary excretion patterns between these dosage forms, which suggested a slower rate of absorption for the macrocrystals than for the microcrystals (1151). The *in vivo* absorption and *in vitro* dissolution characteristics of a commercial suspension, a commercial tablet, and an experimental tablet formulation of salicylamide were compared. The absorption of this drug was shown to be dissolution rate-dependent, and the initial *in vitro* dissolution rate in 0.1 *N* HCl correlated well with the initial absorption rates of the test dosage forms in human subjects (1152). Studies were undertaken to define the effects of the emulsion components on the absorption of heparin, as measured by clearing factor activity, and to determine the optimum composition of the emulsion. Data suggested that heparin absorption is directly related to, and may vary with, the particle size and total surface area of the oil droplets, but that the relationships presented may be unique for the particular surfactant and oil chosen for study (1153). Low concentrations of polysorbate 80 in the water significantly increased the absorption- and exsorption-rate constants of 4-aminoantipyrine in goldfish. It was concluded that polysorbate 80 enhances the transfer of the drug by a direct effect on the biologic membranes and not by interacting with it (1154). In an attempt to develop an oral dosage form of aminoxafen which would produce prolonged, stable plasma levels of total drug, an arbitrary set of *in vitro* dissolution conditions were chosen which correlated well with *in vivo* absorption rates. A one-compartment open model was used to describe the system (1155). The enhanced absorption of dextromethorphan from trichloroacetate buffers appears to be due to the increased surface activity of the dextromethorphan rather than to ion-pair formation. However, thiopental was more strongly absorbed from trichloroacetate solution than from physiologic sodium chloride solution, apparently because of the preferential binding of serum protein with trichloroacetate rather than thiopental, thus leaving more unbound thiopental available for absorption. Dialysis experiments showed the binding of 55% of the thiopental to human albumin in the presence of physiologic phosphate buffer and only 22% in the presence of trichloroacetate solution (1156). The rate of dissolution of one investigational compound

from tablet and capsule formulations could not be related to its *in vivo* absorption in dogs. The rate of partitioning of the drug into organic solvents and its absorption in goldfish and through human buccal membrane depended on the pH of the solution. Absorption was shown to increase with a decrease in the degree of ionization. In man, however, the dissociation constant and the elimination rate of the drug are such that high blood levels are unlikely to occur after oral administration (1157).

Additional studies of the effects of formulation on drug availability are provided in Table XXIX.

Absorption Control and Alteration—The hypothesis that the formation of ion pairs and their transport across the lipid barrier are important mechanisms for drug absorption was examined, using a quaternary ammonium compound, isopropamide, as the cationic component and trichloroacetate as the anionic component of an ion pair. *In vitro*, ion pairing greatly increased organic solubility, while in mice, both the rate and the efficiency of oral absorption of isopropamide were increased when it was administered with an excess of trichloroacetate (1188). The extent of metabolism of the (–) isomer of mandelic acid is not significantly altered in the presence of sulfadiazine, sulfamethazine, or sulfamerazine, and this fact was utilized to calculate the ratio of the rate constants of the overall elimination of mandelic acid in the presence and absence of the sulfa drugs, as a measure of their inhibitory effects on its urinary excretion. It was concluded that the three sulfonamides probably share the same renal tubular transport system for their secretions in humans (1189). Chloramphenicol was shown to retard the biotransformation of tolbutamide, diphenylhydantoin, and dicoumarol in man, resulting in an increase in the half-life values of these compounds in the blood after its administration. A case of chloramphenicol-induced hypoglycemic collapse in a tolbutamide-treated patient was reported (1190). To design a dosage form, especially a sustained-release type, of amphetamine or other drugs which have an approximate 12-hr. half-life in blood and urine, it was recommended that blood studies be conducted to define the pharmacokinetic parameters necessary for calculating the initial and maintenance doses, and that excretion data be used mainly to confirm the half-life of amphetamine beyond the levels which are conveniently measurable in the blood. Blood data are more meaningful, since urine levels of amphetamines are highly sensitive to the urinary pH, re-

1255	Suggested formation of a hydrogen-bonded complex between drug and acceptor group on the neural membrane as a mechanism in the action of local anesthetics

sulting in kidney reabsorption changes and a consequent wide variation in urinary excretion rates. While control of pH compensates for the variation, it is impractical for large-scale clinical studies (1191). The ability of methocarbamol to potentiate aspirin or morphine might be due to the competition between it and aspirin or morphine for glucuronide formation, with consequent enhancement in the aspirin or morphine blood levels (1192).

Additional studies on absorption control and alteration are listed in Table XXX.

Absorption Mechanism—A model was presented which can describe the overall transfer of a drug across biologic membranes in the presence of a complexing agent. This model was applied to the transfer of salicylamide across a cannulated everted rat intestine in the presence of caffeine. The intestinal transfer rate constant

of the salicylamide-caffeine complex was found to be considerably lower than that of salicylamide but essentially the same as that of caffeine (1229). Some fundamentals of micelle formation and of solubilization of water-insoluble substances through micelles were reviewed. The accelerating effect of micellization on rate of solubilization and of transport of solubilizate through bulk liquid was considered. Transport across the membrane is accelerated whether or not micelles are effective within it (1230). Wagner (1231) presented equations to demonstrate the mechanism of gastrointestinal absorption, with special attention to the permeability coefficients for both ionized and nonionized species. The *in vitro* transfer of drugs from a buffered aqueous phase through a barrier consisting of a lipid liquid into another buffered aqueous phase was suggested as simulating the process involved in gastrointestinal absorption, *i.e.*, the partitioning of a drug between the gastrointestinal fluid and the lipoidal membrane and the plasma (1232). For studying the oil-water interface transport of drugs, a two-phase model was investigated. When the oil-water partition coefficient is large, the transport is aqueous diffusion-controlled and the first-order behavior is followed in the aqueous phase with time. Deviation from first-order behavior occurs when the partition coefficient is low, when the diffusion coefficient in the oil is low, when the diffusion coefficient in the aqueous phase is large, or when the thickness of the aqueous diffusion layer is small. These results may be useful in the design and interpretation of both *in vitro* and *in vivo* data on drug transport (1233). Similar investigations involving two-phase methods for investigation of the interphase transport of drugs were reported (1234, 1235). Wagner reviewed the transport of drugs through membranes and barriers other than the gastrointestinal tract, including buccal absorption as well as excretion by three different glands (1236). DMSO, in combination with sodium chloride, decreases skin electrical conductivity, probably by reducing skin resistance and facilitating the absorption of the electrolyte simultaneously with its own absorption (1237). With chlorpromazine, whatever the mechanism of absorption, the final therapeutic effect was shown to depend on the free radical form (1238). Using tritiated digoxin in rats, it was concluded that digoxin is absorbed by a passive nonsaturable transport process not dependent on metabolic energy (1239).

Additional references on the mechanism of absorption are provided in Table XXXI.

Kinetic Studies—Wagner (1256) reviewed certain aspects of pharmacokinetics and biopharmaceutics in relation to drug activity, considering such factors as route of administration, dose and dosage regimen, absorption, distribution, metabolism and excretion, effects of disease, and drug-drug interactions. The dose-dependent elimination of bishydroxycoumarin, known to occur in man and monkeys, can also be observed with warfarin when sufficiently high doses of the latter are administered. This effect is not seen clinically, perhaps, because the therapeutic dose range of warfarin is much lower than that of bishydroxycoumarin. The results suggest that the two coumarin anticoagulants are subject to the same major biotransformation pathways

Ref- erence	Topic
1303	to compare a variety of compounds for their effect on the peritoneal dialysis of salicylate Description of dose-dependent effects in pharmacokinetics, indicating that studies should be done at more than one dose level, since neither humans nor animals have unlimited capacity to metabolize drugs

(1257). A model was presented which can be used to obtain the pharmacokinetic parameters of the two-compartment open system of drugs which are too poorly soluble or too irritating to be administered by rapid intravenous injection. Experimentally, the method involves administering the drug by a constant-rate intravenous infusion until the attainment of infusion equilibrium, and determining the plasma concentrations of drug in the postinfusion period. The approach was applied to literature data and resulted in the evaluation of the two-compartment pharmacokinetics of oxacillin (1258). The apparent volume of distribution at the steady state in a two-compartment open system cannot be used to relate the drug concentration in the plasma to the amount of drug in the body, except at the one point in time when the rate of change of the amount of drug in the peripheral compartment is zero. A new concept of apparent volume of distribution, introduced for the pharmacokinetic analysis of the three-compartment open system, was applied to the two-compartment open system (1259). A graphic method was described for estimating the absorption half-life from the time of the peak level following the extravascular administration of a drug. The method is useful for drug products having absorption rates five or more times faster than their elimination rates (1260). The pharmacokinetics of drug distribution was evaluated for two types of drug administration—*viz.*, constant-rate intravenous infusion and instantaneous intravenous injection. Both modes of administration eventually result in a constant tissue compartment–central compartment distribution ratio of drug. However, the distribution ratios are not equivalent at pseudodistribution equilibrium and at infusion equilibrium. Consequently, at equivalent plasma concentrations, more drug will be in the tissue compartment during pseudodistribution equilibrium than during infusion equilibrium, although the total amount which will enter the tissue compartment is independent of the mode of administration. These findings may have important implications for drug distribution studies and with respect to the relative effectiveness of continuous and intermittent drug administration (1261). The pharmacokinetic analysis of drug concentration in the plasma *versus* time data, achieved by use of multicompartment models, made it possible not only to examine the relationship between drug concentration in the plasma and the intensity of the pharmacologic effect, but also to assess the relationship between pharmacologic effects at the relative drug levels in other apparent compartments of the body (1262). A three-compartment open system was proposed to explain the influence of route of administration

on the area under the plasma concentration–time curve. Computer analysis of the model, using estimated pharmacokinetic parameters, provided a successful prediction of the relative area under the plasma concentration–time curves after oral and intravenous administration of aspirin in man. After intravenous administration, the proposed model yielded a curve which may be described adequately by a biexponential equation (1263). Gladtke (1264) determined the elimination half-life of phenylbutazone after intravenous administration in children to be 21 hr. After oral administration, 85% of the dose entered the blood within 8 hr. In patients with liver disease, the half-life of meprobamate in the blood was shown to increase to 24.3 hr. from the 12.6 hr. observed in the normal patient. In drug addicts it was lowered to 4.5 hr. (1265). Benet and Ronfeld (1266) reviewed the use of different types of volume terms in pharmacokinetic equations. Amsel and Levy (1267), in a pharmacokinetic study of the simultaneous conjugation of benzoic and salicylic acids with glycine, found that in man the availability of glycine is rate-limited by the formation of hippuric acid but not of salicylic acid. Apparently the inhibitory effect of benzoic acid on the formation of salicylic acid is not due to competition for glycine but involves another phase in the biotransformation process. In a study describing the pharmacokinetics of sulfonamides in patients with cirrhosis of the liver, it was noted that the half-life of sulfamethoxypyridazine was not sufficiently different from the control, while the half-life of sulfadimethoxine was significantly diminished as a result of the increased binding of the drug by plasma proteins (1268). Data generated with a two-compartment open model were analyzed according to the one-compartment open model, in an attempt to use single-dose blood level data to predict blood levels after multiple doses (1269).

Additional studies on pharmacokinetics are listed in Table XXXII.

Drug Absorption—Using a model consisting of a thermostated upper and lower chamber fabricated from methyl methacrylate and having various membranes sandwiched between the chambers, Aguiar and Weiner (1304) showed the effect of varying the concentration of surfactants and of propylene glycol on the permeation of chloramphenicol through the barriers. The authors measured the activation energies for permeation and diffusion of this drug through a filter membrane saturated with peanut oil and also those for its permeation through hairless mice skins, at the same time obtaining an estimation of the partition coefficients. The law of corresponding areas was used to assess the percent absorption of a drug, by comparing the relative areas under the plasma concentration–time curves after oral and intravenous administration. If any metabolism occurred in the gut wall or liver, the areas under the curves would not be similar. This was verified using aspirin in dogs (1305). Chiou (1306) concluded that it is almost impossible to obtain an empty stomach in the rabbit by fasting the animal, since the fasting state markedly prolongs the stomach emptying time; thus the rabbit is not a useful animal in which to study drug absorption. A method was reported for studying *in situ* the gastrointestinal absorption of drugs

Table XXXIII—Additional Studies on Drug Absorption

Reference	Topic
1313	Review of percutaneous absorption of medicinal agents
1314	A new method for calculating ionophoretic permeability of the skin
1315	Decrease in sweating ability of the skin as cause of a decrease in blanching and presumably a decrease in percutaneous absorption of steroid
1316	Occurrence of percutaneous absorption of steroids and other large molecules <i>via</i> appendages and through the unbroken stratum corneum
1317	Relative magnitude of percutaneous absorption of various ¹⁴ C-labeled steroids as shown by measuring urinary excretion
1318	Review of the cutaneous penetration of dimethyl sulfoxide
1319	Effect of skin conditions on susceptibility of topical tolinaftate penetration
1320	Demonstration that an increase in the perfusion flow rate significantly increases the penetration rate of some compounds, suggesting that data obtained <i>in vitro</i> may be more meaningful when ideal flow rates are determined and validated with <i>in vivo</i> data
1321	Effect of essential oils on drug absorption
1322	Review of the mathematical treatments used to describe the various parameters involved in drug absorption
1323	Review of drug schedules and drug combinations as factors influencing absorption and efficacy
1324	Review of the relationship between receptor structure and pharmacological activity
1325	Comparability of doxycycline plasma concentrations achieved orally and after i.v. injection in man
1326	Intestinal absorption of six tritium-labeled digitalis glycosides
1327	Intestinal absorption of cardiac glycosides <i>in vitro</i> and <i>in vivo</i>
1328	Significantly higher serum and urine levels obtained with oxolinic acid when administered with food
1329	Absorption of pyrazinamide in man
1330	Correlation of the analgesic effect of aspirin with the blood concentration of salicylic acid, suggesting that aspirin probably exerts its effect through its hydrolytic product, salicylic acid
1331	Demonstration that isonicotinic acid derivatives are absorbed from the skeletal muscle of the rat, their absorption being proportional to the amounts remaining at the injection site and to both their molecular weights and partition coefficients
1332	Gastrointestinal absorption of 2-pyridine aldoxime methiodide and its derivatives
1333	Blood levels of 2-pyridine aldoxime methochloride and symptoms in humans after single and multiple oral doses
1334	Relative absorption of tetracycline and penicillin G after rectal and oral administration in aqueous solution
1335	Independence of the absorption of guanidine and the dose used for clinical control of hypertension
1336	Use of a quaternary ammonium dye to describe biochemical and morphological correlations of intestinal absorption
1337	Colonic absorption of thiamine
1338	Influence of blood flow on the absorption of drugs from the jejunum of the rat

from isolated gut segments of the anesthetized rat. Disappearance of the drugs from the lumen of the small intestine followed apparent first-order kinetics. However, the observed absorption rates were much faster than those normally observed in *in situ* intestinal preparations (1307). The effects of fasting on the intestinal absorption profiles of salicylic acid, barbitol, haloperidol, and chlorpromazine were studied in anesthetized rats. The *in situ* technique employed in the

study yielded absorption rate constants which were realistic and comparable to those observed following oral drug administration. Although apparent deviation in absorption patterns occurred when fasting periods were less than 20 hr., with longer periods the absorption rates were found to decrease significantly, the decrease being dependent on the duration of the fasting period. The unusual drug absorption patterns noted in these studies might be accounted for by one or more of the various physiological and/or biochemical changes which occur within an organism subjected to conditions of prolonged fasting (1308). When prolonged administration of salicylates in amounts comparable to those used in acute rheumatic fever was used, plasma salicylurate formation occurred at an essentially constant rate practically independent of the amount of salicylate in the body, thus demonstrating the capacity-limited formation of salicylurate during the prolonged administration of aspirin (1309). The decline in plasma concentration of dextroamphetamine was more rapid under controlled acidic conditions than under conditions of fluctuating urinary pH. The apparent rate of urinary excretion of amphetamine was proportional to its plasma concentration only under controlled acidic urinary conditions. Under acid conditions, amphetamine was cleared from blood more rapidly than could be accounted for by glomerular filtration, but when urinary pH fluctuated, its clearance could be accounted for by this route (1310). By using crystalline folic acid to study intestinal absorption in rats, it was noted that when increasing doses are introduced into the jejunum the percent of drug absorption decreases, suggesting an active transport mechanism. Absorption from the ileum remains constant with increasing dose, suggesting passive diffusion (1311). Comparative urinary excretion studies after the oral administration of 4'-chloro-2-ethylaminopropiophenone in a sustained-release form and in single or divided doses indicated that when kidney tubular reabsorption is minimized, the biological availability of the drug can be followed by examining the excretion of either the unchanged drug or the metabolites that quickly and directly form from the administered drug (1312).

Additional references on drug absorption are provided in Table XXXIII.

Oral Absorption of Griseofulvin in Dogs: Increased Absorption *via* Solid Dispersion in Polyethylene Glycol 6000

WIN LOUNG CHIOU* and S. RIEGELMAN

Abstract □ Four different dosage forms of griseofulvin were administered orally to dogs: (a) griseofulvin in the solution of polyethylene glycol (PEG) 400; (b) griseofulvin dispersed in PEG 6000 (1:9 w/w) prepared by the fusion method and administered in capsule form; (c) a commercial tablet of micronized griseofulvin; and (d) a commercial capsule of micronized griseofulvin. The drug can be followed in the blood for 8–12 hr. after a 250- or 500-mg. dose. However, the blood data can lead to a false conclusion as to the degree and duration of the absorption process. This is due to fast metabolism ($t_{1/2}$ = 40–50 min.), to absorption being a dissolution rate-limited process, and finally to an assay that is insufficient to follow the total time course of the drug in the body. In contrast, the urinary excretion data for 6-demethylgriseofulvin (6-DMG) yield convincing evidence for prolonged absorption of griseofulvin for over 30 hr. for the commercial preparations. By comparison of the percent 6-DMG excreted to that obtained after i.v. administration, absorption was found to be complete for the solution form, 88% for the PEG dispersion, 45% for the commercial capsule, and 33% for the commercial tablet.

Keyphrases □ Griseofulvin dosage forms, oral—absorption, dogs □ Polyethylene glycol 6000 effect—griseofulvin absorption □ Dissolution rates—griseofulvin dosage forms □ Absorption, dissolution rates—correlation □ Urinary excretion—griseofulvin metabolites

Sekiguchi and Obi (1) were the first to apply the principle of solid dispersions utilizing a water-soluble carrier as a matrix for a poorly soluble drug to increase the rate of dissolution and oral absorption. They proposed the formation of a eutectic mixture of a poorly water-soluble drug with a physiologically inert, readily soluble carrier. Goldberg *et al.* (2) later suggested the formation of solid solutions (mixed crystals) rather than eutectic mixtures to obtain faster dissolution and absorption rates. Recently, Chiou (3) proposed, from the theoretical standpoint, that a poorly soluble or insoluble drug can achieve the fastest rates of dissolution and absorption when dispersed in a glass solution of a water-soluble carrier. Upon exposure to aqueous fluids, the active drug will be released in a state of fine particles (eutectic mixture) or single molecule (solid or glass solution). The enhancement of *in vitro* dissolution rates has been shown with solid dispersions containing chloramphenicol (4, 5), griseofulvin (Gris) (6, 7), and reserpine (8). However, the *in vivo* investigation of such systems has been limited. Only sulfathiazole (1), chloramphenicol (4), and reserpine (9) have been studied.

One major and commonly used approach to enhance oral absorption is micronization. Yet, no study has been reported to compare the absorption of a drug in micronized form and in a solid dispersion form. Therefore, the clinical and practical value of the solid dispersion approach has not been fully established. The main objective of this communication is to compare quantitatively the absorption characteristics of a water-insoluble antibiotic, Gris, in dogs. The absorption properties of these systems in man will be reported in a future article.

In another communication (10), the authors reported that the dissolution rate of Gris was increased considerably when dispersed in the carriers of polyethylene glycol (PEG) 4000, 6000, and 20,000; citric acid; pentaerythritol; and pentaerythrityl tetraacetate. The results obtained after i.v. studies of Gris and its metabolite, 6-demethylgriseofulvin (6-DMG), in the same dogs have also been previously reported (11). The PEG 6000 was selected as a model carrier to test in dogs.

EXPERIMENTAL

Dosage Forms—Four different dosage forms were used for oral studies: 250 mg. of Gris dissolved in 50 ml. of PEG 400; 250 mg. of Gris dispersed in 2250 mg. of PEG 6000 (250 mg. 10% Gris-PEG 6000) by the melting method (10) and packed loosely into five gelatin capsules (size 00); a commercial tablet containing 500 mg. of micronized Gris; and a commercial capsule containing 250 mg. of micronized Gris.

Protocol in Dog Studies—Male, mongrel, conditioned, unanesthetized dogs weighing 19–22 kg. were used throughout the studies. Dogs were fasted with water *ad libitum* for 16 to 18 hr. prior to experiments. The Gris in the solution form was administered through a stomach tube followed by 30 ml. of 50% aqueous PEG 400 solution to rinse the syringe and the stomach tube. The solid dosage forms, mixed with a small amount of ground meat, were swallowed quickly by the dogs. One hundred fifty milliliters of lukewarm tap water was then given through the stomach tube. Dogs were observed for at least 2 hr. to make sure that there was no vomiting of the drug. Food was withdrawn for 8 hr. after administration, while water was freely available.

Blood samples (5 ml.) were drawn at 0, 1, 2, 3, 5, 8, and occasionally up to 12 hr. after drug administration from a cephalic vein with a 22-gauge disposable needle attached to a 6-ml. syringe. For the solution dosage form, additional samples were taken at 15 and 30 min. Urine samples were taken at 0, 2, 5, 8, 30, and 48 hr. through a urethral catheter. After the initial withdrawal of urine, at least 20 ml. of saline was used to wash the bladder. Both the urine and the washing were combined together for the assay. Occasionally, only blood or urine samples were taken.

Samples of urine and plasma obtained after separation from red cells by centrifugation were stored at 4° until required for analysis. The spectrophotofluorometric assay of Gris in the plasma (12) and the UV assay of 6-DMG in the urine (13) were conducted as previously described. An interval of at least 1 week separated each experiment.

In Vitro Dissolution Rate Studies—Dissolution rate studies of 125 mg. of Gris in three solid dosage forms were run in 18 l. of simulated intestinal fluid (14) at 36.7 ± 0.05° in an apparatus previously described (10). For dissolution studies, dispersed Gris was filled in two gelatin capsules (size 00), an equivalent amount of powder from the commercial capsule was refilled in a size 1 gelatin capsule, and a single mass was cut from the commercial tablet. Dissolution was studied using the USP disintegration apparatus

(Scientific Glass Apparatus Co., Bloomfield, N. J.). However, a single cylindrical covered basket, diameter 2.8 cm. and height 5.6 cm., made up of an 8-mesh stainless steel screen, was used instead of the conventional basket-rack assembly, because Gris-PEG preparation was found to stick to the plastic wall in the standard basket.

Gris; \circ , Gris in solution; \square , Gris dispersed in PEG 6000; \blacktriangle , commercial capsule of micronized Gris; and \bullet , commercial tablet of micronized Gris. (All data corrected for 250-mg. dose.)

RESULTS AND DISCUSSION

Plasma Levels of Gris after Oral Administration—The plasma concentration data after oral administrations of four different dosage forms of Gris are shown in Table I and their average values are plotted in Fig. 1.

Although Gris has long been used for antifungal therapy in dogs (15), its oral absorption has not thus far been reported. The recommended dose of 5 mg./lb./day in dogs is the same as that used in man. The results reported from this laboratory (11, 16) indicated that the metabolic rate of Gris in dogs may be 20–30 times faster than that in man. Therefore, it is not surprising that very low blood levels of Gris were obtained from 250 mg. of commercial capsule (Table I) administered to dogs weighing 45 lb. (approximately 5 mg./lb.) as compared with that obtained from man (12). The average peak level was found to be about 0.3 mcg./ml., and the concentration after 8 hr. of administration was almost negligible. Furthermore, even the blood level from the solution dosage form was very low after 8 hr. of administration. It has been reported that the minimal plasma concentration of Gris required for the effective therapy in man is about 1 mcg./ml. (17). Hence, it is highly doubtful that the presently recommended dose in dogs is adequate. Further study of this aspect should be pursued.

Peaks of plasma level of Gris from three solid formulations were all reached at about 3 hr. after administration as found in man (12), cats (18), and rats (19). The absorption from the solution form was much faster, as expected. The peak plasma levels after administration of the Gris-PEG solution were in the range of 15–30 min. in Dogs G and H.

The absorption from the commercially available micronized preparations appears to be quite incomplete. The average peak levels from these preparations are about 25 to 29% of that from Gris dispersed in PEG 6000 on the basis of equal amount of Gris administered.

Figure 3—Plasma concentration of Gris after administration of various dosage forms to Dog H (oral doses all corrected to 50 mg. Gris). Key: Δ , Gris in solution (H-3); \circ , Gris dispersed in PEG 6000 (H-6); \square , commercial capsule of micronized Gris (H-13); \blacktriangle , commercial tablet of micronized Gris (H-14); and \bullet , 50 mg. Gris i.v. (H-9).

Figure 4—Replot of the data shown in Fig. 3 on 500 mg. Gris administered to Dog H (see Fig. 3 for details). Extrapolation difference curves (solid circles and triangles) indicate the faster of the two rate processes.

The solution form of Gris might be presumed to be more completely absorbed and could be used as a standard for comparison of the dosage forms. By comparison with the area under the plasma concentration-time curve in 8 hr. from the solution form, the availability is 77% for Gris dispersed in PEG 6000, 26% for the commercial tablet, and 18% for the commercial capsule. There is, however, a fallacy in this method of comparison, since it was reported in a previous communication (11) that the elimination characteristics of Gris after i.v. administration in some dogs followed dose-dependent kinetics. Therefore, it seems invalid to compare the availability on the basis of the blood area. However, as reported in the previous communication (11), the total urinary excretion of 6-DMG, its major metabolite, was found to be almost constant for every dog studied and to be independent of doses in dogs exhibiting dose-dependent kinetics of Gris. Therefore, it was concluded that the total 6-DMG excretion in the urine can be used to evaluate the extent of drug absorption.

The absorption of micronized Gris preparation in man has been shown in this laboratory to continue for more than 30 or 40 hr.

Figure 5—6-DMG excretion rate plots after oral administration of various dosage forms to Dog H (see Fig. 3 for details). The half-life of 6-DMG excretion from i.v. dose to Dog H is 4.8 hr.

Figure 6—6-DMG excretion rate plots after oral administration of various dosage forms to Dog G (all data corrected to 500-mg. dose). Key: \circ , Gris in solution (G-13); Δ , Gris dispersed in PEG 6000 (G-2); \square , commercial capsule of micronized Gris (G-12); and \bullet , commercial tablet of micronized Gris (G-14).

(12). However, after the first 10 hr., the rate of absorption is much reduced. This may also take place in dogs; the drug concentration might fall below the level of spectrophotofluorometric assay sensitivity after 8 or 12 hr. postadministration, even though the drug is continuing to be absorbed. The authors, therefore, may not be able to follow the drug long enough in the blood to detect the total absorption process. This will be discussed further.

Urinary Excretion of 6-DMG after Oral Administration—Two urinary metabolites, 6-DMG and 6-DMG glucuronide, were previously identified in this laboratory after an i.v. dose of Gris to dogs (16). The excretion of 6-DMG glucuronide was found to contribute only insignificantly to the metabolic process either after i.v. or oral administration of Gris (11).

The excretion of 6-DMG after administration of four different dosage forms is shown in Table II. The average cumulative data for 6-DMG from i.v. (11) and oral doses are shown in Fig. 2. The percent of the total excretion of 6-DMG in 48 hr. from four dogs was surprisingly constant with an average of 55.1%, which is virtually identical to that obtained from i.v. dose, 56.4% (11), and indicates complete absorption from Gris in solution form. Using the amount of metabolite excretion in 48 hr. after the i.v. doses, the metabolite recovery is 88% from the Gris dispersed in PEG 6000, 45% from the commercial capsule, and 33% from the commercial tablet. Therefore, it is evident that the insoluble Gris dispersed in a water-soluble matrix of PEG 6000 does indeed result in a faster and more complete absorption than micronized products. Of additional importance is the fact that the absorption appears to be more consistent from the PEG dispersion.

There appear to be many potential physical and chemical advantages of a solid dispersion prepared with water-soluble carriers. The carriers will obviously be chosen on their ability to dissolve the required amounts of the drug in the solid dispersion. As such, it may show an increased tendency to produce supersaturated solution, fast dissolution rate, and good wetting and dispersion on exposure to the aqueous fluids. Although the micronization of insoluble drugs can increase the specific surface area and thereby increase the dissolution rate, this potential advantage may be easily lost due to the aggregation or agglomeration during the formulation or processing, which may not be overcome by adequate wetting in the biological fluids during the absorption process. It appears that the physicochemical advantages intrinsic in the solid dispersion form markedly influence the biological availability of the Gris in dogs. It is hoped that the approach of solid dispersion can also be applied to other insoluble drugs.

Long Absorption Time of Gris in Dogs—An interesting absorption phenomenon was frequently observed in dogs. Typical plasma concentration curves of Gris after administration of different dosage forms to a dog are shown as semilog plots in Fig. 3. One

Figure 7—Gris dissolution rate data (amount remaining to be dissolved) from 125 mg. in 18 l. of simulated intestinal fluid at 36.7°. Key: (1), commercial capsule; (2), commercial tablet; and (3), capsule of Gris dispersed in PEG 6000.

certainly would wonder why four different preparations with different dissolution rates will have the same postpeak disappearance curve with a half-life of about 2 hr. (even up to 12 hr. postadministration). This would usually be defined as the elimination half-life of the drug.

The elimination half-life ($t_{1/2} = 52$ min.) in this dog after i.v. dose was found to be dose-independent (Fig. 1 in Reference 11). Therefore, it indicates that the postpeak curve is primarily due to the slower process, the absorption process, which continued for at least 8 hr. Further evidence for this contention is seen in Fig. 4 in which some of the data from the previous figure have been redrawn. The linear portions of the postpeak curves for the capsule and tablet experiments have been extrapolated back to zero time, and the method of extrapolation difference has been used to estimate the rate constant for the faster of the two competing processes which primarily contribute to the rising portion of the blood curves. The extrapolation difference values led to the dashed lines representing the contribution from this first-order rate process. These lines show essentially the same slope as found after i.v. administration of Gris (shown as the heavy solid line). This interpretation would require the definition of the postpeak curve as indicative of the apparent absorption rate of the drug with a half-life of approximately 2 hr. Figure 5 includes plots of the 6-DMG excretion rate for the same experiments. The slopes of these curves during the same time interval are compatible with the previous interpretation of the blood data. This unusual pattern of absorption is similar to that of the oral administration of spirinolactone (a drug of similar insolubility to Gris) to man (21) and was left unexplained by Levy (22).

The prolonged slow absorption of Gris can be shown by review of the urinary excretion rate data for the metabolite of Gris which are found in Table II and Figs. 5 and 6. If the absorption process stops at 8 hr., the excretion rate should be the same as that of the slow phase of excretion after i.v. dose of Gris ($t_{1/2} = 3-4.8$ hr. in the two dogs shown). However, it is clear from Figs. 5 and 6 that the apparent excretion rate is much slower. Indeed, the half-life of the processes contributing to the postpeak curves 8 or more hr. after administration of the drug ranges from 10 to 20 hr. The authors interpret this to mean that the absorption process is the rate-limiting step and continues for more than 30 hr. This finding is in agreement with the report of Gris absorption in man from this laboratory (12).

The urinary excretion method described in this communication can serve as a convenient means of screening dosage form effects on a drug which is dissolution rate limited on the absorption. Thus, even though the blood data are of limited value due to slow absorption followed by rapid metabolism, the urinary excretion of the metabolite continues long after the drug is undetectable in the blood.

Correlation between the Absorption and the Dissolution Rate—Dissolution rates of Gris in three solid dosage forms in the 18 l.

Figure 8—Correlation between dissolution rate and total 6-DMG excretion in 48 hours.

of simulated intestinal fluid are shown in Fig. 7. An interesting correlation appears to exist between the *in vitro* dissolution rate data and the *in vivo* data discussed; namely, the cumulative urinary excretion of 6-DMG in 48 hr. was found to correlate linearly with the logarithm of percent of Gris dissolved in 25 min. in the simulated intestinal fluid. This is shown in Fig. 8. It should be noted that similar correlation between the area under the blood concentration-time curve with the specific surface area of Gris powder (23) and the dissolution rates (24, 25) of Gris dosage forms in the simulated intestinal fluid have been reported in the past. The amount of data available to include in this plot is very minimal; it merely serves once again to point out *in vivo-in vitro* correlations can be established.

Synthesis of Some Glycidic Hydrazides and Amides as Potential Psychotropic Agents and Anticholinergic Agents

REYNALDO V. SAENZ*, ROBERT G. BROWN, E. I. ISAACSON†, and JAIME N. DELGADO

Abstract □ A series of glycidic hydrazides and amides was prepared by hydrazinolysis or aminolysis of glycidic esters obtained *via* a modified Darzens condensation. The hydrazides thus obtained were subjected to suitable acylating or alkylating reagents to obtain *N*-substituted hydrazides. The results of a preliminary pharmacological evaluation are summarized. The synthesized compounds were tested for their ability to reverse reserpine hypothermia in mice. Compounds synthesized as potential anticholinergics were evaluated for their spasmolytic activity using isolated rabbit ileum.

Keyphrases □ Glycidic hydrazides, amides—synthesis □ Hydrazides, glycidic—synthesis □ Amides, glycidic—synthesis □ IR spectrophotometry—identity □ Pharmacological screening—glycidic hydrazides, amides

Appropriately substituted hydrazides and amides have been of interest to the medicinal chemist for various reasons. Monoamine oxidase-inhibitory hydrazides have proved to possess dynamic pharmacological properties (*i.e.*, antitubercular and/or antidepressant properties). Amides that are analogous to bioactive esters (*e.g.*, procaine *versus* procainamide) offer models for structure-activity analysis on the basis of the predicted greater metabolic stability of amides due to their greater resonance stabilization.

Since the epoxide group affects the physicochemical properties (*e.g.*, lipid-water partition coefficient) of a compound, this function might also influence pharmacologic properties. Hence, it was decided to prepare α,β -epoxy hydrazides and amides for pharmacologic evaluation and to provide a basis for the study of the effect of the epoxide moiety on bioactivity.

Literature reports and reviews (1-4) substantiate the utility and applications of the Darzens glycidic ester condensation. Consequently, this reaction was applied to the synthesis of α,β -epoxy esters which, when exposed to hydrazinolysis and/or aminolysis, yield potentially active hydrazides and amides.

α,β -Epoxy amides and hydrazides have been of interest to the authors and others (5) as potential therapeutic agents. In appropriately substituted glycidic hydrazides, the presence of the epoxide function may affect the distribution of compounds possessing monoamine oxidase-inhibiting pharmacophores. In addition, the epoxide function may affect the susceptibility of

such compounds to metabolic degradation. Conceivably, the drug-receptor interaction would be influenced as well, depending upon the degree of hydrolysis of the hydrazide linkage. Zeller (6) and others (7) have postulated that certain substituents play an important function in the bioactivity of appropriately substituted hydrazine derivatives. Several basic structural features appear to be associated with optimal monoamine oxidase inhibitory activity. These can be summarized as follows: (a) there should be at least one alkyl substituent on the hydrazine moiety, and (b) *N*-1 alkylation and *N*-2 acylation yield compounds with increased activity and decreased toxicity. On the other hand, disubstitution of either hydrazine nitrogen leads to inactive compounds. The alkyl and aralkyl substituents contribute to electronic, steric, and hydrophobic factors involved in the inhibitor-enzyme interaction, whereas the acyl moiety has been implicated as affecting the distribution and should be of such a nature that it can be easily hydrolyzed (8). Accordingly, the choice of the acyl moiety presumably is important with regard to tissue selectivity and susceptibility to metabolic cleavage to yield the postulated active moiety.

Since this work involves the synthesis of selected α,β -epoxy hydrazides as potential psychotropic agents, it is fundamental to the study of the effect of the epoxide function on absorption, distribution, and metabolic fate of hydrazine derivatives.

Additionally, glycidic amides were prepared modeled after classical anticholinergic agents. Such compounds possessing the α,β -epoxy amide function, in addition to the potential ammonium group and appropriately positioned bulky, semirigid, and hydrophobic moieties, should exhibit anticholinergic spasmolytic activity; those without a potential ammonium function should be less active. Accordingly, it was decided to compare Compound X with the classic anticholinergic atropine as well as with the analogous amides: Compounds VII and VIII, which do not possess potential ammonium functions. The epoxide cycle should affect distribution as well as the receptor interaction; hence, α,β -epoxy amides were chosen for this study.

The compounds described herein were prepared by the application of the following reactions: Darzens

Appropriately substituted hydrazides and amides have been of interest to the medicinal chemist for various reasons. Monoamine oxidase-inhibitory hydrazides have proved to possess dynamic pharmacological properties (*i.e.*, antitubercular and/or antidepressant properties). Amides that are analogous to bioactive esters (*e.g.*, procaine *versus* procainamide) offer models for structure-activity analysis on the basis of the predicted greater metabolic stability of amides due to their greater resonance stabilization.

Since the epoxide group affects the physicochemical properties (*e.g.*, lipid-water partition coefficient) of a compound, this function might also influence pharmacologic properties. Hence, it was decided to prepare α,β -epoxy hydrazides and amides for pharmacologic evaluation and to provide a basis for the study of the effect of the epoxide moiety on bioactivity.

Literature reports and reviews (1-4) substantiate the utility and applications of the Darzens glycidic ester condensation. Consequently, this reaction was applied to the synthesis of α,β -epoxy esters which, when exposed to hydrazinolysis and/or aminolysis, yield potentially active hydrazides and amides.

α,β -Epoxy amides and hydrazides have been of interest to the authors and others (5) as potential therapeutic agents. In appropriately substituted glycidic hydrazides, the presence of the epoxide function may affect the distribution of compounds possessing monoamine oxidase-inhibiting pharmacophores. In addition, the epoxide function may affect the susceptibility of

such compounds to metabolic degradation. Conceivably, the drug-receptor interaction would be influenced as well, depending upon the degree of hydrolysis of the hydrazide linkage. Zeller (6) and others (7) have postulated that certain substituents play an important function in the bioactivity of appropriately substituted hydrazine derivatives. Several basic structural features appear to be associated with optimal monoamine oxidase inhibitory activity. These can be summarized as follows: (a) there should be at least one alkyl substituent on the hydrazine moiety, and (b) *N*-1 alkylation and *N*-2 acylation yield compounds with increased activity and decreased toxicity. On the other hand, disubstitution of either hydrazine nitrogen leads to inactive compounds. The alkyl and aralkyl substituents contribute to electronic, steric, and hydrophobic factors involved in the inhibitor-enzyme interaction, whereas the acyl moiety has been implicated as affecting the distribution and should be of such a nature that it can be easily hydrolyzed (8). Accordingly, the choice of the acyl moiety presumably is important with regard to tissue selectivity and susceptibility to metabolic cleavage to yield the postulated active moiety.

Since this work involves the synthesis of selected α,β -epoxy hydrazides as potential psychotropic agents, it is fundamental to the study of the effect of the epoxide function on absorption, distribution, and metabolic fate of hydrazine derivatives.

Additionally, glycidic amides were prepared modeled after classical anticholinergic agents. Such compounds possessing the α,β -epoxy amide function, in addition to the potential ammonium group and appropriately positioned bulky, semirigid, and hydrophobic moieties, should exhibit anticholinergic spasmolytic activity; those without a potential ammonium function should be less active. Accordingly, it was decided to compare Compound X with the classic anticholinergic atropine as well as with the analogous amides: Compounds VII and VIII, which do not possess potential ammonium functions. The epoxide cycle should affect distribution as well as the receptor interaction; hence, α,β -epoxy amides were chosen for this study.

The compounds described herein were prepared by the application of the following reactions: Darzens

condensation, hydrazinolysis, aminolysis, *N*-acylation, and *N*-benzylation.

Scheme I

The carbonyl compounds (I) (Scheme I) employed as starting materials included pyridine-3-carboxaldehyde, pyridine-4-carboxaldehyde, diphenylacetaldehyde, benzophenone, dibenzosuberone, and xanthone. The Darzens glycidic ester product (II) of each of the foregoing carbonyl compounds was subjected to aminolysis (IV) and/or hydrazinolysis (III). The hydrazides (III) obtained then were treated with either benzyl chloride, benzoyl chloride, or 3,4,5-trimethoxybenzoyl chloride to prepare the substituted hydrazide derivatives (V and VI). The compounds prepared, together with their respective melting points and analytical data, are listed in Table I.

EXPERIMENTAL¹

Preparation of Esters—The glycidic esters, starting materials for the synthesis of the glycidic hydrazides and amides, were prepared according to the method of Omdt and Gisvold (3) with suitable modifications. The yield was better from pyridine-3-carboxaldehyde (60–70%) than from pyridine-4-carboxaldehyde (40–50%). Additionally, among the ketones, dibenzosuberone gave higher yields (40–50%) of the glycidic ester than did xanthone (20–30%). IR spectrophotometry was utilized in the characterization of the

esters described. The IR spectra showed characteristic peaks for the α,β -epoxy ester function: 1720 cm^{-1} ($\text{C}=\text{O}$); 1260 and 880 cm^{-1} (epoxide).

Ethyl 3-(4-Pyridyl)glycidate—Pyridine-4-carboxaldehyde (10.7 g.; 0.1 mole) and ethyl chloroacetate (12.6 g.; 0.1 mole) dissolved in anhydrous ether (150 ml.) were placed in a 3-neck, round-bottom flask equipped with mechanical stirrer, reflux condenser, calcium chloride drying tube, nitrogen inlet, and dropping funnel. Sodium hydride (4.8 g.; 0.1 mole of a 51% mineral oil dispersion) was added slowly to prevent excessive effervescence. Ethanol (4.8 g.; 0.1 mole) was added dropwise while cooling the solution to 0–10°. The mixture was stirred for 18 hr. while it was allowed to come to room temperature. All the while, nitrogen was passed through the reaction mixture. At this time the ether was removed under reduced pressure and replaced with an equal volume of chloroform. The mixture was then refluxed for 4 hr. Water (50 ml.) was added. The resulting two layers were separated. The chloroform layer was washed with a saturated solution of sodium chloride (three 50-ml. portions), a saturated solution of sodium bicarbonate (three 50-ml. portions), and a saturated solution of sodium bisulfite (three 50-ml. portions), and it was dried over anhydrous sodium sulfate. After filtering, the solvent was removed using a Rinco rotatory evaporator. The residue which resulted was characterized as the picrate salt, m.p. 101–102°.

Anal.—Calcd. for $\text{C}_{16}\text{H}_{14}\text{N}_4\text{O}_{10}$: C, 45.50; H, 3.31. Found: C, 45.54; H, 3.42.

Ethyl 3-(3-Pyridyl)glycidate—Pyridine-3-carboxaldehyde (10.7 g.; 0.1 mole) and ethyl chloroacetate (15.9 g.; 0.13 mole) in ethanol (4.6 g.; 0.1 mole) were added via two dropping funnels to a toluene dispersion of sodium hydride (4.8 g.; 0.1 mole) under nitrogen and cooled to 0–10°. The reaction mixture was allowed to come to room temperature and stirred for a period of 12 hr. Glacial acetic acid (3 ml.) and water (150 ml.) were added. The aqueous layer was separated and washed with ether, and the ether extracts were combined with the organic layer. The combined organic portions were washed as before, and the solvents were removed under reduced pressure. The crude epoxy ester was chromatographed on a silicic acid column developed with ether. The oil which was isolated was identified on the basis of its elemental analysis.

Anal.—Calcd. for $\text{C}_{10}\text{H}_{11}\text{NO}_3$: C, 62.15; H, 5.73. Found: C, 61.98; H, 5.95.

Ethyl 3,3-Diphenylglycidate—Benzophenone (18.2 g.; 0.1 mole) was dissolved in anhydrous ether (100 ml.) and placed in a 3-neck flask equipped as previously described. Ethyl chloroacetate (12.6 g.; 0.1 mole), dissolved in anhydrous ether (50 ml.), was added. While cooling the solution to 0–10°, freshly prepared sodium ethoxide (6.8 g.; 0.1 mole) was dissolved in anhydrous ether (150 ml.) and slowly added to prevent excessive effervescence. Stirring was continued for 18 hr. The ether was removed and replaced with an equivalent amount of anhydrous chloroform, and the mixture was refluxed for 18 hr. Glacial acetic acid (3 ml.) and water (150 ml.) were added cautiously. The organic layer was removed and washed as before and was concentrated under reduced pressure. The concentrate was distilled under reduced pressure; the product, distilling at 120–128° at 5 mm., solidified at room temperature and had a melting point of 46°.

Anal.—Calcd. for $\text{C}_{17}\text{H}_{16}\text{O}_3$: C, 76.10; H, 6.01. Found: C, 75.76; H, 5.92.

Ethyl 3-Xanthylglycidate—Ethyl 3-xanthylglycidate was synthesized in a manner analogous to that used for ethyl 3,3-diphenylglycidate, using xanthone and ethyl chloroacetate as the starting materials. On concentration of the organic layer, the residual material was characterized in the form of Derivatives IX and X, Table I.

Ethyl 3-Dibenzosuberylglycidate—Ethyl 3-dibenzosuberylglycidate also was prepared according to the foregoing method, using ethyl chloroacetate and dibenzosuberone. Chromatography (silicic acid column) was used to purify the product.

Anal.—Calcd. for $\text{C}_{19}\text{H}_{18}\text{O}_3$: C, 77.58; H, 6.16. Found: C, 77.86; H, 5.94.

Ethyl 3,3-Diphenylmethylglycidate—Ethyl 3,3-diphenylmethylglycidate was synthesized as previously described, employing diphenylacetaldehyde and ethyl chloroacetate. The product was purified by column chromatography on silicic acid and was characterized in the form of the corresponding *N,N*-diethylamide derivative (Compound XI, Table I).

¹ Reported melting points are uncorrected. A Thomas-Hoover Unimelt apparatus was used for the melting point determinations. Elemental analyses were conducted by the Schwarzkopf Micro-analytical Laboratory, Woodside, N. Y. IR spectral analyses were conducted with a Beckman IR-8 spectrophotometer.

Synthesis of α,β -Epoxy Hydrazides—The hydrazides were prepared by hydrazinolysis of the esters, and the yields were in the range of 25–30% of theory. IR spectral analyses were conducted on representative compounds, and the data substantiated the structures in Table I. The IR spectra showed characteristic peaks:

1600 cm^{-1} (>C=O); 1260 and 880 cm^{-1} (epoxide).

1-[3-(4-Pyridyl)glycidyl]hydrazine—Ethyl 4-pyridylglycidate (4.8 g.; 0.025 mole) was dissolved in anhydrous benzene (80 ml.) and ethanol (15 ml.) and placed in a flask equipped with a Dean-

Stark separator. Hydrazine (anhydrous 95%) (0.8 g.; 0.025 mole) was added dropwise while stirring. After all of the hydrazine was added, the mixture was refluxed for 4 hr. At this time, most of the alcohol had been collected in the Dean-Stark separator, denoting approximate completion of the hydrazinolysis. The solvent was removed under reduced pressure, and the semisolid remaining was cooled to induce crystallization. The product was dried *in vacuo* and characterized.

Anal.—Calcd. for $C_8H_9N_3O_2$: C, 53.63; H, 5.06. Found: C, 53.97; H, 4.97.

1-[3-(3-Pyridyl)glycidyl]hydrazine—A procedure analogous to that employed for the 4-pyridyl isomer was used to synthesize and characterize the compound.

Anal.—Calcd. for $C_8H_9N_3O_2$: C, 53.62; H, 5.06. Found: C, 53.92; H, 5.54.

1-[3-(4-Pyridyl)glycidyl]-2-benzyl Hydrazine (Compound IV, Table I)—1-[3-(4-Pyridyl)glycidyl]hydrazine (2.2 g.; 0.0125 mole) was dissolved in anhydrous ether (40 ml.) and, while stirring, benzyl chloride (1.42 g.; 0.0125 mole) was slowly added. Additional ether (20 ml.) and 5% aqueous sodium hydroxide solution (10 ml.) were added to the mixture. The ether layer was separated, dried, and concentrated under reduced pressure. The resulting product was purified *via* crystallization from ethanol-isopropyl ether.

1-[3-(3-Pyridyl)glycidyl]-2-benzyl Hydrazine (Compound I, Table I)—The corresponding 3-pyridyl analog was prepared similarly to the 4-pyridyl isomer.

N - 1 - [3 - (4 - Pyridyl)glycidyl] - N - 2 - (3,4,5 - trimethoxybenzoyl)hydrazine (Compound VI, Table I)—3-(4-Pyridyl)glycidyl hydrazine (4.4 g.; 0.025 mole) was dissolved in anhydrous benzene (60 ml.) with the aid of ethanol (10 ml.). Pyridine (2 ml.) was added. 3,4,5-Trimethoxybenzoyl chloride (3.7 g.; 0.025 mole) was added, and the mixture was refluxed for 6 hr. At this time, water (15 ml.) was added to dissolve the salt formed. The nonaqueous layer was separated, washed with a saturated solution of sodium bicarbonate, dried, and concentrated under reduced pressure. The resulting product was recrystallized from anhydrous ether.

N - 1 - [3 - (3 - Pyridyl)glycidyl] - N - 2 - (3,4,5 - trimethoxybenzoyl)hydrazine (Compound III, Table I)—This compound was prepared in a manner similar to that used for the 4-pyridyl isomer.

1-[3-(4-Pyridyl)glycidyl]-2-benzoyl Hydrazine (Compound V, Table I)—3-(4-Pyridyl)glycidyl hydrazine (5 g.; 0.028 mole) was dissolved in anhydrous pyridine (30 ml.) and anhydrous benzene (60 ml.). The benzoyl chloride (5 g.; 0.036 mole) was added as quickly as possible. The resulting mixture was refluxed for 6 hr. and then poured into 250 ml. of water. The aqueous layer was removed and washed with benzene. The combined organic solutions were washed with 5% aqueous sodium bicarbonate solution and dried. After filtering, the solution was concentrated under reduced pressure. The product was isolated by crystallization from a water-ethanol mixture and characterized.

1-[3-(3-Pyridyl)glycidyl]-2-benzoyl Hydrazine (Compound II, Table I)—This compound was prepared according to the procedure described for the 4-pyridyl analog.

Synthesis of α,β -Epoxy Amides— α,β -Epoxy *N,N*-Diethyl Amides—The compounds, together with their respective melting points and/or analytical data, are listed in Table I. Compounds VII–XII were prepared by treating the respective glycidic esters with diethylamine in a procedure according to that given for *N,N*-diethyl-3,3-diphenylmethyl glycidamide. The yields obtained ranged between 30–35%. IR spectral analyses were conducted on representative compounds, and the data substantiated the structures in Table I.

The IR spectra showed characteristic peaks: 1650 cm^{-1} ($>\text{C}=\text{O}$); 1260 and 880 cm^{-1} (epoxide).

N,N-Diethyl 3,3-Diphenylmethylglycidamide (Compound XI, Table I)—Ethyl 3,3-diphenylmethylglycidate (7.0 g.; 0.025 mole) was dissolved in anhydrous benzene (75 ml.) with the aid of anhydrous ethanol (15 ml.). Diethylamine (2.0 g.; 0.027 mole) was slowly added. The mixture was refluxed for 6 hr. At this time, it was cooled and a methyl halide was added to remove unreacted amine. The filtered solution was concentrated under reduced pressure. The oil which resulted was chromatographed on silica.

N-3-Xanthylglycidyl-*N*-methylpiperazine (Compound X, Table I)—Ethyl 3-xanthylglycidate (3.5 g.; 0.0126 mole) was dissolved in anhydrous benzene (80 ml.) with the aid of anhydrous ethanol (10 ml.) and heat. *N*-Methylpiperazine (1.3 g.; 0.0125 mole) was added, and the mixture was refluxed for 4 hr. The *N*-methylpiperazyl derivative was separated from the reaction mixture after concentra-

tion under reduced pressure by vacuum distillation. The methyl bromide derivative was prepared by conventional methods.

PHARMACOLOGIC EVALUATION

This pharmacologic evaluation was undertaken to obtain a preliminary indication of some structure-activity relationships among the compounds synthesized. Considering that some of these compounds were synthesized as potential monoamine oxidase inhibitors and others as anticholinergic spasmolytics, it was decided to test for these bioactivities according to the following methods. Compounds I through XII were tested for their ability to reverse reserpine hypothermia in mice. Compounds VII, VIII, and X were evaluated for their spasmolytic activity.

Reversal of Reserpine Hypothermia—Method—The administration of reserpine to normal animals usually results in a gradual depression of the central and peripheral sympathetic systems and is characterized by conditions such as sedation, ptosis, hypotension, bradycardia, and hypothermia (9).

Pre-treatment with a monoamine oxidase inhibitor results in a reversal of the reserpine effects. Symptoms of excitation, exophthalmus, piloerection, mydriasis, and hyperthermia are observed (10).

The method of Garrattini *et al.* (11) was adopted for the estimation of the effect of the test compounds on reserpine-induced hypothermia.

Although only the hydrazides were prepared as potential monoamine oxidase inhibitors, it was decided also to evaluate the amides of the series.

Young male Swiss-Webster mice weighing between 20 and 35 g. were used throughout. The animals were given free access to food and water before and during the evaluation. The testing was scheduled so that no mouse was used more often than once a week.

Prior to the administration of any drug, the rectal temperature of each mouse was determined using a telethermometer with rectal probe. The rectal temperature then was measured at 4, 6, and 24 hr. after the intraperitoneal administration of reserpine, 2.5 mg./kg. One week later, the same group of mice was given a dose of the synthesized drug intraperitoneally, followed by intraperitoneal administration of reserpine 4 hr. later. The ability of the compound to reverse the reserpine-induced hypothermia 4, 6, and 24 hr. after the reserpine injection was noted.

Doses of the individual compounds were isomolar with respect to the standard: iproniazid. Most of the drugs were sufficiently soluble to be given either as a solution or as a stable suspension in propylene glycol.

Results—The experimental results are listed in Table II.

Discussion of Results—The pharmacologic data reveal bioactivity differences among the synthesized compounds in the test method utilized. Some of the more significant may be summarized. Among hydrazine derivatives, the 3-pyridyl series is less active than the 4-pyridyl. Also, among hydrazine derivatives, *N*-benzyl derivatives tend to be more active than the corresponding diacyl derivatives, but a significant exception is found in the case of the trimethoxybenzoyl derivatives which are more active than the benzyl derivatives. Actually, highest activity is found among the trimethoxybenzoyl derivatives. The hydrazine derivatives tend to be more potent than the amides, but some exhibit significant potency in the test.

On the basis of probable metabolic alterations, the bioactivity of the diacylhydrazines *in vivo* could be dependent upon three species. These are: the intact diacyl hydrazine, which should possess little activity; the monoacyl hydrazine, which might possess some activity; and hydrazine which should possess little activity, all to the extent that *in vitro* structure-activity relationships apply. In analogous fashion, the bioactivity of the alkyl acyl hydrazines would be dependent upon two species: the alkyl acyl hydrazine and the alkyl hydrazine. Again, to the extent that *in vitro* structure-activity relationships relate to activity in the intact animal, both of these might possess significant activity. In the case of amides, the likely species would be the amides and the amines. Significant inhibitory potency associated with either of these would not be expected. On the basis of the foregoing, the activity of the compounds synthesized and evaluated would be amides, diacyl hydrazines, and acyl alkyl hydrazines, in increasing order.

As the summary of the results indicates, the results anticipated are, in a general way, obtained, but there are important exceptions

Table II—Effect of the Synthesized Compounds on Body Temperature

	Body Temperature (°F.)

such as the high activity of the trimethoxybenzoyl derivatives and the amides. In this connection, it is well recognized that there is not necessarily a direct relationship between *in vitro* potency and activity *in vivo*. Additionally, it has been demonstrated that imipramine can reverse reserpine-induced hypothermia, probably through some other mechanism than inhibition of monoamine oxidase. The possible operation of these factors might account for the deviations from anticipated results. The possible operation of these factors throughout the series also precludes a precise delineation of structural features associated with activity. Through further biological evaluations and the synthesis of related compounds, it is hoped that this more precise delineation can be made.

Spasmolytic Activity—Method—The method for the determination of spasmolytic activity was adapted from the method of Miller *et al.* (12). The method is simple and convenient and allows potency estimates of a new compound against an established reference drug such as atropine. The method adapted here was the ability of the synthesized compound to reduce the spasm induced by a spasmogen on an isolated rabbit ileum *versus* the ability of the atropine to reduce the spasm of the spasmogen in the rabbit ileum in a set amount of time.

A Tyrode's solution of the following composition in grams per liter of purified water was used as the bath fluid:

Sodium chloride	9.0
Potassium chloride	0.2
Calcium chloride	0.2
Magnesium chloride	0.1
Sodium bicarbonate	1.0
Sodium acid phosphate	0.05
Glucose	1.0

The smooth muscle employed as test tissue was a strip of ileum 1–2 cm. in length, quickly removed from a recently sacrificed rabbit. The strip was suspended in the 10-ml. chamber filled with Tyrode's solution maintained at 37°. The muscle contractions were amplified and recorded on an E. and M. physiograph through a myograph attachment.

The remaining smooth muscle not being used was placed in Tyrode's solution suitably aerated and kept at constant temperature at 37° for subsequent pharmacological evaluation.

Test samples of freshly prepared solutions of the glycidyl compounds were prepared in concentrations of 1.4×10^{-5} mM. An aqueous solution of atropine sulfate, 1.4×10^{-6} mM, was used as the standard spasmolytic agent throughout the study.

An aqueous solution of mecholyl chloride was used as the standard spasmogen in millimolar quantities (1.3 mM).

A glass cylinder of 10-ml. capacity, equipped with an air inlet and a drainage arrangement maintained in a constant-temperature bath, was used throughout. The muscle chamber was equipped with an aerating tube which effectively aerated the muscle strip and efficiently mixed the test drugs.

As soon as the suspended strips had recovered from the contraction caused by the operative manipulations, the testing was begun. The dose of the spasmogen was administered to produce virtually maximum contraction. The spasmolytic agent was introduced without washing out the spasmogen. The degree of relaxation produced in the first 2 min. was noted. Following the observation the drug containing Tyrode's solution was flushed out and replaced with fresh solution. When the strips had relaxed to the former tonus level, they were ready for another trial.

Results—The pharmacological data on the spasmolytic activity of Compounds VII, VIII, and X are represented in Table III,

Table III—Summary of Data Showing Concentration–Response Relationships for the Spasmolytic Effects of Compounds VII, VIII, and X and Atropine Sulfate Against Methacholine Chloride-Induced Spasm in Excised Rabbit Ileum

	Spasmolytic Agent			
	Compound X	Compound VIII	Compound VII	Atropine Sulfate
Ml. added to 10-ml. muscle bath	0.8 ml.	2.0 ml.	2.0 ml., 3.0 ml.	0.2 ml.
Concentration in muscle bath	1.15×10^{-4}	2.88×10^{-4}	2.88 and 4.32×10^{-4}	2.88×10^{-6}
Response: No. positive/No. tried	7/10	6/10	0/10 1/10	8/10
Relative potency	2.5	1.0	0	1×10^2

noting concentration in millimolar quantities as well as relative potency when compared to atropine sulfate.

Discussion of Results—Examination of Compound X reveals that it is about 2.5 times as active as Compound VIII. Compound VII was found to be inactive in the ability to reduce the spasms induced by mechoyl. While spasmolytic activity is present in Compounds X and VIII, the activity present is only about 1/40th and 1/100th, respectively, that of the standard spasmolytic agent, atropine sulfate.

Dissolution of Macromolecules II: Dissolution of an Ethylene–Maleic Acid Copolymer

ALLEN HEYD*, DANE O. KILDSIG, and GILBERT S. BANKER

Abstract Factors influencing the dissolution of an ethylene–maleic acid copolymer have been studied. Polymer swelling, hydrated layer thickness, and solvent pH were shown to influence the dissolution of the polymer. Linear dissolution rates were observed following an initial induction period. Hydrated layer thickness was found to be a controlling factor in the dissolution process. An immersion refractometry method was employed to measure aqueous polymer concentrations during dissolution.

Keyphrases Ethylene–maleic acid copolymer—dissolution Tablets, ethylene–maleic acid copolymer—dissolution study Dissolution test apparatus—diagram Refractometry, immersion—polymer determination

Polymeric materials are widely used in many pharmaceutical systems. In systems utilizing polymer films and particularly in dosage forms in which the polymer is compressed in tablets to produce controlled drug release, the dissolution of the polymer is an important parameter. Polymer systems are frequently sought which, based on their dissolution properties, will provide a particular type of drug release.

Previous investigators of polymer dissolution have studied the dissolution of polystyrene in organic solvents (1–3). However, a detailed investigation of the dissolution in aqueous solvents of polymers having reactive functional groups has not been reported. In an earlier report the surface phenomena associated with the dissolution of such polymers were described (4). The present investigation reports the dissolution of an ethylene–maleic acid (dicarboxylic acid) copolymer as affected by these surface parameters.

EXPERIMENTAL

The ethylene–maleic acid copolymer, referred to as EMA-22, and the polymer tablets used in this study were identical to those used in a previous investigation (4). The measurement of polymer swelling, solvent penetration, and hydrated layer thickness was also identical to that of the earlier study (4).

The dissolution apparatus employed for the study of polymer dissolution is shown in Figs. 1–3. Figure 1 describes the sample holder; Fig. 2 shows the dimensions of the Plexiglas dissolution cell. Figure 3 is a schematic representation of the dissolution unit and the component parts that made up the entire system. The lip of the

The dissolution apparatus employed for the study of polymer dissolution is shown in Figs. 1–3. Figure 1 describes the sample holder; Fig. 2 shows the dimensions of the Plexiglas dissolution cell. Figure 3 is a schematic representation of the dissolution unit and the component parts that made up the entire system. The lip of the

Figure 1—Sample holder. Key: a, compressed disk cavity; b, plunger; c, die housing; d, steel shaft; and e, 1.12-cm. (0.44-in.) die.

die housing of the sample holder (Fig. 1) was placed on the edge of the dissolution cell (Fig. 2), which provided constant sample geometry for each dissolution test. The plunger of the sample holder facilitated exact positioning of the compressed disk. The shaft of the sample holder, which permitted positioning of the holder in the dissolution apparatus, extended through the housing of the holder and was threaded into the plunger (Fig. 1).

A Bausch & Lomb immersion refractometer,¹ utilizing prism A, was used to follow the increase in polymer concentration with time. Standard curves of refractometer reading *versus* polymer concentration were linear over the concentration range used, 0 to 4 mg./ml. The precision of the refractometer method was excellent; identical

Figure 2—Plexiglas dissolution cell. The external dimensions are indicated. The inside dimensions are 6.99-cm. (2.75-in.) total length, 2.87 cm. (1.13 in.) wide, and 3.66 cm. (1.44 in.) deep with the ends having a 1.42-cm. (0.56-in.) radius of curvature.

readings on the refractometer scale were obtained for each replicate sample of each polymer solution.

In conducting the dissolution test, a 1-g. compressed tablet of EMA-22 free acid was positioned in the cavity of the sample holder so that 0.05 cm. of the tablet protruded. The dissolution cell was filled with 60 ml. of solvent, which was allowed to equilibrate to $30 \pm 0.1^\circ$. This volume was sufficient to cover the exposed tablet after the sample holder and the refractometer were precisely positioned in the dissolution cell. A magnetic stirrer unit drove a 1.27-cm. (0.5-in.) stirring bar inside the dissolution cell at 130 r.p.m. Kolthoff's alkaline borate buffer (5) was used to prepare pH 7.4 and 9.4 buffers. The buffers from pH 1.2 to 6.2 were prepared from standard solutions as described by the USP (6). The immersion refractometry method and the technique and apparatus described permitted the dissolution process to be continuously followed without disturbing the system.

RESULTS AND DISCUSSION

The dissolution of EMA-22 in distilled water is shown in Fig. 4. The dissolution rate was linear following an initial induction period.

Figure 4—Linear dissolution rate with initial induction period. Key: a, lag time; b, stabilization period; and a + b, induction period.

Figure 5—Correlation between induction period, a, swelling time, b, and hydrated layer formation, c.

The induction period consisted of a lag time and a stabilization period (Fig. 4). The lag time, or period before measurable concentration appears in solution, is attributed to the time required for initial solvent penetration and initial polymer swelling. During the initial swelling process (0–0.5 min.) in which the largest extent of swelling was achieved (4), little or no polymer dissolved. During the stabilization period, the dissolution rate continuously decreased as the polymer achieved maximum swelling. Also during the stabilization period, maximum hydrated layer thickness was achieved after which the dissolution rate was linear. The correlation between hydrated layer formation, swelling time, and the dissolution induction period is shown in Fig. 5. The establishment of both an equilibrium hydrated layer thickness and maximum swelling was found generally to correlate to the induction period required for achievement of a constant dissolution rate.

The polymer–solvent interaction is responsible for the expansion of the linear chain polymer and the subsequent formation of a gel structure. As the EMA-22 polymer is a dicarboxylic acid, the solvent pH would be expected to influence greatly the dissolution of the polymer (Fig. 6). Contrary to the dissolution of micromolecular weak acids, the equilibrium dissolution rate of the polymer weak acid decreases with increasing pH (Fig. 6). However, the dissolution rates reported in Fig. 6 are the equilibrium values obtained from the linear portion of the curve. The initial dissolution rates did increase with increasing pH but were quickly affected (within 0.5–2 min.) by the swelling phenomena and subsequent hydrated layer

Figure 6—Decrease in equilibrium dissolution rate with increasing pH.

formation. Thus the swollen hydrated layer remains the determining factor in the dissolution of the EMA polymer following swelling equilibrium.

SUMMARY

The dissolution of an ethylene–maleic acid copolymer was investigated using an immersion refractometer for polymer analysis. An induction period was observed consisting of a lag time and a stabilization period, during which the dissolution rate was continuously decreasing until a constant rate was obtained. The solvent pH was found to influence the dissolution of the polymer through its effect on polymer swelling and hydrated layer thickness. These two parameters, swelling and hydrated layer thickness, were primarily responsible for the dissolution properties of the polymer. The refractometer method was adequately sensitive for following polymer dissolution and allowed a continuous determination of polymer concentration without sampling.

Pharmacological Evaluation of Seizures Induced by Electrical Stimulation of the Hippocampus

PENG N. YEOH and HAROLD H. WOLF

Abstract □ A method to induce minimal seizures in unrestrained rats *via* bipolar electrodes implanted in the right dorsal hippocampus has been described. The threshold for such seizures is reproducible, stable over time, and elevated by trimethadione and high doses of diphenylhydantoin. Propranolol and pronethalol also raise seizure threshold, but MJ1999 and D(-)- and L(+)-INPEA are ineffective. The adrenergic agents do not seem to alter seizure threshold by their ability to block β -receptors.

Keyphrases □ Hippocampal stimulation—bipolar electrodes □ Convulsive seizures—electrical stimulation, hippocampus □ Electrically produced seizures—convulsive threshold □ Anti-convulsants effect—electrically produced seizures

Several techniques to produce minimal seizures experimentally have been reported (1). Some involve the application of electric current *via* corneal electrodes to restrained animals, while others employ such chemicals as hexafluorodiethylether and metrazol. The former method is less than ideal, since brief restraint lowers seizure threshold (2), while the latter methods are subject to criticism of possible drug-drug interaction when used in drug studies designed to elucidate seizure mechanisms.

One objective of this study was to develop a method to induce minimal seizures electrically in unrestrained rats. Ideally, such seizures would be easily induced, stable, and reproducible over a long time.

A second objective of this study was to determine whether such seizures would respond to anticonvulsants such as diphenylhydantoin and trimethadione in a manner similar to that observed with other experimentally induced seizures (3-5).

At present, the mechanisms responsible for seizure expression are still not fully known. However, there is much evidence indicating an involvement of catecholamines. For example, Schlesinger *et al.* (6) and Scudder *et al.* (7) reported that mice with higher than normal susceptibility to seizures had lower catecholamine levels. Other studies have shown that reserpine, tetraabenazine, and more selective catecholamine depletors increased seizure susceptibility; while treatment with the catecholamine precursor, L-dopa, in the presence of iproniazid inhibited seizure activity (8-10). In general, the existing evidence seems to relate low catecholamine levels with a high susceptibility to seizure expression.

Some earlier experiments in this laboratory (11) demonstrated that β -adrenergic blocking agents, *e.g.*, propranolol and pronethalol, elevated thresholds in mice to low-frequency electroshock (l. f. ES). In addition, pronethalol protected susceptible mice from audiogenic seizures. Thus, a third objective was to pursue further the effect of selected β -adrenergic blocking agents on convulsive activity by evaluating

their ability to modify threshold for electrically induced hippocampal seizures.

EXPERIMENTAL

The drugs studied were diphenylhydantoin, trimethadione, and the adrenergic agents propranolol [1-isopropylamino-3-(1-naphthoxy)-2-propanol hydrochloride], pronethalol [D,L-1-(2'-naphthyl)-2-isopropylaminoethanol hydrochloride], D(-)- and L(+)-INPEA [D(-)- and L(+)-1-(4'-nitrophenyl)-2-isopropylaminoethanol hydrochloride], and MJ1999 [4'-(2-isopropylamino-1-hydroxyethyl)methanesulfonanilide]. Except for L(+)-INPEA, all these compounds are well-established peripheral β -adrenergic blocking agents (12).

The experimental animals employed were male Wistar albino rats (200-300 g.).¹ Under pentobarbital anesthesia (45 mg./kg.), these rats were stereotactically implanted with stainless steel (0.3-mm. diameter) bipolar electrodes (MS 303-018"-312"-SS-010")² in the right dorsal hippocampus (2.59 mm. lateral to sagittal zero; 3.80 mm. anterior to frontal zero, and 2.50 mm. below the brain surface) according to the rat atlas of König and Klippel (13). The hippocampus was chosen because of its low threshold to seizure expression.

Following surgery, the rats were housed individually in plastic cages (16 × 25 × 25 cm.) with free access to food and water. At least 1 week later, each rat was transferred to a testing chamber (30 × 30 × 50 cm.) equipped with a oneway mirror. The implanted electrodes were then connected to a Grass S4 stimulator in series with a capacitor (to maintain constant waveform), a timer key (set for 6 sec.), and an external resistor (100 ohm). A current passing through the resistor was measured by an oscilloscope and reflected that passing through the electrode. With the key opened, a resistor box was placed in series with the stimulator to measure rat resistance.

In this environment, the rat was able to move about freely. After 5-min. adaptation in the experimental box, the rat was subjected to a series of electrical stimulations of increasing intensities until a minimal seizure was seen.

The stimulus consisted of a train of 0.2-msec. biphasic pulses, 6 sec. in duration with a frequency of 60 c.p.s. A 2-min. interval separated each stimulus. To minimize the total number of stimuli administered to any rat, the following schedule was employed. A starting current intensity of 150 μ amp. was increased in steps of 50 μ amp. At intensities of 600 μ amp., the increment was raised by a factor of 4; above 1000 μ amp., it was raised 10 times the original value. The maximum current intensity administered was 3000 μ amp.

A seizure was defined as the presence of readily observed jaw chopping and/or myoclonic jerks, and the current intensity that just produced such symptoms was defined as the seizure threshold. In drug studies, rats that did not exhibit seizures with the maximum current were assigned seizure thresholds of 3000 μ amp. for statistical computations.

The rats were eventually sacrificed with pentobarbital and perfused with saline, followed by 10% formalin, *via* the right ventricle. Serial collodion sections (30 μ) were stained by the technique of Kluver and Barrera (14) and microscopically examined to localize the electrode tract as well as to evaluate possible tissue damage.

All drug injections were made intraperitoneally. Control animals received the drug vehicle.

To determine appropriate doses and the duration of drug activity, pilot studies were conducted based on drug-induced neurotoxicity.

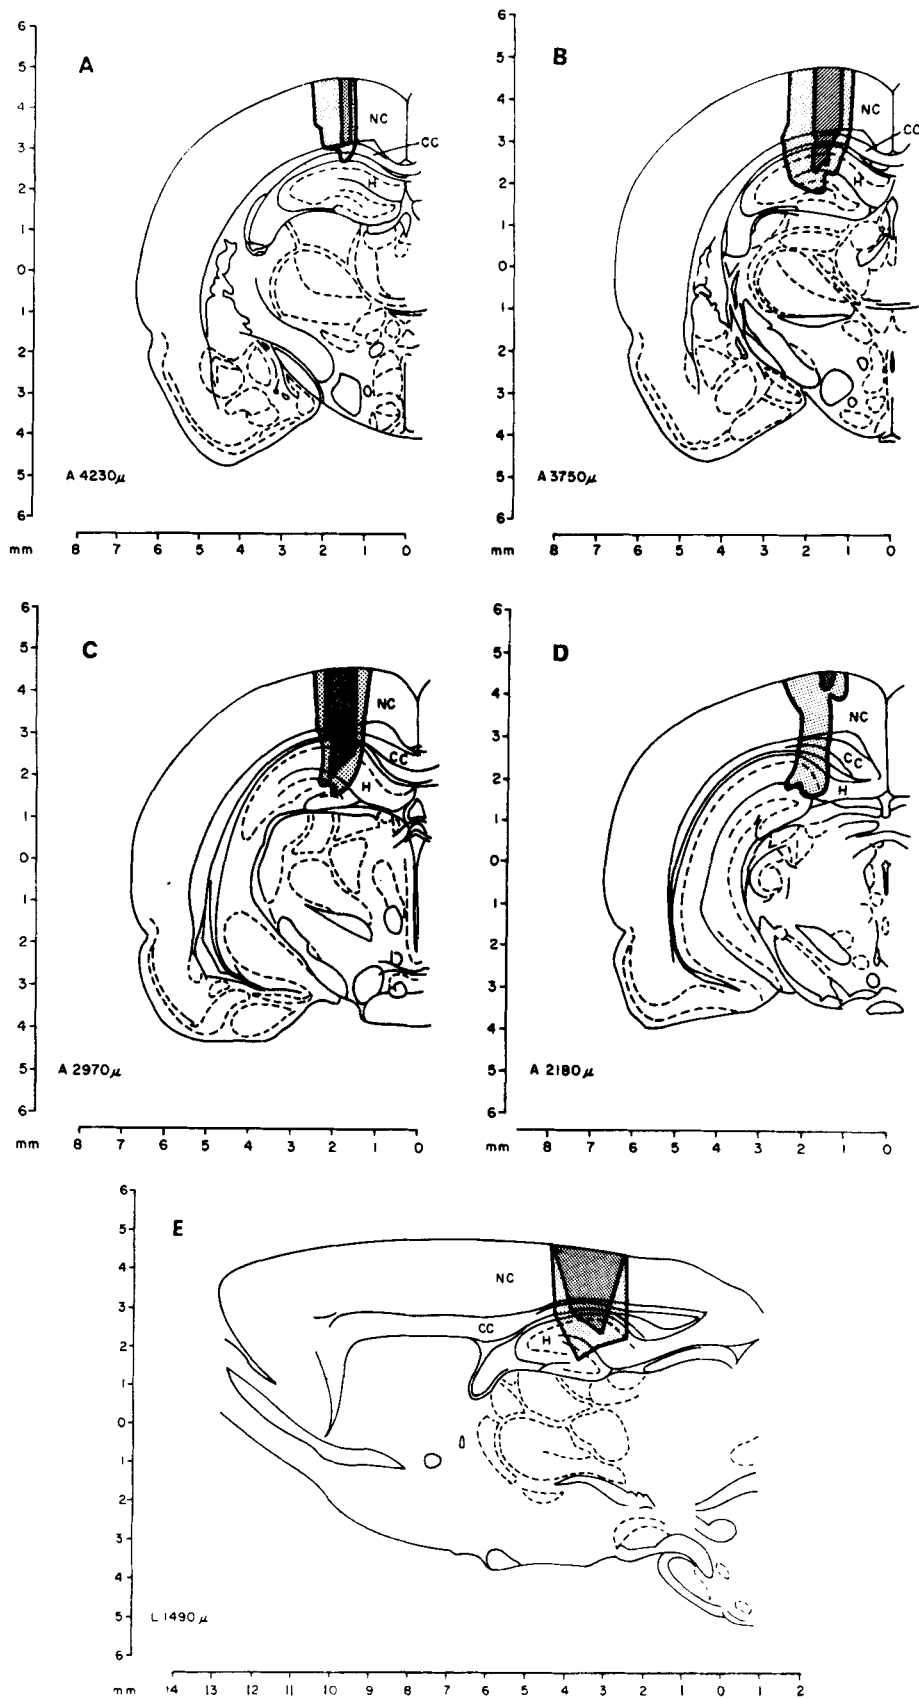

Figure 1—Minimal (▨) and maximal (---) extent of the lesions projected on frontal sections (A–D) and sagittal section (E) at the stated distances from frontal and sagittal zeroes, respectively. Key: NC, neocortex; CC, corpus callosum; and H, hippocampus.

Table I—Stability of Rat Resistance

Min. between Test	Mean Resistance (kohm) Initial	Mean Resistance (kohm) Final	Difference Mean
2	12.51	11.93	0.58 ^a
15	13.05	13.62	0.57 ^a
20	12.80	12.94	0.14
30	12.91	14.09	1.18 ^a
1440	13.39	13.61	0.22 ^a

^a $p < 0.05$.

This was defined as the failure of a rat to stay on a rotating rod (6 r.p.m.) for 1 min., given three trials. Drug-induced neurotoxicity in 50% of the rats (TD_{50}) with 95% confidence limits was calculated using the method of Litchfield and Wilcoxon (15).

In the evaluation of drug effects on seizure threshold, groups of 6–10 rats (average of 8) with a predetermined stable seizure threshold (SST) were employed. Half of these received the drug and the other half received the drug vehicle. Seizure threshold after drug treatment (DST) and control seizure threshold (CST) were determined at the time of peak neurotoxic effect of the drug. A crossover design with a 7-day interval was employed, so each rat served as its own control. Threshold ratios, *i.e.*, DST/SST and CST/SST, with 95% confidence limits were calculated by the method described by Goldstein (16).

RESULTS AND DISCUSSION

The lesion produced by electrode implantation was reconstructed with the aid of the atlas of König and Klippel (13) and is shown in Fig. 1. Tissue damage extended from about 2.2 to 4.2 mm. anterior to frontal zero and from 1.1 to 2.5 mm. lateral-sagittal zero. Only the neocortex, the corpus callosum, and the dorsal hippocampus in this region were affected. In all the animals studied, the electrode tip lay in the right dorsal hippocampus between 3.7 and 3.8 mm. anterior to frontal zero, but it was 1.1–2.0 mm. lateral to sagittal zero. This could be due to the different strain of rat used in this study compared to those employed for the construction of the König and Klippel atlas.

The stability of rat resistance over time was evaluated; these data, presented in Table I, were analyzed by a paired comparison *t* test.

Over time intervals ranging from 2 to 1440 min., rat resistance varied significantly in all but one test. These results emphasize the importance of taking the instantaneous rat resistance into consideration in any measurement of current intensity passing through the brain. Therefore, in all subsequent studies, rat resistance was measured during every stimulus, and the actual current intensity passing through the electrodes was thus recorded.

The stability of hippocampal seizure threshold over time is presented in Fig. 2. The vertical bars denote 95% confidence limits, and any point where a bar does not cross 1.0 indicates a significant change in seizure threshold. These data indicate that hippocampal seizure threshold remained essentially stable over time intervals ranging from 10 to 60 min. between determinations. Additional studies with injection of saline between tests also produced no apparent change in threshold over the same time intervals.

The results obtained in the neurotoxicity studies are represented in Table II. The time of peak effect varied from 10 min. for tri-

Figure 2—Stability of hippocampal seizure threshold over time. Threshold ratio was determined by dividing the final seizure threshold by the initial seizure threshold ($n = 6$).

Table II—Neurotoxicity of Drugs

Drug	Time of Peak Effect, min.	$TD_{50} \times 10^{-1}$, mmoles/kg.
Diphenylhydantoin	60	8.30 (5.90–11.60) ^a
Trimethadione	10	32.80 (29.50–33.40)
Propranolol	15	1.11 (1.04–1.18)
Pronethalol	15	1.23 (0.99–1.52)
MJ1999	30	>8.0
D(–)-INPEA	20	2.06 (1.35–3.15)
L(+)-INPEA	20	2.08 (1.51–2.87)

^a Figures in parentheses represent 95% confidence limits.

methadione to 60 min. for diphenylhydantoin. The remaining compounds exhibited peak activity between 15 and 30 min. As would be expected from previous studies (4, 5), the neurotoxicity potency of trimethadione was quite low compared to that of the other drugs tested. Complete toxicity studies for MJ1999 were not conducted, due to the limited amount of drug available and its relative nontoxicity. No toxic effect was seen with 8×10^{-1} mmoles/kg. The choice of 30 min. as the time of peak activity for this agent was based on observable gross central nervous system depression and on previous work (17).

The effect of diphenylhydantoin on seizure threshold is demonstrated in Fig. 3. Control solution did not alter seizure threshold significantly in this or any subsequent studies. At doses of 0.5 and 1.0×10^{-1} mmoles/kg., diphenylhydantoin did not have a significant effect; a higher dose of 2.5×10^{-1} mmoles/kg. produced a slight but significant elevation of threshold. These results agree with those reported for this compound on other types of experimentally induced minimal seizures, since low doses have no effect on thresholds for minimal electroshock, metrazol, and l.f. ES seizures, while higher doses have been shown to increase l.f. ES seizure threshold (4, 5, 18). Diphenylhydantoin also raises the convulsive threshold of the motor cortex in the monkey (19).

Several workers who measured electrical afterdischarges evoked by stimulation of specific brain areas in monkeys, cats, and rabbits (19–21) generally observed an increase in threshold and shorter discharge duration in the motor cortex, hippocampus, thalamus, and septal area following diphenylhydantoin treatment. However, the compound has been reported to produce no effect on cortical or hippocampal afterdischarges in the rabbit (22), although transcortical spread of abnormal activity from chronic epileptogenic focus in the visual cortex (rabbit) can be suppressed by this agent (23). In view of the wide variation in the animal species employed, the dose, the route of drug administration, the electrical stimulus, and the brain regions stimulated, it is difficult to correlate these data with the present findings. However, diphenylhydantoin is known to have a nonspecific stabilizing action on excitable membranes (24). This is thought to result from a more efficient extrusion of sodium ions from brain cells, probably by stimulation of the metabolic sodium pump (25–27). This activity may account for the slight elevation of seizure threshold induced by the high dose of diphenylhydantoin.

Similar data obtained with trimethadione are presented in Fig. 4. All four doses raised threshold significantly, and an apparent dose-response relationship was seen. The efficacy of trimethadione

Figure 3—Effect of diphenylhydantoin on hippocampal seizure threshold ($n = 6$). Key: \circ , propylene glycol; and Δ , diphenylhydantoin.

Figure 4—Effect of trimethadione on hippocampal seizure threshold ($n = 10$). Key: \circ , propylene glycol; and Δ , trimethadione.

in this procedure was further emphasized by the absence of seizures in several animals at the maximum stimulus employed. Again, these data reflect anticipated results, because trimethadione is known to elevate minimal seizure threshold as measured by other techniques (4, 5).

Schallek and Kuehn (20) found trimethadione to be superior to diphenylhydantoin in increasing seizure thresholds at cortical and other brain sites. Furthermore, thresholds to electrical afterdischarges in the motor cortex and the thalamus are elevated, while the duration of these afterdischarges is reduced in several species subsequent to treatment with the drug (19–22). Morrell *et al.* (23) observed that trimethadione not only suppresses chronic epileptogenic foci but also depresses the projection of seizure activity from cortical foci to the thalamus and to the contralateral side. This

Figure 6—Effect of pronethalol on hippocampal seizure threshold ($n = 10$). Key: \circ , saline; and Δ , pronethalol.

action may well be due to the ability of the drug to intensify the depression of synaptic transmission following each transmitted volley of impulses (28). Such an action would prevent the build-up and maintenance of an oscillating system between the thalamus and the cortex, postulated to be involved in the precipitation of minimal seizures (26, 29, 30). Thus, the ability of trimethadione to increase seizure threshold in this study may reflect this suppression of showers of impulses at central synapses.

The effects seen with a highly potent β -adrenergic blocking agent, propranolol (31, 32), are illustrated in Fig. 5. At doses higher than 0.25×10^{-1} mmol/kg., it elevated seizure threshold, and again there was an apparent dose-response relationship. An increase in seizure threshold of about 275% was seen with the highest dose employed. At this dose level, several rats did not exhibit seizures even when the maximum stimulus was administered. Since propranolol is known to have central depressant activities, the effect of pronethalol, a less potent β -adrenergic blocking agent with some central stimulant properties, was studied in an attempt to separate effects due to nonspecific central depression from β -blockade. The results are shown in Fig. 6. At low doses, pronethalol increased seizure threshold significantly. A 50% elevation was observed with 0.5×10^{-1} mmol/kg. This is about one-fifth the effect seen with the same dose of propranolol. However, higher doses (in the region of $1/2$ TD_{50}) produced no significant alteration of seizure threshold. This could be a reflection of the fact that high doses of pronethalol are known to induce convulsions (33).

Both propranolol and pronethalol have significant local anesthetic properties (34). Thus, the threshold-elevating effects of these two compounds may be related more to this aspect of their activity than to their β -receptor blocking properties. To test this, two blocking agents, MJ1999 and INPEA, reported to be relatively selective as β -adrenergic blocking agents and to possess no local anesthetic action (17, 35), were examined. The results obtained with MJ1999 are seen in Fig. 7. Even with 5 times the effective dose of propranolol, no significant change in seizure threshold was seen.

Similar data obtained with INPEA are presented in Fig. 8. If β -adrenergic blockade was indeed responsible for the elevation of seizure threshold exhibited by propranolol and pronethalol, marked differences between the effects of these two isomers of INPEA would be expected, since only the D(–)-isomer has been reported to be active as a β -adrenergic blocking agent (12). However, both isomers were equally ineffective in changing seizure

Figure 7—Effect of MJ1999 on hippocampal seizure threshold ($n = 8$). Key: \circ , saline; and Δ , MJ1999.

Figure 8—Effect of INPEA on hippocampal seizure threshold ($n = 9$). Key: ○, saline; △, D(–)-INPEA; and ▲, L(+)-INPEA.

threshold, even at doses 4 times greater than the effective dose of propranolol.

Thus, although these data do not explain the mechanism whereby propranolol and pronethalol elevate hippocampal seizure threshold, they do provide evidence that the alteration in seizure susceptibility produced by these agents is not causally related to blockade of β -receptors.

CONCLUSION

The threshold of seizures induced by electrical stimulation of the hippocampus in unrestrained rats has been shown to be stable and reproducible over time. Furthermore, it is modified by typical anticonvulsants in a manner similar to that observed with other types of experimentally induced minimal seizures.

Both propranolol and pronethalol increased seizure threshold. These findings are consistent with those seen in earlier studies with I.f. ES and audiogenic seizures (11). However, other β -adrenergic blocking drugs do not have a threshold-elevating effect. Murmann *et al.* (36) have reported essentially similar results employing different seizure-inducing techniques. They found that propranolol and pronethalol reduced susceptibility of animals to maximal metrazol and maximal electroshock seizures, but reported L(+)- and D(–)-INPEA to be ineffective. MJ1999 has also been demonstrated by Chen *et al.* (10) and Lish *et al.* (17) to be incapable of altering both maximal and minimal electroshock seizures.

The results of the latter portion of this study largely substantiate the hypothesis of Leszkovszky and Tardos (37) and Murmann *et al.* (36) that certain β -adrenergic blocking compounds affect seizure expression by mechanisms other than β -blockade.

However, as stated previously, evidence supporting a catecholamine influence on seizure expression exists in the literature. Moreover, α -adrenergic blocking agents, phenoxybenzamine and phentolamine, have been reported to increase seizure susceptibility (10). In view of this, an investigation of the effects of α -adrenergic blocking agents on seizure threshold is currently in progress and should provide useful information.

N-Chlorosaccharin as a Possible Chlorinating Reagent: Structure, Chlorine Potential, and Stability in Water and Organic Solvents

HAN-SON DAWN*, IAN H. PITMAN, TAKERU HIGUCHI†, and STEPHEN YOUNG*

Abstract □ *N*-Chlorosaccharin is shown by its low chlorine potential ($pK_{cp} = 4.85$ at 25°) to be a stronger chlorinating reagent in water than the commonly used chloramine-T or *N*-chlorosuccinimide. Its possible usefulness as a detoxifying or chlorinating reagent was further indicated by its solubility and stability in a variety of solvents. The mechanism of a reaction in which the imide bond of *N*-chlorosaccharin was cleaved in aqueous hypochlorite solution was also investigated.

Keyphrases □ *N*-Chlorosaccharin—synthesis □ Chlorine potential—*N*-chlorosaccharin □ Hypochlorite solution—*N*-chlorosaccharin degradation □ IR spectrophotometry—identity □ UV spectrophotometry—identity □ Iodometric titration—analysis

N-Chloro imides [e.g., *N*-chlorosuccinimide (I)] (1) and sulfonamides [e.g., chloramine-T (II)] (2) are widely used as chlorinating and oxidizing reagents. The chlorinating power of these molecules, expressed as their chlorine potential, pK_{cp} ,¹ has been shown (3) to be related to the acidity of their nonchlorinated con-

jugates, with the stronger chlorinating agent being derived from the stronger acid. Thus, because saccharin (III) is a stronger acid ($pK_a = 1.31$) (4) than succinimide ($pK_a = 9.62$) (5) or *p*-tolylsulfonamide ($pK_a = 10.3$) (6), it was expected that *N*-chlorosaccharin (IV) would be an even stronger chlorinating reagent than I or II.

When attempting to determine the K_{cp} value of IV, it was found that other reactions were occurring beside the transfer of positive chlorine between IV and water. These included acid dissociation of saccharin, cleavage of the imide bond of IV by the hypochlorite ion, formation of *N,N*-dichloro-*o*-sulfamylbenzoic acid (V) (and

possibly the monochloro derivative), and slow decomposition of V to yield *o*-carboxylbenzenesulfonic acid (VI) and gaseous compounds. The overall reaction scheme is believed to be as shown in Scheme I.

Scheme I

In this communication, evidence is reported for this reaction scheme together with values of the equilibrium constant, K_{cp} , and second-order rate constant, k_1 . Approximate values of the solubility of IV in carbon tetrachloride, ethyl acetate, acetone, 1,4-dioxane, and chloroform were also determined, and the stability of its solutions in these solvents and methanol was investigated.

STRUCTURE AND SOLUBILITY OF *N*-CHLOROSACCHARIN

A chlorinated derivative of saccharin was precipitated (7) as a white crystalline powder (m.p. $148\text{--}150^\circ$) when chlorine gas was passed into cold aqueous solutions of saccharin. This substance was confirmed to be *N*-chlorosaccharin by elemental analysis, iodometric estimation of its positive chlorine content (one equivalent of positive chlorine per molecule), and from a comparison of its IR spectrum to those of saccharin (III), *N*-methylsaccharin (VII), and *o*-methylsaccharin (VIII). The conclusion that the chlorine in the molecule had substituted the imide proton of saccharin was deduced from the facts that: (a) the substance liberated positive chlorine in water (this would not be expected if the chlorine atom was substituted in the benzene ring), and (b) its IR spectrum contained no peaks above 3000 cm^{-1} (i.e., in the N—H and O—H stretching region). The conclusion that it was *N*-chlorosaccharin and not the isomeric *o*-chloro derivative came from the observation that its IR spectrum contained a strong peak in the carbonyl stretching fre-

¹ For a chloro compound, R_2NCl , $pK_{cp} = -\log_{10} K_{cp}$, where K_{cp} is the equilibrium constant for the reaction $R_2NCl + H_2O \rightleftharpoons R_2NH + HOCl$.

quency range (at 1750 cm^{-1}). A similar carbonyl stretching peak was present in the spectra of saccharin (II) and *N*-methylsaccharin (1750 cm^{-1}), but *o*-methylsaccharin did not contain any significant peaks between 1625 and 2000 cm^{-1} . *o*-Chlorosaccharin would have been expected to have similar spectral characteristics to this latter compound (VIII).

Although *N*-chlorosaccharin had very low solubility in water (estimated solubility 0.1 g./l. at 25°), it was considerably more soluble in organic solvents as shown in Table I. UV spectral analysis and iodometric titration indicated that the *N*-chlorosaccharin content of the solutions in Table I did not change more than 3% during 3 hr. at 25° .

Chlorine Potential of *N*-Chlorosaccharin—A substance with a UV spectrum closely resembling that of *N*-chlorosaccharin was rapidly (complete within 30 sec.) formed when a solution of saccharin ($1.16 \times 10^{-4}\text{ M}$) in 6.8 N sulfuric acid was mixed with an equal amount of aqueous hypochlorous acid ($1.34 \times 10^{-3}\text{ M}$). When similar mixtures were made at higher pH values (in monochloroacetic acid–sodium monochloroacetate buffers), the spectra which were rapidly generated resembled those of mixtures of saccharin, sodium saccharin, and *N*-chlorosaccharin. These rapidly generated spectra did not change more than 3% during 3 min. at pH values below 3.8. They did, however, change appreciably over longer periods because of reactions that will be shown to involve cleavage of the imide bond of *N*-chlorosaccharin followed by slow decomposition of the ring-opened intermediate. Similar spectral behavior was observed when 0.5-ml. aliquots of a solution of *N*-chlorosaccharin in ethyl acetate ($9.72 \times 10^{-3}\text{ M}$) were mixed with 20 ml. of solutions of hypochlorous acid in various buffers. *N*-Chlorosaccharin was added as its ethyl acetate solution because of its slow rate of dissolution in water.

These initial rapid reactions are believed to be due to the establishment of the equilibria:

where SH and S^- are the saccharin and saccharin anion, respectively; SCl is *N*-chlorosaccharin; and $K_{cp} = [\text{SH}][\text{HOCl}]/[\text{SCl}]$. The value of K_{cp} was calculated from spectrophotometric measurements of equilibrium concentrations of reactants and products following mixing of aqueous solutions of saccharin with buffered solutions of hypochlorous acid or of ethyl acetate solutions of *N*-chlorosaccharin with buffer solutions. Results from several series of experiments are included in Table II.

The mean value for K_{cp} in water was $1.4 \times 10^{-5}\text{ M}$ at 25° (excluding the K_{cp} values calculated from Experiments 6 and 7 where 2.4% ethyl acetate was present).

Thus, *N*-chlorosaccharin has a lower chlorine potential ($\text{p}K_{cp} = -\log K_{cp} = 4.85$) than *N*-chlorosuccinimide (8) ($\text{p}K_{cp} = 7.91$) and chloramine-T (8) ($\text{p}K_{cp} = 7.77$). Its value is very close to that which would be predicted (3) (5.27) on the basis that *N*-chlorosaccharin is a complex between a polarizable nitrogen containing anion (S^-) and the Lewis acid (Cl^+). For such a case the chlorine potential would be

expected to be related to the $\text{p}K_a$ of saccharin by the identity $\text{p}K_{cp} = 0.28\text{ p}K_a + 4.90$.

Degradation of *N*-Chlorosaccharin in Aqueous Hypochlorite Solution—The previously mentioned changes in the UV spectrum of an equilibrium mixture of saccharin, saccharin anion, and *N*-chlorosaccharin increased in rate when the pH of the solution was raised or when the concentration of hypochlorous acid was increased. These changes are believed to be due to a relatively fast cleavage of the imide bond of *N*-chlorosaccharin followed by a slower decomposition of the chlorinated *o*-sulfamylbenzoic acid. Results in Fig. 1 show the change in UV absorbance at $282\text{ m}\mu$ in a 2-cm. cell plotted against time following the mixing of a solution of saccharin ($5.60 \times 10^{-4}\text{ M}$) in an acetic acid–sodium acetate buffer at pH 3.9 with an equal volume of aqueous hypochlorous acid ($1.05 \times 10^{-2}\text{ M}$). After the reaction had proceeded for longer than 40 min., unidentified gases were evolved. The UV spectrum, which was measured 3 min. after mixing the reactants, is shown in Fig. 2 to be almost identical to that obtained 3 min. after mixing equal volumes of solutions of *o*-sulfamylbenzoic acid ($6.00 \times 10^{-4}\text{ M}$) and hypochlorous acid ($1.37 \times 10^{-2}\text{ M}$).

The reactions occurring in the hypochlorous acid–saccharin system could be quenched by adding drawn samples to excess sodium bisulfite to reduce the positive chlorine. When the drawn samples were added to sodium bisulfite at progressively longer time intervals after the reactants had been mixed, and the solution was placed on a silicic acid–sulfuric acid column, saccharin and *o*-sulfamylbenzoic acid (identified by their UV spectra in chloroform and their retention time on the column as compared to authentic materials) were eluted with a chloroform–butanol mixture. The amount of saccharin obtained decreased, and the amount of *o*-sulfamylbenzoic acid increased initially and then decreased as the time elapsed before the addition to sodium bisulfite increased. Results of the amounts of saccharin and *o*-sulfamylbenzoic acid obtained are plotted as a function of time before addition to sodium bisulfite in Fig. 3. *o*-Carboxylbenzenesulfonic acid, which was also expected to be a product of the degradation of *N*-chlorosaccharin, could not be eluted from the column with chloroform–butanol mixtures because of its high acidity. It was, however, eluted with aqueous phosphate buffer after the saccharin and *o*-sulfamylbenzoic acid had been removed. It was identified by the similarity of its UV spectra in 1 M HCl and 0.1 M NaOH to that of authentic material. Thus, the changes in UV absorbance and product analysis are consistent with the proposed reaction scheme for degradation of *N*-chlorosaccharin.

Figure 1—Observed change in absorbance at $282\text{ m}\mu$ in a 2-cm. cell containing initially $5.25 \times 10^{-3}\text{ M}$ HOCl and $2.8 \times 10^{-4}\text{ M}$ saccharin in pH 3.9, 0.03 M acetate buffer at 25° .

Figure 2—UV spectra: (1) Mixture of saccharin and hypochlorous acid in 3×10^{-2} M acetate buffer after 3 min. (with same concentration of hypochlorous acid as reference), pH 4.9. (2) Mixture of hypochlorous acid and *o*-sulfamyl benzoic acid (with same concentration of hypochlorous acid as reference), pH 3.30. Observed absorptivities were calculated by dividing absorbances by $[\text{saccharin}]_{\text{added}}$ or $[\text{o-sulfamyl benzoic acid}]$ and the pathlength of the cell.

Kinetic data for the ring-cleavage reaction were obtained from measurements of changes in UV absorbance at 282 $m\mu$ following addition of 1 ml. of solutions of saccharin ($1.74 - 2.18 \times 10^{-3}$ M) and 1 ml. hypochlorous acid ($5.78 - 2.88 \times 10^{-2}$ M) to 4.6 ml. acetate buffer of ionic strength, 1, 0.5 M. Under these conditions (where the initial concentration of hypochlorous acid, $[\text{HOCl}]_{\text{added}}$, was greatly in excess of the added concentration of saccharin, $[\text{SH}]_{\text{added}}$, the ring-cleavage reaction was pseudo-first-order; a pseudo-first-order rate constant, k_1' , was calculated by taking the maximum absorbance as the absorbance of the pure product. Because it is not known whether this product was *N,N*-dichloro-*o*-sulfamylbenzoic acid, *N*-chloro-*o*-sulfamylbenzoic acid, or an isomer of these, an unspecified intermediate was included in the reaction scheme. However, it is believed that irreversible ring cleavage was the rate-determining step in the reaction. On this basis, the rate equation for consumption of total saccharin species, SH_{total} $\{[\text{SH}_{\text{total}}] = [\text{SH}] + [\text{S}^-] + [\text{SCI}]\}$ would be:

$$\text{rate} = \frac{k_1 K_{a,2} [\text{HOCl}]_{\text{added}}^2 [\text{SH}_{\text{total}}]}{[\text{H}^+][\text{HOCl}]_{\text{added}} + K_{a,1} K_{cp} + K_{cp} [\text{H}^+]} \quad (\text{Eq. 3})$$

where $K_{a,1}$ and $K_{a,2}$ are the acid dissociation constants of saccharin and hypochlorous acid ($K_{a,2} = 2.82 \times 10^{-8}$) (9). Thus the second-order rate constant would be related to the pseudo-first-order rate constant k_1' at different pH values and added hypochlorous acid concentrations by the identity

$$k_1 = k_1' \frac{[\text{H}^+][\text{HOCl}]_{\text{added}} + K_{a,1} K_{cp} + K_{cp} [\text{H}^+]}{K_{a,2} [\text{HOCl}]_{\text{added}}^2} \quad (\text{Eq. 4})$$

Figure 3—Integrated absorbance areas under the first and second elution peaks obtained at various reaction times for the mixture of hypochlorous acid and saccharin. The system initially contained 3.90×10^{-3} M hypochlorous acid and 4.85×10^{-4} M saccharin, pH 3.4.

Av.				1.8 ± 0.2

Values of k_1 calculated in this way are included in Table III.

The consistency of values of k_1 in Table III is strong evidence in support of the proposed reaction scheme. The kinetics of degradation of the chlorinated *o*-sulfamylbenzoic acid were not determined.

The overall reaction scheme is essentially the same as that proposed by Chattaway (7) to account for the degradation of *N*-chlorosaccharin in solutions of caustic alkalis.

Stability of *N*-Chlorosaccharin in Methanol—Methanolysis of *N*-chlorosaccharin to saccharin and methyl hypochlorite was a more favorable reaction than hydrolysis to saccharin and hypochlorous acid. Thus, when *N*-chlorosaccharin was dissolved in anhydrous methanol, it was quantitatively converted to saccharin and methyl hypochlorite by the following reaction:

When this reaction was complete (after 20 min.), the titer of iodine against positive chlorine was within 6% of theoretical, indicating that the reaction mixture was still a potential chlorinating system.

The rate of consumption of *N*-chlorosaccharin and the rate of formation of saccharin were pseudo-first-order reactions; from measurements of changes in concentration with time, a pseudo-first-order rate constant, k_m , with a value $4.1 \times 10^{-3} \text{ sec.}^{-1}$ at 25° was calculated. When known amounts of water were added to the methanol, the rate of conversion of *N*-chlorosaccharin to saccharin increased linearly as shown in Fig. 4. The catalytic rate constant for water was calculated from this plot to be $10^{-2} \text{ M}^{-1} \text{ sec.}^{-1}$. No further studies were undertaken to determine the mechanism of this reaction.

The chemical literature contains what the authors believe to be erroneous references (2, 9) to a reaction between *N*-chlorosaccharin and methanol to yield *N*-methylsaccharin. Although these references are apparently based on studies of Remsen and Dohme (10), the original work makes no mention of this reaction and treats instead the reaction between methanol and the product formed by reaction

Figure 4—Plot of $k_{\text{obs.}}$ against concentration of water in methanol for reaction of *N*-chlorosaccharin in aqueous methanol.

^a $[\text{SH}]_{\text{added}} = 1.77 \times 10^{-4} M$, $[\text{HOCl}]_{\text{added}} = 1.06 \times 10^{-3} M$. Buffer concentration = 0.04 M (monochloroacetate). Absorbance measured at 270 m μ in a 2-cm. cell. ^b $L = [(A - A_0)(K_{a,1} + [\text{H}^+])/([\text{H}^+][\text{HOCl}]_{\text{added}})]$.

of saccharin and phosphorous pentachloride at 70–75°. This latter product is presumably pseudosaccharin chloride (11, 12) and not chlorosaccharin.

CONCLUSION

N-Chlorosaccharin is likely to have only limited usefulness as a chlorinating agent in water because of its poor solubility and slow rate of dissolution. On the other hand, it is readily soluble in several organic solvents and, because it readily releases its positive chlorine in water, it is expected to be a good chlorinating agent in these solvents. The reactions of *N*-chlorosaccharin in aqueous hypochlorite solution or methanol do not reduce the availability of positive chlorine appreciably and these solutions also should be useful chlorinating systems.

EXPERIMENTAL

Reagents and Equipment—All reagents used were of the highest grade commonly available and were normally subjected to further purification before use. Saccharin (Aldrich) was recrystallized from acetone (m.p. 228–229°). *N*-Chlorosaccharin was prepared and purified according to Chattaway (7). The purity of the recrystallized product (m.p. 148–150°), determined iodometrically, was 98% based on active chlorine content. Hypochlorous acid was prepared essentially according to Higuchi and Hasegawa (13). Commercially available bleaching solution (containing 5% sodium hypochlorite) was acidified with boric acid and distilled under vacuum at 50°. The distillate was redistilled under vacuum at the same temperature. A diluted solution of the second distillate was used in the reactions. The diluted solutions fell in the concentration range of 2×10^{-2} to $4 \times 10^{-2} M$. Monochloroacetic acid (J. T. Baker, A. R. grade) was recrystallized from benzene before use. Water used throughout this study was finally distilled from acid permanganate to remove possible volatile nitrogenous contaminants.

^a $[\text{SCl}]_{\text{added}} = 1.58 \times 10^{-4} M$, $[\text{SH}]_{\text{added}} = 3.79 \times 10^{-5} M$. Buffer concentration = 0.05 M (monochloroacetate). All solutions contained 2.4 vol.-% of ethyl acetate. Absorbances were measured at 270 m μ in a 2-cm. cell. ^b Using Eq. 9 and 10 to calculate K_{cp} , the values $1.96 \times 10^{-4} M$ (added concentration of SCl + added concentration of SH) and $1.58 \times 10^{-4} M$ (added concentration of SCl) were used for the terms " $[\text{SH}]_{\text{added}}$ " and " $[\text{HOCl}]_{\text{added}}$."

Methanol (Allied Chemical, reagent grade) was dried according to Vogel (14). *o*-Methylsaccharin (VIII) was prepared by following the procedure used by Meadow and Reid (12) (m.p. 180–181°). *N*-Methylsaccharin (VII) was synthesized according to Brackett (15) (m.p. 131–132°). 1,4-Dioxane (Allied Chemical, reagent grade) was purified according to Vogel (14).

Cary 11, 14, or 15 recording spectrophotometers, which were thermostated at $25.0 \pm 0.2^\circ$ by circulating water, were used to measure absorbances. pH values were measured using a Corning 12 research pH meter.

CALCULATIONS AND PROCEDURES

Solubility of *N*-Chlorosaccharin in Organic Solvents—Solubility was estimated by measuring the maximum concentration of *N*-chlorosaccharin that could be dissolved by stirring with the solvent in a sealed vessel at 25°. Samples of solution were removed every 15 min. and analyzed by UV spectrophotometry and iodometric titration for *N*-chlorosaccharin and positive chlorine, respectively. When the concentration of the solution in the presence of undissolved crystals did not change during 45 min., it was assumed to be saturated.

Acid Dissociation Constant and Molar Absorptivity of Saccharin—Because saccharin is a strong acid, the absorbance of the neutral molecule in water was difficult to measure. Its acid dissociation constant, $K_{a,1}$, could not be calculated directly by using the relationship:

$$K_{a,1} = \frac{(A - A_{\text{SH}})[\text{H}^+]}{(A_{\text{S}^-} - A)} \quad (\text{Eq. 6})$$

where A is the absorbance of an equilibrium solution of saccharin and saccharin anion, and A_{SH} and A_{S^-} are the absorbances of the same solution at pH values where 99% of the saccharin is in the form of its neutral molecule and anion, respectively. Although the value of A_{SH} could not be measured, values of A_{S^-} , A (both in a 5-cm. cell at 270 m μ) and $[\text{H}^+]$ were measured for the equilibrium solutions formed when 1-ml. aliquots of aqueous solutions of saccharin ($3.80 \times 10^{-3} M$) were added to 20 ml. of solutions of HCl and KCl (total concentration $2 \times 10^{-1} M$) at 25°. Plots of $(A_{\text{S}^-} - A)/[\text{H}^+]$ against A gave a straight line with a slope of 20.4 and an intercept on the Y -axis when $A = 0$ of 21.7. From Eq. 6 it can be seen that the slope of this line and the intercept of the Y -axis are related to $K_{a,1}$ and the molar absorptivity of saccharin, $\epsilon_{\text{SH}}^{270}$, by the identities

$$K_{a,1} = \frac{1}{\text{slope}} \quad \text{and} \quad \epsilon_{\text{SH}}^{270} = - \frac{\text{intercept}}{\text{slope} \times [\text{SH}]_{\text{added}} b} \quad (\text{Eq. 7})$$

where b is the pathlength of the spectrophotometer cell. From results of the experiment, values of $K_{a,1} = 4.91 \times 10^{-2}$ (lit. 2.5×10^{-2} at 18°) (16) and $\epsilon_{\text{SH}}^{270} = 1119$ in water at $25.0 \pm 0.2^\circ$ were calculated.

Determination of the Hydrolytic Constant, K_{cp} Value, for *N*-Chlorosaccharin—The K_{cp} value was calculated from the ab-

sorbance, A , of an equilibrium solution of saccharin (SH), saccharin anion (S^-), N -chlorosaccharin (SCI), and hypochlorous acid by using the equation:

$$\frac{(A - A_0)(K_{a,1} + [H^+])}{[H^+]\{[HOCl]_{\text{added}} - [(A - A_0)/(A_\infty - A_0)] [SH]_{\text{added}}\}} = \frac{A_\infty}{K_{cp}} - \frac{A}{K_{cp}} \quad (\text{Eq. 8})$$

A_0 and A_∞ were the absorbances of the solution under conditions where >99% of the added saccharin was in the form of saccharin plus saccharin anion and N -chlorosaccharin, respectively, and $K_{a,1}$ was the acid dissociation constant of saccharin. Values of A_0 , A , and $[H^+]$ could be measured directly, but values of A_∞ could not because of the difficulty of working at pH values where the saccharin would not be dissociated to an appreciable extent. Also, A_∞ could not be calculated from the identity

$$A_\infty = \epsilon_{\text{SCI}} [SH]_{\text{added}} b + \epsilon_{\text{HOCl}} ([HOCl]_{\text{added}} - [SH]_{\text{added}}) b \quad (\text{Eq. 9})$$

until a sufficiently accurate value of the molar absorptivity of N -chlorosaccharin, ϵ_{SCI} , was available.

Inspection of Eq. 8 shows that when $[HOCl]_{\text{added}}$ is much larger than $[SH]_{\text{added}}$ and at a wavelength where $\epsilon_{\text{SCI}} > \epsilon_{\text{SH}}$ or ϵ_{S^-} a plot of

$$\frac{(A - A_0)(K_{a,1} + [H^+])}{[H^+][HOCl]_{\text{added}}}$$

against A at different pH values would give a straight line from which values of K_{cp} [= $-(1/\text{slope})$] and A_∞ [= $(-\text{intercept}/\text{slope})$] could be calculated. A value of ϵ_{SCI} could then be calculated from this A_∞ value and used to calculate A_∞ values for subsequent experiments where $[HOCl]_{\text{added}}$ was not much greater than $[SH]_{\text{added}}$. This was the method used to compute K_{cp} values. Typical sets of results for experiments carried out under conditions where: (a) $[HOCl]_{\text{added}} \gg [SH]_{\text{added}}$; (b) $[HOCl]_{\text{added}}$ was not much greater than $[SH]_{\text{added}}$, and (c) N -chlorosaccharin was added to buffered solution of saccharin are shown in Tables IV, V, and VI, respectively.

Determination of the Rate Constant for the Cleavage of Imide Bond of N -Chlorosaccharin—A saccharin stock solution, acetate buffer solutions (0.5 M with ionic strength adjusted to 0.5 by adding sodium sulfate) of different pH values, and hypochlorous acid of various concentrations were prepared and brought to 25°. Then 4.6 ml. of buffer solution of desired acidity was mixed with 1.0 ml. of saccharin solution in a 2-cm. cell. Into this cell 1.0 ml. of hypochlorous acid of desired concentration was injected. The cell was quickly shaken and placed in a spectrophotometer. The change of absorbance at 282 $m\mu$ was then recorded. At the end of the fast reaction (after the absorbance had passed its maximum reading), the pH of the mixture was determined.

Chromatographic Separation of the Components of the Reaction Mixture of Saccharin and Hypochlorous Acid—A partition column was prepared as follows: 20 ml. of 2 N sulfuric acid was added to 20 g. of silicic acid and mixed well. A slurry was made with 40 ml. of chloroform and packed into a glass column (50 cm. long, 2 cm. in diameter) containing a plug of glass wool and having a Teflon stopcock.

A 10-ml. portion of the reaction mixture was added to 2 ml. of 4 N sulfuric acid which contained sufficient sodium bisulfite to quench the reaction by reducing the positive chlorine and, consequently, N -chlorospecies were converted into their conjugate nonchlorinated derivatives. Five milliliters of the quenched reaction mixture was

then chromatographed according to the following procedure: 5 g of silicic acid was added to the mixture and a slurry was made with 10 ml. of chloroform. The slurry was then packed on the top of the column.

Saccharin was eluted with 100 ml. of 2% butanol in chloroform and o -sulfamyl benzoic acid with 100 ml. of 6% butanol in chloroform. The integrated absorbance was obtained by adding the absorbances of all fractions (10 ml. eluate in each fraction) that contained the same component.

Alcoholysis of N -Chlorosaccharin to Saccharin in Methanol—A stock solution of N -chlorosaccharin was made up in ethyl acetate ($4.00 \times 10^{-2} M$). Then 0.02 ml. of this solution was injected into a 1-cm. stoppered cell containing 2.0 ml. of methanol or aqueous methanol. The disappearance of N -chlorosaccharin was then followed spectrophotometrically at 276 $m\mu$.
