Ultracentrifugation was carried out at $200,000 \times g$ for 16 hr. at $21 \pm 1^\circ$.

CALCULATION OF BINDING PARAMETERS

The basic theory of the calculation of ligand-protein equilibria has been described in detail (11, 13, 18, 19). In many cases, a clear interpretation of experimental data is hampered by the occurrence of more than one type of binding site, one or more interacting types of binding sites, or by cooperative binding phenomena. In certain cases, particularly when important chemical and physical characteristics of the macromolecule are known, the correction function, $f(r)$, can lead to the desired result (20).

Various curve-fitting techniques can be employed for the determination of the number of individual binding sites and association constants by solving a set of i simultaneous linear equations for a system of i binding types (21).

A graphic method, employed when the characteristics and concentration of the protein are unknown, has been described by Rosenthal (22), making it possible to determine the physicochemical parameters of binding systems which consist of one ligand and one or more proteins containing one or more noninteracting binding

sites. This method also yields information about the distribution of the ligands on the different types of binding sites.

Equations for the characterization of pure hydrophobic interaction mechanisms between phenols (23) or polycyclic hydrocarbons (24) and proteins have been developed from the protein association constants and partition coefficients of the ligand in question. Crothers (25) developed a computational method for the calculation of binding isotherms for heterogeneous polymer systems.

Theoretical studies toward determination of the binding functions of ligands that interact with a polymerizing protein system have been carried out by Nichol *et al.* (26). According to these authors, pronounced sigmoidal binding curves, as in the case of allosteric systems, are to be expected.

RESULTS

BKG–Bovine Albumin (BA)—The binding equilibrium of BKG and BA was investigated using three methods: difference spectrophotometry, equilibrium dialysis, and sedimentation in the ultracentrifuge.

The spectrophotometric titration of $5 \times 10^{-5} M$ BKG solutions in 0.01 M phosphate buffer, pH 7.0, with corresponding BA solutions (molar excess range of BKG 1 to 100) yielded at saturation a binding stoichiometry of BA–BKG = 1:3.6 (Fig. 2). Difference spectra, involving constant BA concentrations and variable BKG concentrations with corresponding BKG solutions as reference, show under like conditions absorption maxima at 413 and 632 $m\mu$, the longwave red-shift maximum yielding the same stoichiometry (1:3.8). Since the absorption maxima of free BKG are 400 and 616 $m\mu$, the charge transfer band of the albumin-bound BKG exhibits a shift of 13 and 16 $m\mu$, respectively. At 616 $m\mu$, a simultaneously appearing hypochromic effect of $32 \pm 4\%$ can be measured.

The evaluation of the experimental binding curves, as obtained by means of dialysis and ultracentrifugation, is based on the follow-

ing model, which has also been successfully employed in the case of EOS–albumin interaction. This model assumes that the use of dilute solutions allows the activities of the components to be equated to their concentrations and, furthermore, that interactions between individual binding sites as well as cooperative binding phenomena are absent or negligible. If r is the mean degree of binding, *i.e.*, number of moles of bound ligand per mole of protein, and c_f the concentration in moles/liter of the free ligand at equilibrium, then

$$r = \sum_{i=1}^q \frac{n_i \cdot k_i \cdot c_f}{1 + k_i \cdot c_f} \quad (\text{Eq. 1})$$

where n_i represents the maximal number of the equivalent binding sites of q different types, and k_i is the corresponding intrinsic association constants. In the case of two types of binding sites, Eq. 1 becomes

$$r = \frac{n_1 \cdot k_1 \cdot c_f}{1 + k_1 \cdot c_f} + \frac{n_2 \cdot k_2 \cdot c_f}{1 + k_2 \cdot c_f} \quad (\text{Eq. 2})$$

or for one type of binding site,

$$r = \frac{n_1 \cdot k_1 \cdot c_f}{1 + k_1 \cdot c_f} \quad (\text{Eq. 3})$$

or

$$\frac{r}{c_f} = k_1 \cdot n_1 - k_1 \cdot r \quad (\text{Eq. 4})$$

Thus, r/c_f as a function of r (Scatchard plot) yields the number of binding sites, n_1 , when $r/c_f \rightarrow 0$ and the negative slope of the straight line corresponds to the intrinsic association constant k_1 . Assuming that $r \neq f(\Delta F_e)$, where ΔF_e is the electrostatic free-energy change, the Scatchard plot yields a curve resulting from interference of the individual curves representing the two types of binding sites. Hence, Eq. 4 can be written

$$\frac{r}{c_f} = \frac{r_1 + r_2}{c_f} = k_1 \cdot n_1 - k_1 \cdot r_1 + k_2 \cdot n_2 - k_2 \cdot r_2 = k_1 \cdot n_1 + k_2 \cdot n_2 - [(k_1 - k_2)r_1 + k_2 \cdot r] \quad (\text{Eq. 5})$$

and in the limit, when r_1 , r_2 , and $r \rightarrow$ zero,

$$\frac{r}{c_f} \rightarrow k_1 \cdot n_1 + k_2 \cdot n_2 \quad (\text{Eq. 6})$$

For $r/c_f \rightarrow 0$,

$$r \rightarrow n_1 + n_2 \quad (\text{Eq. 7})$$

From Eq. 5, one obtains the negative slope:

$$-\frac{d(r/c_f)}{dr} = k_2 + (k_1 - k_2) \frac{dr_1}{dr} \quad (\text{Eq. 8})$$

For $k_1 \gg k_2$ and low values of r , $dr_1/dr = 1$ as a first approximation; hence the negative slope is $-k_1$, valid for the experimental range $dr_1/dr \simeq 0$, where $d(r/c_f)/dr$ approaches $-k_2$ and r reaches its limiting value of $n_1 + n_2$.

For the determination of the slopes $-k_1$ and $-k_2$, n_1 and n_2 , as well as of the y -intercept $k_1 n_1 + k_2 n_2$ for $r \rightarrow 0$, the authors developed a best-fit computer program which also permitted the calculation of the standard free-energy (free-enthalpy) changes, ΔF_1° and ΔF_2° , from the obtained intrinsic association constants.

The binding parameters obtained for the BKG-BA interaction at pH 7.0, 5.0, and 3.5 are listed in Table I; the corresponding binding curves are shown in Figs. 3 and 4. In all dialysis and ultracentrifuge experiments, three BKG concentrations were used (4×10^{-5} , 10^{-4} , and $5 \times 10^{-4} M$), and the BA concentration was varied within the range 5×10^{-6} to $1.25 \times 10^{-4} M$.

EOS-BA—For the characterization of this interaction, spectrophotometry and ultracentrifugation were employed.

Spectrophotometric titrations at 23° of $2.5 \times 10^{-5} M$ EOS solutions at pH 7.0, 5.0, and 3.5 with 2.5×10^{-5} to $3.1 \times 10^{-7} M$ BA solutions of corresponding pH values yielded at saturation BA-EOS stoichiometries of 1:3.2, 1:2.1, and 1:0, respectively. Normal and difference spectra demonstrate a red-shift maximum between 532 and 534 m μ and a clear isobestic point at 520–522 m μ (Fig. 5).

The binding parameters, as obtained from ultracentrifuge experiments, are listed in Table II. In these experiments, the EOS concentration was held constant at $2.5 \times 10^{-5} M$, whereas the BA concentration was varied in the range 6×10^{-6} to $1.25 \times 10^{-4} M$.

IP-BA—Free-enthalpy, enthalpy, and entropy changes of the IP-BA interaction were determined by means of equilibrium dialysis in an IP concentration range (2×10^{-5} to $2 \times 10^{-4} M$)

which produces 1:1 complex formation; the BA concentration was $2 \times 10^{-5} M$. When $r = 1$ (1:1 complexing), Eq. 3 becomes

$$r = \frac{k_1 \cdot c_f}{1 + k_1 \cdot c_f} \quad (\text{Eq. 9})$$

or

$$\frac{1}{r} = \frac{1}{c_f \cdot k_1} + 1 \quad (\text{Eq. 10})$$

The $1/r$ plotted as a function of $1/c_f$ yields, at 20 and 4°, intercepts of 1.04 ± 0.05 and 0.98 ± 0.07 , respectively. The binding parameters and thermodynamic functions are listed in Table III. Analogous experiments with human albumin (HA) yielded an approximately 35% lower association constant.

Binding studies performed in the gravitational field of the ultracentrifuge, with a 13.7 to 360 molar excess of IP and BA concentrations of 10^{-5} and $0.5 \times 10^{-5} M$, yield the straight-line binding curve depicted in Fig. 6. The binding parameters calculated according to Eq. 4 are listed in Table IV.

DMI-BA—The interaction of DMI and BA, as studied under the same experimental conditions (21°, pH 7.0, ionic strength $I = 0.04$), is of a more complex nature. The Scatchard plot yields, for values of r in the range 0–8, a curve with an initially positive slope $d(r/c_f)/dr$ and a maximum at $r \simeq 6$; therefore, the model introduced previously cannot be employed for the DMI-BA interaction. For the interpretation of this mechanism of interaction, an r versus c_f plot (Fig. 7) seems to be useful. In the concentration range leading to 1:1 complex formation, the DMI interaction is of the type described for IP.

DISCUSSION

BKG-BA Interactions—Within the limits of experimental error, various methods [equilibrium dialysis, ultracentrifuge sedimentation, and ultrafiltration (27, 28)] yield under identical experimental conditions the same binding parameters such as association constants and number of binding sites (compare Table I). If the intrinsic association constant determined by Rodkey (27) by means of ultrafiltration and that determined in this paper are averaged, the result is $k_1 = 5.45 \times 10^6 \text{ l./mole}$, with a relative error of 3.5%. In this context, the number of primary binding sites as a function

of pH is of interest. Spectrophotometric titration yielded $n_1 = 3.6$ at pH 7.0. At pH 5.0 and 3.5, the red shift of the difference spectrum has disappeared, but ultracentrifuge experiments yield n_1 values of 58 ± 2 and 108 ± 8 . This allows the conclusion that the additional binding sites are chemically different from the ones exhibited at pH 7.0. It can be assumed that the four binding sites observed in the native state of the albumin are lost by unfolding of the protein at low pH. It must be recalled that at pH 7.0, secondary binding sites ($n_2 = 3$ to 4) are also detectable. However, because $k_2 \ll k_1$, n_2 cannot be determined accurately from the experimental data; k_2 is about 5×10^6 l./mole and is thus comparable with the observed intrinsic association constant at pH 3.5, $k_1 = 4.7 \times 10^6$ l./mole.

The albumin molecule is known to undergo a reversible conformation change at pH ≈ 4 (29). Electrostatic interaction forces within the albumin molecule cause an expansion of the molecule to take place, leading to the formation of a species of the so-called *F*-form having greater electrophoretic mobility and higher viscosity (30). In contrast, the *N*-form (native state) has significantly more compact packing. The binding forces for hydrophobic molecules are strongly diminished by an *N*-*F* transition (30, 31).

At pH 3.5, the binding mechanism is relatively simple: the albumin molecule carries a positive excess charge, and the *N*-*F* transition has occurred. BKG is present as a univalent anion, so the obtained free-enthalpy change of $\Delta F_1^\circ \approx -5100$ cal./mole can be attributed to electrostatic interactions. The number of binding sites, $n_1 = 108 \pm 8$, may be accounted for by the basic (cationic) amino acid residues. This binding model (Eq. 3) is confirmed by the straight line in Fig. 4 and by the agreement of the experimentally determined $n_1 k_1$ value (5.15×10^6 l./mole) and the calculated one (5.11×10^6 l./mole).

At pH 5.0, two different binding curves are obtained. Since $k_1 > k_2$, the latter value and thus ΔF_2° may have been somewhat over-

Table IV—IP—BA Interaction Showing Binding Parameters by Ultracentrifuge Sedimentation at 21°^a

pH	Ionic Strength	n_1	k_1 , 10^3 l./mole	ΔF_1° , cal./mole
7.4	0.04 ^b	6.31 ± 0.24	3.59 ± 0.12	-4781
7.0	0.04 ^b	6.05 ± 0.19	3.76 ± 0.13	-4808
7.0	0.19 ^c	6.12 ± 0.16	6.36 ± 0.41	-5114

^a For identification of ^b and ^c, see Table I.

estimated (Table I). A more realistic value for ΔF_2° would be around -3800 cal./mole. It is likely that ΔF_1° (-4950 cal./mole) represents electrostatic interactions involving the monovalent BKG anion and ΔF_2° (-3800 cal./mole) those with the bivalent BKG anion. In the BKG-HA system, Rodkey (28) observed a 20% decrease in the association constant at pH 4.8 as compared to pH 3.4. A weak conformational change of the albumin molecule at pH 5.0 appears sufficient for the exposure of the same number of binding sites as is observed in the case of the *N*-*F* transition. Conformational changes induced by ligand-protein interaction or protein unfolding also should not be excluded.

At pH 7.0, the binding mechanism appears not to be of a solely electrostatic nature. This is not surprising since the albumin molecule, which is in its native state, has a negative excess charge, causing electrostatic repulsion forces with respect to the BKG which exists as the bivalent anion only at pH 7.0. At an ionic strength of 0.19, the negative free-enthalpy change for the primary reaction ($n_1 \approx 4$) is approximately 4000 cal./mole higher than the ΔF_1° assumed for the bivalent anion at pH 5.0. However, $-\Delta F_1^\circ$ is increased by about 500 cal./mole through the decrease of the ionic strength by a factor of 5. This confirms the participation of stabilizing electrostatic interaction forces.

In conclusion, the following interpretation of the BKG-BA interaction emerges: (a) four primary binding sites predominantly interacting by means of proton donor-acceptor forces (hydrogen bonds), electron donor-acceptor forces, and possibly hydrophobic forces (total $-\Delta F_1^\circ = 4000$ cal./mole), and stabilized further by electrostatic forces ($-\Delta F_1^\circ \approx 3800$ cal./mole, dependent on ionic strength); and (b) three to four secondary binding sites apparently interacting by means of electrostatic forces only ($-\Delta F_2^\circ \approx 5000$ cal./mole, $k_2 \approx 5 \times 10^4$ l./mole).

Hydrophobic binding of straight-chain fatty acids by BA, involving stabilizing electrostatic forces, were also observed by Ray *et al.* (32).

Figure 7—IP—BA and DMI—BA interactions. Degree of binding (r) versus free concentration (c_i). Key: \circ , imipramine; and Δ , desipramine. Ultracentrifuge sedimentation, pH 7.0, ionic strength 0.04. For further details, see Results.

EOS-BA Interactions—At pH 3.5, the simple binding model with one type of binding site is again confirmed. It also can be assumed that electrostatic forces predominate because of the unfolding of the albumin molecule, its positive excess charge, and the charge distribution of the ligand. An increase of the ionic strength by a factor of about 3 produces a decrease of the free-enthalpy change by about 700 cal./mole (Table II), but the number of binding sites remains unchanged ($n_1 \approx 60$) and is considerably smaller in comparison to BKG.

At pH 7.0, the ionic strength dependence of the free-enthalpy change is opposite for the two types of binding sites. The primary binding sites ($n_1 \approx 4$) are likely to interact by means of van der Waals' forces, since an increased electrolyte concentration reduces the dielectric constant of water and thus increases the association constant (by a factor of about 2). Although in a strictly physical sense the van der Waals forces apply only to dispersion forces, the authors employ the term in a broader sense according to Martin (33), whereby it should be noted that dipole-dipole interactions are stabilized by energy effects and true dispersion forces by entropy effects. The free-enthalpy change involving the secondary binding sites ($n_2 \approx 6$) is approximately 2000 cal./mole smaller than $-\Delta F_1^\circ$. However, in this case, electrostatic forces appear to predominate, since an increase of the ionic strength by a factor of 5 reduces the $-\Delta F_2^\circ$ by about 450 cal./mole (Table II).

Spectrophotometric titrations at pH 7.0 and 5.0 yielded binding stoichiometries of BA-EOS = 1:3.2 and 1:2.1, respectively.

The binding mechanism at pH 5.0 appears to be more specific than for BKG, since $n_1 + n_2$ is smaller by about 80 binding sites. An accurate interpretation of the binding mechanism at this pH, which is the approximate isoelectric point of albumin, is again difficult. Despite comparable ionic strengths, $-\Delta F_1^\circ$ is about 1400 cal./mole lower than at pH 7.0.

Finally, from the interaction data at hand, no structural relationships between ligand and protein can be derived. A possible participation of ϵ -amino groups of lysine is indicated by preliminary experiments showing that the majority of these groups are blocked for dinitrofluorobenzene after binding of BKG or EOS.

IP-BA and DMI-BA Interactions—From the temperature dependence, the resulting thermodynamic functions, and the ionic strength dependence of the IP-BA binding reaction in the 1:1 complexing range, it can be concluded that participation of van der Waals' forces is predominant. From the negative enthalpy change of 5700 cal./mole, it can be concluded that the forces under consideration are energetically stabilized, probably by dipole-dipole interactions. Hydrophobic forces cannot be excluded, since the entropy function ($\Delta S_1^\circ = -2.2 \text{ cal.} \times \text{degree}^{-1} \times \text{mole}^{-1}$) is very small. However, it is certain that they do not constitute the main interaction forces in contrast with sulfonamide-albumin binding, where Clausen (34) measured positive ΔS values of 20–30 cal. $\times \text{degree}^{-1} \times \text{mole}^{-1}$. In the case of IP, a decrease of the ionic strength by a factor of 5 produces at constant temperature a reduction of the intrinsic association constant by almost 50% and a corresponding reduction of the free-enthalpy change by about 300 cal./mole. Both equilibrium dialysis and ultracentrifuge sedimentation yield, under like conditions, the same binding parameters (Tables III and IV). The obtained number of binding sites averages $n_1 = 6.2 \pm 0.2$. The reason for the somewhat weaker binding tendency of human albumin may lay in the higher degree of purity of the bovine preparation employed (35).

UV difference spectra (performed with a Cary 14 recording spectrophotometer) at various degrees of binding (r_i) demonstrate marked red shifts at 21° within both the 220–235 and 260–310 m μ wavelength bands. According to Wetlaufer (36), red shifts are commonly associated with aromatic ($\pi \rightarrow \pi^*$) and peptide transitions. According to other authors (32, 37, 38), these red shifts are produced by tyrosine side-chain chromophores. This short wavelength red shift and its sign are typical of protein complexes in which the higher tryptophan-associated sites are not engaged. These spectroscopic data are also obtained by the binding to albumin of long-chain fatty acid anions (38). On the basis of the number of binding sites ($n_1 \approx 6$), it can be assumed that tyrosine residues participate directly or indirectly in the IP-BA interaction.

Herskovits *et al.* (39–41) studied, with the aid of the solvent perturbation technique, the location of tyrosyl and tryptophyl residues in bovine serum albumin. Their results, at pH 6.8, show that about 70% of the 18 to 21 tyrosyl residues appear to be buried in the folds of the native protein, while the remaining tyrosyl

groups are accessible to perturbants with molecule diameters less than 5.2 Å. The two tryptophyl residues present in the protein are found to be nearly fully exposed to perturbants with less than 4.4 Å diameter, while about 50% exposure is observed with perturbants having greater than 5.2 Å diameter.

The data obtained in the case of the DMI-BA interaction indicate the involvement of a far more complicated mechanism than with IP-BA. The postulated binding models fail to explain the data. The r versus c_f plot of DMI (Fig. 7) yields a sigmoidal curve. In contrast to IP, UV difference spectra show blue shifts in the long wavelength and, particularly, in the short wavelength regions. The sigmoidal binding curve and the UV spectral properties allow the following interpretations for the DMI-BA complex. (a) Tyrosyl or tryptophyl residues are directly or indirectly involved. (b) A primary interaction of DMI and BA induces a change of the tertiary structure, *e.g.*, by a certain degree of unfolding, or a conformational change presumably in secondary segments of the polypeptide chain. This is suggested by the variation in reactivity of the binding sites involved. The binding mechanism is thus governed by cooperative phenomena. (c) The number of binding sites amounts to at least eight (Fig. 7).

Finally, it should be noted that the binding parameters obtained by different methods need not necessarily agree. Thus, the fraction calculated to be bound by gel filtration was one-third that found with equilibrium dialysis under identical experimental conditions (42). Such a disparity is determined by structural characteristics of ligands and gel phase. A combination of several methods is, therefore, advisable to avoid false conclusions. Supplementary NMR data on IP-BA and DMI-BA interactions are currently being collected and will be published.

Pharmacokinetic Model for Chlordiazepoxide·HCl in the Dog

S. A. KAPLAN, M. LEWIS, M. A. SCHWARTZ, E. POSTMA, S. COTLER, C. W. ABRUZZO, T. L. LEE, and R. E. WEINFELD

Abstract □ A six-compartment open-system model is presented to elucidate the physiological disposition of chlordiazepoxide and its two pharmacologically active biotransformation products, Ro 5-0883/1 and Ro 5-2092, in the dog following the intravenous administration of 10 mg./kg. chlordiazepoxide·HCl. The pharmacokinetic parameters used in the model were obtained by administering each of the three compounds separately. Excellent agreement was obtained between the plasma levels of intact drug, Ro 5-0883/1, and Ro 5-2092 found after administration of chlordiazepoxide·HCl and the calculated levels of each generated from the model. The main features of chlordiazepoxide disposition were: (a) its complete biotransformation to Ro 5-0883/1; (b) elimination of Ro 5-0883/1 almost entirely by biotransformation with up to 50% proceeding to Ro 5-2092 by oxidative deamination; and (c) elimination of Ro 5-2092 by urinary excretion and further biotransformation.

Keyphrases □ Chlordiazepoxide·HCl and metabolites, disposition—pharmacokinetic model □ Biotransformation, dogs—chlordiazepoxide·HCl □ Plasma levels—chlordiazepoxide and metabolites □ Urinary excretion—chlordiazepoxide and metabolites □ TLC—separation □ Fluorometry—analysis

Chlordiazepoxide¹ (7-chloro-2-methylamino-5-phenyl-3H-1,4-benzodiazepine 4-oxide) is extensively used in the treatment of anxiety states and other psychic disorders (1, 2). Chlordiazepoxide has been shown (3–5) to be biotransformed in dog and man to the *N*-demethyl chlordiazepoxide (Ro 5-0883/1), which undergoes further deamination to form the "lactam" (Ro 5-2092). The structure of chlordiazepoxide together with those of the two biotransformation products, both of which are pharmacologically active (2, 6, 7), is presented in Scheme I.

This study reports the development of a pharmacokinetic model to describe the physiological disposition

Scheme I

of chlordiazepoxide, Ro 5-0883/1, and Ro 5-2092 following the intravenous administration of chlordiazepoxide·HCl to dogs. To elucidate an appropriate pharmacokinetic model, each of the three compounds was separately administered intravenously to two dogs. The pharmacokinetic parameters thus obtained for each compound were used to establish the model for the disposition of chlordiazepoxide·HCl.

EXPERIMENTAL

Protocol—Two male dogs, weighing 10.5 and 13.0 kg., each received single 10-mg./kg. i.v. doses of chlordiazepoxide·HCl, Ro

This study reports the development of a pharmacokinetic model to describe the physiological disposition

Scheme I

of chlordiazepoxide, Ro 5-0883/1, and Ro 5-2092 following the intravenous administration of chlordiazepoxide·HCl to dogs. To elucidate an appropriate pharmacokinetic model, each of the three compounds was separately administered intravenously to two dogs. The pharmacokinetic parameters thus obtained for each compound were used to establish the model for the disposition of chlordiazepoxide·HCl.

EXPERIMENTAL

Protocol—Two male dogs, weighing 10.5 and 13.0 kg., each received single 10-mg./kg. i.v. doses of chlordiazepoxide·HCl, Ro

¹ Chlordiazepoxide·HCl is the active ingredient in Librium marketed by Hoffmann-La Roche Inc., Nutley, N. J.

Figure 1—Computer-simulated curves and experimental data points following the intravenous administration of 10 mg./kg. chlordiazepoxide·HCl to Dog 1.

5-0883/1, and Ro 5-2092, with approximately 2 weeks between doses. The chlordiazepoxide and Ro 5-0883/1 were administered in aqueous solution as the hydrochloride, whereas the Ro 5-2092 was administered in propylene glycol solution. Five-milliliter blood specimens (heparinized) were obtained at various times after drug administration, and the plasma was separated. Total urine output for 3 days was collected following the administration of each drug.

Analytical Method—A differential fluorometric assay procedure (5) allowed for the specific determination of chlordiazepoxide, Ro 5-0883/1, and Ro 5-2092 when all three were present in a single plasma specimen. The sensitivity of the procedure was 0.2–0.3 mcg. of each compound per milliliter of plasma using a 1-ml. specimen.

Figure 2—Computer-simulated curves and experimental data points following the intravenous administration of 10 mg./kg. chlordiazepoxide·HCl to Dog 2.

Figure 3—Computer-simulated curves and experimental data points following the intravenous administration of 10 mg./kg. Ro 5-0883/1 to Dog 1.

For the analyses of urine, a TLC step was added to the assay procedure to eliminate interfering urinary fluorescence. The ether extract of urine was evaporated to dryness; the residue was reconstituted in 100 μ l. ethanol and spotted on Brinkmann neutral TLC plates, F-254, with appropriate standards. Following development in ethyl acetate-ethanol (90:10), the areas corresponding to chlordiazepoxide (R_f 0.25), Ro 5-0883/1 (R_f 0.16), and Ro 5-2092 (R_f 0.43) were scraped from the plate. Chlordiazepoxide was eluted from the silica gel with 0.1 *N* sulfuric acid, Ro 5-0883/1 with 7.0 *N* sulfuric acid, and Ro 5-2092 with 0.1 *N* sodium hydroxide. The analytical procedure for each compound then followed that described for plasma specimens (5). This procedure was carried out with 10-ml. urine specimens.

RESULTS AND DISCUSSION

The plasma level curves following the administration of 10-mg./kg. i.v. doses of chlordiazepoxide·HCl, Ro 5-0883/1, and Ro 5-2092 to Dogs 1 and 2 are presented in Figs. 1–6.

Figure 4—Computer-simulated curves and experimental data points following the intravenous administration of 10 mg./kg. Ro 5-0883/1 to Dog 2.

Figure 5—Computer-simulated curve and experimental data points following the intravenous administration of 10 mg./kg. Ro 5-2092 to Dog 1.

The plasma level curves of each of the three intravenously administered compounds were apparently biexponential. This suggested that the pharmacokinetic evaluation of each compound would require a minimum of a two-compartment open-system model (8). The calculated volume of the central compartment, V_p , for each of the three compounds was never less than 30% of body weight. This further suggested that the central compartment of the two-compartment open-system model consisted of plasma plus readily accessible body spaces, e.g., liver and kidneys. Therefore, elimination was assumed to occur from the central compartment, as indicated in the model presented in Scheme II.

In this model, k_{cp} and k_{pc} are the first-order rate constants into and out of the peripheral compartment, and k_{el} is the sum of the simultaneous processes of biotransformation and elimination, all assumed to be first-order processes.

The experimental plasma level data of chlordiazepoxide, Ro 5-0883/1, and Ro 5-2092 obtained following the intravenous administration of each of the three compounds were fit to the biexponential equation, $C_p = Ae^{-\alpha t} + Be^{-\beta t}$, by means of a "least-squares estimation of nonlinear parameters" evaluation programmed in FORTRAN IV for use on a GE-605 digital time-sharing system (9). The parameters thus obtained (A , α , B , and β) are presented in Table I. A and B are the ordinate axis intercepts of the biexponential curve, and α and β are the hybrid rate constants reflecting the overall rate processes. The individual rate constants (k_{cp} , k_{pc} , and k_{el}) associated with the two-compartment open-system model were calculated according to Riegelman *et al.* (8) and are presented in Table I.

The 0-74-hr. urinary excretion levels in Dog 2 following the administration of chlordiazepoxide·HCl indicated no excretion of intact chlordiazepoxide, whereas 1.6% of the administered dose was recovered as Ro 5-0883/1 and 5.0% was recovered as Ro 5-2092.

Previous studies (10) indicated that following an oral 10-mg./kg. dose of chlordiazepoxide·HCl to a dog and examination of the 0-48-hr. urine, there was no recovery of intact chlordiazepoxide and that 1.1% of the dose was recovered as Ro 5-0883/1 and 7.2% was recovered as Ro 5-2092. These findings are similar to those of Dog 2. Schwartz (11) found that following the single oral administration of 4 mg./kg. ^{14}C -chlordiazepoxide·HCl to two dogs and examination of the 0-72-hr. urinary excretion levels, there was no recovery of intact chlordiazepoxide, whereas 0.2 and 0.5% of the dose were excreted as Ro 5-0883/1 and 1.3 and 3.0% were excreted as Ro 5-2092 in the two dogs, respectively.

Scheme II—Two-compartment open-system pharmacokinetic model

Figure 6—Computer-simulated curve and experimental data points following the intravenous administration of 10 mg./kg. Ro 5-2092 to Dog 2.

Further information on the biotransformation of chlordiazepoxide and of Ro 5-0883/1 was obtained by examining the areas under the Ro 5-0883/1 plasma level curves following the intravenous administration of chlordiazepoxide·HCl, *i.e.*, formed Ro 5-0883/1, and of administered Ro 5-0883/1, respectively. The (formation curve/administered curve) area ratios for Ro 5-0883/1 were 0.88 and 0.99 in Dogs 1 and 2, respectively. This would suggest virtually complete conversion of chlordiazepoxide to Ro 5-0883/1.

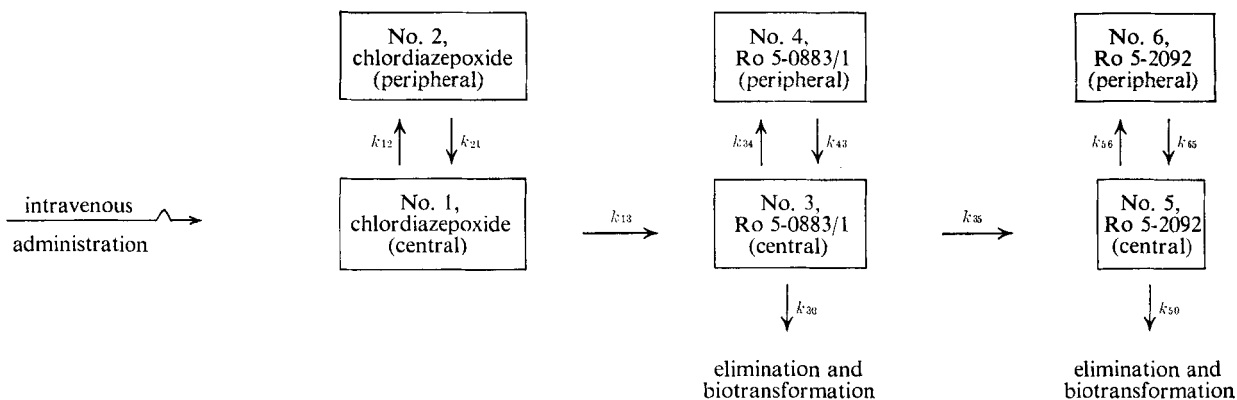

The areas under the formation curves of Ro 5-2092 were determined following the administrations of both chlordiazepoxide·HCl and Ro 5-0883/1 and compared with those following the administration of Ro 5-2092. The (formation curve/administered curve) area ratios were 0.28 and 0.28 in Dog 1 following chlordiazepoxide·HCl and Ro 5-0883/1 administration, respectively, and 0.24 and 0.22 in Dog 2. This would further indicate that chlordiazepoxide is completely biotransformed to Ro 5-0883/1 since Ro 5-0883/1 is the precursor of Ro 5-2092, and both chlordiazepoxide and Ro 5-0883/1 produce equivalent amounts of Ro 5-2092.

Therefore, inasmuch as all the chlordiazepoxide·HCl administered was biotransformed to Ro 5-0883/1, the formation constant of Ro

Scheme III—Six-compartment open-system pharmacokinetic model for the physiological disposition of chlordiazepoxide·HCl

5-0883/1, k_{13} , was taken to be equal to that of the elimination-rate constant, k_{el} , of chlordiazepoxide. The formation constant of Ro 5-2092, k_{35} , was determined by adapting the absorption-rate equation of Loo and Riegelman (12). This constant was determined by utilizing the formation data of Ro 5-2092 following the administrations of both chlordiazepoxide·HCl and Ro 5-0883/1, and the rate constants, k_{cp} , k_{pc} , and k_{el} obtained following the intravenous administration of Ro 5-2092.

Based on these considerations, a six-compartment open-system pharmacokinetic model to describe the physiological disposition of chlordiazepoxide in the dog was developed, as indicated in Scheme III.

In the model, k_{12} , k_{21} , k_{34} , k_{43} , k_{56} , and k_{65} are the first-order rate constants of distribution of the compounds indicated in the model; k_{13} and k_{35} are the first-order rate constants of formation of Ro 5-0883/1 and Ro 5-2092, respectively; k_{30} is the sum of the simultaneous processes of elimination of Ro 5-0883/1 and biotransformation to compounds other than Ro 5-2092; and k_{50} is the sum of the simultaneous processes of elimination and biotransformation of Ro 5-2092. All the elimination and biotransformation processes are assumed to be first order.

Solution of the differential equations (13) describing the six-compartment open-system model, as presented in Appendix A, yields the following expressions to describe the plasma level-time curves for Compartments 1, 3, and 5, respectively, following a single intravenous administration of chlordiazepoxide·HCl:

$$C_1 = A_{13} e^{-a_3 t} + A_{14} e^{-a_4 t} \quad (\text{Eq. 1})$$

$$C_3 = A_{33} e^{-a_3 t} + A_{34} e^{-a_4 t} + A_{35} e^{-a_5 t} + A_{36} e^{-a_6 t} \quad (\text{Eq. 2})$$

$$C_5 = A_{53} e^{-a_3 t} + A_{54} e^{-a_4 t} + A_{55} e^{-a_5 t} + A_{56} e^{-a_6 t} + A_{57} e^{-a_7 t} + A_{58} e^{-a_8 t} \quad (\text{Eq. 3})$$

where C_1 , C_3 , and C_5 are the concentrations of the three compounds in the central compartment. The coefficients A_{1j} , A_{3j} , and A_{5j} and the hybrid rate constants a_3 – a_8 are determined as a function of all the rate constants: k_{12} , k_{21} , k_{13} , k_{34} , k_{43} , k_{30} , k_{35} , k_{56} , k_{65} , and k_{50} . The six-compartment open-system model describing the physiological disposition of chlordiazepoxide was programmed in FORTRAN

Table II—Pharmacokinetic Parameters for the Physiological Disposition of Chlordiazepoxide·HCl in Dogs in Terms of a Six-Compartment Open System

^a $k_{30} = k_{el}$ (Ro 5-0883/1) – k_{35} . ^b k_{50} corrected for formation data.

IV for use in the GE-605 digital time-sharing system (14). This program allowed for the simulation of drug quantity in the various compartments of the model as a function of time.

Confirmation of the proposed model required coincidence of simulated and experimental plasma level curves for Compartments 1, 3, and 5 following a single intravenous administration of chlordiazepoxide·HCl. The pharmacokinetic parameters (k_{cp} , k_{pc} , and k_{el}) obtained for each of the three individually administered compounds (Table I) were utilized as computer input for the six-compartment open-system model. The constants for the six-compartment model are summarized in Table II. In addition, to allow for comparison of the experimental and simulated data of the three compounds following the administration of chlordiazepoxide·HCl, the plasma levels of Ro 5-0883/1 and Ro 5-2092 were converted to chlordiazepoxide equivalents. The three curves drawn in solid lines in Figs. 1 and 2 represent the simulated curves and corresponding experimental data points following the intravenous administration of 10 mg./kg. chlordiazepoxide·HCl to Dogs 1 and 2, respectively.

The simulated plasma curves agreed very well with the experimental data in the chlordiazepoxide and Ro 5-0883/1 compartments utilizing the pharmacokinetic parameters obtained following the intravenous administration of each of the three compounds. The simulated plasma level curves of Ro 5-2092, however, did not correlate as well since they exhibited a slower elimination rate than did the experimentally obtained plasma level curves. This small deviation appears to be reflected in differences noted in the experimentally obtained plasma level data following the intravenous administration of Ro 5-2092 as compared with the Ro 5-2092 plasma levels obtained following the administration of chlordiazepoxide or Ro 5-0883/1. The data indicate that the apparent elimination-rate constant of Ro 5-2092 when produced as a biotransformation product was greater than the apparent elimination-rate constant observed after administered Ro 5-2092. This phenomenon has been previously observed for other drugs (15, 16).

These findings indicated that k_{50} of the six-compartment open-system model would have to be calculated from the formation curve of Ro 5-2092 and not from the data following the intravenous administration of Ro 5-2092. Therefore, the elimination-rate constant of Ro 5-2092 was recalculated utilizing the formation data by rearranging Eq. A13 of Appendix A and solving for k_{50} :

$$k_{50} = \frac{\beta \cdot k_{56} - \beta^2 + \beta \cdot k_{65}}{(k_{56} - \beta)} \quad (\text{Eq. 4})$$

where β is a_8 of Eq. 3. Since the data of the elimination phase of the Ro 5-2092 formation curve are utilized, the terms $A_{53} e^{-a_3 t}$, $A_{55} e^{-a_5 t}$, and $A_{57} e^{-a_7 t}$ of Eq. 3 rapidly approach zero. Therefore, Eq. 3 reduces to

$$C_5 = A_{54} e^{-a_4 t} + A_{56} e^{-a_6 t} + A_{58} e^{-a_8 t} \quad (\text{Eq. 5})$$

This elimination phase was fit to the triexponential equation by means of the "least-squares estimation of nonlinear parameters" (9), keeping A_{54} , A_{56} , A_{58} , a_4 , and a_6 constant.

Substituting the new k_{50} into the computer program for the six-compartment open-system model resulted in an excellent simulation of the Ro 5-2092 levels in both dogs (dashed lines in Figs. 1 and 2).

CONCLUSION

A pharmacokinetic model for the disposition of chlordiazepoxide·HCl in the dog has been presented in terms of a six-compartment open system. The excellent agreement between the simulated and experimental data reflects the reliability of the assumption of first-order kinetics for all processes. The model (Scheme III) provides a basis for the elucidation and quantitation of chlordiazepoxide and its pharmacologically active biotransformation products, Ro 5-0883/1 and Ro 5-2092. The pathways in man (3-5) have been shown to be similar to those in the dog to the extent to which they are described in Scheme III. It is expected that this model will be useful for the interpretation of future human pharmacokinetic studies.

The main features of the physiological disposition of chlordiazepoxide·HCl in the dog were: (a) its biotransformation to Ro 5-0883/1 as the exclusive route of drug elimination; (b) the elimination of Ro 5-0883/1 almost entirely by biotransformation, with up to 50% going to Ro 5-2092 and the remainder going to an unidentified biotransformation product; and (c) the elimination of Ro 5-2092 by urinary excretion and further biotransformation.

$$\begin{bmatrix} a_3 - (k_{12} + k_{13}) & k_{21} & 0 \\ k_{12} & a_4 - k_{21} & 0 \\ k_{13} & 0 & a_5 - (k_{34} + k_{35} + k_{30}) \\ 0 & 0 & k_{34} \\ 0 & 0 & k_{35} \\ 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} A_{1j} \\ A_{2j} \\ A_{3j} \\ A_{4j} \\ A_{5j} \\ A_{6j} \end{bmatrix} = \begin{bmatrix} D_0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix} \quad (\text{Eq. A14})$$

APPENDIX A

Determination of Kinetic Constants for Six-Compartment Open-System Model—The six-compartment open-system model is presented in Scheme III. The transfer and elimination process in the six-compartment open-system model may be described as follows:

$$\frac{dC_1}{dt} = C_2 k_{21} - C_1 (k_{12} + k_{13}) \quad (\text{Eq. A1})$$

$$\frac{dC_2}{dt} = C_1 k_{12} - C_2 k_{21} \quad (\text{Eq. A2})$$

$$\frac{dC_3}{dt} = C_1 k_{13} - C_3 (k_{34} + k_{35} + k_{30}) + C_4 k_{43} \quad (\text{Eq. A3})$$

$$\frac{dC_4}{dt} = C_3 k_{34} - C_4 k_{43} \quad (\text{Eq. A4})$$

$$\frac{dC_5}{dt} = C_3 k_{35} - C_5 (k_{56} + k_{50}) + C_6 k_{65} \quad (\text{Eq. A5})$$

$$\frac{dC_6}{dt} = C_5 k_{56} - C_6 k_{65} \quad (\text{Eq. A6})$$

where C_n is the amount of drug in the designated compartment, and the numerical subscripts for C define the compartment. These simultaneous differential equations were solved by: (a) obtaining the eigen values of the eigen vector matrix, and (b) evaluating the corresponding eigen vectors (9).

The eigen values, a_j 's, are obtained as solutions of the characteristic equation:

$$\begin{vmatrix} a_3 - (k_{12} + k_{13}) & k_{21} & 0 & 0 & 0 & 0 \\ k_{12} & a_4 - k_{21} & 0 & 0 & 0 & 0 \\ k_{13} & 0 & a_5 - (k_{34} + k_{35} + k_{30}) & 0 & 0 & 0 \\ 0 & 0 & k_{34} & a_6 - k_{43} & 0 & 0 \\ 0 & 0 & k_{35} & 0 & a_7 - (k_{56} + k_{50}) & 0 \\ 0 & 0 & 0 & 0 & k_{56} & a_8 - k_{65} \end{vmatrix} = 0 \quad (\text{Eq. A7})$$

which have the roots:

$$a_3 = \frac{(k_{12} + k_{21} + k_{13}) + \sqrt{(k_{12} + k_{21} + k_{13})^2 - 4(k_{21}k_{13})}}{2} \quad (\text{Eq. A8})$$

$$a_4 = \frac{(k_{12} + k_{21} + k_{13}) - \sqrt{(k_{12} + k_{21} + k_{13})^2 - 4(k_{21}k_{13})}}{2} \quad (\text{Eq. A9})$$

$$a_5 = \frac{(k_{34} + k_{43} + k_{30} + k_{35}) + \sqrt{(k_{34} + k_{43} + k_{30} + k_{35})^2 - 4(k_{43}k_{30} + k_{43}k_{35})}}{2} \quad (\text{Eq. A10})$$

$$a_6 = \frac{(k_{34} + k_{43} + k_{30} + k_{35}) - \sqrt{(k_{34} + k_{43} + k_{30} + k_{35})^2 - 4(k_{43}k_{30} + k_{43}k_{35})}}{2} \quad (\text{Eq. A11})$$

$$a_7 = \frac{(k_{56} + k_{65} + k_{50}) + \sqrt{(k_{56} + k_{65} + k_{50})^2 - 4(k_{65}k_{50})}}{2} \quad (\text{Eq. A12})$$

$$a_8 = \frac{(k_{56} + k_{65} + k_{50}) - \sqrt{(k_{56} + k_{65} + k_{50})^2 - 4(k_{65}k_{50})}}{2} \quad (\text{Eq. A13})$$

The eigen vectors, A_{ij} , are then obtained as solutions to the $6(j = 3, 4, \dots, 8)$ vector equations:

$$\begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ k_{43} & 0 & 0 \\ 0 & k_{34} & 0 \\ 0 & 0 & k_{65} \\ 0 & k_{56} & a_8 - k_{65} \end{bmatrix} \begin{bmatrix} A_{1j} \\ A_{2j} \\ A_{3j} \\ A_{4j} \\ A_{5j} \\ A_{6j} \end{bmatrix} = \begin{bmatrix} D_0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix} \quad (\text{Eq. A14})$$

where D_0 = initial dose.

The eigen vectors, A_{ij} , thus obtained are:

$$A_{13} = \frac{D_0(k_{21} - a_3)}{(a_4 - a_3)} \quad (\text{Eq. A15})$$

$$A_{14} = D_0 - A_{13} \quad (\text{Eq. A16})$$

$$A_{2j} = \frac{k_{12}A_{1j}}{(k_{21} - a_j)} \quad j = 3, 4 \quad (\text{Eq. A17})$$

$$A_{3j} = \frac{k_{13}(k_{43} - a_j)A_{1j}}{[(a_j - k_{34} - k_{35} - k_{30})(a_j - k_{43}) - k_{43}k_{34}]} \quad j = 3, 4 \quad (\text{Eq. A18})$$

$$A_{36} = \left[-A_{33} - A_{34} + \frac{(a_6 - k_{43})}{k_{34}}(-A_{43} - A_{44}) \right] \frac{(k_{43} - a_6)}{(a_6 - a_5)} \quad (\text{Eq. A19})$$

$$A_{36} = - \sum_{j=3}^5 A_{3j} \quad (\text{Eq. A20})$$

$$A_{4j} = \frac{A_{3j} k_{34}}{(k_{43} - a_j)} \quad j = 3, 4, 5, \text{ and } 6 \quad (\text{Eq. A21})$$

$$A_{5j} = \frac{A_{3j} k_{35} (k_{65} - a_j)}{(a_j - k_{56} - k_{50})(a_j - k_{65}) - k_{56} k_{65}} \quad j = 3, 4, 5, \text{ and } 6 \quad (\text{Eq. A22})$$

$$A_{57} = \left[- \sum_{j=3}^6 A_{5j} + \frac{(a_8 - k_{65})}{k_{56}} \left(- \sum_{j=3}^6 A_{6j} \right) \right] \frac{(k_{65} - a_7)}{(a_8 - a_7)} \quad (\text{Eq. A23})$$

$$\begin{vmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ k_{43} & 0 & 0 \\ 0 & a_6 - k_{43} & 0 \\ 0 & 0 & a_7 - (k_{56} + k_{50}) \\ 0 & k_{56} & a_8 - k_{65} \end{vmatrix} = 0 \quad (\text{Eq. A7})$$

$$A_{58} = - \sum_{j=3}^7 A_{5j} \quad (\text{Eq. A24})$$

$$A_{6j} = \frac{A_{5j} k_{56}}{k_{65} - a_j} \quad j = 3, 4, \dots, 8 \quad (\text{Eq. A25})$$

For a general model composed of n individual two-compartment open-model units, as seen in Scheme IV, the solutions of eigen values

Scheme IV—General model composed of n individual two-compartment open-model units

and eigen vectors may be generalized as follows. Where:

$$\begin{aligned} i &= 1, 3, 5 \dots & i+1 &= \text{peripheral compartment} \\ i &= \text{central compartment} & k_{io} + k_{i(i+2)} &= k_{el} \end{aligned}$$

the general solution of the eigen values would therefore be:

$$a_{i-1} = \frac{(k_{ep} + k_{pe} + k_{io} + k_{i(i+2)}) + \sqrt{(k_{ep} + k_{pe} + k_{io} + k_{i(i+2)})^2 - 4(k_{io} + k_{i(i+2)})k_{pe}}}{2} \quad (\text{Eq. A26})$$

$$a_j = \frac{(k_{ep} + k_{pe} + k_{io} + k_{i(i+2)}) - \sqrt{(k_{ep} + k_{pe} + k_{io} + k_{i(i+2)})^2 - 4(k_{io} + k_{i(i+2)})k_{pe}}}{2} \quad (\text{Eq. A27})$$

Where $j = 3, 4, 5 \dots i+3$, the general solution of the eigen vector A_{ij} for the i th central compartment is:

$$A_{ij} = \frac{A_{(i-2)j} k_{(i-2)i} (k_{pe} - a_j)}{(a_j - k_{ep} - k_{el}) (a_j - k_{pe}) - k_{ep} k_{pe}} \quad j = 3, 4, 5 \dots j-2 \quad (\text{Eq. 28})$$

$$A_{i(i-1)} = \left[-\sum_{j=3}^{j-2} A_{ij} + \frac{(a_{i+3} - k_{pe})}{k_{ep}} \left(-\sum_{j=3}^{j-2} A_{(i+1)j} \right) \right] \times \frac{(k_{pe} - a_{i+2})}{(a_{i+3} - a_{i+2})} \quad j = i+2 \quad (\text{Eq. A29})$$

$$A_{ij} = -\sum_{j=3}^{j-1} A_{ij} \quad j = i+3 \quad (\text{Eq. A30})$$

Therefore, the general solution of the eigen vectors, A_{ij} , for the $i+1$ th peripheral compartment is:

$$A_{(i+1)j} = \frac{A_{ij} k_{ep}}{k_{pe} - a_j} \quad j = 3, 4, 5 \dots i+3 \quad (\text{Eq. A31})$$

Solubility of Alkyl Benzoates I: Effect of Some Alkyl *p*-Hydroxybenzoates (Parabens) on the Solubility of Benzyl *p*-Hydroxybenzoate

F. SHIHAB, W. SHEFFIELD, J. SPROWLS, and J. NEMATOLLAHI

Abstract □ The solubility features of a homologous series of alkyl *p*-hydroxybenzoates (parabens) with alkyl groups, in an ascending order from methyl to *n*-butyl, were investigated together with benzyl paraben and methyl *p*-methoxybenzoate. A phenomenon of mutual solubilizing potential was observed to exist when the solubility of a mixture of an alkyl paraben and benzyl paraben in 60% polyethylene glycol 400-water was examined. The analysis was carried out by means of UV spectrophotometry and NMR spectroscopy. The

scope of application of these esters for their antimicrobial properties, for which they are primarily employed in pharmaceutical sciences, is envisaged to be augmented by considering factors influencing solubility.

Keyphrases □ Parabens—mutual solubilizing potential □ Polyethylene glycol—water system—paraben solubility □ UV spectrophotometry—analysis □ NMR spectroscopy—analysis

A gross solubilizing effect of alkyl *p*-hydroxybenzoates (parabens) on benzyl paraben in polyethylene glycol 400-water (designated as PEG-H₂O) mixture was first

observed by Sprowls (1). Owing to the interest of pharmaceutical scientists in the physicochemical properties of parabens (2-4), which are employed both as medicinal

Scheme IV—General model composed of n individual two-compartment open-model units

and eigen vectors may be generalized as follows. Where:

$$\begin{aligned} i &= 1, 3, 5 \dots & i+1 &= \text{peripheral compartment} \\ i &= \text{central compartment} & k_{io} + k_{i(i+2)} &= k_{el} \end{aligned}$$

the general solution of the eigen values would therefore be:

$$a_{i-1} = \frac{(k_{ep} + k_{pe} + k_{io} + k_{i(i+2)}) + \sqrt{(k_{ep} + k_{pe} + k_{io} + k_{i(i+2)})^2 - 4(k_{io} + k_{i(i+2)})k_{pe}}}{2} \quad (\text{Eq. A26})$$

$$a_j = \frac{(k_{ep} + k_{pe} + k_{io} + k_{i(i+2)}) - \sqrt{(k_{ep} + k_{pe} + k_{io} + k_{i(i+2)})^2 - 4(k_{io} + k_{i(i+2)})k_{pe}}}{2} \quad (\text{Eq. A27})$$

Where $j = 3, 4, 5 \dots i+3$, the general solution of the eigen vector A_{ij} for the i th central compartment is:

$$A_{ij} = \frac{A_{(i-2)j} k_{(i-2)i} (k_{pe} - a_j)}{(a_j - k_{ep} - k_{el}) (a_j - k_{pe}) - k_{ep} k_{pe}} \quad j = 3, 4, 5 \dots j-2 \quad (\text{Eq. 28})$$

$$A_{i(i-1)} = \left[-\sum_{j=3}^{j-2} A_{ij} + \frac{(a_{i+3} - k_{pe})}{k_{ep}} \left(-\sum_{j=3}^{j-2} A_{(i+1)j} \right) \right] \times \frac{(k_{pe} - a_{i+2})}{(a_{i+3} - a_{i+2})} \quad j = i+2 \quad (\text{Eq. A29})$$

$$A_{ij} = -\sum_{j=3}^{j-1} A_{ij} \quad j = i+3 \quad (\text{Eq. A30})$$

Therefore, the general solution of the eigen vectors, A_{ij} , for the $i+1$ th peripheral compartment is:

$$A_{(i+1)j} = \frac{A_{ij} k_{ep}}{k_{pe} - a_j} \quad j = 3, 4, 5 \dots i+3 \quad (\text{Eq. A31})$$

agents and for inhibition of the growth of microorganisms in food, cosmetics, and pharmaceutical preparations, extensive research on the solubility property of parabens and their potential to affect the solubility of each other in a given solvent was presumed to be valuable.

Using 60% PEG–H₂O as a solvent, a preliminary observation revealed that, in contrast to the solubility of the individual parabens, combining two parabens enhances the degree of solubility of both esters. This suggested the existence of a mutual solubilizing phenomenon among parabens. After this empirical observation, a few experiments were designed in an effort to characterize some solubility properties and the solubilizing potential of each member of the homologous series of alkyl parabens (methyl, ethyl, *n*-propyl, and *n*-butyl) together with benzyl paraben and methyl *p*-methoxybenzoate.

Three different solubility aspects of parabens were investigated.

First, the solubility of each paraben in the series was determined in various percentages of PEG–H₂O (0–100% PEG). UV spectrophotometry was employed for quantitative measurements. The solubility information obtained, besides its usefulness *per se*, was found valuable for further solubility study, wherein a mixture

of two parabens rather than a single paraben was used. Accordingly, for the solubility study of a mixture of two parabens, a solvent containing 60% PEG in H₂O was adopted. In this solvent the solubilizing affect of the parabens on each other was envisaged to be more pronounced; their individual quantitation in the mixture, using NMR (5), could be performed with adequate accuracy.

Second, four pairs of parabens (combination of benzyl paraben with each of the alkyl parabens in the homologous series: methyl, ethyl, *n*-propyl, and *n*-butyl paraben) were subjected to solubility evaluation in an effort to examine the solubilizing effect of the parabens constituting the pair on each other (mutual solubilizing potential). The procedure consisted of adding each paraben in the pair to 60% PEG–H₂O until the solids remained in equilibrium with the solution.

Third, the solubility of benzyl paraben was determined in 60% PEG–H₂O solutions of methyl, ethyl, *n*-propyl, and *n*-butyl paraben, respectively, prepared in five different concentrations (0.1, 0.2, 0.3, 0.4, and 0.5 *M*). Due to the limited solubility of methyl *p*-methoxybenzoate, only the solubilizing effect of 0.1 *M* of this ester on benzyl paraben was evaluated. The analysis was performed by using NMR.

EXPERIMENTAL

All the compounds employed in the experiments were analytical reagents: methyl *p*-hydroxybenzoate (Lot No. 5266),¹ ethyl *p*-hydroxybenzoate (Lot No. 5082),¹ *n*-propyl *p*-hydroxybenzoate (Lot No. 5294),¹ *n*-butyl *p*-hydroxybenzoate (Lot No. 5158),¹ benzyl *p*-hydroxybenzoate (Lot No. 1167),¹ methyl *p*-methoxybenzoate (methyl anisate Lot No. 1702),² and polyethylene glycol 400 USP YE 889.³

The analyses were carried out by using UV spectrophotometry (Beckman DB) and/or NMR spectrometry (Varian Associate A-60) at ambient temperature.

The solvents were prepared by mixing accurately weighed quantities of polyethylene glycol 400 and water. The percentages are expressed on a weight-to-weight basis.

The molar solution of each paraben was prepared by weighing accurately a precalculated quantity of the desired paraben in a volumetric flask and then dissolving the solid in 60% PEG–H₂O by gentle shaking.

The solubility of each paraben was determined by adding the compound beyond its saturation point to the solvent and shaking the mixture in a constant-temperature water bath (27.0 ± 0.1°) for 24 hr.

The solubility of benzyl paraben in the 0.1, 0.2, 0.3, 0.4, and 0.5 *M* solutions of each of the methyl, ethyl, *n*-propyl, and *n*-butyl paraben and in the 0.1 *M* of methyl *p*-methoxybenzoate was determined by

PEG	43.39	42.13
Water	58.36	56.66
Lower Phase		
Butyl paraben	54.31	51.94
PEG	40.53	38.66
Water	9.72	9.40

adding solid benzyl paraben, beyond its saturation point, to the solution and shaking the flask in a constant-temperature water bath ($27.0 \pm 0.1^\circ$) for 24 hr. The analysis of the solutions was carried out by using NMR spectrometry.

For determining the solubilizing effect of one paraben on the other, benzyl paraben and one of the alkyl parabens were added alternately and portionwise into 60% PEG-H₂O until a noticeable quantity of each paraben remained undissolved.

The samples for analysis were obtained by withdrawing the solution with a pipet on whose tip had been tied one layer of Whatman No. 1 filter paper for the purpose of ensuring the exclusion of solid particles.

If NMR was to be used for the analysis, the samples were instilled into an NMR tube as such. For UV analysis, a known volume of the sample was diluted further with 50% ethanol using volumetric flasks. The absorbance values were recorded at $\lambda = 256 \text{ m}\mu$.

RESULTS AND DISCUSSION

Table I and Fig. 1 depict the results of experiments on the solubility of parabens in various proportions of PEG-H₂O. Probably due to a decrease in the polarity of the solvent, the solubility of parabens increases as a function of increase in the proportion of PEG to H₂O. In the homologous series of parabens employed in these experiments on a mole-to-mole basis up to a concentration of 40% PEG-H₂O, the solubility of each member was found to be slightly lower than its next lower homolog. If molar concentrations were converted to weight percentage, a reverse trend was observed for butyl paraben in 60% and for all the others in 80% PEG-H₂O and 100% PEG.

A sharp increase in the solubility of butyl paraben beyond 60% PEG-H₂O is probably due to the lipophilic nature of the butyl chain.

Figure 2—Solubility of benzyl paraben in 60% PEG-H₂O solutions of a homologous series of alkyl parabens in concentrations ranging from 0.1 to 0.5 M. Key: \diamond , methyl; Δ , ethyl; \square , n-propyl; and \circ , n-butyl.

Table III—Solubility and Parabens, in Moles/Liter (M) (60% PEG-H₂O and 27°) Determined for Each Paraben Both when Dissolved Individually and as a Combination of Two (NMR Used for Analysis)

Paraben (Single)	Solubility (M)	Parabens (Combined)	Solubility (M)
Methyl	1.1854	Methyl + Benzyl	1.3195
Benzyl	0.3301	Benzyl + Ethyl	0.6841
Ethyl	0.8346	Ethyl + Benzyl	1.0827
Benzyl	0.3301	Benzyl	0.7934

As indicated in Table I, the solubility of butyl paraben in 60% PEG-H₂O was recorded at the point just prior to its separation into two phases. Beyond this point the addition of more butyl paraben causes a formation of two layers. The constituent of each phase was determined quantitatively by the method described in the *Appendix*. The authors know of no previous explicitly described analysis of the two phases whose formation in alcoholic solvents also has been observed and reported (4). Nor has an unequivocally convincing explanation yet been expressed regarding the physicochemical features of each phase.

Table II depicts the quantity of each component present in each phase; details of the calculations are given in the *Appendix*.

The peaks for water and PEG in the NMR spectrum of the upper phase occur at δ 4.6 and 3.6, respectively. As shown in the calculations, correction has been made for the contribution of two protons to the water peak by the 2OH's per molecule of PEG. There was no contribution from the phenolic OH of the butyl paraben due to its low concentration in the upper phase (no phenyl proton peak was observed at a spectrum amplitude in which the water and PEG integral values were determined).

For the lower phase, the concentration of butyl paraben was determined by comparing its NMR spectrum with that of a standard, analogous to the previously reported method (5). Similarly, the concentration of PEG was calculated, and then the quantity of H₂O was obtained by the difference (by subtraction from the weight of 1 ml. of the solution).

The formation of a two-phase system as a result of dissolving a high quantity of butyl paraben in 60% PEG-H₂O is probably due to the predominant occupation of etheric oxygen of polyethylene glycol by hydrogen bonding with phenolic OH of the paraben. Considering the preferred conformation of polyethylene glycol, such a hydrogen bond will restrict the free rotation of the phenyl group because of interference between phenyl hydrogens *ortho* to OH and methylene hydrogens of PEG. The butyl groups of two butyl parabens hydrogen bonded to two alternate oxygens, as becomes obvious by observing a molecular model,⁴ can line up by van der Waals' force and maintain a relatively rigid structure. The net result becomes the formation of a complex, nonpolar enough to be capable of squeezing out water. The water, as it is compelled to form a separate phase, by virtue of hydrogen bonding carries with itself polyethylene glycol molecules which are not bound to butyl paraben.

A similar phase separation was also observed during the determination of mutual solubilizing potential of both benzyl paraben-propyl paraben and benzyl paraben-butyl paraben mixtures. The mechanism of formation of a two-phase system in this case is presumed to be analogous to that postulated for the butyl paraben. However, the benzyl paraben with a bulky nonpolar aralkyl moiety, like its butyl analog, is capable of participating in complex formation. The solubility expression for these two systems henceforth was thought to be meaningless and unsuitable for inclusion in a table. Table III, therefore, includes the experimental results of the mutual solubilizing potential of only two pairs of combinations (methyl paraben-benzyl paraben and ethyl paraben-benzyl paraben).

The solubilizing potential of the alkyl parabens to affect the solubility of benzyl paraben, as depicted in Fig. 2, increases in the ascending order of the alkyl chain of the homologous series and,

⁴ The molecular model was constructed by using Dreiding Plastic Stereo model (Rinco Instrument Co., Inc. Greenville, Ill.).

Table IV—Solubility of Benzyl Paraben in Moles/Liter (*M*) in the 60% PEG–H₂O Solution of the Alkyl Parabens Ranging from 0.1 to 0.5 *M* at 27° (Analyzed by Using NMR)

R ₁	R ₂	0.0 <i>M</i>	0.1 <i>M</i>	0.2 <i>M</i>	0.3 <i>M</i>	0.4 <i>M</i>	0.5 <i>M</i>

except for propyl paraben, seems to follow a linear relationship with respect to the concentration of each member in the series. Knowledge of whether or not the odd-number carbon chain of propyl paraben is an influencing factor on causing the curve to bend toward the *x*-axis requires additional experiments with higher homologs.

The solubilizing effect of methyl *p*-methoxybenzoate on benzyl paraben, as shown in Table IV, is somewhat similar to butyl paraben. The substitution of a lipophilic group, OCH₃, for OH of methyl paraben apparently enhances the solubilizing potential of the ester.

A theoretical consideration of this and the mutual solubilizing phenomenon in general is under study. The practical aspect of solubility is envisaged to possess application in pharmaceutical preparation and microbiological research and development.

APPENDIX

The following abbreviations are used in the equations: integral peak value = *I*, apparent = app., molar concentration = *M*, weight in grams = *w*, butyl paraben = BuPab, density of solution = *d*, solution = sln., and standard = st.

The PEG 400 formula is: OH–CH₂–CH₂–(OCH₂–CH₂)₈–OH.

Upper Phase—Both UV and NMR were used for analysis.

$$(\text{H}_2\text{O})_{\text{app.}I} - (\text{PEG})_I \times 1/18 = (\text{H}_2\text{O})_I \text{ (correction for } 2 \text{ OH/mole of PEG) (Eq. 1)}$$

$$\frac{(\text{PEG})_I}{(\text{H}_2\text{O})_I} \times 1/18 = \frac{(\text{PEG})_M}{(\text{H}_2\text{O})_M} \text{ (molar ratio) (Eq. 2)}$$

$$\frac{(\text{PEG})_M}{(\text{H}_2\text{O})_M} \times \frac{400}{18} = \frac{(\text{PEG})_w}{(\text{H}_2\text{O})_w} \text{ (weight ratio) (Eq. 3)}$$

Weight of BuPab in g./ml. determined using UV = (BuPab)_{w/ml.}
Weight of 1 ml. of solution – (BuPab)_w = (PEG + H₂O)_{w/ml.}

$$\frac{(\text{PEG} + \text{H}_2\text{O})_{w/ml.} \times (\text{PEG})_w}{(\text{PEG})_w + (\text{H}_2\text{O})_w} = (\text{PEG})_{w/ml.} \text{ (Eq. 4)}$$

$$\frac{(\text{PEG} + \text{H}_2\text{O})_{w/ml.} \times (\text{H}_2\text{O})_w}{(\text{PEG})_w + (\text{H}_2\text{O})_w} = (\text{H}_2\text{O})_{w/ml.} \text{ (Eq. 5)}$$

Molecular Scale Drug Entrapment as a Precise Method of Controlled Drug Release II: Facilitated Drug Entrapment to Polymeric Colloidal Dispersions

C. T. RHODES*, K. WAI†, and G. S. BANKER

Abstract □ Further studies have been carried out to investigate drug-polymer flocculation as a means of molecular scale drug entrapment. It has been shown that a suitable organic acid greatly increases the degree of interaction between the drug and the polymer and provides a mechanism controlling both interaction and subsequent drug-release properties. Results of tests indicate that the products prepared by the facilitated entrapment method possess excellent sustained-action characteristics. In addition, the drug entrapped as the carboxylate salt or in conjunction with the appropriate dicarboxylic acid, while demonstrating substantially complete drug-dissolution release in intestinal fluid, could be maintained in the entrapped form in aqueous suspensions during storage periods in excess of 1 month. X-ray diffraction analysis confirmed the molecular scale level of entrapment of the drug in the polymer flocculated systems.

Keyphrases □ Drug entrapment, molecular scale—controlled-release method □ Polymer-drug interaction—drug salt form effect □ Particle-size effect—drug release from polymer-drug flocculates □ X-ray diffraction—polymer-drug flocculates

Although control of the intensity and duration of drug action has been of interest to the medical and pharmaceutical profession for many years, it is only recently that controlled-action pharmaceuticals have been exploited commercially to any extent.

The advantages resulting from prolongation of drug action have been summarized by Wilson (1). Perhaps the most important is the maintenance of therapeutic effect for extended periods of time, particularly when continuous action at a therapeutic level is essential for efficient therapy. Another factor of importance is the convenience offered to the patient by this type of preparation. It has also been reported that the number of occasions when patients forget their medicine is significantly reduced when sustained-action preparations are used (2).

Optimization of drug action, including improved drug safety, may often be approached by controlling the rate of drug delivery to the absorption pool from the dosage form. A very rapid rate of drug delivery from the dosage form undoubtedly often does not represent the optimum delivery system.

It is somewhat surprising, in view of the many advantages offered by sustained-action or controlled-release dosage forms, that greater use has not been made of this approach in designing drug delivery systems. Although some drugs are inadequately absorbed along the gastrointestinal tract or have an insufficient margin of safety between therapeutic and toxic doses for sustained-action formulation to be feasible, other reasons are apparent for the still limited application of this frequently advantageous approach to the pharmacodynamic improvement of drug action.

These reasons include, but are not limited to, the fact that most approaches to sustained-release formulation have involved empirical coating methods applied to nonuniform particulate drug-containing systems, which are coated at several thicknesses or with several compositions to provide a range of release characteristics. The manufacturing sequence of such products is subject to considerable variation, and control is difficult. Such processes are often costly and the resultant products are expensive; development and manufacture of such dosage forms are also complex, at least somewhat imprecise, and time consuming. Molecular scale quantitative approaches to the physicochemical binding of drugs by polymers, by ion exchange, or by complexation mechanisms offer a number of advantages over conventional coating techniques. Optimization of drug action to provide precisely controlled drug release rates will only become possible when accurate methods of drug entrapment and release, based on physicochemical phenomena, are developed.

The present paper reports studies performed during the development of a new method for the formulation of sustained- or controlled-action pharmaceuticals. The technique described involves application of stoichiometric entrapment of drugs by polymer flocculation, the products being suitable for administration in either solid or liquid dosage forms.

Earlier work by Goodman *et al.* (3) indicated that the molecular scale interaction between drugs and polymers could facilitate the quantitative development of reproducible sustained-action pharmaceuticals. The method developed by the present authors is similar to that previously described (3). However, it has been found that the properties of drug-polymer flocculates, in which the drug contains an amino functional group, can be markedly improved if a suitable organic acid is included in the formulation. The presence of such a carboxylic acid anion has been shown to increase the amount of drug which may be bound by the polymer and to provide improved control of drug release from the polymer flocculate. The inclusion of the carboxylic acid in the drug-polymer flocculate has also made possible the development of liquid and other dosage forms.

The described method of molecular scale drug entrapment by these studies is extremely simple (3) and offers many advantages over the conventional lengthy and intricate methods used in the preparation of sustained-action pharmaceuticals. The present paper describes a method of facilitated drug entrapment in which a solution of the drug and an appropriate carboxylic acid is added slowly to a suitable polymer emulsion. The resultant flocculate is washed and dried.

Table I—Effect of Carboxylic Acid Anion upon the Entrapment of Chlorpheniramine by the Acrylic Copolymer Emulsion

Chlorpheniramine Salt	Initial Concn. of Drug Soln., % w/v	% Drug Bound	% Drug in Dry Flocculant

^a Obtained from Smith Kline & French Laboratories, Philadelphia, Pa.; all other salts synthesized.

Products so obtained may be readily milled to a fine powder, tableted, encapsulated, or suspended to provide controlled-release systems.

EXPERIMENTAL

Effect of Drug Salt Form upon Binding—To determine the effect of the drug anion moiety on the polymer-drug interaction, solutions of various salts of chlorpheniramine were employed to produce polymer flocculation. In this study, 100 ml. of each drug solution was used to coagulate 100 ml. of an acrylic copolymer emulsion.¹ Each flocculated system was mixed for 30 min. and then filtered under reduced pressure, the filtrate being collected and assayed for drug content. The drug salts used were either obtained commercially or synthesized. Those that were synthesized were recrystallized one to three times from an isopropanol-ether solvent mixture and vacuum dried at 40°; the purity was checked by melting point and IR analyses. Results of the flocculation studies are shown in Table I.

Effect of Particle Size on *In Vitro* Drug Release—The dissolution release of chlorpheniramine from a chlorpheniramine maleate-acrylic copolymer entrapment product in both simulated gastric juice (without enzyme) and simulated intestinal juice (without enzyme) was determined as a function of particle size (Table II). One-half-gram samples of each polymer-drug particle-size fraction were placed in 50 ml. of gastric or intestinal fluid, rotated at 37° according to the method of Goodman *et al.* (3), and assayed at the times specified.

Release of Drug from Aqueous Solutions of Polymer-Drug Flocculates—In the initial study, 5-g. quantities of chlorpheniramine maleate-acrylic copolymer product containing 3.7% drug, as a 60-mesh undersize powder, were suspended in 100 ml. of selected vehicles in 4-oz. reagent bottles, which were shaken daily throughout the test period. The amount of drug released at room temperature into the various vehicles was determined over a period of 30 days (Table III).

A more detailed study was also performed to investigate the effect of drug concentration upon release rate. In this experiment, 5-g. quantities of polymer-drug material were placed in 60-ml. volumes of vehicle, and the resultant suspensions were rotated continuously at 37° for the time specified (Tables IV and V).

X-Ray Diffraction Studies of Drug-Polymer Flocculates—X-ray diffraction patterns of a commercially available sustained-action pharmaceutical,² which makes use of polymeric materials as matrices, were studied as well as drug-entrapped products made by the method described herein. All patterns were obtained with copper K- α radiation generated to 40,000 v., using a General Electric XRD-5 source and the General Electric powder diffraction camera, 143.2-mm. diameter. One-half-millimeter glass capillary

Table II—Release of Chlorpheniramine Maleate from a Polymer-Drug Entrapment Product^a in Gastric and Intestinal Media as a Function of Particle Size and Time

tubes were used to rotate the sample in the beam. Results are shown in Fig. 1.

DISCUSSION

Studies with selected drug salts indicated that the addition of a stoichiometric quantity of an appropriate organic acid to the drug hydrochloride salt solutions, or the use of a drug carboxylate as the flocculant solution, greatly increased the amount of drug that could be bound by the polymer. The data shown in Table I clearly indicate the utility of the organic acid anion, since 80-90% of the drug was bound in the presence of such an anion-entrapment facilitator whereas only half the amount of drug could be bound when no facilitator was present, *i.e.*, the hydrochloride drug salt. Entrapment was facilitated equally well regardless of whether the drug carboxylate salt was prepared and entrapped or a stoichiometric quantity of the carboxylic acid was added to the drug hydrochloride salt solution. It is also significant that a 2% solution of the hydrochloride salt could only be entrapped to the extent of 54% efficiency while a 5% solution of the adipate was 96% entrapped and a 10% solution of the succinate was entrapped with 86% efficiency.

The results in Table II show several desirable features of the entrapment system from the point of view of a potential controlled-release product. Even though there is apparently a strong interaction between the drug and polymer, over 90% of the drug is available in simulated intestinal juice. Further, even though particle size has some effect upon the release in gastric juice, this dependency is not great. The release in intestinal juice appears to be substantially independent of particle size. Also, the facts that about one-third of the available drug is not released in gastric juice, even after as long as 24 hr., and as little as 5 or 10% is released in selected buffers, even on stirring for 30 days (Table III), indicate the potential of these products for controlled-release or sustained-action liquid dosage forms.

Table III describes the dissolution release of the drug from a finer than 60-mesh 3.7% chlorpheniramine maleate-polymer entrapment product. The drug, in the products made by this technique, is evenly distributed throughout the polymer matrix; the drug remains associated to the polymer without alteration

after high-speed milling in a comminutor and is contained in the various particle-size fractions in the same concentration. While substantial drug release was indicated in gastric fluid and nearly complete release in intestinal fluid (Table II), minimal drug dissolution occurs at pH values of 4.5–6, and drug dissolution in vehicles which correspond to this pH was minimal (less than 3% in orange syrup in 30 days).

Results shown in Table IV further indicate that the products obtained by this flocculation technique have potential for use as controlled release-suspensions, since the amount of drug released from suspensions in vehicles at pH values between about 4 and 6 is very low.

Continuous stirring of a distilled water suspension over a 30-day period produced no substantial alteration in the release pattern as compared with a similar suspension that was only shaken daily (Table III). Likewise, samples stored at an elevated temperature demonstrated no significant difference in release rate. The results recorded in Table V show that particle size has a negligible effect upon the amount of drug release from suspensions buffered at pH 4.5; this property of the product is, of course, most advantageous for sustained-action liquid suspensions.

Figure 1 presents photographs of the X-ray diffraction patterns of a molecular scale entrapment product, a physical mixture of the drug plus polymer employed in the entrapment system, and a commercially available polymer-drug matrix system.²

Photo A of Fig. 1 is a photograph of the X-ray diffraction pattern of a commercial methamphetamine hydrochloride-polymer matrix system (15 mg./tablet, tablet weight 115 mg.). The diffraction lines show crystalline methamphetamine hydrochloride to be present. All the lines listed in Pattern Number 5-0246 for methamphetamine hydrochloride, American Society for Testing Materials, are found in Fig. 1A. Thus, in this product the drug is not dispersed within the

Table V—Release of Chlorpheniramine from a Chlorpheniramine Maleate-Polymer Entrapment Product (3.7% Drug) in pH 4.5 Buffer as a Function of Particle Size

	24	48	120
30/40 mesh	4.7	4.8	5.1
80/120 mesh	5.4	5.4	5.5
170/230 mesh	5.3	5.4	5.5

Figure 1—X-ray diffraction patterns: A, commercial methamphetamine-polymer matrix product; B, commercial product following drug extraction; C, chlorpheniramine acid succinate; D, chlorpheniramine acid succinate, 25% as a flocculated polymer, 75% as a physical mixture; and E, chlorpheniramine acid succinate-polymer entrapment product containing 25% drug.

product at the molecular level but merely consists of a physical compressed mixture of crystalline drug and polymer.

After leaching the commercial product with 0.1 N hydrochloric acid for 2 days, the X-ray diffraction pattern (Fig. 1B) shows that nearly all of the crystalline drug has been removed. The faint lines remaining may be due to talc, coloring agent, or other components of the tablet. The polymer itself shows no crystalline X-ray pattern. It is, however, responsible for the heavy, undefined, scattered radiation apparent in Fig. 1B.

Figure 1C shows the X-ray diffraction pattern of crystalline chlorpheniramine acid succinate. Figure 1D reproduces the diffraction pattern of a mechanical mixture of chlorpheniramine acid succinate (25%) and the acrylic copolymer as mechanically separated from the polymer emulsion, clearly showing the presence of crystalline drug. However, Photo E of Fig. 1, a picture of the X-ray diffraction pattern of a chlorpheniramine acid succinate-

acrylic copolymer entrapment product containing 25% drug, is quite different. The diffraction pattern indicates that crystalline drug is absent. The absence of crystalline drug in this sample demonstrates that the drug in the entrapment product is uniformly dispersed at a molecular level.

The mechanism by which the carboxylic acid anion facilitator increases the amount of drug bound by the polymer is of considerable theoretical interest and is the subject of a further study. Several modes of action appear possible. The formation of complex ions between the polymer carboxyl group, drug, and acid anions has been suggested, the resultant electrostatic forces binding the drug to the polymer. Presumably, inclusion-type complex formation may also be involved to some extent.

SUMMARY

A new method for the preparation of sustained-action pharmaceuticals by stoichiometric entrapment of drugs in polymer floculates is described.

The advantages of the use of a suitable entrapment facilitator, an organic acid, to enhance the binding of drugs by polymers is demonstrated.

In vitro tests indicate that the products obtained by this technique could be used in either solid or liquid dosage forms.

Molecular Scale Drug Entrapment as a Precise Method of Controlled Drug Release III: *In Vitro* and *In Vivo* Studies of Drug Release

C. T. RHODES*, K. WAI†, and G. S. BANKER

Abstract □ Controlled-release drug-entrapped systems of phenylephrine and phenylpropanolamine have been prepared by the facilitated molecular scale drug-entrapment method previously described. Variables influencing the entrapment process, such as flocculation pH and rate of agitation, have been investigated. These variables are readily controllable. The influence of various polymers and carboxylic acid anions on the entrapment and release of the drugs was examined. Tests applied to the products so obtained indicate that they are well suited for pharmaceutical use. An *in vivo* study verified the sustained-release properties of a molecular scale entrapped phenylpropanolamine.

Keyphrases □ Drug entrapment, molecular scale—release-rate control □ Flocculation pH effect—drug binding, release □ Stirring rate effect—drug binding □ Release rates, *in vivo*, *in vitro*—polymer-bound drug

Parts I and II of this series described the development of a method of molecular scale drug entrapment for the physicochemical preparation of controlled-release pharmaceuticals; the advantages offered by this new technique were also discussed (1, 2). Part I described the flocculation of polymeric colloidal dispersions as a mechanism of precise drug entrapment. It was demonstrated that the resultant drug-polymer floculates, when administered as a fine powder, exhibited very satisfactory sustained-action characteristics. However, less success was obtained when weakly basic drugs such as phenylephrine were used as flocculants.

In Part II the study of drug entrapment by polymer flocculation was considerably extended. It was shown that the presence of a carboxylic acid anion greatly facilitated drug entrapment, increasing the binding of the drugs by the polymer, which substantially increased the efficiency of the drug-entrapment process and provided added control over drug release.

acrylic copolymer entrapment product containing 25% drug, is quite different. The diffraction pattern indicates that crystalline drug is absent. The absence of crystalline drug in this sample demonstrates that the drug in the entrapment product is uniformly dispersed at a molecular level.

The mechanism by which the carboxylic acid anion facilitator increases the amount of drug bound by the polymer is of considerable theoretical interest and is the subject of a further study. Several modes of action appear possible. The formation of complex ions between the polymer carboxyl group, drug, and acid anions has been suggested, the resultant electrostatic forces binding the drug to the polymer. Presumably, inclusion-type complex formation may also be involved to some extent.

SUMMARY

A new method for the preparation of sustained-action pharmaceuticals by stoichiometric entrapment of drugs in polymer floculates is described.

The advantages of the use of a suitable entrapment facilitator, an organic acid, to enhance the binding of drugs by polymers is demonstrated.

In vitro tests indicate that the products obtained by this technique could be used in either solid or liquid dosage forms.

Molecular Scale Drug Entrapment as a Precise Method of Controlled Drug Release III: *In Vitro* and *In Vivo* Studies of Drug Release

C. T. RHODES*, K. WAI†, and G. S. BANKER

Abstract □ Controlled-release drug-entrapped systems of phenylephrine and phenylpropanolamine have been prepared by the facilitated molecular scale drug-entrapment method previously described. Variables influencing the entrapment process, such as flocculation pH and rate of agitation, have been investigated. These variables are readily controllable. The influence of various polymers and carboxylic acid anions on the entrapment and release of the drugs was examined. Tests applied to the products so obtained indicate that they are well suited for pharmaceutical use. An *in vivo* study verified the sustained-release properties of a molecular scale entrapped phenylpropanolamine.

Phenylephrine and phenylpropanolamine, two weakly basic amine drugs which initially presented considerable difficulty as to efficient entrapment and adequately retarded release utilizing the entrapment procedure, were selected for detailed study to assess the utility and applicability of the facilitated entrapment technique in a rigorous manner. Results presented in this paper show that sustained-action products of both of these drugs may be readily prepared utilizing the facilitated entrapment method. Studies made to determine the optimum conditions for facilitated entrapment were also conducted.

EXPERIMENTAL

Phenylephrine Studies—*Efficiency of Various Dicarboxylic Acid Anions in Binding Drug to Polymer*—The binding of phenylephrine¹ by an acrylic copolymer latex,² hereafter referred to as acrylic copolymer emulsion 1 or acrylic copolymer 1, in the presence of a variety of anions was examined in the following manner. One-fortieth of a mole quantities of drugs, as the hydrochloride, together with an equivalent amount of carboxylic acid anion and sufficient sodium hydroxide to produce the facilitator moieties of Table I, was dissolved in 50 ml. of distilled water and added over a period of 5 min. to 50 ml. of the polymer emulsion, which was stirred continuously. The flocculate was separated from the supernatant liquid by filtration, and the drug content of both product and filtrate was determined by the peak height assay method (3). Results are shown in Table I.

Effect of Flocculation pH upon Binding and Release of Drug—A stock solution of phenylephrine maleate (0.25 M) was prepared, and 50-ml. quantities were added to 50-ml. volumes of polymer emulsion, the pH of which had been previously adjusted by addition of suitable amounts of sodium hydroxide solution. The flocculated products, which resulted from the addition of the drug electrolyte solutions to the polymeric colloidal dispersions, were collected by filtration, dried, and reduced to a 60-mesh powder. The concentration of drug in the dry flocculates and the amount of drug released after shaking for 30 min. in simulated gastric juice (without enzyme) at 37° are recorded in Table II.

Effect of Stirring Rate upon Binding of Phenylephrine—Solutions of phenylephrine maleate were used to flocculate acrylic copolymer

emulsion 1, as described in the previous section but without pH adjustment. Flocculation was effected at different stirring rates using a standard three-bladed marine propeller, driven by a laboratory mixer employing Variac speed control. The effect of stirring rate upon percentage of drug bound is shown in Table III. Attempts to effect flocculation at higher stirring rates by the use of a high-shear mixer with a rotor/stator head were unsuccessful; the flocculate blocked the narrow aperture of the mixing head.

Influence of Polymer on Drug Entrapment—Goodman *et al.* (1) preliminarily investigated the usefulness of two related polymeric dispersions as entrapment matrices. In this phase of the research the influence of the polymer on drug entrapment was more closely studied. Twenty-five polymer dispersions were screened for pH solubility properties and apparent pKa values in order to select the potentially best materials for possible use as entrapment matrices. Those which demonstrated potentially useful solubility and coagulation properties were subjected to further drug flocculation studies. Polymeric systems with reasonable flocculation values (the volumes of a stock solution of phenylephrine maleate, 0.5 M, required to effect flocculation) are listed in Table IV. The physical properties of some of the flocculates, in particular the ease with which they could be dried and milled, are also noted in Table IV.

The two most satisfactory products, derived from a second acrylic acid copolymer emulsion³ (hereafter referred to as acrylic copolymer emulsion 2 or acrylic copolymer 2) and a styrene-acrylic copolymer emulsion,⁴ together with the previously described acrylic copolymer emulsion 1,² were further examined. The percentage of drug bound

by the various polymers was determined, and the amount of drug released after shaking a 60-mesh powder at 37° in simulated gastric juice (without enzyme) for 30 min. was measured (Table V).

In Vitro Release Study—The *in vitro* release rates of phenylephrine from phenylephrine maleate-acrylic copolymer entrapment products were examined by the method described in Part I of this series (Table VI).

Phenylpropanolamine Studies—Efficiency of Various Carboxylic Acid Anions in Drug Binding—Experiments similar to those performed with phenylephrine were conducted. The results are shown in Table VII.

In Vitro Release Study—An *in vitro* study of the release of drug from a phenylpropanolamine acetate-acrylic copolymer 1 entrapment product, as a 60-mesh powder, was performed (Table VIII) in the same manner as was employed for the phenylephrine entrapment products.

In Vivo Release Study—Five adult healthy male subjects were used in this test. They were given a capsule dose of 50 mg. of phenylpropanolamine: (a) in the form of the USP product and (b) as a 60-mesh powder of the phenylpropanolamine acetate-acrylic copolymer 1 entrapment product. The amount of drug appearing in the urine was determined over a 24-hr. period by the method described by Heimlich *et al.* (4). From the data so obtained, the time for half the drug to be excreted, the biological half-life, was determined (Table IX).

DISCUSSION

The results in Tables I and VII show considerable variation in the efficiency with which the various facilitators assist in the binding of these weak basic amine drugs to the acrylic polymer. For both drugs (Tables I and VII) the order of facilitator entrapment efficiency is very similar. Further, replacement of all acidic hydrogen atoms on the polybasic facilitators appears to enhance entrapment efficiency. No direct relationship between facilitator efficiency and pKa is immediately discernible. It is thought that both electronic and steric factors control the activity of the acid anions in the entrapment process.

The effect of an increase in the flocculation pH value was twofold. It increased both the amount of drug bound and the rate at which drug was released. These effects are probably due to one or

4.5	2.3	74
6	7.3	94
8	7.3	97

^a Product contained 9.76% drug.

both of two factors. First, an increase in pH will increase the amount of phenylephrine present in the unionized form and reduce the proportion present as the ionized species. The increase in the amount of drug bound may reflect the ability of the unionized species to interact with the polymer, possibly by a different mechanism to that operating in the binding of the ionized drug. Second, an increase in flocculation pH will alter the solubility of the polymer, since it will produce an increase in the proportion of ionized polymer carboxyl groups. The results shown in Table II do not suggest that an increase in flocculation pH is advantageous in the preparation of sustained-action pharmaceuticals by the carboxylic acid facilitated entrapment method.

The increase in the amount of drug bound with an increase in stirring rate (Table III) may possibly be attributed to the effect of high shear increasing the area of polymer surface available to drug in the aqueous phase by dispersing particle flocs, thus facilitating interaction.

Examination of a number of polymer emulsions for use as molecular scale entrapment matrices for potential controlled drug-release applications resulted in the discovery of two additional polymers, acrylic copolymer emulsion 2 and the styrene-acrylic copolymer emulsion, which appeared to be well suited for this purpose (Tables IV and V). These two polymer emulsions flocculated completely; the products obtained could be easily filtered, dried, and milled. Results of preliminary *in vitro* release studies compare favorably with those obtained earlier with acrylic copolymer 1.

The results in Table VI indicate that the phenylephrine maleate-acrylic copolymer 1 product possesses very satisfactory *in vitro* release characteristics, with approximately one-half of the total drug being released in the first 30 min. for two of the products and the remainder becoming available at a steady rate during the next 6.5 hr. Similar results are shown in Table VIII for the phenylpropanolamine acetate-acrylic copolymer 1 product.

Preliminary *in vivo* tests of the phenylpropanolamine entrapment product also indicate the sustained-action properties of the phenylpropanolamine product. For all subjects the rate of excretion of drug from the polymer flocculate was lower than from the untreated drug. The mean time for half the total dose to be excreted was 4.6 hr. for the USP product, as compared with 8.0 hr. for polymer-drug entrapment product (Table IX).

SUMMARY

Further studies of the facilitated molecular scale entrapment technique for the preparation of controlled-release or sustained-action pharmaceuticals are reported. The efficiency of a number of carboxylic acid anions in facilitating drug entrapment was studied, as were pH and mechanical effects on the facilitated entrapment.

Table IX—*In Vivo* Release Data for Phenylpropanolamine-Acrylic Copolymer 1 Entrapment Sustained-Release Product

Subject Weight, lb.	Biological Half-Life of Phenylpropanolamine, hr.	Biological Half-Life of Phenylpropanolamine Polymer Product, hr.
205	5.0	7.8
175	6.0	9.8
139	5.3	7.0
139	3.0	8.5
130	3.8	6.8
Average	4.6	8.0

In vitro and *in vivo* tests of phenylephrine and phenylpropanolamine products, obtained by the facilitated molecular entrapment method, confirmed the pharmaceutical utility of this technique.

These results indicate that the drug-polymer entrapment products prepared by the facilitation method possess considerable potential for exploitation as sustained-action or controlled-release pharmaceuticals.

Selected Pharmacological Studies of a Series of Substituted Imidazo(4,5-*d*)pyridazines

G. G. FERGUSON, H. C. HEIM, and G. D. APPELT

Abstract □ A general pharmacological screening program was applied to a series of 10 substituted imidazo(4,5-*d*)pyridazine compounds. All of the compounds produced depression of spontaneous activity in rats, and six of the compounds produced significant lengthening of hexobarbital "sleeping times." In addition, two of the compounds produced a partial reversal of reserpine hypothermia, measured by a rectal temperature monitoring apparatus, and seven of the compounds produced significant inhibition of monoamine oxidase using a Warburg apparatus. One compound produced monoamine oxidase inhibition when a spectrophotometric assay was employed.

Keyphrases □ Imidazo(4,5-*d*)pyridazines—pharmacological screening □ CNS activity—imidazo(4,5-*d*)pyridazines □ Monoamine oxidase inhibition—imidazo(4,5-*d*)pyridazines □ Reserpine-induced hypothermia—imidazo(4,5-*d*)pyridazine blocking effect

In recent years, considerable interest has arisen in the development of compounds having potential antineoplastic effects. Robins (1), for example, reported the synthesis of a series of over 1300 purine derivatives and included antineoplastic screening data on active compounds. The compounds studied in this report, the imidazo(4,5-*d*)pyridazines, were synthesized by Gerhardt *et al.* (2) as possible purine antimetabolites and are representative of 75 compounds in that series (Table I).

Little has been reported concerning the pharmacology of imidazopyridazines or similar compounds, other than antineoplastic screening data. Dimmling and Hein (3) found that certain types of imidazole derivatives decreased contractility of the frog heart and produced damage to leukocytes and macrophages. Certain pyrimidazole derivatives have shown local anesthetic effects (4), and other pyridine and pyridine-pyrrolidine imidazole compounds have been shown to have CNS depressant effects (5). Rinaldi *et al.* (6) showed some protection of mice to the effects of X-ray exposure with imidazole and benzimidazole derivatives. Certain de-

rivatives of phenylimidazopyridine carboxylic acid have been shown to have diuretic effects (7). It was felt that a survey of the general pharmacological properties of this series of compounds might be useful to further consideration of them as possible antineoplastic agents. In this paper, studies of certain effects of these compounds on the CNS are reported.

EXPERIMENTAL

Evaluation of Gross CNS Effects—Adult Houston-Cheek albino rats, weighing between 200 and 350 g., were used for measurements of spontaneous activity and for determinations of hexobarbital "sleeping time." Spontaneous activity measurements were done using a "light box" similar to that proposed by Dews (8). Each animal was injected with a dose intraperitoneally of drug suspended in alkalized distilled water (pH 9), placed in a stimulus-free chamber for 15 min. to allow for absorption of the drug, then placed in the activity box, and monitored for spontaneous activity for 1 hr.

In vitro and *in vivo* tests of phenylephrine and phenylpropanolamine products, obtained by the facilitated molecular entrapment method, confirmed the pharmaceutical utility of this technique.

These results indicate that the drug-polymer entrapment products prepared by the facilitation method possess considerable potential for exploitation as sustained-action or controlled-release pharmaceuticals.

rivatives of phenylimidazopyridine carboxylic acid have been shown to have diuretic effects (7). It was felt that a survey of the general pharmacological properties of this series of compounds might be useful to further consideration of them as possible antineoplastic agents. In this paper, studies of certain effects of these compounds on the CNS are reported.

EXPERIMENTAL

Evaluation of Gross CNS Effects—Adult Houston-Cheek albino rats, weighing between 200 and 350 g., were used for measurements of spontaneous activity and for determinations of hexobarbital "sleeping time." Spontaneous activity measurements were done using a "light box" similar to that proposed by Dews (8). Each animal was injected with a dose intraperitoneally of drug suspended in alkalized distilled water (pH 9), placed in a stimulus-free chamber for 15 min. to allow for absorption of the drug, then placed in the activity box, and monitored for spontaneous activity for 1 hr.

Table II—Effect of the Compounds on Spontaneous Activity in Rats (counts/hr.)^a

^a Each value represents the mean of five trials. ^b Standard error of the mean.

Results were compared to controls having identical treatment except for the use of the test drug.

As a corollary study, rats were tested for the effect of the compounds on the hexobarbital sleeping time. The animals were injected with 20 mg./kg., i.p., of the compound to be tested 2 hr. prior to the administration of 50 mg./kg., i.p., hexobarbital. The length of sleep between the loss and regaining of the righting reflex (sleeping time) was then determined for each animal, and the results were compared to controls (9, 10).

Evaluation of Monoamine Oxidase Inhibition—Initial screening for possible monoamine oxidase (MAO) inhibition was done using the "reserpine reversal" technique of Pletscher (11). Adult Lemberger albino mice, weighing between 25 and 40 g., were restrained in plastic holders; their rectal temperatures were monitored using an electronic thermometer equipped with temperature-sensing probes.¹

The ability of the compounds to reverse the hypothermic effect of reserpine was measured, using four mice for each trial: two control animals received 2.5 mg./kg., i.p., reserpine and two experimental animals were pretreated with 100 mg./kg., i.p., of the compound to be tested 1 hr. prior to treatment with 2.5 mg./kg. reserpine. A small number of animals received 100 mg./kg., i.p., iproniazid to serve as a standard of MAO inhibition. The rectal temperatures were monitored for 4 hr., and the effects of the drugs on the reserpine-induced hypothermia were noted.

As a further evaluation of possible MAO inhibition, the effects of the compounds on rat brain mitochondria were investigated. Brain mitochondria were prepared, according to the method of Brody and Bain (12), and MAO activity was determined in the presence or absence of inhibitor by conventional manometric techniques (13) or spectrophotometrically (14). In the manometric determinations, Warburg flasks contained in the main compartment a final concentration of 0.01 *M* phosphate buffer (pH 7.8), 0.017 *M* compound, and the mitochondrial suspension representing 50 mg. wet weight of tissue in a total volume of 1.8 ml. The side arm of the flask contained 0.3 ml. of 0.1 *M* tyramine. After the flasks were allowed to equilibrate at 37° for 15 min., the manometer valves were closed and the side arm contents of each flask were tipped in. Oxygen uptake was recorded at 10-min. intervals for a total period of 90 min.

Those compounds which showed significant MAO inhibition using the manometric technique were then tested using a direct spectrophotometric assay for MAO activity. The 3 ml. reaction mixture contained in a final concentration 0.03% commercial emulsifier,² 0.09 *M* phosphate buffer (pH 7.4), 0.00016 *M* compound, and 0.017 *M* *p*-dimethylaminobenzylamine hydrochloride, with mitochondrial suspension representing 50 mg. wet weight of tissue. The conversion of *p*-dimethylaminobenzylamine hydrochloride to its aldehyde derivative by MAO was observed by determining the increase in density of the solution at 355 mμ, according to the method of Deitrich and Erwin (14). Readings were taken at 1-min. intervals for 5 min. after the reaction began.

RESULTS AND DISCUSSION

All imidazopyridazine derivatives, except Compound 1, produced significant depression of spontaneous activity at all dosage levels

In studies using the Warburg respirometer, Compounds 4–10 produced significant inhibition of monoamine oxidase at the end of 90 min. (Table V). Upon further testing of these compounds with the spectrophotometric technique, it was found that Compound 9 produced noncompetitive MAO inhibition (Fig. 1).

While Compounds 4–10 produced significant MAO inhibition in the Warburg studies, only Compound 9 produced significant inhibition of the enzyme in the spectrophotometric assays. Several factors may be involved in the explanation of these findings. The concentrations of the drugs used were quite different in the two studies. The concentration of the compounds used in the Warburg studies was approximately 100 times that of the compounds used in the spectrophotometric assays. The substrates used were different in the two studies, and thus the influence of the inhibiting drug on the reaction system might have been different in each case. Finally, if the inhibition seen was irreversible, the 15-min. preequilibration

in the Warburg flasks in the absence of substrate would be quite different from the conditions in the spectrophotometric studies, in which the inhibitor and substrate were added essentially together with no preequilibration time allowed.

SUMMARY

This study involved the evaluation of pharmacological activity of a group of 10 imidazo(4,5-*d*)pyridazine compounds which were originally synthesized as antineoplastic agents.

All of the compounds were found to exert CNS depressant effects. Compounds 1, 2, 4, 6, 8, and 10 prolonged the hexobarbital sleeping time in rats. Compounds 5 and 8 produced a partial reversal of reserpine-induced hypothermia in mice.

Compounds 4–10 inhibited MAO in Warburg studies, and Compound 9 inhibited MAO in a spectrophotometric assay technique.

Mathematical Optimization Techniques in Drug Product Design and Process Analysis

DALE E. FONNER, Jr.*, JAMES R. BUCK, and GILBERT S. BANKER

Abstract □ Optimization techniques represent analytical tools available to the researcher in his search for the best possible solution to a particular problem. Methodologies have been developed for structuring typical pharmaceutical development problems into a framework whereby sophisticated mathematical techniques can be employed to arrive at an optimal solution. Pharmaceutical product and process design problems were structured as constrained optimization problems and subsequently solved by the Lagrangian method of optimization. This optimization method was employed to generate optimal formulations in typical tablet design problems and to locate optimizing levels of processing variables in a typical encapsulation design problem.

Keyphrases □ Drug product design—mathematical optimization techniques □ Process analysis—mathematical optimization techniques □ Lagrangian method—optimization, drug design □ Optimum tablet design—techniques □ Tablets, optimization design—phenylpropanolamine HCl

Pharmaceutical product and process design problems are normally characterized by multiple objectives. In designing a product, for example, the pharmaceutical scientist must often meet prespecified control limits which define or influence such dosage form characteristics as the unit cost, physical stability, chemical stability, or physiological availability of the active ingredient. The parameters describing these dosage form characteristics represent response or dependent variables, and any limits or conditions placed on these response variables represent objectives. The magnitude of the observed value for each response variable generally depends upon levels of one or more of the controllable (independent) variables. Mathematically speaking, the j th response variable is measured as y_j , and the responses obtained are a function of levels of one or more of the controllable variables, X_1, X_2, \dots, X_n . Thus,

$$y_j = f_j(X_i), \quad j = 1, 2, \dots, r; \quad i = 1, 2, \dots, n \quad (\text{Eq. 1})$$

where f_j is the relationship between the one or more X_i controllable variables and each response variable y_j . The geometrical representation of y_j as a function of possible combinations of levels of the controllable variables defines a response surface (Fig. 1). The task of the pharmaceutical scientist frequently involves locating levels of the one or more X_i controllable variables that meet limits or conditions placed on each y_j response variable.

The response variables of product and process design problems are often affected differently by particular combinations of the controllable variables due to interaction effects (1–5). If the response variable effects are nonadditive, the response surface is highly complicated. Unless the program of experimentation is statistically well designed and an extensive series of experiments is conducted, accurate estimates of the response variable

Figure 1—Representative graph of Eq. 1 for two controllable variables, X_1 and X_2 .

from a fixed set of controllable variables are virtually impossible (6).

Design problems are further complicated when objectives are competing. As a particular controllable variable is increased in most pharmaceutical design problems, one response variable tends to improve while another response variable is degraded. For example, compressional force or the concentration of granulating agent employed may produce competing effects on tablet friability and disintegration time or on tablet hardness and drug-release rate. Achievement of the best product or process design under conditions of competing objectives and interactive effects by guesswork or trial and error is time consuming, unreliable, costly, and often unsuccessful. Furthermore, the pharmaceutical researcher who employs such techniques may not recognize how close a particular solution lies to the optimal solution.

One way of dealing with complex pharmaceutical design problems is to structure them as constrained optimization problems. Problems structured in this way can be solved by any one of a number of existing techniques; one of the more versatile techniques is the Lagrangian method. This study investigated the usefulness of a systematic optimization approach in solving pharmaceutical product and process design problems.

Constrained mathematical optimization methods would appear to be broadly applicable to many pharmaceutical product design and process analysis problems. Data which are currently being generated by preformulation research programs during drug product design

should permit the use of optimization techniques in an increasing number of product design or process analysis programs.

Optimization techniques have the capability in pharmaceutical research of: (a) saving time and minimizing costs in achieving the desired product design; (b) improving the reliability of the research effort to achieve the optimal or near optimal product or process design solution; and (c) improving quality and assuring quality of the final drug product as affected by product and/or process design.

THEORY

Optimization problems may be broadly classified as either unconstrained or constrained. Unconstrained optimization involves the maximization or minimization of a function in which no restrictions or limits have been placed on the controllable variables or functions of the controllable variables. For example, optimization of

$$y = f(X_i), \quad i = 1, 2, \dots, n \quad (\text{Eq. 2})$$

represents an unconstrained optimization problem and can be solved by classical calculus techniques (7). For a function of n controllable variables, the location of relative optima requires solving a set of n simultaneous equations. The n simultaneous equations result from partially differentiating Eq. 2 with respect to the n controllable variables. The global optimum is then established by evaluating $f(X_i)$ at the relative optimum points and selecting the most extreme of all the solutions obtained.

A constrained optimization problem (7) is one in which a function is optimized subject to restrictions or limits placed on the controllable variables. Mathematically, the problem is to optimize

$$y = f(X_i), \quad i = 1, 2, \dots, n \quad (\text{Eq. 3})$$

such that:

$$g_j(X_i) = \alpha_j, \quad j = 1, 2, \dots, p \leq n \quad (\text{Eq. 4})$$

$$g_j(X_i) \geq \alpha_j, \quad j = p + 1, \dots, m \quad (\text{Eq. 5})$$

Equation 3 represents the function to be optimized and is generally referred to as the objective function. Equations 4 and 5 are referred to as equality and inequality constraints for the specified constants α_j . Only the greater than or equal to relationship is represented, since $h(X_i) \leq 0$ may be written as $g(X_i) = -h(X_i) \geq 0$. Thus, the constrained optimization problem involves locating levels of X_i that produce an optimal response in $f(X_i)$ such that the constraints of the problem are not violated. If the objective function and constraints are linear, the problem can be solved by linear programming techniques (8–10). If nonlinearities exist in the objective function and/or one or more of the constraints, the constrained optimization problem of Eqs. 3–5 becomes a nonlinear programming problem. Several techniques capable of dealing with nonlinear programming problems have been developed (11–13). Since systems of pharmaceutical interest are often characterized by the presence of many interactions, nonlinear models frequently result.

The Lagrangian Method—Of the techniques available for solving the constrained optimization problem in its general form (Eqs. 3–5), the most versatile method appears to be the Lagrangian method (7, 14, 15). *Appendix A* contains two numerical examples illustrating this method of optimization. The Lagrangian method has many desirable properties because this method: (a) locates the optimum directly and does not search infeasible points; (b) generates only feasible solutions; (c) efficiently handles inequality as well as equality constraints; and (d) deals with nonlinearities in the objective function and/or constraints.

Inequality constraints are converted to equality constraints by incorporating a slack variable, q_j , which must be nonnegative to assure that its value is positive in the Lagrange function (16). Thus, Eq. 5 may be written as follows:

$$g_j(X_i) - q_j^2 = \alpha_j, \quad j = p + 1, \dots, m \quad (\text{Eq. 6})$$

The slack variable, q_j , in effect absorbs the slack created by the

original inequality relationship. For a less than or equal to constraint, the minus sign in Eq. 6 is replaced with a plus sign. Once the inequality constraints have been converted to equality constraints, the next step is to form the Lagrange function, F , which is equal to the objective function plus the products of the Lagrange multiplier, λ_j , and the constraint (7). For the general constrained optimization problem (Eqs. 3–5), the Lagrange function becomes

$$F = f(X_i) + \sum_{j=1}^p \lambda_j [g_j(X_i) - \alpha_j] + \sum_{j=p+1}^m \lambda_j [g_j(X_i) - q_j^2 - \alpha_j] \quad (\text{Eq. 7})$$

As shown in Eq. 7, one Lagrange multiplier is introduced for each constraint, and one slack variable is introduced for each inequality constraint.

If the task is to minimize the objective function, then the Lagrange function is minimized with respect to the controllable variables X_i and maximized with respect to the Lagrange multipliers λ_j , giving a so-called minimax solution (17, 18). In maximizing the objective function, the resulting solution is a maximin solution relative to X_i and λ_j , respectively. Either form of the resulting solution is a stationary point in which the tangent of the Lagrange function is zero with respect to each X_i and λ_j . Therefore, the values of the controllable variables which jointly satisfy each partial derivative of the Lagrange function with respect to X_i ($i = 1, 2, \dots, n$), λ_j ($j = 1, 2, \dots, p, \dots, m$), and q_j ($j = p + 1, \dots, m$), each set equal to zero, provides stationary points including a constrained extreme of the objective function. These satisfying values, X_i^* , can be obtained by the simultaneous solution to the $n + m$ equations. Each set of X_i^* values obtained is a root to this set of equations and denotes a stationary point. If a set of equations gives multiple roots, then each root may be substituted into the objective function to find the one that is the desired extreme. If the equations obtained from partially differentiating the Lagrange function result in a set of simultaneous nonlinear equations, then numerical methods must be used to locate the simultaneous solution point (14).

The Lagrange multiplier has an interesting interpretation directly relating to optimization problems (19). The numerical value of λ_j represents a measure of the instantaneous rate of change of the objective function with a change of the constraint's limiting value. Thus, the value of λ_j is useful in projecting the expected gain or loss in the objective function accompanying a change in constraint of one unit.

The Lagrangian method of solving constrained optimization problems assumes that a mathematical relationship exists which relates the response variable to levels of the controllable variables. Theoretically, mathematical models can be derived from a knowledge of the natural laws governing the system. However, underlying mechanisms in pharmaceutical product and process design problems are often so complicated that the formulation of an analytical mathematical model is out of the question. If an analytical model is impossible to derive, then an empirical mathematical model may be developed by using multiple-regression techniques (4, 20). Thus, it is usually possible to fit a polynomial to the response surface which can be expected to give an adequate approximation of the response surface over the region of experimentation. The Lagrangian method has been applied to a constrained optimization problem involving polynomial models generated by multiple-regression techniques (21).

EXPERIMENTAL

A typical product design problem was studied in this investigation. It involved locating levels of the binder and disintegrant that optimized tablet physical properties and drug availability in a model tablet formulation. An optimization method was used to solve a constrained tablet design problem involving a restriction placed on the urinary elimination rate of the drug. A process design problem was also analyzed utilizing regression models describing powder encapsulation (4).

Model Tablet Design, Preparation, and Evaluation—A model tablet system was employed to demonstrate the advocated design procedure. Tablets containing various concentrations of a disintegrant and binder were prepared. The effect of the binder and dis-

integrant concentration on tablet hardness, friability, volume, *in vitro* release rate, and urinary excretion rate of drug in human subjects was recorded. Phenylpropanolamine hydrochloride¹ was the drug chosen based on its relatively low dose, safety, quantitative urinary excretion reflecting drug availability, and ease of assay from the urine. The model tablet system employed: (a) represented commonly used ingredients in tablet formulations; (b) produced tablets that did not split or fracture during the friability test; and (c) contained levels of binder and disintegrant that significantly affected tablet hardness, friability, volume, and *in vitro* release rate of the drug. The tablet formulas studied were all contained within the following limits:

Phenylpropanolamine hydrochloride	50 mg.
Dicalcium phosphate dihydrate ²	q.s.
Corn starch ³	1-41%
Stearic acid USP ⁴	5-45%

Tablet weight = 400 mg.

To achieve reproducible friability and *in vitro* $t_{50\%}$ release rate data, it was necessary to control the moisture content of the tablets. The starch, therefore, was dried for 4 hr. at 120°, and all tablet ingredients were individually stored in a vacuum desiccator containing anhydrous calcium sulfate⁵ for 24 hr. prior to compression. Tablets were individually compressed, utilizing 0.95 cm. ($\frac{3}{8}$ in.) standard cut tooling, to a load of 3000 lb. on a pneumatic press.⁶ The load was maintained for 10 sec., and all tablets were stored in a vacuum desiccator for at least 24 hr. prior to use. Karl Fischer moisture determinations were conducted to ensure that the moisture content of the tablets remained below 1%. At least five replicate tablets, each based on a separate powder mixture of a particular formulation, were used to obtain a measure of tablet volume, hardness, friability, and *in vitro* $t_{50\%}$ release rate for all nine tablet formulations studied.

Tablet hardness in kilograms was determined using a Pfizer hardness tester.⁷ Since tablet moisture content affected tablet friability, a special friabilation apparatus was fabricated in which humidity control was possible. This apparatus consisted of a 1.5-oz. amber, dry square bottle whose bottom was covered with a 0.25-in. layer of Wood's metal (soft solder). A 0.08-cm. ($\frac{1}{32}$ -in.) thick piece of Teflon was dried over the Wood's metal to provide a smooth standard surface for tablet contact. A silica gel bag,⁸ wrapped in muslin, was attached to the cap of the bottle. Attrition was provided to the tablet in the bottle by placing the entire unit in an Eberbach shaker unit⁹ oscillating at 275 ± 3 c.p.m., with a stroke length of 3.8 cm. (1.5 in.). Friability was measured as the percent weight loss of an individual tablet after 40 min. of shaking. The conditions selected for the friabilation test were found to give reproducible data and to distinguish real friability differences existing among the nine different tablet formulations.

Tablet volume was computed from the cylindrical tablet volume and the spherical segment volume of the standard cup punches used. The volume of the spherical segment was calculated as (22)

$$V = 1/6\pi h(3r^2 + h^2) \quad (\text{Eq. 8})$$

where r is the radius of the segment and h is its depth. Punch diameter [0.94 cm. (0.3720 in.)] and punch depth [0.10 cm. (0.0410 in.)] were measured with calipers. The volume of each spherical segment was calculated to be $V = 0.037 \text{ cm.}^3$ (0.0023 in.³). The crown thickness of the tablets was measured using an Ames micrometer.¹⁰

The *in vitro* release rate tests were conducted in a 250-ml., three-necked, round-bottom flask, utilizing 200 ml. of distilled water as the solvent, at $37 \pm 1^\circ$. Agitation was provided by a model 12 Stedi-Speed adjustable stirrer¹¹ equipped with a two-bladed, 3.18-cm. (1.25-in.) diameter stainless steel impeller, which was operated at 130

Table I—Tablet Formulations Used in the Optimization Study

Formulation No.	Mg. of Ingredient per Tablet			
	Phenylpropanolamine HCl	Dicalcium Phosphate $\cdot 2\text{H}_2\text{O}$	Starch	Stearic Acid
1	50	326	4 (1%)	20 (5%)
2	50	246	84 (21%)	20

± 2 r.p.m. This agitation level provided solvent circulation but did not disturb the particles formed by the disintegrating tablet at the bottom of the flask. Five-milliliter aliquots were removed at selected time intervals for analysis, with each aliquot being replaced by 5 ml. of distilled water. The concentration of drug in the bulk solvent was corrected for drug lost from the previous samples. Each aliquot was filtered through a Millipore filter (0.65- μ pore opening), and its absorbance was determined at 256.4 μ . Cumulative percent of drug released *versus* time plots were prepared for each of the replicate tablets of each formulation. The time for 50% of the drug to be released ($t_{50\%}$) was determined graphically from each plot.

The nine tablet formulations listed in Table I define a full 3^2 factorial design. Levels of stearic acid and starch were equally spaced to permit a trend analysis of the data in the framework given by Davies (6). Replication provided an estimate of the experimental error involved, and experiments were randomized to prevent systematic biasing of the estimates of experimental effects.

Urinary Excretion Rate—The urinary excretion rate of phenylpropanolamine hydrochloride was determined for four different tablet formulations (Formulations 1, 3, 4, and 7 of Table I) and for a control solution of the drug. The control solution contained 47.66 mg. of drug in 200 ml. of distilled water. Five healthy human male subjects were used. Each subject was separately administered all four of the dosage forms and the control solution of drug at time intervals of $7 \times t'_{50\%}$ or longer, where $t'_{50\%}$ represents a measure of the urinary elimination rate half-life in hours of the last formulation administered. The order of administration of the dosage forms and the order in which the individuals were tested were randomized. A modification of the assay of Heimlich *et al.* (23) was used for the drug urinalysis in which cyclohexane was employed as the extracting solvent. Three standards were run during each assay in which three known amounts of drug were added to a blank urine sample; the sample had been collected from each subject prior to administration of the dosage form. Semilog plots of cumulative percent drug remaining in the body *versus* time were made, the least-squares equation for each line was solved, and the $t'_{50\%}$ value was calculated.

RESULTS AND DISCUSSION

The effects of varying concentrations of stearic acid and starch, the controllable variables X_1 and X_2 , on the tablet response variables of hardness (y_1), *in vitro* $t_{50\%}$ release rate (y_2), friability (y_3), and volume (y_4), are presented in Table II. A two-factor analysis of variance (24) for homogeneity of variances disclosed that the *in vitro* $t_{50\%}$ release rate (y_2) and friability (y_3) data appearing in Table II were not homoscedastic at the 99% confidence level. A transformation was found which, when applied to the $t_{50\%}$ and friability data, resulted in statistically equal variances at the nine different experimental conditions. An arithmetic plot was prepared showing the combination of standard deviation and mean value for each experimental condition of the *in vitro* release rate and of the friability. In both cases the standard deviations were found to be proportional to the mean values, as indicated in the least-squares proportions of Eqs. 9 and 10, with correlations of fit exceeding 0.99:

$$S_{y_2} = (0.7356 \times 10^{-1})\bar{y}_2 \quad (\text{Eq. 9})$$

$$S_{y_3} = (0.8274)\bar{y}_3 \quad (\text{Eq. 10})$$

^a The y_1 is tablet hardness in Pfizer kilogram units. ^b The y_2 is *in vitro* release rate as measured by time in minutes for 50% of the drug to be in solution ($t_{50\%}$). ^c The y_3 is tablet friability as measured by percentage weight loss. ^d The y_4 is tablet volume in cubic inches.

Brownlee (25) has shown that when $S_y = k\bar{y}$, the natural logarithmic transformation stabilizes the variances. This transformation was applied to the release rate and friability data; the results appear in Table III. Three units were added to each transformation of friability datum to eliminate negative logarithmic values. The test for homogeneity of variances was then applied to the transformed data, and the existence of homoscedasticity could not be rejected at the 99% confidence level.

Regression Models—In stepwise regression, there are two basic versions: forward and backward (26). In this study, a backward stepwise regression analysis program¹² was utilized to generate polynomial models relating the response variables to the controllable variables. The results of the regression analysis appear in Table IV. Although the multiple-correlation coefficients for the regression models were high (Table IV), the predictive power of each model required further evaluation. A valid means of extending the polynomial evaluation is to select experimental conditions or treatments not included in the original set of experimental conditions and to compute both the predicted response and its associated confidence interval. The result of a new experiment can then be compared with the prediction to determine if the new experimental result is con-

tained within the confidence interval. Four new experimental conditions were tested, and these formulations corresponded to the possible combinations of $X_1 = 15$ and 35% and $X_2 = 11$ and 31%. The predictions from the polynomial models were determined, and the 95% confidence intervals about a single prediction were computed. Construction of confidence intervals associated with multiple regression can be found in Chew (20). Next these formulations were prepared and the responses in question experimentally determined. Results of these analyses are given in Table V. The experimental response values all fell within the 95% confidence interval about a single prediction (Table V), with one exception. Thus, acceptance of the regression models in Table IV for predictive purposes in this study appears to be reasonable.

Contour Graphs—Contour graphs illustrate combinations of the controllable variables producing the same response. For each pre-designated response of y_j , X_2 was solved at values of $X_1 = 2, 4, 6, \dots, 40$. A computer program for this purpose for use on the IBM 7090 was written, and contours were set by interpolation from the X_1 and X_2 values obtained in the program output. The generated contour graphs are presented in Figs. 2–5. Contour graphs not only give various combinations of the controllable variables which produce the same response, but they also provide other interesting and useful information. For example, from the contour graph for tablet hardness (Fig. 2), it can be seen that to maintain a tablet hardness of 6.0 kg., the ratio of starch to stearic acid must be about 2:1; for a tablet hardness of 12.0 kg., the ratio needs to be about 1:2. For the sake of illustration, assume that the requirements on the final tablet are that hardness be 8–10 kg. and *in vitro* $t_{50\%}$ be 20–33 min. The solution to this problem is readily

Figure 2—Contour curves for tablet hardness (kilogram), illustrating levels of starch and stearic acid producing similar responses.

¹² This regression analysis program was developed for use on the IBM 7090 by M. Dale Fimpic of the Sandia Corp.

^a These analyses were performed on a polynomial of the form $y_i = B_{i0} + B_{i1}X_1 + B_{i2}X_2 + B_{i3}X_1^2 + B_{i4}X_2^2 + B_{i5}X_1X_2 + B_{i6}X_1X_2^2 + B_{i7}X_1^2X_2 + B_{i8}X_1^2X_2^2$, where $i = 1, 2, 3$, and 4. ^b Since the logarithmic transformation was applied to *in vitro* $t_{50\%}$ and tablet friability data to stabilize the variances, trend and regression analyses were performed on the transformed data.

available by superimposing the contour graphs for tablet hardness and *in vitro* $t_{50\%}$ on each other. Figure 6 illustrates the desired solution space (shaded portion of graph). Figure 6 points out the fact that there are many combinations of X_1 and X_2 producing responses which meet these restrictions on tablet hardness and *in vitro* release rate. When this is the case, the final selection of levels of X_1 and X_2 can be based on some other criterion such as cost. The reader interested in the different types of contour graphs and their physical interpretation is referred to Box (27).

Constrained Optimization—Since a reasonably rapid release rate of drug is generally an important objective in the design of solid dosage forms, optimization of this parameter was employed in studying the applicability of constrained optimization to a pharmaceutical product design problem. The problem was thus to locate levels of stearic acid (X_1) and starch (X_2) that minimized the *in vitro* release rate, such that the average tablet volume did not exceed 0.442 cm.³ (0.0270 in.³) and the average friability value did not exceed 2.72%. Expressed mathematically, this constrained optimization problem was to minimize

$$y_2 = f_2(X_1, X_2) \quad (\text{Eq. 11})$$

such that the following constraints were not violated:

$$5 \leq X_1 \leq 45 \quad (\text{Eqs. 12-13})$$

$$1 \leq X_2 \leq 41 \quad (\text{Eqs. 14-15})$$

$$y_3 = f_3(X_1, X_2) \leq 2.72 \quad (\text{Eq. 16})$$

$$y_4 = f_4(X_1, X_2) \leq 0.0270 \quad (\text{Eq. 17})$$

Equations 12-15 serve as constraints to keep the X_1 and X_2 values in the known experimental region.

Figure 7 represents a graphical analysis of the constrained optimization problem defined by Eqs. 11-17. The shaded portion of the graph defines the region of feasible solutions where none of the constraints is violated. Any pair of X_1 and X_2 values within the shaded region meets the friability and volume constraints as well as the minimum starch percentage (Eqs. 14, 16, and 17), without consideration of such nonbinding constraints as those of Eqs. 12, 13, and 15. The dashed contour lines of Fig. 7 represent *in vitro* $t_{50\%}$ responses of 12, 20, and 33 min. Since this family of contour lines is decreasing in the direction of Point A, it is also evident that the minimum starch percentage of Eq. 14 will not be binding in a minimization problem. By eliminating obviously nonbinding inequality constraints, the optimization problem of Eqs. 11-17 reduces to the following: minimize

$$\ln y_2 = B_{20} + B_{21}X_1 + B_{22}X_2 + B_{23}X_1X_2 + B_{24}X_1^2X_2 + B_{25}X_1^2X_2^2 \quad (\text{Eq. 18})$$

such that

$$B_{30} + B_{32}X_2 + B_{33}X_1^2 + B_{35}X_1X_2 + B_{36}X_1X_2^2 + B_{37}X_1^2X_2 + B_{38}X_1^2X_2^2 + q_1^2 - (\ln 2.72 + 3.0) = 0 \quad (\text{Eq. 19})$$

$$B_{40} + B_{41}X_1 + B_{42}X_2 + B_{43}X_1^2 + B_{45}X_1X_2 + B_{46}X_1X_2^2 + B_{48}X_1^2X_2^2 + q_2^2 - (0.0270 \times 10^2) = 0 \quad (\text{Eq. 20})$$

Table V—Verification of Generated Polynomial Models

35.0	31.0		0.0283	0.0281 — 0.0286	0.0284

^a This value fell slightly outside the 95% confidence range for a single prediction.

Figure 3—Contour curves for *in vitro* $t_{50\%}$ (minute), illustrating levels of starch and stearic acid producing similar responses.

In Eqs. 18–20, the regression models developed earlier (Table IV) have been substituted into Eqs. 11, 16, and 17. The slack variables q_1 and q_2 have been included in Eqs. 19 and 20 in order that these constraints may be written as equality constraints. The formulated Lagrange function is then

$$F = B_{20} + B_{21}X_1 + B_{22}X_2 + B_{25}X_1X_2 + B_{26}X_1X_2^2 + B_{28}X_1^2X_2^2 + \lambda_1(B_{30} + B_{32}X_2 + B_{33}X_1^2 + B_{35}X_1X_2 + B_{36}X_1X_2^2 + B_{37}X_1^2X_2 + B_{38}X_1^2X_2^2 + q_1^2 - 4.000) + \lambda_2(B_{40} + B_{41}X_1 + B_{42}X_2 + B_{43}X_1^2 + B_{45}X_1X_2 + B_{46}X_1X_2^2 + B_{48}X_1^2X_2^2 + q_2^2 - 2.70) \quad (\text{Eq. 21})$$

where λ_1 and λ_2 are terms known as Lagrange multipliers. As can be seen from Eq. 21, one is introduced for each constraint.

The original constrained optimization problem involving three equations has now been converted into an unconstrained minimax problem involving one equation. The minimax solution of Eq. 21 defines values of X_1 and X_2 which minimize the *in vitro* $t_{50\%}$ value subject to the constraints on tablet friability and volume. When this Lagrange function is partially differentiated with respect to each variable, each differentiation is set equal to zero, and the set of six equations is solved simultaneously, the values of each variable are

$$\begin{aligned} X_1^* &= 22.5\% & \lambda_1 &= 0.50 & q_1 &= 0.0 \\ X_2^* &= 26.8\% & \lambda_2 &= 2.90 & q_2 &= 0.0 \end{aligned}$$

By substituting these values of X_1 and X_2 into Eq. 18, $t_{50\%}^* = 17.9$ min., which is the best release rate that can be achieved under the restrictions involved. Since $q_1 = q_2 = 0.0$, both previously described constraints are binding as indicated by Fig. 7, where it is evident that the contour line for $t_{50\%}^* = 17.9$ min. would pass

Figure 4—Contour curves for tablet friability (percent weight loss), illustrating levels of starch and stearic acid producing similar responses.

Figure 5—Contour curves for tablet volume (cubic inch), illustrating levels of starch and stearic acid producing similar responses.

through Point A, where the contour lines for $y_3 = 2.72\%$ and $y_4 = 0.442 \text{ cm.}^3$ (0.0270 in.³) cross.

Sensitivity Analysis—The solution to a constrained optimization problem may depend heavily upon the restricting values assigned to the secondary objectives or constraints. Consequently, minor modifications in these restricting values may result in a substantial improvement in the primary objective. Sensitivity analysis serves to identify the changes in the primary objective resulting from such modifications of the restricting values. Sensitivity analysis involves solving the constrained optimization problem for systematic changes of the restricting values assigned to the secondary objectives. Mathematically, the problem is to minimize $\ln y_2$, such that

$$\ln y_3 + 3.0 \leq \ln \alpha_k + 3.0 \quad (\text{Eq. 22})$$

$$5 \leq X_1 \leq 45, \text{ and } 1 \leq X_2 \leq 41 \quad (\text{Eqs. 23–24})$$

The restraining values of percent friability (α_k) were allowed to assume the following values: 0.3, 0.4, 0.5, 0.6, 1.0, 2.0, 3.0, 4.0, 5.0, 6.0, 7.0, and 8.0. These results are shown in Fig. 8, and they demonstrate that substantial improvements in $t_{50\%}^*$ can be obtained for values of α_k up to about 1–2%. Beyond 2%, the rate of decrease of $t_{50\%}^*$ is very low. Consequently, the scientist designing the drug product can evaluate the potential gains in the primary objective which accrue from modifications of restraining values on secondary objectives. An objective decision on whether or not restraining values on secondary objectives should be relaxed (or tightened), and by how much, is thus made possible. Also, the locus of X_1^* and X_2^* points may be shown as a function of α_k , as demonstrated by Fig. 9, so that any decision on the revision of α_k can immediately provide a revised solution in terms of the tablet formulation.

Frequently, it is useful to consider the sensitivity of multiple constraints which requires a Lagrangian solution for each different combination of restricting values. For example, if the friability restriction was retained as α_k and a tablet volume constraint of

Figure 6—Feasible solution space defined by hypothetical restrictions on tablet hardness and *in vitro* $t_{50\%}$ release rate. Key: ---, hardness contours (kilogram); and —, *in vitro* $t_{50\%}$ contours (minute).

Figure 7—Graphical analysis of constrained optimization problem defined by Eqs. 26–32. Key: O, *in vitro* $t_{50\%}$ (minute); ◇, volume (cubic in.); ○, hardness (kilogram); and Δ, percent starch.

β_k' was added, then each α_k, β_k' combination requires a new solution that provides $t_{50\%}^*$, X_1^* , and X_2^* values. The results for nine combinations of α_k and β_k' for this example are shown in Table VI. An examination of the X_1^* and X_2^* values indicates that none of the experimental condition constraints was binding. Figure 10 provides a graphic illustration of $t_{50\%}^*$ as a function of α_k and β_k' . Figure 10 demonstrates that a sizable improvement in $t_{50\%}^*$ can be achieved by relaxing α_k and β_k' values, but the rate of improvement drops off sharply past the midvalue of $\alpha_k = 2.70$ and $\beta_k' = 0.0270$.

Constrained Optimization and *In Vivo* Studies—Clinical trials performed on a new drug in its various dosage forms or dosage form modifications may result in information on the relationship between blood levels, level of therapeutic action, duration of action, toxicity properties, and the absorption rate or possibly the consequent elimination rate of the drug. Establishment of such relationships could lead to criteria being established on the absorption rate or consequent elimination rate in order that the best therapeutic response and/or duration of effect and minimal toxicity be achieved. The results of urinary elimination-rate studies performed on certain formulas used in this investigation are presented in Table VII. The time in hours for 50% of the drug to be eliminated ($t'_{50\%}$) was used as a measure of the urinary elimination rate of the drug as modified by the availability from the respective formulation. The linear correlation coefficients for the semilog plots of drug retention *versus* time all exceeded 0.98, indicating that the excretion of phenylpropanolamine hydrochloride followed an apparent first-order process. A comparison of the mean *in vitro* ($t_{50\%}$) and *in vivo* ($t'_{50\%}$) data showed that the rank order of the formulations was the same for each criterion. Further analysis revealed that the logarithm of the mean *in vivo* $t'_{50\%}$ data correlated very highly ($r = 0.993$) with the mean *in vitro* $t_{50\%}$ data on a linear scale. Figure 11 depicts this plot and illustrates the correlation. The confidence bands about the $t'_{50\%}$ values represent 95% confidence intervals. It would appear that prediction of the *in vivo* $t'_{50\%}$ response from a knowledge of the *in vitro* $t_{50\%}$ response can be made fairly accurately for the tablet system used in this study, employing the correlation curve appearing in Fig. 11.

To illustrate the utility of the constrained optimization approach as applied to *in vivo* data, a sample constrained optimization problem was formulated and solved using the Lagrangian method.

Figure 8—Optimum *in vitro* $t_{50\%}$ release rate as a function of restrictions on tablet friability.

Figure 9—Optimizing values of stearic acid and starch as a function of restrictions on tablet friability. Key: A, percent starch; and B, percent stearic acid.

The following situation was assumed to exist in this illustrative example:

1. The primary objective was to minimize tablet friability or its equivalent ($\ln y_3 + 3$).

2. Secondary objectives were to maintain a reproducible fill in the packaging container and to avoid noticeable differences in tablet size so that the tablet volume (y_4) is held within the interval 0.0261–0.0269.

3. Another secondary objective was to keep the *in vivo* elimination half-life below 6.5 hr. for the desired therapeutic effect of this drug.

In constrained optimization form, the problem may be mathematically stated as: minimize

$$(\ln y_3 + 3.0) = f_3(X_1, X_2) \quad (\text{Eq. 25})$$

such that

$$2.61 \leq y_4 \times 10^2 \leq 2.69, \text{ and} \quad (\text{Eqs. 26–27})$$

$$0.69937 + (0.1908 \times 10^{-2})(e^{\ln y_2}) \leq \log 6.5 \quad (\text{Eq. 28})$$

In Eq. 28, the left-hand side of the equation represents the least-squares estimate of the curve appearing in Fig. 11, and $\ln y_2$ as a function of X_1 and X_2 can be found in Table IV.

Employing the Lagrangian method, the solution to the constrained optimization problem (Eqs. 25–28) was found to be as follows: $X_1^* = 34.1\%$, $X_2^* = 13.3\%$, and $y_3^* = 0.64\%$ wt. loss. The volume constraint of Eq. 26 was nonbinding, and the other two constraints (Eqs. 27–28) were binding. To demonstrate further the validity of this approach to tablet design, a formulation was prepared using the optimal percentages of stearic acid and starch (34.1 and 13.3%, respectively) and the empirical test results were

Table VI—Optimizing Percentages of Stearic Acid and Starch and the Corresponding Optimal *In Vitro* Release Rate as a Function of Simultaneous Restraining Values on Tablet Friability and Volume

compared with the theoretical values predicted. These results appear in Table VIII, and the *in vivo* urinary elimination rate curves appear in Fig. 12. The mean tablet volume of 0.442 cm.³ (0.0270 in.³) and the mean $t'_{50\%}$ excretion of 6.4 hr. were very close to the theoretical predictions of 0.0269 and 6.5, respectively. By optimizing the tablet friability, a cohesive tablet was formed, with an average friability weight loss of about 0.58%, which is sufficiently close to the theoretical prediction of 0.64%.

Pharmaceutical Process Optimization—Reier *et al.* (4) have recently quantified the weight and weight variation of filled capsules with controllable process variables. They found the significant set

0.444 (0.0271)	0.55	6.3
Mean: 0.442 (0.0270)	0.58	6.4

of controllable variables to be: (a) machine speed, r.p.m. (X_1); (b) capsule size, cm.³ (X_2); (c) specific volume, ml./g. (X_3); (d) flowability, in.² (X_4); and (e) presence or absence of talc (X_5). Regression models relating these controllable variables with mean gross capsule weight (y_1), capsule weight standard deviation (y_2), and capsule weight coefficient of variation (y_3) were given. These regression models can be employed to formulate an unconstrained optimization problem for determining levels of machine speed (X_1), specific volume (X_3), and flowability (X_4), which minimize the capsule weight coefficient of variation (y_3). Assuming that talc is present in the formulation, the model for y_3 , using the data of Reier *et al.* (4), becomes

$$y_3 = 4.15 + 0.04X_1^2 + 0.23X_3^2 - 1.86X_4 + 0.45X_4^2 - 0.15X_1X_3 - 0.11X_1X_4 \quad (\text{Eq. 29})$$

Taking the first partial derivatives of Eq. 29 with respect to X_1 , X_3 , and X_4 , setting these expressions equal to zero, and solving this set of three simultaneous linear equations produced the following: $X_1^* = 13.3$ r.p.m., $X_3^* = 4.34$ ml./g., and $X_4^* = 3.75$ in.² At this global minimum, $y_3^* = 0.78\%$. However, the values for X_1^* and X_3^* far exceed values used by the authors in deriving Eq. 29 and may, therefore, not be valid. An interesting point is, however, that this information would suggest using a light, free-flowing powder and a high machine speed to minimize capsule weight variation. Since the maximum machine speed used by Reier *et al.* (4) was 8.7 r.p.m., the optimization problem may be reformulated using this maximum machine speed as fixed, or:

$$y_3 = 7.18 - 1.31X_3 - 2.82X_4 + 0.23X_3^2 + 0.45X_4^2 \quad (\text{Eq. 30})$$

The solution to Eq. 30 is a global minimum at $X_3^* = 2.85$ ml./g. and $X_4^* = 3.13$ in.², with the criterion of $y_3^* = 0.90\%$ at this minimum. Insofar as these regression models hold for various possible formulations, which appear to be reasonably general, the values $X_1^* = 8.7$, $X_3^* = 2.85$, and $X_4^* = 3.13$ for the controllable variables minimize the capsule weight coefficient of variation. If y_3 is independent of capsule size, which appears valid for at least moderate variations, then the solution to this optimization problem holds for various capsule sizes.

However, it may not always be practical to utilize these optimum operating conditions. Often the bulk formulation, capsule size, and weight are specified in advance. As an example, assume the following information has been prespecified: (a) capsule size = No. 0, or $X_2 = 0.699$; (b) capsule weight = 400 mg., or $y_1 = 400$; (c) specific volume of powder = 2.80 ml./g., or $X_3 = 2.80$; and (d) talc is present, or $X_5 = +1$. The objective is to locate levels of machine speed (X_1) and flowability (X_4) which minimize the capsule weight

Figure 11—Correlation of *in vivo* and *in vitro* release rate data.

Figure 12—Urinary excretion data from five humans for the optimal tablet formulation of 34.1% stearic acid and 13.3% starch. Key: O, Subject 1; Δ , Subject 2; \square , Subject 3; \bullet , Subject 4; and \blacktriangle , Subject 5.

coefficient of variation. This represents a constrained optimization problem which may be formulated as follows: minimize

$$y_3 = 6.09 - 1.86X_4 + 0.04X_1^2 - 0.45X_4^2 - 0.42X_1 - 0.11X_1X_4 \quad (\text{Eq. 31})$$

such that

$$548.49 - 32.27X_1 - 11.20X_2 + 1.92X_1^2 = 400 \quad (\text{Eq. 32})$$

The Lagrangian expression then becomes

$$F = 6.09 - 1.86X_4 + 0.04X_1^2 + 0.45X_4^2 - 0.42X_1 - 0.11X_1X_4 + \lambda(148.49 - 32.27X_1 - 11.20X_2 + 1.92X_1^2) \quad (\text{Eq. 33})$$

By partially differentiating Eq. 33 and solving this set of nonlinear equations, it was found that $X_1^* = 5.63$ r.p.m., $X_4^* = 2.47$ in.², and $y_3^* = 1.62$. Thus, for a 400-mg. No. 0 capsule, whose contents have a specific volume of 2.8 ml./g., the minimum coefficient of variation possible is 1.62, and this is achieved at a machine speed setting of 5.63 r.p.m. and a flowability value of 2.47 in.²

SUMMARY

The use of constrained optimization techniques, employing the Lagrangian method, has been successfully applied to complex pharmaceutical product and process design problems involving many competing objectives. Location of optimal solutions to pharmaceutical design problems by this analytical-mathematical approach has been demonstrated. In most situations the location of the theoretical optimal solution point can provide the starting reference for adjustments due to other practical considerations, thereby permitting more rapid and accurate solution of the design problem. The steps involved in solving a design problem *via* the constrained optimization approach may be summarized as follows:

Identify important response variables y_j , $j = 1, 2, \dots, r$, the significant set of controllable variables X_i , $i = 1, 2, \dots, n$, and measures on both classes of variables.

Determine a mathematical relationship between each y_j as a function of X_i , either analytically or empirically.

Select the response variable which is of greatest importance as the principal objective to be optimized and place control limits on the remaining response variables.

Solve the resultant constrained optimization problem by one of the several existing techniques.

In addition to finding optimal solutions to constrained pharmaceutical problems, the application of sensitivity analysis studies to such problems was also illustrated. The rate of change of the optimal response in the principal objective to changes of restrictions on the competing or lesser important objectives was analyzed for a product design problem.

The mathematical and statistical techniques described in this paper are suggested as an improvement over the trial-and-error approach widely employed today in pharmaceutical product and process design. Improved reliability of the research effort and a saving in time and money are the direct results of this sophisticated approach to pharmaceutical research problems.

APPENDIX A

Example 1—Locate the levels of X_1 and X_2 which maximize

$$y = X_1X_2 \quad (\text{Eq. A-1})$$

such that

$$X_1 + X_2 = 4 \quad (\text{Eq. A-2})$$

Since the constraint in Eq. A-2 is already in the form of an equality constraint, the Lagrangian function can be formed immediately:

$$F = X_1X_2 + \lambda(X_1 + X_2 - 4) \quad (\text{Eq. A-3})$$

Taking the first partial derivatives of the Lagrangian function (Eq. A-3) and setting the resulting equations equal to zero,

$$\partial F / \partial X_1 = X_2 + \lambda = 0 \quad (\text{Eq. A-4})$$

$$\partial F / \partial X_2 = X_1 + \lambda = 0 \quad (\text{Eq. A-5})$$

$$\partial F / \partial \lambda = X_1 + X_2 - 4 = 0 \quad (\text{Eq. A-6})$$

Solving these three equations simultaneously, $X_1^* = 2$, $X_2^* = 2$, and $\lambda = -2$. Substituting these values of X_1 and X_2 back into the objective function (Eq. A-1), it was found that $y^* = 4$. Thus, the maximum response in y that can be obtained subject to the constraint of $X_1 + X_2 = 4$ is 4 units. This constrained optimization problem is represented graphically in Fig. A-1. Contour curves for objective function responses of 2, 4, and 6 units are shown. The dashed, straight line in Fig. A-1 represents the constraint (Eq. A-2), and Point A depicts the optimal solution point ($X_1^* = 2$, $X_2^* = 2$).

Example 2—Locate the levels of X_1 and X_2 which minimize

$$y = X_1^2 + X_2^2 \quad (\text{Eq. A-7})$$

such that

$$X_1 + X_2 \geq 4 \quad (\text{Eq. A-8})$$

Figure A-1—Graphical solution for constrained optimization problem of Eqs. A-1 and A-2. Key: ---, contour line for $X_1 + X_2 = 4$.

Figure A-2—Graphical solution for constrained optimization problem of Eqs. A-7 and A-8. Key: ----, contour line for $X_1 + X_2 = 4$.

The inequality constraint of Eq. A-8 must first be converted to an equality constraint by introducing a slack variable, q . Thus, Eq. A-8 may be written as

$$X_1 + X_2 - q^2 = 4 \quad (\text{Eq. A-9})$$

and the Lagrangian function becomes

$$F = X_1^2 + X_2^2 + \lambda(X_1 + X_2 - q^2 - 4) \quad (\text{Eq. A-10})$$

Taking the first partial derivatives of Eq. A-10 and setting these expressions equal to zero,

$$\partial F / \partial X_1 = 2X_1 + \lambda = 0 \quad (\text{Eq. A-11})$$

$$\partial F / \partial X_2 = 2X_2 + \lambda = 0 \quad (\text{Eq. A-12})$$

$$\partial F / \partial \lambda = X_1 + X_2 - q^2 - 4 = 0 \quad (\text{Eq. A-13})$$

$$\partial F / \partial q = -2\lambda q = 0 \quad (\text{Eq. A-14})$$

Solving these four equations simultaneously, $X_1^* = 2$, $X_2^* = 2$, $q = 0$, and $\lambda = -4$. At this optimal solution point, $y^* = 8$ units. This constrained optimization problem is represented graphically in Fig. A-2. Point A in Fig. A-2 illustrates the minimum response in y that can be achieved under the restriction that $X_1 + X_2 \geq 4$. At the simultaneous solution point for Eqs. A-11–A-14, it is noted that $q = 0$. Thus, at the optimal solution point, $X_1 + X_2 = 4$.

Effect of Structural Similarity on Molecular Interaction in Aqueous Solution: Interaction of Phenazine and Tetramethylpyrimido-pteridinetetrone with Alkylxanthines and Benzene Derivatives

KIICHIRO KAKEMI, HITOSHI SEZAKI, TAKAYOSHI MITSUNAGA, and MASAHIRO NAKANO*

Abstract □ The molecular interactions in water of phenazine and tetramethylpyrimidopteridinetetrone (TMPPT) with alkylxanthines and benzene derivatives were studied by means of the phase solubility technique. Alkylxanthines showed a greater affinity toward phenazine than toward TMPPT. Benzene derivatives, on the other hand, formed more stable complexes with TMPPT than with phenazine. These results are discussed in terms of structural similarity between interacting species. Studies concerning the effects of solvent on the extent of complex formation have revealed that water plays a unique role in these interactions. The observation that complexation between two structurally dissimilar compounds is favored over that between two similar compounds suggested that some forces other than mere hydrophobic bonding should be taken into consideration. It is postulated that the results are best rationalized by hydrophobic bonding stabilized by a type of bonding similar to polarization bonding.

Keyphrases □ Molecular interaction, aqueous solutions—structural similarity effect □ Phenazine—alkylxanthines, benzene derivatives—interaction □ Tetramethylpyrimidopteridinetetrone—alkylxanthines, benzene derivatives—interaction □ Phase solubility—molecular interactions □ UV spectrophotometry—analysis

While molecular interaction in nonpolar solvents can best be understood on the basis of hydrogen bonding or charge transfer complexation, a mechanism of molecular interaction in aqueous solution still remains largely unsolved. Earlier workers initially believed that hydrogen bonding was responsible for complexation in aqueous solution. Considerable evidence has since been accumulated to dispute this interpretation (1). The application of the charge transfer complexation theory in nonpolar solvents (2) to aqueous solutions is not in accord with present knowledge of interactions in aqueous solution. Such an interaction has been shown to be quite weak or nonexistent in an aqueous environment (3), since a typical charge transfer band is not usually observed in water (3). It is thought that thermal electron transfer leading to the formation of radicals or reactions may be responsible for the appearance of such a band in some cases.

The more or less nonpolar molecules in water tend to come together, reducing the number of water-solute contacts. This phenomenon is known as hydrophobic bonding. Solvophobic bonding refers to a similar phenomenon in any solvent. The source of stability of a complex in aqueous solution has been attributed either to a favorable enthalpy term [large surface energy of water (4, 5)] or to a favorable entropy term [increased ordering of water around the hydrophobic group in a solute molecule (6, 7)]. The "squeezing-out" effect proposed by Higuchi and Lach as early as 1954 (8) is essentially the same as the theory by Sinanoğlu and Abdunur (4, 5). Studies on the effect of solvents on the extent of complexation (9–11) generally support the hydrophobic bonding theory. Complexes stabilized

in aqueous solution tend to dissociate in less polar and nonpolar solvents, except when solute molecules associate by hydrogen bonding or charge transfer interaction (12).

From a considerable amount of work concerning complex formation in aqueous solution, Higuchi (13) concluded that hydrophobic bonding alone cannot be responsible for interaction in aqueous solution. He suggested that interacting molecules may be divided into groups or classes such that compounds which belong to the same class do not interact very strongly with each other while those belonging to different classes bind strongly.

In pursuit of the elucidation of the mechanism of molecular interaction in water the present study was undertaken by selecting two model compounds, phenazine and tetramethylpyrimidopteridinetetrone (TMPPT) so that the extent of interaction can be monitored by the increase in their solubility in the presence of

phenazine

TMPPT

complexing agents. The choice of phenazine and TMPPT is based on simplicity in their spectrophotometric assay and on the polarizable nature of the former in contrast to the polar nature of the latter. The present results demonstrate that there is some discrimination in molecular interaction even in aqueous media, the extent of interaction being greater between polar and polarizable compounds than that between two polar compounds or two polarizable molecules. The results are further interpreted in terms of additional stabilization of complexes by polarization bonding (14) in the presence of hydrophobic bonding contribution due to water as solvent.

EXPERIMENTAL

Materials—Phenazine (Aldrich) was recrystallized from methanol-water, m.p. 171°. 1,3,7,9-Tetramethylpyrimido(5,4-g)pteridine-2,4,6,8(1*H*,3*H*,7*H*,9*H*)-tetrone (abbreviated as TMPPT; Alfred Bader Chemicals, Aldrich) was used without further purification since its NMR spectrum indicated no impurity; m.p. >340°. With the exception of *N*-substituted amides (15), complexing agents were obtained from commercial sources and purified whenever necessary. Water was purified by distillation. Organic solvents employed were of spectroscopic grade.

Methods—Phenazine (or TMPPT) in excess of the solubility was added to vials containing aqueous solutions (5 ml.) of varying concentrations of the complexing agent. Complexing agent concentrations were obtained by dilution of a stock solution. The vials were

Figure 1—Solubility diagrams of phenazine in the presence of 8-methoxycaffeine (□), theophylline (●), *N,N*-dimethylcinnamamide (○), and sodium salicylate (Δ) in water at 25°.

closed and shaken in a constant-temperature water bath at 25° for about 40 hr. The equilibrated contents of the vials were quickly filtered through sintered-glass funnels (medium porosity) under reduced pressure. Samples (2 ml.) were then diluted with water and the total concentration of phenazine (or TMPPT) solubilized was measured spectrophotometrically at 366 mμ (or at 360 mμ for TMPPT) employing a spectrophotometer (Shimadzu QV-50). The observed solubility of phenazine (or TMPPT) was plotted against the concentration of complexing agent added. Stability constants were calculated from the solubility diagrams according to the following manner.

1:1 Complex—Where a straight line was obtained in the plot, the formation of a 1:1 complex was assumed and the stability constant was calculated from Eq. 1 (16);

$$K_{1:1} = \frac{\text{slope}}{\text{intercept}(1 - \text{slope})} \quad (\text{Eq. 1})$$

1:1 and 1:2 Complexes—Where an upward curve was obtained in the plot, the formation of both 1:1 and 1:2 complexes given by

Figure 2—Solubility diagrams of TMPPT in the presence of *N,N*-dimethylcinnamamide (○), sodium salicylate (Δ), 8-methoxycaffeine (□), and theophylline (●) in water at 25°.

Eqs. 2 and 3 was assumed and the stability constants defined by Eqs. 4 and 5 were computed.

$$K_{1:1} = \frac{C_{AB}}{C_A^\circ(C_B - C_{AB} - 2C_{AB_2})} \quad (\text{Eq. 4})$$

$$K_{1:2} = \frac{C_{AB_2}}{C_{AB}(C_B - C_{AB} - 2C_{AB_2})} \quad (\text{Eq. 5})$$

where C_A° , C_B , C_{AB} , and C_{AB_2} are the solubility of *A* in the absence of *B*, the total concentration of *B*, the equilibrium concentration of *AB*, and that of *AB*₂, respectively. From the material balance, the apparent solubility of *A*, C_A , is given by

$$C_A = C_A^\circ + C_{AB} + C_{AB_2} \quad (\text{Eq. 6})$$

From Eqs. 4-6 the following equation was obtained (17):

$$\frac{C_A - C_A^\circ}{C_A^\circ(C_B - C_{AB} - 2C_{AB_2})} = K_{1:1} + K_{1:1}K_{1:2}(C_B - C_{AB} - 2C_{AB_2}) \quad (\text{Eq. 7})$$

Since C_{AB} and C_{AB_2} were not known experimentally, they had to be calculated by an iteration (17). The initial values for $K_{1:1}$ and $K_{1:2}$ were obtained from Eq. 7 by ignoring the C_{AB} and C_{AB_2} terms. The first approximate values for C_{AB} and C_{AB_2} were obtained from Eqs. 4 and 5, i.e.,

$$C_{AB} = K_{1:1}C_A^\circ C_B \quad (\text{Eq. 8})$$

$$C_{AB_2} = K_{1:1}K_{1:2}C_A^\circ C_B^2 \quad (\text{Eq. 9})$$

The C_{AB} and C_{AB_2} values were then put into Eq. 7 to obtain better values for $K_{1:1}$ and $K_{1:1}K_{1:2}$. These steps were repeated until a convergent straight line was obtained.

RESULTS

The solubility diagrams of phenazine in the presence of theophylline, 8-methoxycaffeine, *N,N*-dimethylcinnamamide, and sodium salicylate are shown in Fig. 1. The solubility diagrams for the TMPPT systems are shown in Fig. 2.

Similar solubility measurements were carried out for both phenazine and TMPPT in the presence of 1,3-dimethyluracil, β-hydroxyethylphthalimide, cinnamamide, sodium benzoate, sodium cinnamate, benzoic acid, phenol, benzamide, anisamide, and *N*-methylbenzamide. The solubility diagram of phenazine in the presence of caffeine is shown in Fig. 3, while that of TMPPT is presented in Fig. 4.

A downward trend in the solubility diagram of the TMPPT-caffeine system is apparent in Fig. 4. Guttman (18) earlier found that the solubility diagram for the interaction of riboflavin with caffeine was similarly convex. He has explained this tendency on the basis of the dimerization of caffeine (19). When the dimerization of caffeine was taken into consideration for the present system, a straight line was obtained giving $K_{1:1}$ of 19 M⁻¹. In this calculation, equilibria $2C \rightleftharpoons C_2$ and $T + C \rightleftharpoons TC$ were taken into consideration, while the contribution from $2T \rightleftharpoons T_2$ was neglected because of low concentrations of *T* present, where *C* = caffeine and *T* = TMPPT. A value of $K_d = 12.7 \text{ M}^{-1}$ (19) was used in the calculation. The upward curve in Fig. 3, on the other hand, clearly demonstrates the presence of higher order complexes as well as a 1:1 complex. Stability constants computed from such solubility data are presented in Table I for the complexes formed in each system. A typical example of the iterative procedure used, when applicable, for calculating $K_{1:1}$ and $K_{1:2}$ values is illustrated in Fig. 5 for the interaction of phenazine with 8-methoxycaffeine.

The effects of solvent on molecular interaction were examined for the interaction of TMPPT with *N,N*-dimethylcinnamamide. The results shown in Table II clearly indicate the important part played by water as a solvent. Studies with less polar solvents than those employed, such as carbon tetrachloride and cyclohexane, could not be made because of insolubility of TMPPT in such solvents.

Figure 3—Solubility diagram of phenazine in the presence of caffeine in water at 25°.

DISCUSSION

Results shown in Figs. 1–4 and Table I clearly indicate that cyclic amides (alkylxanthines, 1,3-dimethyluracil, and β -hydroxyethylphthalimide) interacted much more strongly with phenazine than with TMPPT, while benzene derivatives (with the exception of benzamides) interacted more strongly with TMPPT than with phenazine. Although benzamides appeared to complex with both phenazine and TMPPT to the same extent, the complexing behavior of other agents toward these model compounds unequivocally supports the view that compounds belonging to the same class (benzene derivatives and phenazine on the one hand and cyclic amide and TMPPT on the other) do not interact very strongly, while those belonging to different classes (cyclic amides and phenazine on the one hand and benzene derivatives and TMPPT on the other) interact strongly in aqueous solutions (13). Phenazine and benzene derivatives may be classified as polarizable since the charge distribution in phenazine and in the benzene ring of the benzene derivatives are expected to be more or less uniform, although the benzene derivatives have net dipole moment. Cyclic amides including TMPPT, on the other hand, are classified as polar because the charge distribution in 1,3-dimethyluracil, the six membered ring of the alkylxanthines, and the maleimide group of β -hydroxyethylphthalimide, are considered to be very much irregular (20). The observed complexing behavior between these compounds may be summarized as in Scheme I.

Scheme I

Though the interaction of TMPPT with phenazine cannot be determined experimentally because of the low solubility of these compounds, the interaction of cyclic amides with benzene derivatives has been reported to be appreciable (16). It should be pointed out

Table I—Stability Constants of Phenazine and TMPPT Complexes in Water at 25°

Complexing Agent	Phenazine		TMPPT	
	$K_{1:1}$ M^{-1}	$K_{1:2}$ M^{-1}	$K_{1:1}$ M^{-1}	$K_{1:2}$ M^{-1}
Theophylline	166	24	13	—
Caffeine	314	20	19	—
8-Methoxycaffeine	345	42	21	—
1,3-Dimethyluracil	23	—	2.3	—

Benzamide	11	—	13	—
Anisamide	34	—	31	—
<i>N</i> -Methylbenzamide	15	—	13	—

here that distinction between polar and polarizable molecules may become obscure when a compound carries both polar and polarizable groups.

The present studies concerning the effects of solvent on complex formation (Table II) have quantitatively demonstrated the specific role played by water as a solvent. Since both TMPPT and *N,N*-dimethylcinnamamide have no hydrogen capable of forming hydrogen bonds, the possibility of direct hydrogen bonding between the interactants can be ruled out. The results do not appear to support charge transfer as the major force responsible for the interaction since there seems little tendency for stabilization of the complex in less polar solvents (21).

A valid mechanism for this associative behavior of organic molecules in aqueous media should, therefore, take into account both the selective nature of interaction and the important role of water as the environment which facilitates such interactions. The following hypothesis is proposed in order to give a rationale to the present knowledge of interactions. Water seems to have a role of bringing solute molecules together (hydrophobic bonding). When two solute molecules are brought together, a bonding similar to polarization bonding may become operative and stabilizes the complex. The detailed reasoning on which the hypothesis is based follows.

If one of the direct interactive mechanisms such as hydrogen bonding, charge transfer complexation, or interactions due to orientation forces and induction forces were the primary forces which bind two solutes together, even larger stability constants in less polar solvents than in water would be expected. The authors' results (9) as well as others' (10, 11), however, showed that the extent of interaction is greatest in water, decreasing with increasing

Figure 4—Solubility diagram of TMPPT in the presence of caffeine in water at 25°.

Figure 5—Analysis of the solubility data for the interaction of phenazine (A) with 8-methoxycaffeine (B) in water at 25°. Key: O, first iteration; Δ, second iteration; and ●, third and further iterations.

percentage of polar organic solvents in water-organic solvent mixtures, and it is very small in pure organic solvents. The extent of interactions in various solvents was correlated with the surface free energy of the solvent (10, 22). Sinanoğlu and Abdunur attributed the main interactive force to the large enthalpy of water (4, 5). Observed results (Table I), however, cannot be rationalized merely by solvophobic bonding. If the bonding were merely due to the squeezing-out property of a solvent, it would not be expected to discriminate among polar and nonpolar molecules to such an extent as was observed since the solvophobic bonding is not affected very much by the nature (polar or nonpolar) of the molecule (5).

The present data cannot be explained by dispersion force alone. The dispersion interaction energy, E , is given by (23)

$$E = -\frac{3}{2r^6} \cdot \frac{I_1 I_2}{I_1 + I_2} \alpha_1 \alpha_2 \quad (\text{Eq. 10})$$

where α_i = polarizability of Molecule i , I_i = ionization potential of Molecule i , and r = intermolecular separation. Since the ionization potential varies but little for organic molecules (23), the dispersion energy is mainly affected by polarizability. Then a complexing agent with a large polarizability would bind with both phenazine and TMPPT strongly. This is not the case. Thus forces such as the dispersion force do not seem to be the sole source of stability of the complex in aqueous solution. It is important to note here that the present finding of favorable binding between structurally dissimilar molecules over that between structurally similar molecules is contrary to what is expected on the basis of

dispersion interaction (24). The theory provides for a self-recognition of a molecule by an identical molecule. If the dispersion force is responsible for the stability of the complex, the difference in energy, E , between the interaction of Molecule A with Molecule B, A-B, and self-interactions, A-A and B-B, as depicted by Arrangements 1 and 2:

is proportional to

$$\begin{aligned} & -(\alpha_A^2 + \alpha_B^2) - (-2\alpha_A\alpha_B) \\ & = -(\alpha_A - \alpha_B)^2 \leq 0 \end{aligned}$$

Then it would be concluded that Arrangement 1 is more energetically stable than Arrangement 2 (24). Again this has been found not to be the case.

Thus a bonding with some degree of selectivity between dissimilar molecules must be sought. Polarization bonding (14) describes weak interactions between polar groups of one component and a polarizable second component in crystalline state. This kind of bonding in a crystalline xanthine complex has recently been postulated by Shefter (25). He also pointed out that in order to propose molecular models for xanthine complexes of pharmaceutical interest, one should take into account polarization interactions. The exact nature of polarization bonding is not known, although it has been proposed that polycyclic hydrocarbon-tetramethyluric acid complexes in the crystalline state (26-28) are due to this bonding. The interactive force seems to be very weak and effective only when the polar and polarizable molecules are in close proximity as in the crystalline lattice. The bonding was not observable in non-polar solvents such as cyclohexane and benzene (29). It may be speculated, however, that molecular interactions similar to polarization bonding in crystalline complexes may become operative in water when two molecules are brought together by hydrophobic bonding. Polarization bonding, however, has to be distinguished from the classical induction interaction described by (23)

$$E = -\frac{\mu_1^2 \alpha_2 + \mu_2^2 \alpha_1}{\epsilon^2 r^6} \quad (\text{Eq. 11})$$

where μ_i = dipole moment of Molecule i and ϵ = effective value for the dielectric constant of the medium. The formula describes the energy of interaction when the size of a molecule is smaller than the intermolecular distance. Thus the formula is not applicable to the case when the size of the molecule is larger than the intermolecular distance as is the case of complexes of planar molecules in aqueous solution. The most favorable relative orientation of two flat molecules seems to be that of stacking one of the molecules on top of the other (30, 31). A new theoretical development which describes an induction interaction applicable to such a vertically stacked complex of large flat molecules seems to be essential in order to understand theoretically the observed results.

Current works in the authors' laboratories have revealed that cyclic amides employed in the present studies are salted-out by tetramethylammonium chloride while benzene derivatives are salted-in by the same salt (32). Again differences in nature of these molecules in aqueous solution seem to play a part.

Binding Specificity between Small Organic Solutes in Aqueous Solution: Classification of Some Solutes into Two Groups According to Binding Tendencies

TAKERU HIGUCHI* and HARALD KRISTIANSEN

Abstract □ Experimental data have been obtained which appear to show that the binding between organic species dissolved in water apparently takes place most effectively *between* members of two large, distinct classes of structures, classified arbitrarily as A and B types. Typical examples of Class A are the uncharged alkyl-xanthenes and tetramethylpyrimidopteridinetetrone. Among the compounds in Class B are various benzene derivatives, salicylates, and *trans*-cinnamic acid anions. Many drugs may be included in the present classification system; some examples for which data are available are caffeine, theophylline, and prednisolone in Class A, and phenacetin, promethazine, and menadione in Class B. The complexing tendencies of series of systems involving pairs of interacting organic molecules in aqueous solution were investigated by the phase-solubility technique. Stability constants for some caffeine interactions were evaluated by means of partitioning studies.

Keyphrases □ Organic solute binding specificity—aqueous solution □ Solutes, small organic—binding tendency classification □ Stability constants—solute binding □ Solubility—solute interaction effect □ Spectrophotometric analysis—organic solutes

Water strongly stabilizes a large number of molecular complexes, apart from its participation in hydrophobic bonding (1). Water provides a medium which seems to be unique for the molecular binding tendencies of organic molecules (2-10), many of them of great biological and pharmacological importance. In the last few years a number of papers have reported the properties of pyrimidines, purines, and the important nucleoside and nucleotide polymers in the aqueous environment. It has conclusively been shown, for example, that

the bases associate to varying degree in aqueous solution, evidently through plane-to-plane stacking (11-16). It is believed that molecular interactions between adjacent bases in nucleic acid strands to a major extent are responsible for the structural stability of nucleic acids in solution (17-19).

The exact nature of the force or balance of forces operating between the complex components in aqueous solution still is the subject of controversial discussions in the literature. The observed binding between organic molecules in water is, however, firmly believed to be strictly physical in nature. As pointed out earlier (1, 5, 6), the observed intensity of binding cannot be rationalized on the basis of simple charge-transfer-type interactions (the binding constants are extremely low in alcohol, dioxane, and purely nonpolar solvents), dispersion forces (little or no interactive tendency is evident among systems of low polarizability), hydrophobic associations (very small contributions from flexible alkyl side chains), or hydrogen bonding alone. The matter is, of course, complicated by the possible interplay of different interacting forces. The problem is obviously related to the structure of liquid water, which in itself is a very intricate one, and many safe conclusions have not been made so far (20-25).

In this article the authors present their most recent observations carried out on series of systems involving pairs of interacting molecules in aqueous solution. These results have strongly reinforced a growing belief

Stability constants for some caffeine interactions were evaluated by means of partitioning studies.

Keyphrases □ Organic solute binding specificity—aqueous solution □ Solutes, small organic—binding tendency classification □ Stability constants—solute binding □ Solubility—solute interaction effect □ Spectrophotometric analysis—organic solutes

Water strongly stabilizes a large number of molecular complexes, apart from its participation in hydrophobic bonding (1). Water provides a medium which seems to be unique for the molecular binding tendencies of organic molecules (2-10), many of them of great biological and pharmacological importance. In the last few years a number of papers have reported the properties of pyrimidines, purines, and the important nucleoside and nucleotide polymers in the aqueous environment. It has conclusively been shown, for example, that

the bases associate to varying degree in aqueous solution, evidently through plane-to-plane stacking (11-16). It is believed that molecular interactions between adjacent bases in nucleic acid strands to a major extent are responsible for the structural stability of nucleic acids in solution (17-19).

The exact nature of the force or balance of forces operating between the complex components in aqueous solution still is the subject of controversial discussions in the literature. The observed binding between organic molecules in water is, however, firmly believed to be strictly physical in nature. As pointed out earlier (1, 5, 6), the observed intensity of binding cannot be rationalized on the basis of simple charge-transfer-type interactions (the binding constants are extremely low in alcohol, dioxane, and purely nonpolar solvents), dispersion forces (little or no interactive tendency is evident among systems of low polarizability), hydrophobic associations (very small contributions from flexible alkyl side chains), or hydrogen bonding alone. The matter is, of course, complicated by the possible interplay of different interacting forces. The problem is obviously related to the structure of liquid water, which in itself is a very intricate one, and many safe conclusions have not been made so far (20-25).

In this article the authors present their most recent observations carried out on series of systems involving pairs of interacting molecules in aqueous solution. These results have strongly reinforced a growing belief

that the observed binding in water takes place most effectively *between* members of two large classes of structures. Typical examples of these two apparently natural classes, arbitrarily called Classes A and B, are:

Class A	Class B
Caffeine	Benzoates and salicylates
Theophylline	Cinnamates
Prednisolone	Cinnamamides
Tetramethylpyrimido- pteridinetetrone	Naphthoic acids
	Phenols and naphthols
	Aromatic aminoacids
	Phenacetin
	Menadione
	Tryptophan

Although members of Classes A and B bind noticeably with others within their own class, the strongest interactions seem to be between the two groups.

For the purpose of expressing the extent of interaction between the complexing pairs, in this report the authors have assumed that essentially only 1:1 and 1:2 complexes were formed. The experimental data have been analyzed to yield stability constants for formation of these species. Most of the equilibrium constants were obtained through a systematic investigation using tetramethylpyrimidopteridinetetrone (TMPPT), cinnamamide, and/or *N,N*-dimethylcinnamamide as model compounds. TMPPT has a planar molecular structure similar to the alkylxanthines. The binding behavior of this compound for organic molecules appeared to be very strong, and it was felt that it would provide a useful insight into the general phenomenon of molecular association in water.

EXPERIMENTAL

Materials—Caffeine, theophylline, and phenacetin of USP grade and antipyrine NF were used directly. Caffeine and theophylline were dried at 110° prior to use. *N,N*-Dimethylcinnamamide was synthesized from cinnamoyl chloride and dimethylamine in ether and recrystallized from water-methanol, m.p. 102–103°. 1,3,7,9-Tetramethylpyrimido(5,4-*g*)pteridine-2,4,6,8(1*H*,3*H*,7*H*,9*H*)-tetrone (TMPPT),¹ m.p. > 320°, was used usually without further purification.² All other compounds used were from commercial sources and were purified by recrystallization from appropriate solvents. Their melting points were found to deviate no more than 2° from literature reports. 7-(2-Dimethylaminoethyl)-theophylline,³ phenylbutazone (lot SN 34514), and 10-(2-dimethylaminopropyl)phenothiazine hydrochloride (promethazine hydrochloride, control no. F-663110) were used.⁴

All reagents used for buffered solutions and the organic solvents used were of analytical grade. The water was purified by redistillation.

¹ Aldrich Chemical Co.

² The material as received was found to contain no significant amount of interfering impurities from analysis of its saturated solution. An appropriately diluted sample of an aqueous solution in equilibrium with a large excess of unpurified material revealed the same spectral characteristics as those found in solutions of the recrystallized substance. Accurately prepared solutions from both untreated and recrystallized material showed identical, highly characteristic spectra over the range 220–400 m μ ; λ_{max} , 233 m μ (ϵ 49,000), 264 (ϵ 11,875), 271 (ϵ 12,000), 362 (ϵ 25,500); λ_{min} , 303 m μ (ϵ 1500). The equilibrium solubility in water of unpurified and recrystallized material was found to be the same. Since this is a characteristic physical property of a pure compound, just as is the melting point, the unpurified substance was considered to be essentially free of interfering impurities.

Anal.—Untreated material: Calcd. for C₁₂H₁₂N₆O₄: C, 47.37; H, 3.98; N, 27.62. Found: C, 47.21; H, 3.87; N, 27.82.

³ Dimethazan.

⁴ Supplied by Endo Laboratories Inc., Geigy Pharmaceuticals, and Wyeth Laboratories Inc., respectively.

Procedure—Solubility Studies—The experimental method for most of the systems investigated was the phase-solubility technique, which recently was reviewed in detail (26). An equal amount of the slightly soluble material to be tested, in considerable excess of its normal solubility, was added into each of several 15-ml. screw-cap vials. Increments of a stock solution of the complexing agent (the ligand) were pipetted into the vials, and the solution in each vial was brought to a constant final volume of 10 ml. with the necessary amount of the solvent. The vials were closed, and the screws were securely sealed with parafilm and masking tape.

When the hydroxy-substituted benzoic and cinnamic acids were tested, the vials were closed and sealed under slight nitrogen pressure to prevent oxidation of the acids.

Solubility equilibrium was obtained by tumbling the vials in a water bath thermostated at 25.0 \pm 0.1° for at least 48 hr. It was determined that this was sufficient time to ensure solubility equilibrium for all of the substances tested.

When the ligand was the ionized form of an acid (and the solid phase material was a neutral molecule over a wide pH range), a stock solution was prepared *in situ* upon dissolving the acid in 0.1 *M* sodium bicarbonate; pH was adjusted to 8.3 with the necessary amount of sodium hydroxide. The vials were then prepared so that the resulting solution in each also was 0.1 *M* with respect to the bicarbonate. When the ligand was the unionized form of the acid, a 0.005 *M* sulfuric acid solution was used as the solvent to depress ionization of the ligand. A phosphate buffer of pH 6.5 was used for the theophylline (pK_a 8.8) systems to ensure that essentially all theophylline was in its neutral form. Stock solutions of the aromatic acids were then made up by adding an equivalent amount of base and phosphate buffer to the desired volume. For some of the acids, pH 6.7–6.8 was maintained in the theophylline systems. For 8-chlorotheophylline, apparent pK_a 5.3 (27), in its neutral form, a monochloroacetate buffer of pH 2.9 was used. Theophyllinate and 8-chlorotheophyllinate systems were tested at pH 11.3 and in 0.1 *M* bicarbonate, respectively.

The pK_a of phenylbutazone, determined spectrophotometrically in water (25.0°), was found to be 4.56 \pm 0.02. A stock solution of the sodium salt was prepared *in situ* by dissolving the compound in a solution containing an equivalent amount of sodium hydroxide.

The pK_a of TMPPT, determined by the solubility technique outlined by Albert and Serjeant (28), in hydrochloric acid solutions was found to be -0.55 ± 0.10 .

Following equilibration, the content of the vials was filtered through Pyrex sintered-glass filters and analyzed for total solid solubilized.

Analysis—An aliquot of the filtered samples diluted with methanol was determined spectrophotometrically in most instances on a Cary 16 spectrophotometer. (Sometimes a Cary 15 or a Cary 14 instrument was used.) The analytical wavelength chosen for the determination of the solubilized material was one where the ligand did not absorb. In some cases, small absorbances due to the presence of the ligand were subtracted from the observed values.

The dilution of the filtered samples with methanol prior to analysis was consequently carried out for all systems, because the complex formation in this solvent was practically negligible. In this way the complexes formed in water were essentially broken down so that the measured absorbances were due to uncomplexed substances. In water, noticeable spectral perturbations occurred with some of the compounds upon complex formation. In all cases, an exactly known concentration of the analyzed compound in methanol was used as the standard. The maximum water content in the diluted samples was 2%.

When the theophylline was the solid phase material, it was separated from the complexing agent by extraction with a mixture of 3 parts chloroform and 1 part isopropyl alcohol and measured spectrophotometrically in this solvent.

Partitioning Studies—Since it has been shown (29) that caffeine undergoes self-association rather markedly in water, a phase diagram with caffeine as the solid phase cannot be unambiguously interpreted. For this reason a partitioning technique was employed so that the binding of caffeine in relative low concentration with some of the ionized aromatic acids could be studied. The experimental operation was essentially the one described by Guttman and Higuchi (29), but the total caffeine concentration was kept constant. The distribution of caffeine between 10% chloroform in isooctane and a 0.1 *M* sodium bicarbonate solution containing varying amounts of the ionized form of the acid was studied at 25.0 \pm 0.2°.

Calculation of Equilibrium Constants—Solubility Method—Phase diagrams were made by plotting the total molar concentration found in solution of the substance to be tested, S_t , versus the total concentration of ligand, L_t . The quantitative description of the different types of phase diagrams was treated by Higuchi and Connors (26). In the cases where the diagrams indicated formation of only soluble complexes and appeared to be first order with respect to the ligand, the apparent $K_{1:1}$ stability constants were evaluated according to Eq. 1:

$$K_{1:1} = \frac{\text{slope}}{S_0(1 - \text{slope})} \quad (\text{Eq. 1})$$

where S_0 is the equilibrium solubility in the absence of L and thus equal to the intercept in the plot. The data were treated by the method of least squares to get the best fit values for slope and intercept. For this purpose, a computer program was used on an Olivetti-Underwood Programma 101.

Methods are available to obtain the individual stability constants from phase diagrams exhibiting a positive curvature (26), and some assumptions usually are made depending upon the extent of complex formation. Therefore, the calculations applied when this type of diagram was observed in the present study will be outlined.

The assumption was made that only two complexes were formed, SL and SL_2 ,⁵ with the stability constants given by:

$$K_{1:1} = \frac{[SL]}{[S][L]} \quad (\text{Eq. 2})$$

$$K_{1:2} = \frac{[SL_2]}{[SL][L]} \quad (\text{Eq. 3})$$

Concentrations in molar units are represented by the brackets. The mass balance equations are:

$$S_t = [S] + [SL] + [SL_2] \quad (\text{Eq. 4})$$

$$L_t = [L] + [SL] + 2[SL_2] \quad (\text{Eq. 5})$$

By combining Eqs. 2-4 and since $[S] = S_0$,

$$\frac{S_t - S_0}{[L]} = K_{1:1}S_0 + K_{1:1}K_{1:2}S_0[L] \quad (\text{Eq. 6})$$

and a plot of the left-hand term of Eq. 6 versus $[L]$ gives both $K_{1:1}$ and $K_{1:2}$ from slope and intercept. However, free ligand concentration, $[L]$, is not known. To obtain the estimate of $[L]$, the first step is to assume that all complexed was in the SL form. Then Eq. 5 reduces to:

$$[L] = L_t - (S_t - S_0) \quad (\text{Eq. 7})$$

and Eq. 6 takes the form:

$$\frac{S_t - S_0}{L_t - (S_t - S_0)} = K_{1:1}S_0 + K_{1:1}K_{1:2}S_0[L_t - (S_t - S_0)] \quad (\text{Eq. 8})$$

The first estimate of $K_{1:1}$ and $K_{1:2}$ came from a plot of the left-hand side of Eq. 8 versus $L_t - (S_t - S_0)$.

Combining Eqs. 2-5 and solving for $[L]$,

$$[L] = \frac{-(K_{1:1}S_0 + 1) + \sqrt{(K_{1:1}S_0 + 1)^2 + 8K_{1:1}K_{1:2}S_0L_t}}{4K_{1:1}K_{1:2}S_0} \quad (\text{Eq. 9})$$

The quadratic form of Eq. 9 was used in computing the free ligand concentration from the known values of S_t and L_t and the preliminary stability constants obtained from Eq. 8. Thus, the stability constants obtained from the exact Eq. 6 should represent better values than those obtained from Eq. 8. The procedure of getting better $K_{1:1}$ and $K_{1:2}$ values involved repeated computations in using Eqs. 9 and 6 successively, after the initial $K_{1:1}$, $K_{1:2}$, and $[L]$ were calculated from Eqs. 8 and 9.

Convergent values for slope and intercept (constant values for the stability constants) were usually obtained after three to four

iterations. The data for the linear plots were treated by a computer-programmed least-squares method, and the calculations of $[L]$ were also programmed.

Partitioning—It was assumed that the ligand, for all practical purposes, was present only in the aqueous phase, since the aromatic acids would be ionized at the pH used in these studies. The free caffeine was distributed between the two solvents. For the interaction of the substance S with the ligand L in the aqueous solution,

$$K_{1:1} = \frac{[SL]}{[S]_{\text{aq.}}[L]} \quad (\text{Eq. 10})$$

where $[SL]$, $[S]_{\text{aq.}}$, and $[L]$ are the molar concentrations of the complex, free S , and L species.

The partition coefficient (PC) was defined as: $PC = \text{molar concentration of } S \text{ in aqueous phase} / \text{molar concentration of } S \text{ in organic phase}$, or

$$PC = \frac{S_{t,\text{aq.}}}{[S]_{\text{org.}}} = \frac{S_t - [S]_{\text{org.}}}{[S]_{\text{org.}}} \quad (\text{Eq. 11})$$

where S_t is the total molar concentration of the substance S in the system, and $[S]_{\text{org.}}$ is the molar concentration of S in the organic phase. The mass balance equations for the aqueous phase are:

$$S_{t,\text{aq.}} = [S]_{\text{aq.}} + [SL] \quad (\text{Eq. 12})$$

$$L_t = [L] + [SL] \quad (\text{Eq. 13})$$

Defining for simplicity,

$$(PC)_0 = \frac{[S]_{\text{aq.}}}{[S]_{\text{org.}}} \quad (\text{Eq. 14})$$

Combining Eqs. 10, 11, and 12,

$$PC = (PC)_0 + K_{1:1}(PC)_0[L] \quad (\text{Eq. 15})$$

As a first approximation, the authors set $[L] = L_t$ and got a preliminary estimate of $K_{1:1}$ from slope and intercept by plotting PC against $[L]$ in Eq. 15, $K_{1:1} = \text{slope}/\text{intercept}$.

Now, combining Eqs. 10 and 13 with 14,

$$[L] = \frac{L_t}{1 + K_{1:1}(PC)_0[S]_{\text{org.}}} \quad (\text{Eq. 16})$$

Free ligand concentration could then be calculated from Eq. 16 from the initial estimate of $K_{1:1}$ and the known values of $(S)_{\text{org.}}$.

Equations 15 and 16 were used successively until convergent values for the slope were obtained (note that the intercept is a constant in the system), i.e., constant values of $[L]$ and $K_{1:1}$. The linear plots were fitted by a programmed least-squares method. Provided only a single 1:1 complex is present in the system under investigation, the final $K_{1:1}$ value should represent the true stability constant.

RESULTS

The stability constants calculated from phase-solubility studies for the binding of a variety of compounds to TMPPT, cinnamamide, and *N,N*-dimethylcinnamamide are listed in Table I. Data for some other interacting systems are given in Table II. Typical increases observed in the solubility of the pyrimidopteridine compound in the presence of benzoate and cinnamate anions are shown in Fig. 1. The solubility of the compound is increased more than 25 times with 0.05 *M* ferulic acid anion. The upward curvature in the plot is also easily recognized, indicating the formation of higher order associations with the added material. Another apparent feature of the TMPPT complexes of this type was their yellow color, which increased in intensity with the number of substituents on the ligand. Unsubstituted *trans*-cinnamate and benzoate did not appear to form colored complexes. Spectrophotometric studies showed a shift toward longer wavelengths of the 362-m μ absorption band of TMPPT in the presence of the cinnamate anions.

In general, the solubility diagrams for TMPPT as the solid phase material were either linear over the whole concentration range of ligand used or showed a positive curvature, as in Fig. 1. In a few instances, notably for *p*-anisidine, 2,6-dihydroxybenzoic acid, 4-

⁵ It is not possible to prove that the equilibria occurring in solution are restricted to the formation of only two complexes; neither is it possible to show that these equilibria are actually occurring. Nevertheless, with the assumptions made, it is possible to describe accurately the phase-solubility diagrams and thus express the extent of complexation.

Table I—Stability Constants (liters/mole) for the Interaction of Various Compounds with TMPPT and Cinnamamides in Water at 25°

Ligand	TMPTT	Cinnamamide	<i>N,N</i> -Dimethylcinnamamide
1 Caffeine	11.9	37.5	37.6
2 Theophylline	12.8	27.3	27.5
3 8-Methoxycaffeine	19.1	48.5	54.0
4 8-Chlorotheophylline	18.5	39.3	
5 Theophylline-7-acetic acid	5.0	22.7	
6 Theophylline-7-acetate	5.9	20.0	17.3
7 Phenylbutazone, sodium salt	6.0	5.0	
8 Antipyrine	1.9	3.6	
9 Imidazole	2.3	0.8	
10 Theophyllinate	56.2 (7.1) ^a	14.3	
11 8-Chlorotheophyllinate	154.1 (11.6)	25.8	
12 Phenacetin	43.3	8.0	6.8
13 Phenol	13.1 (5.7)	1.7	
14 4-Chlorophenol	29.2	2.7	
15 Sodium sorbate	4.2	1.4	
16 <i>p</i> -Anisidine	14.9 ^b	2.4	
17 10-(2-Dimethylaminopropyl)phenothiazine hydrochloride	65.5 (2.7)	11.5	
18 7-(2-Dimethylaminoethyl)theophylline	10.0		31.0
19 β -Hydroxyethyltheophylline	7.8		27.3
20 Sodium salicylate	44.3 (4.7)		1.9
21 2,6-Dihydroxybenzoate	102.1 (37.1)		5.9
22 2,6-Dihydroxybenzoic acid	96.6 ^b		6.1
23 Nicotinamide	5.5		3.9
24 4-Hydroxycoumarin	99.0 ^b		10.8

^a The numbers in parentheses are the 1:2 stability constants for TMPPT–ligand, also expressed in l./mole. ^b Calculated from initial increase in solubility of TMPPT. An insoluble complex is also formed.

hydroxycoumarin, and 3-methoxy-4-hydroxymandelic acid anion, there was an initial linear increase in the solubility of TMPPT with ligand concentration, followed by a plateau region where precipitation of an insoluble complex occurred. The slopes were always considerably less than one for the diagrams or portions of them exhibiting increasing linear behavior or at any point in the diagrams showing curvature. The calculation of stability constants from the

diagrams where a linear increase in the solubility of TMPPT was observed was based on the assumption that a single 1:1 complex was formed. Both 1:1 and 1:2 stability constants were evaluated from the phase diagrams showing positive curvature. Studies of the partitioning of TMPPT between water and an organic phase composed of 25% chloroform in isooctane (v/v) indicated that this compound did not self-associate to a detectable extent in water. This observation was given the interpretation that higher order associations of the compound should not interfere with the evaluation of reliable stability constants from the phase-solubility diagrams.

The interactions of the unionized form of *trans*-cinnamic, caffeic, and ferulic acid with TMPPT gave insoluble complexes. These interactions were not investigated further since the authors were primarily interested in the associations taking place in solution. The formation of insoluble complexes has also been found for theophylline interactions with a series of unionized benzoic acids (5).

The 1:1 stability constants in Table II for the interaction of caffeine with some of the ionized aromatic acids require some additional explanation. The calculated constants from the partitioning data were dependent upon the total caffeine concentration. To get the most reliable 1:1 constants for these systems, several experiments were carried out with different caffeine concentrations in

Table II—Stability Constants for the Interaction of Some Organic Molecules in Water at 25°

Interacting System	$K_{1:1}$ l./mole	$K_{1:2}$ l./mole
TMPTT–sodium benzoate	9.2	
TMPTT– <i>trans</i> -cinnamic acid anion	40.7	10.4
TMPTT– <i>d,l</i> -mandelic acid anion	4.2	
TMPTT–mandelamide	2.8	
TMPTT–5-phenyl-2,4-pentadienoic acid anion	128	25.9
TMPTT– <i>p</i> -aminohippuric acid anion	29.2	
TMPTT– <i>p</i> -coumaric acid anion	106	26.1
TMPTT–3-methoxy-4-hydroxybenzoic acid anion	50.5	14.6
TMPTT–3-methoxy-4-hydroxymandelic acid anion	139 ^a	
TMPTT–caffeic acid anion	202	75
TMPTT–ferulic acid anion	228	85

each. Figure 2 shows the data for the interaction of caffeine with ferulic acid anion with the apparent $K_{1:1}$ constants, calculated as outlined in the *Experimental* section, plotted against the caffeine concentration. The increase in stability constants with increasing caffeine concentration strongly suggests that higher order caffeine complexes are formed. This is not surprising, because caffeine has been found to exist in aqueous solution as monomer, dimer, and tetramer (29), and all the caffeine species might possibly associate with the aromatic anion. This was supported with data from the solubility technique, which showed that one molecule of the anion brought close to two molecules of caffeine into solution. When the linear plot in Fig. 2 was extrapolated to zero caffeine concentration, the value of 46.0 for the $K_{1:1}$ constant was believed to represent the best "true" constant.

When the two cinnamamides were used as solid phase material in the solubility technique, only a linear increase in the solubility was observed. The slopes of the solubility diagrams were in every instance less than one. Partitioning studies between water and 10% chloroform in isooctane (v/v) indicated that self-association of cinnamamide and *N,N*-dimethylcinnamamide in the aqueous phase did not occur. The calculation of stability constants from the phase diagrams was made assuming formation of a single 1:1 complex in the systems.

Studies were attempted with vitamin A acid anion and phenothiazine as complexing agents, but they did not lead to definitive results. The salt form of vitamin A acid apparently formed micelles at very low concentrations, and phenothiazine was unstable in solution.

DISCUSSION

Earlier studies indicated that there is relatively little specificity in the type of interactions under present consideration. For example, if the stability constants of complexes formed by Compound 1 with a series of other species were plotted against the stability constants derived using Compound 2 for the same series of interactants, it has been shown that the points fall essentially on a straight line passing through the origin (6, 7). The present investigation strongly suggests, however, that there are at least two broad classes, labeled here as Class A and Class B. The data collected indicate that although members of Class A and Class B will interact with others within their own class, the strongest binding seems to be between the two groups.

Thus, for example, TMPPT and theophylline have been classified as being in Class A. *N,N*-Dimethylcinnamamide and γ -resorcylic acid anion are considered to be in Class B. As listed in Table I, the former two interact weakly, K equal to 12.8 l./mole, with each

Scheme I—A-B system interactions in water at 25°. The numbers on the arrows represent the 1:1 stability constants for the interacting species. I, TMPPT; II, theophylline; III, *N,N*-dimethylcinnamamide; and IV, 2,6-dihydroxybenzoate

Figure 2—Plot of apparent $K_{1:1}$ stability constants from partitioning data of the caffeine-ferulic acid anion system as a function of total caffeine concentration at 25°.

other; the latter pair interact even more weakly with K less than 6 l./mole. The four constants for the crossinteractions are substantially larger, being 27.5, 57.4, 102, and 300 l./mole. This is shown diagrammatically in Scheme I. The same trend is revealed by examining Scheme II, where the TMPPT-caffeine system represents the A-A interaction with K equal to 11.9 l./mole. The cinnamamide-ferulic acid anion system, with a K of 8.0 l./mole, is the B-B interaction. The four possible A-B interactions have 1:1 stability constants of 37.5, 46.0, 70, and 228 l./mole.

The possible existence of such a generic difference in the binding behaviors of these compounds is strongly supported by the plots shown in Figs. 3 and 4. Here the stability constants listed in Table I for the interactions of the various complexing agents with cinnamamide (Class B) and *N,N*-dimethylcinnamamide (Class B) have been compared with those for the interactions of the same compounds with TMPPT (Class A). Both Figs. 3 and 4 show that all the compounds fall readily in two groups, those binding the cinnamamides strongly and TMPPT weakly, and those characterized by the opposite binding tendencies. Thus, these plots demonstrate that a large number of organic compounds may be classified as belonging to either of the two categories, A or B. Such a classification is apparently valid among the compounds tested that showed relatively strong binding tendencies. However, the classification may, of course, be somewhat obscure for compounds that tended to bind rather weakly with any interactant. Examples of the latter type

Scheme II—A-B system interactions in water at 25°. The numbers on the arrows represent the 1:1 stability constants for the interacting species. I, TMPPT; V, caffeine; VI, cinnamamide; and VII, ferulic acid anion

from the present data are phenylbutazone, antipyrine, imidazole, sodium sorbate, and nicotinamide.

From Figs. 3 and 4, it is seen that the apparent two classes of compounds fall essentially on their own straight line passing through the origin in the plots, thus indicating a reasonable linear free energy relationship for the A-B interactions. The rationale for this type of plot is that the difference in the free energy ($\delta\Delta G^\circ$) for the binding of one class of compounds to TMPPT compared to the cinnamamides is expressed by the slope. That a linear free energy relationship exists does not, of course, imply that a single binding mechanism is operating among the two categories of interactants. It has been found that simple linear free energy relationships are not necessarily limited to closely related reactions but might apply to entire groups of reactions (30). The free energy changes involved in these systems, in general, are small. From the slopes of the lines drawn in Figs. 3 and 4, it was calculated that the binding of Class A compounds to the cinnamamides (Class B) was favored by about 600 cal./mole compared to the binding of the same class to TMPPT (Class A). For the binding of Class B compounds, TMPPT was favored over the cinnamamides by 1000–1500 cal./mole.

The present data suggest that all the investigated neutral xanthines and the pyrimidopteridine compounds constitute the same class, Class A. Examination of previously reported stability constants for prednisolone and hydrocortisone interactions (5, 6) indicates that these compounds also apparently may be classified as being in the same A category. Class B consists of a large number of aromatic

compounds. Apparently all benzoate derivatives, phenols, naphthols, cinnamates, and naphthoates, for which data are available, form much stronger complexing pairs with the Class A compounds than with members of their own group. In Class B the cinnamates appear to be among the strongest binders. Since molecular complexation is believed to be a possible mechanism for drug-receptor interactions *in vivo*, it is interesting to note that drugs like phenacetin and salicylate, according to the present classification system, are typical B compounds. The observed binding of the phenothiazine derivative (promethazine hydrochloride) that was tested indicated that it apparently fit into the same Class B. The strong binding to TMPPT of the biologically important metabolite 3-methoxy-4-hydroxymandelic acid anion (K equal to 139 l./mole) showed that it most likely belongs to Class B. The stability constants reported for the interaction of menadione and tryptophan with some alkyl-xanthines (7, 31) further suggest that both these compounds may be members of Class B.

Some insight into factors that confer characteristics of A and B compounds can be gained by correlating the data for the theophylline systems. The ionized form of theophylline and 8-chlorotheophylline bind TMPPT stronger than cinnamamide, whereas the reverse is true for the uncharged form of these xanthines. While the neutral xanthines were labeled Class A compounds, Fig. 3 shows that their ionized forms fit nicely into Class B. Recently, it was also shown that theophyllinate binds stronger to 8-methoxy-caffeine than its neutral form (32), and neutral theophylline had a stronger affinity for some cinnamate esters than theophyllinate (10). For a long time it has been assumed, and in some cases confirmed by experiment (5, 8, 32), that the stronger solvation around the ions compared to the neutral molecules should decrease the complexing capability in water. The theophyllinate behavior cannot be explained in this way. Although the binding with cinnamamide is reduced, theophyllinate and 8-chlorotheophyllinate bind TMPPT markedly stronger than do the corresponding neutral forms. The 1:1 stability constants were found to be 12.8 and 18.5 l./mole for the interaction with theophylline and 8-chlorotheophylline, respectively, compared to 56 l./mole for the binding of TMPPT to theophyllinate and 154 l./mole for the interaction with 8-chlorotheophyllinate. On the other hand, data for the neutral and ionized forms of theophylline-7-acetic acid show that when the negative charge is adjacent but isolated from the imidazole ring in theophylline, there is no significant change in the binding strength with either cinnamamide or TMPPT. The neutral and ionized molecules interacted with cinnamamide to give K equal to 22.7 and 20.0 l./mole, respectively. The corresponding constants for the interaction with TMPPT were 5.0 and 5.9 l./mole.

An important factor regarding the observed behavior of the theophyllinates appears to be the great change in the resonance structures of both theophylline and 8-chlorotheophylline upon formation of their anions. In theophylline-7-acetic acid, the resonance character of the heterocyclic ring system of the molecule cannot be affected by ionization of the carboxylic group. The binding of the theophyllinates, in general, resembled the binding of the

Figure 4—A plot of the 1:1 stability constants for N,N-dimethylcinnamamide and TMPPT with each of the indicated compounds. The numbers refer to the compounds listed in Table I.

benzoates and the cinnamates with TMPPT. All these ligands gave yellow, soluble complexes with TMPPT, and the solubility diagrams were all characterized by an upward curvature. The neutral alkylxanthines, on the other hand, interacted in a first-order manner with TMPPT, and no colored complexes were formed.

Since the difference in electronic character of the two forms of theophylline crudely appears to be responsible for their differences in binding with the A-B system compounds, one is tempted to speculate if this reflects any important property which would clearly distinguish an A from a B compound. Still there are contradicting opinions about the electronic properties of, for example, the purine derivatives. Although Pullman and Pullman (33) found from MO calculations that a correlation existed between the electron donating properties of the purines and their solubilizing effect on hydrocarbons (33), the influence of the medium was not taken into account. Hanna and Sandoval (34) carried out NMR studies of caffeine in complexes with benzene and mesitylene in carbon tetrachloride, and they concluded that caffeine acts as a typical acceptor in these complexes. This is, of course, contrary to the predictions made from MO theory. It is evident that the effect of the solvent environment on the extent of complex formation has to be taken into account (1). In attempts to rationalize the observed data, many problems arise because knowledge about this refinement is far from complete.

The interacting species listed in Tables I and II represent structurally a spectrum of different planar aromatic and heterocyclic molecules. Both neutral and ionized species have been tested. The substituents on the compounds are differently oriented, and some would be expected to exert an electron-withdrawing effect while others should be donating electrons and, in any case, affect the π -orbitals of the aromatic and heterocyclic ring systems. The variations in structure appear to be pronounced within each of the proposed two classes of interacting species. In general, therefore, it seems impossible to ascribe the interactions to any localized binding site. The binding of one class of compounds to a member of the other class must be mainly nonspecific in nature. The same reasoning is applicable to the observed weak binding between members of the same class. However, since the collected data clearly demonstrated that there are at least two broad classes of compounds, some selectivity must be operating among the interactants. In other words, a particular molecule must be able to recognize an A from a B compound. This property of the interactants seems to eliminate the important contribution to the stability of the complexes due to dispersion forces. The dispersion energy of attraction can be expressed in terms of a single parameter, the product of the polarizabilities of the interacting molecules (35, 36). Thus, if dispersion forces were important for the binding in water, one would not expect to see the observed selectivity since all the molecules would be more or less "blind."

At the present time, the authors believe that charge-transfer complexes of the formal type (37) are not a major factor in stabilizing these complexes in water. Experiments have shown that the binding in these systems is considerably reduced in media less polar than water (1), and this is the opposite effect of what should be expected if charge-transfer was a major factor (38). But the possibility cannot be excluded that a mechanism of nonclassical "donor-acceptor" type, peculiar to water, may be operating in the interactions being considered. It is clear that factual information about the role of water in these interactions is lacking. This may be the main reason why no satisfactory explanation has emerged as to the exact nature of the forces involved, although numerous complex interactions in aqueous media have been reported.

The complex geometry of the systems investigated cannot be described with great assurance since they exist only in solution in equilibrium with the uncomplexed components. With all the possible solute-solute, solvent-solvent, and solute-solvent interactions taking place simultaneously in aqueous solution, any detailed structural or mechanistic interpretation can only be speculative and may involve assumptions that are far from safe. However, some progress in understanding the spatial arrangement of complexes of organic molecules in aqueous solution is evident from previous studies. In general, it has been shown that planarity of the interacting molecules is important (5-7), and it has been observed that expansion of the ring system from a benzenoid to the naphthalene structure led to substantial increased binding with, for example, theophylline (5, 6). Recently, it was reported that a reasonable linear correlation existed between the standard unitary free energy change and the estimated planar area of the smaller neutral inter-

actants for theophylline complexes with a series of cinnamate esters and related compounds, and it was postulated that the 1:1 complexes were most likely of a plane-to-plane orientation (10). NMR measurements of the tryptophan-caffeine complex have suggested that the geometry apparently corresponded to plane-to-plane stacking (7). The effect of increased planar area upon the complex stability is substantially confirmed by the present study. For example, by increasing the planar surface from that of a typical alkylxanthine like caffeine or theophylline to the three-membered heterocyclic ring system in the pyrimidopteridine compound, the more favorable is the observed binding in water. The coplanarity of the benzene ring with the ethylenic bond and the carboxylate in the series of cinnamic acid anions increases the planar surface area of these molecules compared to the benzoates and other benzene derivatives. It is evident from the present data that the cinnamic acid anions, in general, are much stronger binders than the latter type of compounds, notably toward the Class A compounds. However, it cannot be ascertained at the present time if the strong binding tendency of the cinnamates is due to the increase in surface area or to the extended conjugation with increased π -electron delocalization in the molecular system. It may be suggested that a combination of both the effects contributes favorably to the observed binding.

Since the strongest binding, in general, is seen with compounds that are polycyclic in nature (of which there are examples of both Class A and Class B compounds in the present study) or contain extended conjugation, the view that planar area overlap of the partners in the complex takes place has considerable appeal. But it is not possible to make any conclusions, which at this time may be more than speculative, regarding the preferred mutual orientation of the components in these complexes in solution. Again it is felt that the role of water may be essential for the modes of orientation.

Alkaloids of Tylophora II: Structural Studies

KOPPAKA V. RAO

Abstract □ Structural studies on the six alkaloids isolated from *Tylophora crebriiflora* (N. O. Asclepiadaceae) are described here. Spectral data indicate that five of these alkaloids (A-E) possess the dibenzo[*f,h*]-pyrrolo[1,2*b*]isoquinoline skeleton known to be present in tylocrebrine. They differ in the number, nature, and distribution of the oxygen-bearing substituents and in the presence or absence of a benzylic-type hydroxyl. An oxygen substitution pattern of 3, 4, 6, and 7 is suggested for Alkaloids A, B, and C and that of 2, 3, 4, 6, and 7 for Alkaloids D and E. Alkaloid F is shown to be a seco analog of tylocrebrine with a 1,2-diphenyl *cis* stilbene skeleton.

Keyphrases □ Alkaloids—*Tylophora crebriiflora* □ Structural studies—*T. crebriiflora* alkaloids □ NMR spectroscopy—structure □ IR spectrophotometry—structure □ UV spectrophotometry—structure

The isolation of six new alkaloids designated as A, B, C, D, E, and F, together with the known compounds tylocrebrine and tylophorine from *Tylophora crebriiflora*, S. T. Blake (N. O. Asclepiadaceae), was described in Part I (1). An examination of the analytical and spectral data indicated that Compounds A-E resemble tylocrebrine (I) in that they possess the dibenzo[*f,h*]-pyrrolo[1,2*b*]isoquinoline skeleton with four or five oxygen-bearing substituents. The studies that provided evidence for the structures of these new members are described in this paper.

DISCUSSION

Alkaloid A, $C_{24}H_{27}NO_6$, resembles tylocrebrine in its UV and IR spectra and in having four methoxyl groups. The extra oxygen atom is in the form of a hydroxyl group, as shown by the formation of a monoacetate (bands at 1725 and 1225 cm^{-1} in IR and a sharp 3-proton peak at τ 7.85 in the NMR spectrum). Clemmensen reduction or catalytic hydrogenation converts Alkaloid A to a nonhydroxylic compound $C_{24}H_{27}NO_4$, thus indicating that the hydroxyl is benzylic. In its spectral and chromatographic behavior, the reduction product is almost indistinguishable from tylocrebrine, but

the mixed melting (decomposition) point seems to indicate that the two may not be identical.

The presence of the benzylic hydroxyl in Alkaloid A is analogous to the case of tylophorinine (II, $R = OH$), another known member of this group (2). In this compound, the hydroxyl was placed at 14 instead of 9 (for numbering, see Structure I), because the latter structure would have represented a highly labile carbinolamine system and the stability of the compound was inconsistent with such a structure (2). This was later confirmed by synthesis (3). In an analogous manner, the stability of Alkaloid A strongly suggests the location of the hydroxyl to be 14. This is also supported by the following NMR spectral evidence: the chemical shifts of the benzylic $CH(OH)$ protons in tylophorinine and Alkaloid A are very close: τ 3.96 and 3.87, respectively. The corresponding chemical shift of the same proton in the acetates of both compounds is τ 3.48; in both cases, it is split as a doublet, as would be expected. It is, therefore, concluded that Alkaloid A has the hydroxyl at 14.

Alkaloid B, $C_{23}H_{25}NO_4$, has three methoxyl groups. The fourth oxygen is part of a phenolic group (UV spectral shift in base and band at 3540 cm^{-1}). This is supported further by the formation of a monoacetate (1750 cm^{-1} in IR and a 3-proton peak at τ 7.59). Methylation with diazomethane leads to a tetramethoxy compound, $C_{24}H_{27}NO_4$, which is almost indistinguishable from tylocrebrine on the basis of spectral and chromatographic data, but the mixed melting (decomposition) point suggests that the two may not be identical.

Alkaloid C, $C_{23}H_{25}NO_5$, shows features similar to both A and B. It has three methoxyls and forms a diacetate (1725 and 1760 cm^{-1} in IR and 3-proton peaks at τ 7.87 and 7.59 for the alcoholic acetate and phenolic acetate groups, respectively). It can be converted by methylation to Alkaloid A and by Clemmensen reduction to B. Hence, this compound is the desmethyl derivative of Alkaloid A, and the position of the phenolic hydroxyl in B and C is the same. The transformations are shown in Scheme I.

Alkaloids D and E have the compositions $C_{25}H_{29}NO_6$ and $C_{25}H_{29}NO_5$, respectively. They each have five methoxyl groups. Clem-

Keyphrases □ Alkaloids—*Tylophora crebriiflora* □ Structural studies—*T. crebriiflora* alkaloids □ NMR spectroscopy—structure □ IR spectrophotometry—structure □ UV spectrophotometry—structure

The isolation of six new alkaloids designated as A, B, C, D, E, and F, together with the known compounds tylocrebrine and tylophorine from *Tylophora crebriiflora*, S. T. Blake (N. O. Asclepiadaceae), was described in Part I (1). An examination of the analytical and spectral data indicated that Compounds A-E resemble tylocrebrine (I) in that they possess the dibenzo[*f,h*]-pyrrolo[1,2*b*]isoquinoline skeleton with four or five oxygen-bearing substituents. The studies that provided evidence for the structures of these new members are described in this paper.

DISCUSSION

Alkaloid A, $C_{24}H_{27}NO_6$, resembles tylocrebrine in its UV and IR spectra and in having four methoxyl groups. The extra oxygen atom is in the form of a hydroxyl group, as shown by the formation of a monoacetate (bands at 1725 and 1225 cm^{-1} in IR and a sharp 3-proton peak at τ 7.85 in the NMR spectrum). Clemmensen reduction or catalytic hydrogenation converts Alkaloid A to a nonhydroxylic compound $C_{24}H_{27}NO_4$, thus indicating that the hydroxyl is benzylic. In its spectral and chromatographic behavior, the reduction product is almost indistinguishable from tylocrebrine, but

the mixed melting (decomposition) point seems to indicate that the two may not be identical.

The presence of the benzylic hydroxyl in Alkaloid A is analogous to the case of tylophorinine (II, $R = OH$), another known member of this group (2). In this compound, the hydroxyl was placed at 14 instead of 9 (for numbering, see Structure I), because the latter structure would have represented a highly labile carbinolamine system and the stability of the compound was inconsistent with such a structure (2). This was later confirmed by synthesis (3). In an analogous manner, the stability of Alkaloid A strongly suggests the location of the hydroxyl to be 14. This is also supported by the following NMR spectral evidence: the chemical shifts of the benzylic $CH(OH)$ protons in tylophorinine and Alkaloid A are very close: τ 3.96 and 3.87, respectively. The corresponding chemical shift of the same proton in the acetates of both compounds is τ 3.48; in both cases, it is split as a doublet, as would be expected. It is, therefore, concluded that Alkaloid A has the hydroxyl at 14.

Alkaloid B, $C_{23}H_{25}NO_4$, has three methoxyl groups. The fourth oxygen is part of a phenolic group (UV spectral shift in base and band at 3540 cm^{-1}). This is supported further by the formation of a monoacetate (1750 cm^{-1} in IR and a 3-proton peak at τ 7.59). Methylation with diazomethane leads to a tetramethoxy compound, $C_{24}H_{27}NO_4$, which is almost indistinguishable from tylocrebrine on the basis of spectral and chromatographic data, but the mixed melting (decomposition) point suggests that the two may not be identical.

Alkaloid C, $C_{23}H_{25}NO_5$, shows features similar to both A and B. It has three methoxyls and forms a diacetate (1725 and 1760 cm^{-1} in IR and 3-proton peaks at τ 7.87 and 7.59 for the alcoholic acetate and phenolic acetate groups, respectively). It can be converted by methylation to Alkaloid A and by Clemmensen reduction to B. Hence, this compound is the desmethyl derivative of Alkaloid A, and the position of the phenolic hydroxyl in B and C is the same. The transformations are shown in Scheme I.

Alkaloids D and E have the compositions $C_{25}H_{29}NO_6$ and $C_{25}H_{29}NO_5$, respectively. They each have five methoxyl groups. Clem-

mensen reduction of Alkaloid D affords E. Based on arguments similar to those already advanced, Compound D is the 14-hydroxy derivative of E. The arrangement of the methoxyl groups will be discussed later in the paper.

At the time they proposed the structure of tylocrebrine, Gellert *et al.* (4) considered two possible alternatives for the arrangement of the methoxyl groups, as shown in Structures I and Ia. To make a choice, both isomers were synthesized and compared with the natural tylocrebrine. It was observed that the spectral and physical properties of both isomers were very similar to each other, which made the comparison somewhat difficult. Hence, they subjected both synthetic compounds to Hofmann degradation and found that the product from Ia depressed the melting point of the corresponding derivative of natural tylocrebrine. Thus, Structure I was selected as the correct one for tylocrebrine.

The NMR spectrum of tylocrebrine (Fig. 1) shows resonance peaks which correspond to four aromatic protons, four methoxys, and benzylic and methylene protons of expected chemical shifts and splitting patterns. The spectrum, however, cannot distinguish between Structures I and Ia. The peak at τ 0.7 can be assigned to the proton at 4 (or 5), the peak at τ 2.74 to the proton at 1 (or 8), and the quartet at τ 2.33, 2.49, 2.74, and 2.89 to protons at 7 and 8 (or 1 and 2), depending on whether Structure I or Ia is being considered.

The spectrum of Alkaloid A (Fig. 2B) shows general similarity to that of tylocrebrine, with an additional peak due to the benzylic hydroxyl and a shifted peak due to the proton at 14. In spite of the otherwise general similarity, one striking feature may be noted; that is the downfield shift (by 44 c.p.s.) of one-half of the AB quartet as compared with its position in the spectrum of tylocrebrine (Fig. 2A). The other half of the quartet also shows a slight downfield shift of 10 c.p.s. In the spectrum of the acetyl derivative of A (Fig. 2C), it can be seen that the larger downfield shift is not present and the positions of the peaks are very close to those of tylocrebrine.

A parallel situation exists in the spectra of Alkaloids B, C, and the diacetyl derivative of C (Figs. 2D, 2E, and 2F). The direction and magnitude of the downfield shift are the same as already noted. Also, in an analogous manner, the spectrum of the diacetate of C (Fig. 2F) is very close to that of Alkaloid B.

It appears that a hydroxyl function in the benzylic position has a strong deshielding effect on one of the two protons which form the AB system; protection of the hydroxyl by acetylation nullifies this effect. Since the hydroxyl group is located at 14 instead of 9 for reasons already stated, and since the 14-hydroxyl group is more likely to affect the proton at 1 than that at 8, it is apparent that the AB system is due to the protons at 1 and 2 rather than those at 7 and 8. This suggests that an oxygen substitution of the type shown in Ia is present in Alkaloid A.

Very similar arguments have been used recently by Wiegreb *et al.* (5) in assigning the structure for their Alkaloid A isolated from

Figure 1—NMR spectrum of tylocrebrine. Key: A, offset 200 c.p.s.

Figure 2—NMR spectra of tylocrebrine, Alkaloid A, O-acetyl A, Alkaloid B, Alkaloid C, and O-acetyl C.

Cyanchum vincetoxicum (L.) Pers. Because of the ambiguity of the NMR spectrum in distinguishing between the two methoxyl patterns: 3, 6, 7 (II, R=H) and 2, 3, 6 (IIa), they introduced a substituent at 9 (a cyano group). Based on its deshielding influence on the protons at 8 and 7, the choice was made as the 2, 3, 6 isomer (IIa).

As further evidence for the structure of Alkaloid A (*T. crebri-flora*), a comparison of the NMR spectra of deoxytylophorinine (II, R=H), tylophorinine (II, R=OH), and acetyltylophorinine (II, R=OCOCH₃) was undertaken. The location of the benzylic hydroxyl at 14 and the methoxyl pattern of 3, 6, 7 were established by synthesis by Govindachari *et al.* (3). Portions of the spectra pertinent to the discussion are shown in Figs. 3A, 3B, and 3C. Although the spectra are slightly more complex because of the additional proton in Ring A, one can recognize the half of the AB quartet in question. In deoxytylophorinine (Fig. 3A), these two peaks are located at τ 2.17 and τ 2.02; while in tylophorinine (Fig. 3B), which has the 14-hydroxyl group, these are shifted downfield to τ 1.75 and τ 1.60. In acetyltylophorinine (Fig. 3C), the peaks are shifted upfield to τ 2.24 and τ 2.09. Thus, introduction of the 14-hydroxyl group in deoxytylophorinine brings about a downfield shift of 25 c.p.s. of the peaks due to the proton at 1, and acetylation of the hydroxyl nearly cancels this effect. Based on these strong analogies, it appears that Alkaloid A is represented better by Struc-

Figure 3—NMR spectra of deoxytylophorinine, tylophorinine, and O-acetyltylophorinine.

ture IIIa instead of III. It is thus possible that the reduction product of Alkaloid A will be the isomer of Structure Ia.

Alkaloids D and E contain five methoxys each, and it has already been shown that D is the 14-hydroxy derivative of E. Their UV spectra bear much closer resemblance to the spectra of tylocrebrine and Alkaloid A than that of tylophorine, the 2, 3, 6, 7-tetramethoxy derivative. In the NMR spectra of both D and E (Figs. 4B and 4A), the familiar AB pattern characteristic of tylocrebrine and its derivatives is lacking. This suggests that the vicinal proton system (1, 2 or 7, 8) is absent and that the additional methoxyl is located at one of these. The 2-position was chosen for the following reasons. In the spectrum of E (Fig. 4A), the peak at τ 0.79 can be assigned to the proton at 5, and the signal at τ 2.87 (2 protons) can be assigned to those at 1 and 8. In the spectrum of D (Fig. 4B), the peak at τ 1.0 is equal to two protons (5 and 1), and the signal at τ 2.17 is equal to one proton (8). Thus the signal due to one of the protons is shifted downfield (105 c.p.s.) as a result of the introduction of the hydroxyl at 14. The most probable explanation appears to be that the additional methoxyl is located at 2 and the downfield shift (105 c.p.s.) observed is that due to the proton at 1 under the deshielding influence of the 14-hydroxyl. The NMR spectrum of the acetate of D (Fig. 4C) supports this view; the peak at τ 0.92 is again equal to one proton (5) and the other two peaks due to the protons 1 and 8 can be clearly seen upfield at τ 2.80 and 2.89, almost at the same positions as they are in E. The structures of E and D are represented in IV and V.

The magnitude of the downfield shift of the H-1 peak under the influence of the 14-hydroxyl appears to be roughly a function of the extent of substitution in Ring A. When there is only one methoxyl and three protons (at 1, 2, and 4), the shift is 25 c.p.s.; with two methoxyls and two protons (at 1 and 2), the shift is 44 c.p.s.; and

with three methoxyls and one proton (at 1), the shift is 105 c.p.s. This suggests that the 14-hydroxyl group might be involved in some type of a hydrogen bonding with the π -electron system of Ring A. In addition to the observations of Wiegrebé *et al.* (5) already mentioned, similar effects were noted in the catechin series where they were attributed to the presence of a pseudoequatorial hydroxyl in close proximity to the aromatic system (6).

The site of demethylation in Alkaloids B and C will now be considered. They both have the 3, 4, 6, 7-substitution pattern, and one of the four groups is a phenolic hydroxyl. A comparison of the NMR spectra of A and C shows that the only significant difference between the two is the upfield shift (by 25 c.p.s.) of the signal due to the proton at 5. On acetylation, this shift becomes absent. The effect appears to be due to the increased electron density as a result of the close proximity to the phenolic hydroxyl. An examination of models indicates that the effect will be more pronounced if the hydroxyl is present at 4 than at 6. As a further support, the sharp band at 3540 cm^{-1} in IR suggests the presence of a hindered phenolic hydroxyl (7). Alkaloids B and C also give a positive Gibb's test (2,6-dibromo-*N*-chloroquinonimine), and this requires the phenolic group to be present at 4 since it is the only one with a free *para*-position. Also, the ready oxidizability to quinonoid products indicates the presence of a hindered phenolic group. Thus, B and C are represented by VI and VII.

Alkaloid F differs from all the hitherto known members of the tylophora alkaloids in its physical properties. Chief among these is the UV spectrum, which shows a relatively broad maximum at $288\text{ m}\mu$ ($\log \epsilon$, 4.03) and a shoulder at $240\text{ m}\mu$ ($\log \epsilon$, 4.2), in contrast with the sharp maximum in the region $257\text{--}263\text{ m}\mu$ ($\log \epsilon$, 4.8) shown by all the other members. However, the molecular formula, $\text{C}_{24}\text{H}_{29}\text{NO}_4$, differs from that of tylocrebrine by only two hydrogen atoms and they both contain four methoxyl groups. The mass spectra of both show intense peaks at $M-69$ mass units, which can be explained as being the result of a retro Diels-Alder type of fission with the expulsion of a neutral fragment, $\text{C}_4\text{H}_7\text{N}$. This result gives strong support to the presence of the indolizidine system in F. The NMR spectrum shows only two signals in the aromatic region at τ 3.39 and τ 3.43 in a ratio of 2:1 and shows general similarity to the spectrum of tylocrebrine otherwise. The absence of signals below τ 1.0 indicates alteration of the phenanthrene part of the skeleton. On oxidation with permanganate, veratric acid is isolated as the most significant product. Based on these results, Structure VIII is proposed. The physical properties and the proposed structure show that it is identical with septicine isolated earlier from *Ficus septica* (8).

Tylocrebrine and Alkaloids A, B, and C give dark-red solutions when treated with a number of oxidizing agents such as ceric sulfate, nitric acid, bromine water, or chromic acid. In contrast, tylophorine and tylophorinine do not respond to this reaction. In the cases of the two members (B and C) that possess the phenolic hydroxyl group, this oxidation can be achieved not only by the mentioned reagents but also by nitrous acid, periodate, and lead tetra-

Figure 4—NMR spectra of Alkaloid E, Alkaloid D, and O-acetyl D.

acetate. The reaction product from Alkaloid A has the composition $C_{22}H_{21}NO_5$ with only two methoxyl groups. The compound appears to be an orthoquinone formed by the loss of two methoxyl groups, and the spectral evidence is in agreement with its formulation as IX. The requirement for the hindered methoxyl (or hydroxyl) group is indicated by the absence of the oxidation with tylophorine or tylophorinine.

EXPERIMENTAL

General Method of Acetylation—A solution of the alkaloid (0.2–0.5 g.) in acetic anhydride (5–10 ml.) and pyridine (0.5–1 ml.) was heated at 100° for 2 hr. The cooled solution was diluted and made slightly basic. The precipitated solid was filtered and crystallized from methanol.

The acetate of Compound A is a colorless crystalline solid, m.p. $197\text{--}198^\circ$.

Anal.—Calcd. for $C_{26}H_{29}NO_6$: C, 69.16; H, 6.47; N, 3.10. Found: C, 69.13; H, 6.52; N, 3.03.

The acetate of Compound B is a colorless crystalline solid, m.p. $226\text{--}228^\circ$.

Anal.—Calcd. for $C_{26}H_{27}NO_5$: C, 71.25; H, 6.46; N, 3.32. Found: C, 70.75; H, 6.51; N, 3.36.

The diacetate of Compound C is a colorless crystalline solid, m.p. $216\text{--}218^\circ$.

Anal.—Calcd. for $C_{27}H_{29}NO_7$: C, 67.63; H, 6.10; N, 2.92. Found: C, 67.78; H, 6.17; N, 2.83.

The acetate of Alkaloid D is crystallized from ether-isopropyl ether. It is a colorless crystalline solid, m.p. $188\text{--}190^\circ$.

Anal.—Calcd. for $C_{27}H_{31}NO_7$: C, 67.34; H, 6.49; N, 2.91. Found: C, 67.27; H, 6.51; N, 2.79.

General Procedure for Clemmensen Reduction—Zinc dust (50 g.) was washed twice with acetone. It was then suspended in water (250 ml.) and treated with concentrated hydrochloric acid (25 ml.) and aqueous mercuric chloride (5 g. in 100 ml.). After standing for 10 min., the clear solution was decanted off and the zinc amalgam washed with water twice and kept under water.

A mixture of the alkaloid (0.5 g.), 2 N hydrochloric acid (50 ml.), and zinc amalgam (approximately 10 g.) was boiled under reflux for 24–36 hr. Aliquots were tested by paper chromatography for completion of the reaction. At the end, the clear solution was decanted off and enough sodium acetate added to pH 4–5. The solution was ex-

tracted twice with chloroform and the solvent extract concentrated to dryness. The solid was crystallized from a mixture of chloroform and methanol.

When reduced by this method, Alkaloid A gave a colorless crystalline solid, m.p. $219\text{--}220^\circ$. Mixed melting point with tylocrebrine was $210\text{--}215^\circ$.

Alkaloid C gave a colorless crystalline solid identical with Alkaloid B, and Alkaloid D gave a crystalline solid identical with Alkaloid E.

Hydrogenation of Alkaloid A—A solution of Alkaloid A (0.5 g.) glacial acetic acid (10 ml.) was hydrogenated in the presence of Adanis catalyst (0.2 g.) at 50 p.s.i. for 48 hr. The reaction mixture was filtered, diluted with water, heated with a slight excess of ammonia, and extracted with chloroform. Paper chromatography of the extract showed the presence of unchanged starting material, which was removed by countercurrent distribution in the chloroform–ethyl acetate–3% aqueous acetic acid (7:3:10) system. The hydrogenation product was recovered and crystallized twice from chloroform–methanol. It was identical with the product obtained from Clemmensen reduction.

Oxidation of Alkaloid A—A solution of Alkaloid A (1 g.) in 1 N HCl (10 ml.) was cooled in an ice bath and treated with 5% ceric sulfate (15 ml.). The dark-red solution was extracted with chloroform in the presence of sodium acetate. The dark-red extract was concentrated to dryness, and the solid crystallized from methylene chloride. The quinone hydrochloride is a maroon-red crystalline solid, m.p. $>300^\circ$.

Anal.—Calcd. for $C_{22}H_{21}NO_5 \cdot HCl$: C, 63.53; H, 5.33, N, 3.36, and $OCH_3(2)$, 14.91. Found: C, 63.72; H, 5.52; N, 3.26, and OCH_3 , 15.32.

SUMMARY

Of the six alkaloids, A, B, C, D, E, and F, isolated from *T. crebriflora*, S. T. Blake, five (A–E) retain the dibenzo[*f,h*]pyrrolo[1,2*b*]isoquinoline skeleton present in tylocrebrine. The distribution of the oxygen-bearing substituents in these compounds is discussed based on the NMR spectral evidence. An oxygen substitution pattern of 3, 4, 6, and 7 is suggested for Alkaloids A, B, and C and that of 2, 3, 4, 6, and 7 for Alkaloids D and E. Alkaloid F is an interesting member, and a structure based on tetramethoxy stilbene is proposed for this.

Allylic Phosphate Hydrolysis: Kinetics and Mechanism of Degradation of 3 β ,17 α -Dihydroxy-6 α -methylpregn-4-en-20-one 17-Acetate, 3-Phosphate

T. O. OESTERLING and J. H. GUSTAFSON*

Abstract □ The kinetics and mechanism of degradation of 3 β ,17 α -dihydroxy-6 α -methylpregn-4-en-20-one 17-acetate, 3-phosphate (I) was studied as a function of pH and temperature. At low pH the least stable moiety is the allylic phosphate ester at C₃, while the most reactive function at high pH is the acyl ester at position 17. At pH 7 and 37°, the rate of phosphate ester hydrolysis is approximately 10⁴ times faster than hydrolysis of the 17 α -acetoxy function. Between pH 4 and 10 at 37° and between pH 2 and 6 at 4°, the rate of phosphate ester hydrolysis is first order with respect to hydrogen-ion concentration. The major products of allylic phosphate hydrolysis are an epimeric mixture of C₃ alcohols, supplying evidence that the reaction occurs principally by carbon-oxygen bond fission. The activation energy for phosphate ester hydrolysis of I is 21.5 \pm 0.9 kcal./mole.

Keyphrases □ 3 β ,17 α -Dihydroxy-6 α -methylpregn-4-en-20-one 17-acetate, 3-phosphate degradation—kinetics, mechanism □ pH, temperature effects—allylic phosphate hydrolysis □ TLC—separation, identification □ Mass spectroscopy—identification □ NMR spectroscopy—identification

The synthesis and bioactivity of 3 β ,17 α -dihydroxy-6 α -methylpregn-4-en-20-one 17-acetate, 3-phosphate (I) have been reported by Morozowich *et al.* (1). It is a highly water-soluble progestational agent, which could be administered intravenously when rapid high levels of progestin are required such as in threatened abortion or premature labor. *In vivo*, I is enzymatically metabolized to form the corresponding C₃ alcohol (II) (1) and other potent progestational agents such as the 3-keto analog (2).

The two moieties that are least stable from the standpoint of development of a chemically stable parenteral formulation of I are the acetoxy function at C₁₇ and the allylic phosphate ester at C₃. Esters such as the C₁₇-acyl function of I are highly susceptible to general acid-general base catalysis. Turner (3) reported that the 17 α -acetoxy function of 3 β ,17 α -diacetoxyallopregnan-20-one was completely hydrolyzed after standing overnight in 0.25 *N* methanolic sodium hydroxide at room temperature. However, these type esters are usually much less reactive near neutral pH where, on the other hand, allylic phosphates such as the C₃ moiety of I are relatively unstable. For example, the half-life for phosphate hydrolysis of I at pH 8.78 and 37° is approximately 5 days (1).

Most previous studies of hydrolysis of allylic phosphate esters have been confined to those of acyclic monoterpene and sesquiterpene alcohols. The enzyme-catalyzed synthesis of squalene from mevalonic acid proceeds through acyclic terpenol phosphate and pyrophosphate intermediates such as farnesyl and geranyl pyrophosphate (4-6). These intermediates have been isolated and their properties studied to elucidate their role in the biochemical process. Such acyclic allylic phosphates are very unstable in acid and hydrolyze through carbonium-ion intermediates.

This report describes the kinetics and mechanism of degradation of I. The effects of pH and temperature on the rates of hydrolysis of the C₃-phosphate and C₁₇-acyl esters have been studied, and the major products of degradation have been identified.

EXPERIMENTAL

Materials—3 β ,17 α -Dihydroxy-6 α -methylpregn-4-en-20-one 17-acetate (II), 3 β ,17 α -dihydroxy-6 α -methylpregn-4-en-20-one 17-acetate, 3-phosphate (I), and 17 α -acetoxy-6-methylpregna-3,5-diene-20-one (XII) containing less than 2% impurities were used.¹ All other chemicals were reagent grade.

Kinetic Studies—Phosphate Ester Hydrolysis—The pH of reaction mixtures of I was maintained by a pH stat technique or by the

¹ Supplied by the research laboratories of The Upjohn Co.

buffers shown in Table I. Individual buffers were prepared from 3-chloropropionic acid, acetic acid, maleic acid, boric acid, ammonium hydroxide, and disodium carbonate and were adjusted to the desired pH at the temperature of the run by the addition of sodium hydroxide or hydrochloric acid. The ionic strength of buffered reaction mixtures was adjusted by the addition of potassium nitrate. Reactions were initiated by mixing temperature-equilibrated aqueous solutions of I with the buffer so that the final concentration was: I, 0.001 *M*; buffer, 0.05 *M*; and ionic strength, 0.1. After placing the mixture in a constant-temperature bath, 1.0-ml. samples were withdrawn at appropriate times, added to 1.0 ml. of 0.1 *M* NH_4OH , and refrigerated until assayed for inorganic phosphate. The pH of the reaction mixture was measured periodically during the run; if the pH varied by more than 0.2 unit from the initial pH, the run was discarded. All reaction mixtures in which phosphate ester hydrolysis was measured were prepared with freshly boiled deionized water.

For reaction mixtures where the half-life of phosphate ester hydrolysis was less than 1 hr., special techniques were employed. One-milliliter portions of an aqueous solution of I containing 2 mg./ml. were equilibrated at the temperature of the run. To obtain one time point, 1.0 ml. of equilibrated buffer was added with a syringe. At an appropriate time the reaction was quenched by the addition of 2.0 ml. of 0.1 *M* ammonium hydroxide with a syringe. Each portion of the reaction mixture was equilibrated for a different length of time until enough samples for kinetic analysis were obtained.

Kinetic runs in which pH was maintained with a pH stat were carried out as follows. Electrodes from the pH stat (Radiometer TTT1C titrator and SBR2C titrator) and the titrant delivery tube were immersed in 39.0 ml. of freshly boiled deionized water in

a stoppered jacketed vessel maintained at $37 \pm 0.1^\circ$. After thermal equilibrium was attained, 40 mg. of I in 1.0 ml. of deionized water was added, and the reaction was initiated by adjusting the pH to the desired value by the addition of 1 *N* HCl or 1 *N* NaOH. Drift in pH during the run was corrected by the addition of 1 *N* HCl or 1 *N* NaOH. At appropriate times, 1.0-ml. aliquots were withdrawn and added to 1.0 ml. of deionized water; the sample was assayed immediately for inorganic phosphate content by the following procedure. Corrections for the volume of titrant added prior to sample withdrawal were incorporated into the assay results.

The amount of inorganic phosphate in each reaction mixture aliquot was determined by Mokrasch's (7) assay. Because of the instability of the mixed reagent used in this assay, a standard was assayed after every three unknowns. Rates of phosphate ester hydrolysis were determined by least-squares analysis of $\log (P_{i,\infty} - P_{i,t})$ -time data, where $P_{i,\infty}$ is the molar concentration of inorganic phosphate present at completion of hydrolysis that is equivalent to the initial molar concentration of I, and $P_{i,t}$ is the molar concentration of inorganic phosphate present at any time.

Acyl Ester Hydrolysis—Reaction mixtures were prepared by mixing 5 ml. of a temperature-equilibrated aqueous solution of I (40 mg./ml.) with a sufficient volume of 0.1 *N* NaOH to give the final desired pH. After diluting to 10 ml. with deionized water, the solution was mixed and placed at 37° . At appropriate times, 1.0-ml. samples were withdrawn and mixed with 1.0 ml. of 0.1 *M*, pH 9 borate buffer. The amount of intact 17 α -acetoxy function remaining in the reaction mixture aliquot was measured by the method of Goddu *et al.* (8) as modified by Forist and Theal (9). Second-order rate constants of acyl ester hydrolysis were obtained by least-squares analysis of $\ln (a-x)/(b-x)$ -time data, where a is the initial concentration of I, b is the initial concentration of sodium hydroxide, and x is the amount of each reacted at any time.

Identification of Products—Degradation products were identified by mass spectral and NMR studies and by comparison of TLC R_f values with authentic samples, when available. TLC studies were carried out by spotting ethyl acetate extracts of quenched reaction mixture aliquots on silica gel G and developing with methanol-acetone-water-chloroform-cyclohexane-hexane (2:10:0.2:80:20:40). Zones were visualized by heating the plates at 100–130° after spraying with 30% ammonium sulfate.

The relative amount of each zone was estimated by scanning the thin-layer plates with a Schoeffel model SD-3000 spectrodensitometer. Samples for mass spectral and NMR analyses were obtained by preparative TLC. Mass spectra were determined with an Atlas CH4 mass spectrometer in which samples were introduced by the direct inlet technique. NMR spectra were determined with a Varian HA-100 spectrometer.

RESULTS AND DISCUSSION

Identification of Products—Table II shows the R_f values of the products in a reaction mixture of I after about 50% phosphate hydrolysis. Also shown are the relative amounts of the zones and the number assigned as molecular ion determined by mass spectral studies of compounds isolated by preparative TLC. In general, the relative amount of each species represented in Table II was independent of pH, although at higher pH the percentages of Zones 2 and 4 tended to increase. Four of the eight degradation products of I (Table II) were present only in trace amounts; of these four, a sufficient sample for mass spectral studies could only be obtained from Zone 1.

Numerous reports have shown that allylic phosphates and pyrophosphates hydrolyze through carbonium-ion intermediates (4–6, 10). Such a mechanism is reasonable for dephosphorylation of I and is compatible with the data shown in Table II. Scheme I shows a possible mechanism by which I could hydrolyze; it involves a carbonium-ion intermediate stabilized by the allylic double bond. The three products in Table II possessing molecular weight 388, the molecular weight of the alcohol which would result from hydrolysis of the C_3 -phosphate, could correspond to three of the four products shown in Scheme I (I–IV). Goodman and Popjak (4) reported that the relative amounts of secondary and tertiary alcohols resulting from pyrophosphate hydrolysis through a carbonium-ion intermediate differ from one compound to another (4). For the case of I, the secondary C_3 epimeric alcohols (II and III) are the most likely products due to the relative instability of tertiary allylic alcohols formed at C_3 and the steric hindrance involved in addition reactions at C_6 . The R_f of Zone 3 is identical to the authentic sample of 3β,17α-dihydroxy-6α-methylpregn-4-en-20-one 17-acetate (II) which, combined with the mass spectral data in Table II, establishes the identity of the major product. The presence of a carbinol proton in the NMR spectra of Zone 5 in conjunction with a molecular weight of 388 was taken as conclusive evidence that Zone 5 represents III, the C_3 epimer of II. Mass spectra of the compounds isolated from Zones 3 and 5 provided further evidence that they are II and III. The signal at m/e 370 (molecular ion minus water) of Zone 3 was of lower intensity than the molecular ion signal typical of equatorial hydroxyl groups (11, 12), while the signal at m/e 370 of the compound from Zone 5 was of greater intensity than the molecular ion signal typical of axial hydroxyl groups (11, 12). The unsaturation in Ring A of II and III slightly distorts the configuration of the C_3 hydroxyl groups. However, probably sufficient axial (Compound III) and equatorial (Compound II) character remains in the 3-hydroxyl groups of these products to show this mass spectral response.

An epimeric mixture of C_3 alcohols could be formed in reaction mixtures of I by means other than the mechanism shown in Scheme I. For example, III could be formed by epimerization of II after phosphate hydrolysis. However, only trace amounts of III were determined by TLC when authentic II was subjected to similar conditions for comparable periods of time, providing evidence that epimerization subsequent to hydrolysis is unlikely. Since a

substantial amount of III was formed in reaction mixtures of I under conditions where epimerization of II is negligible, the mechanism of hydrolysis postulated in Scheme I is quite reasonable and indicates that the reaction proceeds primarily by carbon-oxygen bond fission.

The molecular weights of the other two major products of I, Zones 2 and 4 in Table II, correspond to the alcohol that would result from hydrolysis of the acyl ester at C_{17} . Since hydrolysis of the 17α-acetoxy moiety proceeds with retention of configuration under the conditions of this study (3), Zones 2 and 4 probably represent C_3 epimers of the 17α-deacetoxy derivative of I. By analogy to the products resulting from phosphate hydrolysis, Zone 2 represents 3β,17α-dihydroxy-6α-methylpregn-4-en-20-one (VI), and Zone 4 represents 3α,17α-dihydroxy-6α-methylpregn-4-en-20-one (VII).

The identities of Zones 1 and 6–8 in Table II were not conclusively established. Mass spectral data suggest that Zone 1 may be IV or V, and inspection of Drieding models shows that IV is favored. However, there was an insufficient sample for further tests. Other possible products which might be represented by Zones 6–8 include those that would arise from D-homoannulation of Compounds VI–IX (Scheme II).

Ring expansions, such as the one depicted in Scheme II, are both acid (13) and base (14) catalyzed, and only trace amounts would be expected under the mild conditions of this study.

Secondary and tertiary allylic alcohols, such as Compounds II–V, reportedly undergo facile dehydration in acid to form conjugated dienes of the type represented by XI (15). The R_f of an authentic sample of the diene of Compounds II–V, 17α-acetoxy-6-methylpregna-3,5-dien-20-one (XII), was 0.9 in the solvent system

described in the *Experimental* section, and none of this product was detected in any of the reaction mixtures in Table I. How-

Figure 2—pH-rate profile of phosphate hydrolysis of 3β,17α-dihydroxy-6α-methylpregn-4-en-20-one 17-acetate, 3-phosphate (I). Key: ●, 4°; and ○, 37°.

Figure 3—Arrhenius plot of phosphate hydrolysis of 3 β ,17 α -dihydroxy-6 α -methylpregn-4-en-20-one 17-acetate, 3-phosphate (I) at pH 6.1.

ever, this diene can be detected in lower pH reaction mixtures where phosphate hydrolysis cannot be conveniently measured. For example, when I was treated with 0.25 *N* HCl at room temperature, almost complete conversion to XII occurred after 1 hr.

Rate Studies—The phosphate ester moiety of I hydrolyzed by an apparent first-order process under all experimental conditions. Some typical first-order curves of phosphate hydrolysis are shown in Fig. 1.

The effects of pH and temperature on the rate of phosphate ester hydrolysis of I are shown in Table I. In general, effects of ionic strength and buffer species on the rate constant appear minimal. However, the data at pH 6 and 37° show a slight tendency toward suppression of the rate constant with increasing ionic strength, and the pH 9 data suggest a possible buffer effect. Rate-pH profiles between pH 4 and 10 at 37° and between pH 2 and 6 at 4° are shown in Fig. 2. The slope of the curve of the 4° data is -1.00 and that of the 37° data is -0.97.

Three species of monosubstituted orthophosphate esters such as I contribute to the observed rate constant in the pH range 2-10. Although dissociation constants vary slightly with the nature of the substitution, in general the predominant species at pH 2 is the neutral or undissociated form; in the pH range 3-6, the monoanionic species predominates; and at pH 6-10, the dianion is the major species. The shape of the rate-pH profile depends on the concentration and relative reactivities of these three species. For example, in the case of 2,4-dinitrophenyl phosphate (16) where the dianion is the most reactive of the three species, the observed rate constant is greater in the pH range 6-10 where the dianion is the major species. If the monoanion is more reactive than the neutral or dianionic forms, as in the case of methyl phosphate (17), the rate-pH profile shows a maximum in the neighborhood of pH 4 where the monoanion is present at maximum concentration. The maximum in the pH-rate profile will become less pronounced as the reactivity of the neutral species increases relative to that of the monoanion. Examples of this behavior are glucose-1-phosphate (18) and lincomycin-2-phosphate (19).

Finally, the case arises where the relative reactivity of the neutral form increases to the point where the log of the rate constant shows a linear dependence on pH. The slope of the resulting line can indicate the number of species contributing to the observed rate constant; for example, a plot of log *k* versus pH for the hydrolysis of *tert*-butyl phosphate is a straight line between pH 2 and 7 (20) with a slope of -0.7. The nonunity value of the slope could be interpreted as an indication that more than one species, i.e., monoanion and undissociated, of *tert*-butyl phosphate is contributing to the overall rate constant.

On the other hand, Bunton and Hummer (21) obtained a slope of -1 for the straight-line plot of pH versus log *k* for the hydrolysis of ribose-1-phosphate in the pH range 3.5-7.5. This behavior was

Figure 4—Second-order plot of acyl ester hydrolysis of 3 β ,17 α -dihydroxy-6 α -methylpregn-4-en-20-one 17-acetate, 3-phosphate (I). Key: ●, *a* = 0.04 M, *b* = 0.05 M; and ○, *a* = 0.04 M, *b* = 0.03 M.

attributed to the much higher reactivity of the neutral or undissociated form over the monoanionic or other negatively charged species of ribose-1-phosphate. A similar interpretation can be applied to the data shown in Fig. 2. The major reacting species for phosphate hydrolysis of I is probably the undissociated form over the entire pH range covered in this study. A rate-pH profile of allylic pyrophosphate hydrolysis based on a single-point measurement method has been reported by Goodman and Popjak (4); however, their method of measurement and the possibility of assay variation at high pH preclude direct comparison with Fig. 2.

The phosphate moiety of I is not sufficiently stable to allow measurement of the dissociation constant of the most acidic proton. Thus, no estimate of the specific rate constant for hydrolysis of the neutral species could be obtained. However, the data in Table I clearly show that the neutral form of I is many times more reactive than the analogous species of other types of monosubstituted-orthophosphate esters such as alkyl (17, 20), acyl (22), glycosidic (18, 21), and carbohydrate phosphates as glucose-2-phosphate (23) and lincomycin-2-phosphate (19). In fact, I is also much more reactive than acyclic allylic phosphates and pyrophosphates such as neryl, dimethylallyl, and geranyl (24, 25) phosphate and geranyl, dimethylallyl, neryl, and farnesyl pyrophosphates (4, 5). The half-lives for phosphate hydrolysis of these acyclic allylic phosphates and pyrophosphates range from 2 to 15 min. in 0.1 *N* HCl at 25°, while the extrapolated half-life (Table I) for hydrolysis of I at pH 1 and 25° is about 0.01 min.

An Arrhenius plot of phosphate ester hydrolysis (I) is shown in Fig. 3. The activation energy calculated from the slope of Fig. 3 is 21.5 ± 0.9 kcal./mole. This activation energy represents the reactivity of the neutral species, even though it was present in very low concentration in the reaction mixtures at pH 6.1.

Second-order rate constants obtained for hydrolysis of the 17 α -acetoxy function of I as a function of sodium hydroxide concentration at 37° are shown in Table III. Figure 4 shows typical second-order plots of the 0.03 and 0.05 *N* NaOH data. Extrapolation of the average second-order rate constant in Table III to pH 7 (assuming minimal buffer effects) shows that phosphate ester hydrolysis is about 10⁴ times faster than acyl hydrolysis at C₁₇.

pH Effects on Salicylate Absorption from Hydrophilic Ointment

FRED MARCUS*, JOHN L. COLAIZZI, and HERBERT BARRY, III†

Abstract □ Hydrophilic ointment formulations containing salicylic acid were prepared at different pH levels by inclusion of phosphate buffers. Percutaneous salicylic acid absorption was studied by measuring salicylate blood levels in rabbits at 1.5-hr. intervals from 1.5 to 7.5 hr. after ointment application. The effect of 15% dimethyl sulfoxide in the various formulations was also determined. Formulations without dimethyl sulfoxide produced maximal blood concentrations at the highest pH level (10.78) and higher concentrations at the lowest pH (2.97) than at the intermediate ones (4.48, 6.80, 9.23). Proportionally higher concentration of undissociated species appeared to account for the increased absorption observed at the most acidic pH, while increased dissolution was probably responsible for the greater blood levels recorded at the most alkaline pH. Dimethyl sulfoxide produced a more rapid rate of salicylate absorption as well as greater peak blood levels at each pH. However, its influence on rate of absorption and on peak blood levels was less pronounced at the highest pH levels. This finding seems to indicate that the positive effect of dimethyl sulfoxide on percutaneous salicylate absorption is due in part to its ability to enhance the dissolution of salicylic acid.

Keyphrases □ Salicylate absorption—hydrophilic ointment □ pH effect—salicylate absorption from hydrophilic ointments □ Dimethyl sulfoxide effect—salicylate absorption, hydrophilic ointment □ Percutaneous absorption—salicylate in hydrophilic ointment

Experimental evidence indicates that percutaneous absorption of most drugs occurs by passive diffusion of an undissociated therapeutic entity across a lipoidal barrier (1). Characteristics of an ointment base, in particular its thermodynamic activity and included solvents, influence the rate of release from the base and the rate and quantity of percutaneous penetration and absorption. Knowledge of the specific influence of each

of these factors can aid in the formulation and choice of ointment bases designed to elicit a specified rate and magnitude of percutaneous drug absorption for a particular drug administered topically.

Higuchi (2) indicated that the chief driving force for diffusion and penetration is thermodynamic activity, which for a weakly acidic drug is inversely proportional to the term 10^{pH} . Bhatia and Barber (3) found changes in the local anesthetic activity of ethyl aminobenzoate incorporated into hydrophilic ointment USP buffered at nine different pH values ranging from 3.5 to 10.0. They observed maximum pharmacologic activity at pH 6 and 7 and found a marked decrease when the pH was decreased or increased from that neutral region. Bhatia and Barber (3) attributed their results to the possibility that maximum penetration and pharmacologic activity occurred at or near the pH of rat skin. Stolar *et al.* (4) theorized that the concentration of free salicylic acid present at a pH of 6.2–6.5, in either an aqueous solution of 6.95% sodium salicylate or in a sodium salicylate cream having an aqueous dispersion medium, could not account for the measurable salicylate blood levels observed in rabbits. Blank and Gould (5) observed an increase in the absorption of sodium laurate solutions in contact with excised human skin at reduced pH. They attributed the increase in absorption at the lower pH to the formation of more undissociated lauric acid.

The use of solvents to enhance percutaneous absorption was suggested by the ease with which gases, such as nitrobenzene vapor (6), can penetrate the skin (7–10), and has been confirmed by the greater enhancement of percutaneous absorption produced by the volatile

component of a volatile-nonvolatile topical steroid solution (11).

One nonvolatile solvent, dimethyl sulfoxide (DMSO), which has received much attention in recent years, has been found to enhance the percutaneous absorption of numerous drugs (12–18). Mechanisms proposed to explain the effect of DMSO include its reversible interaction with keratin, the extraction of lipids within the skin by disulfide interchange, the possibility of its interaction with another diffusing solute, and its inhibition of the redox polymerization of hyaluronic acid (19–22). Studies to date have indicated that DMSO is low in toxicity and causes no abnormal changes in the eyes of man, even when applied directly to the eyes (23).

The objective of this study was to determine the influence of pH on the percutaneous absorption of salicylic acid from cream-type bases, using rabbits as the test animals. In addition, the effect of DMSO, which is known to influence the absorption of salicylic acid and sodium salicylate (24), perhaps partially by altering the solubility characteristics of the drug, was investigated at different pH values. The measurement of effects of DMSO at several different pH levels may indicate the optimal combination for either maximizing or retarding the rate and magnitude of percutaneous drug absorption and can provide information on the mechanisms by which pH and DMSO both influence absorption.

MATERIALS AND METHODS

Animals—The study employed a total of 20 white, male, New Zealand rabbits with a weight range of 1.68–3.48 kg. and an average weight of 2.70 kg. They were housed in temperature- and humidity-controlled cages, and were supplied with Purina¹ rabbit chow and water *ad libitum*, except that food was withdrawn for 24 hr. prior to each ointment application.

Preparation of Ointment Base—Salicylic acid² particle size was reduced in a ball mill,³ and the material was passed through an 80-mesh sieve. The powder was dried in a heated vacuum desiccator⁴ at 50° for a minimum of 48 hr. Hydrophilic ointment USP XVII (25), categorized as a water-removable ointment base, was prepared and stored in tight containers in a refrigerator at a constant temperature of 9°.

Ointment bases of various pH values were prepared by substituting the combinations and amounts of salts shown in Table I for the same weight of water in the original formula. The pH was deter-

Table II—Experimental Design for the Four Rabbits Tested at Each pH Level^a

				Trial 2	Trial 3	Trial 4	Trial 4
1	1	No DMSO	No	DMSO	No	DMSO	DMSO
2	1	DMSO	DMSO	No	DMSO	No	DMSO
3	2	No DMSO	No	DMSO	No	DMSO	DMSO
4	2	DMSO	DMSO	No	DMSO	No	DMSO

^a Two variables tested among different animals (Initial Drug Condition and Replications), and, for the four trials, two variables tested in each animal (Drug Condition and Stages). "No" here refers to the absence of DMSO from the ointment base.

mined with a Beckman Zeromatic II pH meter⁵ for the aqueous phase of each ointment base, and a calomel junction electrode⁶ attachment was exchanged for the usual electrode to observe the pH of the emulsion-type bases themselves standardized against acid mantle cream⁶ of pH 4.22. The values obtained with either system, base or aqueous phase, showed only very slight differences, and the aqueous phase pH value was then utilized as the more convenient value.

After each base of each pH was prepared, 10% w/w salicylic acid was incorporated into one set of bases at each pH, and 10% w/w salicylic acid plus 15% w/w DMSO⁷ was incorporated into another set of bases at each pH.

Test Procedures—The rabbits were weighed, and hair was removed with an Oster animal clipper⁸ from the dorsal area and the ears 24 hr. prior to the ointment application. A 5-g. sample of ointment was spread uniformly over a rectangular area, 6.35 × 12.70 cm., on the dull side of a sheet of aluminum foil. This was applied to the shaved dorsal area of the rabbit and carefully pressed down with the aid of adhesive tape and an elastic bandage. After the 7.5-hr. test period, the tape and remaining ointment were removed, and a small amount of white petrolatum was applied to prevent chapping before the rabbit was returned to its cage.

Six blood samples were taken at intervals of 1.5 hr., the first immediately before the ointment was applied (to provide the zero time value) and the last 7.5 hr. afterward. Prior to each blood collection, the animal was set into a rabbit restraining box. One ear was warmed by manual massage and the heat from a small lamp, and a clip was placed near the base of the back of the ear to block venous blood flow as soon as the marginal ear vein distended. After the vein was pierced with a lancet⁹ at a point 1 cm. above the clip, 0.5 ml. of blood was withdrawn into a syringe containing 0.1 ml. of heparin,¹⁰ 5000 u./ml. The blood and heparin mixture was added to 5.0 ml. of a bifunctional protein precipitant and color developer in a centrifuge tube and analyzed for salicylate content according to a method originally described by Trinder (26) and more recently employed by Stelzer *et al.* (24).

Experimental Design and Statistical Analysis—The 20 rabbits were divided into five groups of four each, and each group was tested with a different pH level of ointment (2.97, 4.48, 6.80, 9.23, and 10.78). The animals were tested in pairs, one rabbit with DMSO and the other with no DMSO added to the ointment. Two such pairs (replicates) were tested with each pH level. The rabbits were given four tests, with a 7-day interval between each test. Two tests were with DMSO and the other two with no DMSO added to the ointment. Table II summarizes the experimental design for the four rabbits tested with each pH level.

Since the time of peak blood level varied in different animals and under different conditions, the blood level at any one time interval or for all intervals averaged together depended partly on absorption rate. A measure of maximal blood level, independent of rate, was obtained by recording for each animal, in each test, the highest of

^a Expressed as milligram percent of salicylic acid, at five time intervals after application of ointment at one of five pH values with or without DMSO.

the five blood levels in the span from 1.5 to 7.5 hr. after application of the ointment. A statistical analysis of the effects of DMSO and pH was performed for these peak blood levels as well as for blood levels as a function of time.

The milligram percent blood level of salicylic acid for each rabbit, at each of the five collection times from 1.5 to 7.5 hr., was corrected for the zero time blank. The BMD 02V Analysis of Variance Program for the IBM 7090 digital computer provided the test for statistical significance (27, 28). The analysis included three variables tested among different animals (five pH levels, two initial drug conditions, and two replications), two variables comprising different ointment applications for each animal ("no DMSO" or "DMSO" conditions, and the two stages), and one variable comprising different blood samples for each ointment application (five time periods). The residual variance for testing statistical significance, as in previous studies (29–32), consisted of the pooled interactions of all appropriate variables with the randomly selected variable (two replications). Mechanical failure of the spectrophotometer caused loss of the data on blood levels for two rabbits tested at pH 2.97 in the second of their two tests with DMSO and also in the second of their two tests with no DMSO. The scores for the first test under the same conditions were used, and the degrees of freedom for the residual variance was reduced accordingly in statistical tests for variations among different ointment applications.

For variables with more than two levels (five pH values and five time periods), the appropriate orthogonal polynomial function was used in prior studies (29–32) to test the hypothesis that increasing pH or time intervals resulted in a progressive, monotonic change in scores (linear) or monotonic change in one direction to an intermediate pH or time, followed by a monotonic change in the opposite direction (quadratic).

RESULTS

Table III summarizes the effects of the experimental treatments on blood levels of salicylic acid. Each value in the table represents an average value of blood levels obtained from the four rabbits assigned to one of the five pH levels. The value for each rabbit at

Figure 1—Mean blood levels of salicylic acid at five time intervals after application of ointment, with all five pH values combined. Key: ●, DMSO added; and ○, no DMSO.

each of the five time periods represents the average for two tests with and two without the addition of DMSO to the ointment.

The values in the extreme right-hand column of Table III, averages for the five pH levels, are portrayed as Fig. 1. At each time interval, the addition of DMSO resulted in higher blood levels of salicylic acid. This effect of DMSO was statistically highly reliable ($F = 76.24$, $df = 1/26$, and $p < 0.001$). More rapid absorption with DMSO is shown by a large difference at the earliest (1.5 hr.) interval. The difference in the shape of the two curves in Fig. 1 resulted in a statistically significant linear function in the interaction between DMSO treatment and time intervals ($F = 12.77$, $df = 1/136$, and $p < 0.001$).

Figures 2 and 3 portray the blood levels over the entire time span of the experiment for the tests with and without DMSO at the two extreme pH levels (2.97 and 10.78). Figure 2 shows the greater effect of DMSO on salicylic acid blood levels at the lowest pH of 2.97 than at the highest pH of 10.78 (Fig. 3) throughout the five time intervals. In spite of the large difference in magnitude of DMSO effect, both figures show that DMSO caused higher blood levels at the early time intervals and a decline in blood levels at the later intervals. This decline was greater and began at an earlier time interval at the highest pH of 10.78. Similarly, the tests with no DMSO showed maximal blood levels at 4.5 hr. at the highest pH of 10.78. The tests with no DMSO showed maximal blood levels at 4.5 hr. at the highest pH of 10.78, whereas the blood levels continued to rise throughout the 7.5 hr. at the lowest pH of 2.97.

To obtain an overall measure of the effect of pH, the blood levels at all five time intervals were averaged together, as shown in Fig. 4. Figures 5 and 6 show the average salicylic acid blood levels as a function of pH at the earliest interval of 1.5 hr. and at the latest interval of 7.5 hr., respectively. The diminished effect of DMSO at the later time interval is evident from a comparison between Figs. 5 and 6. Blood levels of salicylic acid were generally higher at the lowest and the highest pH values than at the intermediate pH levels, both with and without DMSO and at both time intervals.

Figure 2—Mean blood levels of salicylic acid at five time intervals after application of ointment at the lowest pH of 2.97. Key: ●, DMSO added; and ○, no DMSO.

Figure 3—Mean blood levels of salicylic acid at five time intervals after application of ointment at the highest pH of 10.78. Key: ●, DMSO added; and ○, no DMSO.

The decrease in blood levels at the last two time intervals (6.0 and 7.5 hr.) in tests with DMSO treatment (Figs. 1–3) indicates that salicylate available for absorption decreased to the extent that the rate of metabolism and elimination exceeded the rate of absorption at these time intervals. The continuing rise in blood levels at these time intervals after application of the ointment without DMSO further indicates the more gradual rate of absorption in the absence of DMSO. The biasing effect of the decline of blood levels of salicylic acid with DMSO added, at the later time intervals, was removed by using the highest value in the series of five time intervals for each experimental run, as shown in Fig. 7. This analysis resulted in higher average blood levels than in Fig. 4, as would be expected, but otherwise the results in the two figures are rather similar. The lowest blood level occurred at the second lowest pH (4.48), with progressively higher blood levels as the pH increased to 6.80, 9.23, and 10.78. The lowest pH (2.97) also increased blood levels greatly above those obtained with pH 4.48. Statistical analysis of the peak blood levels (Fig. 7) showed a highly reliable effect of DMSO ($F = 48.55$, $df = 1/26$, and $p < 0.001$) and a highly reliable quadratic function of pH ($F = 10.78$, $df = 1/9$, and $p < 0.01$).

The quadratic function of pH was similar whether or not DMSO was added to the ointment. However, the highest blood levels were obtained at the lowest pH with DMSO and at the highest pH without DMSO. This indicated a tendency for the effect of DMSO to decrease with progressively increasing pH. The test of this differential effect of DMSO, shown in Fig. 7, revealed a linear function for the interaction between DMSO and pH ($F = 3.26$, $df = 1/26$, and $p < 0.10\%$).

Solubility of salicylic acid was estimated by the amount visible immediately after adding 100 g. of salicylic acid to 1000 ml. of water. Most of the salicylic acid remained in suspension, whereas solution was complete when 150 g. of DMSO was substituted for an equivalent weight of water.

DISCUSSION

The results of this investigation show that at the lowest pH the blood levels of salicylic acid obtained with the emulsion-type ointment base (without DMSO) exceed the blood levels obtainable at the intermediate pH values. As Higuchi (2) theorized, decreasing the pH of a vehicle would be expected to increase the thermodynamic activity of the undissociated form of a weakly acidic drug like salicylate. As Table IV demonstrates, the highest concentration of undissociated salicylic acid is present at the lowest pH. The much

lower concentrations of the undissociated species at the three intermediate pH values probably account for the lower levels observed. These findings agree with those of Blank and Gould (5) who noted the increased percutaneous absorption of sodium laurate solutions at pH values at which undissociated lauric acid was present in relatively greater concentration.

Although the three intermediate pH values produced lower blood salicylate levels than the most acidic ointment, a progressive increase in blood levels was observed as the intermediate pH values rose. At the most alkaline pH value, the salicylate levels observed were higher than for any of the other ointments without DMSO, even higher than the levels observed at the most acidic pH. The apparent increase in absorption as the pH values increased might be explained by the more rapid rate of dissolution of salicylic acid that occurs with increasing pH. The rate of dissolution of salicylic acid has been shown to increase by a factor of nearly 15.9 when the pH of an aqueous buffer solution was increased from 1.5 to 6.8, and by a factor of nearly 2 when the pH was increased from 6.8 to 9.0 (33). It is well established that dissolution *in vivo* is often a rate-limiting step in the gastrointestinal absorption process; higher blood levels due to increased absorption can result from a more rapid rate of dissolution of the drug. Although a far greater proportion of salicylate is present in the dissociated form at the more alkaline pH levels, the undissociated species is probably still the absorbing species, because when one molecule of the undissociated species is absorbed (lost from the ointment), another molecule must be formed from the dissociated species to maintain the equilibrium (1).

As Fig. 4 indicates, when the DMSO was incorporated into the ointment bases, the maximum blood levels were achieved at the

Figure 7—Mean blood levels of salicylic acid as a function of pH at the time of peak blood level between 1.5 and 7.5 hr. after application of ointment. Key: ●, DMSO added; and ○, no DMSO.

Table IV—Comparative Percentages of Undissociated Salicylic Acid in the Aqueous Phase at Each pH and Comparative Total Molar Solubilities of the Drug at Each pH^a

pH of Aqueous Phase	Percent of Salicylic Acid in Undissociated Form in Aqueous Phase at 25°	Total Molar Solubility at 25°
2.97	50	3.20×10^{-2}
4.48	2.997	5.30×10^{-1}
6.80	0.014	— ^c
9.23	— ^b	— ^c
10.78	— ^b	— ^c

^a Percentages were determined from the Henderson-Hasselbalch buffer equation (without correcting the activity coefficients). Total solubilities were determined from the equation:

$$\text{pH} = \text{pK}_a + \log \frac{S - S_0}{S_0}$$

where K_a is the dissociation constant of salicylic acid, S is the total solubility (the sum of the molar concentration of salicylic acid in solution plus the molar concentration of salicylate ion), and S_0 is the molar concentration of salicylic acid in water. ^b Essentially complete dissociation. ^c Complete solubility.

lowest rather than highest pH. Therefore, DMSO appears to function as a penetration facilitator of acidic drug molecules more efficiently at the most acidic pH. DMSO completely solubilized the salicylic acid in the aqueous phase, and this increased activity of salicylic acid appears to have been an important factor in the increased percutaneous absorption of the drug. It is not surprising that DMSO enhanced overall percutaneous salicylate absorption to the greatest extent at the most acidic pH, since this is the pH at which undissociated salicylic acid is present to the greatest extent. Thus, solubilization of the less water-soluble (but more absorbable) form into the aqueous phase of the base, from which percutaneous absorption occurs more readily, could have maximal effect.

At the more alkaline pH levels, as dissolution factors become less rate limiting and as a decreasing proportion of undissociated salicylic acid is present, the degree to which the solubilizing effect of DMSO could promote absorption would be expected to diminish. The present results confirm this expectation, but DMSO enhanced absorption even at the most alkaline pH value where its solubilization effect would be minimal. This suggests that DMSO also enhances percutaneous absorption by other mechanisms, possibly by direct action on the skin and cutaneous tissue.

With no DMSO present in the ointment and with all pH values combined, as in Fig. 1, the blood levels gradually rose over the time period from 1.5 to 7.5 hr., reaching an apparent plateau at about 5.5 hr., at which time the rate of absorption apparently approximated the rate of disappearance of drug from the blood. When DMSO was incorporated into the ointments and with all pH values combined, the blood level at 1.5 hr. was more than double that obtained without DMSO. At 3.0 hr., the blood level rose to the extent that it was still almost double the value for no DMSO. The steeper initial slope observed with DMSO indicates an increased absorption rate following initial application of the drug. The subsequent decline might indicate that with DMSO the store of absorbable salicylic acid is exhausted more rapidly. Another possible reason for the decline is that the DMSO, which is itself absorbed rapidly, is no longer available to facilitate salicylate absorption. Thus, it is probable that the effect of DMSO is underestimated at later time periods, when its rapid absorption has exhausted the concentration of the solvent.

Comparison of Plasma Concentrations of Warfarin Measured by Both Simple Extraction and TLC Methods

P. G. WELLING, K. P. LEE, URMILLA KHANNA*, and J. G. WAGNER

Abstract □ Human volunteers received 25-mg. single oral doses of sodium warfarin. Ninety-three plasma samples were independently assayed by: (a) a simple extraction method, and (b) a TLC method using a UV instead of a fluorescent end-point. Both assays employed 7.5-cm. pathlength cells and the Cary 14 UV spectrophotometer. The assays were concluded to be equivalent and to measure only unchanged warfarin after single doses, since: (a) the least-squares line forced through the origin when assays by the extraction method were plotted against assays by the TLC method had a slope of 1.00; (b) of the differences (TLC — extraction), 44 were positive, 2 were zero, and 47 were negative; and (c) average elimination half-lives of warfarin estimated from terminal plasma concentrations measured by the two methods were not significantly different. The absolute value of the differences averaged 0.17 mcg./ml. with a SD of 0.14 mcg./ml. One may assume that each assay had an average deviation of 0.085 mcg./ml. from the "true" warfarin concentration and that the deviation was independent of the plasma concentration in the range studied (0.1–4.5 mcg./ml.).

Keyphrases □ Warfarin, plasma determination—method comparison □ Extraction procedure—warfarin determination in plasma □ TLC—warfarin determination in plasma □ UV spectrophotometry—analysis

An analytical method, developed by O'Reilly *et al.* (1), for the measurement of unchanged warfarin in plasma has been used by several investigators (2–6) to study the absorption, distribution, and metabolism of this compound and to correlate prothrombin times with plasma concentrations of the drug. Although other analytical techniques have been used (4, 7), the O'Reilly assay, involving a series of extractions and UV determination, has proved to be the simplest and most reliable procedure.

Recently, Lewis and Ilnicki (8) published, in abstract form, data suggesting that the O'Reilly assay was not specific for unchanged warfarin in plasma. TLC evidence was mentioned, indicating that two other compounds, presumably warfarin metabolites, could be detected at a stage in the assay which necessitated their being included in the final estimation. The implication of this report is clear and throws some doubt on the validity of all data using the original assay.

Interest in the pharmacokinetics of warfarin made it necessary to investigate this problem further. The data reported here are part of a more detailed study, the results of which will be published later. The objects of this particular investigation were: (a) to increase the sensitivity of the existing O'Reilly assay by variation of plasma and solvent volumes and measuring techniques in order to measure lower plasma drug concentrations, and (b) to develop a new assay, based on the abstract of Lewis and Ilnicki (8), specific for unchanged warfarin and equally as sensitive as the modified O'Reilly assay. Thus, the second assay would assess the validity of the first.

EXPERIMENTAL

Assay Methods—Modified O'Reilly Assay—After some experimentation, the following procedure was found to give reproducible linear absorbance-to-concentration ratios over the required plasma concentration range (0.1–4.5 mcg./ml.).

To 1,2-ethylenedichloride¹ (EDC, reagent grade, 20 ml.) in a square-sided 50-ml. bottle, fitted with a polyethylene-lined screw cap, were added plasma (4 ml.), distilled water (2 ml.), and 3 *N* hydrochloric acid (1 ml.). The bottle was tightly closed and horizontally agitated in a Kahn shaker for 10 min. The contents were then poured into a 125-ml. separator fitted with a Teflon tap. The bottle was allowed to drain into the funnel for 30 min., which was sufficient time for separation of the organic phase from the emulsion. The EDC layer was drained into a second separator, to which was then added 0.1 *M* phosphate buffer, pH 7.2 (5 ml.). After shaking for 4 min. and allowing 4 min. for phase separation, the EDC layer was run off. Exactly 15 ml. of this washed EDC extract was added to a third separator, shaken for 4 min. with 2.5 *N* sodium hydroxide (5 ml.), and allowed to stand for 4 min.

The EDC layer was discarded, and the alkaline aqueous phase containing sodium warfarin was poured into a 15-ml. centrifuge tube. This was centrifuged at 1500 r.p.m. for 5 min. to separate residual EDC; the absorbance of the clear aqueous solution was read by scanning in a 7.5-cm. pathlength cell from 380 to 280 μ in a Cary 14 spectrophotometer.

The subject's zero-hour plasma was carried through each assay batch and was used as the reference solution in the spectrophotometer. Pooled plasma, from the hospital blood bank, was spiked with warfarin (0.5 ml. of a 40 mcg./ml. aqueous solution per 9.5 ml. of plasma) to a concentration of 2.0 mcg./ml. This was included in each assay batch and measured against unspiked blood bank plasma to determine assay reproducibility.

In this and in the TLC assay, a baseline drift was observed when scanning from 360 to 308 μ , giving an average net absorbance ($A_{308}-A_{360}$) of 0.025 (*SD* = 0.004). This figure, hereafter referred to as "cell correction," was deducted from all net absorbance readings. The baseline drift is presumably due to the cell composition or the long pathlength used and not to their being unmatched, because the drift remained constant on reversing the cell positions.

Plasma concentrations of warfarin were calculated using Eq. 1:²

$$\text{plasma concentration} = \frac{A_{308}-A_{360} - (\text{cell correction})}{0.183} \quad (\text{Eq. 1})$$

TLC Assay—This assay is similar to that reported by Lewis and Ilnicki (8). Estimation of warfarin by UV absorption was, however, substituted for fluorescence. The problem of fluorescence fading with exposure of acetone solutions of warfarin to UV light and the consequent difficulty in reassaying samples were therefore avoided [Corn and Berberich (7)]. At the plasma concentrations used in this study, the fluorescence technique seemed to offer no advantage over the method used.

Methodology in this assay was the same as in the modified O'Reilly assay up to the point of obtaining the 15 ml. of washed EDC extract.

Specificity was achieved in this assay by separating warfarin from other EDC extractable material, present after washing with phosphate buffer, by TLC. In all steps subsequent to obtaining 15 ml. of buffer-washed EDC extracts, contact of warfarin solutions with light was minimized. Glass containers were wrapped in aluminum foil. Volume reduction of solutions under nitrogen and plate develop-

ment were done in the absence of light, and application of solutions to TLC plates was done in a minimum of light.

It has been shown in this laboratory that EDC and acetone solutions of warfarin are light sensitive. Reproducible results cannot be obtained in this assay, in which warfarin must remain in the solution for longer periods, unless these precautions are taken.

The 15-ml. washed EDC extract was reduced to dryness in a 50-ml. wide-mouthed centrifuge tube at room temperature under nitrogen. The tube was washed down with 3, 2, and 1 ml. of EDC and taken to dryness each time to concentrate material at the bottom of the tube. The contents were redissolved in a minimum volume of EDC, quantitatively transferred by capillary tube to 250-μ thick silica gel GF 254³ chromatography plates (20 × 20 cm.), and developed in EDC-acetone (9:1).

Warfarin could be clearly detected at the lowest plasma concentration by its quenching of plate fluorescence under a wide-range UV lamp. The use of quenching on fluorescing plates is more sensitive than warfarin fluorescence on normal plates and eliminates the need to expose the plates to ammonia vapor before detection.

The spot at R_f 0.50–0.54 due to warfarin was scraped off into a 15-ml. centrifuge tube with a small spatula and eluted by agitating with acetone (3 × 1.5 ml.) on a vortex mixer, centrifuging at 2000 r.p.m., decanting, and finally washing the walls of the tube down with 1 ml. of acetone, centrifuging, and decanting again. Plate areas from blank plasmas at identical R_f values to warfarin were identically treated to yield reference solutions in the spectrophotometer.

The acetone solution was taken to dryness under nitrogen at room temperature. The warfarin was redissolved by vigorous agitation in 2.5 *N* sodium hydroxide (5 ml.) for 10 min. on a vortex mixer. After centrifuging at 2000 r.p.m. to precipitate any remaining silica gel, the clear supernatant was measured as before and the plasma warfarin concentration was calculated using Eq. 2:²

$$\text{plasma concentration} = \frac{A_{308} - A_{360} - (\text{cell correction})}{0.167} \quad (\text{Eq. 2})$$

In the use of both assays, all the plasma samples from one phase of the study for a particular subject were assayed at the same time.

The developed chromatograms from dosed subjects were identical to those from warfarin-spiked plasma. Spots at R_f 0.91, 0.85, and 0.25 were identical to blank plasma in all cases. A spot at R_f 0.1 was also observed in blank plasma in 18 out of 24 cases. No other spots could be detected.

The 4'-OH, 6-OH, and 7-OH metabolites have R_f values of 0.22, 0.18, and 0.23, respectively, in this system. These R_f values are not affected when chromatographing the metabolites in combination with the parent drug.

Assay Standardization—On six different days, human plasma was spiked with warfarin at 0.1–4.0 mcg./ml. concentrations. The absorbances obtained in the modified O'Reilly assay gave rise to the statistics given in Table I. Multiple samples of plasma spiked at one concentration only were also assayed using 1-cm. cells in a Beckman DB recording spectrophotometer. The results of these assays, and also equivalent figures for a 7.5-cm. light path, are given in Table II.

As a consequence of these data, it was decided to divide the observed net absorbance of final extracts in the modified O'Reilly assay by 0.183 to obtain the plasma warfarin concentration.

Table III lists recoveries of warfarin from thin-layer plates at five different concentrations on 4 separate days. The average recovery was 91.7%. Therefore, the expected net absorbance/concentration ratio in the TLC assay is $0.183 \times 0.917 = 0.168$. The actual ratio obtained when pooled plasma was spiked with warfarin was 0.167 (Table IV). Therefore, the figure 0.167 was substituted for 0.183 in the TLC assay.

In both assays the sensitivity compared to the original O'Reilly assay (1) has been increased by a factor of

$$\frac{4}{2} \times \frac{7.5}{1} \times \frac{4}{5} = 12 \quad (\text{Eq. 3})$$

where the fractions represent plasma volumes, cell pathlengths, and sodium hydroxide volumes, respectively.

Clinical Study—Six healthy adult human volunteers, four male and two female, weighing between 120 and 200 lb. and between 21 and 30 years of age, were selected. All had normal vital signs and screening laboratory values. No barbiturates or other enzyme-inducing agents were permitted to be taken for 30 days preceding initiation of the study. No medication, apart from warfarin and menadiol diphosphate (tetrasodium salt),⁴ was permitted for a period of 7 days before commencement to the end of the study. The study was arranged as a two-phase crossover design. In each phase each subject ingested orally a 25-mg. dose of warfarin sodium as five 5-mg. tablets or one 25-mg. tablet. The tablets were swallowed whole. Subjects were fasted overnight and for 4 hr. postadministration of drug. Eight fluid ounces of water was taken within 1 hr. after arising and also when the tablets were ingested. No other beverage, water, or food was taken until 4 hr. after dosage. After this period, food and liquids were allowed *ad libitum*.

Twenty milliliters of blood was taken from a forearm vein just before dosing (0 hr.) and at 1, 4, 8, 12, 24, 48, 72, and 96 hr. after dosing. The blood was drawn into one or two Vacutainer tubes containing EDTA as the anticoagulant. After centrifuging, the plasma was aspirated off into a second tube and quick-frozen at -18° until required.

To reduce the possibility of hemorrhage, each subject was administered a 10-mg. dose of menadiol diphosphate (2 × 5-mg. tablets) 1 day before, on the same day, and 3 days following warfarin dosage in each phase of the crossover study. This compound and its metabolites have been shown in this laboratory not to interfere with the O'Reilly or the TLC assay for warfarin. The plasma concentrations, arranged according to the experimental design, will be reported in a forthcoming publication.

Materials—As a standard, USP reference standard warfarin acid was solubilized as the sodium salt by dissolving in 0.1 *M* phosphate buffer, pH 7.5. A stock solution of concentration 100 mcg./ml. was kept refrigerated, and aliquots were taken and brought to room temperature before use. Plasma used for assay standardization and for controls was obtained from the blood bank, University of Michigan Medical Center.

NaOH, and absorbance read in 7.5-cm. pathlength cells) based on results obtained. ^c Assays on Day 8 were run by a different analyst than those on Days 1-7.

4'-OH, 6-OH, and 7-OH metabolites of warfarin were donated.⁵ All other chemicals and solvents were reagent grade and were not further purified before use.

RESULTS

Because this report is concerned only with the sensitivity and comparison of results of two methods of assay, no specification of plasma levels of warfarin obtained from the five 5-mg. or the one 25-mg. dosage is made here.

In the modified O'Reilly assay, the average net absorbance ($A_{308} - A_{360}$ - cell correction) of final extracts from subjects' zero-hour plasmas, using water in the reference cell, was 0.216 with a *SD* of 0.056. When corrected for cell pathlength and plasma and sodium hydroxide solution volumes, this figure is equivalent to an average of 0.018 absorbance unit compared with 0.010 reported by O'Reilly *et al.* (1). The average net absorbance of final extracts from unspiked blood bank plasma was 0.261, with a *SD* of 0.024, yielding an O'Reilly equivalent of 0.022.

In the TLC assay, the average net absorbance of final extracts from subjects' zero-hour plasmas was 0.155 with a *SD* of 0.030 and an O'Reilly equivalent of 0.013. The average net absorbance of final extracts from unspiked blood bank plasma was 0.158 with a *SD* of 0.035 and an O'Reilly equivalent of 0.013.

Hence, both assays gave higher blanks than reported by O'Reilly *et al.* (1). A reduction in the net absorbance of the blanks was obtained by the TLC purification step.

In Fig. 1 the plasma concentration of warfarin measured by the modified O'Reilly method is plotted on the ordinate against the corresponding plasma concentration of warfarin measured by the TLC method for the 93 plasma samples analyzed by both methods. The slope of the least-squares line forced through the origin is 1.00; this is the exact theoretical value for equivalence of the assays.

For the differences (TLC assay - O'Reilly assay), there were 44 positive values, 2 zero values, and 47 negative values. These differences are plotted against the averages, namely (TLC assay + O'Reilly assay)/2, in Fig. 2. It appears that the differences are independent of plasma concentration in the range studied. The average absolute value of the difference was 0.17 mcg./ml. with a *SD* of 0.143 mcg./ml. If the average of the two assays on each plasma sample is taken as the true concentration of warfarin, the average deviation of an assay value from the true concentration is 0.085 mcg./ml.

From Fig. 3 it may be seen that the UV spectra of final extracts from both assays are essentially identical. However, since the metabolites of warfarin have spectra similar to the parent compound (9), small amounts of metabolite would not be detected by this method. This evidence is, therefore, of minor importance.

Elimination half-lives of warfarin were estimated from terminal plasma concentrations of warfarin from each of the 12 sets of plasma samples assayed by both methods. The method of least squares was applied to the logarithms of the plasma concentrations of each set, which appeared to be randomly distributed about a straight line

when plotted against time; the slopes of the least-squares lines were divided into the logarithm of 2 to obtain the half-lives. In Fig. 4 the elimination half-life estimated from plasma samples assayed by the modified O'Reilly method is plotted on the ordinate against the elimination half-life estimated from plasma samples assayed by the TLC method on the abscissa. The least-squares line free to pass through any intercept had a slope of 0.99 and an intercept of 2.5, which was not significantly different from zero. The least-squares line forced through the origin had a slope of 1.0, and this line is drawn through the points in Fig. 4. The average half-life of 37.4 hr. obtained with the modified O'Reilly assay was not significantly different from the average half-life of 35.2 hr. obtained with the TLC assays by a paired *t*-test ($t = 0.95, p > 0.25$).

DISCUSSION

O'Reilly (10) showed that the binding strength of warfarin metabolites to crystalline human albumin was 7- to 17-fold less than that of unchanged warfarin. He suggested that the introduction of the polar hydroxyl groups by metabolism greatly decreases the hydrophobic binding of warfarin metabolites, not only to albumin but also to the receptor sites for the unchanged drug; this allows for their ready renal clearance and accounts for the loss of anticoagulant activity. This may explain why warfarin metabolites are present in urine but not in plasma in measurable amounts.

Since the TLC assay employed measures only unchanged warfarin in plasma, from the data presented it may be concluded that the original and the modified O'Reilly assays are specific for unchanged warfarin in plasma. Results reported here strongly support the countercurrent distribution studies of O'Reilly *et al.* (1), which indicated the specificity of his assay method. If warfarin metabolites are present in plasma, they must be present in minute amounts and, in such trace amounts, would not invalidate the O'Reilly assay as a

specific method. It is feasible that warfarinlike products detected on thin-layer plates after spotting extracts from plasma by Lewis and Ilnicki (8) were degradation products which arose from the action of light on warfarin during their TLC assay procedure. However, if these authors were using a very high dose of warfarin, then the possibility of an increase in the activity of hydroxylating enzymes at high plasma concentrations of drug, causing a disproportionate increase in plasma metabolites, would also be a feasible explanation for their results.

If a metabolite also had a long half-life in the body, its concentration in blood could build up after multiple doses of drug to levels that would invalidate the conclusions reached following administration of single doses of drug.

SUMMARY

Ninety-three plasma samples obtained from human volunteers,

Figure 2—Plot of difference between assays against average of assays.

Figure 3—UV spectra of final extracts from TLC and modified O'Reilly assays.

following ingestion of 25-mg. single oral doses of warfarin sodium, were independently assayed by a modification of the method of O'Reilly *et al.* (1) and by a TLC method. There was no detectable evidence of the presence of warfarin metabolites on any of the TLC plates developed from extracts of plasma from subjects dosed with warfarin in this study. The UV spectra of final extracts from both assays were essentially identical. Comparison of the 93 pairs of plasma concentrations arising from the application of the two assay methods on the same plasma samples and the 12 pairs of elimination half-lives of warfarin, estimated from terminal plasma concentrations, measured by the two assay methods indicated that the assays gave equivalent results. It is concluded that the original and the modified O'Reilly assay methods are specific for unchanged warfarin in plasma in the concentration range of 0.1–4.5 mcg. warfarin/ml. plasma observed in this study.

Salt Effects in Aqueous Solutions of Urea

RICHARD E. LINDSTROM and ALEXANDER R. GIAQUINTO

Abstract □ It is suggested, when working with drug-urea-water systems, that more than passing consideration be given to the effect or effects produced by addition of a fourth component, as, for example, when an acid is used to adjust pH. Data are cited which indicate that these effects are measurable and often predictable. Solubility data for methyl salicylate and methyl benzoate are given as functions of varying acid, salt, and urea concentrations. These data represent the equilibrium solubilities of the esters in the various systems at 30°. The solubilities were obtained by sampling and subsequent determination of the ester concentration using UV spectrophotometry. A mathematical model was derived which permits a quantitative evaluation of salt effects in urea solutions. The theoretical calculations, based on this model, were found to be in good agreement with the experimental values observed for neutral and pH 1 solutions of methyl salicylate and methyl benzoate in urea. Extension of these findings to an earlier investigation indicates that significant error in interpretation of solubility in urea may result if these salt effects are disregarded.

Keyphrases □ Urea aqueous solutions—salt effects □ Methyl salicylate and benzoate solubility—urea-water mixture □ Electrolyte, HCl concentration effects—methyl salicylate and benzoate solubility □ UV spectrophotometry—analysis

The introduction of a fourth component into a urea-drug-water system will produce changes in both the physical and chemical properties of the system. Understandably, the inclination is to disregard or minimize the resultant effects, especially when the rationale of the investigation appears to be unaltered by doing so. However, it is imperative that some quantitative estimate be obtained before following this premise, since the magnitude of these effects may be large enough to require reassessment of the object of the experiment.

Work on systems involving urea-water mixtures are particularly prone to questionable assumptions. For example, during their study of the solubility of salicylic acid in urea solutions, various authors (1-3) sought to preclude ionization of the salicylic acid by making the

solutions pH 1 with strong acid. In two instances, the workers made the solutions 0.1 *N* in H⁺. Taking note of observed irregularities in this matter, however, Feldman and Gibaldi (1) were careful to adjust the pH of each solution to 1. These two different procedures result in systems that are not equivalent, a fact that may have been responsible for the differences in observations and conclusions. The strong acid which was added in these studies is certain to exhibit a characteristic influence on the solubility of any additional solutes. Whether this influence is significant and measurable in multicomponent mixtures of urea, water, drug, and salt is typical of the problem which should concern the investigator.

Wetlaufer *et al.* (4) demonstrated that salt effects do exist in urea solutions. These workers found that the solubility of skatole in aqueous urea-sodium chloride solutions was measurably less than in solutions of the same urea concentration but containing no sodium chloride. Additionally, it was estimated that this "salting out" approximated that observed when the solubility of skatole in water and in water-sodium chloride solution was compared. Thus, it would seem that the salt effects are not only measurable but also are relatively independent of the urea concentration. In that event, one is in a favorable position to quantify similar effects in urea solutions in general.

THEORETICAL CONSIDERATIONS

The phenomena of "salting in" and "salting out" have been described empirically by the Setschenow equation (5):

$$\log S^0/S = KC \quad (\text{Eq. 1})$$

where S^0 and S are the molar solubilities of a nonelectrolyte in pure water and in a solution containing C moles/l. of electrolyte, respectively. The symbol, K , is an empirical salt parameter, which is characteristic of both the electrolyte and nonelectrolyte species.

Salt Effects in Aqueous Solutions of Urea

RICHARD E. LINDSTROM and ALEXANDER R. GIAQUINTO

Abstract □ It is suggested, when working with drug-urea-water systems, that more than passing consideration be given to the effect or effects produced by addition of a fourth component, as, for example, when an acid is used to adjust pH. Data are cited which indicate that these effects are measurable and often predictable. Solubility data for methyl salicylate and methyl benzoate are given as functions of varying acid, salt, and urea concentrations. These data represent the equilibrium solubilities of the esters in the various systems at 30°. The solubilities were obtained by sampling and subsequent determination of the ester concentration using UV spectrophotometry. A mathematical model was derived which permits a quantitative evaluation of salt effects in urea solutions. The theoretical calculations, based on this model, were found to be in good agreement with the experimental values observed for neutral and pH 1 solutions of methyl salicylate and methyl benzoate in urea. Extension of these findings to an earlier investigation indicates that significant error in interpretation of solubility in urea may result if these salt effects are disregarded.

Keyphrases □ Urea aqueous solutions—salt effects □ Methyl salicylate and benzoate solubility—urea-water mixture □ Electrolyte, HCl concentration effects—methyl salicylate and benzoate solubility □ UV spectrophotometry—analysis

The introduction of a fourth component into a urea-drug-water system will produce changes in both the physical and chemical properties of the system. Understandably, the inclination is to disregard or minimize the resultant effects, especially when the rationale of the investigation appears to be unaltered by doing so. However, it is imperative that some quantitative estimate be obtained before following this premise, since the magnitude of these effects may be large enough to require reassessment of the object of the experiment.

Work on systems involving urea-water mixtures are particularly prone to questionable assumptions. For example, during their study of the solubility of salicylic acid in urea solutions, various authors (1-3) sought to preclude ionization of the salicylic acid by making the

solutions pH 1 with strong acid. In two instances, the workers made the solutions 0.1 *N* in H⁺. Taking note of observed irregularities in this matter, however, Feldman and Gibaldi (1) were careful to adjust the pH of each solution to 1. These two different procedures result in systems that are not equivalent, a fact that may have been responsible for the differences in observations and conclusions. The strong acid which was added in these studies is certain to exhibit a characteristic influence on the solubility of any additional solutes. Whether this influence is significant and measurable in multicomponent mixtures of urea, water, drug, and salt is typical of the problem which should concern the investigator.

Wetlaufer *et al.* (4) demonstrated that salt effects do exist in urea solutions. These workers found that the solubility of skatole in aqueous urea-sodium chloride solutions was measurably less than in solutions of the same urea concentration but containing no sodium chloride. Additionally, it was estimated that this "salting out" approximated that observed when the solubility of skatole in water and in water-sodium chloride solution was compared. Thus, it would seem that the salt effects are not only measurable but also are relatively independent of the urea concentration. In that event, one is in a favorable position to quantify similar effects in urea solutions in general.

THEORETICAL CONSIDERATIONS

The phenomena of "salting in" and "salting out" have been described empirically by the Setschenow equation (5):

$$\log S^{\circ}/S = KC \quad (\text{Eq. 1})$$

where S° and S are the molar solubilities of a nonelectrolyte in pure water and in a solution containing C moles/l. of electrolyte, respectively. The symbol, K , is an empirical salt parameter, which is characteristic of both the electrolyte and nonelectrolyte species.

For the case of low nonelectrolyte concentration, it can be assumed that the interactions between the molecules of nonelectrolyte are minimal and may be disregarded (6). Equation 1 then becomes

$$\log S^{\circ}/S = kC \quad (\text{Eq. 2})$$

where k is a salt parameter of considerably less complexity than K . Because of the relatively low solubilities of the drugs involved in the present study, as well as the availability of pertinent salt parameters in this form, it is convenient to use k rather than K . Mention is made of the more complex term, K , to emphasize the need for consideration of an alternative when the solubility of the drug or nonelectrolyte is proportionately greater.

The salt parameter, k , is often referred to as the "salting-out" constant. This may be misleading since the inference is that all electrolytes reduce the solubility of nonelectrolyte or drug species. Such is not the case. Referring to Eq. 2, it is seen that k is a salting-out constant if positive, but it becomes a salting-in constant if negative. Long and McDevitt (6) compiled data which show that the magnitude and algebraic sign of k are determined by the nature of the electrolyte and nonelectrolyte. For solutions of benzoic acid, the salt constant is positive when the electrolyte is composed of small ions, and it becomes increasingly negative as the size of the ions increases. For example, in sodium chloride, $k = +0.18$; while in tetraethylammonium iodide, $k = -0.63$. On replacing benzoic acid with salicylic acid, the same constants decrease by approximately 0.01.

At this point it is apparent that the solubility of a sparingly soluble drug varies in a regular fashion with the concentration of added electrolyte. Furthermore, the magnitude of the solubility of the drug in electrolyte solution relative to that in pure water is indicative of the nature of the electrolyte. One might now ask whether a similar rationalization is possible when the solvent is a urea-water mixture. In this regard, findings of Wetlaufer *et al.* (4) hold some promise. On substitution into Eq. 2, their data yield a value of $k = 0.13$ for the solubility of skatole in pure water relative to that in a 0.15 M NaCl solution. This compares favorably with $k = 0.18$, obtained for the solubility of skatole in a 7 M urea solution relative to that in a solution of the same urea concentration but 0.15 M in sodium chloride as well. These results suggest that the solubilizing of the urea and the salting out of the sodium chloride may be additive effects.

PRESENT INVESTIGATION

An extension of these findings was undertaken in the present investigation. The solubility of methyl salicylate and of methyl benzoate was studied as a function of varying urea and hydrochloric acid concentrations in an attempt to identify and estimate the effect of added electrolyte on the solubility of these esters in urea-water mixtures. The work presupposes the establishment of two criteria upon which subsequent interpretations are dependent. First, the salt parameter, k , is a characteristic of a particular electrolyte, at least in the case where the solutes are electrolytes of similar structure. Second, the salt parameter is relatively independent of the urea concentration.

EXPERIMENTAL

The solubilities of methyl salicylate and methyl benzoate were studied as a function of urea concentration in both neutral solutions and solutions adjusted to pH 1. In addition, the solubility of methyl salicylate was studied as a function of urea concentration in solutions containing sodium chloride. The experimental uncertainty was estimated to be 1%.

Materials—Urea, reagent grade;¹ methyl salicylate, Eastman grade;² methyl benzoate, reagent grade;³ hydrochloric acid, Baker analyzed reagent;¹ sodium chloride, reagent grade;¹ and methanol, absolute,¹ were used without further purification in this investigation.

Method—The neutral urea solutions, ranging in concentration from 0 to 5 M , were prepared in 25-ml. volumetric flasks by dissolving the appropriate amount of urea in distilled, deionized water

and diluting to volume. The acidic urea solutions, also ranging in concentration from 0 to 5 M , required additional precautions. The desired amount of urea was placed in a 25-ml. beaker and dissolved in a minimum of water. Then, by using a Corning model 10 pH meter, the solution was adjusted to pH 1 with concentrated hydrochloric acid. Enough water and acid were added to bring the volume of the solution to approximately 22–23 ml. The solution was transferred to a 25-ml. volumetric flask, where the volume of the solution was adjusted to the mark using 1-ml. portions of a 0.1 N hydrochloric acid solution, each of which had previously been used to rinse the original beaker. A final check of the resulting solvent system showed no measurable change from pH 1. All urea solutions were prepared on the day of their use.

Each 25-ml. sample of urea solution was transferred to a 50-ml. glass-stoppered flask. One milliliter of the methyl ester was introduced using a pipet. This quantity assured ample excess. The flask and contents were then placed in a shaker bath, thermostated at $30 \pm 0.2^{\circ}$, and allowed to equilibrate for 24 hr.

After the equilibration period, three 1-ml. samples of the clear supernatant were withdrawn from each flask by pipet. The pipets were equipped with a simple, cotton prefilter to exclude extraneous material and were preheated to ensure the continuous solubility of the ester within the sample. The samples were subsequently diluted to an appropriate volume, using a 1:10 water-methanol solvent mixture. The absorbance at 306 $m\mu$ for methyl salicylate or at 272 $m\mu$ for methyl benzoate was obtained with a Beckman DB-G spectrophotometer. The ester concentration was then obtained from a Beer's law plot. It had previously been determined that neither the acid nor the urea offered interference with the spectral measurements.

The work involving sodium chloride was handled in the same manner. Again, it was found that the salt offered no spectral interference.

pH of Urea-Water-HCl Mixtures—A 50-ml. sample of 8.0 M urea was transferred, by pipet, to a 100-ml. beaker which had been suspended in a bath thermostated at 30.0° . Electrodes from a Corning model 10 pH meter were then positioned so that contact was made with the urea solution in the beaker. Constant boiling hydrochloric acid, 20.248% by weight, was introduced in a stepwise fashion from a 50-ml. buret. The quantities of acid required for the mixture to reach pH values of 3.0, 2.5, 2.0, 1.5, and 1.0 were re-

Figure 1—pH of aqueous solutions containing both urea and hydrochloric acid.

Table I—Solubility of Methyl Salicylate in 1.5 *M* Sodium Chloride Solutions of Varying Urea Concentration at 30°

Urea Concentration, <i>M</i>	Solubility, mg./ml.	Salt Parameter, <i>k</i>
0	0.46	0.20
3	0.90	0.18
4	1.06	0.18
5	1.29	0.16

corded. The molar concentration of urea and of HCl at each of these pH values was calculated by assuming ideal additivity of the volumes of mixture and added titrant. The entire procedure was repeated for 1.0, 4.0, and 6.0 *M* urea solutions.

RESULTS AND DISCUSSION

This work may be viewed as the result of three successive determinations, each of which was dependent upon the preceding. Initially, it was necessary to establish the fact that a characteristic salt effect was identifiable and would yield quantitative results in solutions of varying urea concentration. The solubility of methyl salicylate in solutions of urea and sodium chloride was studied for this purpose. A parameter was then derived that represented the salt effects influencing the solubility of methyl salicylate in solutions of urea and hydrochloric acid. Finally, predictions based on the proposed model were compared with the experimental values observed for the solubility of methyl benzoate, also in solutions of urea and hydrochloric acid.

Methyl Salicylate-Urea-Sodium Chloride—The existence of measurable and predictable salt effects was verified by determining the solubility of methyl salicylate in solutions that were 1.5 *M* in sodium chloride but which contained varying concentrations of urea. This high concentration of sodium chloride represents an upper limit of the ionic strength in the hydrochloric acid-urea solutions shown in Fig. 1. At the same time, it provides data which may serve as an indication of the limit to which meaningful quantitative relationships may be extended.

Table I gives the observed solubility of methyl salicylate in aqueous systems of the indicated composition, as well as the salt

Table II—Solubility of Methyl Salicylate and Methyl Benzoate in Solutions of Urea at 30°

Ester	—Molar Concentration of Urea—					
	0	1	2	3	4	5
Ester Solubility, mg./ml.						
Methyl salicylate (neutral media)	0.95	1.15	1.39	1.69	1.95	2.23
Methyl salicylate (pH 1)	0.88	1.16	1.48	1.79	2.13	2.60
Methyl benzoate (neutral media)	2.42	2.90	3.34	3.75	4.30	4.88
Methyl benzoate (pH 1)	2.16	2.68	3.20	3.90	4.62	5.42

parameters for sodium chloride in each system. The latter were calculated according to Eq. 2 by comparing the solubilities of the ester in solutions of like urea concentration.

Thus, for example,

$$\log \frac{\text{solubility of drug in 5 } M \text{ urea}}{\text{solubility of drug in 5 } M \text{ urea} + 1.5 \text{ } M \text{ NaCl}} = kC \quad (\text{Eq. 3})$$

where the denominator of the log term is the solubility of methyl salicylate in the urea-salt solutions as given in Table I. The numerator is the solubility of methyl salicylate in solutions of urea alone and may be found in Table II. The salt concentration, *C*, is 1.5 in all cases.

The results shown in Table I establish the criteria necessary for continued effort on the overall problem. The salt parameter for sodium chloride in these solutions agrees well with the value cited earlier (6) with regard to the effect of this salt on the aqueous solubility of salicylic acid. In view of the high concentration of salt used in the present work, the agreement is excellent. Additionally, the parameter is in fair agreement with the value calculated in connection with the solubility of skatole (1). This is as expected, since skatole bears some structural resemblance to methyl salicylate. Furthermore, the salt parameter appears to be only slightly dependent on the urea concentration. Presumably, even this small dependence will vanish at lower salt concentrations, where the change in sodium chloride activity with urea concentration decreases (7).

From the foregoing, it must be concluded that the solubility of a drug in urea-water systems containing electrolyte relative to that in electrolyte-free solutions may be approximated in a quantitative fashion. This, in turn, assumes prior knowledge of the sign and magnitude of the salt parameter and a realization that the predictions are less valid at high salt and high urea concentrations. The effects under consideration are not those by which urea-solute or urea-solvent interactions alter drug solubility, but are simply those which are presumed to result from the presence of electrolyte species.

Methyl Salicylate-Urea-Hydrochloric Acid—In contrast to the work already discussed, the solubility of methyl salicylate in urea solutions at pH 1 presents an interesting complication. Unlike the obviously consistent and predictable effect produced by adding sodium chloride, Fig. 2 suggests the salt effect of hydrochloric acid is strongly dependent on the urea concentration. In the absence of urea, hydrochloric acid salts out the ester. Then, as the urea concentration is increased, a salting in appears, which offsets the initial effect and soon predominates. As seen from Fig. 1, the concentration of hydrochloric acid is increasing along with that of the urea. This suggests the possibility of a relationship between the increasing salt effect and the increasing acid concentration. However, a direct correlation seems impractical since hydrochloric acid characteristically salts out benzoic acid derivatives (6), and the addition of more acid should further decrease the solubility of the methyl salicylate. The answer to this paradox rests with observations that these solutions may contain another species in addition to the obvious components.

Consider, first, the fact that the solubility of methyl salicylate increases with additional acid and urea. In terms of the earlier discussion, this phenomenon results when the ions of the added electrolyte are large. Although one might regard the hydronium ion and its associated waters of hydration as being large, an explanation of the enhanced solubility on the basis of additional hydrochloric acid is out of the question. The results of this investigation, as well as those cited from other workers, have shown that this acid definitely salts out the ester.

Figure 2—Solubility of methyl salicylate in solutions of urea. Key: □, experimental points determined in neutral media; ○, experimental points determined at pH 1; —, plot of Eq. 5; and - - -, plot of Eq. 6.

Figure 3—Solubility of methyl salicylate in solutions of urea adjusted so as to exclude the salting out of the hydrochloric acid. Key: —, plot of Eq. 5; and - - -, plot of Eq. 7.

Second, the activity of the hydrochloric acid is drastically reduced in urea solutions, as implied from Fig. 1. Of the explanations for this particular phenomenon, the formation of some proton-urea complex seems the more feasible at the present time. Thus, Bull *et al.* (8) studied the conductance of hydrochloric acid in aqueous solutions of urea. Their findings suggest the existence of an electrolyte species that is considerably less mobile, and presumably bulkier, than the proton. This view has been supported by spectral (9) and dilatometric (10) evidence, as well. In essence, these workers have described an electrolyte species which is capable of salting in.

By assuming this interaction to be a fact, it becomes possible to rationalize the conditions that account for the observed ester solu-

Figure 4—Solubility of methyl benzoate in solutions of urea containing the hydrochloric acid-urea complex. Key: O, values calculated according to Eq. 2; and —, plot of Eq. 11.

bilities in acid media. For example, consider an aqueous solution saturated with respect to methyl salicylate at pH 1. The concentration of ester in this solution is approximately 0.05 mg./ml. less than it would be in neutral media because of the salting out caused by the nearly 0.1 *M* concentration of hydrochloric acid. If this solution is made 5 *M* in urea, Fig. 1 shows that the hydrochloric acid concentration must be increased to 0.90 *M* to maintain the pH at 1. At the same time, the concentration of methyl salicylate increases to 2.60 mg./ml. Since the pH is 1, the activity of the hydrochloric acid must, likewise, remain at 0.1 *M*, as in the original solution. As a result, the new solution is 0.8 *M* in a species which is not contributing to the acidity *per se*. This is the quantity of hydrochloric acid that has interacted with the urea to form the larger, salting-in species. In that event, the concentration of unreacted or pure urea has decreased to 4.2 *M*. Thus, the final solution may be described as being 0.1 *M* in acid, 4.2 *M* in urea, and 0.8 *M* in the complex and containing 2.60 mg./ml. of methyl salicylate.

The use of the term "complex" to define the acid-urea interaction product does not necessarily imply that the authors advocate complex formation in the customary sense. The exact nature of the interaction is uncertain and open to conjecture. Use of the term is simply an expediency, which will be employed throughout the remainder of this report. Additionally, it appears that the authors have tacitly assumed a relatively simple relationship between the observed pH values and the corresponding concentrations of the electrolytes in each solution. Unfortunately, such a relationship is inaccurate. However, since the final conclusion is unaffected by this assumption, it was decided to utilize this approach to simplify the discussion.

Salt Parameter for the Complex—A straightforward calculation of a salt parameter for the complex was precluded by the presence of a second salt, namely, the "unreacted" hydrochloric acid. This situation is simplified considerably if the data are adjusted so as to exclude the salting-out effect of the hydrochloric acid. An attempt was made to quantify this effect, using the data of both the methyl salicylate and methyl benzoate solubilities at pH 1. The adjustments proved to be unduly complicated; in view of the associated experimental uncertainties, the attempt was abandoned in favor of a more direct but approximate procedure. Since the activity of the acid is presumed to be constant by virtue of maintaining the pH at 1, and in view of the findings with regard to the initial study on the salt effects at constant sodium chloride concentration, it was assumed that the salting-out effect of the hydrochloric acid was the same over the entire range of urea concentrations studied. Thus, in equation form, the assumption was

$$\log S^{\circ}/S^{*} = \text{constant} \quad (\text{Eq. 4})$$

where S° is the solubility of ester in neutral media; and S^{*} is the solubility of ester in a hypothetical solution containing water, urea, and the acidic form of the hydrochloric acid only. The error introduced is minimized by the fact that the salting-out effect is, in addition, relatively small. Using a parameter of 0.1 (4), the constant in Eq. 4 becomes 0.01. This particular value is not derivable from the present data, but it does reflect the magnitude of the effect.

The actual adjustment is illustrated in Fig. 3. The dashed curve in Fig. 2, which represents the solubilities of methyl salicylate at pH 1, has been shifted upward so that its intercept now corresponds with that of the solid curve, representing the solubilities in neutral media. In effect, this cancels the salting out of the "acidic" hydrochloric acid.

The use of empirical equations presents a more quantitative view of the procedure. Equations 5 and 6 are the result of a least-squares treatment of the data in Table II and represent the solubilities of methyl salicylate, S , as functions of urea concentration, U , in neutral media and at pH 1, respectively.

$$S = 0.94 + 0.211 U + 0.010 U^2 \quad (\text{Eq. 5})$$

$$S = 0.89 + 0.247 U + 0.018 U^2 \quad (\text{Eq. 6})$$

If the curve is shifted upward, Eq. 6 becomes

$$S = 0.94 + 0.247 U + 0.018 U^2 \quad (\text{Eq. 7})$$

and, to a good approximation, represents the solubility of methyl salicylate in urea solutions that contain the acid-urea complex only.

The salt parameter for the complex may be determined by using the appropriate values obtained from Eqs. 5 and 7 and Fig. 1. The variables used in Eq. 2 are defined as: S° = the solubility of methyl salicylate in a solution containing U moles/l. of urea and C moles/l. of the complex; C = the molar concentration of the complex, found by subtracting 0.1 M from the concentration of hydrochloric acid in a U M urea solution at pH 1; and S° = the solubility of methyl salicylate in neutral media containing U' moles/l. of unreacted urea, where $U' = (U - C)$.

As an example, consider the solubility of methyl salicylate in 5 M urea at pH 1. It was shown earlier that this solution, while 5 M in total urea, is only 4.20 M in unreacted urea. Substitution of the latter value in Eq. 5 gives $S^\circ = 2.01$ mg./ml. Using 5 M in Eq. 7, one finds $S = 2.63$ mg./ml. Since the solution is presumably 0.80 M in the complex, Eq. 2 becomes

$$\log 2.01/2.63 = 0.80 k \quad (\text{Eq. 8})$$

A similar treatment also was applied to solutions 1, 2, 3, and 4 M in urea. The pertinent data are listed in Table III. Subsequently, a value of $k = -0.160$ was determined from the slope of a $\log S^\circ/S$ versus C plot.

Methyl Benzoate-Urea-Hydrochloric Acid—The basic premise of this paper may now be tested by using the salt parameter for the complex to predict analogous effects on the solubility of other non-electrolyte solutes. The methyl benzoate solubility data, given in Table II, were used for this purpose. In neutral media and at pH 1, respectively, these data may be represented as

$$S = 2.52 + 0.295 U + 0.038 U^2 \quad (\text{Eq. 9})$$

$$S = 2.16 + 0.457 U + 0.039 U^2 \quad (\text{Eq. 10})$$

On shifting the intercept, as is done with the data on methyl salicylate to exclude the salting out of the acidic hydrochloric acid, Eq. 10 becomes

$$S = 2.52 + 0.457 U + 0.039 U^2 \quad (\text{Eq. 11})$$

If the proposed method is correct, it should be possible to calculate solubility data at pH 1, given data in neutral media and the necessary parameters for Eq. 2. In a like manner, the data in neutral media may be determined from those at pH 1. As an example, assume that the solubilities of methyl benzoate in neutral urea solutions are known and that the data at pH 1 are desired. The procedure is to (a) calculate the product $k C$, using the value $k = -0.160$ and the appropriate C ; (b) determine S° , using the corresponding U' and Eq. 9; and (c) calculate S , using Eq. 2. For purposes of illustration, it is convenient to use the values for C and U' given in Table III. Thus, at $U' = 4.20$, S° is found to be 4.43 mg./ml. and C is 0.80. On substitution, Eq. 2 becomes

$$\log 4.43/S = (-0.160)(0.80) \quad (\text{Eq. 12})$$

from which the solubility of methyl benzoate in a 5 M urea solution at pH 1, S , is calculated to be 5.95 mg./ml. Five such values were derived and are indicated by circles in Fig. 4. For comparison, the figure includes a curve representing Eq. 11. The agreement is excellent and attests to the validity of the proposed concepts.

An interesting situation becomes evident when these findings are extended to an earlier investigation reported by Feldman and Gibaldi (1). These workers determined the thermodynamic changes associated with the solution of salicylic and benzoic acids in urea solutions at pH 1. Their results are based on a direct application of solubility data, without regard for the salting-in effects suggested in the present study. As such, the calculated free energy changes are probably too high, and actually represent a composite of the salting-in and urea-water effects. By way of comparison, the parameters previously outlined indicate that the free energy values derived by Feldman and Gibaldi for their 3 M urea systems should be reduced by 110 cal./mole. In turn, this would require an adjustment of the observed entropy changes. On the average, these alterations would represent approximately 25% of the reported values.

pH of Urea-Water Solutions—Figure 1 is a composite of the results obtained by titrating various urea solutions with concentrated hydrochloric acid, according to the procedure outlined in the *Experimental* section. The data at pH 1 were used in the present investigation. The additional values are included for informational purposes only. It is not presumed that this figure represents other

Table III—Data Employed in Calculation of the Salt Parameter, k

5	0.80	4.20	2.01	2.63	0.118

than a good approximation. The observations are similar to those described by Bull *et al.* (8), except that the current data were obtained for much higher acid concentrations.

A problem in interpretation arises with the realization that these are not actually pH values. With a change in solvent from water to a urea-water mixture, the term pH loses its meaning, and there is no assurance that a pH meter is indicating hydrogen-ion activity. As a result, there are additional uncertainties in the assumptions made earlier with regard to the concentration of "free" or uncomplexed HCl. None of these uncertainties, however, greatly affects the findings of this investigation.

The determination of actual hydrogen-ion activities is beyond the scope of the present work. Nevertheless it is still possible to estimate the effect of changing solvents by using a modification of the Born equation (11). On substituting the appropriate dielectric constants, one finds that a 1-mv. change in potential may be expected on transferring a 1-1 electrolyte of given activity from water to a solvent having the dielectric constant of a 5 M urea solution. This is, admittedly, an oversimplification of a complex problem, but the treatment should convey the magnitude of the effect. In relation to the practice of equating pH and concentration, the effect would seem to be negligible.

While it would be desirable from the standpoint of establishing a more accurate value for the salt parameter, k , a precise knowledge of the "free" HCl concentration is unnecessary for the present purpose. In the final analysis, the term $\log S^\circ/S$ relates the ester solubilities in HCl-urea solutions. Through the relationship $S^\circ = f(U-C)$, this term is found to be somewhat insensitive to variations in the concentration of uncomplexed acid. For example, a 25% error in "free" acid concentration produces only a 5% error in $\log S^\circ/S$ in 1 M urea. This is considerably smaller than the potential error if the salt effect is disregarded completely. In view of the results, it appears that the approximation, $\text{pH} = \text{"free" acid concentration}$, is reasonable. It is by no means precise. A more precise analysis will depend on a quantitative evaluation of the activity coefficients as a function of ionic strength and solvent composition.

CONCLUSION

It is well to emphasize that the model proposed in this paper is speculative. To indicate otherwise would presuppose intimate knowledge of a solvent system which is, to say the least, complex and little understood. The treatment, of necessity, is based on circumstantial evidence. However, the high degree of self-consistency within the model cannot be denied, and it would seem that any real judgment against it must await additional evidence. At this time, there appears to be little reason why a similar analysis cannot be applied to any aqueous urea solution, provided, of course, that the characteristic salt constant is known or determined.

Common Receptor-Complement Feature among Some Antileukemic Compounds

KWANG-YUEN ZEE-CHENG and C. C. CHENG

Abstract □ A common structural feature was found among some nonalkylating antileukemic agents such as aminopterin, anthramycin, 5-azacytidine, bisketopiperazines, camptothecin, cytosine arabinoside, daunomycin, demecolcine, emetine, glutarimide antibiotics, harringtonine, 6-mercaptopurine riboside, methotrexate, sangivamycin, streptonigrin, tylocerebrine, tylophorine, vinblastine, and vincristine. This structural feature consists of a triangulation composed of one nitrogen and two oxygen atoms with rather definite interatomic distances. This structural characteristic may contribute to the *in vivo* binding to one of the pertinent receptor sites involved in leukemia geneses.

Keyphrases □ Antileukemic compounds—common receptor complement □ Structural similarity, antileukemic agents—triangular pattern, nitrogen, oxygen atoms □ Oxygen, nitrogen pattern, interatomic distances—antileukemic activity

In connection with structure-activity studies of various oncolytic agents, a common structural feature was noted among a number of antileukemic agents. The purpose of this paper is to present a preliminary account of this observation.

THEORETICAL

The tylophora alkaloids (1), tylocerebrine (I) and tylophorine (II), were found to possess antileukemic activity against leukemia L-1210 in mice (2). The nucleus of these alkaloids, phenanthro-[9,10:6',7']indolizidine (III) (3), however, is devoid of the activity (4) exhibited by the polysubstituted methoxy derivatives.

The antibiotic streptonigrin (IV), the structure of which contains an *o*-aminoquinone unit (5), exhibits a broad spectrum of inhibitory activity against a number of leukemias, lymphomas, carcinomas, and other tumor systems (6-13). Although the *o*-aminoquinone unit is also present (5) in two other types of antitumor antibiotics (mitomycin C and actinomycin D, for example), a synthetic compound, 7-amino-6-methoxy-5,8-quinolinedione (V) (14), which possesses a partial structure of this antibiotic in that it contains the *o*-aminoquinone unit, failed to retain the original antileukemic activity.¹

It has been reported that the hydroxyl and carbonyl groups presented in the lactone ring portion of camptothecin (VI) (15–19) may account for the antileukemic activity displayed by this alkaloid. Modification or replacement of these functions resulted in deprivation of its oncolytic property (15, 18, 19).

A comparative study of the structure of these compounds, using the Briegleb (20)–Stuart (21) molecular models, revealed that there is a common atomic arrangement among these very differently constituted molecules. Three electronegative atoms, containing at

least one lone pair of electrons—one nitrogen and two oxygen atoms—form a triangle with very distinct parameters. The interatomic distances are rather definite, as shown in Fig. 1.

The triangular arrangements in Compounds I, II, IV, and VI are indicated by dotted lines. It is obvious that no such relationship could be found in Compounds III and V.

This interesting observation immediately prompted an examination of the structure of other compounds with antileukemic activity (at least active *versus* L-1210). This included demecolcine (VII) (22–24); aminopterin (VIIIa) (25–28); methotrexate (VIIIb) (27) [many related compounds such as dichloromethotrexate, 2,4-diaminopyrimidine analogs of aminopterin and methotrexate, and

^a Interatomic distance of conformed conformation.

quinazoline antifolates, which can have similar triangular arrangements, also displayed antileukemic activity (29–35)]; vinblastine (IXa) and vincristine (IXb) (36–44); the methyl ether of anthramycin (X) (45–49); daunomycin (XI) (50–56); the glutarimide antibiotics cycloheximide (XIIa, actidione), E-72 (XIIb), and streptovitacin A (XIIc) (57–69); bisdiketopiperazines (XIII, R = H, CH₃) (70, 71); harringtonine (XIV) (72); sangivamycin (XV) (73–75) [toyocamycin (76), which lacks the side-chain amide group, is devoid of antileukemic activity]; 6-MP riboside (XVI) (77–80) [the active form of 6-MP riboside, as well as for 6-MP, is 6-MP ribonucleotide (80)] and related compounds (80–83); cytosine arabinoside (XVII) (84–89); 5-azacytidine (XVIII) (90–95); and emetine (XIX) (96). The interatomic distances (Table I) indicated by the dotted lines, determined from the Briegleb (20)–Stuart (21) molecular models, with minor deviations in the values of anthramycin and harringtonine, are all intriguingly within the limitations of the values shown in Fig. 1.

The relationship between the triangular pattern and antileukemic activity is further substantiated by the reports that neither daunomycinone (the aglycone of daunomycin) nor the amino sugar daunosamine possesses antileukemic activity,¹ and that the indole and indoline units of vinblastine and vincristine, when separated, are also inactive (97, 98). Triangular patterns of different sizes and shapes have been reported in explaining sites of other receptors (99–101) (the muscarinic, nicotinic, histamine, serotonin, inflammatory, etc.). Although some of the triangulations are also composed of one nitrogen and two oxygen atoms, the compounds were inactive against leukemia L-1210.¹ The interatomic distances in these cases differ markedly from those illustrated in Fig. 1.

DISCUSSION

It appears that the triangular pattern, which is present among the aforementioned antileukemic compounds of both synthetic and

Figure 1—N—O—O triangular pattern.

natural origin, may actually contribute to the binding to one of the pertinent receptor sites (99–107) in certain biopolymers (proteins, polysaccharides, nucleic acids, etc.) involved in leukemia geneses. Thus, it may result in inhibiting the active site of the enzymes, in altering the specificity of enzyme systems, in disturbing the template molecules in transcription process, in changing the permeability of certain biological membranes, or in causing other interruptions of biological functions. Admittedly, the present observation is quite empirical, and the facts as presented are oversimplified. Additional work, such as molecular orbital calculations of preferred conformations of molecules and electron-density distribution of atoms, is definitely needed to verify the finding. Furthermore, the triangular pattern cannot be used to explain the antileukemic activity of some other compounds including hydroxyurea,² ellipticine,² and biological alkylating agents. Nevertheless, perhaps the receptor-complement feature can be used to explore the *in vivo* drug interaction in greater detail. It can also be regarded, among other considerations,³ as one of the working hypotheses in designing better and more useful antileukemic drugs.

Theoretical Justification of Reciprocal Rate Plots in Studies of Water Vapor Transmission through Films

DANE O. KILDSIG, RONALD L. NEDICH*, and GILBERT S. BANKER

Abstract □ A theoretical equation has been developed justifying the graphical representation of vapor permeation data by $1/\text{rate}$ versus film thickness plots. The permeability coefficient for the film may be determined from the slope of this plot and has units in square centimeters per second. The intercept at zero film thickness is dependent upon the geometry of the experimental design and the diffusion coefficient for the vapor within the diffusion cell. The derivation of the equation assumes a nonequilibrium condition for water vapor in the diffusion cell, as well as the existence of steady-state conditions.

Keyphrases □ Water vapor—transmission through films □ Film transmission—water vapor □ Reciprocal rate plots, vapor transmission—theoretical justification □ Polymeric, unplasticized films—water vapor transmission

The passage of water vapor through polymer films, with reference to the free films having potential application as tablet film coatings, has been reported in the

pharmaceutical literature (1-3). In the first of these studies (1), a vacuum was created on one side of the film so that a pressure difference existed across the film. More recently (2, 3), the transfer of water vapor through films has been studied in which a water vapor pressure difference existed but in which the total pressure, atmospheric, was the same on both sides of the film. In these investigations (2, 3), a linear relationship was found between the reciprocal of the rate of water vapor permeation and film thickness. In one case (2), the authors stated: "An interesting relationship is observed when $(w/t)^{-1}$ is plotted against thickness of film; although no theoretical basis for such a plot can be proposed at the present time, we feel it is worth presenting." The research described by this study and the accompanying theory present a theoretical justification for the linear relationship between the reciprocal of rate of water vapor permeation and film thickness.

THEORY

Previous investigations have used equations that relate the rate of vapor transfer to the water vapor pressure differential existing across the film. Alternatively, an expression may be used relating this rate to the concentration difference existing across the film:

$$\frac{R}{a} = \frac{PA \Delta C}{a} \quad (\text{Eq. 1})$$

where R is the rate of permeation, P is the permeability coefficient, A is the area of the film, a is its thickness, and ΔC is the water vapor concentration difference across the film. ΔC may be expressed in any suitable units such as molecules. The type of transmission cell used in previous investigations (2, 3) is shown in Fig. 1, where $\Delta C = C_1 - C_2$.

In calculating ΔC , the diffusion of water vapor from the surface of the liquid to the polymer film must first be considered. Because the distance between the liquid and the film influences the rate of water vapor transmission through the film (4), it can be assumed that the vapor pressure at the film surface is not in equilibrium with the liquid surface, and that a vapor pressure difference exists through this distance. The diffusion through this distance is given by Fick's one-dimensional equation:

$$\frac{\partial C}{\partial t} = \frac{D \partial^2 C}{\partial x^2} \quad (\text{Eq. 2})$$

Figure 1—Schematic diagram of water vapor transmission cell depicting water concentrations existing at various surfaces. C_0 = concentration of molecules above liquid surface, C_1 = concentration of molecules at inside film surface, and C_2 = concentration of molecules at outside film surface.

Theoretical Justification of Reciprocal Rate Plots in Studies of Water Vapor Transmission through Films

DANE O. KILDSIG, RONALD L. NEDICH*, and GILBERT S. BANKER

Abstract □ A theoretical equation has been developed justifying the graphical representation of vapor permeation data by $1/\text{rate}$ versus film thickness plots. The permeability coefficient for the film may be determined from the slope of this plot and has units in square centimeters per second. The intercept at zero film thickness is dependent upon the geometry of the experimental design and the diffusion coefficient for the vapor within the diffusion cell. The derivation of the equation assumes a nonequilibrium condition for water vapor in the diffusion cell, as well as the existence of steady-state conditions.

Keyphrases □ Water vapor—transmission through films □ Film transmission—water vapor □ Reciprocal rate plots, vapor transmission—theoretical justification □ Polymeric, unplasticized films—water vapor transmission

The passage of water vapor through polymer films, with reference to the free films having potential application as tablet film coatings, has been reported in the

pharmaceutical literature (1-3). In the first of these studies (1), a vacuum was created on one side of the film so that a pressure difference existed across the film. More recently (2, 3), the transfer of water vapor through films has been studied in which a water vapor pressure difference existed but in which the total pressure, atmospheric, was the same on both sides of the film. In these investigations (2, 3), a linear relationship was found between the reciprocal of the rate of water vapor permeation and film thickness. In one case (2), the authors stated: "An interesting relationship is observed when $(w/t)^{-1}$ is plotted against thickness of film; although no theoretical basis for such a plot can be proposed at the present time, we feel it is worth presenting." The research described by this study and the accompanying theory present a theoretical justification for the linear relationship between the reciprocal of rate of water vapor permeation and film thickness.

THEORY

Previous investigations have used equations that relate the rate of vapor transfer to the water vapor pressure differential existing across the film. Alternatively, an expression may be used relating this rate to the concentration difference existing across the film:

$$\frac{R}{a} = \frac{PA \Delta C}{a} \quad (\text{Eq. 1})$$

where R is the rate of permeation, P is the permeability coefficient, A is the area of the film, a is its thickness, and ΔC is the water vapor concentration difference across the film. ΔC may be expressed in any suitable units such as molecules. The type of transmission cell used in previous investigations (2, 3) is shown in Fig. 1, where $\Delta C = C_1 - C_2$.

In calculating ΔC , the diffusion of water vapor from the surface of the liquid to the polymer film must first be considered. Because the distance between the liquid and the film influences the rate of water vapor transmission through the film (4), it can be assumed that the vapor pressure at the film surface is not in equilibrium with the liquid surface, and that a vapor pressure difference exists through this distance. The diffusion through this distance is given by Fick's one-dimensional equation:

$$\frac{\partial C}{\partial t} = \frac{D \partial^2 C}{\partial x^2} \quad (\text{Eq. 2})$$

Figure 1—Schematic diagram of water vapor transmission cell depicting water concentrations existing at various surfaces. C_0 = concentration of molecules above liquid surface, C_1 = concentration of molecules at inside film surface, and C_2 = concentration of molecules at outside film surface.

where D is the diffusion coefficient for water vapor in air. If a steady state is assumed,

$$\frac{\partial C}{\partial t} = 0 \quad (\text{Eq. 3})$$

Therefore,

$$\frac{D\partial^2 C}{\partial x^2} = 0 \quad (\text{Eq. 4})$$

or

$$\frac{\partial C}{\partial x} = \text{constant} \quad (\text{Eq. 5})$$

$\partial C/\partial x$ may be related to the concentration of water vapor by the equation

$$\frac{\partial C}{\partial x} = \frac{C_1 - C_0}{L} \quad (\text{Eq. 6})$$

where L is the distance between the liquid surface and the film, and C_0 is the equilibrium concentration of water molecules above the liquid surface (Fig. 1). The steady-state assumption may be justified by observing the rate dependence on the liquid-film distance and the linearity of the rate of water vapor transmission.

The quantity of water that has evaporated and diffused, W , during time t is given by

$$W = \frac{-DA'A(C_1 - C_0)}{L} \quad (\text{Eq. 7})$$

where A' is the area of the liquid surface.

Because the diffusion coefficient, D , may be dependent upon the concentration difference, $C_1 - C_0$ (5), the diffusion coefficient is more accurately represented by the mean diffusion coefficient, \bar{D} , of the form

$$\bar{D} = \frac{1}{C_1 - C_0} \int_{C_0}^{C_1} D(c) dc \quad (\text{Eq. 7a})$$

In the absence of data quantifying the concentration dependence of D on water vapor concentration for the water vapor-air system, only the observed mean value of the diffusion coefficient, \bar{D} , can be determined.

The concentration of water vapor at the inside surface of the film, C_1 , may then be calculated from the equation:

$$C_1 = C_0 - \frac{WL}{\bar{D}A't} \quad (\text{Eq. 8})$$

If the effective film surface area is assumed to be equal to the liquid surface area, Eq. 8 may be written as

$$C_1 = C_0 - \frac{WL}{\bar{D}At} \quad (\text{Eq. 9})$$

Further assumption of steady-state diffusion within the diffusion cell implies that $W/t = R$, where the symbols are as previously defined. As a result, Eq. 9 becomes

$$C_1 = C_0 - \frac{RL}{\bar{D}A} \quad (\text{Eq. 10})$$

If C_2 , the concentration of water outside the film, is maintained at zero, $\Delta C = C_1$. Therefore,

$$\Delta C = C_0 - \frac{RL}{\bar{D}A} \quad (\text{Eq. 11})$$

Substituting this relationship for ΔC into Eq. 1 and taking the reciprocal yield

$$\frac{1}{R} = \frac{a}{PAC_0} + \frac{L}{DAC_0} \quad (\text{Eq. 12})$$

It can be seen from this equation that a plot of $1/\text{rate of permeation}$

Table I—Description of the Polymers Employed

versus film thickness should be linear with a slope of $1/PAC_0$ and an intercept of $L/\bar{D}AC_0$.

EXPERIMENTAL

Polymer Selection and Solution Preparation—Methylhydroxypropoxyl ethers of cellulose,¹ viscosity grades 5-7, 50, and 400 cps., were selected for use in this study (Table I). Their selection was based on their ability to form free unplasticized films, their solubility in aqueous and organic solvent systems, and their widespread commercial use as pharmaceutical coating materials.

Solutions, 3% w/v, were prepared by dispersing the polymers in either deionized water or an organic solvent system consisting of methylene chloride, methyl alcohol, and isopropyl alcohol in a 40:30:30 ratio. The solvents were cooled to 5° prior to polymer addition and were stirred until the dispersions reached room temperature. The solutions were brought to volume and allowed to solvate for a minimum of 24 hr. before use.

Preparation of Free, Unplasticized Film Samples—Free films were prepared by pouring the polymer solutions onto a clean, leveled surface of aluminum foil. Film area was controlled by the use of a

Figure 2—Transmission of water vapor through the cellulose films as a function of time:

4	5-7 cps.	Organic

rectangular 10 × 15-cm. Plexiglas frame, and film thickness was varied by adjusting the volume of the polymer solution employed. Organic cast films were allowed to evaporate for 12 hr. at room temperature before removal from the substrate. Films cast from deionized water were dried in an oven at 50° for 12 hr. before removal from the substrate. Films cast from deionized water, which were dried for 48-60 hr. at room temperature, showed no significant difference in permeation properties compared with those dried in the oven at 50°. The film was removed from the aluminum foil by peeling the substrate away in strips.

Film samples were cut from the sheet with a metal cylinder having an internal diameter of 2.35 cm. Film thickness was determined with a micrometer. The samples were stored in a desiccator over calcium sulfate for 5 days prior to use.

Transmission Cell and Environmental Chamber—The type of experimental design used in this study was similar to that used in previous investigations (2, 3).

A saturated solution of sodium tartrate was placed in each transmission cell (Fig. 1), maintaining a relative humidity of 91% at 30° equivalent to a vapor pressure of 28.96 mm. of mercury. Since the film-to-liquid surface was found to be a critical factor in the reproducibility of results, a sufficient volume of the saturated solution (approximately 5 ml.) was utilized to ensure an initial distance of 4.5 cm. between the liquid surface and the film sample. The cells were placed within a glovebox at 30° and maintained at a relative humidity below 3% using anhydrous calcium sulfate. Each cell was weighed on an analytical balance within the glovebox initially and at 12-hr. intervals for a 72-hr. period. The value of C_0 , the equilibrium concentration of vapor existing above the solution having a vapor pressure of 28.96 mm. of mercury, was calculated to be 9.2×10^{17} molecules/cm.³, using the ideal gas law.

Table II—Permeability Coefficients for Water Vapor Permeation through Methylhydroxypropoxyl Ethers of Cellulose Films

RESULTS AND DISCUSSION

The transmission of water vapor through the polymer films was linear with time and dependent on film thickness and composition (Fig. 2). For a given polymer the relationship between 1/rate and film thickness was linear, as predicted by Eq. 12 (Fig. 3). The permeability coefficient, P , which reflects the interaction of the vapor with the film and its diffusion through the film, can be determined from the slope in Fig. 2, since the slope is $1/PAC_0$, and C_0 and A are constants. The permeability coefficients for films of the three molecular weight grades of the hydroxypropyl methylcellulose polymer, for films cast from both an organic solvent and water, are shown in Table II. Without exception the water-cast films had a lower permeability coefficient, although this difference decreased as the molecular weight of the polymer increased and is probably not significant for the water-cast *versus* organic solvent-cast 400-cps. polymer films.

This approach, *i.e.*, the method of data expression shown in Fig. 3, provides a direct experimental method for determining permeability coefficients. When determined in this manner, the units of P are square centimeters per second, and the solubility coefficient, S , in the relationship $P = DS$ is dimensionless. The linearity of the graphical data (Fig. 3) indicates that P is independent of film thickness over the range of thickness studied.

The permeability of the film does affect the concentration gradient existing in the diffusion cell. As the permeability of the film decreases and the rate of water vapor transfer through the film decreases, the concentration gradient within the diffusion cell, $C_0 - C_1$, decreases, and equilibrium conditions are approached. Conversely, an increase in film permeability increases the concentration gradient, $C_0 - C_1$. Although the concentration gradient across the film, $C_1 - C_2$, decreases, the increased permeability of the film would result in a greater total flux through the film.

The intercept in Fig. 2, $L/\bar{D}AC_0$, is dependent on the geometry of the experimental design and the value of the mean diffusion coefficient, \bar{D} . Since L remained essentially constant during the experiment (a maximum change of 1% occurred), the values of \bar{D} were readily calculated from the intercept values ($L/\bar{D}AC_0$) and are reported in Table III. The values determined for \bar{D} are lower, although of the same order of magnitude, compared to those for water vapor-air in a semiinfinite column (Table III) and must reflect the dependence of the diffusion coefficient on water vapor concentration. The linearity of Fig. 3 also indicates that \bar{D} is a function of concentration only and is not dependent on film thickness. As such, the observed variations in \bar{D} do not affect the magnitude of the permeability coefficient nor the graphical method used in determining the permeability coefficient.

SUMMARY AND CONCLUSIONS

In the past, investigators have graphically represented water vapor permeation data by plotting 1/rate *versus* film thickness. A theoretical basis for this relationship was not apparent. A theoretical justification for this relationship has been derived, based on the

observation that an equilibrium does not exist between the liquid surface and the film for water vapor. The resulting equation readily leads to the calculation of a permeability coefficient for the film; the units of P are the same as the diffusion coefficient, square centimeters per second. A steady state was assumed to exist within the diffusion cell following the lag time. This was justified by the linearity of the graphical data in Fig. 1. The theory was tested with films of unplasticized methylhydroxypropoxyl ethers of cellulose cast from water and an organic solvent and the permeability coefficients were calculated from the slope of $1/\text{rate}$ versus film thickness. This provides a direct experimental method for easily determining permeability coefficients and, by maintaining constant cell geometry, relative permeability values can be assigned to any film or series of films.

Potential Anticancer Agents VI: 5-Substituted Pyrimidine-6-carboxaldehydes

CHUNG IL HONG*, CLAUDE PIANTADOSI†, and J. LOGAN IRVIN

Abstract □ A series of 5-substituted pyrimidine-6-carboxaldehydes and their derivatives were synthesized and tested for inhibition of growth of the Ehrlich ascites carcinoma and Ehrlich carcinoma. Further studies included inhibition of incorporation of L-phenylalanine-1- ^{14}C and formate- ^{14}C into proteins, and orotic acid-5- ^3H , thymidine-2- ^{14}C , and formate- ^{14}C into nucleic acids of the ascitic tumor cells *in vitro*. The following compounds were found to be particularly active as inhibitors: 2-mercapto-4-hydroxy-5-(3-phenylpropyl)pyrimidine-6-carboxaldehyde (VIII-2), 2-mercapto-4-hydroxy-5-(4-phenylbenzyl)pyrimidine-6-carboxaldehyde (VIII-3), and 2-mercapto-4-hydroxy-5-(α -naphthylmethyl)pyrimidine-6-carboxaldehyde (Ic). The best compounds of this series are equally as effective as 5-fluorouracil and 2-mercapto-4-hydroxy-5-(4-chlorobenzyl)pyrimidine-6-carboxaldehyde (Ib) in inhibiting formate incorporation into DNA and growth of the ascitic tumor. They are more effective than 5-fluorouracil in inhibiting incorporation of formate and orotic acid into RNA, thymidine into DNA, and phenylalanine into proteins. The active compounds also showed a strong inhibitory activity against respiration of the ascitic tumor. Compounds VIII-2 and VIII-3 also inhibited growth of the Ehrlich carcinoma as a solid tumor after subcutaneous transplantation, but in these tests the drugs were more toxic to the host when injected intraperitoneally since the drugs were not preferentially absorbed by the tumor cells in contrast to the tests *versus* the ascites form of the carcinoma.

Keyphrases □ Pyrimidine-6-carboxaldehydes, 5-substituted—synthesis □ Anticancer activity—5-substituted pyrimidine-6-carboxaldehydes □ Protein synthesis inhibition—5-substituted pyrimidine-6-carboxaldehydes □ Nucleic acid synthesis inhibition—5-substituted pyrimidine-6-carboxaldehydes □ Tumor aerobic respiration inhibition—5-substituted pyrimidine-6-carboxaldehydes

In earlier studies (1-3) on 5-substituted derivatives of Compound I, it was observed that 5-fluoro (Ia) and 4-(4-chlorobenzyl) (Ib) substituents resulted in derivatives possessing strong inhibitory activity against the Ehrlich ascites carcinoma.

It was further observed that this series of 5-substituted pyrimidine-6-carboxaldehydes inhibited incorporation of amino acids and formate into proteins, and of orotic acid, thymidine, and formate into nucleic acids of the tumor cells *in vitro* (3). Compound Ib was equally as effective as 5-fluorouracil (FU) in inhibiting formate incorporation into DNA and growth of the tumor and more effective than FU in inhibiting incorporation of formate and orotic acid into RNA, thymidine into DNA, and phenylalanine and glycine into proteins. However, Compound Ib had only negligible inhibitory activity against the folate reductases.

The fact that an enhanced inhibitory activity was obtained by the introduction of benzyl substituents in the 5-position led to the synthesis of further derivatives of pyrimidine-6-carboxaldehydes containing bulky substituents in the 5-position in order to study the structure-activity relationship of these analogs in the test system.

RESULTS AND DISCUSSION

Chemistry—The majority of the α -substituted β -keto esters (VI) were prepared by the alkylation reaction of ethyl γ,γ -dimethoxyacetate (IV) with an alkyl (benzyl or naphthylmethyl) halide

RESULTS AND DISCUSSION

Chemistry—The majority of the α -substituted β -keto esters (VI) were prepared by the alkylation reaction of ethyl γ,γ -dimethoxyacetoacetate (IV) with an alkyl (benzyl or naphthylmethyl) halide

Scheme I

in the presence of sodium ethoxide in 70% yield. Claisen condensation of isopropyl ester (V) with methyl dimethoxyacetate (III) in benzene in the presence of sodium hydride afforded the α -alkyl (*n*-hexyl and *n*-dodecyl) and α -aralkyl (2-phenylethyl and 3-phenylpropyl) β -keto esters in 95% yield. The isopropyl esters were employed to reduce self-condensation (4). Due to extensive decomposition during fractionation, the crude esters were used without purification. The condensation of the β -keto ester with thiourea gave the pyrimidine acetal (VII) in 30% yield. With guanidine hydrochloride, the yield was 45%.

When the guanidine reaction was performed utilizing guanidine hydrochloride and sodium methoxide in boiling ethanol, the intermediate guanide (2-methoxyacetyl-2-substituted acetyl guanide) separated during the 1st hour (5). This guanide was redissolved and cyclized to the pyrimidine acetal (VII). Hydrolysis of the acetals (VII) was accomplished in dioxane with 10% H_2SO_4 or 10% HCl, resulting in a 60% yield of the pyrimidine-6-carboxaldehydes (VIII). Dioxane was used as a solvent for those acetals which did not dissolve in acid solution, and hydrolysis was completed in about 1 hr. Claisen condensation of the phenylacetone nitriles with methyl dimethoxyacetate and ethanolic sodium ethoxide gave α -acylphenylacetone nitriles (II) in 50% yield. Compound II was converted to the enol ether by diazomethane and then condensed with guanidine to give Compounds VII-16 and VII-17. These pyrimidine acetals were then hydrolyzed with aqueous 0.4 N HCl to the aldehydes (VIII-16, 17) (Scheme I).

The pyrimidine aldehydes (VIII) contained a molecule of ethanol when recrystallized from ethanol or ethanol-water. This molecule of ethanol was removed by heating at 100° for several hours *in vacuo*. Although a molecule of ethanol could be removed, some compounds were found to have one or one-half molecule of water, which was difficult to remove. The Cannizzaro reaction of Compound VIII-2 with 25% KOH yielded the corresponding alcohol (XI) and acid (XII) in good yield. The alcohol was precipitated at pH 7–8, and the acid was precipitated at lower pH (1–3). The thiosemicarbazones (IX), hydrazones (X), and Schiff bases (X) were prepared in the usual manner in good yields. Compound XII was decarboxylated by heating in tetralin, resulting in Compound XIII. Scheme II shows the sequence of reactions discussed.

Screening Tests—Test versus Ehrlich Ascites Carcinoma—The compounds were tested *versus* the Ehrlich ascites carcinoma in Swiss-Webster white mice by a slight modification of procedures

described previously (6, 7). Twenty-four hours after the inoculation, each control mouse received an intraperitoneal injection of 0.2 ml. of dimethyl sulfoxide (DMSO), and each experimental mouse received a solution of the tested compound in DMSO. The intraperitoneal injections of control and experimental mice were continued twice daily for 6 days (one injection on the last day; total of 11 injections). On the 7th day, all surviving mice in control and experimental groups were sacrificed. The volume of ascitic fluid was measured for each sample of ascitic fluid by centrifugation in heparinized capillary tubes. The total packed-cell volume (TPCV) of tumor cells was calculated in each case together with average values and standard deviations.

The results of tests of representative compounds are recorded in Table I. The results showed that almost all compounds had an inhibitory activity and low toxicity at the dosage of 50–100 mg./kg./day. Compounds Ic, VIII-2, VIII-3, VIII-10, X-4, and XII showed strong activity against the tumor growth at the dosage of 10–60 mg./kg./day. Compounds Ic, VIII-2, VIII-3, and VIII-10 were as effective as Compound Ib, but they showed greater toxicity than Ib. Since VIII-6 showed less activity than Ic, the α -substituted naphthalene derivative seemed to be superior to the β -substituted compound. Also, the unsubstituted naphthylmethyl derivative (Ic) was found to be a better compound than the methyl-substituted derivatives (VIII-7 and VIII-8).

The 5-dodecyl-pyrimidine-6-carboxaldehyde (VIII-10) showed greater antitumor activity than the 5-hexyl derivative (VIII-9), but both compounds were quite toxic. Since Compound Ic was found to be more active than VIII-13, the SH group at the pyrimidine 2-position seemed to be a better functional group than NH_2 for anticancer activity in this system. A similar observation was noticed for Compound Ib in a previous study (3). The aldehyde group at the pyrimidine 6-position also seemed to be very important for activity, because Compounds Ib and VIII-2 showed superior activity when compared with corresponding acetal (VII-2), thiosemicarbazone (IX-2), hydrazones (X-4 and X-5), and Schiff bases (X-1 and X-2). Furthermore, the corresponding alcohol and carboxylic derivatives (XI and XII) were found to be less active than the corresponding aldehyde derivative (VIII-2).

Test versus Ehrlich Carcinoma (Solid Tumor)—The compounds were also tested *versus* the Ehrlich solid tumor in Swiss-Webster white mice by a modification of a procedure described previously (8). Each mouse (initial weight approximately 30 g.) received a subcutaneous injection of 0.2 ml. of 10% ascitic fluid (containing 1.4×10^7 carcinoma cells) into the inguinal region or the back shoulder region on one side. For each assay the mice were divided into a control group of eight mice and several experimental groups of eight mice each. Seventy-two hours after the inoculation, each control mouse received an intraperitoneal or a subcutaneous (tumor area) injection of 0.2 ml. DMSO, and each experimental mouse received a solution of the tested compound in DMSO. The intraperitoneal or subcutaneous injections of control and experimental mice were continued once daily for 9 days (total of nine injections). On the 12th day after inoculation, all surviving mice in control and experimental groups were sacrificed. The solid tumors were carefully taken out and weighed. The average weight of solid tumor was calculated in each case together with standard deviations. The results of the more active pyrimidine analogs on solid tumor growth are listed in Table II.

These compounds showed some activity and high toxicity against the solid tumor as opposed to a strong activity and low toxicity against the ascites tumor. Compound VIII-2 showed 74% inhibition with no mortality at a dosage of 16.46 mg./kg./day on subcutaneous injection, while this compound showed 25% inhibition with 3/8 mortality at a similar dosage on intraperitoneal injection. A similar result was obtained with Compound VIII-3. Compounds Ib and Ic showed 20% inhibition at a dosage of 15–20 mg./kg./day. FU showed 50% inhibition at a dosage of 16.06 mg./kg./day on intraperitoneal injection. However, subcutaneous injection did not enhance the inhibitory activity for FU and Ib. Administration of 31.6 mg./kg./day of Ib resulted in complete mortality. The higher toxicity of these compounds in the tests *versus* the solid tumor in comparison with the tests *versus* the ascites tumor can be explained on the basis that in the latter tests the compounds are immediately in contact with the carcinoma cells upon intraperitoneal injection, and the rapid uptake by these cells minimizes the concentrations attained in normal tissues of the host animal. On the other hand, when the compounds are injected intraperitoneally in the tests *versus* the

Scheme II

solid tumor, the tumor cells do not have a preferential opportunity to absorb the drugs, and higher concentrations are attained in normal tissues of the host. The lower toxicity upon subcutaneous injection in the region of the tumor also can be explained upon the basis of preferential uptake by tumor cells, as well as a slower rate of rise in drug concentration in the peripheral circulation.

Inhibition of Protein Synthesis—The effects of the compounds upon protein synthesis were studied by determining the inhibition of incorporation of L-phenylalanine-1-¹⁴C and formate-¹⁴C into the proteins of Ehrlich ascites carcinoma cells, which were incubated aerobically for 1 hr. with labeled substrate and the compound *in vitro* in Krebs-Ringer phosphate (KRP) buffer at 37 ± 1° by a procedure described previously (1). After the incubation, the acid-soluble fraction (ASF) and the total proteins were isolated and freed of lipids and nucleic acids. Each protein preparation was dissolved in 2.0 ml. of 0.3 N NaOH, and 0.2 ml. of the protein solution

was transferred to a glass scintillation vial. To each vial, 0.2 ml. of hyamine hydroxide 10-X and 16 ml. of POPOP-PPO tyloxapol¹ scintillation fluid were added for determination of radioactivity in a Packard liquid scintillation spectrometer, model 3320.

The effects of the compounds upon incorporation of L-phenylalanine-1-¹⁴C and formate-¹⁴C into proteins of the carcinoma cells are recorded in Tables III and V. Compounds Ic, VIII-1, VIII-2, VIII-3, VIII-6, VIII-7, VIII-9, VIII-10, IX-2, and X-4 almost completely inhibited the incorporation of L-phenylalanine-1-¹⁴C into proteins at the concentrations of 0.48–0.96 mM. Compounds Ic, VIII-2, and VIII-3 showed 90–95% inhibition of formate-¹⁴C incorporation into proteins at 0.77 mM.

The effects of the homologous 5-alkylpyrimidine-6-carboxaldehydes (Id, VIII-1, and VIII-2) are shown in Fig. 1. The phenylpropyl derivative (VIII-2) was found to be the most active compound among them, and the activity decreased in the order: C₆H₅CH₂CH₂CH₂ > C₆H₅CH₂CH₂ > C₆H₅CH₂. However, the difference in activity was not significant; only a 5–10% difference in inhibition existed at a concentration range of 0.24–0.48 mM. These compounds lost their inhibitory activity at a concentration of 0.12 mM. The difference in activity might be explained from the binding difference by

¹ In 1 l. of toluene, 5 g. of 2,5-diphenyloxazole (PPO) and 0.3 g. of 1,4-bis(4-methyl-5-phenyloxazolyl)benzene (dimethyl-POPOP) were dissolved. Two liters of this POPOP-PPO solution and 1 l. of tyloxapol (Triton X-100) were mixed.

^a T = treated group; C = controls; and TPCV = total packed-cell volume of tumor cells on final day of assay. The average standard deviation for TPCV of all control groups was ± 0.44 ml. ^b The compound, 5, 10, 25, 50, 100, or 150 mg., was dissolved in 20 ml. of DMSO. Each mouse (initial weight approximately 30 g.) received two intraperitoneal injections of 0.2 ml. of the drug solution daily. ^c Data from Reference 5. ^d 5-Fluorouracil; data from Reference 3.

hydrophobic bonding with these groups to the enzyme which might be involved at the inhibitory site. This hypothesis seems to be plausible, because the 5-hydrocarbon chain alkylpyrimidine-6-carboxaldehydes (VIII-9 and VIII-10) showed 95–98% inhibition at a con-

centration of 0.96 mM, while 2-thioorotic aldehyde (TOA) showed no activity at 0.65 mM and only 70% inhibition at 1.96 mM (1). The aldehyde group at pyrimidine 6-position appears to be essential, since Compound VIII-2 showed an increased inhibitory activity

^a 0.1 μ mole/ml. (0.2 μ Ci). ^b ASF = acid-soluble fraction. ^c 1.122×10^3 counts/min./mg. ^d 1.751×10^3 counts/min. ^e Data from Reference 5. ^f FU = 5-fluorouracil; data from Reference 3.

over the alcohol (XI) and the acid (XII) derivatives. The 5-naphthylmethyl-pyrimidine-6-carboxaldehydes were also found to be very effective compounds against the incorporation of L-phenylalanine-1-¹⁴C into proteins. However, the 2-amino-5-naphthylmethyl derivatives (VIII-13 and VIII-14) showed 70% inhibition at a concentration of 0.96 mM, while the corresponding 2-mercaptopyrimidine derivatives showed 95–98% inhibition at the same concentration.

When an amino acid is concentrated in a cell, it rapidly equilibrates with exogenous amino acids and is competitively displaced by certain structurally related analogs (9). The radioactivity of the ASF obtained after 1 hr. incubation of a suspension of Ehrlich ascites cells and L-phenylalanine-1-¹⁴C is due to unchanged L-phenylalanine-1-¹⁴C and other compounds produced metabolically from L-phenylalanine-1-¹⁴C. Inhibition of L-phenylalanine-1-¹⁴C transport into the cell interior or relatively faster biochemical reactions involving L-phenylalanine-1-¹⁴C may reduce the total radioactivity in the ASF of the cell. The inhibition of L-phenylalanine-1-

Figure 1—Effects of phenylalkylpyrimidine-6-carboxaldehydes on incorporation of L-phenylalanine-1-¹⁴C into proteins of Ehrlich ascites carcinoma cells in vitro. L-Phenylalanine-1-¹⁴C: 0.1 μ mole/ml.; 0.2 μ Ci.

¹⁴C incorporation into the ASF by the compounds listed in Table III may be the result of such effects. However, inhibition of incorporation into protein was always greater than inhibition of incorporation into the ASF. Compounds VIII-2, VIII-6, VIII-7, VIII-9, and VIII-10 gave 70–90% inhibition of accumulation in the ASF at a concentration of 0.96 mM. Compounds VIII-1 and VIII-2, however, stimulated L-phenylalanine-1-¹⁴C incorporation into the ASF to 220% of controls at 0.48 mM concentration. This increase in accumulation of radioactivity in the ASF could result in part from the inhibition of incorporation of phenylalanine into protein, which would produce a “pile-up” of phenylalanine-1-¹⁴C in the ASF.

Inhibition of Nucleic Acid Synthesis—The effects of the compounds upon nucleic acid synthesis were studied by determining the inhibition of incorporation of orotic acid-5-³H and formate-¹⁴C into RNA and of thymidine-2-¹⁴C and formate-¹⁴C into DNA of Ehrlich ascites carcinoma cells. These cells were incubated aerobically for 1 hr. with the labeled substrate and the compound *in vitro* in KRP buffer at $37 \pm 1^\circ$ by a procedure described previously (3).

Incorporation of Orotic Acid-5-³H and Thymidine-2-¹⁴C into Nucleic Acids—Each incubation flask contained 5 ml. of a 20% suspension of tumor cells in KRP buffer (pH 7.1–7.2), 1 ml. of KRP buffer containing orotic acid-5-³H (0.04 μ mole/ml., 10 μ Ci), thymidine-2-¹⁴C (0.1 μ mole/ml., 1 μ Ci), glucose (5 mg./ml.), and 0.2 ml. of the compound in DMSO.

After incubation, the acid-insoluble residue was obtained and washed as previously described (1). The acid-insoluble residue then was suspended in 5 ml. of 0.5 N HClO₄ and heated for 30 min. at 95°. At the end of heating, the tubes were centrifuged, and the supernatant was neutralized with KOH. To each glass scintillation

	2.0	4.00	1.06	72
X-4	1.0	4.00	3.79	5

^a For calculation of Q_{O_2} value, 2 ml. of 10% cell suspension was considered as equivalent to 32 mg. dry weight.

vial, 0.2 ml. of the neutralized solution, 0.2 ml. of hyamine hydroxide 10-X, and 16 ml. of the scintillation fluid were added for determining radioactivity. The radioactivities of ^{14}C and ^3H were determined according to Kabara *et al.* (10), and the exact channel ratios of ^{14}C and ^3H were determined (1). The concentration of RNA was determined by the orcinol reaction and corrected for the interference by DNA. The amount of DNA was determined by the diphenylamine reaction (11). The specific activities were calculated as c.p.m. (^3H)/mg. of RNA and c.p.m. (^{14}C)/mg. of DNA.

The effects of the compounds upon incorporation of orotic acid-5- ^3H into RNA and thymidine-2- ^{14}C into DNA of the carcinoma cells are recorded in Table IV. Compounds Ib and VIII-2 showed complete inhibition of thymidine-2- ^{14}C incorporation into DNA—

thymine at a concentration of 0.96 mM. A recent study with Compound Ib (12) showed that the inhibition of thymidine incorporation into DNA was possibly due to the inhibition of thymidine monophosphate (TMP) kinase by this compound.

Compounds Ib, Ic, VIII-2, and VIII-3 showed 80–95% inhibition of incorporation of orotic acid-5- ^3H into RNA at a relatively high concentration (1.92 mM) of the compounds.

The previous work showed that the conversion of orotic acid to orotidylic acid was inhibited by some of the 5-fluoroorotic aldehyde derivatives (1). The 5-substituted pyrimidine derivatives might also inhibit this conversion. The possibility that Compound XII is acting as an antimetabolite of orotic acid does not seem to be valid. While this compound was quite active as a growth inhibitor in this system, it showed no inhibition against incorporation of L-phenylalanine into proteins and of orotic acid into RNA at a concentration of 0.96 mM.

Incorporation of Formate- ^{14}C into Nucleic Acids—Each incubation flask contained 5 ml. of a 40% suspension of tumor cells in KRP buffer, 1 ml. of glucose in KRP buffer (3 mg./ml.), 1 ml. of formate- ^{14}C in KRP buffer (0.318 $\mu\text{mole/ml.}$, 8 μCi), and 0.2 ml. of the compound in DMSO. After incubation, nucleic acids were isolated as sodium nucleates. The proteins also were isolated for evaluation of inhibition of formate incorporation into protein. RNA was separated from DNA by hydrolyzing with 0.3 N KOH at 37° for 16–18 hr. After purification, the radioactivities were counted for each nucleic acid by a procedure described previously (1). The effects of the compounds upon incorporation of formate- ^{14}C into the nucleic acids of ascites cells are recorded in Table V. Compounds Ic, VIII-2, and VIII-3 showed almost complete inhibition of incorporation of formate into DNA and RNA at a concentration of 0.77 mM, and they were as active as 2-mercapto-5-(4-chlorobenzyl) pyrimidine-6-carboxaldehyde (Ib) as previously reported (3). These compounds are practically identical in activity with FU in inhibiting formate incorporation into DNA, but they are more active than FU in inhibiting formate incorporation into RNA. Compound XIII was less active than Compound VIII-2, which further indicates the im-

portance of the aldehyde group at the 6-position.

In the initial studies by Chae (13), the effects of the 5-fluoroorotic aldehydes on the incorporation of labeled formate into DNA-purines were not investigated because of the low radioactivity in the purines of DNA; the radioactivity could be mainly accounted as DNA-thymine. In the present experiments, the total radioactivity of DNA was counted without separation of each base. Therefore, the authors did not determine whether the radioactivity was counted mainly from DNA-thymine or whether the DNA-purines made a significant contribution. However, since previous studies (13) indicated a low radioactivity from DNA-purines, the authors assumed that the radioactivity was counted mainly from DNA-thymine. This assumption indicated that probably the inhibition of incorporation of formate-¹⁴C into DNA by the 5-substituted pyrimidine derivatives might be attributable to inhibition of thymidylate synthesis by these compounds.

A recent study (12) also indicated that these compounds inhibited TMP kinase, and the inhibition of formate incorporation into DNA might be due to these two inhibitions. It was also observed (12) that Compound *Ib* inhibited the incorporation of formate-¹⁴C into guanine of RNA 2–4 times more than the formate incorporation into adenine of RNA. Furthermore, Compound *Ib* showed 75–80% inhibition of incorporation of labeled 5-amino-4-imidazolecarboxamide (AICA) and hypoxanthine (Hx) into guanine of RNA at a concentration of 0.25 mM, while this compound showed practically no inhibition against incorporation of AICA and Hx into adenine of RNA at the same concentration. These results would indicate that one of the possible steps inhibited by *Ib* is the conversion of xanthosine monophosphate (XMP) to guanosine monophosphate (GMP). Since the incorporation of formate-¹⁴C into adenine of RNA was also inhibited by *Ib*, there must be other possible inhibition steps which utilize formate or THFA coenzymes. However, the 5-substituted pyrimidine derivatives were essentially inactive as folate reductase inhibitors when compared with accepted antifolates such as aminopterin, pyrimethamine, and trimethoprim (3). Therefore, the inhibition of formate incorporation into DNA and RNA

by these compounds could not be attributed to inhibition of the folate reductases.

Inhibition of Aerobic Respiration of the Tumor—The effects of the compounds upon aerobic respiration of the Ehrlich ascites tumor were studied by measuring oxygen consumption by means of the Warburg apparatus. To each Warburg flask was added 2 ml. of the 10% cell suspension in KRP buffer, and 0.2 ml. of 20% KOH was added in the center well which contained a small piece of filter paper. Three-tenths milliliter of drug solution in DMSO (or 0.3 ml. of DMSO for the control) and 0.3 ml. of 0.5 M glucose solution were then added to each sidearm. For the thermobarometer, 2.6 ml. of distilled water was added to the flask and 0.2 ml. of 20% KOH in the center well. The flasks were equilibrated in a 37° water bath for 15 min. after gassing with oxygen (10 min.). After equilibration the stopcocks were closed, and the contents of the flask were then mixed. Readings were taken every 10 min. thereafter for 1-hr. For each experiment, at least two controls and one thermobarometer were needed.

The oxygen uptake for respiration was calculated by the method described previously (14). The change in readings, corrected for thermobarometer, was multiplied by the flask constant (K_{O2}), resulting in the oxygen uptake (μl. O₂/hr.).

Two milliliters of the 10% cell suspension contained 32 mg. dry weight of cells. Therefore, Q_{O2} (microliter O₂ taken up per milligram dry weight of cells per hour) was calculated by dividing the oxygen uptake by 32 mg. The inhibitory activity was calculated from the mean value (Q_{O2}) of the duplicate experiments of each sample.

The effects of the compounds upon aerobic respiration of the Ehrlich ascites tumor are recorded in Table VI.

Compounds *Ib*, *Ic*, VIII-1, and X-2 showed 55–80% inhibition of respiration at a concentration of 1 mM in the presence of added glucose. Most of these compounds did not show an enhanced inhibitory activity at an increased concentration (2 mM).

There may be two possible explanations for the inhibition of respiration by these compounds. Since preliminary data seem to indicate that these analogs inhibit the synthesis of AMP and GMP

Table IX—Thiosemicarbazones of 5-Substituted Pyrimidine-6-carboxaldehydes

(12), such inhibition could result in inhibition of oxidative phosphorylation and synthesis of the coenzymes which participate in glycolysis, the tricarboxylic acid cycle, and the electron-transport system. The second possibility may be a direct inhibition of the oxidative enzymes themselves by the compounds. However, these compounds have less inhibitory effect upon respiration than upon the synthesis of nucleic acids and proteins. Consequently, it seems likely that the inhibition of growth of the carcinoma cells by these compounds is attributable to the latter rather than to the former. The elucidation of the sites of inhibition will be the subject for further research.

EXPERIMENTAL²

Melting points were taken in capillary tubes in a Mel-Temp apparatus and have been corrected. The designation of a roman numeral followed by an arabic numeral indicates a specific compound number in the table indicated by the roman numeral (Tables I–VI).

Isopropyl-5-phenylvalerate (V)—This compound was prepared by a known procedure (4) from 5-phenylvaleric acid and isopropyl alcohol; yield 79% of crude product; b.p. 102–105° (0.4 mm.).

The isopropyl-4-phenylbutyrate (b.p. 100–102° at 0.4 mm.), isopropyl octanoate, and isopropyl myristate were all prepared in an analogous manner.

Isopropyl α-(3-Phenylpropyl)-γ,γ-dimethoxyacetoacetate (VI)—This compound was prepared by a known procedure (4) from isopropyl 5-phenylvalerate and methyl dimethoxyacetate; yield 99% of crude product.

The isopropyl α-(2-phenylethyl)-γ,γ-dimethoxyacetoacetate, isopropyl α-(n-hexyl)-γ,γ-dimethoxyacetoacetate, and isopropyl α-(n-dodecyl)-γ,γ-dimethoxyacetoacetate were all prepared by a similar procedure.

2-Bromomethylnaphthalene—A mixture of 56.8 g. (0.4 mole) of 2-methylnaphthalene, 71.2 g. (0.4 mole) of *N*-bromosuccinimide, and 0.2 g. of benzoyl peroxide in 500 ml. of carbon tetrachloride was refluxed with magnetic stirring for 10 hr. The hot reaction mixture was filtered, and the filtrate was evaporated *in vacuo*. The crude product was recrystallized from petroleum ether (30–60°); yield 70.7 g. (80%) of white crystals, m.p. 55–56°.

Anal.—Calcd. for C₁₁H₉Br: C, 59.75; H, 4.10. Found: C, 59.73; H, 4.09.

The other chloromethylnaphthalenes used were commercially available.

Ethyl α-(4-Phenylbenzyl)-γ,γ-dimethoxyacetoacetate (VI)—To a sodium ethoxide solution prepared from 2.88 g. (0.125-g. atom) of sodium in 75 ml. of absolute ethanol, 23.8 g. (0.125 mole) of ethyl γ,γ-dimethoxyacetoacetate (15) and 25.34 g. (0.125 mole) of *p*-phenylbenzyl chloride were added. The brown solution was refluxed gently with magnetic stirring for 9 hr., during which time sodium chloride separated. The neutral reaction mixture was filtered, and

the sodium chloride was washed with 20 ml. of absolute ethanol. The combined filtrate was dried with anhydrous magnesium sulfate for 3 hr., and the ethanol was evaporated *in vacuo* at 80–90°. A light-brown oil was obtained; yield 44 g.

The α-benzyl-β-keto esters and α-naphthylmethyl-β-keto esters were prepared in an analogous manner. Because of the extensive decomposition that occurred during distillation, the crude esters were used for the next step.

2-Mercapto-6-(dimethoxymethyl)-5-(3-phenylpropyl)-4-pyrimidol (VII-2)—To a sodium ethoxide solution prepared from 5.72 g. (0.248 g. atom) of sodium in 200 ml. of absolute ethanol, 80 g. (about 0.248 mole) of crude isopropyl α-(3-phenylpropyl)-γ,γ-dimethoxyacetoacetate and 18.9 g. (0.248 mole) of dried thiourea were added. The mixture was refluxed with magnetic stirring for 12 hr. During the refluxing, a yellowish-brown precipitate separated. The solvent was evaporated *in vacuo*, and the residue was dissolved in 600 ml. of water. The aqueous mixture was filtered, and the filtrate was extracted twice with 200 ml. portions of ether. The aqueous solution was acidified with 10% aqueous HCl, resulting in the separation of a brown oil. This oil solidified gradually in an ice bath after several hours. The brown precipitate was filtered and washed with cold water. Recrystallization from ethanol gave 9.5 g. (12%) of white crystals; m.p. 118–120°. Table VII lists the compounds prepared in an analogous manner.

2-Amino-6-(dimethoxymethyl)-5-(2-phenylethyl)-4-pyrimidol (VII-12)—A mixture of 41 g. (about 0.133 mole) of crude isopropyl α-(2-phenylethyl)-γ,γ-dimethoxyacetoacetate and a solution of guanidine [from 12.7 g. (0.133 mole) of guanidine hydrochloride and 3.06 g. (0.133 g. atom) of sodium in 100 ml. of absolute ethanol] was refluxed with stirring for 6 hr. The white precipitate, which separated during the 1st hour, gradually dissolved to yield a reddish-brown solution. The solution was evaporated to dryness under reduced pressure, and 500 ml. of water was added. The mixture was acidified with acetic acid. After cooling at 0° for several hours, the gummy precipitate was filtered and washed with cold ethanol and ether. The product was recrystallized from ethanol; yield 18 g. (47%) of white crystals, m.p. 219–221°. Table VII lists the compounds prepared by a similar procedure.

2,4-Diamino-6-(dimethoxymethyl)-5-(4-fluorophenyl)pyrimidine (VII-17)—This compound was prepared by a known procedure (3) from guanidine hydrochloride and α-(dimethoxyacetyl)-*p*-fluorophenylacetone; yield 18.7% of white crystals, m.p. 259–260°.

2,4-Diamino-6-(dimethoxymethyl)-5-phenylpyrimidine (VII-16) was prepared in an analogous manner.

2-Mercapto-4-hydroxy-5-(3-phenylpropyl)pyrimidine-6-carboxaldehyde (VIII-2)—A mixture of 2 g. (6.25 mmoles) of VII-2, 20 ml. of 10% aqueous HCl, and 30 ml. of dioxane was refluxed for 1 hr. The cooled yellow solution was diluted with ethanol-water (1:1) to turbidity. After being cooled at 0° for several hours, the crystals were filtered and washed with water. The crude product was recrystallized from ethanol and dried at 100°; yield 1.6 g. (93.5%) of yellow crystals, m.p. 168–170°. Table VIII lists the compounds prepared in an analogous manner.

2-Amino-4-hydroxy-5-(2-phenylethyl)pyrimidine-6-carboxaldehyde (VIII-12)—A mixture of 5 g. (17.3 mmoles) of VII-12, 30 ml. of

² Analyses were performed by M-H-W Laboratories, Garden City, MI 48135

10% aqueous HCl, and 50 ml. of dioxane was refluxed for 1 hr. The solvent was evaporated *in vacuo*, and the residue was triturated with 25 ml. of cold water and then dissolved in warm 2-methoxyethanol. The solution was decolorized with charcoal and then poured into 100 ml. of saturated aqueous NaHCO₃. The pale-yellow powder was collected on a filter and washed with water. Recrystallization from ethanol–water (1:1) and drying at 100° gave 4 g. (95%) of yellow crystals, m.p. > 300° dec. Table VIII lists the compounds prepared by a similar procedure.

Thiosemicarbazone of 2-Mercapto-4-hydroxy-5-benzylpyrimidine-6-carboxaldehyde (IX-1)—To a warm solution of 0.616 g. (2.5 mmoles) of *Ia* in 30 ml. of ethanol was added a warm solution of 0.23 g. (2.5 mmoles) of thiosemicarbazide in 15 ml. of 80% ethanol. The solution was refluxed for 20 min. and filtered while warm. After cooling at 0° for 1 hr., the yellow crystals were filtered and washed with cold ethanol. The crude product was recrystallized from ethanol; yield 0.5 g. (62.5%) of yellow crystals, m.p. 200–201°. Table IX lists the compounds prepared by a similar procedure.

N-[2-Mercapto-4-hydroxy-5-(4-chlorobenzyl)-6-pyrimidylmethylidene]-N,N-dimethylethylenediamine (X-1)—A stirred mixture of 0.7 g. (2.5 mmoles) of *Ib* in 30 ml. of absolute ethanol and 0.22 g. (2.5 mmoles) of N,N-dimethylethylenediamine was refluxed for 30 min. White to yellow crystals separated. This was filtered, washed with cold ethanol, and recrystallized from ethanol; yield 0.7 g. (80.5%), of yellow crystals, m.p. 181–183° dec. Table X lists the compounds prepared by a similar procedure.

Hydrazones of the Pyrimidine Aldehydes (X-4 and X-5)—To a solution of 2.5 mmoles of the aldehyde *Ib* in 50 ml. of 50% aqueous acetic acid was added a solution of 2.5 mmoles of the respective hydrazide in 20 ml. of 50% aqueous acetic acid. It was heated at 80–90° for 10 min., during which time yellow crystals precipitated. After cooling at 0° for 1 hr., the crystalline precipitate was collected by filtration and recrystallized from ethanol. Table X lists these derivatives.

2-Mercapto-6-hydroxymethyl-5-(3-phenylpropyl)-4-pyrimidol (XI) and 2-Mercapto-4-hydroxy-5-(3-phenylpropyl)pyrimidine-6-carboxylic Acid (XII)—To a cold solution of 1.5 g. of KOH in 6 ml. of water was added 1.5 g. of VIII-2. The mixture was left standing at room temperature for a total of 48 hr. The yellow solution was diluted with 20 ml. of water and filtered. To the filtrate, 10% aqueous HCl was added to bring the mixture to pH 7–8, resulting in the precipitation of white crystals (XI). After cooling at 0° for 1 hr., the white crystals were filtered and washed thoroughly with cold water. The filtrate was further acidified with 10% aqueous HCl, resulting in precipitate of yellow crystals (XII). After cooling at 0° for 1 hr., the yellow crystals were filtered and washed with cold water. Both products were recrystallized from ethanol:

The alcohol (XI); yield 0.65 g. (86%), m.p. 214–215°. *Anal.*—Calcd. for C₁₄H₁₆N₂O₂S: C, 60.87; H, 5.80. Found: C, 61.07; H, 5.84.

The acid (XII); yield 0.65 g. (82%), m.p. 271–273° dec. *Anal.*—Calcd. for C₁₄H₁₄N₂O₃S: C, 57.93; H, 4.83. Found: C, 57.88; H, 4.98.

2-Mercapto-5-(3-phenylpropyl)-4-pyrimidol (XIII)—A mixture of 0.3 g. (1.03 mmoles) of XII and 20 ml. of tetralin was refluxed for 5 hr. The brown solution was cooled at 0° for 1 hr. The precipitate was filtered and washed with toluene. The crude product was dissolved in 10 ml. of 10% aqueous NaOH and acidified with 10%

aqueous HCl to pH 7, resulting in a white precipitate. Recrystallization from ethanol gave 62 mg. (24.5%), m.p. 172–174°.

Anal.—Calcd. for C₁₃H₁₄N₂O₂S: C, 63.41; H, 5.69. Found: C, 62.96; H, 5.86.

Colorimetric Determination of Atropine, Homatropine, Scopolamine, and Their Derivatives by the Ferric Hydroxamate Method

JOSEPH A. FELDMAN and BRUCE J. ROBB*

Abstract ☐ The purpose of this study was to develop a procedure for the quantitative analysis of the salts of the solanaceous alkaloids in the presence of their hydrolysis products. The salts taken were atropine sulfate, homatropine hydrobromide, homatropine methylbromide, scopolamine hydrobromide, and scopolamine methylbromide. The ferric hydroxamate procedure was used. The conditions necessary for a reproducible reaction were established; a procedure of sufficient sensitivity was developed which will allow unit dose analysis; and an analysis was developed which will permit the salts of the solanaceous alkaloids to be quantitatively analyzed in the presence of their degradation products.

Keyphrases ☐ Atropine, homatropine, scopolamine dosage forms—analysis ☐ Solanaceous alkaloids with degradation products—analysis ☐ Ferric hydroxamate method—solanaceous alkaloid analysis ☐ Colorimetric analysis—spectrophotometer

Atropine and its synthetic homolog homatropine are, respectively, the tropic acid and mandelic acid esters of the aminoalcohol tropine, whereas scopolamine is the tropic acid ester of scopine. The official assay methods for these drugs have inadequate sensitivity; a single assay sample for Scopolamine Hydrobromide Injection requires a minimum of 40 ml. of the solution, and at least 100 tablets are needed for the USP XVII assay of Atropine Sulfate Tablets. Another limitation of the compendial assays is that they do not discriminate between the intact ester drugs and their inactive hydrolysis products. The USP XVII assays (1) for Atropine Sulfate Injection, Homatropine Hydrobromide Ophthalmic Solution, and Scopolamine Hydrobromide Injection provide for chloroform extraction of the bases from ammoniacal solution followed by evaporation of the extracts and acidimetric titration. Chafetz and Daly (2) recently observed that tropine is extracted along with homatropine base in the USP XVII assay, invalidating it as a stability-indicating method. They proposed a selective method for homatropine; however, their method is inapplicable to tropic acid esters. Separative techniques have also been applied to the solanaceous alkaloids (3). This report describes a method which: (a) is generally applicable to the solanaceous alkaloids and their derivatives; (b) is stability indicating; and (c) affords adequate sensitivity for unit-dose analysis.

Hydroxylaminolysis of esters and formation of colored complexes of the hydroxamic acids so derived with ferric ion afford convenient means for determination of esters in the presence of their alcohol and acid constituents. Siegel *et al.* (4) used this reaction to follow the hydrolysis rates of methylphenidate. Vincent and

Table I—Absorbance Concentration Relationships

5.0	0.650	0.600	0.540	0.650	0.890

Schwal (5) evaluated a ferric hydroxamate colorimetric procedure for the analysis of alkaloid drugs with ester and lactone functions such as the veratrum alkaloids, cocaine, aconitine, and pilocarpine. However, they reported that atropine, homatropine, and scopolamine gave only very faint colors. Kinetic studies (6–8) have shown that these compounds are easily hydrolyzed in alkali; hydroxylaminolysis of esters is a base-catalyzed reaction. The inference derived from these observations was that conditions wherein formation of the hydroxamate was facilitated and the rate of the competing ester saponification inhibited would afford colors intense enough to be analytically useful. Such conditions were attained by use of a large excess of hydroxylamine at ice-water bath temperature. The method was applied to atropine sulfate, homatropine hydrobromide, homatropine methylbromide, scopolamine hydrobromide, and scopolamine methylbromide. The potential utility of the method in the analysis of dosage forms of these compounds is indicated.

EXPERIMENTAL

Reagents and Supplies—Saturated hydroxylamine HCl (83 g. in 100 ml.), 10.5 M potassium hydroxide, 4 M hydrochloric acid, and 0.37 M ferric chloride in 0.1 M hydrochloric acid were filtered before use if necessary and stored under refrigeration. Absorbance data were obtained with 11.67-mm. diameter cylindrical cells in a Bausch and Lomb Spectronic 20 spectrometer.

All chemicals used were USP, NF, or analytical reagent grade.

Standard Preparation—Dissolve an accurately weighed amount of the appropriate reference standard in water, and dilute the solution quantitatively and stepwise to obtain a concentration of about 600 mcg./ml.

Assay Preparation—Tablets—Weigh and finely powder not less than 20 tablets. Extract a weighed amount with water, filter the extract if necessary, and dilute it quantitatively to represent a concentration of about 600 mcg./ml.

Solutions—If the solution is preserved with chlorobutanol or parabens, extract it with ether as described by Brochmann-Hanssen

et al. (9). Transfer an appropriate volume of the injection or ophthalmic solution to a volumetric flask and dilute it to represent about 600 mcg./ml.

Procedure—Transfer 5-ml. portions of the assay preparation, the standard preparation, and water to separate 50-ml. conical flasks chilled in an ice-water bath. Successively pipet 1 ml. of hydroxylamine HCl reagent and 1 ml. of potassium hydroxide solution into each flask, and mix. After 1 hr., add 2.0 ml. of 4 *M* hydrochloric acid (pH 1.2–1.4) and 1.0 ml. of ferric chloride reagent to each flask, mixing after each addition. Remove the flasks from the ice-water bath, allow the gas evolution to subside, and determine the absorbance of the assay and standard solutions *versus* the blank at the wavelength of maximum absorbance at about 540 μ in a suitable spectrometer. Calculate the amount of drug, in milligrams, in the sample taken from the formula: $0.001 C(A_U/A_S)$, in which *C* is the concentration in micrograms per milliliter of the standard preparation, and A_U and A_S are the absorbances of the solutions from the assay preparation and from the standard preparation, respectively.

RESULTS AND DISCUSSION

Color Intensity—The absorbance values found in trials of this procedure are presented in Table I, from which conformance to Beer's law is evident. According to Aksnes (10), the color results from a 1:1 complex of ferric ion and hydroxamic acid.

Since tropohydroxamic acid is formed by three of the compounds and mandelohydroxamic acid by the homatropine derivatives, the molar absorptivities for atropine and the scopolamine derivatives, on the one hand, and for the other two compounds, on the other, should be identical if ester saponification or other side reactions do not occur. It is evident that scopolamine methylbromide, although it has the highest molecular weight, is converted to the hydroxamate most efficiently. Since reference standards are reacted concomitantly, the differences in molar absorptivities are of little practical consequence. The molar absorptivities, ϵ , in liters/mole/centimeter for atropine sulfate, homatropine hydrobromide, homatropine methylbromide, scopolamine hydrobromide, and scopolamine methylbromide are, respectively, 420, 350, 385, 490, and 615. The color intensity obtained in this procedure is about 10 times that reported by Vincent and Schwal (5) for atropine, homatropine, and scopolamine, from which one may calculate ϵ -values of 41, 35, and 92, respectively. The increase in absorptivity effected by the procedure reported here affords a useful analytical method.

Two precautions must be taken to achieve a procedure that produces absorbance values conforming to Beer's law. First, the volume taken of the assay preparation must be constant (5 ml. in the procedure proposed). Second, the pH of the solution prior to the addition of the ferric chloride reagent must be adjusted to a value of 1.2–1.4.

The main advantage of this analysis, in addition to its sensitivity, is the fact that the analysis reaction is specific for esters and will not react with the degradation products of ester hydrolysis, the acids and aminoalcohols. To verify this, the procedure was performed on several of the degradation products which might be formed by the hydrolysis of the esters involved. Tropic acid, mandelic acid, tropine, and scopoline were tested alone in solution and in combinations. These solutions did not absorb any energy at 540 μ .

Instrumental reproducibility, according to the manufacturers, will account for a relative error of 10% at a concentration of 0.5 mg./5 ml. However, by taking proportionate quantities of reaction solutions, unit-dose solutions containing concentrations of 0.5 mg./ml.

(2.5 mg./5 ml.) can be analyzed at a relative instrumental error of 4%.

The procedure was also applied to a typical scopolamine hydrobromide injection formulation which contained 0.4 mg./ml. of scopolamine hydrobromide, mannitol, acetate buffer, and a non-ester preservative. A control was run which contained everything but the scopolamine hydrobromide, and no interference from the formulation was found. The lack of absorbance by the blank, while the absorbance of the formulation containing the scopolamine hydrobromide reflected the proper concentration of the compound, signifies that the procedure is applicable to the analysis of formulations containing esters and ester salts of solanaceous alkaloids.

CONCLUSION

A procedure that allows for the quantitative analysis of several of the salts of the solanaceous alkaloids was developed. The conditions necessary for reproducible reaction were established; a procedure of sufficient sensitivity was developed which will allow for unit-dose analysis; and an analysis was developed which will permit the salts of the solanaceous alkaloids to be selectively and quantitatively analyzed in the presence of their degradation products. Official USP and NF procedures leave much to be desired as far as analyzing for these compounds in the presence of their degradation products. It is hoped that the proposed procedure will offer a better means of analysis for the salts of the solanaceous alkaloids.

Spectrophotofluorometric Determination of Mestranol in Oral Contraceptive Tablets

THERON JAMES

Abstract □ A rapid, reliable fluorometric method has been developed for assaying 17 α -ethynylestradiol-3-methyl ether (mestranol) in some oral contraceptive tablets. The method utilizes the native fluorescence of mestranol. No separations are required and the method is applicable in the presence of norethynodrel, ethynodiol diacetate, or norethindrone. Chlormadinone acetate interferes in the procedure. The method is sensitive (0.8–1.0 mcg./ml.) and applicable to single-tablet analyses. The accuracy under the conditions studied was $\pm 1.29\%$, and the precision ranged from ± 0.896 to $\pm 1.73\%$.

Keyphrases □ Mestranol determination—tablets □ UV spectrophotometric, fluorometric, colorimetric analyses, mestranol—comparison □ Fluorometry—analysis

The estrogenic component of oral contraceptives is usually 17 α -ethynylestradiol-3-methyl ether (mestranol). Because of its low dosage in tablets, mestranol is difficult to assay. UV (1–3), GLC (4–8), and colorimetric (9–14) methods have been proposed but all lack specificity or are unsuitable for routine analysis.

Several fluorometric procedures have also been reported (13, 15–20). The procedures involved induced fluorescence where reagent preparation, temperature, and time are all very critical for reproducibility. Use of fluorescence does increase sensitivity, but the methods currently available suffer the same limitations and drawbacks as colorimetric methods.

Duggan *et al.* (21) reported that natural estrogens possess native fluorescence. Mestranol, a synthetic estrogen, also possesses native fluorescence, whereas the more common progestins do not fluoresce appreciably. To date, methods that utilize native fluorescence (22) usually require internal standards and excipient blanks which are not readily available except to the manufacturer. Conceivably, each commercial product could have different excipients which would preclude the use of a "universal excipient blank."

The proposed assay procedure overcomes these limitations and is applicable to a variety of commercial products. No internal standards or excipient blanks are required, no preliminary separations are necessary, and the method is suitable for single-tablet analysis.

EXPERIMENTAL

Apparatus—A recording spectrophotofluorometer¹ with 1-cm. cells was used. The following instrument parameters were employed: xenon lamp; meter multiplier, 0.01; sensitivity, 45–50; 1P21 photomultiplier; slit arrangement No. 4; excitation wavelength, about 284 m μ ; and emission wavelength, about 327 m μ .

Standard Preparation—Prepare a solution containing 0.8–1.0 mcg. of mestranol² per ml. in absolute ethanol.

Table I—Fluorometric Assay of Commercial Tablets Containing Mestranol

Mestranol Found, mg./Tablet (Mestranol Declared, 0.1 mg./Tablet)		
Sample 1 ^a	Sample 2 ^a	Sample 3 ^b
0.101	0.0997	0.0979
0.101	0.100	0.0986
0.105	0.0984	0.100
0.104	0.103	0.101
0.103	0.101	0.0991
0.101	0.100	0.0985
Av. = 0.102	Av. = 0.100	Av. = 0.0995
SD = $\pm 1.73\%$	SD = $\pm 1.59\%$	SD = $\pm 0.896\%$

^a Samples 1 and 2 also contain norethindrone, 2 mg./tablet. ^b Sample 3 also contains norethynodrel, 2.5 mg./tablet.

Procedure—Rinse all glassware with ethanol prior to use. Grind at least 20 tablets to pass a 60-mesh sieve. Accurately weigh a portion of powder equivalent to one tablet, and transfer to a 50-ml. centrifuge tube (for single-tablet analysis, place tablet in centrifuge tube and crush with glass rod). Pipet 20 ml. of absolute ethanol into the tube, stopper securely, and shake on a mechanical shaker for 30 min. Centrifuge to clarify the solution. Pipet an aliquot of the supernatant, equivalent to 20–25 mcg. of mestranol, into a 25-ml. volumetric flask, and dilute to volume with absolute ethanol.

Fluorescence Determination—Adjust the spectrophotofluorometer to read 70% emission, at 327 m μ , with the standard solution. Determine the fluorescence spectra of the standard and sample solutions by scanning from 285 to 400 m μ . Make calculations using the maximum emission at about 327 m μ . Use absolute ethanol as a blank and correct for it.

RESULTS AND DISCUSSION

Progestins commonly associated with mestranol in contraceptive tablets exhibit negligible native fluorescence. However, because of their relatively high concentrations in tablets as compared to mestranol (as much as 25:1), concentration quenching will occur. This could affect the fluorescence of mestranol but is effectively negated by diluting samples to large volumes. Recovery samples containing norethindrone (a progestin) and mestranol gave low recoveries for mestranol when the norethindrone concentration in the final solution was 100 mcg./ml. or more. This same sample gave 100% recovery when the norethindrone concentration was 50 mcg./ml. or less.

The accuracy of the method was demonstrated by five assays of a synthetic mix. The average mestranol recovery was 99.8%, with a standard deviation of $\pm 1.29\%$.

Table I gives results of the fluorometric assay for three commercial products. Samples 1 and 2 were labeled to contain 2 mg. of norethindrone and 0.1 mg. of mestranol per tablet; Sample 3 was labeled to contain 2.5 mg. of norethynodrel and 0.1 mg. of mestranol per tablet. The standard deviation ranged from ± 0.869 to $\pm 1.73\%$.

Table II compares the data obtained by UV (23) and colorimetric (12) methods with results by the present fluorometric method. Results by the fluorometric method compare favorably to those by the colorimetric method. The samples represent four different manufacturers.

Mestranol in combination with chlormadinone acetate could not be determined by the fluorometric procedure without prior separation, because the excitation wavelength for mestranol (about 284 m μ) is too close to the absorption peak for chlormadinone acetate (283.5 m μ).

Assay of Emetine Hydrochloride Injection

KATALIN ACEL and MURRAY M. TUCKERMAN

Abstract □ Data are presented for the DAB 7 assay of emetine hydrochloride and for quantitative assay of emetine hydrochloride injection by a method previously reported for injections of aminsalts. The method involves nonaqueous titration of a chloroform-eluted sample from a magnesium oxide-siliceous earth mixture. Thermogravimetric data show that emetine hydrochloride forms no stable hydrates, that water can be lost even at room temperature, and that loss still continues slowly beyond the usual drying temperature so that it is difficult to render the material anhydrous. For these reasons, it is suggested that emetine hydrochloride and emetine hydrochloride injection be labeled with the content of anhydrous emetine hydrochloride. Permissible variation should be $\pm 1\%$ for emetine hydrochloride and $\pm 5\%$ for the injection.

Keyphrases □ Emetine HCl injection—analysis □ Potentiometric titration—analysis □ Titrimetry—analysis

Emetine Hydrochloride Injection USP XVII has a peculiar definition in that "it contains an amount of anhydrous emetine hydrochloride ($C_{29}H_{40}N_2O_4 \cdot 2HCl$)

equivalent to not less than 84% and not more than 94% of the labeled amount of emetine hydrochloride" (1). Thus it is the only pharmaceutical preparation formulated at less than 100% of label claim. This peculiar definition is necessitated by the official definition of Emetine Hydrochloride USP XVII as a hydrate of uncertain composition, which "contains not less than 98.0% and not more than 101.5% of $C_{29}H_{40}N_2O_4 \cdot 2HCl$, calculated on the anhydrous basis" (2).

Water is determined as follows: "Dry it at 105° for 2 hr.: it loses not less than 8% and not more than 14% of its weight" (2). The average water content of the solid is thus 11%, which corresponds to the average requirement for the injection of 89% of anhydrous material.

An attempt was made to assay emetine hydrochloride injection by a previously proposed method (3). The method involves distributing the sample over a mixture of magnesium oxide and purified diatomaceous earth held on a sintered-glass filtering funnel, eluting the

Assay of Emetine Hydrochloride Injection

KATALIN ACEL and MURRAY M. TUCKERMAN

Abstract □ Data are presented for the DAB 7 assay of emetine hydrochloride and for quantitative assay of emetine hydrochloride injection by a method previously reported for injections of aminosalts. The method involves nonaqueous titration of a chloroform-eluted sample from a magnesium oxide-siliceous earth mixture. Thermogravimetric data show that emetine hydrochloride forms no stable hydrates, that water can be lost even at room temperature, and that loss still continues slowly beyond the usual drying temperature so that it is difficult to render the material anhydrous. For these reasons, it is suggested that emetine hydrochloride and emetine hydrochloride injection be labeled with the content of anhydrous emetine hydrochloride. Permissible variation should be $\pm 1\%$ for emetine hydrochloride and $\pm 5\%$ for the injection.

Keyphrases □ Emetine HCl injection—analysis □ Potentiometric titration—analysis □ Titrimetry—analysis

Emetine Hydrochloride Injection USP XVII has a peculiar definition in that "it contains an amount of anhydrous emetine hydrochloride ($C_{29}H_{40}N_2O_4 \cdot 2HCl$)

equivalent to not less than 84% and not more than 94% of the labeled amount of emetine hydrochloride" (1). Thus it is the only pharmaceutical preparation formulated at less than 100% of label claim. This peculiar definition is necessitated by the official definition of Emetine Hydrochloride USP XVII as a hydrate of uncertain composition, which "contains not less than 98.0% and not more than 101.5% of $C_{29}H_{40}N_2O_4 \cdot 2HCl$, calculated on the anhydrous basis" (2).

Water is determined as follows: "Dry it at 105° for 2 hr.: it loses not less than 8% and not more than 14% of its weight" (2). The average water content of the solid is thus 11%, which corresponds to the average requirement for the injection of 89% of anhydrous material.

An attempt was made to assay emetine hydrochloride injection by a previously proposed method (3). The method involves distributing the sample over a mixture of magnesium oxide and purified diatomaceous earth held on a sintered-glass filtering funnel, eluting the

Figure 1—Thermogravimetric study of emetine hydrochloride.

liberated base with chloroform, and titrating the eluates with perchloric acid. However, due to the low requirement in meeting label claims, this could not be used as a guide to recovery. Therefore, a more extensive investigation was pursued.

EXPERIMENTAL

Procedure A—Weigh accurately 170 mg. of emetine hydrochloride, previously dried at 105° for 3 hr. Dissolve it in 40 ml. of glacial acetic acid; add 10 ml. of mercuric acetate T.S. and 6 drops of 0.25% *p*-naphtholbenzein in glacial acetic acid. Titrate to the green end-point. Perform a blank titration and make any necessary correction. Concomitantly determine the end-point potentiometrically. This is essentially the method of DAB 7 (4).

Weigh an amount of dried, assayed emetine hydrochloride, equivalent to 325.0 mg. of anhydrous salt, and dissolve in enough distilled water to make 5.00 ml. Assay by *Procedure B*.

Procedure B—Distribute 2.00 ml. of the solution over 3 g. of a mixture of 1 g. of chromatographic magnesium oxide and 10 g. of high flowrate, purified siliceous earth¹ held on a coarse-porosity, sintered-glass filtering funnel. Elute with five 10-ml. portions of warm (55°) chloroform, mixing each portion well with the contents of the crucible and then draining with gentle suction into 40 ml. of glacial acetic acid. Add 6 drops of *p*-naphtholbenzein indicator and titrate to the green end-point. Perform a blank titration and make any necessary correction. Concomitantly, determine the end-point potentiometrically (3).

The content of anhydrous emetine hydrochloride in the dried material found by duplicate titration by *Procedure A* was: potentiometric, 97.535 ± 0.077%; and indicator, 98.250 ± 0.084%.

Recovery from the standard solution found by duplicate titration by *Procedure B* was: potentiometric, 98.92 ± 0.25%; and indicator, 99.03 ± 0.15%.

Recovery from a commercial injection found by triplicate determination was 87.66 ± 0.76%, using the indicator end-point.

DISCUSSION

Data for recovery of assayed material show that the proposed method for the injection is accurate and reproducible enough for use as a method of control. Recovery from the commercial product is

satisfactory in view of an 89 ± 5% requirement. The authors were troubled, however, by the low result obtained in the assay of the supposedly anhydrous solid, which differs significantly from 100% and barely meets the 98.0% minimum required if the indicator end-point value is taken. The sample used had been dried to constant weight, as shown by drying for an additional hour, so that the discrepancy was difficult to explain.

A sample of the original material was submitted for thermogravimetric analysis. A copy of the record is shown in Fig. 1 for a 10.8-mg. sample heated at 5°/min. in a nitrogen atmosphere. From this it can be concluded that:

1. Emetine hydrochloride forms no stable hydrates.
2. Water loss takes place even at room temperature. This usually indicates that the water content of the solid will fluctuate with the relative humidity.
3. Slow loss continues to take place at temperatures above 105°, so that the drying time specified in USP XVII would not be expected to remove all moisture. Moisture loss is so slow, however, that the sample will appear to have reached constant weight by the usual criterion. It is suggested, therefore, that emetine hydrochloride be defined in terms of its content of anhydrous salt without drying. The definition should then read: "contains not less than 99% and not more than 101% of the labeled content of anhydrous emetine hydrochloride." The injection should also be labeled in terms of content of anhydrous salt.
4. A new sample of emetine hydrochloride was obtained for moisture determination by the Karl Fischer titrimetric method (5). The reagent was standardized in triplicate against sodium tartrate dihydrate containing 15.61% water to yield a value of 6.276 ± 0.021 mg. H₂O/ml. The moisture in the emetine hydrochloride sample, determined in duplicate, was 9.40 ± 0.01%. Moisture content by drying to constant weight was 9.27%. This finding again shows that drying to constant weight does not quite remove all of the moisture. The close agreement between the oven-drying method and the Karl Fischer method suggests that the titrimetric procedure should be adopted.

Colorimetric and Gas Chromatographic Analyses of Arecoline in Capsule Preparations

BARBARA J. KOVENSKY and CHARLES W. POOLE

Abstract □ Two procedures have been developed for the quantitative determination of arecoline hydrobromide in capsule preparations. In the colorimetric assay, the arecoline salt was converted to the base with aqueous sodium bicarbonate, extracted into chloroform, and reacted with methyl orange. The absorbance was determined at 527 mμ. With the GLC method, the arecoline salt was converted to the base in a 5:100 triethylamine-chloroform solution and directly injected onto the column, using nicotine as the internal standard. The GLC method was found to be faster and more accurate.

Keyphrases □ Arecoline capsules—analysis □ Colorimetric analysis—spectrophotometry □ GLC—analysis

Arecoline hydrobromide, methyl 1,2,5,6-tetrahydro-1-methylnicotinate hydrobromide, is a parasympathomimetic agent. Its major pharmaceutical uses are as a cathartic for horses and a teniacide for dogs.

The only officially recognized assay pertaining to this material has its major application with the raw material (1). Until 1960, when Stainier and Gloesener (2) published their somewhat laborious gas chromatographic procedure, the compound had been virtually ignored in light of advanced analytical instrumentation.

The presence of arecoline hydrobromide in many soft gelatin capsule preparations necessitated these investigations. First a colorimetric assay was developed and subsequently a faster and more convenient gas chromatographic assay.

EXPERIMENTAL

Colorimetric Assay—Preparation of Sample and Standard—Fifty milligrams of arecoline hydrobromide dissolved in 500 ml. of water served as the standard. Capsules sufficient to yield a sample of 10 mg. of arecoline hydrobromide were cut into a 200-ml. centrifuge bottle; 25 ml. of chloroform was added, and the sample was swirled to disperse the fill material. To the solution, 0.1 N H₂SO₄ (100 ml.) was added; then the sample was shaken for 10 min. and centrifuged to separate the biphasic mixture.

Assay Procedure—A 5-ml. aliquot of the aqueous phase and the standard were each transferred to 200-ml. centrifuge bottles. Five milliliters of water and 1 g. of sodium bicarbonate were then added to the solutions. The samples (i.e., the prepared sample and standard) were heated on a steam bath until effervescence subsided and then cooled to room temperature. Chloroform (100 ml.) was added to the samples, which were then shaken for 10 min. The samples were centrifuged and the aqueous phase was discarded.

A 40-ml. portion of each sample was transferred to a 50-ml. glass-stoppered centrifuge tube along with a 40-ml. portion of chloroform as a reagent blank. One milliliter of a saturated aqueous solution of boric acid and 1.0 ml. of a saturated aqueous solution of methyl orange were added to each sample and the reagent blank. The resulting solutions were shaken for 20 min., centrifuged, and the water layer discarded. A 15-ml. aliquot of each was then transferred to 50-ml. glass-stoppered tubes, and 1.0 ml. of a 2% H₂SO₄ solution in absolute ethanol was added. The absorbance was read at 527 mμ against the reagent blank.

Figure 1—Representative chromatogram: a, arecoline (4.5 min.); and b, nicotine (8 min.).

Calculations—The potency of arecoline hydrobromide in milligrams per capsule was calculated using the following formula:

$$\frac{A_u}{A_s} \times \frac{10}{\text{number of capsules}} = \text{mg. arecoline HBr/capsule (Eq. 1)}$$

where A_u is the absorbance of assay sample solution, and A_s is the absorbance of standard solution.

Gas Chromatographic Assay—Preparation of Sample and Standard—A 52.0-mg. sample of arecoline hydrobromide was weighed into a 250-ml. centrifuge bottle to use as the standard. Capsules comprising a 52.0-mg. sample of arecoline hydrobromide were cut open and dispersed in a 250-ml. centrifuge bottle. To both sample and standard, a 5:100 triethylamine solution in chloroform (100 ml.) was added, and the samples were shaken for 10 min. A 50-ml. portion of water was added to extract any compound

Table I—Comparison of the Two Assay Procedures

Product Lot	Capsule Claim, mg.	Methyl Orange	Recovery, %	GLC	Recovery, %
I	25.92	25.5	98.3	25.8	99.5
II	25.92	25.0	96.5	25.1	96.8
III	4.14	4.1	97.6	4.2	103.0
IV	34.56	31.8	92.0	33.4	96.8
V	2.70	2.7	100.0	3.3	121.1
VI	35.5	29.4	85.0	33.8	97.8

from the shell surfaces. The biphasic mixture was shaken, centrifuged, and the water layer discarded.

The standard and sample solutions were then diluted 1:1 with a 0.5 mg./ml. solution of nicotine in chloroform, the internal standard. Two microliters of each solution was injected onto the column.

Gas Chromatograph—A Varian 2100 chromatograph with a hydrogen-flame ionization detector was used with a model 480 electronic digital integrator equipped with a Victor Digit-matic printout.

Column and Conditions—A 1.52 m. \times 0.63 cm. \times 2 mm. (5 ft. \times 0.25 in. \times 2 mm.) Pyrex column was packed with 5% polyethylene glycol 20 M¹ and 0.2% KOH on 60/80 diatomaceous earth.² The column was preconditioned overnight at 170° in a stream of helium. The operating conditions were as follows: column temperature, 120°; injector temperature, 235°; detector temperature, 250°; carrier gas, helium, 57 ml./min.; detector gas, hydrogen, 25 ml./min.; air, 300 ml./min.; and sensitivity, 124×10^{-12} amp./mv.

Identification of Constituents—The relative retention times were arecoline, 4.5 min., and nicotine, 8 min.

Calculations—The potency of arecoline hydrobromide in milligrams per capsule was calculated according to the following formula:

$$As \cdot \frac{Ca}{Ar} \cdot X = \text{mg. arecoline HBr/capsule} \quad (\text{Eq. 2})$$

where *As* is the area of the arecoline peak in sample/area of internal standard peak, *Ca* is the concentration of arecoline hydrobromide in mg./ml. in the standard solution, *Ar* is the area of arecoline peak in prepared standard/area of internal standard peak, and *X* is the dilution factor.

RESULTS AND DISCUSSION

Several gelatin capsule preparations were assayed by the method proposed in the "Official Methods of Analysis" (1). The method was found inadequate for capsules, because the average dosage level of arecoline hydrobromide is 1–8 mg. The number of capsules needed to procure the necessary 100.0-mg. sample created severe emulsion problems. The overabundance of gelatin made it virtually impossible to separate the two phases required for the assay. The

Table II—Statistical Treatment of GLC Procedure

Sample No.	Claim, mg.	Amount Recovered, mg.	Recovery, %
1A	54.5	52.0	95.4
1B	54.5	56.1	102.9
1C	54.5	52.6	96.5
IIA	54.5	55.5	101.8
IIB	54.5	54.6	100.2
IIC	54.5	52.9	97.1

Mean		54.2	99.4
SD			3.0

methyl orange colorimetric method proposed here, although sensitive to any trace of amines or ammonia compounds on the glassware, did suffice as an analytical tool for assaying low concentrations of arecoline hydrobromide.

In an attempt to conserve the relatively large amount of time necessary for running the assay colorimetrically, the investigation then turned to developing a quicker, more precise instrumental method. A perusal of the literature revealed Stainier and Gloesener's (2) chromatographic assay of arecoline. Their samples of arecoline were hydrolyzed with KOH, and the corresponding alcohols were assayed quantitatively. Since the method was rather indirect, it was felt that arecoline could be chromatographed directly by merely converting the hydrobromide salt to its base in an appropriate solvent and injecting the arecoline directly onto the proper column.

A typical chromatogram is shown in Fig. 1. The peaks are well resolved and symmetrical; absorption effects appear to be absent.

Table I shows a comparison of values for each of the proposed methods, which were each run on six capsule lot preparations of varying concentrations of arecoline hydrobromide. In each case, a greater part of the theoretical claim was recovered with the gas chromatographic method, which also took less time to complete. Nine samples, each containing 54.5 mg. of arecoline hydrobromide, showed a mean percent recovery of 99.4 with a relative standard deviation from the mean of ± 3.0 (Table II). The precision of the colorimetric assay was found in experimental studies to be of the magnitude of $\pm 6.0\%$.

Characterization of the Content Uniformity Plan

C. B. SAMPSON, H. L. BREUNIG, J. P. COMER, and D. E. BROADLICK

Abstract □ The operating characteristic of the official content uniformity plans is developed in terms of proportion defective in a lot. This proportion defective is represented as a function of the means and variances, respectively, of the drug substance weight and the tablet weight. It is then shown that the probability of acceptance of a lot can be derived for each process from knowledge of only: (a) the coefficient of variation, and (b) the proportional process bias. That is, the proportion defective in a lot is considered in terms of departures from theoretical drug substance weight and target tablet weight and their coefficients of variation which can arise in normal manufacturing operations. A completely worked example of these calculations outlines the procedure. The tables show, through computer calculation, the probability of acceptance arising through the interplay of several selected values of the coefficients of variation and of the proportional process bias.

Keyphrases □ Tablet content uniformity—determination □ Content uniformity, tablets—sampling plan □ Defective tablets, proportion—determination □ Formulas, tablet—content uniformity determination

The content uniformity sampling plans for tablets in USP XVII and NF XIII have the disadvantages that all information available to the analyst is not efficiently utilized and that the probability of acceptance of a lot cannot be evaluated in terms of departures from the theoretical drug content and target tablet weight.

A new procedure for estimating content uniformity in pharmaceutical products has been proposed by Comer *et al.* (1). Information from both tablet weights and assays may be utilized to provide more efficient estimates of mean potency and tolerance limits. In the present paper, the authors develop the operating characteristics of current official sampling plans for content uniformity tests. Formulas are presented for studying the effect of slight changes in drug content and tablet weight during manufacture upon the probability that a lot of material will meet the official content uniformity limits. These formulas include not only the coefficients of variation of both tablet weight and assay data but also what are described as proportional process biases in these variables. Similar statements concerning the USP weight variation test have been made by Roberts (2).

STRUCTURE

The primary forces which determine the amount of drug substance in the unit dose of pharmaceutical tablet forms are: (a) the weight of drug substance per weight of formulation material as estimated by assay, say P , and (b) tablet weights, say Y .

If a population is assumed to be normal, then the population parameters of interest are the mean, μ , and the variance, σ^2 . Such a normal distribution is denoted by the conventional $N(\mu, \sigma^2)$. Then, restating the assumption of normality, the population of tablet weights is assumed to be normally distributed with mean μ_y

and variance σ_y^2 , i.e., $N(\mu_y, \sigma_y^2)$. Similarly, the distribution of single-unit assay measurements is $N(\mu_p, \sigma_p^2)$. For consistency, say that Y is measured in milligrams per tablet and P in milligrams of drug substance per milligram of formulation material. It is further assumed that the concentration of drug, P , is independent of the weight of the tablet, Y . The unbiased estimates of μ_p , μ_y , σ_p^2 , and σ_y^2 are denoted by \bar{p} , \bar{y} , s_p^2 , and s_y^2 , respectively. These estimates are based on n_p observations on the P distribution and n_y observations on the Y distribution.

The variable of interest is PY , the weight of drug substance in milligrams per tablet. Some distribution-free results concerning the mean and variance of PY are now presented. Since P is assumed to be independent of Y , the population mean, μ_{py} , is given by the product of the respective population mean, $\mu_p\mu_y$, and the population variance, σ_{py}^2 , is equal to $\mu_p^2\sigma_y^2 + \mu_y^2\sigma_p^2 + \sigma_p^2\sigma_y^2$. [See, for example, Goodman (3).] The unbiased estimates of μ_{py} and σ_{py}^2 are easily shown to be

$$\hat{\mu}_{py} = \bar{p}\bar{y} \quad (\text{Eq. 1a})$$

$$\hat{\sigma}_{py}^2 = \bar{p}^2s_y^2 + \bar{y}^2s_p^2 + \left(1 - \frac{1}{n_p} - \frac{1}{n_y}\right)s_p^2s_y^2 \quad (\text{Eq. 1b})$$

The distribution of PY is not easily determined, but some exact distribution results have been reported by Craig (4), Aroian (5), and DeZur and Donahue (6). These results are somewhat mathematically intractable and are not readily amenable to practical utilization. However, Aroian (5) has demonstrated that as the ratios σ_p/μ_p and σ_y/μ_y , singly or together, become small, the distribution of PY approaches normality. These ratios, denoted by γ_p and γ_y , respectively, are called population coefficients of variation.

Also, approximate formulas for skewness and kurtosis have been worked out for the product of two random variables. [See Burr (7).] Skewness and kurtosis are measures of shape of distribution which, along with the mean and variance, characterize most distributions fairly well. Skewness is a measure of symmetry and has a value of zero for symmetric distributions. Kurtosis measures flatness or peakedness and equals 3.0 for a normal distribution and 1.8 for the rectangular (uniform) distribution.

Sampson (8) evaluated the skewness and kurtosis formulas, performed some Monte Carlo simulations, and concluded that, for the coefficients of variation of magnitudes usually encountered and considered acceptable in tablet manufacture, the assumption of normality for the distribution of PY is reasonable, provided P and Y have normal distributions.

With this structure in mind, the probability of meeting content uniformity requirements for various population coefficients of variation for the respective populations of single-unit assays and of tablet weights is developed.

OPERATING CHARACTERISTIC FORMULAS

The current content uniformity sampling plan for tablets in USP XVII (9) and NF XIII (10) may be summarized as follows: Individually assay 10 tablets. If all 10 are within 85–115% of the mean of the tolerances specified in the official monograph, then the requirements are met. If one of 10 fails, i.e., falls outside the limits, then 20 more tablets are individually assayed. If only one of the combined sample of 30 falls outside limits, the lot is passed. All other possibilities result in failure to meet requirements.

A tablet outside of limits is defined as a "defective." The probability of accepting a lot with a proportion, π , of defective units

under this sampling plan is

$$P_{\pi} = (1 - \pi)^{10} + 10\pi(1 - \pi)^9 \quad (\text{Eq. 2})$$

P_{π} is easily derived from the criteria for the sampling plan and delineates the operating characteristic curve for various values of the proportion defective π . Once π is evaluated in light of this structure, Eq. 2 characterizes the content uniformity plan.

The lower and upper allowable limits for a particular characteristic of a product unit are denoted by L and U , respectively. If the mean of the tolerances specified by the official monograph is μ , then $L = 0.85\mu$ and $U = 1.15\mu$ for the official plan. If label claim is μ , then the process is expected to operate such that $\mu = \mu_p\mu_y$; therefore, $1 - \pi = \Pr[L < PY < U] = \Pr[0.85\mu_p\mu_y < PY < 1.15\mu_p\mu_y]$ may be evaluated. It is probable that the parameter mean for the drug substance in formulation material may be running not exactly at μ_p but at $\mu_p + \Delta_p$ for a given point in time, where Δ_p is some incremental change and may be positive or negative. Similarly the process may not be making tablets that weigh on the average μ_y but rather $\mu_y + \Delta_y$. With this in mind, π is computed as a function of the coefficients of variation, $\gamma_p = \sigma_p/\mu_p$ and $\gamma_y = \sigma_y/\mu_y$, and also of what may be termed proportional process biases, $\delta_p = \Delta_p/\mu_p$ and $\delta_y = \Delta_y/\mu_y$. That is, π is a function only of γ_p , γ_y , δ_p , and δ_y ; when the processes are running on target so that δ_p and δ_y both equal zero, then π is dependent only upon γ_p and γ_y , the population coefficients of variation.

From these definitions,

$$\mu_{py} = (\mu_p + \Delta_p)(\mu_y + \Delta_y) = \mu_p\mu_y(1 + \delta_p)(1 + \delta_y) \quad (\text{Eq. 3})$$

$$\begin{aligned} \sigma_{py}^2 &= (\mu_p + \Delta_p)^2\sigma_y^2 + (\mu_y + \Delta_y)^2\sigma_p^2 + \sigma_p^2\sigma_y^2 \\ &= \mu_p^2\sigma_y^2(1 + \delta_p)^2 + \mu_y^2\sigma_p^2(1 + \delta_y)^2 + \mu_p^2\mu_y^2\gamma_p^2\gamma_y^2 \end{aligned} \quad (\text{Eq. 4})$$

Furthermore:

$$\begin{aligned} 1 - \pi &= \Pr[L < PY < U] \\ &= \Pr\left[\frac{L - \mu_{py}}{\sigma_{py}} < \frac{PY - \mu_{py}}{\sigma_{py}} < \frac{U - \mu_{py}}{\sigma_{py}}\right] \\ &= F\left[\frac{U - \mu_{py}}{\sigma_{py}}\right] - F\left[\frac{L - \mu_{py}}{\sigma_{py}}\right] \end{aligned} \quad (\text{Eq. 5a})$$

where $F[\cdot]$ may be found in tables of the cumulative distribution of the standardized normal function. [For example, see Beyer (11).] From Eqs. 3 and 4,

$$\frac{U - \mu_{py}}{\sigma_{py}} = \frac{1.15\mu_p\mu_y - \mu_p\mu_y(1 + \delta_p)(1 + \delta_y)}{[\mu_p^2\sigma_y^2(1 + \delta_p)^2 + \mu_y^2\sigma_p^2(1 + \delta_y)^2 + \mu_p^2\mu_y^2\gamma_p^2\gamma_y^2]^{1/2}} \quad (\text{Eq. 5b})$$

By combining and cancelling terms on the right-hand side, this becomes

$$\frac{U - \mu_{py}}{\sigma_{py}} = \frac{1.15 - (1 + \delta_p)(1 + \delta_y)}{\gamma_{py}} \quad (\text{Eq. 6})$$

where

$$\gamma_{py} = [\gamma_y^2(1 + \delta_p)^2 + \gamma_p^2(1 + \delta_y)^2 + \gamma_p^2\gamma_y^2]^{1/2} \quad (\text{Eq. 7})$$

Similarly,

$$\frac{L - \mu_{py}}{\sigma_{py}} = \frac{0.85 - (1 + \delta_p)(1 + \delta_y)}{\gamma_{py}} \quad (\text{Eq. 8})$$

By carrying out the calculations of Eqs. 7, 6, 8, and 5a and inserting into Eq. 2, the probability of accepting a lot for given values of γ_p , γ_y , δ_p , and δ_y may be computed.

ILLUSTRATION

Suppose that for a given tablet item labeled at 10 mg. drug per tablet, the process specifications stipulate that the target weight for the granulation is 0.1 mg. of drug substance per milligram of formulation material, i.e.,

$$\mu_p = 0.1 \text{ mg./mg.} \quad (\text{Eq. 9})$$

^a When $\delta_p = \delta_y = 0$, the tables are symmetrical.

The repeatability of assay determinations, which also reflects homogeneity, is given by a standard deviation of, say,

$$\sigma_p = 4 \times 10^{-3} \text{ mg./mg.} \quad (\text{Eq. 10})$$

Similarly, the target weight for compression and weighing may be

$$\mu_y = 100 \text{ mg./tablet} \quad (\text{Eq. 11})$$

and the repeatability of compression and weighing may be

$$\sigma_y = 3.0 \text{ mg./tablet} \quad (\text{Eq. 12})$$

Assume, however, that for a particular lot the process is running low on formulation and high on compression so that

$$\mu_p + \Delta_p = 0.093 \text{ mg./mg.} \quad (\text{Eq. 13})$$

and

$$\mu_y + \Delta_y = 101 \text{ mg./tablet} \quad (\text{Eq. 14})$$

with the standard deviations remaining the same.

Then, by definition, $\delta_p = -0.07$, $\delta_y = 0.01$, $\gamma_p = 0.04$, and $\gamma_y = 0.03$. Calculating from Eq. 3,

$$\begin{aligned} \mu_{py} &= (0.1)(100)(1 - 0.07)(1 + 0.01) \\ &= 9.393 \text{ mg. drug/tablet} \end{aligned} \quad (\text{Eq. 15})$$

and from Eq. 7,

$$\begin{aligned} \gamma_{py} &= [(0.04)^2(1 + 0.01)^2 + (0.03)^2(1 - 0.07)^2 \\ &\quad + (0.04)^2(0.03)^2]^{1/2} \\ &= 0.04911 \end{aligned} \quad (\text{Eq. 16})$$

From Eq. 6:

$$\begin{aligned} \frac{U - \mu_{py}}{\sigma_{py}} &= \frac{1.15 - (1 - 0.07)(1 + 0.01)}{0.04911} \\ &= 4.29 \end{aligned} \quad (\text{Eq. 17})$$

And, similarly, from Eq. 8,

$$\begin{aligned} \frac{L - \mu_{py}}{\sigma_{py}} &= \frac{0.85 - (1 - 0.07)(1 + 0.01)}{0.04911} \\ &= -1.818 \end{aligned} \quad (\text{Eq. 18})$$

By Eq. 5a,

$$\begin{aligned} 1 - \pi &= F[4.29] - F[-1.818] \\ &= 1.00 - 0.03454 \text{ (Reference 11)} \end{aligned} \quad (\text{Eq. 19})$$

and thus $\pi = 0.03454$.

By Eq. 2

$$\begin{aligned} P_{0.03454} &= (0.96546)^{10} + 10(0.03454)(0.96546)^9 \\ &= 0.8283 \end{aligned} \quad (\text{Eq. 20})$$

for the values given for γ_p , γ_y , δ_p , and δ_y .

That is, if the label claim is 10 mg. of drug substance per tablet and if the processes are running at $\mu_p = 0.093 \text{ mg./mg.}$ and $\mu_y =$

Table II—Probability of Meeting Content Uniformity Requirements

γ_p	γ_y		
	0.01	0.03	0.05
when $\delta_p = -0.04$, $\delta_y = 0.02$			
0.01	1.0000	1.0000	0.9954
0.03	1.0000	0.9997	0.9663
0.05	0.9896	0.9539	0.7871
when $\delta_p = 0.09$, $\delta_y = -0.08$			
0.01	1.0000	1.0000	0.9986
0.03	1.0000	1.0000	0.9786
0.05	0.9836	0.9459	0.7943
when $\delta_p = 0.07$, $\delta_y = -0.01$			
0.01	1.0000	0.9986	0.7794
0.03	0.9996	0.9560	0.6310
0.05	0.8593	0.6823	0.4063

101 mg./tablet with coefficients of variation of 3% for P and 4% for Y , then the probability of meeting the content uniformity requirements as specified in USP XVII and NF XIII is 0.8283.

Although it is not feasible to publish complete tables of $P[\pi]$ for even a representative indexing of γ_p , γ_y , δ_p , and δ_y , a few additional examples (Tables I and II) are included.

DISCUSSION

Recalling that the probabilities of meeting content uniformity requirements depend only upon the four parameters δ_p , δ_y , γ_p , and γ_y , it is convenient to note that these probabilities are symmetric with respect to the pairs (δ_p, γ_p) and (δ_y, γ_y) . That is, if $(\delta_p, \gamma_p) = (0.07, 0.03)$ and $(\delta_y, \gamma_y) = (-0.01, 0.05)$, then the probability of acceptance is the same as if $(\delta_p, \gamma_p) = (-0.01, 0.05)$ and $(\delta_y, \gamma_y) = (0.07, 0.03)$. This can be easily verified from Eqs. 6 and 7.

The IBM Mathpack Subroutine NDTR (12) was used to calculate the function $F[]$. Since this particular subroutine has a maximum error of $7(\times 10^{-7})$, the computed probabilities are in general more accurate than if they were computed using $F[]$ from usual tabled sources of the cumulative normal distribution. The difference is in the fourth decimal place and of little practical significance.

Note that several probabilities in Tables I and II are given as

1.0000. This means that, even though it is not absolutely certain that a lot will meet content uniformity requirements under the indexed parameter conditions, the probabilities of acceptance are so high that rounding to four decimal places carries these values to 1.0000.

The formulas in this paper compute the probability of meeting content uniformity requirements for given population parameters γ_p , γ_y , δ_p , and δ_y . They characterize the content uniformity sampling plan and are to be used as supplemental information in making decisions before and during the production of particular products.

Solid-Phase Synthesis and Degradation of a Model Polypeptide by an Automated Approach

ANDREW M. TOMETSKO*, JOHN TISCHIO, and JOHN GARDEN, II

Abstract □ The solid-phase synthesis and degradation of a model polypeptide, L-leucyl-L-leucyl-L-leucyl-L-leucyl-L-leucyl-L-alanine, was carried out using a computer-oriented automated approach. Two computer programs were used to generate control paper tapes for the total synthesis and degradation of the model peptide. Encouraging results were obtained in automating the degradation of polypeptides on the solid phase and in carrying out the degradation in a nonaqueous solvent system. The course of the synthesis and the degradation was monitored by amino acid analysis of acid

hydrolyzates of the resin which were taken periodically. The automated solid-phase degradation of naturally occurring polypeptides and proteins should be possible through modifications of the described approach.

Keyphrases □ Polypeptide—automated synthesis, degradation □ Amino acid sequence, computer controlled—polypeptide synthesis □ Degradation, polypeptide, Edman—automated □ Automated system—peptide synthesis, degradation

Classical methods have been employed in the chemical synthesis (1–6) and Edman degradation (7–10) of polypeptides and proteins. Recently, a number of labora-

tories have automated solid-phase polypeptide synthesis (11–14); in one instance (15), the automation of classical sequential analysis of polypeptides has been reported.

Solid-Phase Synthesis and Degradation of a Model Polypeptide by an Automated Approach

ANDREW M. TOMETSKO*, JOHN TISCHIO, and JOHN GARDEN, II

Abstract □ The solid-phase synthesis and degradation of a model polypeptide, L-leucyl-L-leucyl-L-leucyl-L-leucyl-L-leucyl-L-alanine, was carried out using a computer-oriented automated approach. Two computer programs were used to generate control paper tapes for the total synthesis and degradation of the model peptide. Encouraging results were obtained in automating the degradation of polypeptides on the solid phase and in carrying out the degradation in a nonaqueous solvent system. The course of the synthesis and the degradation was monitored by amino acid analysis of acid

hydrolyzates of the resin which were taken periodically. The automated solid-phase degradation of naturally occurring polypeptides and proteins should be possible through modifications of the described approach.

Keyphrases □ Polypeptide—automated synthesis, degradation □ Amino acid sequence, computer controlled—polypeptide synthesis □ Degradation, polypeptide, Edman—automated □ Automated system—peptide synthesis, degradation

Classical methods have been employed in the chemical synthesis (1–6) and Edman degradation (7–10) of polypeptides and proteins. Recently, a number of labora-

tories have automated solid-phase polypeptide synthesis (11–14); in one instance (15), the automation of classical sequential analysis of polypeptides has been reported.

Studies in this laboratory have been directed toward the development of automated techniques that might be applicable to solid-phase synthesis and solid-phase degradation of polypeptides. Toward this goal an Automatic Chemical Reaction System (ACRS) (16) has been designed and constructed to carry out the physical operations involved in the synthesis and/or degradation following commands punched in a paper tape. Another phase of this research program has involved the development of computer approaches for generating the paper tape containing the commands for executing the synthesis or degradation (*e.g.*, amino acid additions, filtration steps, stirring sequences, deblocking steps, wash cycles, and activation steps).

Although the synthesis of polypeptides on the solid phase has been extensively studied and discussed (17–21), reports on solid-phase degradation have been limited to studies employing a resin-bound isothiocyanate functional group (22, 23) and to studies with the peptide bound to the resin but using methylisothiocyanate (MTC) in the degradation (24, 25). Dijkstra *et al.* (25) suggested that MTC is preferable to the classical phenylisothiocyanate (PTC) due to its higher solubility in aqueous solvents. They also suggested that PTC interacts unfavorably with the resin under their reaction conditions. Since Edman and Begg (15) demonstrated nearly quantitative coupling of PTC with free amines, and since the nature of the solvent could have a considerable influence on the interactions occurring within a chemical system, a study of the degradation using PTC in nonaqueous solvent systems seemed worthwhile. Information concerning the use of PTC with solid-phase degradative systems in nonaqueous solvents has been limited (26).

In this article, the authors report the application of ACRS to the solid-phase synthesis and degradation of a model polypeptide, L-leucyl-L-leucyl-L-leucyl-L-leucyl-L-leucyl-L-alanine. This model peptide was chosen to study: (a) the use of PTC for the degradation of polypeptides in conjunction with a solid-phase (polystyrene) matrix; (b) the solid-phase degradation in a nonaqueous solvent that would be more compatible with both PTC and the resin; and (c) the feasibility of automating the synthesis and Edman degradation of polypeptides by applying a computer-oriented automated approach.

EXPERIMENTAL

Chemicals—All reagents were of analytical grade. L-Amino acids,¹ trifluoroacetic acid (TFA),² and chloromethylated polystyrene³ were used. *tert*-Butyloxycarbonyl (*t*-BOC) amino acids were prepared by the method of Schwyzler *et al.* (27).

Preparation of *tert*-Butyloxycarbonyl Alanine (*t*-BOC ala.) Resin—The *t*-BOC ala. resin was prepared according to the method of Merrifield (17). Specifically, chloromethylated polystyrene (25 g., 0.7 meq./g.) was refluxed for 48 hr. with *t*-BOC ala. (9.88 g.) and triethylamine (Et₃N) (7.65 ml.) in absolute ethanol (150 ml.). The resin was filtered and washed three times with ethanol (50 ml. each) and three times with methanol (50 ml. each) and then was dried *in vacuo*. Amino acid analysis of an acid hydrolyzate of resin gave an alanine content of 0.523 meq./g.

Automatic Chemical Reaction System (ACRS)—ACRS (16) is an electromechanical device, which was designed and constructed to

Table I—Sequence of Chemical Additions for Coupling an Amino Acid

10. CHCl ₃	Wash (three times)	2.0 each	6
Total time/cycle =			202

execute automatically the physical operations normally involved in solid-phase synthesis or degradation. Specifically, it is capable of measuring and dispensing appropriate chemicals into a reaction vessel, stirring chemicals, filtering, timing events, and, generally, controlling the synthetic or degradative processes. The information for every operation is punched onto a paper tape. The paper tape is fed into the ACRS unit, which translates the punched holes into physical operations such as turning on a stirrer or operating valve networks. Obviously, the ACRS is merely assisting by executing operations which would normally be carried out by the investigator.

The principal component of this type of reaction system is the decoder which translates the command tape. In essence, this approach divides the synthesis or degradation into two categories: (a) those features that are primarily physical in nature (*e.g.*, measuring and adding chemicals), and (b) those features that are primarily chemical in nature (*e.g.*, removal of protecting groups and coupling of amino acids). By assuming the burden of the first category, the ACRS permits the investigator to concentrate more on the chemical aspects of the synthesis or degradation.

Preparation of Control Tape with Computers—In the automated approach discussed in this report, the sequence of operations involved in the chemical synthesis or degradation is incorporated onto a paper tape. Methods for preparing the command tape quickly and accurately are extremely important. Manual methods could be used to prepare the control tape. However, such methods are very time-consuming and increasingly subject to error as the number of commands increase. These difficulties led to a search for a more rapid and reliable means for preparing control tapes. Since the linear progression of commands with time is analogous in form to a one-dimensional array, a computer appeared to be an obvious candidate for setting up a simple array of commands of any reasonable dimension (*e.g.*, 30,000 commands). Once the computer program for generating the command array is available, the computer provides a control tape with speed (60 commands/sec.) and with reliability for any number of commands.

By using this approach for the synthesis of polypeptides, it is only necessary to specify the amino acid sequence, and the computer generates a one-dimensional array of commands for the complete synthesis. To specify the desired amino acid sequence, a set of data cards is prepared with the name of each amino acid punched onto a separate card. The cards are then placed in the data deck in the order that the amino acids occur in the polypeptide chain. Thus, if the sequence gly.val.leu.phe is desired, four cards corresponding to gly, val, leu, and phe, respectively, are arranged in order and inserted at the end of the data section of the program. For a 100-amino acid protein, 100 cards in the appropriate sequence are used. The program and data are read into the computer, which generates all of the commands involved in the complete synthesis of the peptide. With a functional program,⁴ an investigator (with little or no programming experience) could generate a control tape of any desired length within minutes by simply supplying the desired amino acid sequence.

Computers—Computer programs⁴ were written in the FORTRAN IV language and processed by an IBM 360-44 computer and a PDP-7 computer (University of Rochester). In this process, an array of commands was generated by the IBM 360-44 and copied

4	0.207 ^a	0.840 ^a	1:4.06 ^a	1:4
5	0.195 ± 0.008	0.945 ± 0.010	1:4.86	1:5

^a Values present are from one experiment since sampling from the second experiment was taken 5 min. after the addition of the fifth leucine and activating agent. (See Discussion.)

onto a magnetic tape. The magnetic tape was then read by the PDP-7 computer which produced a paper tape paralleling the commands on the magnetic tape.

Chemical Synthesis—The automated chemical synthesis of the model polypeptide, L-leucyl-L-leucyl-L-leucyl-L-leucyl-L-leucyl-L-alanine, was carried out using the sequence of operations shown in Table I. Initially, stock solutions of the various reagents were prepared and placed in the ACRS unit. These solutions consisted of: (a) 0.2 M *t*-BOC leu in chloroform (CHCl₃); (b) 0.2 M dicyclohexylcarbodiimide (DCC) in CHCl₃; (c) 10% Et₃N in CHCl₃; (d) 50% TFA in CHCl₃; (e) ethanol; and (f) CHCl₃. The desired amino acid sequence was read into the computer (*i.e.*, five data cards calling for leucine) along with the FORTRAN IV program deck. A one-dimensional array of commands for the synthesis of the peptide was then set up by the computer and copied onto a magnetic tape. The magnetic tape was then read by a PDP-7 computer which produced the control paper tape. The ACRS unit (through its decoder) executed the following operations from the tape.

A sample of deblocked *t*-BOC ala. resin (3.0 g.) in the reaction vessel was treated three times with CHCl₃ to wash and swell the resin. A solution of *tert*-butoxycarbonyl-L-leucine (30 ml.) was then added, the mixture was stirred for 1 min., and a solution of DCC in CHCl₃ (30 ml.) was added. The resulting mixture was stirred at room temperature for 2 hr. and filtered. The resin was washed three times with each of the wash reagents: CHCl₃, ethanol, and CHCl₃, respectively (60 ml. of each reagent); the deblocking reagent [50% TFA in CHCl₃ (60 ml.)] was added. The deblocking mixture was stirred for 30 min. and filtered. Control experiments indicated that complete cleavage of the BOC group was obtained within 15 min. under these conditions. The resin was washed with CHCl₃ (60 ml.) three times, and 10% Et₃N in CHCl₃ (60 ml.) was added. The mixture was stirred for 10 min. and was filtered and washed three times with CHCl₃.

The resin was then ready for the next amino acid addition in subsequent positions of the control tape. The internal timer of the ACRS unit was set to move the control tape to the next position at 1.5-min. intervals. Following the last wash (Step 10 in Table I) in each coupling cycle, a sample of the resin was removed from the reaction vessel and dried. This resin (10–15 mg.) was then transferred to a hydrolysis tube, and a solution of 6 N HCl in 50% dioxane (1 ml.) was added. The tube was then sealed and incubated at 110° for 48 hr. Table II shows the average amino acid analysis of an acid hydrolyzate after each amino acid addition cycle for two experiments. In Fig. 1, the leucine residues on the resin during each experiment were plotted as a function of the reaction cycle (dotted line), together with the theoretically expected values (solid line).

Edman Degradation of the Model Peptide—As in the automated synthesis described, a control tape was prepared for the series of operations involved in the degradation of the resin-bound polypeptide. A computer program was used to set up an array of commands, which were copied onto a magnetic tape and subsequently translated into punched holes on a paper tape by the PDP-7 computer. The general sequence of operation is shown in Table III. In this case, stock solutions consisted of: (a) PTC–Et₃N–50% pyridine in dimethyl formamide (DMF) (1:1:8); (b) 50% pyridine in DMF; (c) CHCl₃; (d) 10% Et₃N in CHCl₃; and (e) 50% TFA in CHCl₃. The stock solutions were placed in the ACRS unit, and the paper control tape for the degradation was fed into the ACRS. Initially, the resin with the synthetic peptide attached was washed three times with 50%

Table III—Sequence of Chemical Addition for Edman Degradations

Chemical Additions	Operation	Time, min.	Total Time, min.
1. 50% pyridine in DMF	Wash (three times)	2.0 each	6
2. PTC	Derivative formation	120.0	120
3. 50% pyridine in DMF	Wash (three times)	2.0 each	6
4. CHCl ₃	Wash (three times)	2.0 each	6
5. TFA in CHCl ₃	Cyclization	120.0	120
6. CHCl ₃	Wash (three times)	2.0 each	6
7. 10% Et ₃ N in CHCl ₃	Neutralization	10.0	10
8. CHCl ₃	Wash (three times)	2.0 each	6
			Total time/cycle = 280

pyridine in DMF (60 ml.). The PTC solution (60 ml.) was then added. The reaction mixture was stirred under nitrogen for 120 min. and was filtered. After washing the resin three times with 50% pyridine in DMF and three times with CHCl₃, a solution of 50% TFA in CHCl₃ (60 ml.) was added. The resulting mixture was stirred for 120 min. and was filtered and washed with CHCl₃ (60 ml.) three times. The resin was stirred for 10 min. with 10% Et₃N in CHCl₃ (60 ml.) and was filtered and washed with CHCl₃ (60 ml.) three times.

This sequence of operations was repeated for each cycle (amino acid removal) in the degradation. The progress of the degradative process was monitored by analyzing the residual peptide attached to the resin after the final wash in each degradative cycle (Step 8 in Table III) as described. The change in leucine to alanine ratio indicated the progress of the degradation. Table IV shows the average amino acid analysis of acid hydrolyzates after each degradation cycle for two experiments. In Fig. 2, the leucine residues on the resin during each experiment were plotted as a function of the degradation cycle (dotted lines), together with the theoretically expected values (solid line).

RESULTS AND DISCUSSION

The studies with the model polypeptide, L-leucyl-L-leucyl-L-leucyl-L-leucyl-L-leucyl-L-alanine, have demonstrated the feasibility of applying computer-oriented automated techniques to the chemical synthesis and/or degradation of polypeptides and proteins. The ACRS unit with the computer-generated control tape carried out

Figure 1—The number of leucine residues present in an acid hydrolyzate of the resin is plotted as a function of the synthetic cycle. Theoretical values are indicated by the solid lines and circles. Experimental values are illustrated with dotted lines and with triangles in one case and with squares in the other. Leucine residues were determined with respect to the alanine content of the resin (Table II).

Figure 2—The number of leucine residues present in an acid hydrolyzate of the resin is plotted as a function of the degradative cycle. Theoretical values are indicated by the solid line and circles. Experimental values are illustrated with dotted lines and with triangles in one case and with squares in the other. Leucine residues were determined with respect to the alanine content of the resin (Table IV).

most of the physical operations involved in the synthesis and degradation of the model peptide. Progress of the amino acid incorporation into the growing chain was evidenced by the increase in leucine ratio in the amino acid analysis of an acid hydrolyzate of the resin-bound peptide.

Figure 1 compares the experimental values (dotted lines) for two different experiments with the theoretically expected values (solid line). The results indicate that the amount of leucine incorporated into the growing polypeptide chain is close to the theoretically expected amounts. Ultimately, it is desirable and necessary to drive the synthesis at each step to completion (at least 98% or higher yield at each step) to avoid a heterogeneous final product and a massive isolation and purification problem. For a synthesis to run under optimum conditions, information concerning the progress of each reaction step would be extremely important. Not only would such information provide an indication of the current status of the synthesis, it would also suggest future changes in the experimental approach which would accelerate the synthesis or optimize the yield of the reactions involved.

In Fig. 1 the triangle at Cycle 4 provides an example of the information that could be used to reevaluate the experimental approach. In this case, a sample of resin for acid hydrolysis was removed from the reaction vessel 5 min. after the addition of the new (activated) amino acid. The amino acid analysis of the resin demonstrated that leucine had been significantly incorporated into the polypeptide during this brief period. These results are consistent with those of Esko *et al.* (28) for the reaction of leucine with polypeptides on the solid phase. Other amino acids gave differences in reaction time for 90% completion extending from a few minutes to 24 hr. The rapid incorporation observed in this study would suggest a modification in reaction time in future studies and would result in the addition of more leucine residues per day. Reaction conditions [e.g., Esko *et al.* (28)] that are specific for each amino acid could be readily incorporated into the computer program and the resulting paper command tape. In this case, when the amino acid sequence is specified, those conditions that are specific for a given amino acid (e.g., reaction time, amount and concentration of chemicals to be added, and temperature of the reaction) would be generated by the computer in essentially the same time taken to generate the tape for reaction cycles that are identical for each amino acid. Information concerning the different chemical characteristics should be forthcoming in future studies and should permit the implementation of reaction conditions tailored to each amino acid.

The Edman degradation is an obvious choice for monitoring the current status of a synthetic operation at each major step since the free *N*-terminal amino acid is readily removed. The resulting peptide

Table IV—Amino Acids on the Resin following Edman Degradation

Degradation Cycles	Average mmoles of Amino Acid/g. of Resin		Ratio of Alanine to Leucine	
	Alanine	Leucine	Experimental	Theoretical
0	0.195 ± 0.008	0.945 ± 0.010	1:4.86	1:5
1	0.154 ± 0.012	0.600 ± 0.067	1:3.90	1:4
2	0.214 ± 0.002	0.623 ± 0.001	1:3.00	1:3
3	0.228 ± 0.008	0.483 ± 0.042	1:2.12	1:2
4	0.231 ± 0.012	0.322 ± 0.043	1:1.45	1:1
5	0.231 ± 0.037	0.212 ± 0.079	1:0.92	1:0

can then be analyzed as in this study, or the amino acid thiohydantoin derivative could be characterized and quantitated. A degradation following a coupling sequence could indicate the presence of free (uncoupled) *N*-terminal amino acid, while a degradation following a deblocking cycle would indicate the extent to which the preceding coupling cycle has gone to completion and the extent that the preceding amine protective group has been deblocked. The model peptide in this study does not lend itself to this type of interpretation because of the repeating sequence of leucine residues. In future studies, degradative methods will be used to evaluate the synthesis at each step for peptides containing different amino acids in adjacent positions.

This model peptide did indicate that the solid-phase degradation of polypeptides following computer-generated programs is indeed feasible in the nonaqueous solvent systems employed in this study. Figure 2 demonstrates the progress during the degradation of the model peptide in two different experiments (dotted lines). Beginning with the intact peptide attached to the resin, subsequent degradation steps reduced the leucine to alanine ratio by about one residue until the *N*-terminal of the residual peptide was within three amino acid residues of the resin. At this point, removal of additional leucine residues became more difficult. The nature of the decrease in cleavage is unclear and will be studied further. This lower cleavage rate has been reproduced in a number of experiments and is also in agreement with the results of Laursen (24). Attempts were made to overcome the reduction by employing different chemical preparations, solvents, and reaction conditions, but results consistent with Fig. 2 were obtained in each case. It is possible that the free amine is rendered inaccessible due to interactions between the smaller peptides and the resin. More experiments are needed to clarify this point.

Automation of the classical Edman degradation approach (15) has greatly accelerated the process of sequential analysis of proteins with the removal of 15 amino acid residues in 24 hr. The computer-oriented automated approach to solid-phase degradations discussed in this report should be equally useful in determining the amino acid sequence of proteins, with some modifications in the described method. Studies on the automated solid-phase degradation of naturally occurring polypeptides are currently being carried out in this laboratory.

NOTES

Effect of Mescaline HCl on Resistance of Male Mice to Histamine Stress

A. STANLEY WELTMAN, ARTHUR M. SACKLER, and LEROY JOHNSON

Abstract □ Single intraperitoneal injections of mescaline HCl caused significant decreases in the ability of albino mice to tolerate histamine phosphate when administered intraperitoneally 40 min. after mescaline. The dose levels of mescaline HCl ranged from 5–100 mg./kg. of body weight. Eight subcutaneous injections of mescaline (100 mg./kg. of body weight) administered during a 2-week period showed no difference between the LD₅₀ values of the test *versus* saline control groups when challenged with histamine 24 hr. after the eighth and last dose of mescaline. No effects were noted in the body weights and growth patterns of the test mice in the 2-week investigation.

Keyphrases □ Mescaline HCl—effect on histamine tolerance, mice □ Histamine tolerance, mice—effect of mescaline HCl □ Hallucinogens, mescaline—acute *versus* prolonged effects on growth, histamine stress resistance

Previous investigations have demonstrated that LSD-25 stimulates adrenocortical activity and inhibits growth, metabolism, and gonadal and thyroidal function in female (1–3) and male rats (4). LD₅₀ analyses of male rats given eight sequential injections of LSD-25 spaced during a 2-week period presented suggestive evidence of increased ability of the treated animals to tolerate histamine stress (5). Parallel studies with male mice receiving mescaline HCl (6) revealed identical, but somewhat smaller alterations in adrenal and thyroidal function but no effects on body weight and food consumption. Adrenal weights and adrenocortical activity [*i.e.*, thymus involution and white blood cell count (WBC) decreases] were significantly increased (6). The lesser effects produced by mescaline *versus* LSD-25 may be attributed to the lower potency of mescaline. The equivalent hallucinogenic dose of mescaline

in humans is 4000 times greater than that of LSD (7). As with LSD-25 (3, 4, 8), various physiological findings have demonstrated the development of tolerance or accommodation of the treated mice to mescaline (6). The present investigation sought to determine acute *versus* prolonged effects of mescaline administration on body growth and the resistance of male mice to histamine stress.

EXPERIMENTAL

Three series of young male experimental albino mice (Carworth Farms, CFW) averaging 22 g. in body weight were selected for histamine LD₅₀ analyses. Series I and II test and control mice were challenged intraperitoneally with histamine phosphate 40 min. after receiving a single intraperitoneal injection of mescaline HCl dissolved in normal saline or equivalent doses of saline. Series III mice received histamine phosphate 24 hr. after the eighth and final subcutaneous injection of mescaline HCl or normal saline. The eight injections were administered over a 2-week period on alternate days with the exception that on the 13th and 14th days, the two doses were given consecutively.

Series I consisted of 225 mice divided equally into three groups (two test groups and one saline control). The two doses of mescaline administered were 5 and 20 mg./kg. body weight. Series II consisted of an equivalent number of mice also divided equally into two test and one control groups. The test mice received a single dose of either 50 or 100 mg./kg. body weight of mescaline HCl. Series III was represented by a single test (100 mg./kg.) and normal saline group. In general, the various test groups were challenged with 5–6 dose levels of histamine phosphate and utilized 15–19 mice per dose level. The appropriate challenging doses of histamine, depending on the susceptibility of the test and control groups, ranged from 350–1450 mg. histamine base/kg. body weight. Finney's (9) method of probit analysis was used to calculate the LD₅₀ values and dose-response lines.

To determine further the effects of various doses of mescaline on survival periods, the time of death following histamine phosphate

injections was recorded for Series II animals. Proportionate numbers of mice receiving 50 or 100 mg./kg. of mescaline or normal saline were selected for analyses from groups given 850, 1050, and 1250-mg./kg. doses of histamine phosphate.

Prior to initiation of the investigation, all animals were housed for 1 week to acclimatize the mice to laboratory conditions. The animals were housed five per cage in stainless steel cages 40.64 × 45.72 × 27.94 cm. (16 × 18 × 11 in.) in an air-conditioned laboratory maintained at 22.7° (73° F). The mice used in the acute studies were weighed immediately prior to administration of the mescaline to permit calculation of the approximate doses of mescaline HCl and histamine phosphate. Animals used in the 2-week study were weighed initially and at the end of each week. Previous studies have indicated that prolonged isolation (10) or excessive crowding (11) and temperature changes (12) can produce metabolic and endocrinological alterations. Similarly, to minimize handling (13) and auditory stress (14, 15) influences, all animals were handled alike, and care was taken to prevent harsh and extraneous loud noises. The average level of the laboratory background noise during the period of experimentation was 68 decibels at daytime and 85 decibels at nighttime due to the increased nocturnal activity of the animals in the colony room.

RESULTS AND DISCUSSION

Standard *t*-test analyses (16), as indicated in Table I, revealed no significant differences between the various body weights of the

randomly selected mice in the acute Series I and II tests *versus* control group studies. All *p* values had higher probabilities than the 0.05 level used for statistical significance. Table I also presents the LD₅₀ data for the Series I and II groups administered single intraperitoneal doses of mescaline 40 min. before the histamine challenge. In both series, all doses of mescaline (5, 20, 50, and 100 mg./kg.), when compared with their respective controls, showed significant decreases in the resistance of the test mice to histamine stress (*i.e.*, 5 mg./kg. *versus* saline, *p* = 0.05). No significant difference was noted between the LD₅₀ values of the two saline controls of Series I and II (*p* = 0.86). Comparisons further revealed significant differences between the various doses of mescaline when each level was compared with the other (*i.e.*, 20 *versus* 50 mg./kg., *p* = <0.01; 50 *versus* 100 mg./kg., *p* = 0.01; *etc.*). An exception was observed in the comparison of the LD₅₀ values of the 5 *versus* 20-mg./kg. dose. The *p* value of 0.09, although low, was not statistically significant. Analyses of the slopes of the regression equations for the mescaline and saline groups, on the other hand, showed no significant differences (*p* = >0.05) between the various slope values when the test groups were compared with their respective controls and each other. In accord with LD₅₀ findings, standard *t*-test analyses (16) of the time of death following histamine injections likewise revealed that prior administration of 50 or 100 mg./kg. of mescaline significantly hastened the onset of death. Compared to saline controls (control death time: 5.2 ± 0.2 min.), 50 mg./kg. of mescaline significantly reduced the time of death by 43.8% (*p* = <0.01) and 100 mg./kg. by 49.4% (*p* = <0.001). The difference in the time of death between the two mescaline doses was not statistically significant (*p* = 0.36).

At the time of histamine challenge, comparable studies with additional test and control groups revealed that at 40 min. the test mice had recovered from the depressive influences of mescaline and were displaying heightened locomotor activity when compared to the saline controls (17). The reduction in resistance to histamine may reflect the combined effects of two nonspecific stress agents (mescaline and histamine) administered within too short a time period of each other (40 min.). The decrease in resistance may also be related to hypoglycemic influences of mescaline. Speck (18) reported significantly lower blood glucose levels in male rats given single injections of mescaline at doses of 5 mg./100 g. body weight.

Table II presents the final body weights and the LD₅₀ values of the test (100 mg./kg.) *versus* control group receiving eight repeated injections of mescaline (Series III). The findings indicated no differences between the initial body weights of the test and control groups (21.9 ± 0.3 g.) and no effects on the final body weights of the test *versus* control mice at the completion of the prolonged 2-week study (*p* = 0.81). Analyses further revealed no statistically significant differences between the LD₅₀ values (*p* = 0.82) or the slopes of the regression equations (*p* = 0.39) of the test *versus* saline control group. The two LD₅₀ control values of the acute Series I and II were significantly higher than the control of Series III (*p* values = <0.01). This difference in LD₅₀'s may possibly reflect the influences of eight repeated saline injections, a 2-week age factor, or biological and environmental variables resulting from a year's lapse in time between the previous series and Series III. Despite evidence of increased adrenocortical activity (6), as demonstrated in related test groups (*i.e.*, increased adrenal weights, thymic involution, and WBC decreases), no marked or significant increase was noted in the ability of the test mice to withstand histamine stress. Feasibly, other than the route of administration of mescaline, the difference in the increased mortality demonstrated by the mice receiving a single *versus* repeated doses might rest in the time lapse between the successive doses of mescaline and histamine challenge. In the acute study, the time period was 40 min. *versus* 24 hr. for the prolonged 2-week investigation. Further groups are required to duplicate the 40-min. time interval in mice receiving eight injections and the 24-hr. period in mice receiving a single injection. It should be noted that contrary to hypoglycemic effects produced by a single dose, Speck (18) reported hyperglycemia in rats injected daily for 1.5 months. In an additional 2-week study of mice receiving 50- or 100-mg./kg. doses of mescaline subcutaneously, significant increases were noted in blood glucose levels of both groups of test mice (19).

In conclusion, single intraperitoneal doses of mescaline (5–100 mg./kg.) were found to decrease significantly the resistance of male mice to histamine stress when challenged 40 min. later. Repeated injection of mescaline HCl administered subcutaneously

during 2 weeks showed no significant effects on the histamine LD₅₀ values of test *versus* control groups despite findings of increased adrenocortical activity (6). This may be related to the time interval factor between mescaline and histamine challenge. Histamine in this last instance was administered 24 hr. after the last mescaline injection. No significant effects were noted on body weights and growth patterns of mice in the 2-week investigation as demonstrated by the present and previous findings (6).

Teratogenic Effects of Audiogenic Stress in Albino Mice

CHARLES O. WARD, MICHAEL A. BARLETTA, and TANIS KAYE

Abstract □ The teratogenic effects of audiogenic stress were studied in 60-day-old pregnant Swiss-Webster mice by exposing the pregnant dams to the effects of a noise generator for varying periods during pregnancy. The most severe fetal effects were noted when the pregnant dams were stressed on Days 8-17 and Days 10-15 of pregnancy. In an attempt to discern the days of greatest susceptibility to stress, a second group of mice was studied, and it was determined that Days 7-8 was the period of maximal susceptibility. The teratogenic effects produced by audiogenic stress included a reduction in fetal weight, complete or partial resorption of fetuses, cranial hematoma, dwarfed hind limbs, and tail defects.

Keyphrases □ Teratogenicity—audiogenic stress effects, albino mice □ Audiogenic stress, effects—teratogenicity, albino mice

The maternal organism has been exposed to a wide variety of noxious chemicals and environmental changes in an effort to determine the effects of such exposure on fetal development (1-4). Procedures that only affect the maternal organism have, however, received little attention until recently. Environmental stresses to which virtually all maternal organisms are subjected during pregnancy have been proven to exert real and deleterious effects on fetal development (5-8). Geber (5) recently demonstrated that decreased fetal weight as well as resorption frequency can be produced in the offspring of rats subjected to audiovisual stress for varying periods during development. The stress of

handling pregnant dams (6) and severe audiogenic stress (7) have been shown either to block pregnancy completely or to reduce the chance for successful fetal development. The purposes of this investigation were to study the effects of audiogenic stress on pregnant albino mice in an attempt to determine the effects of such stress on fetal development and also to determine the period of pregnancy in which the fetus is most susceptible to the deleterious effects of stress.

METHODS

Sexually mature Swiss-Webster mice, received at 60 days of age, were used throughout this study. They were kept in a separate room in the animal quarters for 1 week prior to breeding to allow for adjustment to their surroundings. When proestrus was determined by the technique of vaginal smearing (9), two females were placed with each male for an 11-hr. period. When the sexes were separated, the presence of a vaginal plug was taken as proof of pregnancy. This was then Day 0. Between 20-35% of the mated females became pregnant using this technique. Pregnant females were then isolated and kept in separate cages for the duration of pregnancy.

The stress chamber was rectangular [25.40 × 20.32 × 60.96 cm. (10 × 8 × 24 in.)] and constructed of stainless steel. Pregnant mice as well as controls were placed in this chamber in a separate room, and the stressed dams were subjected to the effects of a noise generator which consisted of a motorcycle horn connected to a micro-switch timer and set to deliver an output of 82-85 decibels¹ at a

¹ Sound Level Meter, Type 1551-A, General Radio Co., Cambridge, Mass.

during 2 weeks showed no significant effects on the histamine LD₅₀ values of test *versus* control groups despite findings of increased adrenocortical activity (6). This may be related to the time interval factor between mescaline and histamine challenge. Histamine in this last instance was administered 24 hr. after the last mescaline injection. No significant effects were noted on body weights and growth patterns of mice in the 2-week investigation as demonstrated by the present and previous findings (6).

frequency of 320-580 c.p.s. The timer delivered these noise levels for 60-75% of each hour in an intermittent fashion, *i.e.*, 3 min. on, 2 min. off. Background noise was measured as 35-50 decibels at a frequency of 20-32 c.p.s.

Food and water were continuously supplied to both control and experimental groups; control mice were placed in the exposure chamber for 5-hr. periods on each day of pregnancy.

Both experimental and control females were sacrificed on Day 18 of pregnancy; a laparotomy was performed, the uterus was exposed and incised, and the fetuses were removed. Care was taken to note uterine distribution of fetuses as well as any vacant uterine sites which were indicative of fetal resorption. The fetuses were then weighed on a Class A torsion balance to the nearest 0.01 g.; transumbilical and crown-rump measurements were taken to the nearest millimeter, and the fetuses were then divided into two groups. Every third fetus was placed in 90.0 ml. of a 1.0% potassium hydroxide solution to which 6.0 mg. of Alizarin red S was added to stain the bones selectively. The remaining fetuses were placed in Bouin's solution for several days and then examined microscopically after gross dissection, according to established techniques (9). The following parameters were recorded: total number of normal and abnormal fetuses, litter size, fetal weight, crown-rump and transumbilical distances, number of litters resorbed or delivered, and any demonstrable fetal malformations.

RESULTS AND DISCUSSION

The results of this investigation, summarized in Table I, clearly demonstrate the deleterious effects of audiogenic stress on the developing fetus. The most severe fetal effects were observed when the pregnant dams were stressed 8 hr./day on Days 8-17 of pregnancy, with 40% of the litters resorbing and a mean fetal weight of 0.44 g. compared to a control value of 1.45 g. The next period of greatest susceptibility was Days 10-15 of pregnancy when, although no litters resorbed, the mean fetal weight was 0.87 g. In all cases, the crown-rump and transumbilical distances were decreased when the mean fetal weight was decreased, indicating that this parameter is also a good indication of fetal development. In none of the stressed groups was the litter size or the uterine distribution altered over control values. These observations are in agreement with Geber (5) and Sontag *et al.* (7), who reported decreased fetal weight as a result of audiovisual and audiogenic stress. But the observations contradict the findings of Geber (5) as well as those of Thompson and Sontag (10) with regard to litter size, because these investigators reported decreased litter size and no effect on either litter size or fetal weight, respectively. The latter, however, stressed their experimental groups only during the last trimester of pregnancy.

It is evident from Table I that, when murine pregnancy was studied in 2-day intervals, the period of greatest susceptibility to the effects of audiogenic stress was Days 7-8 of pregnancy, with 100% of the litters resorbing before Day 18.

The teratogenic effects observed (cranial hematoma, dwarfed hind limbs, and tail defects) compare favorably with those reported by other investigators (5). These effects have been attributed to the

endocrinologic effects of stress on either the maternal or fetal organism, including the discharge of catecholamines and steroid hormones from the adrenals and decreased maternal and fetal blood flow, especially of the uterine and placental vasculature, thus causing fetal hypoxia and even possibly delaying or preventing the implantation of the fertilized ova (5). This observation correlates also with the findings of Weir and DeFries (6) who reported a decreased rate of pregnancy when fertilized dams were subjected to the stress of handling prior to implantation. The adaptation to maternal stress, suggested by Geber (5), did not appear to be a factor in this investigation, because the data demonstrate that, in general, the more severe the stress, the greater the effect on fetal development. Maternal adaptation would also not be a factor in the portion of this investigation in which the murine pregnancy cycle was studied in 2-day segments. While maternal influences in fetal development as the result of stress are the most plausible explanation for the spectrum of teratogenic effects, the direct effects of sound on the fetus itself cannot be disregarded (7).

The significance of this study is that teratogenic effects have been produced with no manipulations of either the fetus or the maternal organism other than environmental alterations of maternal and/or fetal physiological mechanisms. Also, the period of greatest susceptibility to environmental audiogenic stress appears to be during the period of implantation (Table I), which compares favorably to the period of susceptibility to chemical stress factors, *i.e.*, the administration of known teratogenic drugs (11).

Thermal Dissociation of Sulfonylureas: Dissociation of Tolbutamide in a Series of Aliphatic Alcohols and in Polyethylene Glycol 400

F. BOTTARI, M. MANNELLI, and M. F. SAETTONI

Abstract □ A study on the thermal dissociation of tolbutamide (I) in a series of 12 primary aliphatic alcohols, C₁ to C₁₈, and in polyethylene glycol 400 USP at 80° is presented. It is shown that the compound dissociates in only one of two possible fashions, i.e., only to give butylamine and *p*-toluenesulfonyl isocyanate. In all cases, an *N*-(*p*-toluenesulfonyl)carbamate, formed by reaction of the sulfonyl isocyanate with the alcohols, was present in the equilibrium mixture. *p*-Toluenesulfonamide and alkyl *N*-butylcarbamates, arising from the other possible dissociation, were never evidenced. The results are consistent with a mechanism involving, as the first step, a preferential conversion of I into one of two possible tautomeric forms.

Keyphrases □ Sulfonylureas—thermal dissociation in alcohols, polyethylene glycol 400 □ Tolbutamide—thermal dissociation in alcohols, polyethylene glycol 400 □ Dissociation, thermal—tolbutamide in alcohols, polyethylene glycol 400 □ TLC—separation, identification □ UV spectrophotometry—analysis □ Alkyl *N*-(*p*-tosyl)carbamates—formation, synthesis

Although 1,3-disubstituted sulfonylureas, in view of their importance as oral hypoglycemic agents, have been widely investigated from the synthetic and analytical standpoint, little is known about their chemical reactivity. The acid hydrolysis of tolbutamide (I), carbutamide, and chlorpropamide has been investigated by Vogt (1), and Haussler and Hajdú (2) have reported on the hydrolytic breakdown of I in alkaline solution. More recently, Ulrich and Sayigh (3) have described a method for the preparation of isocyanates based on the pyrolysis of some sulfonylureas in high-boiling solvents.

In a previous communication (4), it was reported that the tolbutamide, carbutamide, or chlorpropamide content of some o/w creams for topical use showed a significant decrease when the said drugs were dissolved at 70–80° in the oil phase of the emulsions. No such decrease occurred when the sulfonylureas were incorporated into the bases at room temperature. A series of tests, carried out by heating at 80° the mixtures of I with the single components of the oil phase, showed that the observed effect was due to some components containing hydroxyl groups, such as stearyl alcohol or polyethylene glycol. This led to the investigation of the behavior of I, chosen as a representative member of the series, in a number of alcohols, in an attempt to establish the reaction course both on a qualitative and quantitative basis. Indeed, although the thermal dissociation¹ of symmetrical and unsymmetrical mono- and disubstituted ureas has been investigated under various experimental conditions (5, 6), no studies

could be found in the literature on the dissociation of pharmacologically active sulfonylureas at relatively low temperatures and in media such as may occur in pharmaceutical vehicles.

The results of a preliminary investigation on the dissociation of I at 80° in 12 primary alcohols (methyl, ethyl, *n*-propyl, *n*-butyl, *n*-pentyl, *n*-hexyl, *n*-octyl, *n*-decyl, *n*-dodecyl, *n*-tetradecyl, *n*-hexadecyl, and *n*-octadecyl alcohols) and in polyethylene glycol (PEG) 400, a common constituent of pharmaceutical preparations, are the subject of this paper.

EXPERIMENTAL

A Beckman model DU spectrophotometer was used for all analyses. TLC separations were carried out on Merck F 254 silica gel plates, using the benzene–acetone–methanol–acetic acid (70:20:5:5) solvent system described by Kaistha and French (7). Tolbutamide (I) was the medicinal grade drug; it was crystallized from benzene to constant melting point (127–129°) and was shown by TLC to be free from contaminants or decomposition products. *p*-Toluenesulfonamide² was crystallized from ethanol, m.p. 136–137°. *n*-Butylamine was distilled prior to use, b.p. 77–78°. All alcohols (Table I) were anhydrous, analytical reagent grade products. Their purity was checked by gas chromatography. PEG 400 was found to contain 2% H₂O by azeotropic distillation with toluene, and it was used as such. *p*-Toluenesulfonyl isocyanate (III) was prepared from *p*-toluenesulfonamide and oxalyl chloride as indicated by Franz and Osuch (8). *N*-(*p*-Toluenesulfonyl)carbamates, Compounds 1–12, were prepared from III and the appropriate alcohols by the method of McFarland and Howard (9); analyses and physical constants are reported in Table II. Some of the compounds had been described previously (footnotes ^c and ^d, Table II), but no analytical data had been given. "PEG

¹ The term "dissociation" is preferred to the terms "decomposition" and "dearrangement" used by earlier authors, since the process is the reversal of the formation reaction (6).

^a Determined on a Kofler block and uncorrected. All compounds were crystallized from petroleum ether, boiling range 60–80°. ^b Solvent system: benzene–acetone–methanol–acetic acid (70:20:5:5); see text. ^c Cf. L. Fishbein, *J. Chromatogr.*, **30**, 245(1967). ^d Synthesis described by A. Nováček and B. Vondráček, Czech. pat. 96,582 (Sept. 1960); through *Chem. Abstr.*, **55**, 15420g(1961). ^e Analyzed as the sodium salt.

400 *N*-(*p*-tosyl)carbamate," prepared from III and excess PEG 400, was not purified.

Procedure for Study of Dissociation of I in Anhydrous C₁–C₁₈ Alcohols—Mixtures containing I (50 mg.) and an alcohol (450 mg.) were placed in 5-ml. ampuls. The sealed ampuls were heated at 80° in an electrically controlled oil bath. The reaction temperature was selected after some preliminary trials; temperatures below 80° were insufficient for a quick dissolution of the drug in some alcohols, while higher temperatures favored formation of small amounts of unidentified side products. After 2 hr. or, for the reaction in *n*-octadecyl alcohol, at the time intervals specified in Fig. 1, the ampuls were cooled and their contents were quantitatively dissolved in acetone (25 ml.). Ten 50-μl. portions of the solution were applied on a chromatoplate as a row of points. Appropriate reference solutions [I, *N*-(*p*-tosyl)carbamates and butylamine] were also applied. After development, the areas corresponding to I (R_f 0.68) and to the *N*-(*p*-tosyl)carbamates (R_f reported in Table II) were evidenced by examination under a shortwave UV light and were marked. Their identity was confirmed by comparison with the standards. The marked areas were removed from the plate and quantitatively eluted with ethanol (10 ml.). The UV absorption of the solutions at 228 mμ (I) and at 226 mμ (carbamates) was recorded, applying a correction for the blank extinction value. The

amounts of I and of *N*-(*p*-tosyl)carbamate were obtained by comparison with suitable standard curves. The procedure gave errors not exceeding ±5%, as proven by separate tests carried out with standard solutions of I and of carbamates. The location of butylamine (R_f 0.04) was evidenced by spraying the "standard" portion of the plates with 0.5% ninhydrin solution and heating briefly at 60°. The corresponding "sample" area was removed and quantitatively eluted with ethanol (10 ml.). The determination of the butylamine content of the solution was carried out by the ninhydrin method outlined by Kaistha and French (7). In this case also, the error did not exceed ±5%.

When methyl and ethyl alcohols were used as solvents, a quantitative estimation of I and of the *N*-(*p*-tosyl)carbamates was impossible, since the substances had almost identical R_f 's and could not be separated. In these cases, the extent of dissociation of I was calculated from the amount of amine found in the equilibrium mixtures.

Dissociation of I in PEG 400 and in 2% Aqueous C₁–C₈ Alcohols—One-gram samples of 10% w/w solutions of I were placed in 5-ml. flasks and heated 2 hr. at reflux temperature (methyl and ethyl alcohols) or at 80° (*n*-propyl, *n*-butyl, *n*-pentyl, *n*-hexyl, and *n*-octyl alcohols). Each flask was connected to a small gas absorption trap containing a Ba(OH)₂ solution. Evolution of CO₂ was qualitatively evidenced by a white precipitate in the trap. After cooling, a sample (500 mg.) of each mixture was dissolved in acetone (25 ml.) and processed as described previously. In this case, a *p*-toluenesulfonamide reference solution (R_f 0.58) was also applied to the plates. For PEG 400, a quantitative estimation of the *N*-(*p*-tosyl)carbamate could not be effected.

Reaction of III with Aqueous Alcohols—To 1-g. samples of the alcohols mentioned in the preceding paragraph, placed in 5-ml. ampuls, 0.1 g. of III was added. The ampuls were sealed and heated 30 min. at 80°. After cooling, a sample (500 mg.) of each mixture was dissolved in acetone (25 ml.) and processed as described. The products consisted of a mixture containing approximately equal portions of *p*-toluenesulfonamide and of the *N*-(*p*-tosyl)carbamate of the alcohol used as solvent.

RESULTS AND DISCUSSION

The results obtained heating 10% solutions of I in 12 straight-chain primary alcohols and in PEG 400 are summarized in Table I. In all cases, the reaction practically reached equilibrium within 2 hr., after which time about 40% of I had disappeared and other compounds, identified as *n*-butylamine and the *N*-(*p*-tosyl)carbamate of the alcohol used as solvent, were formed in stoichiometric amounts. All tosylcarbamates (Table II) were independently synthesized; some of them (Compounds 8, 9, 10, 11, and 12) were unknown. In the case of PEG 400, the carbamate had the same chromatographic behavior of a sample obtained from *p*-toluenesulfonyl isocyanate and PEG 400. No attempts were made at purification of this "PEG 400 *N*-(*p*-tosyl)carbamate" on consideration of its probably complex composition. The overall reaction of I with alcohols is indicated as (I) in Scheme I.

Figure 1—Concentrations of tolbutamide (I) (●) and of *n*-octadecyl *N*-(*p*-tosyl)carbamate (Compound 12) (■) versus time at 80°. Initial concentration of I in *n*-octadecyl alcohol is 10% w/w (37 mmol/L/100 g.).

Scheme I

A more detailed study of the behavior of a 10% solution of I in *n*-octadecyl alcohol at 80° is shown in Fig. 1. The tolbutamide concentration (initially 37 mmol/100 g.) was found to diminish as carbamate (and butylamine, not shown in the figure) formation increased, until an equilibrium mixture containing about 6.2% (23.0 mmol/100 g.) of I, 6.5% (14.0 mmol/100 g.) of *n*-octadecyl *N*-(*p*-tosyl)carbamate (Compound 12), and 1.0% (13.7 mmol/100 g.) of butylamine was reached after about 1.5 hr.

In every case, the amounts of *n*-butylamine and of *N*-(*p*-tosyl)carbamate present in the mixture satisfactorily accounted for the amount of I which had disappeared. A prolonged heating (5–10 hr.) of the solutions of I in higher alcohols resulted in formation of very small amounts of a third compound, evidenced by a fluorescent spot on the chromatographic plates. The *R_f* of this spot (e.g., 0.88 for the reaction in *n*-octadecyl alcohol) was in all cases different from those of all the possible dissociation products of I, and investigation in this direction was not pursued.

The presence of 2% water in some solvents (PEG 400 and alcohols C₁–C₈) did not influence the equilibrium concentrations of I and of *n*-butylamine. However, the equilibrium mixtures contained about 2% of *p*-toluenesulfonamide and a correspondingly reduced amount of *N*-(*p*-tosyl)carbamate. Furthermore, evolution of CO₂ during the reaction was observed when water was present.

The reported results might be rationalized as follows. Mono- and disubstituted ureas and some sulfonylureas are known to

dissociate on heating to isocyanates and amines (3, 5, 6). The thermal dissociation of *p*-ethoxyphenylurea, for example, in aqueous solution leads to *p*-ethoxyphenyl isocyanate, ammonia, and, in minor amounts, phenetidine and isocyanic acid (10). The isocyanates originating from the dissociation are often evidenced indirectly, e.g., through derivatives formed with suitable reagents. The reaction medium itself can function in some cases as one such reagent; *sym*-di-*p*-ethoxyphenylurea was assumed to dissociate to phenetidine and *p*-ethoxyphenyl isocyanate, since it gave phenetidine and *n*-butyl *N*-(*p*-ethoxyphenyl)carbamate on heating in *n*-butanol (11). The results seem to be in line with these data, and they suggest that tolbutamide dissociates on heating in the presence of alcohols to butylamine and *p*-toluenesulfonyl isocyanate. Interaction between the latter compound and the alcohol used as solvent would give the observed *N*-(*p*-tosyl)carbamate. The reactions are indicated as (2) and (3) in Scheme I.

The additional formation of *p*-toluenesulfonamide and carbon dioxide, when water is present in the reaction mixtures, can be explained assuming that water might compete with the alcohols for *p*-toluenesulfonyl isocyanate. The latter is known to react readily with water as indicated in (4), Scheme I (12). Support for this hypothesis came from experiments in which *p*-toluenesulfonyl isocyanate was allowed to react with a series of aqueous alcohols. In all cases, a mixture of *N*-(*p*-tosyl)carbamate and *p*-toluenesulfonamide was obtained, and CO₂ evolved during the reaction.

A significant outcome of the present study is the observation that tolbutamide, under the experimental conditions described, dissociates in only one of two possible fashions. The alternative dissociation leading to *p*-toluenesulfonamide and alkyl *N*-butylcarbamates as the end products could not be detected even to a minimal extent. A tentative rationalization of this phenomenon is presented in Scheme II, where the mechanism for the thermal dissociation of I has been patterned after that proposed by Hoshino *et al.* (6) for *sym*-diphenylurea. It can be seen that path (a), leading to the observed products, requires tautomerization of I to V, while path (b), leading to *p*-toluenesulfonamide and butyl isocyanate, requires tautomerization to VII. Tautomerization of I to V should be strongly favored by the high acidity of the NH group bound to the sulfonyl group. Furthermore, even if a small amount of VII was present at equilibrium, its subsequent conversion into the ion VIII should be rather difficult, since it would require protonation of a nitrogen atom endowed with a very low basicity. Conversely, formation of the ion VI from V should occur easily, on account of the greater degree of basicity of the nitrogen bound to the alkyl group.

Solvent effects and/or reaction temperature might play a significant role in determining the fashion and extent of the reaction. A relevant example is the formation of good yields of alkyl isocyanates and sulfonamides from 1,3-disubstituted sulfonylureas under pyrolysis conditions, where a completely different mechanism is probably operative (3). Moreover, although this proposed dissociation mechanism receives strong support from several analogous examples reported in the literature, alternative mechanisms, such as

Scheme II

alcoholysis, should not be entirely disregarded. Additional experiments are needed to obtain a satisfactory picture of the reaction. Further work, aimed at collecting kinetic data for the dissociation of I and of other pharmacologically active sulfonylureas in different media, is now in progress.

Molecular Association of Barbitol and Caffeine in 2:1 Crystalline Complex

B. M. CRAVEN and G. L. GARTLAND

Abstract □ The crystal structure of the 2:1 complex of barbitol with caffeine has been determined by X-ray diffraction methods. The crystals are triclinic, space group $P\bar{1}$, with $a = 14.627$, $b = 14.160$, $c = 6.902$ Å, $\alpha = 95^\circ 15'$, $\beta = 92^\circ 48'$, and $\gamma = 100^\circ 45'$, and with four barbitol and two caffeine molecules in the cell. The block-diagonal least-squares refinement of 496 atomic positional and thermal parameters, based on 4665 X-ray intensity data, gave a final R factor of 0.05. The structure consists of ribbons of barbitol molecules linked by $\text{NH}\cdots\text{O}=\text{C}$ hydrogen bonds. Caffeine molecules are bound to the ribbon by an $\text{NH}\cdots\text{N}(9)$ hydrogen bond and by an unusual interaction involving C(8)H with two barbitol oxygen atoms. Weak interactions of nonhydrogen-bonded caffeine carbonyl groups with barbitol carbonyl groups may also be important in this crystal. There is minimal overlap of the flat ring systems of the component molecules.

Keyphrases □ Molecular association—barbitol—caffeine 2:1 crystalline complex □ Barbitol, molecular association—caffeine in 2:1 crystalline complex □ X-ray diffraction—barbitol—caffeine 2:1 crystalline structure, determination

Barbiturates (1–3) and xanthenes (4, 5) form crystalline complexes with a variety of other molecular species as well as with each other (6–8). The crystal complex of barbitol with caffeine was chosen for study because consideration of the structure of the component molecules (Fig. 1) shows that the nature of barbitol–caffeine association must differ in two important respects from that found in previously determined crystal structures of complexes of purines and pyrimidines.

The strong association by pairs of hydrogen bonds, which occurs in complexes of barbiturates with adenine derivatives (3, 9) and which is analogous to the hydrogen bonding in the crystal structures of nucleic acid base pairing model systems (10), cannot occur between

barbitol and caffeine. As a hydrogen-bonding donor caffeine can at most form a weak C(8)H hydrogen bond

The stacking together of flat molecules with extensive overlap of their π -bonded ring systems has been found in complexes of tetramethyluric acid with pyrene (11) and caffeine with 5-chlorosalicylic acid (5). This type of interaction, which has been termed polarization bonding, is postulated as an important cohesive factor in xanthine complexes (12). However, in the complex of caffeine with barbitol, overlap of the two flat ring systems is largely prevented by the ethyl groups, which shield each side of the barbitol ring.

The crystal structure of the 2:1 barbitol–caffeine complex was determined to reveal the detailed geometry of molecular association.

EXPERIMENTAL

Triclinic crystals (m.p. 142°) of the complex were obtained as described by Higuchi and Lach (6). The lattice parameters are $a = 14.627$, $b = 14.160$, $c = 6.902$ Å, $\alpha = 95^\circ 15'$, $\beta = 92^\circ 48'$, and $\gamma = 100^\circ 45'$. The space group is $P\bar{1}$, and there are four barbitol and two caffeine molecules in the unit cell. The X-ray intensity data (4665 reflections) were collected on a four-circle automatic diffractometer using $\text{CuK}\alpha$ radiation. All 40 nonhydrogen atoms of the crystal chemical unit were found in the first E map, derived from an application of the direct method of phase determination similar to that described by Karle (13). All 34 hydrogen atoms were subsequently found in a difference Fourier synthesis. The positional and anisotropic thermal parameters for heavier atoms and positional and isotropic thermal parameters for hydrogen atoms were refined by a block-diagonal least-squares procedure to give a final R factor of 0.05.

Description of the Structure—The crystal structure consists of stacks of hydrogen-bonded ribbons, one of which is shown in Fig. 2. The backbone of the ribbon is made up of the barbitol molecules,

alcoholysis, should not be entirely disregarded. Additional experiments are needed to obtain a satisfactory picture of the reaction. Further work, aimed at collecting kinetic data for the dissociation of I and of other pharmacologically active sulfonylureas in different media, is now in progress.

Molecular Association of Barbitol and Caffeine in 2:1 Crystalline Complex

B. M. CRAVEN and G. L. GARTLAND

Abstract □ The crystal structure of the 2:1 complex of barbitol with caffeine has been determined by X-ray diffraction methods. The crystals are triclinic, space group $P\bar{1}$, with $a = 14.627$, $b = 14.160$, $c = 6.902$ Å, $\alpha = 95^\circ 15'$, $\beta = 92^\circ 48'$, and $\gamma = 100^\circ 45'$, and with four barbitol and two caffeine molecules in the cell. The block-diagonal least-squares refinement of 496 atomic positional and thermal parameters, based on 4665 X-ray intensity data, gave a final R factor of 0.05. The structure consists of ribbons of barbitol molecules linked by $\text{NH}\cdots\text{O}=\text{C}$ hydrogen bonds. Caffeine molecules are bound to the ribbon by an $\text{NH}\cdots\text{N}(9)$ hydrogen bond and by an unusual interaction involving C(8)H with two barbitol oxygen atoms. Weak interactions of nonhydrogen-bonded caffeine carbonyl groups with barbitol carbonyl groups may also be important in this crystal. There is minimal overlap of the flat ring systems of the component molecules.

Keyphrases □ Molecular association—barbitol-caffeine 2:1 crystalline complex □ Barbitol, molecular association—caffeine in 2:1 crystalline complex □ X-ray diffraction—barbitol-caffeine 2:1 crystalline structure, determination

Barbiturates (1–3) and xanthines (4, 5) form crystalline complexes with a variety of other molecular species as well as with each other (6–8). The crystal complex of barbitol with caffeine was chosen for study because consideration of the structure of the component molecules (Fig. 1) shows that the nature of barbitol-caffeine association must differ in two important respects from that found in previously determined crystal structures of complexes of purines and pyrimidines.

The strong association by pairs of hydrogen bonds, which occurs in complexes of barbiturates with adenine derivatives (3, 9) and which is analogous to the hydrogen bonding in the crystal structures of nucleic acid base pairing model systems (10), cannot occur between

barbitol and caffeine. As a hydrogen-bonding donor caffeine can at most form a weak C(8)H hydrogen bond

The stacking together of flat molecules with extensive overlap of their π -bonded ring systems has been found in complexes of tetramethyluric acid with pyrene (11) and caffeine with 5-chlorosalicylic acid (5). This type of interaction, which has been termed polarization bonding, is postulated as an important cohesive factor in xanthine complexes (12). However, in the complex of caffeine with barbitol, overlap of the two flat ring systems is largely prevented by the ethyl groups, which shield each side of the barbitol ring.

The crystal structure of the 2:1 barbitol-caffeine complex was determined to reveal the detailed geometry of molecular association.

EXPERIMENTAL

Triclinic crystals (m.p. 142°) of the complex were obtained as described by Higuchi and Lach (6). The lattice parameters are $a = 14.627$, $b = 14.160$, $c = 6.902$ Å, $\alpha = 95^\circ 15'$, $\beta = 92^\circ 48'$, and $\gamma = 100^\circ 45'$. The space group is $P\bar{1}$, and there are four barbitol and two caffeine molecules in the unit cell. The X-ray intensity data (4665 reflections) were collected on a four-circle automatic diffractometer using $\text{CuK}\alpha$ radiation. All 40 nonhydrogen atoms of the crystal chemical unit were found in the first E map, derived from an application of the direct method of phase determination similar to that described by Karle (13). All 34 hydrogen atoms were subsequently found in a difference Fourier synthesis. The positional and anisotropic thermal parameters for heavier atoms and positional and isotropic thermal parameters for hydrogen atoms were refined by a block-diagonal least-squares procedure to give a final R factor of 0.05.

Description of the Structure—The crystal structure consists of stacks of hydrogen-bonded ribbons, one of which is shown in Fig. 2. The backbone of the ribbon is made up of the barbitol molecules,

Figure 1—Molecular structure and atomic nomenclature for (a) barbitol and (b) caffeine. Unlabeled atoms are carbon and hydrogen, shown as large and small spheres, respectively. Both molecules are drawn with the stereochemistry including hydrogen atom orientation, which was determined in the crystal structure determination of the 2:1 complex. The barbitol molecule is Molecule B viewed as in Fig. 2.

which are linked by $\text{NH} \cdots \text{O}=\text{C}$ hydrogen bonds. The ribbons are puckered so as to avoid close contact between the nonhydrogen-bonded carbonyl oxygen atom O(6) of barbitol Molecule A and the ethyl group of Molecule B' further along the same ribbon. Each caffeine molecule is associated with a ribbon by accepting an $\text{NH} \cdots \text{N}(9)$ hydrogen bond from barbitol and by an unusual type of interaction $\text{C}(8)\text{H} \cdots \text{O}(2)$, with two barbitol carbonyl groups. The angles $\text{C}—\text{H} \cdots \text{O}$ are 144° and 130° with e.s.d.'s of 4° , and the corresponding $\text{H} \cdots \text{O}$ distances are 2.32 and 2.64 Å with e.s.d.'s of 0.05 Å. Only the former distance is appreciably shorter than the sum of the appropriate van der Waals' radii (2.6 Å) as listed by Pauling (14).

Figure 2 shows that the ethyl and methyl groups of the barbitol and caffeine molecules generally project outward from the border of the hydrogen-bonded ribbon. The mode of assembly of ribbons to

form the three-dimensional crystal structure gives rise to close packing of these alkyl groups, as well as partial overlap of stacked flat ring systems.

There are 11 $\text{H} \cdots \text{H}$ distances less than 2.6 Å between alkyl hydrogen atoms of adjacent ribbons, of which the shortest is 2.32 Å. In stacking along the z -direction, *i.e.*, above or below the page in Figs. 2 and 3, there are five such distances between barbitol ethyl groups, four between barbitol ethyl and caffeine methyl groups, and one between caffeine methyl groups. There are two such distances between barbitol ethyl groups of laterally adjacent ribbons.

The superposition of the flat ring systems of caffeine and barbitol in the crystal structure is shown in Fig. 3. Corresponding interatomic distances are listed in Table I.

Details concerning molecular structure and stereochemistry in this crystal structure will be reported.

DISCUSSION

In barbiturate crystal structures, there are two types of intermolecular hydrogen-bonding linkage. These may be termed "cyclic" if the molecules are linked by a pair of $\text{NH} \cdots \text{O}=\text{C}$ hydrogen bonds, as between barbitol A \cdots A' and barbitol B \cdots B' (Fig. 2), or "noncyclic" if only one hydrogen bond is formed, as between barbitol A \cdots barbitol B. Although there are both cyclic and noncyclic barbitol linkages in the 2:1 complex with caffeine and also in barbitol polymorph I (15), there are crystal structures in which the hydrogen bonding is exclusively cyclic, as in barbitol polymorph II (15) and amobarbital polymorphs I and II (16), or exclusively noncyclic, as in γ -methylamobarbital (17).

Further possibilities for hydrogen-bonding variations arise when there are insufficient NH or other donor groups to form crystal structures in which all three barbiturate carbonyl oxygen atoms are hydrogen bonded. Under these circumstances, $\text{C}(2)—\text{O}(2)$ and $\text{C}(4)—\text{O}(4)$ ¹ usually accept one hydrogen bond each and $\text{C}(6)—\text{O}(6)$ is not hydrogen bonded as in the 2:1 complex of barbitol with caffeine (Fig. 2), the 1:2 complex of phenobarbital with 8-bromo-9-ethyladenine (3), barbitol I, γ -methylamobarbital, and amobarbital I and II. In barbitol II, both $\text{C}(4)—\text{O}(4)$ and $\text{C}(6)—\text{O}(6)$ are hydrogen bonded and $\text{C}(2)—\text{O}(2)$ is not. These crystal structures all contain hydrogen-bonded ribbons with different geometries. In vin-barbital I (18), heptabarbital (19), and barbitol IV (20), $\text{C}(4)—\text{O}(4)$ forms two hydrogen bonds while $\text{C}(6)—\text{O}(6)$ and $\text{C}(2)—\text{O}(2)$ are not hydrogen bonded. There is no case as yet in which only $\text{C}(2)—\text{O}(2)$ is hydrogen bonded.

Thus the barbitol-barbitol hydrogen bonding in the 2:1 complex with caffeine represents only one of the variety of different modes that have been found in barbiturate crystal structures.

Although only three crystal structures containing caffeine have so far been determined, the hydrogen-bonding behavior of this molecule is more consistent. In caffeine hydrate (21), the 1:1 complex of caffeine with 5-chlorosalicylic acid (5) and in the presently reported structure (Fig. 2), atom N(9) is the acceptor for a normal hydrogen bond [$\text{HOH} \cdots \text{N}(9)$, $-\text{COOH} \cdots \text{N}(9)$, and $>\text{NH} \cdots \text{N}(9)$, respectively], while the caffeine carbonyl groups $\text{C}(2)—\text{O}(2)$ and $\text{C}(6)—\text{O}(6)$ are nonhydrogen bonded, or at most these oxygen atoms are acceptors in very weak $\text{CH} \cdots \text{O}$ interactions.

While such consistency may be fortuitous, it suggests that for caffeine the N(9) hydrogen-bonding acceptor site is favored over the carbonyl oxygen atoms.

Crystal structures containing caffeine are also similar in that the $\text{C}(8)\text{H}$ bond of the caffeine is directed more or less toward a carbonyl oxygen atom of another molecule. The occurrence and geometry of $\text{CH} \cdots \text{O}$ hydrogen bonds in xanthine and other crystal structures have been reviewed by Sutor (22). More recently, Donohue (23) has doubted the inference that $\text{H} \cdots \text{O}$ distances between 2.2 and 2.6 Å in $\text{CH} \cdots \text{O}$ interactions are hydrogen bonds, at least in the sense that this term is used for $\text{O}—\text{H} \cdots \text{O}$, $\text{N}—\text{H} \cdots \text{O}$, and $\text{N}—\text{H} \cdots \text{N}$ systems. Whether or not these are called hydrogen bonds, the recurrence of $\text{H} \cdots \text{O}$ distances less than 2.5 Å between caffeine $\text{C}(8)\text{H}$ and carbonyl oxygen atoms suggests that an attractive interaction is present which is stronger than the usual van der Waals' effect.

¹ In the isolated molecule (Fig. 1), $\text{C}(4)—\text{O}(4)$ and $\text{C}(6)—\text{O}(6)$ are symmetry-related but distinct from $\text{C}(2)—\text{O}(2)$.

Table I—Intermolecular Distances^a

Hydrogen Bonding Distances ^b		Other Intermolecular Distances Involving Caffeine ^c	
N(1)A···O(2)B	2.98 Å	N(1)C···O(2)B	3.40 Å
N(3)A···O(4)A	2.94	N(3)C···C(8)C	3.35
N(1)B···N(9)C	2.99	C(4)C···C(8)C	3.31
N(3)B···O(4)B	2.93	C(4)C···N(9)C	3.28
		C(5)C···N(9)C	3.42
		C(6)C···N(1)B	3.53
C(8)H···O(2) distances		C(8)C···N(3)C	3.35
C(8)C···O(2)A	3.16 Å	N(9)C···C(4)C	3.28
C(8)C···O(2)B	3.35	N(9)C···N(9)C	3.39
		C(2)C···O(2)A	3.04 Å

		N(9)C···N(7)C	3.40
		N(9)C···C(7)C	3.43

^a Atomic nomenclature is as in Fig. 1. The labeling A, B, or C refers to barbital molecules (A and B as shown in Fig. 2) and caffeine (C). The barbital ring systems for both Molecules A and B are numbered so that C(6)—O(6) is the nonhydrogen-bonded carbonyl group. E.s.d.'s in the interatomic distances range between 0.005 and 0.009 Å. ^b See Fig. 2 for the distances involving hydrogen-bonded hydrogen atoms. ^c For each distance, the atom listed on the left belongs to the caffeine molecule shown centrally in either Fig. 3a or 3b. The column at the left gives distances to molecules "above," i.e., in the positive z-direction, as in Fig. 3a; the column at the right gives distances to molecules "below," i.e., in the negative z-direction, as in Fig. 3b.

Figure 2—The hydrogen-bonded ribbon structure observed in the crystal structure of the 2:1 complex of barbital and caffeine. The ribbon repeating unit is from barbital A (bottom left) to barbital A' (upper right). Barbital Molecules A and B are crystallographically independent. The ribbons are viewed normal to the plane of the caffeine five-membered ring. Spheres of decreasing size represent oxygen, nitrogen, carbon, and hydrogen-bonded hydrogen atoms, respectively.

(a)

(b)

Figure 3—Molecular overlap in the crystal structure of the 2:1 complex of barbituric acid with caffeine. A central caffeine molecule is shown overlapped by the hydrogen-bonded ribbon "above" in (a) and "below" in (b), where "above" corresponds to the positive *z*-direction in the crystal. The view is the same as in Fig. 2, i.e., along the normal to the plane of the caffeine five-membered ring. Arrows in (b) indicate the overlapping carbonyl groups.

The overlap of flat ring systems of barbituric acid and caffeine in the 2:1 complex is restricted to the partial overlap of the five-membered rings of the caffeine molecules with each other and to the overlap of caffeine carbonyl groups with those of barbituric molecules (Fig. 3). The caffeine-caffeine interatomic distances such as N(9)···N(9)

(3.39 Å) and N(9)···N(7) (3.40 Å) are all longer than the usual van der Waals' distances (Table I), from which it is concluded that these caffeine-caffeine interactions are not significant as a structure-determining influence.

The caffeine carbonyl-barbituric carbonyl overlap is of greater interest because the short intermolecular C···O distances (3.02 and 3.04 Å) and the approximately antiparallel C=O···C=O stacking resemble the configuration found in the crystal structures of the non-pharmacologically active barbiturates, violuric acid monohydrate (24) and diluric acid trihydrate (25).

Bolton (26) has pointed out a number of crystal structures, including anhydrous barbituric acid and alloxan, which have intermolecular C=O···C=O distances ranging from as short as 2.77 Å, but with a different geometry such that the C=O bond of one carbonyl group is directed toward the carbon atom of a second. Bolton describes these as dipole-dipole interactions, emphasizing that the carbonyl groups in each case are flanked by electron-withdrawing groups which might be expected to enhance the polar character of the C=O bond.

Prout and Wallwork (27) consider the two different orientations for the carbonyl-carbonyl interactions as examples of a general class of intermolecular dipole-dipole or induced dipole interactions involving polar groups such as C=O and P=O and/or polarizable groups such as aromatic systems and carbon-carbon double bonds. For previously determined xanthine crystal structures, where steric factors permit more extensive molecular overlap, Shefter (12) has summarized results showing a tendency for carbonyl groups to lie over the delocalized π -bonded ring systems of adjacent molecules.

The crystal structure of the 2:1 complex of barbituric acid with caffeine appears to be dominated by barbituric-barbituric and barbituric-caffeine interactions, with NH···O and NH···N hydrogen bonding playing a major role. The C(8)H···O and C=O···C=O interactions may also be important, but the nature of these interactions and the extent to which they impose steric relationships in the environment of the component molecules are not yet well understood. These weaker interactions merit further study because they may enhance drug molecular association in solution and drug binding *in vivo* at sites where polar or polarizable groups are favorably oriented.

Influences of Heredity and Environment on Alkaloidal Phenotypes in Solanaceae

MARK J. SOLOMON* and FRANK A. CRANE

Abstract □ Modern biometrical analysis of reported data on *Atropa belladonna* L. indicates varying heritabilities at successive stages of plant ontogeny, exhibiting almost complete additivity at the early flowering stage. A discussion of the importance of this observation with accompanying consideration of more general implications is presented.

Keyphrases □ Phenotypes, alkaloidal, in Solanaceae—heredity, environmental influences □ Solanaceae biovariation—selecting for alkaloidal phenotypes, effects of heredity, environment □ Genetic variation, Solanaceae alkaloidal phenotypes—equations, phenotypic scale diagram

Research efforts involving selection for or against alkaloidal phenotypes are relatively rare in the literature. Such studies are lengthy, involved, and relatively wasteful in time and effort in comparison to the information obtained.

Upon reviewing the literature on Solanaceous alkaloidal biovariation, the authors noted that Sievers (1) had grown plants of *Atropa belladonna* L. for economic reasons during World War I and collected data on total alkaloidal content, expressed as milligrams atropine per gram dry weight of powdered leaf. These data lent themselves to heritability analysis (h^2 , the potential for selection under artificial or natural conditions), utilizing modern statistical and biometric techniques (2).¹

The authors' analysis of Sievers' data is summarized in Table I. Since Sievers analyzed parental types and their respective progeny at different stages of ontogeny, the following conclusions may be drawn:

1. Heritability (h^2) is present.
2. This heritability varies with ontogeny, ranging from high values (maximum value of 1) during vegetative and early flowering stages to lower values in early and late fruiting stages.
3. Heritability is maximum at the flowering stage of ontogeny, reaching almost complete additivity.

To the writers' knowledge, this analysis represents the first application of quantitative genetic techniques to tropane alkaloid biovariation, and it is the first example

of quantitative estimation of a relationship of plant ontogenesis to a tropane alkaloid.

DISCUSSION

Without the information obtained from Sievers' original data (1) and the authors' later interpretation, four models of genetic control appear possible if workers do not postulate genetic and environmental control of alkaloidal phenotypic variation to occur, as most geneticists would assume. These models are:

1. Alkaloidal phenotypes are not inherited; *i.e.*, they are all environmentally controlled.
2. Alkaloidal phenotypes are inherited in Mendelian fashion; *i.e.*, they are monogenic with no environmental control.
3. Alkaloidal phenotypes are the product of multiple allele segregation (with no environmental control).

Figure 1—Alkaloidal phenotypic scale for one gene in the biosynthetic pathway of an alkaloid (26). * A hypothetical case: presence of both dominant alleles would produce a final contribution of 0.5% alkaloidal content. The double recessive G_2G_2 would produce a concentration of 0.1%. If the alleles are additive, the heterozygote A_1A_2 would be 0.3%. If dominance is present, the G_1G_2 genotype would have the value of 0.4%.

G_1G_1 = homozygous dominant (maximum contribution to alkaloidal phenotype)

G_2G_2 = homozygous recessive (minimum contribution to alkaloidal phenotype)

G_1G_2 = heterozygote value (0 point or deviation if dominance is present)

d = dominance deviation from midparent

mp = midparent value (additive value of G_1G_1 + additive value of G_2G_2 divided by 2)

α_1 = average effect when G_1 is substituted for G_2

α_2 = average effect when G_2 is substituted for G_1

α_T = total average effects on the phenotype

a = additive effect due to one allele substitution

p = frequency of G_1 allele in population

q = frequency of G_2 allele in population

$p + q = 1$ since each gene has only two alleles

¹ The statistical techniques used for this analysis were not known in 1915. It is a tribute to his scientific acumen that Sievers' data could be analyzed over a half-century later to yield these results.

Table I—Effect of Ontogenesis on Heritability of Total Alkaloids (Determined as Atropine) in Leaves of *A. belladonna* [Determined from the Data of Sievers (1)]

Statistic	Flowering		Fruiting		Overall
	Before	After	Early	Late	
h^2 ^a	0.8838	0.9520	0.4828	0.3097	0.7240
95% CL _{h^2} ^b	0.7874–0.9801	0.8344–1.0000+	0.4007–0.5648	0.2270–0.3924	0.6158–0.8321
Regression equation ^c	$y = 0.1294 + 0.8838x$	$y = 0.0098 + 0.9520x$	$y = 0.2360 + 0.4828x$	$y = 0.4443 + 0.3097x$	$y = 0.2991 + 0.7240x$

^a h^2 = heritability, s_a^2/s_p^2 . When $s_p^2 = s_a^2$, then $h^2 = s_p^2/s_p^2$. ^b 95% CL _{h^2} = in 19 of 20 cases the heritability will be between these limits. ^c Regression equation: x = parental value; y = progeny values. Five randomly selected progeny per parent were used to avoid weighting factors. See Falconer (2) for technique, p. 179.

4. Alkaloidal phenotypes are the product of a polygenic system (quantitative inheritance with some environmental control and possible genetic-environmental interaction).

Model 1—In view of Sievers' data and other corroborating evidence, this model is not feasible for *A. belladonna*. Furthermore, other genera in the Solanaceae exhibit evidence of genetic control. The increased numbers of genes in autotetraploids demonstrated by Rowson (3, 4) and recently extended by Solomon and Crane (5) indicate that increased numbers of genes cause increased alkaloid concentration. Stry (6), working with "Poinsettia aneuploids" and "Globe aneuploids," indicated that the 17·18 and 21·22 chromosomes of *Datura* regulate alkaloid production and further implicate genetic control.

The work of Hills *et al.* (7) on crosses of *Duboisia* species and of Evans *et al.* (8, 9) on *Datura* species indicates that genes may regulate the presence or absence of specific alkaloids in interspecific hybrids.

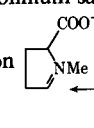

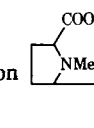

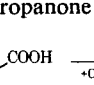

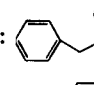

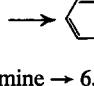

Lecat (10) demonstrated that selection for increased morphine content in *Papaver somniferum* var. *nigrum* is possible. Good chemical screening for alkaloids is based on the empirical premise that if alkaloids are found in a given species, other members of the genus and other genera in the family have a greater probability of producing alkaloids than a random sampling of the plant kingdom. Thus, it appears that genetic control of alkaloidal biovariation and all resulting implications in natural selection and fitness considerations may be generalized to other families in higher plants.

Model 2—Although Mendelian segregation may be responsible for the presence or absence of specific alkaloids in interspecific genetic studies (7–9) in view of the complex set of biochemical reactions thought to be responsible for various alkaloidal biosyntheses, a single-gene mechanism of inheritance within a particular species should be considered highly unlikely (Table II). Such a mechanism would indicate one gene regulating more than one enzymatically controlled reaction for the biosynthesis of hyoscyamine and possibly even more steps in the biosynthesis of scopolamine. A monogenic mechanism of inheritance would also require that the one gene regulating the alkaloidal phenotype in *Datura* would have the unlikely task of being located on two different chromosomes (the 17·18 and 21·22) at the same time (6).

Model 3—The many types of biochemical transformations involved in the alkaloid biosynthesis already demonstrated for *Datura* effectively eliminate the multiple-allele model as a total explanation of alkaloid inheritance. But even with another model, the possibility of multiple alleles at any genic locus identified with regulating alkaloid inheritance must be considered. This explanation would have to be confined to individual steps in particular biosynthetic schemes rather than to the total biosynthesis of the final alkaloidal product.

Model 4—Quantitative characteristics or metrical characters such as secondary plant product concentrations, *i.e.*, alkaloid concentrations, are usually assumed to be polygenically controlled. Geneticists assume *a priori* that such characteristics have, by their

Table II—Outline of Major Steps Involved in Hyoscyamine and Hyoscine Biosynthesis

Gene ^a (Possible)	Hypothetical Function of Enzyme	Type of Reaction
I	<i>N</i> -Methylation	$N: \rightarrow N-Me$: Ornithine $\rightarrow \alpha$ - <i>N</i> -methylornithine

^a Genes are designated by Roman numerals. The dominant alleles would be I_{A1}, I_{A2}, I_{A3} The recessive alleles would be I_{a1}, I_{a2}, I_{a3}

basic nature, genetic and environmental variation. Since Beadle's (11) statement of the "one-gene-one-enzyme" hypothesis, it has been assumed that one gene regulates one biochemical step through one enzyme. Reexamination of Table II indicates 12 possible biosynthetic reactions resulting from enzymatic activity (12). Thus, there appears to be a high probability that extensive additive genetic variance, estimated by heritability, should be possible. Sievers' data (1) and the writers' analysis indicate that this is the case.

Figure 1 summarizes recognized aspects of established polygenic relationships. A hypothetical numerical example relating to alkaloidal polygenic contributions is given. Significantly, each gene in the biosynthetic pathway has an additive genetic variance which contributes to the rate of selection, either artificial or natural, for or against the final phenotype. This rate of selection, designated as h^2 , is the term for heritability. Thus, the presence of heritability in a parent-offspring regression analysis, as demonstrated by Sievers' data, indicates that additive genetic variance is present and that polygenic inheritance applies.

Other types of variation than additive genetic variation are possible. These variances are summarized by the following equation:

$$s_p^2 = s_e^2 + s_g^2 + s_{ge}^2 + s_a^2 + s_d^2 + s_i^2 \quad (\text{Eq. 1})$$

where $s_a^2 + s_d^2 + s_i^2 = s_g^2$

and

- s_p^2 = total observed variation (phenotypic)
- s_e^2 = total environmental variation
- s_g^2 = sampling error induced by not using an infinite population
- s_{ge}^2 = genetic-environmental variation
- s_g^2 = total genetic variation
- s_a^2 = total additive genetic variation
- s_d^2 = total dominant deviation variation
- s_i^2 = total epistatic or intergenic variation

The total average effects of all the genes affecting the final concentration of alkaloids in the phenotype would simulate a normal distribution because of the large number of frequency classes possible. The enzymes listed in Table II need not be specific for a particular step in alkaloid biosynthesis but may be involved in general metabolic activity as well. A polygenic model requires only that a number of enzymes and their respective genes controlling production of the final product, alkaloid, additively produce the final concentration.

Therefore, since the heritability, h^2 , varies with ontogeny of the plant in *A. belladonna*, the ratio of the additive genetic variance to the total phenotypic variance also appears to vary. Thus, it appears that the additivity, or the ability to select for or against total alkaloidal variation expressed as milligrams atropine per gram dry weight of powdered leaf, also varies with the ontogeny of the plant.

Most pharmacognosists have stressed the importance of environmental effects on the alkaloids of Solanaceous plants. Such environmental variables as photoperiod, temperature, inorganic nutrition, and their ratios have been reported to influence growth and alkaloid production (13-25). These environmental studies were made on uniform strains of plants, assuming genetic influence as nonvariable. In view of Sievers' data and the authors' analyses, heritability, additivity, and, therefore, the possibility of selection are present. Moreover, the high heritabilities observed in the early vegetative and early flowering phases indicate that natural selection under various environmental circumstances would most probably occur at these stages of ontogeny.

CONCLUSIONS

Modern biometric analysis of reported data on *A. belladonna* indicates that heritability, or the possible rate of selection, either

natural or artificial, for the total alkaloids of this species varies with the ontogeny of the plant, reaching maximum levels (almost complete additivity) at the early flowering stage. Reexamination of existing information in pharmacognostical literature indicates that the polygenic model, rather than the three alternative models, appears most satisfactory for explanation of the biovariation of alkaloidal concentrations in specific phenotypes. The presence or absence of particular alkaloids in interspecific hybrids and their genetic segregants may be explained, however, by the usual Mendelian laws.

Complexes of Ergot Alkaloids and Derivatives IV: Investigations into the Nature of Ergot Alkaloid-Xanthine Complexes

H. V. MAULDING and M. A. ZOGLIO*

Abstract □ Studies of the effect of xanthines on the solubility of molecules related to the proteinaceous ergot alkaloids indicate the indole moiety to be a primary site for complexation. The tendency of indole and several analogs to form intermolecular complexes with caffeine was surveyed. This property leads to considerable solubility elevation for many of the compounds examined. Apparent equilibrium or association constants are calculated based on an assumed 1:1 complex between the indole substrate and xanthine ligand. Experimental evidence with several simple indoles and caffeine indicates general adherence to this principle. These relatively uncomplex compounds and even larger more complicated molecules such as methysergide exhibit this property of increased solubility through interaction. These substances may be treated in a somewhat rigorous manner contrary to the intricate proteinaceous alkaloids previously examined.

Keyphrases □ Ergot alkaloid-xanthine complexes—solubility effect □ Xanthine-ergot alkaloid complexes—solubility effect □ Spectrophotometry—analysis

The oral administration of ergotamine tartrate with caffeine has been reported to bring about an enhancement of the clinical activity of the alkaloid against migraine headaches (1, 2).

In the course of investigating the physicochemical nature of the combination, several ergot alkaloids and their analogs, such as ergotamine, 9,10-dihydroergocristine, and methysergide, have been observed to possess the capacity for interaction with caffeine and other xanthines in aqueous solution (3–6). This mutual attraction is exemplified by: (a) increased solubility; (b) increased dissolution-rate constant, and (c) altered partitioning-rate constants depending on pH. These changes are noted on inclusion of xanthines as compared to the alkaloids alone (3–6). Recent biological results (7) were found to be in good agreement with the postulation that complex formation leads to increased enteral absorption of ergotamine and ergot alkaloids.

A series of papers in 1957 reported that caffeine and related compounds complex with a wide variety of organic compounds (8–10) as well as with themselves (11). This behavior of caffeine and other xanthines has been studied by means of solubility (8, 11, 12), spectral (13), and kinetic (9, 10, 14) techniques.

It was believed that an investigation of simpler indoles might give some clue regarding the nature of the complex present in complicated ergot alkaloids. A project was initiated to examine indole and several congeners to determine structural factors affecting interaction and delineation of structure-activity relationships. It was hoped this approach would help in the eventual unraveling of the nature and stoichiometry of the species comprising the ergot-xanthine complex, the ultimate aim being application of these and other data to formulation of more suitable medicinal agents.

EXPERIMENTAL

Watertight, screw-capped vials (18-ml. capacity) containing exactly 10 ml. of solvent, 100 mg. of substrate (indole compound), and varying amounts of caffeine were clamped onto the edge of metal disks, 15.24 cm. (6 in.) in diameter, mounted on a motor-driven shaft and rotated vertically at 6 r.p.m. in a constant-temperature bath at $30 \pm 0.2^\circ$. After exactly 24 hr., samples were withdrawn using pipets with filters attached and analyzed for the indole compound by the Van Urk method (3). Each sample was run at minimum in triplicate.

RESULTS AND DISCUSSION

The absence of observable spectral changes precluded utilization of this technique in these experiments. The kinetic method was not employed because of the absence of a suitable reaction for study, thus leaving solubility analysis. This mode has previously been found to be practicable in the study of proteinaceous ergot derivatives, although certain problems have arisen from their erratic solubility properties (3–6).

The usual experimental operation involves addition of an equal weight (in excess of its normal solubility) of the slightly soluble substrate into each of several vials containing a fixed amount of solvent. Varying amounts of xanthine were placed in the vials, which were rotated 24 hr. in a constant-temperature bath. The solution phase was withdrawn by means of a filter pipet with care taken not to include undissolved indole. Assays were performed by the Van Urk (15) method, which lends itself to most molecules containing the indole nucleus. The colors formed absorbed at various wavelengths, depending on the compound in question (Table I).

Data obtained by the solubility analysis scheme may be treated in the following manner, as summarized by Connors and Mollica (16) and using their symbolism. The term S in Eq. 1 represents substrate, indole compound, and L represents ligand, xanthine:

$$mS + nL \rightleftharpoons S_mL_n \quad (\text{Eq. 1})$$

The strength of the complex is given in terms of K_{mn} , which is the stability or association constant:

$$K_{mn} = \frac{[S_mL_n]}{[S]^m[L]^n} \quad (\text{Eq. 2})$$

Table I—Absorptivity and Wavelengths of Maximum Absorbance of Indole Compounds

Figure 1—Solubility phase diagram for the indole-caffeine system at 30° in pH 6.65 phosphate buffer.

The parsimonious approach stipulates assumption, in lieu of conflicting information, of a 1:1 stoichiometry brought about by a single complex to be responsible for the results. Thus the values for m and n (Eqs. 1 and 2) are 1. Making proper substitutions in these equations, one obtains the following (16):

$$S_t = \frac{K_{11}S_0L_t}{1 + K_{11}S_0} + S_0 \quad (\text{Eq. 3})$$

In Eq. 3 the quantities S_t and S_0 are the total concentrations (moles/l.) of indole or alkaloid in solution at various finite and zero xanthine concentrations, respectively. K_{11} is the association constant as previously stated, and L_t is xanthine concentration in moles/liter.

A plot of L_t against S_t gives a straight line with a slope of

$$\frac{K_{11}S_0}{1 + K_{11}S_0}$$

and a y-intercept of S_0 or the solubility at zero ligand concentration. If a single 1:1 complex is present, the apparent K_{11} , written K'_{11} may be written (16):

$$K'_{11} = \frac{\text{slope}}{y\text{-intercept} (1 - \text{slope})} \quad (\text{Eq. 4})$$

The compounds considered in this work were run at pH 6.65 in phosphate buffer. The simpler substances such as indole, 1-methylindole, and 5-methoxyindole all have pKa values of 2 or less. Therefore, they are essentially present in only the neutral species at the hydrogen-ion concentrations employed. The same is true for cal-

feine. As a result of negligible protonation of both molecules (substrate and ligand) at these pH values, the result should be binding between two neutral species. Methysergide possesses a pKa of 6.62 ± 0.02 (6), which indicates any study concerning the molecule at pH 6.65 is at the point of half-ionization, i.e., pH = pKa.

Caffeine was chosen as the best candidate for the ligand for several reasons. It is more soluble than the naturally occurring xanthines such as theophylline and theobromine and offers the best basis for comparison. Much of the earlier work was done with this compound, even though it does complex to an appreciable extent with itself in aqueous solutions (8–14). Caffeine exhibits about 2% solubility at 30°. For this reason, caffeine (ligand) concentrations of greater than 20 mg./ml. were not generally examined.

When the concentration of proteinaceous alkaloid is plotted versus caffeine concentration, a strictly linear function is not generated (3). Positive and negative deviations from this linearity take place more or less at random, depending on the alkaloid, xanthine, and solvent in some unknown manner (4, 5). With simple

Figure 3—Phase solubility diagram for the 1-methylindole-caffeine system at 30° in pH 6.65 phosphate buffer.

indoles, this is not the situation, as may be seen in Figs. 1-3. These substances have K'_{11} values; other pertinent information is listed in Table II.

CONCLUSION

The stoichiometry of the complex has not been delineated but slopes of less than one as encountered in Figs. 1-3 imply a 1:1 complex. This does not prove the absence of other complex species (16).

Table II illustrates that all K'_{11} values, including that of methysergide, are of approximately the same magnitude. This indicates that a good portion of the capacity for complexation of the high molecular weight ergot alkaloids lies within the indole moiety of the molecule. The role the cyclic tripeptide portion plays in the mutual attraction of caffeine and related xanthines for these proteinaceous alkaloids has yet to be spelled out; however, it is likely that these protein substituents may alter binding in some way.

Absolute Configuration of (+)-trans-2-o-Tolylcyclohexanol by X-Ray Crystallography

ARTHUR CAMERMAN*, LYLE H. JENSEN, TODD G. COCHRAN†, and ALAIN C. HUITRIC

Abstract □ The determination of the absolute configuration of the 3-nitro-4-bromobenzoate ester of (+)-trans-2-o-tolylcyclohexanol by X-ray crystallographic analysis is reported. The results give unequivocal proof that the original assignments of (1S,2R)-(+)-trans-2-o-tolylcyclohexanol, (1R,2R)-(-)-cis-2-o-tolylcyclohexanol, and (2R)-(+)-2-o-tolylcyclohexanone are correct.

Keyphrases □ X-ray crystallography—configuration, (+)-trans-2-o-tolylcyclohexanol □ (+)-trans-2-o-Tolylcyclohexanol—configuration confirmation, X-ray crystallography

The absolute configurations of (+)-trans-2-o-tolylcyclohexanol (I) and (-)-cis-2-o-tolylcyclohexanol (II) were reported in an earlier communication (1) on the basis of the positive Cotton effect of the carbonyl chromophore of the (+)-2-o-tolylcyclohexanone (III) obtained from the oxidation of I and II. Compounds I and II are two of several key reference compounds currently used in this laboratory in a study associated with Cotton effects of aromatic chromophores. Although the original assignment of absolute configurations of I and II was considered reliable, an unquestionable proof was desired. Unequivocal proof is now given from X-ray crystallographic analysis of the 3-nitro-4-bromobenzoate ester of I that the initial assignments of (1S,2R)-(+)-trans-2-o-tolylcyclohexanol for I,

(1R,2R)-(-)-cis-3-o-tolylcyclohexanol for II, and (2R)-(+)-2-o-tolylcyclohexanone for III are correct.

Figure 1 shows perspective drawings of the three-dimensional structure and correct absolute configuration of the 3-nitro-4-bromobenzoate ester of (+)-trans-2-o-tolylcyclohexanol.

EXPERIMENTAL

(1S,2R)-(+)-trans-2-o-Tolylcyclohexyl 3-nitro-4-bromobenzoate was prepared by reaction of the known (+)-trans-2-o-tolylcyclohexanol (I) with 3-nitro-4-bromobenzoyl chloride in pyridine. The ester was purified by chromatography on silica gel, using a 50:50 benzene-hexane mixture, and recrystallized from hexane, m.p. 64.5-65.5°, IR (KBr) 1720 cm^{-1} (C=O), 1536, 1352 (NO_2), $[\alpha]_D^{25} + 100^\circ$ (c 1.0, methanol).

The compound crystallizes in space group $P2_12_12$ with the following crystal data:

$$\begin{array}{ll} a = 7.922 \pm 0.002 & \alpha = \beta = \gamma = 90^\circ \\ b = 26.342 \pm 0.008 & D_m = 1.4 \text{ (floatation in CsCl solution)} \\ c = 18.694 \pm 0.006 & D_{\text{calc}} = 1.426 \quad Z = 8 \text{ molecules/unit cell} \end{array}$$

X-ray intensities were measured on a crystal approximately $0.13 \times 0.38 \times 0.53$ mm, to $2\theta = 45^\circ$, corresponding to an interplanar spacing of 0.93 Å, on a computer-controlled, four-circle diffractometer. The $\omega/2\theta$ scan technique using Nb-filtered Mo radiation was employed. A total of 2928 independent reflections were measured, of which 1852 had intensities greater than twice the standard deviation of their measurement. Absorption corrections were applied using the method of De Meulenaer and Tompa (2), and struc-

indoles, this is not the situation, as may be seen in Figs. 1–3. These substances have K'_{11} values; other pertinent information is listed in Table II.

CONCLUSION

The stoichiometry of the complex has not been delineated but slopes of less than one as encountered in Figs. 1–3 imply a 1:1 complex. This does not prove the absence of other complex species (16).

Table II illustrates that all K'_{11} values, including that of methysergide, are of approximately the same magnitude. This indicates that a good portion of the capacity for complexation of the high molecular weight ergot alkaloids lies within the indole moiety of the molecule. The role the cyclic tripeptide portion plays in the mutual attraction of caffeine and related xanthenes for these proteinaceous alkaloids has yet to be spelled out; however, it is likely that these protein substituents may alter binding in some way.

Absolute Configuration of (+)-*trans*-2-*o*-Tolylcyclohexanol by X-Ray Crystallography

ARTHUR CAMERMAN*, LYLE H. JENSEN, TODD G. COCHRAN†, and ALAIN C. HUITRIC

Abstract □ The determination of the absolute configuration of the 3-nitro-4-bromobenzoate ester of (+)-*trans*-2-*o*-tolylcyclohexanol by X-ray crystallographic analysis is reported. The results give unequivocal proof that the original assignments of (1*S*,2*R*)-(+)-*trans*-2-*o*-tolylcyclohexanol, (1*R*,2*R*)-(–)-*cis*-2-*o*-tolylcyclohexanol, and (2*R*)-(+)-2-*o*-tolylcyclohexanone are correct.

Keyphrases □ X-ray crystallography—configuration, (+)-*trans*-2-*o*-tolylcyclohexanol □ (+)-*trans*-2-*o*-Tolylcyclohexanol—configuration confirmation, X-ray crystallography

The absolute configurations of (+)-*trans*-2-*o*-tolylcyclohexanol (I) and (–)-*cis*-2-*o*-tolylcyclohexanol (II) were reported in an earlier communication (1) on the basis of the positive Cotton effect of the carbonyl chromophore of the (+)-2-*o*-tolylcyclohexanone (III) obtained from the oxidation of I and II. Compounds I and II are two of several key reference compounds currently used in this laboratory in a study associated with Cotton effects of aromatic chromophores. Although the original assignment of absolute configurations of I and II was considered reliable, an unquestionable proof was desired. Unequivocal proof is now given from X-ray crystallographic analysis of the 3-nitro-4-bromobenzoate ester of I that the initial assignments of (1*S*,2*R*)-(+)-*trans*-2-*o*-tolylcyclohexanol for I,

(1*R*,2*R*)-(–)-*cis*-3-*o*-tolylcyclohexanol for II, and (2*R*)-(+)-2-*o*-tolylcyclohexanone for III are correct.

Figure 1 shows perspective drawings of the three-dimensional structure and correct absolute configuration of the 3-nitro-4-bromobenzoate ester of (+)-*trans*-2-*o*-tolylcyclohexanol.

EXPERIMENTAL

(1*S*,2*R*)-(+)-*trans*-2-*o*-Tolylcyclohexyl 3-nitro-4-bromobenzoate was prepared by reaction of the known (+)-*trans*-2-*o*-tolylcyclohexanol (I) with 3-nitro-4-bromobenzoyl chloride in pyridine. The ester was purified by chromatography on silica gel, using a 50:50 benzene-hexane mixture, and recrystallized from hexane, m.p. 64.5–65.5°, IR (KBr) 1720 cm^{–1} (C=O), 1536, 1352 (NO₂), $[\alpha]_D^{25} + 100^\circ$ (c 1.0, methanol).

The compound crystallizes in space group P2₁2₁2 with the following crystal data:

$$\begin{array}{ll} a = 7.922 \pm 0.002 & \alpha = \beta = \gamma = 90^\circ \\ b = 26.342 \pm 0.008 & D_m = 1.4 \text{ (floatation in CsCl solution)} \\ c = 18.694 \pm 0.006 & D_{\text{calc}} = 1.426 \quad Z = 8 \text{ molecules/unit cell} \end{array}$$

X-ray intensities were measured on a crystal approximately 0.13 × 0.38 × 0.53 mm, to 2θ = 45°, corresponding to an interplanar spacing of 0.93 Å, on a computer-controlled, four-circle diffractometer. The ω/2θ scan technique using Nb-filtered Mo radiation was employed. A total of 2928 independent reflections were measured, of which 1852 had intensities greater than twice the standard deviation of their measurement. Absorption corrections were applied using the method of De Meulenaer and Tompa (2), and struc-

Figure 1—(1*S*,2*R*)-(+)—trans-2-*o*-Tolylcyclohexyl 3-nitro-4-bromobenzoate.

ture amplitudes were obtained from the intensities in the usual fashion. A sharpened, origin-removed, three-dimensional Patterson synthesis enabled the positions of the two unique bromine atoms to be found; the coordinates of the 50 other nonhydrogen atoms comprising the two molecules in the asymmetric unit were determined in subsequent electron-density maps based on phases calculated from the bromine positions. The positional and thermal parameters of all the atoms were refined using full matrix least squares until a discrepancy factor, *R*, of 0.089 was achieved.

Up to this point the normal bromine scattering curve, f_{Br}^0 , was used with no correction for anomalous scattering of the X-rays by the bromine atoms. At this stage, the absolute configuration of the molecule was determined by the following method. The true bromine scattering curve, including anomalous scattering effects, $f_{Br} = f_{Br}^0 + \Delta f_{Br}' + i\Delta f_{Br}''$, was then applied; structure factors were calculated for molecules with atom coordinates *x*, *y*, and *z* and for molecules with atom coordinates $-x$, $-y$, and $-z$. That is, structure factors were calculated for both possible optical isomers. The discrepancy factor, $R = (\sum ||F_o| - |F_c||) / \sum |F_o|$, was 0.098 for one structure and 0.086 for the other enantiomer. The difference is highly significant (3), and the absolute configuration for this structure is thus unambiguously established as the one giving the lower *R*. One last cycle of least-squares refinement, using the atom coordinates corresponding to the correct optical isomer but neglecting anomalous corrections to the scattering curve, brought *R* down to 0.079. Although hydrogen atoms could be located from a difference Fourier map, they were not included in the calculations since the additional significance does not compensate for the added cost of refinement for a structure of this size.

Muscarinic Receptors: 4-Substituted-3-trimethylammoniumtetrahydrofuran Halides

WENDEL L. NELSON, JOHNNY K. WONG*, FRANK F. VINCENZI, PETER H. BLAKE†, and DONALD L. SMITH

Abstract □ Preparation of the *cis*- and *trans*-4-hydroxy-3-trimethylammoniumtetrahydrofuran and 4-acetoxy-3-trimethylammoniumtetrahydrofuran halides and 3-trimethylammoniumtetrahydrofuran iodide is described. Weak muscarinic activity was noted for the unsubstituted 3-trimethylammoniumtetrahydrofuran salt, being about 1000-fold less potent than acetylcholine. The *trans*-hydroxy and *trans*-acetoxy compounds showed even less activity, and the *cis*-compounds were inactive.

Keyphrases □ 3-Trimethylammoniumtetrahydrofuran halides, 4-substituted—muscarinic receptors, synthesis, pharmacologic testing □ Muscarinic receptors—3-trimethylammoniumtetrahydrofuran halides, 4-substituted, synthesis, pharmacologic testing

The fundamental problem of relating molecular structure to biological activity at various drug receptors becomes extremely difficult when considering small

conformationally mobile molecules such as acetylcholine. Regardless of the existence of preferred conformations in the solid state and in solution (1-5), it should not be assumed that these conformations are those in the drug-receptor surface complex (6).

Various conformationally rigid or semirigid cholinergic agents have been prepared to aid in determination of the architectural features of the drug-receptor complex on various cholinergic sites, *e.g.*, muscarinic, nicotinic, and acetylcholinesterase (7-12). Attempts which incorporate the least number of additional atoms have generally been most successful, although comparisons of closely related compounds in higher series also seem valid (12).

In this study, various analogs of 3-trimethylammoniumtetrahydrofuran iodide were prepared. This system

Figure 1—(1*S*,2*R*)-(+)—trans-2-*o*-Tolylcyclohexyl 3-nitro-4-bromobenzoate.

ture amplitudes were obtained from the intensities in the usual fashion. A sharpened, origin-removed, three-dimensional Patterson synthesis enabled the positions of the two unique bromine atoms to be found; the coordinates of the 50 other nonhydrogen atoms comprising the two molecules in the asymmetric unit were determined in subsequent electron-density maps based on phases calculated from the bromine positions. The positional and thermal parameters of all the atoms were refined using full matrix least squares until a discrepancy factor, *R*, of 0.089 was achieved.

Up to this point the normal bromine scattering curve, f_{Br}^0 , was used with no correction for anomalous scattering of the X-rays by the bromine atoms. At this stage, the absolute configuration of the molecule was determined by the following method. The true bromine scattering curve, including anomalous scattering effects, $f_{Br} = f_{Br}^0 + \Delta f_{Br}' + i\Delta f_{Br}''$, was then applied; structure factors were calculated for molecules with atom coordinates *x*, *y*, and *z* and for molecules with atom coordinates $-x$, $-y$, and $-z$. That is, structure factors were calculated for both possible optical isomers. The discrepancy factor, $R = (\sum ||F_o| - |F_c||) / \sum |F_o|$, was 0.098 for one structure and 0.086 for the other enantiomer. The difference is highly significant (3), and the absolute configuration for this structure is thus unambiguously established as the one giving the lower *R*. One last cycle of least-squares refinement, using the atom coordinates corresponding to the correct optical isomer but neglecting anomalous corrections to the scattering curve, brought *R* down to 0.079. Although hydrogen atoms could be located from a difference Fourier map, they were not included in the calculations since the additional significance does not compensate for the added cost of refinement for a structure of this size.

Muscarinic Receptors: 4-Substituted-3-trimethylammoniumtetrahydrofuran Halides

WENDEL L. NELSON, JOHNNY K. WONG*, FRANK F. VINCENZI, PETER H. BLAKE†, and DONALD L. SMITH

Abstract □ Preparation of the *cis*- and *trans*-4-hydroxy-3-trimethylammoniumtetrahydrofuran and 4-acetoxy-3-trimethylammoniumtetrahydrofuran halides and 3-trimethylammoniumtetrahydrofuran iodide is described. Weak muscarinic activity was noted for the unsubstituted 3-trimethylammoniumtetrahydrofuran salt, being about 1000-fold less potent than acetylcholine. The *trans*-hydroxy and *trans*-acetoxy compounds showed even less activity, and the *cis*-compounds were inactive.

Keyphrases □ 3-Trimethylammoniumtetrahydrofuran halides, 4-substituted—muscarinic receptors, synthesis, pharmacologic testing □ Muscarinic receptors—3-trimethylammoniumtetrahydrofuran halides, 4-substituted, synthesis, pharmacologic testing

The fundamental problem of relating molecular structure to biological activity at various drug receptors becomes extremely difficult when considering small

conformationally mobile molecules such as acetylcholine. Regardless of the existence of preferred conformations in the solid state and in solution (1-5), it should not be assumed that these conformations are those in the drug-receptor surface complex (6).

Various conformationally rigid or semirigid cholinergic agents have been prepared to aid in determination of the architectural features of the drug-receptor complex on various cholinergic sites, *e.g.*, muscarinic, nicotinic, and acetylcholinesterase (7-12). Attempts which incorporate the least number of additional atoms have generally been most successful, although comparisons of closely related compounds in higher series also seem valid (12).

In this study, various analogs of 3-trimethylammoniumtetrahydrofuran iodide were prepared. This system

offered the opportunity to look at possible analogs of muscarine, in which a conformation similar to the one in which the trimethylammonium head is directed toward C-4 of muscarine is represented by attaching this radical at C-3 in tetrahydrofuran (Structure I). In these com-

pounds, the distance of the two-carbon separation of oxygen from nitrogen is similar to that in the *transoid*-conformation of acetylcholine (ACh).

In addition, the *cis*- and *trans*-3-acetoxy (and hydroxy) analogs were prepared as conformational analogs of ACh in which the acetoxy oxygen and trimethylammonium nitrogen are fixed distances apart, similar to totally eclipsed and eclipsed conformations of ACh. These compounds can also be related to the acetyl- α,β -dimethylcholines held in fixed conformations, with the methyl groups attached to each other through an ether bridge.

Also, the 4-hydroxy compounds could show some structural analogy to muscarine, if the other speculation concerning the position of the trimethylammonium groups proved to be true.

SYNTHESIS

Preparation of Compound 1 (Scheme I) was accomplished from

Scheme I

3-tetrahydrofuranone (Compound 7) which was readily prepared from 1,2,4-butanetriol (13). Dehydration afforded Compound 6, which was oxidized to Compound 7 (14).

Initially, it was planned to convert the oxime of ketone 7 to 3-aminotetrahydrofuran, as reported by Korobitsyna *et al.* (15). In the present study, the reported solid oxime could not be isolated, and the sodium amalgam reduction of the crude oxime failed to produce material that could be proven to be the desired amine. However, direct conversion of ketone 7 to Compound 8 was accomplished using Bach's modification (16) of the Leuckart reductive alkylation procedure, using dimethylformamide and 90% formic acid (17).

The 3,4-disubstituted analogs of tetrahydrofuran were prepared by stereospecific routes from 2,5-dihydrofuran (Scheme II). Epoxi-

Scheme II

dation of Compound 9 at 0° provided 3,6-dioxabicyclo[3.1.0]heptane (Compound 10), which was treated with dimethylamine to yield *trans*-3-hydroxy-4-dimethylaminotetrahydrofuran (Compound 11). Compound 2 was prepared from Compound 11 by quaternization with iodomethane, and Compound 3 by acetylation followed by quaternization.

Formation of Compounds 4 and 5 was accomplished from *trans*-3-carbomethoxyamino-4-iodotetrahydrofuran (Compound 12), which was prepared by addition of iodine isocyanate to Compound 9, followed by methanolysis of the intermediate isocyanate. Pyrolysis (130°) of Compound 12 produced 2,7-dioxo-4-azabicyclo[3.3.0]octan-2-one (Compound 13), which was alkylated by formation of the sodium salt of Compound 13 and dimethyl sulfate. Other alkylation procedures, including sodium hydride-iodomethane, and utilization of other bases, *e.g.*, sodium hydroxide and sodium carbonate, failed.

The stereochemistry of these tetrahydrofuran-fused oxazolidinones, although not in question from the synthetic scheme, is readily assigned from their NMR spectra. This is most apparent in the spectrum of the *N*-methylated derivative (Compound 14) (Structure II).

The signals for H-1 and H-5 are quartets at 5.05 and 4.28 δ , respectively, with $J_{1,5} = 7$ c.p.s., $J_{5,6} = J_{1,8} = 4$ c.p.s. Signals for protons H-6 and H-8 were observed as overlapping quartets at 3.42 and 3.58 δ , $J_{gem} = 10$ c.p.s. The downfield signal was assigned to H-8 on the basis of decoupling experiments. Upon irradiation at the frequency of H-1, H-8 collapsed into a doublet, showing J_{gem} only. Protons H-6' and H-8' apparently have almost identical chemical shifts. A slightly broadened doublet at 4.10 δ , $J_{gem} = 10$ c.p.s., was observed integrating for two protons.

Lithium aluminum hydride reduction of Compound 14 produced *cis*-amino alcohol (Compound 15), which was converted to Compounds 4 and 5 in steps analogous to conversion of Compound 11 to 2 and 3.

PHARMACOLOGY

Muscarinic assays were determined using strips of guinea pig ileum in oxygenated Tyrode's solution. 3-Trimethylammonium iodide (Compound 1) showed significant muscarinic activity, being

active at 1×10^{-4} M, equivalent to 1×10^{-7} M acetylcholine, or 1000-fold less potent, but $\alpha = 1.0$. The *trans*-compounds, 2 and 3, showed activity at 5×10^{-8} M ($\alpha = 1.0$). The *cis*-compounds, 4 and 5, were inactive at concentrations up to 10^{-2} M. The agonist effects were not blocked by hexamethonium, indicating the observed effects are postganglionic parasympathetic in origin. No atropinelike effects were observed for the compounds tested.

The marginal activity of the former compounds, 1, 2, and 3, can be rationalized in terms of a maximal O \rightarrow N $^{+}$ distance, similar to the 1,3-dioxolanes (18) and calculations on muscarine (19), or the extended conformation of acetylcholine (7, 11, 12). However, the low level of activity precludes worthwhile speculation.

EXPERIMENTAL

Melting points were obtained with a calibrated Thomas-Hoover Unimelt apparatus and are corrected. IR data were recorded on Beckman IR-5A and IR-8 spectrophotometers. NMR spectra were determined with Varian A-60 and T-60 spectrometers, using tetramethylsilane (TMS) or 3-trimethylsilyl-1-propanesulfonic acid sodium salt as the internal standard. Microanalyses were conducted by Drs. G. Weiler and F. B. Strauss, Oxford, England.

3-Tetrahydrofuranone (Compound 7)—A mixture of 100 g. (0.94 mole) of 1,2,4-butanetriol and 2.0 g. (0.01 mole) of *p*-toluenesulfonic acid monohydrate was distilled, using a water aspirator at 100–120°, to afford about 100 g. of distillate in 2–3 hr. (13). The product, a mixture of water and 3-hydroxytetrahydrofuran, was not separated but subjected to oxidation as described by Yurev *et al.* (14).

To a cold solution (-10°) of 100 g. of the crude distillate of Compound 6 in 150 ml. of ether was added dropwise a cold (0°) solution containing 100 g. (0.33 mole) of sodium dichromate dihydrate, 120 g. (0.12 mole) of concentrated sulfuric acid, and 150 ml. of water. The stirred solution was kept cold (-10 to 0°) for 5–6 hr. and then overnight at room temperature. The mixture was partitioned between ether and water, and the aqueous layer was extracted four additional times with ether. The combined ether layers were dried (MgSO₄), and solvent was removed, affording 42.1 g. (52% in two steps) of a slightly yellow oil; IR, 3.37, 3.47 (C—H stretching), 5.72 μ (C=O stretching); NMR (CDCl₃) δ : 4.23 (triplet, $J = 7$ c.p.s., C-5 protons), 3.83 (singlet, C-2 protons), 2.47 (triplet, $J = 7$ c.p.s., C-4 protons).

3-Dimethylaminotetrahydrofuran (Compound 8)—In a glass-lined autoclave were placed 6.00 g. (70 mmoles) of Compound 7, 10.0 g. (210 mmoles) of 90.9% formic acid, and 15.3 g. (210 mmoles) of dimethylformamide. The autoclave was sealed and heated at 185° for 16 hr., cooled to room temperature, and opened; the contents were then removed. The crude reaction mixture was acidified with 40 ml. of aqueous 10% HCl and washed with several portions of ether. The aqueous acid extract was made alkaline with aqueous 2 N NaOH and extracted with ether. The combined organic extracts were dried (MgSO₄) and evaporated, affording a colorless oil which was converted to the quaternary ammonium salt without further purification.

3-Trimethylammoniumtetrahydrofuran Iodide (Compound 1)—To a cold (0°) solution of 2.88 g. (25 mmoles) of crude Compound 8 in 10 ml. of acetone was added 9.90 g. (70 mmoles) of iodomethane. After 12 hr., the slightly yellow crystalline solid was collected and recrystallized from methanol-ether, affording 1.50 g. (23% of theory) of Compound 1, m.p. 235–236°, NMR (CD₃OD) δ : 3.06 [singlet, N $^{+}$ -(CH₃)₃ protons], overlapping multiplets centered at 3.65, 4.20, and 4.37 integrating for the five aliphatic protons, 2.43 (multiplet, $W_h = 14$ c.p.s., C-4 methine protons).

Anal.—Calcd. for C₇H₁₄INO: C, 32.70; H, 6.27; N, 5.45. Found: C, 32.86; H, 6.33; N, 5.66.

3,6-Dioxabicyclo[3.1.0]heptane (Compound 10)—To a cold (0°) solution of 34.0 g. (0.186 mole) of *m*-chloroperbenzoic acid in 400 ml. of chloroform was added carefully 12.6 g. (0.18 mole) of 2,5-dihydrofuran (Compound 9) in 100 ml. of chloroform. The solution was maintained at 0° for 18 hr. with constant stirring; it was then extracted with cold aqueous 5% NaOH, washed with H₂O, and dried (MgSO₄). The solvent was removed utilizing a rotary evaporator, affording 10.0 g. (65%) of a slightly yellow, thin oil which was used without further purification.

***trans*-4-Hydroxy-3-dimethylaminotetrahydrofuran (Compound 11)**—To a cold (0°) 150-ml. capacity, steel autoclave chamber were added 5.0 g. (0.058 mole) of Compound 10 and 26.2 g. (0.58 mole)

of anhydrous dimethylamine; 50 ml. of benzene was also added as solvent. The autoclave was sealed and heated at 100° overnight. Initial pressure on the gauge was 100 p.s.i. After cooling to 0° , the autoclave was opened and the contents were removed. The solvent was evaporated and the residual oil distilled, affording 6.08 g. (80%) of a slightly yellow oil, b.p. 82° (1.2 mm.). The product was carried to the next reaction without further purification.

***trans*-4-Hydroxy-3-trimethylammoniumtetrahydrofuran Iodide (Compound 2)**—This compound was prepared by a method similar to that used with Compound 1, using ethyl acetate as solvent. An analytical sample was prepared by crystallization from methanol-ethyl acetate, m.p. 194–195°; NMR (D₂O) δ : 3.22 [singlet, N $^{+}$ -(CH₃)₃], 3.60 (quartet, $J = 6$ c.p.s., C-3 methine proton), 4.25 (multiplet, W_h about 18 c.p.s., five protons).

Anal.—Calcd. for C₇H₁₆INO₂: C, 30.78; H, 5.90; N, 5.13. Found: C, 30.79; H, 5.86; N, 5.15.

***trans*-4-Acetoxy-3-trimethylammoniumtetrahydrofuran Iodide (Compound 3)**—To 2.00 g. (0.015 mole) of *trans*-4-hydroxy-3-dimethylaminotetrahydrofuran (Compound 11) was added 20 ml. of acetic anhydride. After heating the mixture at reflux for 1 hr., excess acetic anhydride and the by-product acetic acid were removed. Aqueous 3% HCl, 100 ml., was added to the residual oil and allowed to stand for 1 hr. The aqueous mixture was washed with ether, made alkaline with aqueous 10% NaOH, and extracted four times with ether. The combined ether extracts were dried (MgSO₄) and the solvent removed, affording 1.95 g. (75%) of a light-yellow oil.

A solution of 1.00 g. (5.7 mmoles) of the crude amino ester in 75 ml. of ethyl acetate and 5 ml. of iodomethane was stoppered and shaken occasionally for 1 hr. A white precipitate formed and was removed by filtration, affording 1.82 g. (100%) slightly yellow solid. An analytical sample was prepared by crystallization from methanol-ethyl acetate, m.p. 231° .

Anal.—Calcd. for C₉H₁₈INO₂: C, 34.29; H, 5.71. Found: C, 34.73; H, 5.71.

The chloride salt of Compound 3 was prepared from the quaternary ammonium salt, Compound 2, which was first converted to the chloride salt by ion exchange, followed by acetylation, m.p. 185° .

Anal.—Calcd. for C₉H₁₈ClNO₂: C, 48.78; H, 8.11. Found: C, 48.49; H, 8.17.

***trans*-3-Iodo-4-carbomethoxyaminotetrahydrofuran (Compound 12)**—To a cold (-15°) solution of 12.6 g. (0.18 mole) of 2,5-dihydrofuran in 540 ml. of anhydrous ether were added 59.9 g. (0.40 mole) of freshly prepared silver cyanate and 45.7 g. (0.18 mole) of iodine. The stirred mixture was allowed to warm to room temperature over a period of 6 hr. After this time, the initially red solution had become a yellow slurry. The inorganic salts (silver iodide and excess silver cyanate) were removed by filtration. Anhydrous methanol, 50 ml., was added to the filtrate, and the resulting mixture was refluxed overnight. After removing the organic solvents utilizing a rotary evaporator, the residual dark-brown oil was dissolved in ether, washed with 10% aqueous sodium bisulfite, with water, dried (MgSO₄), and evaporated, affording 24.4 g. (50% in two steps) of a yellow solid. An analytical sample was prepared by crystallization from ether, m.p. 107 – 108° ; IR (potassium bromide), 3.08 (N—H), 3.40, 3.50 (C—H stretching), 5.98 (C=O stretching).

Anal.—Calcd. for C₆H₁₀INO₂: C, 26.59; H, 3.72; N, 5.17. Found: C, 26.65; H, 3.75; N, 5.14.

2,7-Dioxo-4-azabicyclo[3.3.0]octan-3-one (Compound 13)—A stream of dry nitrogen was passed over 5.0 g. (18.4 mmoles) of *trans*-3-iodo-4-carbomethoxyaminotetrahydrofuran and bubbled through a mixture of benzene and pyridine while heating the solid in an oil bath at a temperature of 130° . When no additional pyridine methiodide formed, the reaction was stopped (about 45 min.), affording 2.0 g. (83.3%) of a brown oil which solidified at room temperature. An analytical sample was prepared by crystallization from methanol-ethyl acetate, m.p. 116 – 117° ; IR (potassium bromide), 3.08 (N—H), 3.35, 3.50 (C—H stretching), 5.77 (C=O). NMR (CD₃OD) δ : 5.17 (quartet, $J = 4$ and 7 c.p.s., methine proton at C-1), 4.33 (quartet, $J = 4$ and 7 c.p.s., methine proton at C-5), 4.40 (broad multiplet, N—H proton), 3.93 (doublet, $J_{gem} = 11$ c.p.s., one proton at C-6 and at C-8), 3.53 and 3.47 (overlapping quartets giving the appearance of a doublet of triplets, $J = 4$ and 11 c.p.s. in each case, one proton at C-6 and at C-8).

Anal.—Calcd. for C₈H₇NO₃: C, 46.51; H, 5.47; N, 10.86. Found: C, 46.61; H, 5.64; N, 11.10.

4-Methyl-2,7-dioxa-4-azabicyclo[3.3.0]octan-3-one (Compound 14)

—A solution of sodium methoxide was prepared from 2.0 g. (0.087 g. atom) of sodium and 150 ml. of anhydrous methanol. After the addition of 5.0 g. (0.04 mole) of Compound 13, the mixture was evaporated to dryness *in vacuo*. The residue was suspended in 200 ml. of dry toluene, and 10 ml. of freshly distilled dimethyl sulfate was added dropwise with stirring and cooling. The reaction was then heated at 100° for 1 hr. An equal amount of H₂O was added to the toluene solution to destroy any excess dimethyl sulfate, and the mixture was partitioned. The aqueous solution was then extracted with five portions of chloroform. The combined chloroform and toluene extracts were dried (MgSO₄) and evaporated, affording 4.67 g. (85%) of a slightly yellow oil which solidified on cooling. An analytical sample was prepared by crystallization from chloroform-hexane, m.p. 80°. NMR (CDCl₃); δ 2.88 (N—CH₃, singlet), 3.42 and 3.58 (two overlapping quartets, $J = 4$ and 10 c.p.s. integrating for two protons tentatively assigned to one proton at C-8 and one proton at C-6). The downfield quartet was assigned to the C-8 proton, because upon irradiation of the C-5 proton the 3.58 δ signal collapsed into a doublet, $J_{\text{gem}} = 10$ c.p.s. Similarly upon irradiation in the 3.4–3.5 region, the C-1 proton collapsed into a singlet $J_{1,5} = 7$ c.p.s., 4.10 (broadened doublet, $J_{\text{gem}} =$ about 10 c.p.s., assigned to one proton at C-8 and one at C-6 which show coupling constants with protons at C-1 and C-5, respectively, approaching zero), 4.28 (quartet partially obscured by doublet, $J = 4$ and 7 c.p.s. assigned to other protons at C-6 and C-8), 5.05 (quartet, $J = 4$ and 7 c.p.s., assigned to proton at C-1).

Anal.—Calcd. for C₆H₈NO₃: C, 50.34; H, 6.34; N, 9.78. Found: C, 49.97; H, 6.36; N, 9.99.

cis-4-Hydroxy-3-dimethylaminotetrahydrofuran (Compound 15)

—All equipment was dried at 120° overnight. A stream of dry nitrogen was passed over a suspension of 2.0 g. (52 mmoles) of lithium aluminum hydride in 200 ml. of anhydrous tetrahydrofuran. Two grams (14 mmoles) of Compound 14 in 50 ml. of tetrahydrofuran was added dropwise over a period of 10 min., and the resulting slurry was refluxed overnight. Excess hydride was destroyed by addition of aqueous 40% Rochelle salt, and the mixture was filtered with suction through a diatomaceous earth¹ pad. The filter cake was extracted four times with ethyl acetate. The combined tetrahydrofuran and ethyl acetate portions were evaporated, affording 1.18 g. (65%) of a slightly yellow oil which turned into a solid upon cooling. An analytical sample was prepared by crystallization from ethyl acetate, m.p. 51°.

Anal.—Calcd. for C₆H₁₃NO₂: C, 54.94; H, 9.90; N, 10.68. Found: C, 54.87; H, 9.68; N, 10.92.

cis-4-Hydroxy-3-trimethylammoniumtetrahydrofuran Iodide (Compound 4)

—This compound was prepared by a method similar to that used with Compound 1 using ethyl acetate as solvent. An analytical sample was prepared by crystallization from methanol-ethyl acetate, m.p. 162°.

Anal.—Calcd. for C₇H₁₆INO₂: C, 30.78; H, 5.90; N, 5.13. Found: C, 31.00; H, 5.78; N, 5.19.

cis-4-Acetoxy-3-trimethylammoniumtetrahydrofuran Iodide (Compound 5)—This compound was prepared from Compound 15 by a method similar to the conversion of Compound 11 to Compound 3. An analytical sample was prepared by crystallization from methanol-ethyl acetate, m.p. 193°.

Anal.—Calcd. for C₉H₁₈INO₃: C, 34.29; N, 4.44; H, 5.71. Found: C, 34.48; N, 4.38; H, 5.71.

Critical Evaluation of Extraction Procedures in Determination of Atropine and Scopolamine from *Datura* Powder

MARK J. SOLOMON* and FRANK A. CRANE

Abstract □ The simultaneous quantitative extraction and determination of atropine and scopolamine from *Datura* powder has been performed. This combination procedure afforded relative precisions of 5.11 and 3.85% for atropine and scopolamine with relative accuracies of -3.02 and -1.47%, respectively. Duplicate determinations of duplicate extractions over a 2-month period indicated that for atropine, 23.92% of the variation was attributable to the determination procedure and 76.08% was attributable to the extraction method. For scopolamine, 29.09% of the variation was due to the determination procedure and 70.91% to the extraction method. Comparisons of the USP percolation, continuous extraction procedure, and differential solvent extraction procedures are given. A theoretical discussion of total variation in quantitative methods in relation to extraction and determination is developed. Attempts to identify an unknown peak related to scopolamine are reported.

Keyphrases □ Atropine, scopolamine, extraction from *Datura* powder—comparison, evaluation of various procedures □ Scopolamine, atropine, extraction from *Datura* powder—comparison, evaluation of various procedures □ *Datura* powder—extraction of atropine, scopolamine, comparison, evaluation of methods

The work of Brochmann-Hanssen and Svendsen (1) led Solomon *et al.* (2) to attempt the GLC determination of atropine and scopolamine from solutions and plant powders. This method provided good accuracy and precision, although dehydration products of atropine and scopolamine were formed. A minor GLC peak attributable to scopolamine was not determined. Wu Chu and Mika (3) are presently studying several substances as internal standards for this partition chromatographic method. Recently, Zimmerer and Grady (4, 5) reported a GLC and spectrophotometric assay for hyoscyamine sulfate, atropine sulfate, scopolamine bromide, and phenobarbital tablets and elixir. This method utilized homatropine as an internal standard.

Wu Chu *et al.* (6) reported an extraction procedure for atropine and scopolamine, utilizing a photodensitometric determination method adapted to the quantitation of plant powders. No attempt was made, however, to combine the extraction method with the GLC method of Solomon *et al.* (2).

Some initial considerations of the problems of combining an extraction and determination procedure indicated that a good quantitative method must not only have good accuracy and precision, but the extraction procedure must have a variation within the range of that of the determination method. Upon closer examination, if: s_q^2 = sampling variation in the total quantitation method, s_d^2 = sampling variation in the determination method, s_e^2 = sampling variation in the extraction method, and

$$s^2 = \sum \frac{(\bar{x} - x)^2}{N} = \sum \frac{(\text{expectancy of } x - \text{value of } x)^2}{\text{number of samples studied}} \quad (\text{Eq. 1})$$

Table I—Overall Precision and Accuracy of Combined Extraction and Determination of a Standard Powder

Statistic	Alkaloid	
	Atropine	Scopolamine
\bar{x} , mg. %	21.87	6.81
95% $CL_{\bar{x}}$, mg. % ^a	21.60–22.14	6.78–6.87
$RSD \times 100\%$ ^b	5.12	3.85
Absolute accuracy, ^c mg.	–0.66	–0.10
Relative accuracy ^d	–3.02	–1.47
N	64	64

^a The mean will occur within these limits in 19 of 20 determinations. ^b Relative standard deviation = $SD/\bar{x} \times 100\%$. ^c Calculated as deviations from the median. ^d Relative accuracy = $\text{absolute accuracy} \times 100\%/\bar{x}$.

where \bar{x}_q = expectancy of the total quantitation method, \bar{x}_d = expectancy of the determination method, and \bar{x}_e = expectancy of the extraction method, it can be shown that

$$s_q^2 = s_d^2 + s_e^2 \quad (\text{Eq. 2})$$

Thus,

$$s_e^2 = s_q^2 - s_d^2 \quad (\text{Eq. 3})$$

For n samples, where n is small enough to be corrected for the small sample bias, after expansion and subsequent simplification, Eq. 3 can be written as

$$\sum_{n=2}^n \frac{(\bar{x}_q + \bar{x}_d - 2x_n)(\bar{x}_q - \bar{x}_d)}{n-1} = \sum_{n=2}^n \frac{(\bar{x}_e - x_n)^2}{n-1} \quad (\text{Eq. 4})$$

If the determination method is vastly improved without improving the extraction procedure,

$$\lim_{n \rightarrow N} (\bar{x}_d - x_n) = 0, \quad \text{where } N \gg n \quad (\text{Eq. 5})$$

By simplifying Eq. 4,

$$\sum_2^N \frac{(\bar{x}_q - x_n)^2}{N} = \sum_2^N \frac{(\bar{x}_e - x_n)^2}{N} \quad (\text{Eq. 6})$$

Thus, an excellent determination procedure coupled with a relatively coarse extraction procedure will produce a quantitative method in which the variation of the extraction procedure is measured with excellent precision and accuracy. Consideration of this problem along with a study of the variation in extraction of *Datura* alkaloids in relation to an established determination method is the purpose of this paper.

MATERIALS AND METHODS

Standard Powder—A standard powder was prepared from the leaf laminae (petiole removed) of 144 DS 2 (7) field-grown plants of

Datura stramonium, forced-air dried at 50°, and ground to a 40-mesh powder.

Extraction Method—Ten grams of the standard powder was extracted by the method of Wu Chu *et al.* (6), scaled up from 4 g., and finally washed to volume in a 5-ml. rather than 10-ml. volumetric flask. Unless otherwise stated, this extraction method was referred to as the "differential solvent extraction method." The USP XVII (8) methods of percolation and continuous extraction procedure were utilized as stated, except for the addition of washed sand as a bulking agent. All continuous extraction procedures were run for 8 hr. to ensure exhaustive extraction.

Determination Procedures—Two-microliter samples of the final extract, brought to volume in a 5-ml. volumetric flask, were quantitated according to the GLC procedure of Solomon *et al.* (2).

Materials—All chemicals used for the chromatographic portion of this paper were analytical reagent grade. Atropine and scopolamine¹ and scopoline² produced a single spot on TLC. Silane-treated glass wool³ was used (9).

Aposcopolamine Synthesis—Aposcopolamine was unavailable commercially, so it was synthesized according to the method of Willstätter and Hug (10). The resulting product was recovered as long needles (m.p. 96.5–97.0°), and the identity was confirmed by NMR and mass spectrometry.

Experimental Designs—The precision and accuracy study (Table I) was run on 64 independent extractions. The study of variation with time (Table II) represents the effect of heirarchal or nested time levels on the variation of the total quantitative method. The USP XVII percolation and continuous extraction procedures, as stated in the Belladonna Leaf Monograph, were compared (Table III), and these procedures were then compared to the differential solvent extraction method in a 3 \times 3 Latin square design (11). All precautions for randomization were taken.

RESULTS AND DISCUSSION

The use of silane-treated glass wool to hold column contents in place decreased the formation of dehydration products but did not eliminate them entirely.

Attempts to identify the minor peak associated with scopolamine occurring at retention time 14.5 min. (236°), as previously reported (2), were not successful. Injection of pure scopoline, the compound considered as the most likely degradation product, afforded a single peak with a retention time 3 min. 24 sec. (170°). Mass spectral analysis of a collection of the effluent at 14.5 min. (236°) retention time for a combined running time of 20 hr. was inconclusive, because only two peaks were obtained (*m/e* 263 and 240). The placement of the scopoline GLC peak and the fact that fragments

of at least *m/e* 263 could be obtained from the unknown compound did indicate, however, that the compound was probably not scopolamine.

Since collection of the compound was not possible with the system available, it was hypothesized that dehydration of scopolamine was occurring similar to the formation of apoatropine from atropine. Synthetic apoatropine was prepared (parent ion *m/e* 285 representing 72% of the base peak of *m/e* 94 in the mass spectrum), but upon injection it afforded a single peak at retention time 16 min. 54 sec. The mass spectral studies of aposcopolamine indicated no fragments between *m/e* 285 (parent ion) and *m/e* 154. Thus, the partial spectrum of the unknown compound and the spectrum of the aposcopolamine definitely appeared dissimilar. The partition pattern of scopolamine and its dehydration product aposcopolamine was parallel to the partition pattern of atropine and apoatropine. Both dehydration products were detected about 1 min. before the parent compound on the methylsilicone gum on a silanized diatomite system. The unknown compound, however, had a retention time of 3.5 min. less than the parent scopolamine.

The differential extraction method was very satisfactory for combination with GLC analysis. The photodensitometric determination method (6) originally reported with this extraction procedure was not as accurate or precise as the GLC method. However, it had the advantage that when the alkaloid was in low concentration, more of the final chloroform extract could be applied to the TLC plate without too much danger of overloading. The GLC determination method was more accurate and precise but dilute solutions required injection of more than 5 μ l., which produced tremendous tailing and even occasional extinction of the flame.

Examination of Table I indicates that the overall relative precision of the combined extraction and determination of the standard powder was 5.12 and 3.85% with relative accuracies of –3.02 and –1.47% for atropine and scopolamine, respectively. The 95% confidence limits of the mean (95% $CL_{\bar{x}}$) indicated that these data were repeatable.

The contribution of the combined extraction and determination components over a 2-month period was examined (Table II). The variation between months or between weeks within months represented the largest component of variation for both atropine and scopolamine, although the components of variation between months, between weeks within months, between extraction sets within weeks (between days within weeks), and between extractions within days were all nonsignificant for both alkaloids quantitated using the determination variance component as the error term. Further examination indicated that 23.92% of the variation for atropine and 29.09% of the variation for scopolamine were attributable to the determination method, while 76.08% of the variation for atropine and 70.91% of the variation for scopolamine were functions of the extraction method. These analyses indicated that the extraction and determination methods were comparable; even though the extraction method was more variable than the determination method, the difference was not so extensive that the

total variation could be considered a total function of either procedure. A comparison, however, of the USP XVII extraction methods with the differential solvent method was indicated.

Statistical analysis of the secondary and tertiary interactions for atropine and scopolamine (Table III) indicated that only the differential solvent method was nonsignificant over the days tested in this experiment. The continuous extraction ($p < 0.05$), percolation ($p < 0.001$), and continuous extraction and percolation combination ($p < 0.001$) methods varied over the period studied (3 randomized days). However, only the percolation method had a significant contribution for days when scopolamine was analyzed ($p < 0.05$). All the methods did not vary significantly between replicates (three) within days as would be expected. These data were interpreted to indicate that although the USP extraction methods may be satisfactory for total alkaloidal quantitation, they may be too variable for the present determination needs. Therefore, this would be an experimental example of the conclusion reached in Eq. 6.

When the orthogonal comparison of the combination of continuous and percolation extraction methods *versus* the differential solvent extraction method was considered, the $F_{1,43}$ value was highly significant for both alkaloids studied ($p < 0.001$). When the continuous extraction and percolation methods were compared, they were highly significantly different ($p < 0.001$) in this study, although USP XVII lists these methods as alternate extraction procedures.

SUMMARY

The combination of the differential solvent extraction and GLC determination methods produced an analytical procedure which was both precise and accurate. Analyses over a 2-month period indicated that time did not produce a significant variation in results. Comparison with USP XVII extraction methods indicated that the differential solvent extraction method was less variable. Comparison of the continuous extraction and percolation methods, listed as alternate quantitative extraction procedures in the belladonna leaf assay, demonstrated that these methods were not as satisfactory extraction procedures in this study as the differential solvent method.

First pKa Values of Some Acid-Base Indicators

V. DAS GUPTA and JOHN B. REED, Jr.*

Abstract □ An attempt was made to estimate the first pKa values of bromocresol green, bromocresol purple, bromophenol blue, cresol red, and phenol red using a method similar to that of Reilley and Sawyer. Values of -0.75 (-2.13 on the Hammett acidity scale) for bromocresol purple, $+1.05$ for cresol red, and $+1.03$ for phenol red were estimated. pKa values of cresol red and phenol red were not estimated on the Hammett acidity scale, since this scale is good only for acidic solutions stronger than 0.1 *M*. Trials to estimate the first pKa values of bromocresol green and bromophenol blue were not successful due to the upper limitation on the strength of commercially available hydrochloric acid. Values of -0.85 (approximately -2.7 on the Hammett acidity scale) or less for bromocresol green and -0.95 (-3.2 on the Hammett acidity scale) or less for bromophenol blue have been predicted.

Keyphrases □ Indicators, acid-base—first pKa determination □ pKa determination, first—acid-base indicators □ Dyes, organic—first pKa determination

Many organic dyes are used as acid-base indicators by scientists in a variety of analytical and industrial applications. Some of these dyes have also found use as diagnostic agents in medicine (1-4). Some of them are used in the quantitative determination of many pharmaceutical amines, since they form stable salts with this group of chemicals (5-8). These amine dye salts can be extracted with organic solvents and the dye component measured spectrophotometrically (9).

Preliminary investigations on bromothymol blue, reported by Gupta and Cadwallader (10), indicated that these dyes may have more than one pKa value. For example, the literature value of about 6.3 for bromocresol purple (11) may be the pKa₂ rather than the pKa₁ value.

The purpose of this research was to determine the first pKa values for: (a) bromocresol green (BCG); (b) bromocresol purple (BCP); (c) bromophenol blue (BPB); (d) cresol red (CR); and (e) phenol red (PR). The usefulness of this information is well documented. For example, without knowing the first pKa value, it is not possible to determine the true partition coefficients of these dyes.

EXPERIMENTAL

Reagents—All chemicals and reagents used were either USP, NF, or A.C.S. grade. All of the dyes were used without further purification.¹

Preparation of Solutions—Each dye (50.0 mg.) was dissolved in 10 ml. of ethyl alcohol in a 100-ml. glass-stoppered volumetric flask, and sufficient distilled water was added to make a total volume of 100 ml. Solutions of lower dye concentration were prepared by diluting this stock solution with hydrochloric acid of various concentrations. The concentrations of the various dyes are reported in Table I. Hydrochloric acid USP was diluted with distilled water to obtain the dilutions needed.

Determination of pKa Values—The pKa values were determined according to the procedure of Reilley and Sawyer (12). Solutions

Table I—Concentrations of Various Dyes Used

	0.00025 ^a

^a More than one concentration was used to obtain readings within the scale of the spectrophotometer.

of each dye in hydrochloric acid solutions of various concentrations were scanned between 360 and 600 mμ, using a Beckman DK2 spectrophotometer. Distilled water was used as the blank. Two wavelengths were chosen where the (H₂I) and (HI⁻) forms of each dye showed a maximum difference in their absorbance. Plots of absorbance *versus* the theoretical pH value ($-\log H^+$) were prepared for each of the two wavelengths selected. Two horizontal lines across each of the plots were drawn, one corresponding to the absorbance of the dye solution having a theoretical pH value of -1.0 and the other corresponding to the absorbance of the dye solution having a theoretical pH value of -0.398 or higher.

Line A represents the absorbance of the dye, *i.e.*, the indicator dye represented as "I," when present entirely in the (H₂I) form. Line B represents the absorbance of the dye when present entirely in the (HI⁻) form. The midpoint of each curve, between Lines A and B,

represents the equal concentration of the (H₂I) and (HI⁻) forms of each dye. This was marked as the midpoint on each curve. The results are presented in Table II. Figures 1–3 are presented as samples. In the case of BCP, the pKa values were also estimated using *H*₀ (Hammett acidity function) instead of theoretical pH. Results are presented in Table II. From these figures, the ratio of (HI⁻) to (H₂I) at various pH values was obtained by measuring the relative distances of the point from the (HI⁻) and (H₂I) lines. Plots of log (HI⁻/H₂I) (vertically) versus theoretical pH were prepared for each of the two wavelengths selected. The point where the line crossed

Figure 2—Determination of the first pKa value of BCP using absorbance values at 530 mμ.

the pH axis corresponded to the pKa₁ value, since (H₂I) = (HI⁻) + (H⁺). The dissociation of (HI⁻) to (I⁻) and (H⁺) can be neglected in the pH range of -1.0 to approximately 2.0, since *K*_s values of these dyes range from 1 × 10⁻⁴ to 5 × 10⁻⁹. The results are presented in Table II. Figure 4 is presented as a sample. In the case of BCP, the pKa values were also estimated using *H*₀ instead of pH. Results are presented in Table II.

DISCUSSION AND CONCLUSIONS

Bromocresol Green—Trials to estimate the first pKa value of this dye were not successful, since the difference between the absorbance readings at the theoretical pH values of -0.875 and -1.0 was so high (Fig. 1) that it was not possible to assume that the whole dye existed in the (H₂I) form at the lowest theoretical pH value of -1.0. It was not possible to prepare dye solutions of much lower theoretical pH values due to the upper limit on the strength of commercially available hydrochloric acid. From Fig. 1, it appears that the first pKa value of this dye is -0.85 (approximately -2.7 on the Hammett acidity scale) or less.

Bromocresol Purple—The first pKa value of this dye was estimated to be -0.75 or -2.13 on the Hammett acidity scale (Figs. 2 and 4 and Table II). The true pKa value may be somewhat lower, since the dye might not be totally in the (H₂I) form at the theoretical pH value of -1.0. This is due to the fact that the difference between the absorbance values at the theoretical pH values of -0.875 and -1.0 (Fig. 2) is not negligible.

Bromophenol Blue—Trials to estimate the first pKa value of this dye were not successful due to the reasons reported for BCG. From Fig. 3, it appears that the first pKa value of this dye is -0.95 (approximately -3.2 on the Hammett acidity scale) or less.

Cresol Red—The first pKa value of this dye was estimated to be +1.05 (Table II). This value appears to be correct, since a transition interval of +0.2 to +1.8 (red to yellow) for this dye has been reported (13). The pKa value of this dye was not estimated on the Hammett acidity scale, since this scale is good only for acidic solutions stronger than 0.1 *M*.

Figure 3—Determination of the first pKa value of BPB using absorbance values at 530 mμ.

Figure 4—Determination of the first pK_a value of BCP using $\log (HI/H_2I)$ (from Fig. 2) versus $-\log (H^+)$ plot.

Phenol Red—The first pK_a value of this dye was estimated to be +1.03 (Table II). The Hammett acidity scale was not used due to reasons previously explained.

It was not possible to take into account the activity coefficients at these higher concentrations of hydrochloric acid. This will, no doubt, cause some error in the determination of the first pK_a values

of these dyes. Wherever possible, the Hammett acidity scale was also used as explained previously.

Analytical Applications—The information provided is very useful for the determination of the true partition coefficients as reported by Gupta and Cadwallader (10). This information could also be useful to correlate the structural formulas of the dyes.

Dipole Moment and Structure of Thiophene Derivatives and Benzene Analogs

E. J. LIEN* and W. D. KUMLER

Abstract □ The dipole moments of 2-halothiophene, 2,2'-bithiophene, 2-thiophenecarboxylic acid derivatives, and the corresponding benzene analogs have been measured in benzene and in dioxane. Evidence is presented that the conformation in 2-thiophenecarboxylic acid derivatives has the thiophene dipole (which has the sulfur negative) opposed to the resultant dipole of the carboxyl or ester group. The conformation in 2,2'-bithiophene is shown to be

cis. In dioxane, there is more resonance interaction between the thiophene ring and the functional groups than between the benzene ring and these groups. The chemical shift and the coupling constant of the NMR spectra of the 2-halothiophenes and 5,5'-dihalo-2,2'-bithiophenes have been assigned.

Keyphrases □ Thiophene derivatives, benzene analogs—dipole moment, structure determination □ NMR spectroscopy—structure

The dipole moment has been shown to be a useful electronic parameter in some structure-activity correlation studies (1), *e.g.*, the insecticidal activity of chlorophenothane (DDT) isomers (2), the cholinesterase inhibitory activity of *N*-alkylsubstituted amides (3), the

respiratory stimulation activity of cyclic ureas and thioureas (4), and the inhibition of viral neuraminidase by dihydroisoquinoline derivatives (5).

The usefulness of dipole moments in structure-activity correlation is more restricted than other physico-

Figure 4—Determination of the first pK_a value of BCP using $\log (HI/H_2I)$ (from Fig. 2) versus $-\log (H^+)$ plot.

Phenol Red—The first pK_a value of this dye was estimated to be +1.03 (Table II). The Hammett acidity scale was not used due to reasons previously explained.

It was not possible to take into account the activity coefficients at these higher concentrations of hydrochloric acid. This will, no doubt, cause some error in the determination of the first pK_a values

of these dyes. Wherever possible, the Hammett acidity scale was also used as explained previously.

Analytical Applications—The information provided is very useful for the determination of the true partition coefficients as reported by Gupta and Cadwallader (10). This information could also be useful to correlate the structural formulas of the dyes.

chemical constants such as Hammett's σ constant or Taft's σ^* constant (6), because the resultant moment of a molecule has to be calculated by vector addition, not by simple addition.

That substitution of a thiophene ring for the benzene ring produces compounds with similar physical and biological properties has long been recognized (7, 8). Based on the concept of "bioisosterism," many thiophene analogs of biologically active compounds containing the benzene ring have been investigated (8).

In considering some of the differences between the two sets of compounds, a knowledge of the conformation of the thiophene compounds and how thiophene transmits resonance effects compared with benzene appeared desirable. It seemed likely that a study of the dipole moments of suitable compounds could give this information.

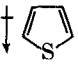

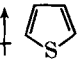

EXPERIMENTAL

The simple halothiophenes¹ were further purified by vacuum distillation. The other thiophene and benzene derivatives were used as provided.² The melting points and the boiling points are given in Table I.

All dipole moments were measured at 25° using a WTW-Dipole Meter model DM01 and a DFL-2 cell. The method of Halverstadt and Kumler (9), programmed for an IBM 1401 by Simpson (10) and converted for an IBM 360/40 computer by the authors, was used to calculate the dipole moments. The solute molar electronic polarization (P_E) was obtained from refractive index measurements. The dipole moments are assembled in Table I.

The NMR spectra of the five compounds examined indicated the samples were of high purity. The NMR spectra were measured on a Varian A-60A spectrometer. The position of the peaks are with reference to that of trimethylsilane (TMS). A complete analysis of the second-order splitting of the ABC pattern for the 2-halothiophenes and the first-order splitting of the AB pattern for the 5,5'-dihalo-2,2'-bithiophenes are summarized in Table II.

RESULTS AND DISCUSSION

The analysis of the dipole moment data is dependent on whether the dipole moment in thiophene has the negative end toward sulfur  or toward the carbons . The latter might result if there were appreciable contributions from forms with a separation of charges such as . The literature con-

tains conflicting opinions in regard to the direction of this dipole (8, 11). A consideration of the dipole moments of 2- and 3-methylthiophenes and 2,5-dichlorothiophenes and 2,5-dibromothiophenes (10, 12) demonstrates, however, that the negative end of the dipole is toward sulfur. This, coupled with the evidence that 2-thiophenecarboxylic acid is essentially flat (13) and that its dipole moment is considerably less than that of benzoic acid, establishes the conformation of 2-thiophenecarboxylic acid as being I or II or a combination of the two but not III:

Only in I or II is the dipole in the thiophene ring in a position to reduce the resultant moment of the carboxyl group. There are conflicting reports on the conformation of 2,2'-bithiophene (12, 14). Thiophene itself has a dipole moment of 0.52 D. The dipole moment of 2,2'-bithiophene (0.96 D in benzene, 1.15 D in dioxane) unequivocally indicates that the two thiophene rings are in a *cis*-conformation rather than in a *trans*-conformation, because the latter conformer should have a moment much lower than 0.52 D:

Generally speaking, dipole moments measured in dioxane are higher than in benzene (positive $\mu_D - \mu_B$), because the local dipoles of dioxane tend to augment the dipole moment of the solute molecules. However, for 2-iodothiophene and 4-iodobiphenyl, negative $\mu_D - \mu_B$ values were obtained. This may be due to the lower electronegativity of iodine as compared with that of bromine or chlorine and a greater contribution of the resonance structures in dioxane, opposing the dipole of the C—I bond:

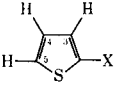

The resonance structure like VIIc is impossible for 5,5'-dihalo-2,2'-

Table II—NMR Data of 2-Halothiophenes and 5,5'-Dihalo-2,2'-bithiophenes (Measured in CDCl₃)

Chemical Shift (δ) p.p.m. Relative to TMS							
							
X	H ₄	H ₃	H ₅	No. of Lines	Coupling Constant, c.p.s.		
					$J_{3,4}$	$J_{3,5}$	$J_{4,5}$
Cl	6.88	6.96	7.07	8	2.5	1.3	5.0
Br	6.84	7.09	7.21	12	4.0	1.5	5.5
I	6.81	7.28	7.42	11	4.0	1.0	5.8

							
X	H ₃ =H _{3'}	H ₄ =H _{4'}		$J_{3,4} = J_{3',4'}$			
Br	6.76	6.88	4	4.0			
I	6.73	7.10	4	3.7			

bithiophene; therefore, positive $\mu_D - \mu_B$ values would be expected. The experimental data fulfill this expectation, since a $\mu_D - \mu_B$ of 1.02 D is obtained for 5,5'-diiodo-2,2'-bithiophene.

For 5-iodo-2,2'-bithiophene, 0.51 D is obtained for $\mu_D - \mu_B$; this may be due to the noncoplanarity of the bithiophene system and the decreased contribution from dipolar forms like VIIc. It has been shown by electron-diffraction study that in biphenyl two benzene rings form an angle of 45° (15).

For the 2-thiophenecarboxylic acid derivatives, the dipole moments measured in dioxane are higher than those of the corresponding benzene ring compounds. This may be attributed to the greater resonance-transmitting character of the thiophene ring, since dioxane tends to stabilize the dipolar forms. In benzene, no such general trend is observed because benzene does not have local dipoles. For the purpose of structure-activity correlation studies, the dipole moments obtained from dioxane may be better than the moments obtained from benzene, since water in the biological system is a highly polar solvent.

For the NMR data in Table II, the assignment of the coupling constant of 2-halothiophenes is simplified by the study of 5,5'-dihalo-2,2'-bithiophenes, since in the latter case only one coupling constant exists ($J_{3,4}$) which is about 4.0 c.p.s. in both cases where the halogen is Br or I. For 2-chlorothiophene, $J_{3,4}$ is somewhat lower (2.5 c.p.s.), probably due to the higher electronegativity of the chlorine atom and lower electron density in the C₃—C₄ bond. The order of the coupling constants varies as $J_{4,5} > J_{3,4} > J_{3,5}$. This is explainable since there is more double-bond character in the C₄—C₅ bond than in the C₃—C₄ bond. $J_{3,5}$ is the smallest because there are four bonds between H₃ and H₅, while only three bonds are between H₃ and H₄.

For the 2-halothiophenes, the chemical shift of the proton at the 4-position appears to be determined by the inductive effect of the halogen, i.e., the higher the electronegativity of the halogen, the lower the field for the resonance of the proton. This is as expected, since the lower the electron density, the less will be the shielding effect due to the diamagnetism of the circulating electrons (16). On the other hand, for the chemical shifts of the protons at the 3- and

5-positions, an opposite order was obtained. Namely, H₃ and H₅ of 2-iodothiophene (least electronegativity of I) appear at a lower field than those of 2-bromothiophene and 2-chlorothiophene. This is probably due to the contribution from the paramagnetic effect of the C—X bond, since this effect would be the greatest for iodine (17). Free halide ion, having a spherically symmetrical charge distribution, will be magnetically isotropic. The C—I bond has less ionic character than the C—Cl bond, and the magnetic anisotropy of the former would be greater than the latter.

Latentiation of Dihydrostreptomycin by Pamoate Formation

H. C. CALDWELL, A. B. REDNICK, G. C. SCOTT, G. J. YAKATAN*, and D. ZIV

Abstract □ Dihydrostreptomycin was formulated as its pamoate salt as part of a search for a long-acting product. In dogs, an intramuscular injection of a cottonseed oil suspension of dihydrostreptomycin pamoate was absorbed more slowly than equivalent doses of dihydrostreptomycin sulfate suspended in cottonseed oil or dissolved in water. Pharmacokinetic studies suggest that plasma data can be described by the one-compartment open model, and that both salts are equally available.

Keyphrases □ Latentiation, dihydrostreptomycin—by pamoate formation □ Pamoate formation—role in dihydrostreptomycin latentiation □ Dihydrostreptomycin pamoic acid salt—synthesis

Dihydrostreptomycin, first reported in 1946 (1), is made by chemical reduction of streptomycin. Both antibacterial agents possess similar activity against Gram-negative and a few Gram-positive bacteria. For example, they are used to treat bovine actinomycosis, calf pneumonia, newborn foal septicemia, horse cystitis, dog acute nephritis, infectious feline panleukopenia, turkey infectious sinusitis, *etc.* (2). But these drugs must be administered often to ensure high blood levels because they are rapidly removed from the blood. For example, after intramuscular injection, dihydrostreptomycin serum concentrations are reduced to about half in several instances, as follows: man, 3 hr. (3); rabbit, 1.5 hr. (4); cow, 3 hr. (5); chicken, 2 hr. (6, 7); goat, 1–2 hr. (8); and cat, 3 hr. (3).

The objective of the present study was to make a long-acting dihydrostreptomycin injectable by making the drug slowly available from the injection site, thus delaying its transit to the bloodstream. Several examples of delayed transport have been reported. Zini (9) reported that dihydrostreptomycin in pectin–procaine solution markedly prolonged significant serum levels after injection in man, but Hammond (5) tested the solution in cattle and found no prolonged serum levels. Malék *et al.* (10) showed that, on injection, antibiotic salts of high molecular weight acids were transported differently and provided more prolonged blood levels than antibiotic salts of inorganic acids. Several potentially useful dihydrostreptomycin salts are known (11–24); they include naphthalenesulfonate (11), chaulmoograte (14), cholate (15), caprylate (17), and laurylsulfonate (20), but the unknown pamoic acid salt¹ was made for this study.

EXPERIMENTAL

Chemical Synthesis—Sodium pamoate (64.8 g.—0.3 equivalent) was dissolved in 600 ml. of distilled water and filtered. This solution was added with mechanical stirring to a solution of dihydrostreptomycin sulfate (73.2 g.—0.3 equivalent) in 400 ml. of distilled water. The gummy precipitate of dihydrostreptomycin pamoate was collected and washed several times with distilled water. It was then dried at 60° in a vacuum oven for 12 hr. to yield 91.5 g. (78%) of tan solid that decomposed at about 230°. In the analysis of pamoic acid, a theoretical value of 50% was calculated.

Table I—Values of k_a , k_e , and Areas Obtained from Data on Administration of Dihydrostreptomycin to Dogs

Salt	Dose, ^a mg./ kg.	$10^5 k_a$, sec. ⁻¹	$t_{1/2a}$, hr.	$10^4 k_e$, sec. ⁻¹	$t_{1/2e}$, hr.	Area, ^b %
Sulfate ^c	4	58.3	0.33	1.76	1.09	100
Sulfate ^d	4	36.8	0.52	1.76	1.09	100
Pamoate ^d	4	5.56	3.46	1.76	1.09	100

^a Calculated as dihydrostreptomycin base. ^b Based on comparison to the actual area of the dihydrostreptomycin sulfate formulation in water. ^c Dosed in water. ^d Dosed in oil suspension.

The values were found to be 50.5% by UV and 49.6% by non-aqueous titration.

Formulation Studies—A 10% suspension of dihydrostreptomycin pamoate was readily prepared by rotating 6 g. of dihydrostreptomycin pamoate (passed through a 100-mesh screen) in 15 ml. of cottonseed oil² in a bottle containing glass beads for 6 hr. The suspension was poured out, and the beads were washed several times with cottonseed oil to make a final 60 ml. of suspension. A 10% suspension of dihydrostreptomycin sulfate in cottonseed oil was prepared in the same way. Dihydrostreptomycin pamoate could not be formulated as an aqueous suspension because it formed a gum.

Plasma Microbiological Assays—Dihydrostreptomycin plasma levels were determined by the *Bacillus subtilis* cylinder plate assay (25) with human serum as the diluent.

Dosing Dogs—Crossover studies were done with three male dogs. First, they were injected intramuscularly with 4 mg./kg. of dihydrostreptomycin (as sulfate) in water and bled at 0, 0.5, 1, 3, 4, and 5 hr. After a rest period of 1 week, the dogs were dosed with 4 mg./kg. of dihydrostreptomycin (as pamoate) in cottonseed oil and bled at 0, 1, 3, 4, 5, 6, 8, 10, 12, and 26 hr. Finally, they were dosed with 4 mg./kg. of dihydrostreptomycin (as sulfate) in cottonseed oil and bled at 1, 3, 4, 5, and 6 hr.

RESULTS AND DISCUSSION

Three injectable dosage formulations of dihydrostreptomycin were compared in dogs. For these studies, the performances of the formulations were judged by their ability to delay absorption. Figure 1 shows that dihydrostreptomycin absorption from the pamoate formulation is slower and more prolonged than from the sulfate formulations. For example, dihydrostreptomycin pamoate in cottonseed oil provides dihydrostreptomycin levels above 3 mcg./ml. for about 7 hr., while dihydrostreptomycin sulfate in water and in cottonseed oil provides plasma levels above 3 mcg./ml. for about 4 and 4.5 hr., respectively. This does not imply that 3 mcg./ml. is a therapeutic plasma level for infections in dogs; it is merely a cutoff point for this comparative study.

Determination of Pharmacokinetic Constants—Plasma data can be described by the $A \xrightarrow{k_a} B \xrightarrow{k_e} C$ consecutive first-order model, where A represents the amount of drug at the injection site, B the amount of drug in the central body compartment (blood and rapidly equilibrating tissues), and C the amount of drug eliminated from the central compartment at any time. The absorption rate constant, k_a , and the elimination rate constant, k_e , govern the drug-transfer rate from the depot and central compartment, respectively.

Semilogarithmic plots of plasma concentration *versus* time were made. An estimate of the elimination rate constant, k_e , was made from the terminal log linear segment of the data given for the administration of dihydrostreptomycin sulfate in water. The assumption was then made that the different formulations should in no way alter the elimination rate constant. The only changes that would normally be expected would be variations in the time and magnitude of the peak blood levels, and these factors are the result of changes

¹ Pamoic acid is 4,4'-methylenebis(3-hydroxy-2-naphthoic acid).

² Wesson Oil, Hunt-Wesson Foods, Fullerton, Calif.

Figure 1—Concentration of dihydrostreptomycin in the plasma of dogs as a function of time after intramuscular administration of 4 mg./kg. of dihydrostreptomycin (as sulfate) in water (□) and in cottonseed oil (X) and of 4 mg./kg. of dihydrostreptomycin (as pamoate) in cottonseed oil (⊙). Dotted lines give one-compartment open-model fits.

in the magnitude of the absorption rate constant, k_a , for the different formulations.

Using this approach of maintaining k_e constant, k_a values for the sulfate data could be obtained graphically by the "feathering" technique, but the pamoate data could not be treated this way because dihydrostreptomycin was more slowly absorbed from this form. Therefore, the k_a and k_e values obtained by this graphical technique were used in an analog computer simulation of the $A \rightarrow B \rightarrow C$ model. This permitted estimation of k_a for the pamoate form. The values of k_a and k_e are given in Table I. These values are only estimates of the true values because there was a lack of data points to characterize completely the blood level curve prior to and after attainment of peak levels. Nevertheless, the values obtained seem to be reasonably good estimates and give both a magnitude and direction to the characterization of the effect of formulation on the blood levels.

Table I also gives the area under the blood level *versus* time curves following administration of dihydrostreptomycin. The area under these curves can be taken as a measure of the availability of drug from its dosage form, especially in the present case where elimination of the drug occurs by a first-order process, and the dosage forms are given by the same route of administration. All areas are expressed as a percentage of the actual area under the curve for dihydrostreptomycin sulfate in water, which was assumed to be the most "available" formulation.

The areas under the blood level *versus* time curves were obtained by plotting the plasma concentration *versus* time on cartesian co-ordinate graph paper, connecting each successive two points by a straight line using dark ink and using a line follower to trace the line and generate a voltage which was fed into an analog computer and integrated as a function of time.³

If elimination is assumed to be a first-order process, the areas under the blood level *versus* time curves should be proportional to dose if all formulations are equally available (26). The data in Table I indicate that this is the situation with the dihydrostreptomycin formulations, because the same dose of dihydrostreptomycin given as pamoate or sulfate salt gives the same area under the blood level *versus* time plot; this shows that the pamoate salt is just as "available" as the sulfate salt. However, the pamoate formulation differs from the others because it is more slowly absorbed.

SUMMARY

A dihydrostreptomycin pamoate suspension in cottonseed oil (dosed intramuscularly) maintained dog plasma levels above 3 mcg./ml. longer than equivalent doses of a dihydrostreptomycin sulfate suspension in cottonseed oil or a solution in water.

³ The line follower was a Moseley type F3B used in conjunction with a Moseley 2D-2 X-Y recorder and a Pace TR-10 analog computer, Electronic Associates, Inc., West Long Branch, N. J.

Plasma data can be described by the $A \xrightarrow{k_a} B \xrightarrow{k_e} C$ model.

The pamoate salt was as available as the sulfate salt, but it was absorbed more slowly.

New Compounds: Potential Antineoplastics VI: 2,4-Diamino-6-hydroxy-5-arylazopyrimidines and 1,3-Dimethyl-5-arylhydrazonoalloxans

H. G. GARG and R. A. SHARMA

Abstract □ A series of 2,4-diamino-6-hydroxy-5-arylazopyrimidines and 1,3-dimethyl-5-arylhydrazonoalloxans has been synthesized by the coupling of aryldiazonium salts with 2,4-diamino-6-hydroxypyrimidine and 1,3-dimethylbarbituric acid, respectively. The former are also obtained by the cyclization of ethyl cyanoglyoxalate arylhydrazones and guanidine hydrochloride in the presence of sodium ethoxide.

Keyphrases □ 2,4 - Diamino - 6 - hydroxy - 5 - arylazopyrimidines—synthesis, potential antineoplastics □ 1,3-Dimethyl-5-arylhydrazonoalloxans—synthesis, potential antineoplastics □ Antineoplastics—2,4-diamino-6-hydroxy-5-arylazopyrimidines, 1,3-dimethyl-5-arylhydrazonoalloxans, synthesis

Several arylazopyrimidine analogs are known to possess considerable antitumor activity (1–3). Recently, the synthesis of a few 2-amino-4,6-dimethyl-5-arylazopyrimidines and related compounds has been reported from the authors' laboratories (4–8). Screening results encouraged the present authors to explore the anticancer activity of more congeners of pyrimidines. Interest in pyrimidines led to the extension of this study to include derivatives of 1,3-dimethylalloxan, because this ring constitutes one of the rings of the interesting antibiotic, ferverulin (9).

This paper describes the synthesis of 2,4-diamino-6-hydroxy-5-arylazopyrimidines (I, Scheme I) and 1,3-dimethyl-5-arylhydrazonoalloxans (II, Scheme II). These were prepared by the coupling of aryldiazonium salts with 2,4-diamino-6-hydroxypyrimidine (10) and 1,3-dimethylbarbituric acid (11), respectively.

The coupling reactions were carried out in different media: water, sodium hydroxide, sodium hydrogen carbonate, and ethanol containing sodium acetate. However, the reaction was found to proceed satisfactorily in the basic medium.

Scheme I

Scheme II

EXPERIMENTAL

Melting points were taken on a Kofler hot-stage apparatus and are uncorrected.

Ethyl Cyanoglyoxalate 4-Chlorophenylhydrazone—A solution of 4-chloroaniline (1.27 g., 0.01 mole) in concentrated hydrochloric acid (6 ml.) was cooled to 0°. Sodium nitrite (0.70 g., 0.01 mole) was gradually added. The diazonium salt solution was filtered into a well-cooled, stirred mixture of sodium acetate (6.0 g.) and ethyl cyanoacetate (1.13 g., 0.01 mole) in ethanol (30 ml.). After 1 hr., the precipitate was filtered off and washed with water; it gave pale-yellow needles (2.26 g., 90%), m.p. 145–146° (from ethanol).

Anal.—Calcd.: . . . Found: Cl, 14.0; C₁₁H₁₀ClN₃O₂ requires Cl, 14.2%.

The details of other ethyl cyanoglyoxalate arylhydrazones which were prepared are given in Table I.

2,4-Diamino-6-hydroxypyrimidine—Ethyl cyanoacetate (22.6 g., 0.2 mole) was mixed with a solution of sodium ethoxide prepared from sodium (4.6 g., 0.2 g.-atom) and anhydrous ethanol (50 ml.). This mixture was allowed to stand while a second solution of sodium ethoxide of the same volume and concentration was prepared. To this solution was added guanidine hydrochloride (19.2 g., 0.2 mole). The sodium chloride was separated by filtration, and the clear filtrate containing guanidine was added to the solution of sodiocyanoacetate. The mixture was heated for 2 hr. under reflux and was then evaporated to dryness at ordinary pressure. The solid product thus obtained was dissolved in water (65 ml.) and acidified with glacial acetic acid (15 ml.). Upon cooling of the solution, 2,4-diamino-6-hydroxypyrimidine was obtained as light-yellow needles (22.16 g., 80%), m.p. 260–265° dec. [lit. (10) m.p. 260–270° dec.].

1,3-Dimethylbarbituric Acid—This was prepared by the procedure of Pfeleiderer and Schundehutte (11) from *N,N'*-dimethylurea (17.6 g., 0.2 mole) and malonic acid (17.6 g., 0.2 mole). The product was obtained as colorless needles (21.84 g., 70%), m.p. 118–119° (from ethanol) [lit. (11) m.p. 124°].

2,4 - Diamino - 6 - hydroxy - 5 - (4 - chlorophenylazo)pyrimidine—*Method A*—A solution of 4-chlorobenzenediazonium chloride from

^a B, bright; Bn, brown; D, deep; Da, dark; F, fibers; G, golden; Gr, green; N, needles; O, orange; P, plates; Pe, pale; R, red; and Y, yellow.

4-chloroaniline (1.27 g., 0.01 mole) in concentrated hydrochloric acid (5 ml.) was slowly added to a well-cooled, stirred mixture of 2,4-diamino-6-hydroxypyrimidine (1.26 g., 0.01 mole) in 2 *N* sodium hydroxide (10 ml.) containing sodium acetate (5.0 g.). The precipitated solid was filtered off and washed with water; it gave bright-yellow needles (2.25 g., 85%), m.p. >300° [from ethanol–dimethylformamide (DMF)].

Anal.—Calcd.: Found: Cl, 13.2; C₁₀H₉ClN₄O requires Cl, 13.5%.

Method B—Guanidine hydrochloride (1.92 g., 0.02 mole) was added to ethyl cyanoglyoxalate 4-chlorophenylhydrazone (5.02 g., 0.02 mole) dissolved in alcoholic sodium ethoxide (1.2 g. of sodium in 50 ml. anhydrous ethanol). After keeping for 1 hr., the mixture was refluxed for 2 hr. and left overnight. The solid, which separated, was collected and washed with water. It was obtained as bright-yellow needles (1.90 g., 70%), m.p. >300° (from ethanol–DMF). The melting point was not depressed upon admixture with the sample prepared by Method A.

Sir:

A number of 1,3-dipolar additions to ynamines or *N,N*-disubstituted-1-amino-1-alkynes have been reported to produce a series of five-membered heterocycles (1-3). For instance, the additions of both aryl

Scheme I

and aroyl azides to *N,N*-dimethylaminophenylacetylene (I) gave the corresponding 1,2,3-triazoles IIa and IIb, respectively (Scheme I). From the 1,3-dipolar additions of a number of substituted benzenesulfonyl azides to the ynamine (I) and *N,N*-diethylaminoprop-1-yne, we have isolated crystalline *N,N*-dialkylamino-1,2,3-triazoles (X and XI) and α -diazoamidines (III-IX). Details about the preparation and characterization of Compounds III-XI (Table I) will be published (4).

Compounds III-XI were subjected to *in vitro* screening for antimetabolites (5). In this method, the detection system utilizes the Gram-positive *Bacillus subtilis* (UC-564) and Gram-negative *Escherichia coli* (ATCC 26). Both of these organisms were grown in two types of agar: (a) nutrient agar—a complex medium containing 0.3% beef extract, 0.5% peptone, and 1.5% agar; and (b) a completely synthetic medium with glucose as the only source of carbon. Acetone solutions of Compounds III-XI at concentrations of 1 mg./ml. were applied onto 13-mm. paper disks, and they were placed on the surface of the seeded agar. The trays containing these paper disks, seeded with *E. coli* and *B. subtilis*, were incubated at 37° for 18 hr., and the zones of inhibition were measured. The results are given in Table I. None of the compounds inhibited the growth of *E. coli*. All the compounds inhibited the growth of *B. subtilis* in synthetic agar but not (or inhibited much less) in nutrient agar. This indicated that some of them could be potential antimetabolites. Furthermore, most of the α -diazoamidines (Compounds III-IX) showed more pronounced activity than the triazoles (X and XI). Compounds IV-VI and IX were further tested by the technique of specific reversal against *B. subtilis*, and the results of these experiments are included in Table II. Once again, all the samples inhibited *B. subtilis* more strongly on synthetic agar than on nutrient agar. However, none of the samples was reversed by amino acids, vitamins, purines, and pyrimidines. Therefore,

Solubility Relationships in Urea-Water Systems

Keyphrases ☐ Urea-water systems—solubilization mechanism ☐ Solute-urea interaction effect—solubility ☐ Transfer, standard free energy—solute in urea solution, water

Sir:

Interpretations regarding the mechanisms of solution in cosolvent systems are facilitated if one can rely on various simplifying assumptions. In urea-water mixtures, for example, it would be convenient to assume that the interactions of the cosolvent with a given solute moiety are specific and predictable. Further, it would be of immeasurable aid if explanations of observed solubility phenomena were possible in terms of purely basic theoretical concepts. Therefore, as part of a larger study of solution properties, we investigated the potential usefulness of certain of these assumptions relative to compounds of intrinsic pharmaceutical interest.

The solubilities of compounds having various moieties in common were determined in water and in 5 M urea solutions at 30°. After equilibrating excess drug in both solvent systems, samples of the resulting solutions were withdrawn, and solubilities were determined spectrophotometrically. The standard free energies of

Table I—Standard Free Energy of Transfer, ΔG_t° , from Water to 5 M Urea Solutions at 30°

Solute	Aqueous Solubility, moles/l. $\times 10^3$	ΔG_t° , cal./mole
Methyl <i>o</i> -methoxybenzoate	41.6	+621
Methyl paraben	19.2	-690
Methyl benzoate	17.8	-480
Methyl salicylate	6.27	-612
Ethyl paraben	5.85	-781
<i>n</i> -Propyl paraben	2.78	-645
<i>n</i> -Butyl paraben	1.34	-792

transfer, ΔG_t° , were then calculated according to the equation used by Wetlaufer *et al.* (1):

$$\Delta G_t^\circ = -RT \ln C_u/C_w + RT \ln N_u/N_w \quad (\text{Eq. 1})$$

where C_u and C_w are the molar concentrations of drug in the urea and water solutions, respectively; and N_u and N_w represent the moles/liter summed over all components of solvent and solute for the urea and water solutions, respectively. In the present investigation, the free energy change is that which accompanies the transfer of 1 mole of drug from water to a 5 M urea solution. These data, along with the aqueous solubilities, are shown in Table I.

The results strongly suggest the following:

1. Moieties having the same chemical structure may not be expected to exhibit parallel interactions in solvent systems of similar composition. In all likelihood, these interactions are also a function of the chemical entity to which a given moiety is attached. This is in contrast to the interpretation by Nozaki and Tanford (2), who reported additive solubility effects for the hydrocarbon groups attached to various amino acids. The data in Table I show that this is not the case. For example, the difference in the standard free energy of transfer between methyl benzoate and methyl paraben is 210 cal./mole. The difference between phenylalanine and tyrosine is only 85 cal./mole for the same conditions of transfer (2).

2. The use of a simple homologous series gives no assurance of success in obtaining consistent resolution of solute-solvent interactions. As might be expected, the interactions observed on transferring alkanes from water to urea solutions vary as methane, ethane, propane, and butane (1). In contrast, the interactions of the parabens vary as propyl, methyl, ethyl, and butyl.

3. Relative hydrophobicity, as determined by a comparison of aqueous solubilities, may not be used to explain differences in enhanced solubilities in urea solutions. The data in Table I illustrate this point. For example, the aqueous solubility of methyl paraben is three times greater than methyl salicylate and seven times greater than propyl paraben, yet the transfer of methyl paraben to a 5 M urea solution is thermodynamically favored over either of these compounds.

4. Direct urea-solute interaction is a significant factor in altering the solubility of drug species. Although this has been shown (3, 4), reports persist in which attempts are made to explain observations solely on the basis of solvent structuring. The latter approach was taken by Feldman and Gibaldi (5) in rationalizing the increased solubility of benzoic and salicylic acids in

these compounds do possess significant antibacterial activity, but this activity is noncompetitive in nature.

3. Relative hydrophobicity, as determined by a comparison of aqueous solubilities, may not be used to explain differences in enhanced solubilities in urea solutions. The data in Table I illustrate this point. For example, the aqueous solubility of methyl paraben is three times greater than methyl salicylate and seven times greater than propyl paraben, yet the transfer of methyl paraben to a 5 M urea solution is thermodynamically favored over either of these compounds.

4. Direct urea-solute interaction is a significant factor in altering the solubility of drug species. Although this has been shown (3, 4), reports persist in which attempts are made to explain observations solely on the basis of solvent structuring. The latter approach was taken by Feldman and Gibaldi (5) in rationalizing the increased solubility of benzoic and salicylic acids in

urea solutions. In turn, Nogami *et al.* (6) analyzed the adsorption of tryptophan from urea solutions in much the same manner, using the Feldman and Gibaldi paper as a reference. There are implications of direct interaction in each of the results of the present investigation. Perhaps the most striking evidence of this interaction is that the introduction of methyl *o*-methoxybenzoate, a liquid, into a 5 *M* urea solution results immediately in the formation of a flocculent white precipitate, the composition of which is currently unknown.

These findings demonstrate the need for caution in interpreting solubility phenomena involving cosolvent systems, in general, and urea-water mixtures, in particular. At present, few, if any, simplifying assumptions appear to be valid for this purpose.

Preparation of Bis(acetylthiobenzyl)sulfide

Keyphrases ☐ Bis(acetylthiobenzyl)sulfide—synthesis ☐ NMR spectroscopy—structure ☐ Mass spectroscopy—structure

Sir:

Bongartz (1), in 1886, obtained a product from the reaction of benzaldehyde and thioacetic acid, m.p. 147–148°, which he believed to be phenylmethanedithiol diacetate (I). In 1952, Cairns *et al.* (2) synthesized this compound from phenylmethanedithiol and found the melting point to be 37–38°.

By utilizing the procedure of Böhme *et al.* (3) in the reaction of benzaldehyde and thioacetic acid to obtain the hydroxymethyl thioester (II), a small amount of a compound, m.p. 150–151°, which displayed the same

properties as the material isolated by Bongartz (1), was obtained. The NMR spectrum showed absorption at 7.32 δ , a singlet at 5.85 δ , and a singlet at 2.29 δ , having an integration ratio of 5:1:3. Mass spectral analysis indicated that the compound contained the following groups:

<i>m/e</i>	<i>m/e</i>
15 CH ₃	77 C ₆ H ₅
28 CO	78 C ₆ H ₆
32 S	90 C ₆ H ₅ CH
43 CH ₃ CO	105 OC ₆ H ₅ CH
58 CH ₃ CS	121 C ₆ H ₅ CHS
60 COS	154 SCH(C ₆ H ₅)S
75 CH ₃ COS	165 CH ₃ COSCH(C ₆ H ₅)

From the NMR and mass spectral data, the following partial structure was assigned:

The elemental analysis and molecular weight indicate the compound to be C₁₈H₁₈O₂S₃. Thus, we propose the structure of the compound reported by Bongartz (1) as phenylmethanedithiol diacetate to be bis(acetylthiobenzyl)sulfide (IV).

The reaction of benzaldehyde with thioacetic acid was conducted as follows. Benzaldehyde, 21.2 g. (0.2 mole), and thioacetic acid, 15.2 g. (0.2 mole), were mixed together and heated at 100° for 18 hr. After cooling, 1.6 g. of a white crystalline solid was obtained. The solid was recrystallized from methanol and then from petroleum ether (63–68°), and it was identified as bis-(acetylthiobenzyl)sulfide (IV), m.p. 150–151°. The NMR and IR are in agreement with the assigned structure.

Anal.—Calcd. for C₁₈H₁₈O₂S₃: C, 59.63; H, 5.00; S, 26.54; mol. wt., 362. Found: C, 59.43; H, 5.02; S, 27.10; mol. wt., 361 (osmometer).

Mass spectral data were obtained from a Nuclide mass spectrometer.

Gas Chromatography in Biology and Medicine. *A Ciba Foundation Symposium.* Edited by RUTH PORTER. J. & A. Churchill, 104 Gloucester Place, London, England. 1969. 224 pp. Price \$9.00.

This is another excellent monograph published under the auspices of the Ciba Foundation. This foundation is well known to those in the chemical and biological sciences for the numerous and excellent symposia it presents annually at which internationally known scientists participate in presenting papers dealing not only with original research but also in presenting lucid reviews of the "State of the Science" in which they are participating. The proceedings of these symposia are published as monographs in their entirety, thus presenting not only the formal papers but also the usually lively discussions which take place following each presentation. These following discussions are often the more interesting part of the proceedings, which are usually omitted in monographs of most other symposia. Once again the high standards of excellence of this Ciba Foundation Symposium have been preserved, resulting in a publication that makes a substantial contribution to the literature available on the subject.

Gas Chromatography in Biology and Medicine is a very appropriate title because this is the area of scientific endeavor where the technique is put to the ultimate tests of sensitivity, specificity, and usefulness. The formal papers published herein were presented at a symposium of the same title held in London, England, February 1969.

The material covered is divided into four main sections. The *Introduction* contains a survey of the historical background of chromatographic separation by A. J. P. Martin and an account of the many significant developments in gas chromatography, especially when used with ancillary techniques such as mass spectrometry and NMR, by S. R. Lipsky.

The second section is devoted to the *design* of the chromatographic system. J. H. Parnell presents a good argument for the use of the shortest column length possible for achieving the desired separation and also recommends that more emphasis be placed in this regard on improving the selectivity factor of a column rather than the number of theoretical plates generated. The subject of detectors is well covered by D. W. Hill, especially with respect to ionization detectors such as electron-capture detectors which are being extensively used in drug analysis at the nanogram to picogram level of detection from biological specimens. The use of the pulsed D. C. mode of E. C. detection produces greater linearity and reproducibility with these detectors. The effects of water vapor on argon ionization detectors is discussed by B. C. H. Warren and M. G. Dalzell, while the use of the W-value detector in the determination of oxygen and anesthetic vapors in expired air is discussed by B. C. H. Warren and J. E. Lovelock—a pioneer worker in the design of ionization detectors.

The *Biological and Medical Application* section covers the bulk of the monograph with several very interesting and informative chapters—*viz.*,

- H. L. Lowe and K. Hagler—Determination of volatile organic anesthetics in blood, gases, tissues, and lipids using their partition coefficients for differential extraction, and represents an interesting thermodynamic approach to the determination of the tissue to gas partition coefficients.
- M. J. Pumes—Measurement of the gas content of blood samples using gas chromatography.
- A. S. Curry—Recent developments in the use of gas chromatography in forensic toxicology.
- D. J. Blackmore—The use of gas liquid chromatography in aircraft accident toxicology. These two chapters give a very informative account of the problems facing the toxicologist and the pathologist in determining whether the cause of death is accidental or intentional. This is an area which tests the analytical competence of the practicing forensic toxicologist in his ability to come up with the right answer to trace amounts of foreign materials recovered from the subject or the scene of event

where the sensitivity and specificity of a gas chromatographic procedure are the only means of obtaining reliable and fool-proof evidence.

- S. Garattini, F. Marcucci, and E. Mussini—Gas chromatographic analysis of benzodiazepines. This is an interesting account of the use of GLC with different detectors (flame and electron capture) in the determination of members of a class of drugs (tranquilizers) and their major metabolites in animal species and in man. The significance of the blood and tissue levels of the drug in animal species, its influence on the pharmacological responses obtained, and the interpretation and extrapolation of these findings to clinical observations seen in man are presented. This chapter highlights the results from several other publications by the same authors.

The final section covers future trends in development where the use of complementary techniques in filtering the information obtained from GLC alone is presented.

R. P. W. Scott—Gas chromatographic and spectrometric techniques, covers the problems of interphasing a mass spectrometer with a gas chromatograph with computerized data handling facilities, a technique which is of great use in the isolation and characterization of drugs and their metabolites in biological extracts. The use of complementary techniques such as IR and NMR using micro cells to enhance sensitivity of detection of the fractions trapped from the effluent of a gas chromatographic column is discussed.

- G. B. Marson—Digital computers and the analysis of chromatographic data, presents some of the hardware used in automating the data handling and interpretation of GLC data.

All the papers presented are concise, well illustrated, and documented with up-to-date literature references making this volume as current as such a monograph can possibly be. The discussions following each presentation are very thought-stimulating and make the reader wish he were participating actively in it rather than reading about it second hand.

This monograph is in keeping, with respect to its content and presentation, with the philosophy of the Ciba Foundation: "Con-societ Gentes"—let the peoples come together. It is a worthy addition to the library of the practicing chromatographer.

The History of Penicillin Production. Chemical Engineering Progress Symposium Series, No. 100, Vol. 66. Edited by ALBERT L. ELDER. American Institute of Chemical Engineers, 345 East 47th St., New York, NY 10017, 1970. vi + 100 pp. 21.5 × 28 cm.

This volume of the *Chemical Engineering Progress Symposium Series* deals with the history and problems of developing mass-produced penicillin, necessitated by the Second World War. The Institute hopes, by historically documenting particular projects, this knowledge might be used to facilitate and expedite future projects of a similar or related nature.

Gas Chromatography in Biology and Medicine. *A Ciba Foundation Symposium.* Edited by RUTH PORTER. J. & A. Churchill, 104 Gloucester Place, London, England. 1969. 224 pp. Price \$9.00.

This is another excellent monograph published under the auspices of the Ciba Foundation. This foundation is well known to those in the chemical and biological sciences for the numerous and excellent symposia it presents annually at which internationally known scientists participate in presenting papers dealing not only with original research but also in presenting lucid reviews of the "State of the Science" in which they are participating. The proceedings of these symposia are published as monographs in their entirety, thus presenting not only the formal papers but also the usually lively discussions which take place following each presentation. These following discussions are often the more interesting part of the proceedings, which are usually omitted in monographs of most other symposia. Once again the high standards of excellence of this Ciba Foundation Symposium have been preserved, resulting in a publication that makes a substantial contribution to the literature available on the subject.

Gas Chromatography in Biology and Medicine is a very appropriate title because this is the area of scientific endeavor where the technique is put to the ultimate tests of sensitivity, specificity, and usefulness. The formal papers published herein were presented at a symposium of the same title held in London, England, February 1969.

The material covered is divided into four main sections. The *Introduction* contains a survey of the historical background of chromatographic separation by A. J. P. Martin and an account of the many significant developments in gas chromatography, especially when used with ancillary techniques such as mass spectrometry and NMR, by S. R. Lipsky.

The second section is devoted to the *design* of the chromatographic system. J. H. Parnell presents a good argument for the use of the shortest column length possible for achieving the desired separation and also recommends that more emphasis be placed in this regard on improving the selectivity factor of a column rather than the number of theoretical plates generated. The subject of detectors is well covered by D. W. Hill, especially with respect to ionization detectors such as electron-capture detectors which are being extensively used in drug analysis at the nanogram to picogram level of detection from biological specimens. The use of the pulsed D. C. mode of E. C. detection produces greater linearity and reproducibility with these detectors. The effects of water vapor on argon ionization detectors is discussed by B. C. H. Warren and M. G. Dalzell, while the use of the W-value detector in the determination of oxygen and anesthetic vapors in expired air is discussed by B. C. H. Warren and J. E. Lovelock—a pioneer worker in the design of ionization detectors.

The *Biological and Medical Application* section covers the bulk of the monograph with several very interesting and informative chapters—*viz.*,

- H. L. Lowe and K. Hagler—Determination of volatile organic anesthetics in blood, gases, tissues, and lipids using their partition coefficients for differential extraction, and represents an interesting thermodynamic approach to the determination of the tissue to gas partition coefficients.
- M. J. Pumes—Measurement of the gas content of blood samples using gas chromatography.
- A. S. Curry—Recent developments in the use of gas chromatography in forensic toxicology.
- D. J. Blackmore—The use of gas liquid chromatography in aircraft accident toxicology. These two chapters give a very informative account of the problems facing the toxicologist and the pathologist in determining whether the cause of death is accidental or intentional. This is an area which tests the analytical competence of the practicing forensic toxicologist in his ability to come up with the right answer to trace amounts of foreign materials recovered from the subject or the scene of event

where the sensitivity and specificity of a gas chromatographic procedure are the only means of obtaining reliable and fool-proof evidence.

- S. Garattini, F. Marcucci, and E. Mussini—Gas chromatographic analysis of benzodiazepines. This is an interesting account of the use of GLC with different detectors (flame and electron capture) in the determination of members of a class of drugs (tranquilizers) and their major metabolites in animal species and in man. The significance of the blood and tissue levels of the drug in animal species, its influence on the pharmacological responses obtained, and the interpretation and extrapolation of these findings to clinical observations seen in man are presented. This chapter highlights the results from several other publications by the same authors.

The final section covers future trends in development where the use of complementary techniques in filtering the information obtained from GLC alone is presented.

R. P. W. Scott—Gas chromatographic and spectrometric techniques, covers the problems of interphasing a mass spectrometer with a gas chromatograph with computerized data handling facilities, a technique which is of great use in the isolation and characterization of drugs and their metabolites in biological extracts. The use of complementary techniques such as IR and NMR using micro cells to enhance sensitivity of detection of the fractions trapped from the effluent of a gas chromatographic column is discussed.

- G. B. Marson—Digital computers and the analysis of chromatographic data, presents some of the hardware used in automating the data handling and interpretation of GLC data.

All the papers presented are concise, well illustrated, and documented with up-to-date literature references making this volume as current as such a monograph can possibly be. The discussions following each presentation are very thought-stimulating and make the reader wish he were participating actively in it rather than reading about it second hand.

This monograph is in keeping, with respect to its content and presentation, with the philosophy of the Ciba Foundation: "Con-societ Gentes"—let the peoples come together. It is a worthy addition to the library of the practicing chromatographer.

Clinical Pharmacology Scope, Organization, Training. By WHO Study Group, World Health Organization, Geneva, Switzerland, 1970. i + 21 pp. 23.5 × 16 cm. Price: Annual Subscription \$16.00. (English)

The role of the clinical pharmacologist has recently received considerable attention. The World Health Organization Study Group on Clinical Pharmacology was convened to suggest means of eliminating the shortage of clinical pharmacologists, to demarcate the scope of clinical pharmacology, and to suggest ways for carrying out drug studies in all parts of the world in a scientific and coordinated manner.

The WHO report provides considerable information relative to clinical pharmacology and could be used as a focus for future discussions concerning this emerging discipline.

Modern Microcrystal Tests for Drugs, The Identification of Organic Compounds by Microcrystalloscopic Chemistry. By CHARLES W. FULTON. Wiley, New York, NY 10016, 1969. xviii + 466 pp. 17.5 × 26 cm. Price \$29.95.

Early in the book a table is presented to illustrate what the author considers the best aqueous tests with the 28 best reagents of the past for identifying alkaloids. The author has added also a number of nonalkaloidal but related substances to the list of materials tested and points out that although many of the tests are old, some of them being over a hundred years old, they yield reliable results with each of the 159 substances tested.

The author then discusses some new procedures that he has developed in microcrystal techniques. He describes tests conducted in acid media and procedures for testing the volatility of various chemical classes of substances. As a toxicologist he extends volatility tests to the detection of putrefactive bases. He also includes chromatography in general procedures for testing unknowns and indicates the usefulness of spectrophotometry.

In separate chapters, tests for barbiturates, sympathomimetics and central stimulants, phenothiazines, and steroids are presented. The author also discusses oxonium and carbonium compounds and iodine-iodide complexes; he describes general coverage tests, specific tests, and color tests.

The author explains crystal shapes in unique descriptive terms and he presents a system of classification of microcrystals. In the last of the 31 chapters are included 192 very good photomicrographs to illustrate his classification of crystal forms and also to illustrate important tests and significant reactions. Accompanying the photomicrographs are word descriptions of the crystal forms.

The index lists all of the substances for which tests are described in the book and includes a directory of essential information for each of these materials. It should be pointed out also that this book contains a very complete bibliography of literature in the form of appropriate references at the conclusion of each chapter.

The advent of many new, potent drugs has complicated the task of the toxicologist in using microcrystal tests for identification purposes. The author has included a number of new synthetic drugs in his tests and he points out that at least two or three different tests

must yield positive results with both the unknown and with known material in order to be sure of the unknown tested. This book is recommended as a useful reference to those working with microcrystal identification techniques.

The Control of Chemotherapy. Edited by P. J. WATT, E. & S. Livingstone Ltd., London, England, 1970. i + 109 pp. 14 × 22 cm. Price \$6.25.

The papers in this volume were presented at a symposium held in March 1969, in the Wright-Fleming Institute, St. Mary's Hospital Medical School, London, England. Starting from the premise that the treatment of infections with chemotherapeutic drugs can only be effective if the drug that is used is one to which the bacteria are sensitive and which can reach the site of infection, the symposium considered areas in which progress may be expected and areas in which inadequate techniques are still in use.

Peyote Constituents: Chemistry, Biogenesis, and Biological Effects

GOVIND J. KAPADIA and M. B. E. FAYEZ

Keyphrases ☐ Peyote constituents—chemistry ☐ Biogenesis—peyote alkaloids ☐ Biological effects—peyote constituents ☐ Mescaline—behavioral effects ☐ Addiction, habituation, tolerance—mescaline ☐ Metabolism—mescaline ☐ Structure-activity relationships—mescaline derivatives

CONTENTS

BACKGROUND.....	1699
CHEMISTRY OF PEYOTE CONSTITUENTS.....	1701
ANALYTICAL METHODS.....	1711
BIOGENESIS OF PEYOTE ALKALOIDS.....	1712
BIOLOGICAL EFFECTS OF PEYOTE ALKALOIDS.....	1717

BACKGROUND

Peyote represents one of the earliest known hallucinogenic drugs, the use of which was exclusively limited to the New World. Today much more potent hallucinogens, of natural and synthetic origin, are known, yet investigation into the chemistry and pharmacology of peyote constituents and their synthetic analogs does not seem to have relented. The literature contains several early surveys covering various aspects of peyote and its constituents. These include articles and monographs dealing with cactus alkaloids (1-7) and natural hallucinogens (8-27) in general and more specialized ones dealing mainly with peyote and its active principle, mescaline (28-40). Several of the earlier articles also cover, more or less adequately, such diverse aspects of peyote as history, cultic and modern uses, chemical composition, synthesis of its constituents—as phenethylamines (41) and tetrahydroisoquinolines (42)—and the pharmacol-

ogy of these products and their synthetic analogs along with their possible medicinal applications (40).

In the past decade or so, there has been no such comprehensive coverage in one review. The need for one is accentuated by the fact that during the past 5 years alone, more than 31 new constituents of peyote were discovered (compared to six before 1900 and five during the 1930's), several synthetic methods were developed, and an important part of the pharmacological and clinical (as well as social) studies and practically all the biogenetic studies of the major peyote constituents were conducted, with impressive revelations made.

Names—Peyote, a member of the family Cactaceae, has received varied taxonomical treatments with time by different botanists. The first "scientific" name given to it was *Peyotl zacatensis* by Hernandez in 1638. The designation *Echinocactus williamsii* was used by Lemaire in 1840, *Anhalonium williamsii* by Engelman, *Lophophora williamsii* by Coulter in 1894, *Anhalonium lewinii* by Lewin, and *A. jourdanianum* by Rebut. Although the name *Echinocactus williamsii* appears in the *Kew Index* (vol. II, p. 813), it does not seem to be as commonly used as *A. lewinii* or *L. williamsii* (7, 37). The latter name is the one more commonly used in the current chemical literature. The introduction of these names, and there seems to be more, appears to be the result of confusion between the different types of peyote which actually belong to a single species (37, 39).* The confu-

* According to E. F. Anderson [*Brittonia*, 21, 299(1969)], the genus *Lophophora*, which has an extensive range within the Chihuahuan Desert of Texas and Mexico, consists of two species, *L. williamsii* and *L. diffusa*. The former is both wide ranging and highly variable morphologically, whereas the latter consists of a single, fairly small population restricted to an area in the state of Querétaro.

sion arises from the differences between the young peyote individual specimens, with eight straight ribs, and the mature ones, with about 12 sinuous ribs, and a third form with irregular ribs, in addition to slight morphological variations according to locality.

Peyote is a popular name given to the cactus under discussion; other less common names are peyotl, pelote, challote, and devil's root. The name peyote derives from peyotl which appears to be of Aztec origin. The sun-dried slices of the plant constitute the "mescal buttons" of commerce. It is this material, which can be preserved for a very long time, that is usually consumed¹ in ritual ceremonies or for nonreligious purposes to produce euphoric effects. The name mescal buttons² is incorrect, since the material is not related to the non-cactus succulent, the mescal proper, from which fermented beverages are prepared. Another incorrect name is "mescal beans," which is also given to the buttons but in fact is the Red Bean, *Sophora secundiflora* (Leguminosae).

Habitat—The cactus (*L. williamsii*) grows wild on the Mexican plateau and in the southwestern United States in dry places, on cliffs, or on rocky slopes. These regions are very hot and the vegetation is subtropical. Peyote is encountered sometimes singly but more often in clusters. It is barely visible, except when in flower, since it is mostly covered with earth and looks like a pebble. Peyote, like most cacti, can be grown practically anywhere under glass or in a room. The plant seems to be capable of standing adverse conditions of drought, heat, and cold.

Description—The peyote plant is a small (rarely exceeding 15–20 cm. in total length), fleshy, spineless cactus, simple or cespitose, proliferous, turbinate with a thick napiform root. The cylindrical stalk, which has horizontal wrinkles, is suberized and grayish-fawn in color. At the top it becomes more chlorophyllose, globular, flattened, and sage-green in color and appears divided into 5–13 thick ribs, only slightly salient, rounded, and separated from each other by well-marked longitudinal grooves. In the center of the spherical portion (2–50 mm. in diameter) of the plant, there is a tuft of silky hairs from which the flowers (usually one or two) emerge; the latter are usually pink but are sometimes white or yellow. The fruit is a flesh-colored, or sometimes grayish-yellow, berry which contains a few small black seeds.

History—Peyote was used and revered—as a panacea, an amulet, and a hallucinogen—in the mountainous regions of northern Mexico centuries before the settlers arrived; it was probably known to the Chichimec tribe long before the Christian era (43). Bernardino de Sahagun (43), a Franciscan missionary and chronicler of the Spanish conquest of Mexico, wrote about peyote, which was eaten by local natives because "it gives them strength and incites them to battle, alleviates fear, and they feel neither hunger nor

thirst, and they say it protects them from every kind of danger." At that time, missionaries and administrators tried to suppress peyote consumption for various social, political, and religious reasons, apparently without much success.

During the 17th and 18th centuries, peyote was used in vast areas stretching northward up to the Arkansas River (44), and it was consumed by many Indian tribes including the Apaches, Comanches, and Kiowas. Although a true peyote cult did not seem to have existed at that time, the drug was taken mainly: (a) by individuals as a medicine and to induce visions leading to prophetic utterances, and (b) collectively to obtain the desired state of trance for ritual dances.

During the 19th century, the ritual use of peyote (peyotism) extended among Indian tribes with their migrations northward and southward and gradually became more fully organized into isolated cult groups (44–46). This led, toward the end of the century, to the establishment of the "Peyote Church." With time, peyote votaries increased in number, variety, and distribution; the Church, founded in Oklahoma, gradually joined in a strange synthesis of old Mexican, Christian, and local religious rites (47). The advocates of this Church remained predominantly Indians, although they were joined by some Negroes, and the cult remained essentially an ethnographical curiosity rather than a serious movement.³ The present believers worship God as the great spirit who, as a master of the universe, infused some of his being into peyote; Christ is regarded as the man who made the cactus available to them when they needed it. Usually the ceremony is conducted at Saturday night gatherings in a large Indian tepee. Participants then sit around a fire and spend the evening in ritual singing, prayer, and contemplation (39).

In the United States, peyote is not regarded as a narcotic drug, although its use is controlled by the federal government except in *bona fide* religious ceremonies of the Native American Church.

The history, economic importance, cultic use, and psychic effects of peyote are described at length by several authors (9–11, 31–33, 35, 38, 45, 49–58).

Constituents of Peyote—The first chemical investigations of peyote were made by Lewin in 1888 (52). While traveling in America, he collected peyote plants; these were identified by Hennings as a new *Anhalonium* species that was named *A. lewinii*. He was able to isolate the first crystalline constituent, an alkaloid which was called anhalonine and shown to be devoid of any hallucinatory action. This initial finding, however, aroused considerable interest in the drug and the possible constituents that would account for the sensory excitations produced in those who took it. Up to that time, the family Cactaceae was regarded as being free of alkaloids; as a result of Lewin's findings, more attention was directed to the study of several other cacti.

In 1894, Heffter (59–64), working with fresh plants, isolated another alkaloid which received the name pello-

¹ The drug is usually taken orally. The buttons, whole or chopped, are brewed with tea or chewed while drinking tea, coffee, wine, or milk (to conceal an unpleasant taste). Less commonly, a liquid concoction is injected intravenously.

² Other slang names include: tops, moon, full moon (a large button) and bad seed.

³ In the United States, about 1950, some ethnologists protested strongly the idea that the use of peyote should be prohibited on the pretext that the Native American Church (practicing peyotism) is a legitimate religious organization with the same right to religious freedom as other churches (48).

tine. Shortly afterward he isolated three additional alkaloids. One, mescaline, was recognized—from pharmacological tests and personal experience—as the hallucinatory principle of peyote; the other two were named anhalonidine and lophophorine (61). In 1899, Kauder (65) discovered an additional alkaloid, anhalamine, besides the previously known pellotine in the mescal buttons. During or about the same period, other cacti yielded related alkaloids (nonhallucinogenic): anhaline (=hordenine) from *Anahalonium fissuratum* and pectenine (=carnegine) from *Cereus pecten-aboriginum* (66) and later from *Carnegie gigantea* (67).

Lewin (52, 53) also made the first pharmacological studies of peyote. His reports were followed by more elaborate and expanded studies made by Prentiss and Morgan (68), Mitchell (69), Ellis (70), Dixon (71), and Mogilewa (72), who described the physiological and special euphoric effects of peyote and its constituent alkaloids.

The elucidation of the structure and the synthesis of all these alkaloids had to wait until Späth made his contributions. He published the first of a series of papers on "Anhalonium alkaloids" in 1919 and continued his work up to 1939 (3, 73–90); his work also included studies on the alkaloids obtained from other Cactaceae. In addition to the previously mentioned alkaloids, Späth isolated from peyote five other products: anhalinine and anhalidine in 1935 (80, 81), *N*-methylemescaline in 1937 (83), *N*-acetylmescaline in 1938 (84), and *O*-methyl-*d*-anhalonidine in 1939 (85).

Interest in peyote, at least in research laboratories, remained dormant after the last contributions of Späth until very recent years, presumably with the resurgence or increase of interest in the psychotomimetic agents and their sources which has become a hallmark of our days. Three tyramine derivatives were identified in peyote during 1965–1966; they are tyramine and its *N*-methyl and *N,N*-dimethyl (hordenine) derivatives (91, 92). The presence of candicine was suggested (92) on the basis of TLC evidence but could not be confirmed in later work (93). All these products were previously encountered in several cacti of other plant species. From 1967 onward, Kapadia and his coworkers examined the relatively minor alkaloidal and related nonbasic (quaternary, acid, and amide) constituents of peyote and identified 26 additional compounds. These include the alkaloids peyophorine (94) and 3-demethylemescaline (95); the quaternary bases anhalotine, lophotine, and peyotine (93); the amides *N*-acetyl-3-demethylemescaline, *N*-acetylanhalamine, and *N*-acetylanhalonine; *N*-formylemescaline, *N*-formyl-3-demethylemescaline, *N*-formylanhalamine, *N*-formylanhalonine, *N*-formylanhalinine, *N*-formylanhalonidine, and *N*-formyl-*O*-

Scheme I

methylanhalonidine (96); six cyclic derivatives of mescaline [succinimide, malimide, maleimide (96), citrimide, isocitrimide lactone, and pyrrole (97)] in addition to two other cyclic amides, mescalotam and peyoglutam (96); and the acids peyonine (98), peyoruvic acid, and peyoxylic acid (99, 100). Agurell and Lundström also identified 3,4-dimethoxyphenethylamine (101) in addition to 3-demethylemescaline (102). Table I contains a list of the hitherto identified constituents of peyote.

CHEMISTRY OF PEYOTE CONSTITUENTS

Phenethylamines—Mescaline and Its Congeners—

Mescaline, 3,4,5-trimethoxy- β -phenethylamine (I), is the active hallucinatory principle of peyote (*L. williamsii*); it occurs in the drug to the extent of 6% and is the main constituent.

The principal synthetic approaches for mescaline and related β -phenethylamine derivatives are basically methods for the construction of the ethylamine side chain onto the appropriately substituted aromatic system.

The first synthesis of mescaline was realized by Späth in 1919 (73). 3,4,5-Trimethoxybenzoic acid was transformed into the corresponding aldehyde and subsequently, by reaction with nitromethane in ethanol solution containing alkali, into the ω -nitrostyrene, which was finally reduced to mescaline in two steps (Scheme I). 3-Demethylemescaline (V) was also prepared as an intermediate toward anhalamine (XIII) by Späth and Röder (90), using essentially the same method after temporary protection of the phenol group. This fundamental sequence was used by many later workers (114–129) in the preparation of mescaline and several of its isomers and analogs. Improvisations have essentially been concerned with the conditions of reaction in the individual steps. The reaction of the benzaldehyde with nitromethane can afford better yields of the ω -nitrostyrene derivative when performed in acetic acid containing ammonium acetate (121, 123, 126, 129, 130), as originally found by Raiford and Fox (131) and Gairaud and Lappin (132), or when an aliphatic primary amine is used as a condensation catalyst (122, 133), as suggested by Worrall and Cohen (134). Erne and Ramirez (118) and Ramirez and Burger (135) found that reduction of the nitrostyrene side chain can be performed with high yield in one step using lithium aluminum hydride⁴ (119, 121, 130, 133). This reduction may also be achieved

⁴ Recently, Kapadia and Shah (136) found that this reaction can also lead to partial demethylation. Thus 4-demethylemescaline resulted, in low yields, from the lithium aluminum hydride treatment of the nitrostyrene discussed, the corresponding phenylacetone nitrile, or mescaline itself; similar treatment of pyrogallol trimethyl ether and some of its derivatives also gave the corresponding syringyl phenols.

^a Products identified by GLC–mass spectrometry in comparison with authentic preparations. ^b The presence of candicine was suggested (92) on the basis of TLC evidence but could not be substantiated in a later study (93); additional work is evidently needed to resolve this question.

electrolytically (115, 137) and by modified catalytic hydrogenation (117, 138–140).

Slota (141) and Slota and Heller (142) followed a different course for the synthesis of mescaline, which does not, however, seem to have attracted the attention of later workers. The appropriately substituted phenylpropionamide was prepared as indicated in Scheme II and finally subjected to Hoffmann degradation to give mescaline.

In another synthesis, Hahn and Wassmuth (116) and Hahn (143) obtained mescaline by reduction of the trimethoxyphenylacetaldehyde oxime which was prepared from the ozonization product of elemicine (Scheme III).

A successful and versatile method for the construction of the ethylamine side chain (144, 145) involves transformation of the substituted benzoic acid into the corresponding phenylacetamide *via* the Arndt–Eistert synthesis, followed by reduction with lithium aluminum hydride (Scheme IV). The use of appropriate amines in

place of ammonia, in the treatment of the diazoketone, affords *N*-substituted phenethylamines (144). This approach was recently used by Kapadia *et al.* (95) in the synthesis of 3-demethylmescaline (V), identified as a minor companion of mescaline in peyote. The suitably substituted phenylacetamide may also be obtained from the corresponding acetophenone *via* the Kindler modification of the Willgerdt reaction (Scheme V), which gives the intermediate phenylacetic acid derivative (146).

Perhaps of only historical interest is the mescaline synthesis of Hadáček *et al.* (147) in which the diazoketone group was transformed by a relatively long route to the ethylamine side chain (Scheme VI).

Mescaline was also synthesized, by Kindler and Peschke (139) and later by Amos (148), from the trimethoxybenzaldehyde through condensation with potassium cyanide, followed by acetylation of the formed mandelonitrile and catalytic hydrogenation (Scheme VII).

A convenient synthetic pathway of mescaline (Scheme VIII), which seems to be of general utility in the prepara-

tion of analogous phenethylamines, involves use of the substituted benzyl alcohol which is transformed into the phenylacetone, *via* the benzyl chloride, with final reduction using lithium aluminum hydride (149–154). Recently, Abdel-Rahman *et al.* (155) obtained excellent yields of mescaline by this route using thionyl chloride in the benzyl chloride preparation and potassium cyanide in aqueous formic acid or dimethyl sulfoxide in the subsequent stage. Benington *et al.* (123, 130, 145, 156) obtained the desirable benzyl chloride derivatives by chloromethylation (using aqueous formaldehyde and concentrated hydrochloric acid or chloromethyl ether in acetic acid) (130) of the appropriately substituted benzene derivative.

The recent review of Patel (40) on mescaline and its analogs gives a comprehensive listing of the various aromatic and *N*-substituted β -phenethylamines reported in the literature which have been obtained essentially by the foregoing methods (115, 137, 142, 157–162).

The most important degradative reactions of mescaline are those used in recent times in biosynthetic studies to determine the location of an introduced label. Cleavage of the ethylamine side chain (Scheme IX) may be

Scheme IX

effected by oxidation with potassium permanganate to give, for example, 3,4,5-trimethoxybenzoic acid from mescaline (163–167) and 4-acetoxybenzoic acid from *O*-acetylhordenine (166). Products comprising both carbon atoms of the side chain may also be obtained, as illustrated by Leete's (164) systematic degradation of mescaline. In the latter, the *N,N*-dimethyl methiodide derivative was subjected to Hoffmann degradation; the resulting styrene was oxidized to a diol with osmium tetroxide followed by cleavage with sodium metaperiodate, yielding 3,4,5-trimethoxybenzaldehyde and formaldehyde.

Several simple *N*-substituted derivatives of mescaline and 3-demethylmescaline are also known to exist in peyote. *N*-Methylmescaline (II) and *N*-acetylmescaline (IV) were identified by Späth and Bruck (83, 84) in 1937–1938; the first was synthesized (83) from mescaline by condensation with benzaldehyde followed by quaternarization with methyl iodide and hydrolysis. By using the technique of combined GLC–mass spectrometry, Kapadia and Fales (96) recently identified the *N*-formyl and *N*-acetyl derivatives of both mescaline (III and IV, respectively) and 3-demethylmescaline (VI and VII, respectively) in the nonbasic fractions of peyote. 3-Demethylmescaline (V) itself was more recently found to be a constituent of peyote, and its synthesis was realized as indicated before (95). 3,4-Dimethoxyphenethylamine (VIII) (\equiv homoveratrylamine) was detected in trace amounts in peyote by Lundström and Agurell (101) using GLC.

Tyramine and Its Derivatives—The presence of tyramine (IX) and *N*-methyltyramine (X) in Cactaceae is an extremely rare event (7, 92). The first was detected by TLC and the second isolated by McLaughlin and Paul (92) from the phenolic fractions of peyote. Hordenine (XI) was isolated (91) from the phenolic fractions, and candicine (hordenine quaternary metho derivative) (XII) was detected by TLC (92) in the quaternary base fractions of peyote by the same workers (*cf.* 93). Both products are known to be constituents of other cacti (7, 168). In a recent report, Todd (169) showed that hordenine, unlike several other phenethylamine and tetrahydroisoquinoline constituents of peyote, occurs only in the roots.

Tetrahydroisoquinolines—The principal reported approaches for the preparation of the peyote tetrahydroisoquinoline alkaloids seem to have depended basically on the general Pictet–Spengler (170), Bischler–Napieralski (171), and Pomeranz–Fritsch (172) isoquinoline syntheses. In the first two types, the appropriately substituted (aromatic 3,4,5-trioxygenated) phenethylamine derivative is the starting material to be transferred into the desirable tetrahydroisoquinoline carrying a methylene or a $\text{CH}\cdot\text{CH}_3$ group at C-1. This additional unit is provided by reaction with an aldehyde in the first type of synthesis and by cyclization of the *N*-acyl derivative in the second type. In both, the unsymmetrically 3,4,5-trisubstituted phenethylamines are likely to follow either (or both) of two possible directions of cyclization. It remains, therefore, as an additional task, to ascertain the exact disposition of the resulting tetrahydroisoquinoline. This problem is not encountered in the syntheses depending on the Pomeranz–Fritsch method and its modifications (173), since the starting material, an *N*-benzylaminoacetaldehyde diethylacetal, can be so substituted as to give only one possible cyclization product. It is a fact that the structure elucidation of the principal tetrahydroisoquinolines of peyote—for which Späth must be credited—was realized largely by synthetic approaches, inspired by biogenetic considerations, rather than by degradative ones.

Anhalamine, Anhalidine, Anhalinine, and Anhalotine—Anhalamine (XIII) was first isolated from peyote by Kauder (65) and is estimated to exist in the cactus to the extent of 0.1% (64). Anhalidine (*N*-methylanhalamine) (XVIII) and anhalinine (*O*-methylanhalamine) (XVI) were discovered by Späth and Becke (80, 81) in peyote, where they exist as minor alkaloidal constituents; their yields are estimated to be 0.001 and 0.01%, respectively.

The first synthesis of anhalamine (XIII) was realized by Späth and Röder (90) through Pictet–Spengler condensation of 3,4-dimethoxy-5-benzoyloxyphenethylamine (XLIII) with formaldehyde (Scheme X). The direction

Scheme X

of cyclization and, hence, location of the phenol group were determined by permanganate oxidation of the *O,N*-diethyl derivative which gave 4,5-dimethoxy-3-ethoxyphthalic acid (79). Anhalinine was also obtained by Späth and Becke (80) by a similar treatment of mescaline (I); anhalidine (XVIII) was obtained simply by treatment of anhalamine with methyl iodide and isolation from the complex reaction mixture (81). During a

Pomeranz–Fritsch reaction of the Schiff base XLIV, obtained as shown in Scheme XI, Inubushi and Fujitani

Scheme XI

(125) found, unexpectedly, that the isoquinoline product had lost the C-1 substituent; they obtained anhalidine (XVIII) by subsequent quaternarization and reduction.

An interesting adaptation of the Pomeranz–Fritsch isoquinoline synthesis, originally developed by Bobbitt *et al.* (173) for the construction of tetrahydroisoquinolines by acid-catalyzed cyclization of the requisite *N*-benzylaminoacetaldehyde diethylacetal followed by hydrogenation, was recently used by Bobbitt and Dutta (174) in a novel synthesis of anhalamine, anhalinine, and anhalidine (Scheme XII).

A relatively simple but less familiar method was earlier developed by Bossi *et al.* (175) for the construction of the heterocyclic ring by polyphosphoric acid

Scheme XII

cyclization of the urethan derivative obtained from the appropriate phenethylamine, followed by stages of reduction of the formed lactam system and introduction of the required substituents. Scheme XIII outlines the ap-

Scheme XIII

plication of this route in the synthesis of anhalamine (XIII) and anhalidine (XVIII). The same sequence of reactions was also used by Kametani *et al.* (154) for the

Scheme XIV

synthesis of the same compounds. In a later report, Bossi *et al.* (176) showed that the Bischler–Napieralski cyclization of *N*-formyl-3,4-dimethoxy-5-benzyloxyphenethylamine (Scheme XIV) occurs in both possible directions—unlike the 5-acetoxy analog (XLVII)—to give a mixture of two dihydroisoquinolines (XLVI).

Reduction and hydrogenolysis finally afforded a binary mixture from which anhalamine (XIII) was isolated. A Pictet-Spengler reaction of 3,4-dimethoxy-5-benzyl-oxyphenethylamine with formaldehyde was found by Brossi *et al.* (176) also to afford products, resulting from cyclization in both directions, including anhalamine (Scheme XV).

Scheme XV

Anhalotine (XIX) was isolated from the fraction of quaternary bases of peyote by Kapadia *et al.* (93) and, as the iodide, was shown to be identical with anhalidine methiodide. *N*-Formylanhalamine (XIV), *N*-acetyl-anhalamine (XV), and *N*-formylanhalidine (XVII) were detected by combined GLC-mass spectrometry in the nonbasic fractions of peyote (96). Synthesis of the formyl derivatives (XIV and XVII) was achieved by treatment of the corresponding base with triethylamine and formic acid, a method recommended by Durand *et al.* (177).

Degradation of the heterocyclic system in tetrahydroisoquinolines was previously used in structure determination work and is currently a means to locate the label in biosynthetic studies. An example is the relatively recent degradation of anhalamine (178), as the *O,N*-dimethyl derivative methiodide, to 3,4,5-trimethoxyphthalic anhydride (loss of C-3 of anhalamine), using the conditions described much earlier by Späth and Becke (179).

Anhalonidine, Pellotine, and Peyotine—Anhalonidine (XX) was first isolated by Heffter (61) who found as much as 5% of it in peyote. *O*-Methyl-*d*-anhalonidine (XXII), an optically active alkaloid, was discovered in very small amounts by Späth and Bruck (85). Pellotine (XXIII) was discovered also by Heffter (60) in 0.74% yield and later by Kauder (65). Späth and Keszler (89) prepared the optically active forms of pellotine

Scheme XVI

Scheme XVII

and, considering the ease with which they racemize, these authors thought that the natural product might be optically active and that racemization occurs by aging of the drug or during the process of isolation.

Anhalonidine and pellotine were the first peyote tetrahydroisoquinoline alkaloids to be synthesized—as early as 1921 by Späth (74). The synthesis was realized employing a Bischler-Napieralski condensation of *N*-acetylmescaline and leading, as indicated in Scheme XVI, to a quaternary iodide which was identical with *O*-methylpellotine methiodide. Anhalonidine (XX) was correlated to pellotine (XXIII) by complete methylation of both to the same product. In an independent synthesis of *rac.* anhalonidine, Späth (76) followed the same route using *N*-acetyl-3,4-dimethoxy-5-hydroxyphenethylamine after a temporary protection of the phenol group by acetylation (XLVII) as shown in Scheme XVII. The direction of cyclization and, hence, location of the phenol group were determined (86) by permanganate oxidation of the *O*-ethyl derivative of pellotine,[†] which gave the known 4,5-dimethoxy-3-ethoxyphthalic acid; this was also confirmed by an analytical approach (82).

In another synthesis of pellotine (XXIII), Späth and Becke (78) subjected the Schiff base (XLVIII), obtained by condensation of 2-benzyl-3,4-dimethoxyacetophenone with aminoacetaldehyde diethylacetal, to Pomeranz-Fritsch cyclization using sulfuric acid (Scheme XVIII). The resulting isoquinoline was quaternarized and finally reduced to *rac.* pellotine. More recently, Brossi *et al.* (175) used the urethan derivative of mescaline (Scheme XIII) in a new synthesis of *rac.* anhalonidine and *rac.* pellotine *via* the 6,7-dimethoxy-8-benzyl-oxytetrahydroisoquinoline intermediate (XLV) as outlined in Scheme XIX. In a later report, Brossi *et al.* (176) obtained, in the Bischler-Napieralski cyclodehydration of *N*-formyl-3,4-dimethoxy-5-benzyl-oxyphenethylamine

Scheme XVIII

Scheme XIX

mine, a mixture of the two possible dihydroisoquinolines (XLVI)—unlike the acetoxy counterpart (XLVII) (76, 86)—which was quaternarized and treated with methyl Grignard reagent to lead eventually to a mixture from which *rac.* anhalonidine (XX) was separated (Scheme XX).

Scheme XX

Very recently, Takido *et al.* (180) made use of Bobbitt's modification (173) of the Pomeranz-Fritsch isoquinoline synthesis. The requisite Schiff base (XLIX), obtained from reaction of the appropriate acetophenone with aminoacetaldehyde diethylacetal, was cyclized to give *rac.* anhalonidine and *rac.* pellotine (Scheme XXI).

Peyotine (XXV) was recently isolated by Kapadia *et al.* (93) by fractionation of the quaternary bases obtained from peyote; it was shown, as the iodide, to be identical with pellotine methiodide. By combined GLC-mass spectrometry technique, Kapadia and Fales (96) proved the presence of *N*-formylanhalonidine (XXI) and *N*-formyl-*O*-methylanhalonidine (XXIV) in the non-basic fractions of peyote.

A useful degradative sequence of anhalonidine, reported by Leete (164), consists in reductive cleavage of the heterocyclic system in the methiodide of *O*-methyl derivative followed by quaternarization and Hoffmann

degradation of the product (Scheme XXII). The resulting styrene derivative was oxidized to a glycol with osmium tetroxide and finally cleaved with sodium metaperiodate, giving 2-ethyl-3,4,5-trimethoxybenzaldehyde and formaldehyde. By use of this systematic degradation, it was possible to ascertain the location of the label

Scheme XXI

at C-3 in anhalonidine resulting from feeding of tyrosine-2-¹⁴C to peyote (164). The Kuhn-Roth oxidative degradation of such alkaloids carrying a methyl group on C-1 is also often resorted to as a diagnosis of the label present

Scheme XXII

in this part of the molecule giving rise to acetic acid (100, 181, 182).

Anhalonine, Lophophorine, Peyophorine, and Lophotine—Anhalonine (XXVI) (as the *l*-form) was first isolated by Lewin (52–54) and was estimated (61) to occur to the extent of about 3% in peyote. Lophophorine (XXIX), as the *l*-form, was found by Heffter (61) to occur in peyote in 0.5% yield. Späth and Keszler (88) resolved the synthetic racemic mixture of anhalonine (87) and showed that natural lophophorine results by *N*-methylation of *l*-anhalonine. Peyophorine (XXX) was discovered fairly recently by Kapadia and Fales (94) as a minor constituent of peyote. It was prepared (94) by *N*-ethylation of anhalonine with diethyl sulfate and by lithium aluminum hydride reduction of *N*-acetylanhalonine (XXVIII); the latter is itself a natural constituent of peyote (94). This is the only *N*-ethylated alkaloid so far found in peyote, and its presence is remarkable in view of the extreme rarity of such moiety in nature (183). *N*-Formylanhalonine (XXVII) is another minor constituent of peyote; it was identified by combined GLC–mass spectrometry in the nonbasic fractions (96).

The synthesis of *rac.* anhalonine (XXVI) and *rac.* lophophorine (XXIX) was realized by Späth and Gangl (87) by a Bischler–Napieralski cyclodehydration of *N*-acetylhomomyristicylamine followed by reduction and quaternarization (Scheme XXIII). The structure was

Scheme XXIII

later confirmed by oxidation to 3,4-methylenedioxy-5-methoxyphthalic acid (80). The quaternary base (XXXI), corresponding to anhalonine and lophophorine and synthesized in 1923 (87), was quite recently shown by Kapadia *et al.* (93) to be itself a constituent of peyote; it was named lophotine.

Alkaloidal Amides—Very little attention has been given to the study of the nonbasic fractions of the alkaloid-bearing Cactaceae (and, in fact, most other alkaloid-bearing plants). This is testified to by the fact that only peyote has been found to contain *N*-formyl derivatives of its own alkaloids. It is also unlikely that *N*-acetyl alkaloidal derivatives have been found in cacti other than peyote. A discussion of these simple amide derivatives of the phenethylamine and tetrahydroisoquinoline constituents of peyote has already been given under the appropriate titles. The probable biogenetic implications of such one- and two-carbon units are discussed later.

The recent GLC–mass spectrometric studies by Kapadia and Fales (96) showed that the nonbasic fractions of peyote contain more complex amide derivatives, the nature of which has been elucidated from mass spectral

considerations and by comparison with synthetic materials. These include the succinimide (XXXII), malimide (XXXIII), and maleimide (XXXIV) derivatives of mescaline, which were synthesized simply by sublimation of the mescaline salts of the corresponding acids. Very recently, Kapadia *et al.* (97) characterized three additional products in the same nonbasic fractions.

These were the citrimide (XXXV), the isocitrimide lactone (XXXVI), and the 2-formyl-5-hydroxymethylpyrrole derivative (XXXVII) related to mescaline. The structures of the first two products were evidenced by mass spectral data and supported by synthesis from mescaline through treatment with citric acid anhydride and isocitric acid lactone, respectively. The constitution of the isolated XXXVII, designated peyoglunal, was postulated from IR, NMR, and mass spectral evidence; its synthesis was attempted.⁵

The nonbasic fractions of peyote were also found (96) to contain two structurally interesting lactams, XXXVIII and XXXIX, related to mescaline (I) and 3-demethylmescaline (V), which were named mescalotam and peyoglutam, respectively. Their constitutions, prompted by biogenetic considerations, were proven by synthesis from the corresponding bases by treatment with α -ketoglutaric acid followed by decarboxylation (Scheme XXIV). The direction of cyclization in

⁵ While this manuscript was in preparation, a product containing XXXVII (GLC–mass spectrometry and other spectral evidence) was obtained by condensation of 2,5-dimethoxy-5-hydroxymethyltetrahydrofurfuraldehyde dimethyl acetal with mescaline. Treatment of desformyl-XXXVII under Riemer-Tiemann conditions also furnished XXXVII (97).

Scheme XXIV

XXXIX was established by NMR evidence (96, 184).

Amino Acids—There does not seem to be any published data regarding the general proteinic amino acid content of peyote, significant and relevant to the biosynthetic processes as they may be. The presence of proline in the amino acid fraction was, however, demonstrated lately by Kapadia *et al.* (185). Among the complex composition of this fraction, containing at least 12 products, two nonproteinic amino acids, named peyoruvic and peyoxylic acids, were characterized by GLC-mass spectrometry and shown to have Structures XL and XLI, respectively (99, 100). Their presence was anticipated on biogenetic grounds, and their synthesis was realized by condensation of 3-demethylmescaline (V) with pyruvic acid and glyoxylic acid, respectively, under physiological conditions.

Peyonine (XLII) is another minor constituent of peyote which was recently isolated (186) from the non-basic fractions. Its structure was determined (98) from spectral evidence and through synthesis by treatment of mescaline with methyl 2,5-dimethoxytetrahydro-2-furoate followed by saponification (Scheme XXV). Peyonine appears to be the first simple pyrrole-2-carboxylic acid derivative isolated from a natural source.

ANALYTICAL METHODS

Several reagents have been used in the detection and

Scheme XXV

identification of mescaline and related compounds (187–192). Some are particularly useful in working with peyote alkaloid mixtures, for example, on thin-layer chromatoplates, such as dansyl chloride for nonphenolic products and tetrazotized benzidine (92) and tetrazotized di-*O*-anisidine (93) for detection and identification of phenolic ones. Also, a number of paper (193–198), thin-layer (92, 105, 169, 199–203), and gas (101, 105, 204–207) chromatographic methods have been reported for the separation and identification of mescaline and other cactus alkaloids. Kapadia and Rao (206) observed a relationship between the retention time and structure of peyote alkaloids and related bases.

Several methods have been recommended for the quantitation of mescaline in biological fluids. They include colorimetric methods depending on measurement of the color formed by interaction with picric acid (208, 209), bromocresol purple (210), and *p*-nitrophenyldiazonium chloride (211, 212). In a fluorometric method (213), mescaline is transformed into a fluorescent isoquinoline derivative; another method (214) is based on the characteristic oscillographic behavior of mescaline in acid and alkaline solutions.

Mass Spectra of Peyote Alkaloids—The spectra of the phenethylamines and tetrahydroisoquinolines invariably exhibit molecular ions with very low intensities. The principal fragmentations result by cleavage of the β -bonds relative to the aromatic ring. The phenethylamines [such as I (215), V (95), and VIII (205)] and their *N*-alkyl-substituted derivatives thus give the benzyl ions *a* (which may also have tropylium structures) and, through transfer of a hydrogen atom from the departing fragment (arrows in Scheme XXVI), the equally important (and often stronger) ions *b*. In tertiary amines, such as peyonine (XLII), the latter type of breakdown obviously does not take place, and the predominant fragment ion is due to Species *a* (98). The spectra are complicated further only by combinations of losses from the aromatic substituent groups. The *N*-formylphenethylamines [III (216)] and *N*-acetylphenethylamines [VII (216)], as well as the related cyclic imide derivatives (XXXII–XXXIV) (96), give as principal fragmentation products ions of Species *a* in addition to styrene ions (*c*), resulting by scission of the C–N bond of the side chain with transfer of hydrogen (as depicted by the arrows in Scheme XXVII) in a McLafferty rearrangement.

The primary reactions exhibited by the tetrahydroisoquinolines [typified by XIII, XV, XVII, XVIII, XXIV, XXIX (216), and XXX (94)] involve expulsion of the C-1 substituent (217), giving the highly stabilized dihydroisoquinolinium ion Species *d* (Scheme XXVIII). The strongest peaks in the spectra are due to ions (Species *e*) formed by collapse of the heterocyclic system through the retro-Diels–Alder reaction. This type of breakdown does not seem to take place appreciably in those products carrying a methyl group on C-1, probably because the elimination of this substituent is more favored and becomes by far the most important reaction. Mescalotam (XXXVIII) and peyoglutam (XXXIX) (96) exhibit relatively strong M^+ ions and ones resulting by loss of the hydrogen atom on C-1 of the tetrahydroisoquinoline system. Fragmentation of the lactam

Scheme XXVI

ring by loss of $\text{CH}_2\text{CH}_2\text{CO}$ gives ions with appreciable abundance which may have Structure *f* (Scheme XXIX).

BIOGENESIS OF PEYOTE ALKALOIDS

Phenethylamines—As with the general interest in peyote and its constituents, studies on the biogenetic origin of mescaline (**I**) and its companion alkaloids, using labeled substrates, were initiated during the late 1950's. Prior to this, Reti (7) expressed certain hypothetical views—fairly reasonable as they later proved—which were unsubstantiated by experimental evidence

Scheme XXVII

and largely based on Guggenheim's fundamental views regarding natural amines (218). It was already a matter of general agreement that the natural aromatic amino acids, such as phenylalanine (**L**), tyrosine (**LI**), and dopa (**LII**) must be biogenetically related to the phenethylamine and tetrahydroisoquinoline alkaloids. Reti visualized the transformations as "simple" processes of decarboxylation, oxidation, *O*- and *N*-methylation, and ring closure with formaldehyde or acetaldehyde equivalents. He thought that tyrosine, which "must" be present in peyote,⁶ undergoes oxidation by tyrosinase

to give dopa, which may then successively suffer decarboxylation to dopamine (**LIII**), oxygenation to 3,4,5-trihydroxy- β -phenethylamine (**LIV**), and *O*-methylation to mescaline (**I**). Scheme XXX shows these transformations; the postulated (7) stages, which in recent years became established by convincing experimental evidence (*vide infra*), are indicated by heavy arrows.

Reti (7) also offered a possible pathway for hordenine (**XI**) and candicine (**XII**) (of which the former is now proven to be a natural constituent of peyote), depending on the initial decarboxylation of tyrosine to tyramine (**IX**) followed—or perhaps preceded—by methylation. The source of the *O*- and *N*-methyl groups as well as the CH_2 in the methylenedioxy groups was assumed to be formaldehyde. It was shown shortly later, by other workers using tracer techniques, that the *N*-methyl groups of *N*-methyltyramine (**X**) and hordenine, found in germinating barley, originate from the *S*-methyl group of methionine (219–221) and also from formate (220, 222). In fact, several studies carried out predominantly during the 1950's showed that the methyl group of methionine serves as the source of *O*- and *N*-methyl groups of many alkaloids and that it may also be the origin of the carbon bridge in methylenedioxy groups (219). The extensive studies of the Marion group (220–226) on the biogenesis of hordenine and *N*-methyltyramine in barley rootlets showed that phenylalanine, tyrosine, and tyramine⁷ are direct precursors.

Working with peyote, Leete reported in 1959 (163) that the feeding of 2- ^{14}C -DL-tyrosine gave mescaline in which all the activity was located on the α -carbon atom; this constituted the first experimental evidence that tyrosine is a precursor in the pathway to mescaline (**I**). It was only in 1966 that the next report, concerning the biogenesis of mescaline, was made by Leete (164) and later by McLaughlin and Paul (166) who had anticipated the existence of simple *N*-methylated tyramines on biogenetic grounds and actually isolated hordenine (**XI**) and *N*-methyltyramine (**X**) and detected tyramine (**IX**) itself (91, 92). Tyrosine (**LI**), which may result

Scheme XXVIII

⁶ Reti (7) also assumed the presence of tyrosine in all cacti since the darkening of cut stems, preceded by a red phase, is characteristic for the whole family, probably due to advanced oxidations involving tyrosinase. Tyrosine and tyrosinase have been found in some cacti.

⁷ The enzyme-controlled *N*-methylations of tyramine in barley were studied by Mudd (227, 228) who isolated a methionine-activating enzyme which converts methionine to *S*-adenosylmethionine, the actual methylating agent; he also purified the enzyme tyramine methyltransferase (229).

postulations of Reti (7) but indicated that two pathways are open from tyrosine to mescaline *via* dopamine,⁹ with one proceeding through dopa and the other through tyramine. In fact, quantitative comparisons made by Rosenberg *et al.* (167) showed that tyramine and dopa appear to be about equally efficient as precursors to mescaline. Similar findings were obtained almost at the same time by Agurell *et al.* (165). However, they reported somewhat different incorporation values and demonstrated that the *O*-methyl groups of mescaline may be derived from methionine. The enzymatic transformations of tyrosine to dopa and then to dopamine are well established in plant systems (172), and the specific enzymes involved (a tyrosinase and a dopa decarboxylase) may be quite different from those that transform tyramine into dopamine and tyrosine into tyramine, respectively (167).

In more recent studies, Lundström and Agurell (178) showed that tyramine, dopamine, and 3,4,5-trihydroxyphenethylamine (LIV) (the latter so far has not been encountered in nature) are all efficient progenitors of mescaline on account of the observed high incorporations of the α -¹⁴C-labeled materials. They also showed that phenethylamine and its 4-methoxy and 3,4-dimethoxy¹⁰ (VIII)—a natural constituent of peyote (101)—derivatives are not significant precursors. These findings extend the previously established sequences a step further by showing that 3,4,5-trihydroxyphenethylamine¹¹ (LIV) may be a stage that follows dopamine *en route* to mescaline. 3,4-Dimethoxyphenethylamine (VIII) seems, however, to be a deadend product resulting from dopamine without being further metabolized to mescaline or to the tetrahydroisoquinoline congeners (*vide infra*).

An alternative pathway from dopamine, namely that proceeding *via* the partially *O*-methylated derivative, was considered by both the Agurell (102, 233) and Paul (232, 234, 235) groups. Indeed, 3-methoxy-4-hydroxyphenethylamine (LVIII) was shown to be an important contributor to the mescaline of peyote; the 3-hydroxy-4-methoxy isomer, in contrast, was not significantly incorporated. Of the several possible pathways from 3-methoxy-4-hydroxyphenethylamine (LVIII) and 3,4,5-trihydroxyphenethylamine (LIV), the work of these two groups, using [α -¹⁴C] (232–235) labeled compounds, afforded a definite choice. Whereas 3,5-dihydroxy-4-methoxyphenethylamine was hardly incorporated (233), the 3-methoxy-4,5-dihydroxy¹² analog (LIX) served as an efficient precursor (232, 233).

The subsequent metabolic stage beyond intermediate LIX *en route* to mescaline was shown to result by methylation of the *meta*- rather than the *para*-hydroxyl group. Thus, 3,5-dimethoxy-4-hydroxyphen-

ethylamine (LX) was utilized to a higher degree, suggesting it as the immediate precursor to mescaline (232, 233, 235). 3,4-Dimethoxy-5-hydroxyphenethylamine (V), which is a constituent of peyote (95, 102), was, however, not significantly incorporated (233, 234). A complete biogenetic scheme is thus available from phenylalanine to mescaline (Scheme XXX, the heavy arrows indicate verified transformations). It will be noted that *meta*-methylations occur along the mescaline pathway from LIII, LIV and from LIX. *para*-Methylations, which also occur to give the natural constituents VIII and V, seem, however, to be the reactions involved in the pathways leading to the tetrahydroisoquinolines.

Kapadia *et al.* (185) carried out a special search by combined GLC-mass spectrometry in the amino acid fraction of peyote for products constituted as LXI–LXV, and they obtained no evidence¹³ for their presence. This is significant since it may indicate that the carboxyl group probably does not survive beyond the stage of dopa in the sequence leading to the more complex alkaloids of the cactus.

Recent studies conducted with another mescaline-producing cactus, *Trichocereus pachanoi* Br. & R., revealed the presence of LVIII and LX (102); these products have so far not been encountered in peyote. Feeding experiments with labeled models (233) suggested that mescaline may be formed in this plant by the same biogenetic sequence operative in peyote (Scheme XXX). The comparatively much higher incorporations of the intermediates IX and LIV observed in *T. pachanoi* may tend to indicate that the LI → IX → LIII → LIV → LIX pathway is a better contributor to mescaline in this source than the alternative pathway(s).

Tetrahydroisoquinolines—In his review on cactus alkaloids, Reti (7) noted that the tetrahydroisoquinoline and phenethylamine alkaloids may be biogenetically related to each other on account of structural similarities and co-occurrence in plant sources. The same was suggested much earlier by Pictet and Spengler (238) who synthesized some simple tetrahydroisoquinolines by reacting the corresponding phenethylamines with formaldehyde; they suggested that a similar type of reaction may be operative in plant tissue. Späth (74) also expressed the same opinion during his earliest studies on peyote constituents. Specifically, formaldehyde and acetaldehyde were regarded as the possible biological sources of the one- and two-carbon units at C-1 of the natural tetrahydroisoquinolines of peyote. Schöpf (239, 240) and Schöpf and Bayerle (241) thought

⁹ Dopamine (LIII) has not been encountered, as yet, in peyote; it is, however, a constituent of another cactus, *Carnegie gigantea* (236).

¹⁰ 3,4-Dimethoxyphenethylamine (VIII) was contemporarily suggested by Paul *et al.* (231) as a direct precursor on account of the high incorporation percentage; later, Rosenberg *et al.* (232) revised this judgment and dismissed this product as an actual participant.

¹¹ The incorporation percentage of this compound reported by Paul *et al.* (231) was comparable to that given by Lundström and Agurell (178, 233), although both groups differed on its significance.

¹² In this connection, Benington and Morin (237) showed that enzymatic oxidation of LVIII in fact yielded LIX while VIII served as a poor substrate.

¹³ It would still, however, be desirable to find out if amino acids corresponding to mono-*O*-methylated analogs of LIV (such as LIX) and LVI are present in the natural mixture.

that only the phenethylamines carrying free hydroxyl groups, which would activate the hydrogen atom involved in the ring closure, are capable of such condensation—a Mannich-type reaction which was demonstrated *in vitro* and shown to proceed at room temperature and in nearly neutral media. Hahn and Schales (242, 243), however, proved that other methoxy and methylenedioxyphenethylamines are also capable of condensation, although to a lesser extent. On the basis of other *in vitro* experiments, Hahn and his coworkers (244–247) suggested that similar condensation with α -keto acids, followed by decarboxylation, may lead in nature to the various tetrahydroisoquinolines.

Battersby and Garratt (182) were the first to show, by feeding experiments, that the tetrahydroisoquinolines of peyote, exemplified by pellotine, may originate from tyrosine. The finding was subsequently confirmed by feeding tyrosine- α - ^{14}C to peyote and isolation of both radioactive anhalonidine (XX), in which all the activity was shown by degradation to reside in C-3 (164, 181), and lophophorine (XXIX) (181). It seemed reasonable that the phenethylamine portion of the tetrahydroisoquinolines would be biosynthesized by routes similar (or, in some stages, identical) to those that lead to mescaline. Lundström and Agurell (178, 233) found that tyramine and dopamine are efficiently incorporated into anhalamine (XIII), and Battersby *et al.* (181) showed the latter precursor to be a step on the pathway toward pellotine (XXIII). Available evidence (up to the time of writing this review) seems to indicate that beyond the stage of dopamine, different pathways exist for the different tetrahydroisoquinoline alkaloids. This may be the case since 3,4,5-trihydroxyphenethylamine (LIV), for example, was well incorporated into anhalamine (178, 233) but hardly in pellotine and anhalonidine (235). 3-Methoxy-4-hydroxyphenethylamine (LVIII) was an insignificant contributor for anhalonine (XXVI) (233) but a better one for pellotine¹⁴ (248), anhalonidine (235), and anhalamine (233, 235). 3-Methoxy-4,5-dihydroxyphenethylamine (LIX), which served as an efficient precursor for anhalamine (233), was poorly incorporated into pellotine (248) and anhalonine (233). Further, 3,4-dimethoxy-5-hydroxyphenethylamine (V) was found to be well incorporated into anhalamine (233, 235) and anhalonidine (235) but insignificantly into pellotine (235, 248) and anhalonine (233). Mescaline itself was also considered as a possible precursor but found to be a poor contributor for anhalamine (178) and pellotine (248); the slight incorporation found may be due to previous partial demethylation.

It would appear, therefore, that the incorporations observed for the intermediates following the stage of dopamine are fragmentary and even inconsistent. Battersby *et al.* (248) suggested that cyclization of 3,4,5-trihydroxyphenethylamine (LIV) to the isoquinoline system precedes *O*-methylation. Lundström and Agurell (233), however, were of the opinion that partial *O*-methylation precedes cyclization and that 3-methoxy-

4,5-dihydroxyphenethylamine (LIX) is a common precursor which, by further methylation on the *para*-hydroxy group, gives 3,4-dimethoxy-5-hydroxyphenethylamine (V); the latter may be the immediate progenitor of the tetrahydroisoquinolines or at least anhalamine. However, the situation, obviously confusing and difficult to explain, certainly calls for additional work to establish more rigorously the pathways followed, probably independently, in the elaboration of the phenethylamine portion of the different tetrahydroisoquinolines. Also, the possibility that they may evolve from each other by transformations involving *O*- and/or *N*-methylations or demethylations should not be overlooked. In fact, Battersby *et al.* (248) demonstrated that *N*-methylation of anhalonidine occurs *in vivo* to give pellotine and that the reverse also occurs to an even greater extent.

There seems to be general agreement that methionine is the sole or main source of the *O*- and *N*-methyl groups in the tetrahydroisoquinoline alkaloids. This was demonstrated by the high incorporations observed into pellotine (181, 248), anhalidine (XVIII) (248), anhalamine, and anhalonidine (178) following the feeding of [methyl- ^{14}C]methionine to peyote.¹⁵ Battersby *et al.* (248) concluded that the *S*-methyl group of methionine is transferred intact, which is in agreement with previous work (249) on nicotine.

The origin of the one-carbon (C-1) and two-carbon (C-1 and C-9) units, present in tetrahydroisoquinolines of the anhalamine (XIII) and anhalonidine (XX) types, respectively, would still have to be accounted for. From feeding studies with [1- ^{14}C]- and [2- ^{14}C]acetate, Battersby *et al.* showed that the *S*-methyl group of methionine cannot be a contributor (181) and that the acetate carboxyl (181, 248) and methyl (248) groups may contribute—but not through direct incorporation¹⁶—equally to each position in the two-carbon unit of pellotine. This unit in anhalonidine was also shown by Lundström and Agurell (178) not to originate from methionine.¹⁷ Assuming that acetate suffers degradation prior to incorporation into the two-carbon unit (of pellotine, for example), Battersby *et al.* (248) studied the metabolism of bicarbonate and formate and found that only the latter could be incorporated into C-1 and C-9 with equal distribution. It became clear, therefore, that the two-carbon unit originates from a precursor to which both atoms of acetate and that of formate can donate and that other contributors must be involved. Battersby *et al.* (248) suggested that glycine, serine, and pyruvate may be considered as likely precursors and even that a C-5 side chain derived from mevalonate, in a suitable precursor akin to lophocericine (LXVI) (251, 252), may be involved by degradation.

¹⁵ The feeding of sodium ^{14}C -formate showed limited incorporation of this source into the *O*-methyl groups of pellotine (248).

¹⁶ In fact, an appreciable proportion of the activity of the sodium [1- ^{14}C]acetate fed to the peyote plant was scattered over the *O*- and *N*-methyl groups and the eight carbon atoms in the rest of the molecule (181). The acetate carboxyl group is known to contribute to the *O*-methyl groups and residues derived from the shikimic acid pathway (250).

¹⁷ With anhalamine, however, the same workers (178) found that the methyl group of methionine can be incorporated into C-1; this may be construed as evidence of a pathway involving the oxidative cyclization of an *N*-methylated derivative of phenethylamine.

¹⁴ The incorporation value (1.5%) given by Battersby *et al.* (248) for this transformation, which those authors regarded as low, is higher than that (0.37%) found by Paul *et al.* (235).

Kapadia and Fales (96) recently suggested that the alkaloid amides mescalotam (XXXVIII) and peyoglutam (XXXIX) discovered in peyote may result *in vivo* by condensation of the appropriate phenethylamines with α -ketoglutarate¹⁸ followed by decarboxylation of the resulting acids, reactions that were also realized *in vitro* (*vide supra*). These authors (96) extended their view, which was based on the original biosynthetic proposals of Hahn and his coworkers (244–247) to account for the origin of the one- and two-carbon units at C-1 in tetrahydroisoquinolines and suggested that they also arise from analogous condensations with the appropriate α -keto acids, namely, glyoxylate and pyruvate, respectively, rather than acetate. More recently, Leete and Braunstein (253) presented experimental evidence indicating that pyruvate can be involved since feeding sodium pyruvate-3-¹⁴C to peyote cactus gave relatively high specific incorporation of the labeled atom into C-9 of anhalonidine. The two-carbon unit (C-1 and C-10) of harmine (LXVII) was similarly reported by Stolle and Gröger (254) to result from C-2 and C-3 of pyruvate; unspecific labeling was, however, obtained after feeding acetate-¹⁴C to the *Peganum harmala* plant. In contrast, O'Donovan and Kenneally (255) found that the feeding of acetate-1-¹⁴C to *Eleagnus angustifolia* plant yielded eleagnine (LXVIII) having predominantly all the activity at C-1.

These facts, along with the recent report of Slaytor and McFarlane (256) that *N*-acetyltryptamine serves as a direct precursor of harman (LXIX) in *Passiflora edulis*, led Leete and Braunstein (253) to suggest that the two-carbon unit in the tetrahydroisoquinoline alkaloids (such as anhalonidine, XX) results by cycliza-

tion from the *N*-acetyl moiety in the corresponding phenethylamine derivatives (such as VII) (Scheme XXXI).

For the origin of such *N*-acetyl groups, acetate must not be considered as the exclusive source since it failed to be incorporated directly into the tetrahydroisoquinolines of peyote (*vide supra*), a fact that may be rationalized by suggesting (253) that peyote contains no enzymes capable of utilizing acetic acid directly for the formation of such an *N*-acetyl derivative (as VII). A biosynthetic scheme was, therefore, proposed (253)

¹⁸ It seems that the Krebs cycle acids conjugate favorably with mescaline (or a suitable precursor) in peyote, as evidenced by the proven (96) presence of the succinimide (XXXII), malimide (XXXIII), and maleimide (XXXIV) derivatives (see above).

Scheme XXXI

whereby pyruvate acts as the primary source of the two-carbon unit and proceeds to acetylcoenzyme A, which then affords VII by contribution to the phenethylamine precursor.¹⁹ The scheme certainly appears attractive, but its validity should be tested by the administration of *N*-acetyl- (and also *N*-formyl-) phenethylamines to peyote and determination of the degree of incorporation into the corresponding tetrahydroisoquinolines.²⁰ This pathway is a marked departure from the views of Hahn *et al.* (244–247) and Kapadia and Fales (96) who proposed that α -keto acids, as likely sources of the one- and two-carbon units, undergo Mannich condensation with the hydroxylated phenethylamines followed by decarboxylation of the intermediate acids (as XL and XLI) to yield the natural alkaloids; several *in vitro* simulations of such reactions were reported (Scheme XXXII).

Scheme XXXII

¹⁹ If taken literally, this would imply that glyoxylate is a source of the one-carbon unit in other tetrahydroisoquinolines (such as anhalamine) and that the *N*-formylphenethylamines, formed by a similar sequence, may be true precursors.

²⁰ It is pertinent in this connection to remember that peyote does actually contain several *N*-acetyl- (IV and VII) and *N*-formyl- (III and VI) phenethylamines (Table I) (96). While this manuscript was in preparation, Professor E. Leete (University of Minnesota, Minneapolis, Minn.) kindly informed the authors of his latest results (100) obtained from feeding *N*-[1-¹⁴C]-acetyl-[α -¹⁴C]-3,4-dimethoxy-5-hydroxyphenethylamine (VII) to peyote. These showed that the *N*-acetyl group was not involved significantly in the elaboration of the C-1 moiety of anhalonidine (XX) or anhalamine (XIII).

The actual presence of such nonproteinic amino acids, named peyoruvic acid (XL) and peyoxylic acid (XLI), in peyote was recently demonstrated by Kapadia *et al.* (99, 100, 185). Both were synthesized by condensation of 3,4-dimethoxy-5-hydroxyphenethylamine (V) with pyruvic acid and glyoxylic acid, respectively, at room temperature and physiological pH and resulted very rapidly in excellent yields. This intensified the belief that similar condensations may likewise operate in the plant tissue. Since normal physiological conditions were found (100) incapable of inducing subsequent decarboxylation, the transformation of both acids (XL and XLI) into the optically active anhalonidine and anhalamine, respectively, evidently necessitates the action of stereospecific decarboxylases. Experimentally, it was found (100, 185) that this could be true since facile decarboxylation of carboxyl-labeled *rac.* peyoruvic and peyoxylic acids (XL and XLI, respectively) could be brought about by short-term incubation with fresh slices of the peyote cactus, nearly half the activity was recovered as [^{14}C]-carbon dioxide. In a similar experiment in which [$9\text{-}^{14}\text{C}$]-peyoruvic acid was used, the decarboxylation product was isolated and found to be the Schiff base LXX, accounting for nearly half the activity. Moreover, feeding of [$1\text{-}^{14}\text{C}$]-peyoruvic²¹ and [$1\text{-}^{14}\text{C}$]-peyoxylic acids to live peyote plants resulted in the incorporation of 6.0 and 6.8% of radioactivity in anhalonidine (XX) and anhalamine (XIII), respectively (100). The joint occurrence of 3-demethylmescaline (V), peyoruvic acid, and peyoxylic acid in peyote—in addition to the tracer experiments—would seem to suggest that the pathway indicated in Scheme XXXII can account for the C-1 moiety in the tetrahydroisoquinolines in addition or preference to that proposed by Leete and Braunstein (253). The isolation of the dihydroisoquinoline LXIII in the relatively short-term slice experiment may suggest that this product is a true intermediate, since it might be stereospecifically reduced to optically active anhalonidine (XX) with NADPH.

More work is certainly needed to establish rigorously the precise biogenetic route followed in the construction of the C-1 moiety in the various tetrahydroisoquinolines. Equally important is the work leading to the elucidation of the biogenetic interrelationships of the various tetrahydroisoquinoline alkaloids of peyote as well as the probable pathways that connect them with their phenethylamine precursors. In the latter, the biogenetic changes in the benzenoid oxygen substituents seem to be of special interest since a convenient explanation for the origin of the methylenedioxy system is still lacking. Kapadia *et al.* (95) recently anticipated the occurrence of homomyristiclylamine (LXXI) in peyote and its probable biogenetic role. Whether the methylenedioxy group,²² present in anhalonine (XXVI) and lophophorine (XXIX), is formed prior to or after

cyclization remains to be established. The C-1 methylene counterpart (LXXII) of the latter compounds has not yet been found in peyote, although its presence is not unlikely from biogenetic reasoning.

BIOLOGICAL EFFECTS OF PEYOTE ALKALOIDS

General Pharmacodynamic Effects—*Mescaline (I)*—

The effects of mescaline on the cardiovascular and respiratory systems were studied by several investigators (259–266). In general, low doses (~ 4 mg./kg.) of mescaline have no remarkable effects on blood pressure. Large doses (20–60 mg./kg.), however, produce a drop in blood pressure, bradycardia, respiratory depression, and vasodilation (259, 261–264, 266); the pressor and depressor effects persist after section of the vagi, greater and lesser splanchnic nerves, adrenalectomy, or atropinization. Moderate doses markedly inhibit the pressor effect of epinephrine without altering its accelerating effect on the cardiac rate. Grace (261), however, observed that the fall in blood pressure produced by mescaline in anesthetized cats could be prevented by vagotomy, decapitation, or atropine. Strong solutions of mescaline arrest the perfused frog heart in diastole due to a direct action on the cardiac muscle (261). Mescaline produces some sensitization to the cardio-depressant action of sodium EDTA (267). Its action on the cardiovascular system and on the nictitating membrane in cats and dogs is potentiated by pretreatment with reserpine (268). A threshold dose (152 mcg./kg. i.v.) causes slight potentiation of the effect of epinephrine on the nictitating membrane of anesthetized cats (269). Mescaline is slightly antagonistic to the vasoconstricting effect of serotonin perfused through the isolated rabbit leg (270).

In concentrations over 0.2%, mescaline causes gradual paralysis and shortening of the isolated gastrocnemius muscle of the frog. It stimulates the contractions of intestine and uterus *in situ* but not when excised (261). The intestinal muscle initially shows contraction but later is paralyzed (262). Other reports, however, show that mescaline causes respiratory stimulation, increases the tone of excised intestine, and slightly anesthetizes the cornea (260) and that it decreases the tonus of the smooth muscle at a concentration of 20 p.p.m. (264). The curarelike blockade of the dog peroneal tibialis anticus nerve-muscle preparation caused by mescaline is antagonized by epinephrine, prostigmine, and potassium chloride (271, 272). In rabbits and cats, it has no direct effect but it potentiates the inhibition of muscular contractions due to *d*-tubocurarine, gallamine, and succinylcholine (273). Mescaline also stimulates the escape reflexes in mice in low doses and inhibits them in high doses (274).

Mescaline facilitates serotonin-induced contractions of the isolated rat uterus at lower concentrations and contracts the uterus at higher doses; atropine has no

²¹ From the [$1\text{-}^{14}\text{C}$]-peyoruvic acid-fed plant, an unknown water-soluble basic substance, accounting for about 90% of the administered radioactivity, was isolated which from spectral (NMR and mass) data appears to be anhalonidine (or a derivative) attached to a polar moiety (100).

²² It does not appear too unlikely that this group may arise from neighboring methoxy and hydroxy groups in the appropriate nucleus, since such transformation of aromatic substituents is a proven (257, 258) biosynthetic event.

effect but chlorpromazine inhibits these uterine contractions (275–278). Mescaline causes vasoconstriction of the umbilical vessels of the human placenta (279). In small doses, it enhances the potentiating effect of serotonin but blocks the prolongation action of reserpine on hexobarbital hypnosis in mice (280). It also augments cerebral serotonin levels and suppresses the protective effect of reserpine against toxicity of amphetamine in mice grouped in small cages (281). The favorable results obtained after administration of mescaline in a few cases of amenorrhea were attributed to an antagonism to serotonin (282).

Mescaline produces hyperthermia, and this effect in rabbits can be potentiated by pretreatment with iproniazid or reserpine (283–285). Jacob *et al.* (286, 287) observed a correlation between the mescaline-induced hyperthermia in rabbits, antianalgesia in mice, and hallucinogenic action in man. In rats, it lowers rectal temperature and is an effective antipyretic agent against tetrahydro-2-naphthylamine-induced fever (288).

A detailed discussion of the clinical pharmacology of mescaline and other related phenethylamines is given by Jacobsen (289).

The LD₅₀'s of mescaline in the rat are 330–410 mg./kg. i.p., 157 mg./kg. i.v., and 534 mg./kg. s.c. (259, 260). These values fall within the ranges given by other investigators for mice, frogs, and guinea pigs (290, 291). Flexor convulsions and respiratory arrest are the terminal events. Dogs fed with mescaline were reported (292) to develop capillary damage in the liver and nitrogen retention. Administration of sodium succinate to mice (0.5 g./kg. i.p.) was found to afford complete protection against mescaline (0.2 g./kg.) (290).

Hordenine (XI)—Heffter (59) gave the earliest description of the pharmacological properties of this compound; it was found to cause paralysis of the CNS in frogs without previous excitation. It was also reported to be highly antiseptic and to have an inhibitory effect on some soluble ferments (293, 294). Small doses of hordenine have no effect on blood circulation, but larger ones produce appreciable hypertension and accelerated pulsation; very large doses cause death by arrest of respiration. Rietschel (295, 296) found that the pressure effect of hordenine is not of central origin but results by stimulation of the heart muscle. Although much less active than adrenalin, it is analogous in its action, resembling ephedrine rather than adrenalin. Other workers reported that hordenine displays a nicotine-like action (297–299) and that in large doses it decreases or reverses the hypertensive effect of adrenalin (300).

Anhalonine (XXVI)—Heffter (62) described some aspects of the activity of this compound and the following ones after their first isolation from peyote. In the frog, injected doses of 5–10 mg. produced an increase in the reflex excitability after a phase of paresis. In the rabbit, similar symptoms resulted but general hyperexcitability predominated.

Anhalonidine (XX)—According to Heffter (62), doses of 20–25 mg. of the hydrochloride produced narcosis in the frog followed by increased excitability. Larger doses caused complete paralysis. Doses of 30–50 mg. provoked a curarizing effect. No significant symptoms have been observed in mammals.

Pellotine (XXIII)—Doses of 5–10 mg. caused temporary convulsions in frogs, dogs, and cats (62). Several authors, cited by Joachimoglu and Keeser (301), believe that pellotine could be used in man as a relatively safe narcotic.

Lophophorine (XXIX)—This base was shown by Heffter (62) to be the most toxic one in peyote; 0.25–1 mg. of injected hydrochloride provoked a long-lasting tetany in the frog. Although the animal recovers, the increased excitability may last for several days. There is no apparent action on the isolated frog heart. A dose of 7 mg./kg. in rabbits causes hyperexcitability and accelerated respiration; progressively higher doses induce tetany (12.5 mg./kg.) and lead to death (15–20 mg./kg.). Intravenous injection of 2.5 mg. causes an increase in blood pressure, but higher doses are hypotensive, without specific action on the heart.

More recently, Brossi *et al.* (176) examined anhalamine, anhalidine, anhalonidine, and pellotine and found all to be hardly active as anticonvulsants, tranquilizers, or muscle relaxants and to have no significant hallucinogenic effects.

Behavioral Effects of Mescaline—On Animals—In rats, mescaline (I) initially depresses the conditioned-avoidance response and then gives rise to a prolonged excitatory phase; the latter effect is dominant when lower doses are used (302). Harmine was found to augment the effect of mescaline (260). Maffii (303,304) observed the effect of mescaline on the secondary conditional response in an experimental avoidance situation and found the ED₅₀ for blocking the response to be 32.5 mg./kg. i.p. Following an injection of 50 mg./kg., only 10% of the animals showed a loss of conditioned response. Dogs under the influence of large doses of mescaline reacted to conditioned stimulus as if it was the unconditioned one (305). Mescaline gave some protection to albino rats bred to have a high incidence of seizures when exposed to a standard sound (306).

Mescaline produced experimental catatonia in mice, guinea pigs, cats, monkeys, pigeons, and other animals (260, 307–314); the catatonic manifestations, however, could be inhibited by chlorpromazine, reserpine, and azacyclonol (315, 316). It caused reduction in the behavior patterns of contentment and sociability but increased excitement, aggressiveness, and defensive hostility (317). It was observed, however, that mescaline inhibited the isolation-induced attack behavior of mice (318). It produced a scratching response in mice, which was antagonized by tetrahydroberberine (319), various tranquilizers, serotonin, *d*-amphetamine, *etc.*, but not by barbiturates, meprobamate, azacyclonol, and mephensin (320–322). Mescaline, given by intracerebral injection, produced aggressive tendencies and paroxysms of ear scratching in mice by doses that were ineffective by other routes (323). It also prolonged and potentiated the analgesic effect of morphine in mice (324).

In Humans—The onset, intensity, duration, and quality of the hallucinations produced in humans upon ingestion of mescaline or peyote depend both on the quantity of the drug and on the individual's cultural background. With mescaline, a latency period, de-

pending upon the route of administration, is followed by a number of disagreeable autonomic symptoms which are felt prior to the phase of inebriation. After an intravenous dose of 0.5 g. of mescaline sulfate, nausea, vomiting, sweating, generalized discomfort, dizziness, headache, palpitation, feeling of hot or cold, pupillary dilatation, and chest, neck, or abdominal cramps occur within 10 min. (325). A small rise in body temperature and systolic blood pressure are also experienced (326). Usually, the heart rate is accelerated somewhat, but sometimes a slight bradycardia is observed instead, as a reflex compensation of the hypertension. In general, the subjective vegetative symptoms like nausea and vomiting subside before the development of the psychic symptoms; the objective vegetative symptoms, such as pupillary dilatation, follow the time course of the psychic effects.

During the phase of mescaline-induced inebriation, the subject goes through abnormal mental states characterized by one or more of the following effects (37):

1. Visual hallucinations: Colors are at first intensified. Then, gradually, the subject shuts his eyes and entoptic phenomena appear, followed by true hallucinations with forms, shades, and movements. Flashing lights and complete scenes are seen, ordinary objects appear to be marvelous, and familiar sounds and music are "seen" in vivid colors.

2. Auditory hallucinations: These are fairly rare but frequently correspond to color and form visions. Hypersensitivity and pain at the slightest noise are also experienced.

3. Abnormal touch, taste, and smell: Paresthesias and alteration in perception of heat and cold occur.

4. Disturbances of personal judgement: The subject's perception of his own body, for example, is largely that it is changing shape, and he becomes unable to locate some parts of it. The perception of space and time becomes altered and both appear to be immensely stretched.

5. Emotional disturbances: An ecstatic euphoria with laughter is usually observed, especially at the beginning of the intoxication. This state is sometimes followed by anxiety and, less frequently, depression. The subject may then become suspicious and hostile, especially toward the person conducting the experiment.

6. Disturbances of the will and thinking: The subject utters words and makes gestures which he simultaneously does not wish to speak or make. He cannot pursue an idea; in tests of concentration and reasoning, failure is almost sure (327).

7. Personality disturbances: These, being the most important effects of mescaline intoxication, are manifested by symptoms similar to those of schizophrenia (328-330). The effect has catatonic features (329, 331). An experienced clinical observer can easily distinguish between schizophrenic reactions and drug-induced psychoses (328). The disorganization of psychic integration was much more apparent in schizophrenics than in normal subjects given mescaline (332). The drug precipitated schizophrenic psychoses in persons suffering from latent schizophrenia and also reactivated

the psychosis in patients who improved after psychosurgery (333).

Detailed descriptions of the mescaline and peyote inebriation are given by various authors (1, 31-33, 35, 38, 58, 63, 71, 292, 325, 328, 334-341).

The reactions induced by LSD, psilocybin, and mescaline are qualitatively similar (326, 342), but mescaline is the least potent. It was noted that mescaline and LSD and their combination produced an enhancement in primary suggestibility (343). In a comparison of the effects of taraxein, a protein fraction obtained from the serum of schizophrenics, with those of mescaline, psilocybin, and LSD, Silva *et al.* (344) found that taraxein produced more dysphoria, blocking, and thought deprivation than did the three psychotomimetics. Secondary symptoms evoked by the protein fraction were more typical of those seen in schizophrenics than those induced by other substances.

The mescaline-induced state of intoxication has been used as an aid in psychotherapy (345). It has been recommended that mescaline be used when it is desirable to shorten a course of therapy, reactivate a stalled treatment of neurosis, and break down memory blocks (345). The studies of Turns and Denber (346) indicate that psychotherapy with mescaline can be effective in carefully selected cases where other methods have failed.

Tolerance, Habituation, and Addiction—Several studies show that human subjects and animals receiving mescaline daily develop tolerance to mescaline (302, 326, 347-351) and cross-tolerance to LSD (326, 350, 351). The tolerance, however, regresses rapidly, and initial responsiveness is attained 3-4 days after the drug is withdrawn. Generally, the tolerance for the vegetative phase does not develop to the same degree as for the psychic phase (352). Speck (259) reported that no tolerance to the hypoglycemia and bradycardia induced by mescaline is observed. Dogs given 5 g./kg. of mescal buttons acquired tolerance to the emetic effects during 1 year of daily ingestion (353). Doses of mescaline producing acute tolerance have no effect on development of the chronic type (354). There seems to be no evidence that peyote and mescaline cause habituation and addiction (37); very few investigators hold a different view (355). Slotkin (44, 49) found that "the habitual use of peyote does not seem to produce tolerance or accrued dependence," an opinion that is also endorsed by many specialists (37) who affirm that peyote should not be regarded as a narcotic drug.

Antagonism and Synergism—The systemic administration of the phenothiazine tranquilizers (356-358), reserpine (356, 358, 359), asarone (360), trioxazine (361), lithium carbonate (362), lysergic acid derivatives (320), benactyzine, methylnonyldioxolane, chlorphenoxamine, *etc.* (358), inhibit various components of the mescaline-induced effects in different animals. Model psychosis produced by mescaline in man can also be inhibited by application of chlorpromazine and meprobamate (363, 364). Reserpine, injected 24 hr. before the mescaline, was found, however, to potentiate the action of the latter in mice (365).

Distribution of Mescaline in Animal Body—Mescaline taken orally is readily absorbed from the intestinal tract. The studies of various workers seem to agree

about the distribution of mescaline taken by injection. Tarsitano (366), working on dogs injected subcutaneously, found the highest concentration in the liver and kidneys but much less in the brain and no appreciable amount in the blood. However, the plasma levels of mescaline were found (367) highest immediately following intravenous injection, and the drug disappeared from the bloodstream after 6–8 hr. The concentrations of mescaline in the liver, spleen, and kidneys were 3–6 times those in the plasma; the brain and blood levels were about the same. These findings were supported by Block and coworkers (368–372) who studied the distribution of mescaline- α - ^{14}C in mice. They found that, shortly after intraperitoneal injection, the highest radioactivity resided in the liver and kidneys with almost none in the brain and spinal cord. It was thus evident that mescaline was rapidly incorporated in the liver proteins. The maximum tissue concentration of mescaline coincided with the period of marked autonomic stimulation, while the highest concentration in liver protein corresponded to the period of hallucinations (372).

From his studies on the incorporation of radioactive mescaline into isolated tissues, Block (373, 374) found that the drug was incorporated in liver homogenates only if the latter were kept under oxygen first and then under nitrogen, and that the reaction rate increased 10-fold by brief heating of the mixture to 55° or by addition of tyramine. These observations indicated that there was an inhibitor, probably amine oxidase, whose action could be blocked by conjugation with tyramine or destroyed by heat, thereby facilitating the incorporation of mescaline. The inhibitor was, however, shown not to be amine oxidase, since several known inhibitors of this enzyme failed to increase mescaline incorporation (373). Moreover, Block (375), working with isolated cell components, found that nuclei could incorporate mescaline readily regardless of the action of tyramine or heat, while mitochondria and microsomes behaved similar to the total homogenate. It was, therefore, concluded that the incorporation-inhibiting factor resides within mitochondria and microsomes but not in the cell nuclei. Block (374) concluded, in general, that mescaline may be incorporated into proteins by a different mechanism from that involved in the case of amino acids; he postulated the following pattern. Oxidation of mescaline to an aldehyde is followed by condensation of the latter with the free amino groups of protein. The resulting Schiff base may subsequently either be hydrolyzed to an aldehyde, which undergoes further oxidation to an acid, or dissociated to mescaline and the oxidatively deaminated protein.

Fischer (376–378) used wool protein as a model surface to simulate the neuroreceptors involved in drug-induced psychoses. He demonstrated that the affinities (expressed in terms of absorption) of mescaline and other psychotomimetic agents, including LSD, for wool protein were parallel with their biological potency. Sympathetic overtones and subsequent adrenergic blockade seemed to contribute toward the precipitation of model psychosis. Neff *et al.* (379) found after administering radioactive mescaline intravenously into cats, which showed peak intoxication after 30 min., that

the highest concentration of radioactivity was localized in the hypophysis, relatively high levels were in the cortical and subcortical gray matter, and very little was in the areas composed largely of myelinated fibers. The maximal mescaline concentration in the brain attained between 0.5 and 2 hr. roughly paralleled the period of maximal intoxication. The biological half-life of mescaline in plasma and cerebrospinal fluid was 1.5–2 hr. In human cerebrospinal fluid, however, Charalampous *et al.* (380) found significant concentrations of radioactivity throughout 9.5 hr. after administration of ^{14}C -mescaline.

Metabolism of Mescaline (I)—About one-half of the mescaline fed to rabbits was found to be excreted as 3,4,5-trimethoxyphenylacetic acid (LXXIII), a pharmacologically inactive metabolite (381, 382). Lesser amounts of the administered mescaline were recovered from dog urine (367). The studies of Block *et al.* (194) showed that rats and mice excreted intraperitoneally injected mescaline- α - ^{14}C in the urine in the form of unchanged mescaline (18.4 and 79.4%), LXXIII (72.4 and 16.2%), and an unidentified product (9.1 and 4.4%), respectively. Spector (383) obtained qualitatively similar results by administering radioactive mescaline to dogs. Later, however, Neff *et al.* (379) found LXXIII to be the sole metabolite identified in the cat brain, plasma, cerebrospinal fluid, and urine. 2-(3,4,5-Trimethoxyphenyl)ethanol (LXXIV) was also found (384, 385) to be a metabolite in urine of rats fed with mescaline- α - ^{14}C ; its formation increases, at the expense of LXXIII, by calcium carbimide pretreatment, presumably because of the inhibition of aldehyde dehydrogenase. Pretreatment with iproniazid, however, markedly inhibits the formation of the acid (LXXIII), presumably by blockade of amine oxidase or a specific mescaline oxidase. Rabbits, estimated to be about 70 times as tolerant to mescaline as man, developed severe reactions by very small doses of mescaline when pretreated with calcium carbimide, implying that aldehyde dehydrogenase inhibition markedly enhances the pharmacological effects of mescaline. The intravenous administration of LXXIV to rabbits produced a mild mescalinelike effect, which was potentiated considerably when the alcohol was taken in combination with calcium carbimide. Based on these observations, it was suggested (385) that 3,4,5-trimethoxyphenylacetaldehyde (LXXV) is responsible for the pronounced pharmacological effects of mescaline.

Musacchio *et al.* (386) and Musacchio and Goldstein (387) identified other mescaline metabolites, in the urine of rats, as *N*-acetyl-3,5-dimethoxy-4-hydroxyphenethylamine (LXXVI), *N*-acetyl-3,4-dimethoxy-5-hydroxyphenethylamine (VII), and *N*-acetylmescaline (IV), in addition to probably *N*-acetyl-3,4-dihydroxy-5-methoxyphenethylamine (LXXVII). They concluded that *N*-acetylation of mescaline may precede *O*-demethylation *in vivo*.

The early studies on metabolism of mescaline in man showed high recovery of the ingested drug in the urine of normal subjects and lesser amounts in psychopathic patients (388), with no evidence for the production of 3,4,5-trimethoxyphenylacetic acid (LXXIII) (382). Different figures for the recovery of mescaline in

the urine were given by various workers (208, 389), depending on the route of administration and duration of the drug. Later studies (381, 390), however, showed that LXXIII was a metabolite which could be detected in human urine. 3,4-Dihydroxy-5-methoxyphenacetylglutamine (LXXVIII) (391) and 3-hydroxy-4,5-dimethoxyphenethylamine (V) (127) were other metabolites of mescaline found in small amounts in human urine. In more recent reports (40), orally taken mescaline was recovered substantially unchanged, in addition to LXXIII, VII, and IV, found in decreasing amounts

in both urine and cerebrospinal fluid. The appearance of LXXIII in human urine also was recently confirmed (392). A discussion of the metabolic fate of mescaline in man is given by Charalampous *et al.* (380).

Several *in vitro* studies (393, 394) showed that rabbit liver contains an enzyme system which oxidizes mescaline readily and that some factor other than oxidase might be involved. Amine oxidase was shown (394, 395) to have little or no effect on mescaline, and this was assumed (396) to be the reason for the high tolerance of rabbits to mescaline; a specific mescaline oxidase was claimed to have been isolated from the rabbit liver which was different from monoamine oxidase (397). Some authors (398) postulated that mescaline oxidase is identical with diamine oxidase, while others (399–401) believe that the oxidative deamination of mescaline can be effected by monoamine oxidase or diamine oxidase or both. However, mescaline was found to be a poor substrate for highly purified human plasma monoamine oxidase (402) and for dopamine- β -oxidase (403). According to Seiler (404), who treated mescaline with mouse brain homogenates, the oxidation is not caused by diamine oxidase but by a monoamine oxidase leading to 3,4,5-trimethoxyphenylacetic acid (LXXIII). Enzyme preparations obtained from rabbit lung produced *N*-methylation of mescaline (405, 406), while rabbit liver preparations caused *O*-demethylation to VII and LX along with oxidation to LXXIII (407). The formation of this acid (LXXIII) was inhibited by iproniazid, semicarbazide, nicotinamide, and triphosphopyridine nucleotide.

The excellent review of Patel (40) gives examples of the numerous studies made on various aspects of biochemical effects of mescaline with ample documentation.

Mode of Action of Mescaline—The following observations were enumerated by Patel (40) as reasons for doubting that mescaline *per se* is psychotomimetic and in support of the assumption that its action is caused by some metabolite.

1. Mescaline inhibited the oxidation of glucose, lactate, or pyruvate only if it was preincubated with brain homogenates for 2–3 hr. (408, 409).

2. In mice it was rapidly incorporated into liver proteins; during the phase of active CNS effects, the brain was almost devoid of it (371).

3. It stimulated the contractions of intestine and uterus *in situ* but not when excised (261).

4. No correlations were observed between the degree or type of behavioral responses and blood levels or rates of excretion of mescaline in man. The period of maximal behavioral changes followed the period of maximal blood level and excretion after 1–2 hr. (390).

5. The effective dose (400 mg.) was much higher than that of other hallucinogens; the effects took 1–2 hr. to develop and 5–6 hr. to reach a maximum (391).

6. The combined effect of mescaline and iproniazid could not be distinguished from that of an equivalent dose of mescaline (385).

Various explanations have been offered by different workers. Quastel and Wheatley (408) assumed that malfunction of the liver may give rise to abnormal amine metabolites which would affect brain respiration and subsequently produce CNS disturbances. It is not very likely that the hallucinogenic effect of mescaline is directly related to its sympathomimetic action on humans, since some substances possessing both the CNS and sympathomimetic properties are not hallucinogenic. The competition for adrenergic receptors leading to the disturbance of adrenergic mechanism was suggested by Speck (259). Quite recently, Clemente and Lynch (410) gave evidence suggesting that mescaline does not act *via* a cholinergic mechanism but rather through catecholamine mechanisms. The disturbance of histamine catabolism in the brain was suggested by Carlini *et al.* (411). Marrazzi and Hart (412) hold the view that "cerebral synaptic inhibition plays a part in the action of hallucinogens either by the direct disruption of normal patterns of synaptic activity as a result of alteration in the normal balance between cholinergic excitation and adrenergic inhibition at susceptible cerebral synapses."

Fischer (413) hypothesized the mode of action of mescaline, which he regarded as inactive *per se*, by suggesting that a metabolite produced *in vivo* by transformation into an indole derivative²³ resembling LSD is actually the active species. The hypothetical LSD-like compound results in very small amounts, perhaps from partially demethylated mescaline or through the condensation of mescaline with norepinephrine or serotonin. Other authors (9, 416) also postulated the *in vivo*

²³ Working on this assumption, Morin *et al.* synthesized 5,6,7-trimethoxyindole (414) and its 2,3-dihydro derivative (415) but found them to be devoid of mescalinelike activity.

Table II—Biological Data for the Isopropylamines

Compound	LD ₅₀ in Mice, mg./kg.	Effective Dose in Man, mg./kg.	Mescaline Units in Humans
LXXIX	260	1700	2.2
LXXX	150	1400	2.7
LXXXI	120	220	17
LXXXII	120	>1900	<2
LXXXIII	130	180	21
LXXXIV	40	210	18

formation of an indole derivative as the active species from mescaline. Snyder and Merrill (417) made molecular orbital calculations for a variety of hallucinogenic and structurally similar nonhallucinogenic analogs in the phenethylamine, amphetamine, and tryptamine series and for LSD. They observed a close correlation between the energy of the highest filled molecular orbital of compounds, an index of electron donation, and their hallucinogenic potency.

Although it appears attractive to suspect an intimate structural relationship among the active species that produce the same type of psychotomimetic effects, further and more thorough inquest should be made.

Structure—Activity Relationships—Several studies showed that alterations in the aromatic ring substituents (418–420) and the side chain can bring about substantial changes in the psychopharmacological properties of mescaline. Smythies and Levy (421), using the rope-climbing test for comparison, found that removal of the 5-methoxy group from mescaline caused about a 50% loss of activity, while demethylation of the 4-methoxy group resulted in a complete loss of activity. Substitution of the benzyloxy group for the 4-methoxyl was found to increase the activity. Ernst (422) confirmed that the presence of the 4-methoxyl group is essential for the manifestation of the hypokinetic rigid syndrome in cats. *N*-Methylation of mescaline seems to result in loss of the psychopharmacological properties of mescaline. Trichocereine (*N,N*-dimethylmescaline) was found (423) to produce no mental disturbances in man. However, it was observed to act on the CNS of normal cats to cause convulsions but to have no effect on decerebrated cats. This compound was shown (424, 425) to cause negligible inhibition of the conditioned-avoidance response but produced marked excitation similar to that induced by amphetamine; increase of the dosage delayed the onset of the excitation.

The introduction of a methyl group on the α -carbon of the phenethylamine system seems to maintain the hallucinogenic properties. In man, α -methylmescaline (LXXIX) (162) was found (426) to produce visual hallucinations in doses lower than that required for mescaline, without having significant effect on blood pressure or respiration. The peak urinary excretion occurred in 2–5 hr., with 20–35% of the ingested dose recovered unchanged in the urine. Several compounds analogous to LXXIX were also prepared and tested by Shulgin (427–429). The results showed that the presence of a 3,4-methylenedioxy group, as in LXXX,²⁴

does not result in loss of activity, while enlargement of this heterocyclic ring or increase in length of the aliphatic side chain in LXXIX results in decreased effect in humans. On the other hand, repositioning of the *meta*-methoxyl, in either LXXIX or LXXX, to an *ortho*-position produces an increase in potency (429).

Table II lists the effective dose (mg./kg.) of these isopropylamines in man, the LD₅₀ (mg./kg.) in mice, and the mescaline units in humans (potency compared to mescaline = 1). The intoxication syndrome produced by these compounds in humans is qualitatively similar to that resulting from mescaline, except that the color effects and nausea are absent. In general, the methylenedioxy derivatives (LXXX, LXXXIII, and LXXXIV) gave more emphatic and pleasant responses. 2,5-Dimethoxy-3,4-methylenedioxyphenethylamine was found (431) to exhibit pharmacodynamic properties similar to those of mescaline. Schwachhofer *et al.* (432) and Schwachhofer and Chopin (433, 434) prepared several α,α -disubstituted derivatives of mescaline and found that the pharmacological properties (435) of only α,α -dimethylmescaline and α -methyl- α -veratrylmescaline are similar to those of mescaline.

A study of behavioral effects of mescaline, β -hydroxymescaline, and *N*-methyl- β -hydroxymescaline in mice performed by Friedman *et al.* (291) revealed that substitutions on mescaline did not substantially alter the biological activity of the parent compound.

LXXIX, R₂ = R₃ = OCH₃, R₁ = H LXXX, R₂ = OCH₃, R₁ = R₃ = H
LXXXI, R₁ = R₃ = OCH₃, R₂ = H LXXXIII, R₃ = OCH₃, R₁ = R₂ = H
LXXXII, R₁ = R₂ = OCH₃, R₃ = H LXXXIV, R₁ = OCH₃, R₂ = R₃ = H

Synthesis and Biological Activity of Deuteriobenzyl-*d*₇-penicillin

PAUL A. LASKAR and ROBERT G. MRTEK

Abstract □ To investigate the deuterium isotope effect on the biological activity of penicillin G, this compound was chemically synthesized by first obtaining phenylacetyl-*d*₇-chloride from phenylacetic-*d*₇-acid and thionyl chloride, followed by condensation of the acid chloride with 6-aminopenicillanic acid. The penicillin was isolated as the 1-ethylpiperidine salt. Yield of the deuteriopenicillin was approximately 60% when a 2:1 (6-aminopenicillanic acid:acid chloride) molar ratio was used. The identity of the deuteriated penicillin was confirmed using several physical constants. From NMR data, the presence of deuterium in the benzyl moiety was found to be greater than 95 atom %. The biological activity of the deuteriopenicillin was compared to that of the protioanalog by a turbidimetric assay procedure using *Staphylococcus aureus*. The results of the biological assay indicate that a significant deuterium isotope effect operates in the antistaphylococcal action of benzylpenicillin. With the test organism chosen, the ratio of the antibiotic potencies was 125% H/D.

Keyphrases □ Deuteriopenicillin—synthesis □ Biological activity—deuteriopenicillin □ Turbidimetric assay—deuteriopenicillin antimicrobial activity □ NMR spectroscopy—identification □ IR spectrophotometry—identification

Deuterium (²H), a rare stable isotope of hydrogen, was discovered by Urey *et al.* (1) in 1932. Extensive work by several investigators has felled the long-standing opinion that deuterium oxide (D₂O) is incompatible with life. The successful mass culture of algae, yeasts, and certain bacteria under conditions of full deuteriation has provided a useful source of fully deuteriated sugars, amino acids, proteins, and certain drugs (2–5). Substitution of deuterium for ordinary hydrogen and deuteriated substrates for protio metabo-

lites has been shown to produce profound changes in biosystems. Isotope effects have been categorized as being either primary or secondary. Measurement of the magnitude of the effect is usually useful in distinguishing between the larger primary mass isotope effects and the smaller secondary effects.

The substitution of deuterium in several drug molecules has been the impetus for many recent research contributions. Isotopically altered drugs have shown widely divergent pharmacologic effects. Elison *et al.* (6) demonstrated a reduced analgesic potency of morphine deuteriated in the *N*-methyl group. Nona *et al.* (7) found an increased antifungal activity with fully deuteriated griseofulvin. Foreman *et al.* (8) investigated the *in vitro* Dutch rabbit liver metabolism of selectively deuteriated amphetamines. Their studies show that the ratio of apparent rate constants (*k_H/k_D*) is 1.9, indicating that the deuterioamphetamine is metabolized more slowly than the protioanalog. One major effect of deuterium substitution in drug-producing organisms has been a general suppression of most nonessential metabolism. Mrtek *et al.* (9) demonstrated an inverse effect between the level of deuteriation in *Claviceps* and the amount of clavine alkaloids produced in saprophytic culture. Multi-milligram quantities of highly deuteriated elymoclavine were obtained only through the use of replacement culture techniques (10). Mohammed *et al.* (11) demonstrated a similar effect with several strains of *Penicillium*. Carlstedt (12) obtained small amounts of highly deuteriated penicillin from large numbers of shake

Keyphrases □ Deuteriopenicillin—synthesis □ Biological activity—deuteriopenicillin □ Turbidimetric assay—deuteriopenicillin antimicrobial activity □ NMR spectroscopy—identification □ IR spectrophotometry—identification

Deuterium (²H), a rare stable isotope of hydrogen, was discovered by Urey *et al.* (1) in 1932. Extensive work by several investigators has felled the long-standing opinion that deuterium oxide (D₂O) is incompatible with life. The successful mass culture of algae, yeasts, and certain bacteria under conditions of full deuteriation has provided a useful source of fully deuteriated sugars, amino acids, proteins, and certain drugs (2–5). Substitution of deuterium for ordinary hydrogen and deuteriated substrates for protio metabo-

lites has been shown to produce profound changes in biosystems. Isotope effects have been categorized as being either primary or secondary. Measurement of the magnitude of the effect is usually useful in distinguishing between the larger primary mass isotope effects and the smaller secondary effects.

The substitution of deuterium in several drug molecules has been the impetus for many recent research contributions. Isotopically altered drugs have shown widely divergent pharmacologic effects. Elison *et al.* (6) demonstrated a reduced analgesic potency of morphine deuteriated in the *N*-methyl group. Nona *et al.* (7) found an increased antifungal activity with fully deuteriated griseofulvin. Foreman *et al.* (8) investigated the *in vitro* Dutch rabbit liver metabolism of selectively deuteriated amphetamines. Their studies show that the ratio of apparent rate constants (*k_H/k_D*) is 1.9, indicating that the deuterioamphetamine is metabolized more slowly than the protioanalog. One major effect of deuterium substitution in drug-producing organisms has been a general suppression of most nonessential metabolism. Mrtek *et al.* (9) demonstrated an inverse effect between the level of deuteriation in *Claviceps* and the amount of clavine alkaloids produced in saprophytic culture. Multi-milligram quantities of highly deuteriated elymoclavine were obtained only through the use of replacement culture techniques (10). Mohammed *et al.* (11) demonstrated a similar effect with several strains of *Penicillium*. Carlstedt (12) obtained small amounts of highly deuteriated penicillin from large numbers of shake

cultures of *Penicillium chrysogenum*. Investigation of the deuterium isotope effect on the antibiotic potency of penicillin may provide important additional information concerning benzylpenicillin, the member of the penicillin group to which all others are compared.

Considerable research has substantiated the hypothesis that one mechanism of antibiotic activity is common to all penicillins. Several workers showed that the presence of a free amino group in the side chain increases Gram-negative activity (13), while Doyle *et al.* (14) noticed that electron-attracting groups in the α -position of the side chain increased acid stability. Similarly, hindering rotation about the single bond in the acyl grouping increases the stability of the molecule toward penicillinase (15). Changes in activity, either in spectrum or relative potency, may be attributed to modifications in the acyl group of the basic penicillin molecule. Repeated attempts to alter the penicillin nucleus have resulted in reduced biological activity when compared to the intact penicillanic derivatives. With respect to benzylpenicillin, it would seem reasonable that deuteration of the benzyl group would alter measurably the antibiotic potency if a significant isotope effect is operating.

The objectives of the present work were to synthesize deuteriobenzyl-*d*₇-penicillin and to compare its antibiotic potency to that of protio benzyl penicillin.

EXPERIMENTAL

Deuteriobenzyl-*d*₇-penicillin—The semisynthetic procedure of Sheehan and Henery-Logan (16) was utilized to prepare the isotopically altered penicillin. Phenylacetyl-*d*₇-chloride was prepared by reacting 1.36 g. (9.15 mmoles) deuteriophenylacetic-*d*₇-acid¹ (98 atom % D) with 4.42 g. (37.2 mmoles) thionyl chloride in a 15-ml. flask with an attached calcium chloride drying tube. The reaction was allowed to proceed at room temperature for 24 hr. with occasional agitation. The excess thionyl chloride, as well as other volatile components, was removed by aspiration. No further purification of the acid chloride was attempted.

Deuteriobenzyl-*d*₇-penicillin was prepared by condensing 0.176 g. (approximately 1.0 mmole) of the partially purified deuteriophenylacetyl-*d*₇-chloride with 0.430 g. (2.0 mmoles) 6-aminopenicillanic acid (6-APA).² The phenylacetyl chloride was added dropwise over a 10-min. period to the stirred chilled solution of 6-APA dissolved in 10 ml. 4% sodium bicarbonate solution and 8 ml. reagent grade acetone. The reaction was conducted at 0–4° with stirring in an open 50-ml. conical flask for 30 min. following completion of addition of the acid chloride. Then the mixture was aspirated to remove excess acetone, and the aqueous mixture was washed once with 5 ml. cold ether A.R. which was discarded. The aqueous portion was layered with 10 ml. cold ether and acidified with 10% cold phosphoric acid to pH 2 as determined by short-range pH paper. The acidified mixture was extracted with two additional 10-ml. portions of cold ether in a small Squibb funnel. The combined ether extracts were washed once with 5 ml. cold water and dried with anhydrous magnesium sulfate. The ether solution was separated from the magnesium sulfate by filtration, and 0.122 g. (1.1 mmoles) 1-ethylpiperidine in 3 ml. dry ether was added to precipitate the deuteriobenzylpenicillin as the 1-ethylpiperidine salt. Twelve milliliters of dry reagent grade acetone was added, and the crystalline precipitate was allowed to stand at approximately –5° overnight. The precipitate was filtered and washed with several portions of cold dry ether. The crystals were dried in a vacuum desiccator at room temperature to constant weight and stored in

the desiccator until used. Yield: 296 mg.; 0.65 mmole; 59% of theoretical calculated on phenylacetic-*d*₇-acid.

Melting points were obtained simultaneously by placing equal size samples of the 1-ethylpiperidine salts of protio benzylpenicillin and deuteriobenzylpenicillin and a mixture of equal parts of each in separate capillary melting tubes. These tubes were inserted in a Mel-Temp melting point apparatus previously heated to 100°. The temperature was increased (3–4°/min.) to 140°. The temperature was then increased slowly (approximately 1°/min.) until melting occurred. NMR spectra of the compounds were determined by using a Varian A-60 Mc.p.s. spectrometer. Each sample (approximately 0.05 mmole) was dissolved in approximately 1 ml. deuterium oxide, using an external TMS standard. All spectra were determined at probe temperature. Integration of the spectra were performed electronically. IR spectra of samples of protio benzylpenicillin and deuteriobenzylpenicillin were obtained using a mineral oil mull in a Perkin-Elmer model 257 grating IR spectrophotometer.

Organisms—A lyophilized pellet of *Staphylococcus aureus* ATCC 6538P was added to 10 ml. Difco Penassay Broth and incubated at 35° for 24 hr. Subcultures were prepared by transferring a loopful of the culture to slants of Difco Penassay Seed Agar and incubating for 18 hr. at 35° prior to storage at 4°. Subcultures were prepared at 7–14 day intervals.

A culture of a clinically isolated penicillinase producing *S. aureus* was obtained.³ This organism was maintained by subculture on Difco Penassay Seed Agar slants at 14-day intervals. Incubation and storage conditions were the same as for *S. aureus* ATCC 6538P.

Solutions—Accurately weighed quantities of authentic samples of the 1-ethylpiperidine salts of protio benzylpenicillin and synthetic deuteriobenzyl-*d*₇-penicillin were used to prepare stock solutions. The stock solutions were prepared by dissolving nearly equal quantities (approximately 0.05 mmole) separately in 0.06 M phosphate buffer, pH 6, and diluting to approximately 1×10^{-9} mole/ml. concentration. Working solutions of desired concentration were prepared by dilution of these stock solutions. All solutions were stored in the dark at 4° for up to 1 week. Solutions for use with the penicillinase organism were prepared identically, except they were diluted to a concentration of 2×10^{-7} mole/ml.

Inocula—A loopful of *S. aureus* ATCC 6538P was transferred to 25 ml. Penassay Broth and incubated at 35° for 18 hr. The full quantity for overnight culture was transferred to 950 ml. Penassay Broth and incubated for 1 hr. at 37.5° prior to use. A loopful of the clinically isolated penicillinase producing *S. aureus* was transferred to 20 ml. Penassay Broth to which yeast extract (1.5 g./l.) had been added, and it was incubated at 35° for 18 hr. The full quantity of inoculum was added to 400 ml. Penassay Broth with added yeast extract (1.5 g./l.) and incubated at 37.5° for 1 hr. prior to use.

Procedure—Assay tubes were prepared by addition of 0.5 ml. of the desired working solution and 9.0 ml. of the inoculated (preincubated) broth to 16 × 125-mm. tubes. Two to four different concentrations were used for each determination, and four tubes were prepared at each concentration. A total of 8 and 10 different concentrations (ranging from 70 to 1200×10^{-12} mole/tube) of deuteriobenzylpenicillin and protio benzylpenicillin, respectively, were used to establish the regression equation. Control tubes were prepared identically, except that 0.5 ml. of 0.06 M phosphate buffer pH 6 (0.0 M benzylpenicillin) was used. Blanks were prepared by incorporating buffer and 0.5 ml. 1:3 formaldehyde USP prior to inoculation with the organism. Both control and blanks were incubated with the test dilutions. The tubes (assay, control, and blank) were arranged randomly in a 48-position rack and incubated in a 37.5 ± 0.1° stirred water bath⁴ for 3 hr. At the end of the assay period, growth was stopped by addition of 0.5 ml. 1:3 dilution of formaldehyde USP. The turbidity was determined by measuring percent transmittancy, using matched round cuvettes (19 × 150 mm.) in a Coleman Jr. spectrophotometer at 650 mμ.

Assay tubes for use with the penicillinase producing *S. aureus* were prepared by placing 0.5 ml. of the desired test solution and 9.0 ml. of inoculated preincubated broth in 16 × 125-mm. tubes.

⁴ Precision Scientific, Chicago, Ill., model 6580.

Eight concentrations were used in each determination. Control and blank tubes were prepared as described. The tubes were incubated in a 48-tube rack in a stirred $37.5 \pm 0.1^\circ$ water bath for 4 hr. Growth was stopped, and turbidity was measured in the same way as before.

RESULTS AND DISCUSSION

Preliminary experiments with protio-phenylacetyl chloride and 6-APA were performed to determine a ratio that would optimize the yield of benzylpenicillin based upon a conservation of the acid chloride. Table I summarizes the results and indicates an optimum ratio of 2:1 (6-APA-phenylacetyl chloride). Yields at the optimum ratio were similar when deuterio-phenylacetyl-*d*₇-chloride was used.

Table II presents a summary of the physical constants for the two isotopic penicillins. The absence of proton signals corresponding to the two α -methylene ($\delta = 3.59$ p.p.m.) and five phenyl protons ($\delta = 7.31$ p.p.m.) in the acyl group indicate the substitution of deuterium in these positions to be greater than 95 atom %. Confirmation of the identity of the synthetic penicillins is assumed on the basis of melting points, elemental analysis, chemical shift of the remaining proton signals in the NMR spectrum, and several IR absorption bands.

Inocula broths were preincubated with overnight cultures of *S. aureus* to obtain organisms in the log phase of growth for the assay, since penicillin exerts its antimicrobial action only on rapidly dividing organisms, i.e., those synthesizing new cell walls. Penicillin has little effect on microbial clones that are metabolizing but not growing or dividing.

Most linear biological assays are commonly based upon a graphical presentation of a transformed measure of some effect that is proportional to the microorganism number, such as turbidity, *versus* log concentration of the test compound (17). Plots of turbidity *versus* dose result in sigmoid curves which may be linearized by suitable transformations. One convenient method is the logarithmic transformation.

In the determination of an isotope effect, the units selected for expression of concentration of penicillin per tube as the independent variable were log (moles $\times 10^{-13}$) rather than a more common expression of weight (microgram or unit) per tube. When dealing with antibiotics of different molecular weights, the toxic effect of drugs on bacterial growth is proportional to the number of moles present but not to the particular weight of the substance used. When concentrations of two isotopically related drugs are expressed as weight per volume, a factor relating the relative change in molecular weight is confounded with the slope of the dose-response relationship. If the molecular weights are not identical as in the case of isotope hybrids, the slope of the regressions for analogs would be anticipated to be different from each other, at least by a factor proportional to the relative molecular weights. Thus, the slopes of the dose-response lines for the two isotopic benzylpenicillins in which log weight is used as an independent variable would not be truly comparable since they differ in their components. A totally linear regression may be expressed as

$$\log \%T = \theta \log \text{moles} + K \quad (\text{Eq. 1})$$

when the independent variable is expressed as moles. In the converse situation, it may be expressed as

$$\log \%T = \theta' \log \text{amt.} + K' \quad (\text{Eq. 2})$$

when the independent variable is expressed as micrograms or units, θ, θ' = slopes of regressions, and K, K' = intercepts. Since the turbidity term is proportional to the moles of substance present, the units of slope relating the concentration term to a measure of the turbidity term may be shown as

$$\theta = \frac{\log \%T}{\log \text{moles}} \quad (\text{Eq. 3})$$

The slope, θ , contains no molecular weight factor. Conversely, if the data are presented as weight of substance, then the components of the slope may be seen as

$$\theta' = \frac{\log \%T}{(\log \text{moles})(\log \text{MW})} \quad (\text{Eq. 4})$$

Table I—Effect of Ratio of Reactants on Yield of Benzylpenicillin

Molar Ratio of 6-APA-Phenylacetyl Chloride	Yield of Benzylpenicillin, ^a %
1.0:1.0	60
1.5:1.0	63
2.0:1.0	69
5.0:1.0	65

^a Calculated on phenylacetyl chloride.

where MW is the mole weight of the substance. Thus, comparing slopes for the isotopic penicillins, from Eq. 3,

$$\frac{\theta_H}{\theta_D} = \frac{\log \%T/\log \text{moles}_H}{\log \%T/\log \text{moles}_D} = \frac{\log \text{moles}_D}{\log \text{moles}_H} \quad (\text{Eq. 5})$$

and since the units are the same,

$$\frac{\theta_H}{\theta_D} = 1 \quad (\text{Eq. 6})$$

Conversely, from Eq. 4,

$$\frac{\theta'_H}{\theta'_D} = \frac{\log \%T/(\log \text{moles}_H)(\log \text{MW}_H)}{\log \%T/(\log \text{moles}_D)(\log \text{MW}_D)} = \frac{(\log \text{moles}_D)(\log \text{MW}_D)}{(\log \text{moles}_H)(\log \text{MW}_H)} = \frac{\theta_H \log \text{MW}_D}{\theta_D \log \text{MW}_H} \quad (\text{Eq. 7})$$

and

$$\frac{\theta'_H}{\theta'_D} = \frac{\log \text{MW}_D}{\log \text{MW}_H} > 1 \quad (\text{Eq. 8})$$

From these equations, using a drug concentration term expressed in moles rather than amount as the independent variable, confounding of the isotope mass differences is avoided. In testing for parallelism between the regression lines for the two antibiotics, if the null hypothesis is accepted, then only random sampling error remains to account for the observed differences between the two slopes, θ_H and θ_D .

The distribution of log $\%T$ has been established to be normal (18). The model developed for this work is univariate, where Y equals log $\%T$ as the random variable. The variance of Y throughout the range of X equals log moles (concentrations of penicillins) was established as homogeneous. Table III summarizes the calculated parameters used in the statistical analysis.

The observed difference between the regression coefficients for the two isotopic benzylpenicillins was tested for level of significance by a t test. The null hypothesis was that there is no difference between the slopes. (See the *Appendix* for the equations used.) No evidence for a difference other than zero was found, and

$SS_{\text{deviations from regression}}$	0.04705	0.02649

parallelism of the regression equations is established on the basis of probability. Furthermore, these data corroborate the suggestion that both deuteriobenzylpenicillin and protio-benzylpenicillin inhibit bacterial growth by the same mechanism. The regression coefficient is a quantitative expression of the association between variables. Since the regression coefficients for protio-benzylpenicillin and deuteriobenzylpenicillin are not significantly different, it is reasonable to conclude that the presence of deuterium in the acyl group of benzylpenicillin does not alter the mechanism of action of the drug with respect to the test organism.

To obtain a valid estimate of a real difference in the antimicrobial potency of the two compounds, the assumption that the two lines are not identical must be tested. Establishment of parallelism between regression lines does not preclude the possibility of identical intercepts. The null hypothesis for the determination of the identity of the two lines tests the significance of the difference between the intercepts of two parallel lines. If the null hypothesis is accepted on the basis of a t test, a statement can be offered in terms of probability that the two regression lines are estimates of the same locus. (See the *Appendix* for summarized calculations.) Application of the test to the data for the two benzylpenicillins indicates that the two intercepts are significantly different ($p < 0.001$). This information, along with the identity of the slopes, indicates that the regression lines for the two benzylpenicillins, although parallel, describe different loci. Satisfaction of the requirement for parallelism and establishment of significantly different intercepts permit the direct comparison of the two lines in terms of horizontal displacement.

The horizontal displacement as a measure of the relative potency of the two drugs may be calculated and confidence limits generated (*Appendix*). Table IV summarizes the results of these calculations. The introduction of deuterium into the acyl group of penicillin has no effect on the mechanism of antimicrobial action. However, a deuterium isotope effect is present and is reflected in a 25% reduction in potency of the deuterium compound compared with its protioanalog.

Comparative assays were performed on several days and grouped together to increase reliability of the relative potency estimate. The absolute antistaphylococcal activity of the antibiotics varied widely from day to day, as indicated by the overlap of data points throughout the concentration range in Fig. 1. Therefore, day-to-day predictions of absolute activity for each antibiotic could not be made. However, day-to-day effects should not be expected to operate on the relative position of the two regression lines with respect to each other (relative potency estimate). On each day the protioanalog regression line was always displaced above the regression line for the deuterioanalog. The variation in displacement as a function of days was assessed for the presence of a significant trend. The log relative potency was graphed as a function of the day on which the experiment was performed (Fig. 2). No significant regression of the displacement on days was found.

Table IV—Relative Potency and Confidence Limits for Isotopic Benzylpenicillin Salt

	Percent
Relative potency (H/D)	125
95% Confidence interval	114–138
99% Confidence interval	106–148

The regression equation calculated for the data in Fig. 2 does not possess a slope that varies significantly from zero ($p \cong 0.70$). As expected, there is no correlation between the log relative potency and the day on which the experiment was completed. If a difference in the rate of decomposition of the two isotopic antibiotics did exist, a significant regression of log relative potency on days could be determined. This information would contribute toward the quantization of the difference in decomposition rate of the two compounds.

Results of preliminary studies obtained with a clinically isolated penicillinase producing *S. aureus* indicate reduced but nearly equal biological activity for the two isotopic penicillins. Direct comparison of the results obtained for *S. aureus* ATCC 6538P and the penicillinase-producing organism may not be appropriate because of the more fastidious nature of the clinically isolated test organism. Further investigation is underway to permit a complete analysis of the deuterium isotope effect on a penicillinase-producing organism (21).

The introduction of deuterium into the benzyl moiety of penicillin G has reduced the antimicrobial activity against a strain of *S. aureus* with respect to the protioanalog. This decrease may result from an altered rate of penetration by penicillin to the site of action in the cell wall or rate of association of penicillin with a crosslinking enzyme. Deuterium introduced into other pharmacologically active compounds has resulted in a decreased rate of binding to the enzyme receptor, with a concomitant increase in the strength of the bond. Since the binding of protio-benzylpenicillin to albumins is mediated by the benzyl moiety and not the β -lactam-thiazolidine nucleus (19), changes in the rate and strength of binding may account for the decreased biological activity of the deuterioanalog. Further work is in progress which will help elucidate the effect of deuterium in the acyl group on the kinetics and extent of binding of benzylpenicillin to macromolecules.

Figure 1—Regression lines calculated for isotopic penicillins. Key: $\hat{Y}_H = 1.46933 + 0.149352X$, and $\hat{Y}_D = 1.454718 + 0.149352X$.

SUMMARY

1. Deuteriobenzyl-*d*₇-penicillin has been chemically synthesized. Phenylacetyl-*d*₇-chloride was first prepared from phenylacetic-*d*₇-acid. Subsequently, the acid chloride was condensed with 6-APA, and the penicillin G was isolated as the 1-ethylpiperidine salt.

2. The presence of deuterium in the benzyl moiety was confirmed using several physical constants.

3. The antimicrobial activity of the deuteriopenicillin was compared to its protoanalogue by a turbidimetric assay procedure using *S. aureus* as the test organism.

4. Identity of the regression coefficients for the isotopic penicillins was established by statistical analysis. This identity indicates that the regression lines are parallel. Parallelism indicates a similar mechanism of antistaphylococcal action for the two isotopic penicillins.

5. Nonidentity of the regression lines was determined using statistical analysis, permitting calculation of a valid estimate of relative potency.

6. The relative potency (H/D), as a quantitative estimate of the deuterium isotope effect, was calculated to be 125%. Neither the 95% nor the 99% confidence interval generated for the estimate includes a relative potency estimate of 100%.

APPENDIX (20)

Slope Test—

$$t = \frac{b_H - b_D}{s_{Db}} \quad (\text{Eq. 1A})$$

where

$$s_{Db} = \left[\bar{s}_{YX}^2 \left(\frac{1}{SS_{\text{dev},H}} + \frac{1}{SS_{\text{dev},D}} \right) \right]^{1/2} \quad (\text{Eq. 2A})$$

and

$$\bar{s}_{YX}^2 = \frac{SS_{\text{dev},H} + SS_{\text{dev},D}}{n_H + n_D - 4} \quad (\text{Eq. 3A})$$

$$t = \frac{2.96}{2.08} \times 10^{-2} = 0.014 \text{ (100 df) (n.s.)} \quad (\text{Eq. 4A})$$

Identity of Lines—

$$t = \frac{\hat{b} - \bar{b}}{s_{(\hat{b} - \bar{b})}} \quad (\text{Eq. 5A})$$

where

$$s_{(\hat{b} - \bar{b})} = \left\{ \bar{s}_{YX}^2 \left[\frac{1}{(\bar{X}_H - \bar{X}_D)^2} \left(\frac{1}{n_H} + \frac{1}{n_D} \right) + \frac{1}{\sum x_H^2 + \sum x_D^2} \right] \right\}^{1/2} \quad (\text{Eq. 6A})$$

and

$$\hat{b} = \frac{\bar{Y}_H - \bar{Y}_D}{\bar{X}_H - \bar{X}_D} \quad (\text{Eq. 7A})$$

and

$$\bar{s}_{YX}^2 = \frac{SS_{\text{dev},H} + SS_{\text{dev},D} + \left[\frac{(b_H - b_D)^2}{1/(SS_{\text{dev},H}) + 1/(SS_{\text{dev},D})} \right]}{n_H + n_D - 3} \quad (\text{Eq. 8A})$$

$$t = 8.86(101 \text{ df})(p < 0.001) \quad (\text{Eq. 9A})$$

Horizontal Displacement—

$$p_x = \left| \bar{X}_D - \bar{X}_H - \frac{(\bar{Y}_H - \bar{Y}_D)}{\bar{b}_{YX}} \right| \quad (\text{Eq. 10A})$$

Confidence Limits of P_x —

$$CL = \left| \bar{X}_D - \bar{X}_H - \frac{(\bar{Y}_D - \bar{Y}_H)}{\bar{b}_{YX}(1 - K^2)} \right| \pm \frac{K}{\bar{b}_{YX}(1 - K^2)} \left[\left(\frac{1}{n_H} + \frac{1}{n_D} \right) \bar{b}_{YX}(1 - K^2) (\sum x_H^2 + \sum x_D^2) + (\bar{Y}_D - \bar{Y}_H)^2 \right]^{1/2} \quad (\text{Eq. 11A})$$

where

$$K = \frac{t^2 \bar{s}_{b_{YX}}^2}{\bar{b}_{YX}^2} \quad (\text{Eq. 12A})$$

and

$$\bar{s}_{b_{YX}}^2 = \frac{\bar{s}_{YX}^2}{\sum x_H^2 + \sum x_D^2} \quad (\text{Eq. 13A})$$

Synthesis of Azabiotin Analogs as Potential Cofactors for Biotin-Dependent Enzymes

HENRY C. WORMSER

Abstract □ As part of a program to synthesize azabiotin analogs and homologs as potential substitutes for the natural coenzyme, several 4- and 5-substituted derivatives of *cis*-hexahydropyrrolo-[3,4-*d*]imidazole-2-one have been prepared. Spectral data and certain side reactions in the synthetic scheme used point to the stereochemistry of the 4-substituted compounds.

Keyphrases □ Azabiotin analogs—synthesis □ Biotin-dependent enzymes—potential cofactor, azabiotin analogs □ NMR spectroscopy—structure □ UV spectrophotometry—structure □ IR spectrophotometry—structure □ Mass spectroscopy—structure

Biotin (I) is a cofactor required for several enzyme-catalyzed carboxylation reactions and, as such, plays a significant role in carbon dioxide fixation reactions. Although a wide variety of compounds closely related

to the vitamin have been prepared, very few have been found to possess significant biochemical and growth-promoting activity in microorganisms and animals.

Recently (1-3), controversy has arisen about the significance of the sulfur atom of biotin with regard to interactions between the enzyme protein and the cofactor. NMR data have indicated that both the ureido oxygen and the sulfur atom should be considered as

potential hydrogen-bond formers with polar groups on a protein to which biotin binds (3, 4) (Tables I and II).

In a preceding paper (5), an approach to the pyrrolo-[3,4-*d*]imidazole nucleus was presented. It was hoped that the method described would be applicable to the preparation of 4-substituted derivatives, ultimately leading to the synthesis of azabiotin. The method, in fact, offers an unequivocal synthetic route to the desired heterobicyclic system. A somewhat modified route had to be adopted to allow the introduction of a side chain on the carbon atom adjacent to the nitrogen of the pyrrolidine ring.

1,3-Dicarbethoxy-4-amino-3-pyrrolines (III and XV in Schemes I and II) had not been employed previously as intermediates for the synthesis of the pyrrolo[3,4-*d*]-imidazole system. Such compounds are readily formed by heating the extensively enolized 1,3-dicarbethoxy-4-pyrrolidones (II and XIV) with ammonium formate in ethanol solution (6, 7). The pyrrolidones were obtained by cyclizations of the Dieckmann type

carried out as described previously (8). Initially, several attempts were made to obtain 1,3-dicarbethoxy-4-ureido-5-methyl-3-pyrroline *via* the condensation of urea with the corresponding pyrrolidone, but the starting materials were invariably recovered unchanged. This failure suggests that the occurrence of this type of reaction is hampered, on the one hand, by a high degree of crowding of the carbonyl group and, on the other, by the poor nucleophilic character of the attacking species. The aminopyrrolines were acetylated in good yields in the presence of acetic anhydride. *N*-Acetyl (IV) proved quite stable. However, XVI, on standing at room temperature, oxidized to the corresponding pyrrole (XVII).

Catalytic reduction with Adams' catalyst of IV, XVI, and XVII afforded stereospecifically in each case the corresponding *cis*-pyrrolidines. However, reduction of the pyrroline XVI with 10% palladium on charcoal gave a 2:1 mixture of *cis*-product XVIII and *trans*-product XXI. The *trans*-products, XXI and VI, were

Scheme 1

Scheme II

independently obtained by base-catalyzed epimerization reactions. The conversion to VI was rather facile, whereas the formation of VI required more drastic conditions. The acetamido pyrrolidines, V and XVIII, were also sought from oximes VIII and XIX, respectively, by catalytic hydrogenation in acetic anhydride. This latter method offered no advantage over the previously outlined procedure and, in both cases, led to the production of mixtures. Hydrazinolysis of ester XVIII under reflux condition afforded exclusively *trans*-hydrazide XXII, whereas milder conditions afforded only *cis*-product XXIII. This latter can be converted to hydrazide XXII by prolonged treatment with hydrazine hydrate under reflux condition or by the addition of sodium ethoxide in ethanol at room tem-

perature. Hydrazide XXII can also be obtained in nearly quantitative yield from the *trans*-ester XXI and hydrazine hydrate in boiling ethanol. These rather facile epimerizations at carbon 3 are significant, because they point to a rather unstable situation arising from steric compression brought about by the *cis* relationships at C-3, C-4, and C-5 of the pyrrolidine ring system and, consequently, the need for relief from this strain. These findings are coupled with similar observations found in the literature (9, 10).

Conversion of hydrazides VII and XXIII to their respective azides and Curtius rearrangement of these intermediates afforded the pyrrolo[3,4-*d*]imidazole derivatives IX and XXIV, respectively. Barium hydrolysis of these two compounds afforded two bicyclic moieties,

^a Hydrochloride salt.

which were functionalized at position 5 to yield the azabiotin analogs listed in Table III.

EXPERIMENTAL¹

1,3-Dicarbethoxy-4-acetamido-3-pyrroline (IV)—A solution of 80.9 g. (0.35 mole) of 1,3-dicarbethoxy-4-amino-3-pyrroline (III) (11) in 250 ml. of acetic anhydride was refluxed for 5 hr. The excess acetic anhydride was removed under reduced pressure, and the crystalline product was collected to yield 89.4 g. (94%), m.p. 123–125°. Several recrystallizations from 95% ethanol gave colorless crystals of IV, m.p. 127–129°. UV spectrum showed $\lambda_{\text{max}}^{\text{EtOH}}$ 274 m μ (e 21,850). IR spectrum (mineral oil) showed bands at 3.01, 5.90, and 6.10 μ .

Anal.—Calcd. for C₁₂H₁₈N₂O₅: C, 53.31; H, 6.71; N, 10.37. Found: C, 53.31; H, 6.64; N, 10.33.

cis-1,3-Dicarbethoxy-4-acetamidopyrrolidine (V)—A solution of 2.0 g. (7.4 mmoles) of IV in 100 ml. of 95% ethanol was hydrogenated in a Parr shaker over 0.2 g. (84.7%) of platinum oxide for 24 hr. Evaporation of the filtered solution under reduced pressure gave a thick, colorless, oily residue, which showed a single spot on TLC (20% methanol in ether). Treatment of the oily product with ether afforded a colorless crystalline material, 1.34 g. (66.5%), m.p. 123–125°. Two recrystallizations from ether gave the analytical sample, m.p. 127–129°. IR spectrum showed bands at 2.90, 3.00, 5.80, and 5.97 μ .

Anal.—Calcd. for C₁₂H₂₀N₂O₅: C, 52.91; H, 7.40; N, 10.29. Found: C, 52.93; H, 7.36; N, 10.20.

¹ Melting points were determined on a Fisher-Johns melting-point stage and a Thomas-Hoover melting-point apparatus which had been calibrated with standard samples. UV absorption spectra were determined in 95% ethanol on a Beckman (model DK2A) recording spectrophotometer. IR absorption spectra were recorded in chloroform (unless otherwise specified) on a Beckman (model 8) recording spectrophotometer. NMR spectra were determined in deuteriochloroform using TMS as reference standard on a Varian A-60A spectrometer. Microanalyses were carried out by Spang Microanalytical Laboratory, Ann Arbor, Mich. Mass spectra were determined on an Atlas CH-4 mass spectrometer with TO-4 ion source. TLC was carried out with silica gel G and silica gel HF₂₅₄₊₃₆₆ (Brinkmann Instruments).

Catalytic Reduction of 1,3-Dicarbethoxy-4-pyrrolidone Oxime (VIII)—A solution of 0.67 g. (2.7 mmoles) of 1,3-dicarbethoxy-4-pyrrolidone oxime (VIII) (12) in 50 ml. of acetic anhydride was hydrogenated at 3 atm. over 0.2 g. (84.7%) of platinum oxide for 24 hr. Evaporation of the excess acetic anhydride afforded a tan crystalline residue, 0.64 g., m.p. 112–115°. Several recrystallizations from ether gave colorless needles, m.p. 122–124°. TLC of this product (15% methanol in chloroform) showed two spots of nearly equal size. Preparative TLC on silica gel HF₂₅₄₊₃₆₆ using the same solvent system gave two crystalline compounds following extraction of the respective bands. The band with the higher *R_f* afforded a substance that was characterized as 1,3-dicarbethoxy-4-acetamido-3-pyrroline (IV), m.p. 126–129°; mixed melting point was not depressed upon admixture with an authentic sample. The band with the lower *R_f* gave *cis*-1,3-dicarbethoxy-4-acetamidopyrrolidine (V), also identical in all respects to the authentic sample prepared by a previous method.

trans-1,3-Dicarbethoxy-4-acetamidopyrrolidine (VI)—A solution of V (0.20 g., 0.74 mmole) and freshly prepared sodium ethoxide (0.05 g., 0.74 mmole) in 15 ml. of absolute ethanol was refluxed for 15 hr. The alcohol was removed under reduced pressure, cold water was added to the residue, and the reaction product was extracted with chloroform. The chloroform extract was washed with water, dried over anhydrous sodium sulfate, and evaporated to dryness. TLC of the residual oil (5% methanol in chloroform) showed two spots: a major spot and a smaller spot corresponding to the starting material (V). Preparative TLC on silica gel HF₂₅₄₊₃₆₆ afforded a colorless oil which crystallized on standing. Recrystallization from isopropyl ether gave 0.13 g. (65%) of colorless needles, m.p. 107–108°. IR spectrum showed bands at 2.91, 3.01, 5.81, and 6.00 μ .

Anal.—Calcd. for C₁₂H₂₀N₂O₅: C, 52.91; H, 7.40; N, 10.29. Found: C, 52.90; H, 7.31; N, 10.19.

cis-1-Carbethoxy-3-hydrazino-4-acetamidopyrrolidine (VII)—A mixture of V (1.0 g., 3.7 mmoles) and hydrazine hydrate (3.0 ml.) was stirred at room temperature for 5 hr. Excess hydrazine hydrate was removed by distillation under reduced pressure, leaving a very viscous oil. Although the product was homogeneous on TLC (20% methanol in ethyl acetate), all attempts to crystallize it failed. IR spectrum (film) showed bands at 3.01, 5.97, and 6.05 μ .

3-Acetyl-5-carbethoxy-*cis*-hexahydropyrrolo[3,4-*d*]imidazole-2-one (IX)—*cis*-Hydrazide (VII) (0.60 g., 2.33 mmoles) was dissolved in 3 ml. of 2 *N* hydrochloric acid, and the cooled solution was treated dropwise with a cold solution of 0.15 g. (2.17 mmoles) of sodium nitrite in 2 ml. of water. The oily, yellow azide was extracted with five 10-ml. portions of ethyl acetate, and the combined extracts were dried over anhydrous sodium sulfate. The filtered solution was then refluxed on a steam bath for 2 hr., and the solvent was evaporated to dryness. On standing, the oily residue crystallized to give 0.46 g. (82%) of IX, m.p. 115–120°. Recrystallization from ether afforded colorless needles, m.p. 119–121°. IR spectrum showed bands at 2.91, 3.05, 5.80, and 5.99 μ .

Anal.—Calcd. for $C_{10}H_{15}N_3O_4$: C, 49.80; H, 6.27; N, 17.43. Found: C, 49.63; H, 6.26; N, 17.55.

***cis*-Hexahydropyrrolo[3,4-*d*]imidazole-2-one (X)**—Bicyclic ureide (IX) (5.0 g., 20.8 mmoles) was hydrolyzed by the method previously described (5). Following workup, 2.49 g. (94%) of a colorless crystalline product was obtained, m.p. 210–214°. Recrystallization from methanol afforded X, m.p. 213–215°; mixed melting point was not depressed by admixture with an authentic sample obtained previously. In addition, 0.042 g. of 5-carbethoxyhexahydropyrrolo[3,4-*d*]imidazole-2-one (XI) was obtained from the reaction mixture, m.p. 221–222°; mixed melting point was not depressed by admixture with an authentic sample.

1,3-Dicarbethoxy-4-amino-5-methyl-3-pyrroline (XV)—A solution of 121.7 g. (0.5 mole) of 1,3-dicarbethoxy-5-methyl-4-pyrrolidone (XIV) (13) and 78.6 g. (1.25 moles) of ammonium formate in 750 ml. of absolute ethanol was heated under reflux for 48 hr. Evaporation of the solvent under reduced pressure afforded a tan crystalline residue. The solid product was treated with 250 ml. of water to dissolve unreacted ammonium formate, and the reaction product was extracted with chloroform. The chloroform extract was washed with water and dried over anhydrous sodium sulfate. Evaporation of the solvent afforded 118.4 g. of crystalline product, m.p. 126–127°. Recrystallization from 95% ethanol gave colorless crystals of XV, 112 g. (93%), m.p. 127–129°. UV spectrum showed $\lambda_{\max}^{\text{EtOH}}$ 274 $m\mu$ (ϵ 21,800). IR spectrum showed bands at 2.85, 2.96, 5.98, and 6.10 μ .

Anal.—Calcd. for $C_{11}H_{18}N_2O_4$: C, 54.52; H, 7.49; N, 11.56. Found: C, 54.63; H, 7.57; N, 11.54.

1,3-Dicarbethoxy-4-acetamido-5-methyl-3-pyrroline (XVI)—A solution of 112 g. (0.46 mole) of XV in 350 ml. of acetic anhydride was refluxed for 12 hr. The excess reagent was distilled under reduced pressure, and the remaining yellow oil crystallized from petroleum ether (b.p. 30–60°), 129.3 g. (98.4%), m.p. 69–70°. UV spectrum showed $\lambda_{\max}^{\text{EtOH}}$ 274 $m\mu$ (ϵ 14,050). IR spectrum showed bands at 3.01, 5.95, and 6.12 μ .

Anal.—Calcd. for $C_{13}H_{20}N_2O_5$: C, 54.91; H, 7.09; N, 9.85. Found: C, 54.77; H, 7.07; N, 9.81.

1,3-Dicarbethoxy-4-acetamido-5-methylpyrrole (XVII)—On standing at room temperature for several weeks, crystalline product XVI turned pale yellow and became quite sticky. TLC revealed two spots. A small portion of the mixture was separated by preparative TLC on silica gel HF₂₅₄₊₃₆₆ (15% methanol in ethyl acetate). The higher R_f band gave the starting material (XVI), m.p. 68–71°; mixed m.p. 68–71°. The lower R_f band gave product XVII, which crystallized from diethyl ether as colorless needles having m.p. 132–133°. This latter product gave no significant UV absorption at 274 $m\mu$ but showed absorption at 216 $m\mu$. IR spectrum showed bands at 2.91, 5.70, 5.90, and 6.20 μ .

Anal.—Calcd. for $C_{13}H_{18}N_2O_5$: C, 55.31; H, 6.43; N, 9.92. Found: C, 55.24; H, 6.24; N, 9.81.

***cis*-1,3-Dicarbethoxy-4-acetamido-5-methylpyrrolidine (XVIII)**—*Method A*—A solution of XVI (3.0 g., 10.6 mmoles) in 100 ml. of 95% ethanol was hydrogenated in a Parr shaker over 0.3 g. (84.7%) of platinum oxide for 24 hr. Evaporation of the filtered solution gave a thick, colorless oil which showed a single spot on TLC (8% methanol in ethyl acetate). Crystallization from isopropyl ether afforded 2.87 g. (95%) of colorless crystals, m.p. 101–103°. The IR spectrum showed bands at 2.91, 5.82, and 5.99 μ .

Anal.—Calcd. for $C_{13}H_{20}N_2O_5$: C, 54.52; H, 7.75; N, 9.78. Found: C, 54.72; H, 7.77; N, 9.73.

Method B—A solution of XVII (1.0 g., 3.5 mmoles) in 50 ml. of 95% ethanol was hydrogenated as in Method A over 0.2 g. (84.7%) of platinum oxide. Following the usual workup, 0.94 g. (93%) of a crystalline product was obtained, m.p. 101–103°. The IR and

TLC mobility of the product were identical to those obtained for the product of Method A.

***trans*-1,3-Dicarbethoxy-4-acetamido-5-methylpyrrolidine (XXI)**—*Method A*—A solution of XVI (0.3 g., 1.06 mmole) in 50 ml. of 95% ethanol was hydrogenated over 0.1 g. of 10% palladium on charcoal for 12 hr. Evaporation of the filtered solution gave a colorless oil which showed two spots on TLC (10% methanol in ethyl acetate). Preparative TLC on silica gel HF₂₅₄₊₃₆₆ afforded 0.19 g. of product XVIII, m.p. 100–102°; mixed melting point was not depressed by admixture with Compound XVIII obtained previously. The lower R_f band gave 0.09 g. of product XXI, which crystallized from isopropyl ether as colorless needles, m.p. 128–129°. IR spectrum showed bands at 2.90, 3.00, 5.80, and 5.95 μ .

Anal.—Calcd. for $C_{13}H_{22}N_2O_5$: C, 54.52; H, 7.75; N, 9.78. Found: C, 54.66; H, 7.74; N, 9.80.

Method B—A solution of XVIII (0.10 g., 0.35 mmole) and freshly prepared sodium ethoxide (0.005 g., 0.07 mmole) in 5 ml. of absolute ethanol was stirred at room temperature for 12 hr. The solvent was removed under reduced pressure, ice was added to the residue, and the product was extracted with chloroform. The chloroform extract was washed with water, dried over anhydrous sodium sulfate, and evaporated to dryness. The tan solid residue (0.082 g., 82%) was recrystallized from isopropyl ether, affording colorless needles, m.p. 128–129°; mixed melting point was not depressed by admixture with the product obtained under Method A.

1,3-Dicarbethoxy-5-methyl-4-pyrrolidone Oxime (XIX)—A mixture of hydroxylamine hydrochloride (3.15 g., 0.045 mole) and sodium acetate trihydrate (6.30 g., 0.046 mole) in 10 ml. of 90% methanol was triturated in a glass mortar. The white suspension was filtered through diatomaceous earth,² and the clear filtrate was added to XIV (4.86 g., 0.02 mole). The solution, which immediately became turbid, was stirred at room temperature for 2 hr., followed by a period of heating at 60° until the reaction mixture failed to give a positive ferric chloride test. Following evaporation of the methanol, the product was dissolved in chloroform, washed with water, and dried over anhydrous sodium sulfate. Evaporation of the chloroform gave a colorless, viscous oil (5.01 g., 97%) which resisted crystallization. IR spectrum showed bands at 2.79, 3.02, 5.79, and 5.94 μ .

Catalytic Reduction of Oxime (XIX)—A solution of oxime (XIX) (4.0 g., 15.5 mmoles) in 75 ml. of acetic anhydride was hydrogenated over 0.2 g. (84.7%) of platinum oxide at 3 atm. for 48 hr. Evaporation of the filtered solution *in vacuo* gave a thick, yellow, oily residue which showed three spots on TLC. The mixture was separated by preparative TLC on silica gel HF₂₅₄₊₃₆₆ (5% methanol in chloroform). The higher R_f band gave 2.4 g. of the starting material (XIX) as an oil (superimposable IR spectra). The intermediate R_f band gave 0.78 g. of a crystalline product (XX), m.p. 186–187°. IR spectrum (mineral oil) showed bands at 3.02, 5.70, and 5.95 μ . An analytical sample was obtained by recrystallization from ethyl acetate, m.p. 188–190°.³

Anal.—Calcd. for $C_{13}H_{22}N_2O_6$: C, 51.66; H, 7.34; N, 9.27. Found: C, 51.60; H, 7.27; N, 9.35.

The lower R_f band gave 0.64 g. of *cis*-ester (XVIII), m.p. 101–102°; mixed melting point was not depressed by admixture with the compound obtained previously.

***trans*-1-Carbethoxy-3-hydrazino-4-acetamido-5-methylpyrrolidine (XXII)**—A solution of 0.14 g. (0.5 mmole) of XVIII in 3 ml. of absolute ethanol was treated with 0.2 ml. of hydrazine hydrate, and the mixture was refluxed for 5 hr. Evaporation of the solvent afforded 0.13 g. of crystalline product, m.p. 195–204°. Recrystallization from ethanol-ether mixture gave 0.11 g. (79.4%) of colorless crystals. The analytical sample had m.p. 211–212°. IR spectrum (mineral oil) showed bands at 3.04, 3.19, 5.96, and 6.05 μ . Mass spectrum (70 ev.) gave a molecular ion at m/e 272.

Anal.—Calcd. for $C_{11}H_{20}N_4O_4$: C, 48.52; H, 7.40; N, 20.57. Found: C, 48.60; H, 7.40; N, 20.58.

***cis*-1-Carbethoxy-3-hydrazino-4-acetamido-5-methylpyrrolidine (XXIII)**—A suspension of 1.99 g. (6.95 mmoles) of XVIII in 6 ml. of hydrazine hydrate was stirred at room temperature for 12 hr. The white suspension was filtered, affording 1.17 g. of a micro-

² Celite, Johns-Manville, New York, N. Y.

³ Compound XX was characterized as an *O*-acetyl pyrrolidinohydroxylamine derivative, since the reduction of oximes presumably involves the intermediacy of hydroxylamines [G. Vavon and Kraljcinovic, *Bull. Soc. Chem. France*, **43**, 231(1928)].

crystalline substance, m.p. 146–152°. Evaporation of the excess hydrazine hydrate *in vacuo* afforded an additional 0.34 g. of product for an overall yield of 79.8%. Recrystallization from ethyl acetate gave 1.24 g. of a crystalline colorless product, m.p. 159–160°. IR spectrum (mineral oil) showed bands at 3.02, 5.85, 5.95, and 6.05 μ . Mass spectrum (70 ev.) gave a molecular ion at *m/e* 272.

Anal.—Calcd. for $C_{11}H_{20}N_4O_4$: C, 48.52; H, 7.40; N, 20.57. Found: C, 48.65; H, 7.46; N, 20.44.

3-Acetyl-4-methyl-5-carbethoxy-cis-hexahydropyrrolo[3,4-*d*]imidazole-2-one (XXIV)—One gram (3.67 mmoles) of hydrazide XXIII dissolved in 4 ml of 2 *N* hydrochloric acid and cooled to –5° was treated dropwise with a cold solution of 0.5 g. (7.2 mmoles) of sodium nitrite in 2 ml. of water. The white precipitate which formed was filtered, m.p. 100–104° dec. The azide was dissolved in 75 ml. of ethyl acetate and heated to reflux on a steam bath for 2 hr. Evaporation of the solvent afforded a yellowish oil which crystallized on standing, 0.62 g. (66%), m.p. 101–105°. Recrystallization from isopropyl ether gave XXIV, m.p. 108–110°. IR spectrum showed bands at 2.89, 3.02, 5.75, and 5.95 μ . Mass spectrum (70 ev.) gave a molecular ion at *m/e* 255.

Anal.—Calcd. for $C_{11}H_{17}N_3O_4$: C, 51.75; H, 6.71; N, 16.46. Found: C, 51.80; H, 6.81; N, 16.59.

4-Methyl-5-carbethoxy-cis-hexahydropyrrolo[3,4-*d*]imidazole-2-one (XXV) and 4-Methyl-cis-hexahydropyrrolo[3,4-*d*]imidazole-2-one (XXVI)—A mixture of 0.60 g. (2.35 mmoles) of XXIV and 3.0 g. (9.51 mmoles) of barium hydroxide octahydrate in 30 ml. of 50% aqueous methanol was refluxed for 12 hr. The creamy suspension was filtered while hot, and the filtrate was evaporated to dryness *in vacuo*. The tan residue was chromatographed over 50 g. of basic alumina, eluting successively with chloroform and 5, 10, 25, and 50% methanol in chloroform. The first three fractions (250 ml. each) afforded 0.40 g. (80%) of a crystalline product, m.p. 145–146°. Recrystallization from ethyl acetate gave an analytical sample, m.p. 145–146°. IR spectrum showed bands at 2.89, 3.09, and 5.82–5.98 (w) μ . Mass spectrum (70 ev.) gave a molecular ion at *m/e* 213.

Anal.—Calcd. for $C_9H_{15}N_3O_3$: C, 50.70; H, 7.09; N, 19.70. Found: C, 50.66; H, 6.99; N, 19.58.

The last two fractions (150 ml. each) gave a white product (0.06 g., 16%), m.p. 206–210°. Recrystallization from ethyl acetate gave XXVI, m.p. 209–210°. IR (mineral oil) showed bands at 3.10 and 5.90 μ . Mass spectrum (70 ev.) gave a molecular ion at *m/e* 141.

Anal.—Calcd. for $C_8H_{11}N_3O$: C, 51.03; H, 7.85; N, 29.76. Found: C, 51.11; H, 7.84; N, 29.69.

***N*-Alkylation of Pyrrolo[3,4-*d*]imidazolones (X and XXVI)**—One part of the secondary amine was refluxed for 12 hr. in the presence of a threefold excess of a nitriloalkyl bromide in the presence

of anhydrous potassium carbonate in absolute ethanol. The salts were filtered, and the filtrate was evaporated to dryness. Recrystallization of the tertiary amines (XIIa, XIIb, XXVIIa, and XXVIIb) was achieved using ethyl acetate.

Hydrolysis to Amino Acid Hydrochlorides (XIIIa, XIIIb, XXVIIIa, and XXVIIIb)—The respective alkylated pyrrolo[3,4-*d*]imidazolone products were heated at 100° for 8 hr. in the presence of concentrated hydrochloric acid. The reaction mixture was evaporated to dryness under reduced pressure, and the crystalline residue was recrystallized from ethanol or ethanol-ether mixtures.

Acetaminophen Prodrugs III: Hydrolysis of Carbonate and Carboxylic Acid Esters in Aqueous Buffers

ELISABETH S. RATTIE, ELIE G. SHAMI*, LEWIS W. DITTERT†, and JOSEPH V. SWINTOSKY†

Abstract □ The hydrolysis rates of four carbonate and five carboxylic acid ester prodrugs of acetaminophen were determined in aqueous buffers at various pH's. The hydrolysis reactions of all the compounds except the hemisuccinate were first order in ester and in hydroxyl ion over the relatively alkaline pH ranges studied. The apparent enthalpies of activation were between 18 and 23 kcal./mole. The results suggest that it should be possible to formulate pharmaceutically stable suspensions of this type of acetaminophen prodrugs.

Keyphrases □ Acetaminophen prodrugs—hydrolysis □ Carbonate, carboxylic acid esters of prodrugs—hydrolysis, aqueous buffers □ Hydrolysis rates—acetaminophen prodrug esters □ UV spectrophotometry—analysis

The synthesis, physicochemical properties, and analgesic activities in rats of several prodrug esters of acetaminophen have been previously reported (1–3). These studies showed that significant differences in analgesic potency and duration of action might be expected following the oral administration of carbonate and carboxylic acid esters of various structures. The expected differences were attributable primarily to differences in the rates of dissolution and absorption of the esters following oral administration. In the case of 4-acetamidophenyl 2,2,2-trichloroethyl carbonate, the peak heights and rates of decline of blood levels of acetaminophen in humans depended upon the particle size of the administered powder (4).

Thus, the dose-time-action profiles of drugs that can be converted into carbonate or carboxylic acid esters might be modified at will by: (a) selecting appropriate

ester structures, and (b) controlling the prodrug's particle size in pharmaceutical formulations. The selection of ester structures on the basis of hydrolysis catalyzed by various body enzymes has been discussed (3), but relatively little information on the chemical stability of drugs of this type has been reported. Therefore, the base-catalyzed hydrolysis of several acetaminophen prodrugs was studied to gain information on their relative hydrolytic stability, which would be useful in the formulation of pharmaceutical dosage forms, and to further elucidate their hydrolysis by esterolytic enzymes.

EXPERIMENTAL

Materials—The synthesis and physical properties of the prodrug esters have been described (2). All other chemicals were reagent grade. A Leeds & Northrup model 7401 pH meter and a Cary model 15 spectrophotometer were used.

Buffer Solutions—Carbonate (pH 10.61, 10.25, 10.0, 9.7, and 9.4)—These buffers were 0.1 M with respect to carbonate ion and were adjusted to ionic strength 0.5 with KCl. The buffers were prepared by dissolving sodium bicarbonate and potassium chloride in distilled water and by adjusting the pH by the dropwise addition of sodium hydroxide.

Phosphate (pH 7.40 and 6.81) and Succinate (pH 5.85 and 5.4)—The method of preparation was similar to that described for the carbonate buffer.

Procedure for Hydrolysis Studies—The hydrolysis rates of the acetaminophen prodrugs in suitable buffers at constant ionic

Figure 1—Plots showing the pseudo-first-order nature of the hydrolysis of 4-acetamidophenyl 2,2,2-trichloroethyl carbonate (II) over the pH range 9.40–10.61 at 25°. The half-lives are shown in Table I.

Figure 2—Plots showing the pseudo-first-order nature of the hydrolysis of 4-acetamidophenyl butyrate (VI) over the pH range 9.70–10.61 at 25°. The half-lives are shown in Table II.

Figure 3—Plot of pseudo-first-order rate constants versus pH for 4-acetamidophenyl 2,2,2-trichloroethyl carbonate (II) over the pH range 9.4–10.61 at 25°.

Figure 4—Plot of pseudo-first-order rate constants versus pH for 4-acetamidophenyl butyrate (VI) over the pH range 9.7–10.61 at 25°.

strength were determined spectrophotometrically by direct UV analysis in the thermostated cell compartment. Fifty milliliters of buffer solution was equilibrated at the approximate temperature in a 50-ml. mixing cylinder. One-half milliliter of anhydrous methanol, containing approximately 0.25 mg. of prodrug, was pipeted into the cylinder, which was then shaken thoroughly. A portion of this mixture was transferred to a 10-cm. sample cell of the spectro-

photometer, and the absorbance at 300 m μ (the absorbance maximum of acetaminophen) was followed until no further change in absorbance could be observed (3). All hydrolysis reactions followed pseudo-first-order kinetics, and plots of $\log (A_{\infty} - A_t)$ versus time were used to determine the first-order rate constants.

RESULTS AND DISCUSSION

Log (*A*_∞ - *A*_{*t*}) versus time plots for 4-acetamidophenyl 2,2,2-trichloroethyl carbonate (II) and 4-acetamidophenyl butyrate (VI) at various pH's are shown in Figs. 1 and 2, respectively. These figures are typical of the hydrolysis behavior of all the prodrug esters and show that the reactions followed pseudo-first-order kinetics at constant pH. Plots of log *k* (the pseudo-first-order rate constant) versus pH were straight lines with slopes essentially equal to 1, showing that the hydrolysis reactions were first order in hydroxyl ion as well as in ester (Figs. 3 and 4). The results of the hydrolysis studies at 25° for the carbonate ester prodrugs are sum-

marized in Table I; those for the carboxylic acid ester prodrugs are shown in Tables I and II were obtained in buffers ranging from 0.03 to 0.5 *M* and in solutions of ionic strength ranging from 0.1 to 0.5. Thus, specific buffer catalysis and salt effects are apparently negligible for these hydrolytic reactions.

The results in Table I show that chlorine substitution in the aliphatic alcohol portion of the carbonate ester (II) markedly

Figure 5—Plot of pseudo-first-order rate constants versus pH for 4-acetamidophenyl hemisuccinate (IX) over the pH range 3.08–10.60 at 25°. The half-lives are shown in Table III.

^a Buffers were 0.1 *M* and adjusted to constant ionic strength 0.5 with KCl.

increased the lability of the ester group to base-catalyzed hydrolysis. The effect was probably due to the electron-withdrawing properties of the chlorine atoms. Chain branching in this alcohol moiety (III) had relatively little influence on the rate of the hydrolysis reaction. Addition of a β -dimethylamino group to the alcohol moiety (IV) caused a dramatic increase in the lability of the ester to base attack. The hydrolysis of IV was first order in hydroxyl ion within the pH region studied (Table I) and can be assigned to an hydroxyl-ion attack on the protonated species.

The results in Table II show that the acetate ester (V) was more labile to base-catalyzed hydrolysis than the ethyl carbonate ester (I). Lengthening the aliphatic chain (VI) or substituting an aromatic hydrocarbon (VII) in the carboxylic acid moiety slightly decreased the lability of the ester group to hydrolysis. Branching of the aliphatic chain near the carboxyl group (VIII) significantly slowed the reaction.

The hydrolysis behavior of the hemisuccinate ester of acetaminophen (IX) was studied extensively because it represents a type of

compound that might display a higher aqueous solubility, especially at higher pH's, than some other prodrug esters. The results shown in Table III and Fig. 5 are very similar to those reported by Gaetjens and Morawetz (5) for phenyl acid succinates. As might be expected, this compound was more stable at low pH's where the free carboxyl group is essentially completely unionized, but it is too labile to be formulated into a suitable pharmaceutical solution under any conditions.

A brief study of the temperature dependency of the hydrolysis reactions showed that, in all cases, the Arrhenius law was obeyed at the pH's studied. A typical Arrhenius plot for Compound I is shown in Fig. 6, and the results for all compounds are summarized in Table IV. The apparent energies of activation are consistent with values previously reported for base-catalyzed ester hydrolyses (5). The conclusion might be drawn from this brief study that stable pharmaceutical suspensions might be formulated from aliphatic carbonate and aliphatic and aromatic carboxylic acid prodrug esters of acetaminophen. A rough extrapolation from pH 10 to pH 5.5, the pH of maximum stability of the acetaminophen amide group

		0.060	42°	

toward hydrolysis (6), yields *t*₉₀ values of approximately 1, 1, 0.2, 0.4, 0.7, and 3.5 years for Compounds I, III, V, VI, VII, and VIII, respectively. These relatively high *t*₉₀ values for the compounds *in solution*, coupled with their relatively low aqueous solubilities (2) and high doses, suggest that it might be possible to formulate pharmaceutical suspensions with some of the prodrug esters that would retain 90% of their potencies for at least 2 years at room temperature.

The more water-soluble prodrugs, *i.e.*, the *N,N*-dimethylethanolamine carbonate (IV) and the hemisuccinate (IX), are too labile to be formulated in liquid dosage forms under any conditions since they hydrolyze very rapidly at both slightly acidic and slightly basic pH's.

Biopharmaceutical Studies on Guaiacol Glycerol Ether and Related Compounds IV: Drug in Blood and Bile

SHUN-ICHI NAITO, MITSUO MIZUTANI, SEIMEI OSUMI, KAZUKO UMETSU, TADAHIRO MIKAWA, YOSHIKO NISHIMURA, and NOBUYOSHI YAMAMOTO

Abstract □ Blood levels of guaiacol glycerol ether mononicotinate in animals were determined, and it appears that the chemical is absorbed with pseudo-first-order reaction by passive transport. Guaiacol glycerol ether mononicotinate does not affect blood pressure and respiration. The compound has no effect on bile flow and the cholesterol value in bile, but it increases the amount of cholesterol excreted in the bile of hypercholesteremic rats receiving polyoxyethylene ethers intravenously. The effect of the metabolites of the compound on cholesterol content in bile was also investigated.

Keyphrases □ Guaiacol glycerol ether mononicotinate—biopharmaceutical studies □ Cholesterol excretion—guaiacol glycerol ether mononicotinate effect □ Colorimetric analysis—spectrophotometer

The hypocholesteremic effects of guaiacol glycerol ether (GGE) and guaiacol glycerol ether mononicotinate (GGE-MN) in animals have been reported (1). In a previous report (2), metabolites of GGE and GGE-MN in rabbit urine were discussed.

Figure 1—Mean plasma level of GGE-MN after oral administration to mice at different doses. Key: A, 100 mg./kg.; B, 200 mg./kg.; and C, 300 mg./kg. GGE-MN was screened through 100 mesh and prepared in suspension form with water. Groups consisted of 10 male mice (dd strain); animals were killed according to the sampling schedule. At time of sacrifice, animals were bled completely, and the equivoluminal mixture of the blood from each group was reserved for analysis. All data concerned with mice show mean values of each group.

The present study was designed to determine the blood levels of GGE-MN in animals and the effects of it and related compounds on bile in animals and the mechanism of hypocholesteremic action.

EXPERIMENTAL

Determination of GGE-MN in Blood (3)—To 1 ml. of plasma in an ice-cold centrifuge tube, 2 ml. of ethanol was added, and the mixture was stirred thoroughly. After the mixture stood for 15 min. in an ice-water bath, 0.5 ml. of the supernatant from centrifugation was mixed with 1 ml. of ethanol, 2 ml. of ammonia buffer solution, and 3 ml. of 10% cyanogen bromide solution. The solution was held at room temperature for 15 min., and absorbance was determined at 400 m μ . A mixture of 0.9 ml. of normal animal plasma and 0.1 ml. of ethanolic GGE-MN solution of known concentration was treated as just described to prepare a calibration curve.

Ammonia buffer solution was prepared to make the equivoluminal mixture of 0.1 M NH₄OH, 0.5 M K₂HPO₄, and 2.0 M NH₄Cl.

Male mice (dd strain, mean body weight 20 g.), female rats (Wistar strain, mean body weight 200 g.), or male rabbits (mean body weight 2 kg.) were used in the study.

Collection of Rabbit and Rat Bile—Rabbits varying in weight from 3.0 to 3.5 kg. were anesthetized with urethan, 1 g./kg. s.c., following a fasting period of approximately 24 hr.

Blood pressure was recorded by a mercury manometer connected

Figure 2—Mean plasma level of GGE-MN after oral administration to rats at different doses. Key: A, 100 mg./kg.; B, 200 mg./kg.; and C, 300 mg./kg. GGE-MN was screened through 100 mesh and prepared in suspension form with water. Each female rat, five rats per group (Wistar), was killed according to the sampling schedule. At the time of sacrifice, each animal was bled completely and the blood was reserved for analysis.

Table I—Pharmaceutical Formulas of GGE-MN Administered to Rabbits

Sample No.	Form	Composition
1	Capsule	GGE-MN, ^a 100 mg.; lactose, 125 mg.; and silicic acid anhydrous, 5 mg.
2	Capsule	GGE-MN, 100 mg.; microcrystalline cellulose, ^b 75 mg.; and silicic acid anhydrous, 5 mg.
3	Tablet	GGE-MN, 100 mg.; microcrystalline cellulose, 84 mg.; CMC-Na, 6 mg.; and talc, 10 mg.
4	Tablet	Film coated on the tablet of Sample 3 by cellulose acetate phthalate solution

^a GGE-MN was screened through 100 mesh. ^b Avicel, Asahi Kasei Kogyo Co. Ltd., Japan.

to a cannula in a carotid artery, and respiration was recorded on a kymograph.

A polyethylene tube was inserted into a bile duct, and the bile was collected for 7.5 hr. following administration of the compound under continuous anesthesia using urethan. At the end of the 1st (control) hr., the compound was administered orally by a stomach tube.

Rats (Wistar strain), varying in body weight from 160 to 190 g., were treated by the same method as the rabbits.

Determination of GGE-MN in Rabbit and Rat Biles—One milliliter of bile instead of plasma was treated according to the method for determination of GGE-MN in blood after oral administration of GGE-MN by a stomach tube.

Collection of Rat Bile at Polyoxyethylene Ethers Hypercholesteremia—Male rats of Wistar strain, weighing from 160 to 190 g., were injected intravenously with 400 mg./kg. of tyloxapol¹ in distilled water, adjusting the volume to 0.2 ml./100 g. of body weight. The test sample was administered intraperitoneally immediately after injection of polyoxyethylene ethers. Collection

Figure 3—Mean plasma level of GGE-MN after oral administration of water suspension to rabbits at different doses. Key: A, 50 mg./kg.; B, 150 mg./kg.; and C, 250 mg./kg. GGE-MN was screened through 100 mesh and prepared in suspension form with water. Four male rabbits weighing about 2 kg. each were used.

Table II—Effect of GGE-MN and Its Related Compounds or Mixtures on Cholesterol Content in Bile of Rats^a Receiving Polyoxyethylene Ethers (400 mg./kg.) Intravenously

Sample	Dose	Total Bile Volume for 7.5 hr. (ml./kg.), Mean Value \pm SE ^b	Total Cholesterol in Bile (mcg./kg.), Mean Value \pm SE ^b
No Polyoxyethylene Ethers Given			
No drug		21.3 \pm 3.1	1730 \pm 445
GGE-MN	300 mg./kg. (i.p.)	28.8 \pm 6.4	2020 \pm 421
GGE-MN	300 mg./kg. (orally)	19.4 \pm 4.3	1578 \pm 312
Polyoxyethylene Ethers, Given i.p.			
Control (no drug)		29.8 \pm 4.8	5398 \pm 536
GGE-MN	300 mg./kg.	26.7 \pm 3.9	6083 \pm 191
GGE-MN	200 mg./kg.	28.5 \pm 8.4	5939 \pm 1513
GGE	300 mg./kg.	27.2 \pm 2.9	7479 \pm 2780
GGE	1 mmole/kg.	25.8 \pm 4.0	5043 \pm 231
GGE	0.7 mmole/kg.	27.9 \pm 6.5	5097 \pm 770
Nicotinic acid	1 mmole/kg.	24.6 \pm 6.8	6366 \pm 964
Nicotinic acid	0.7 mmole/kg.	26.7 \pm 8.1	6642 \pm 1034
Equimolar mixture of GGE and nicotinic acid	1 mmole/kg.	23.0 \pm 3.4	5385 \pm 647
Equimolar mixture of GGE and nicotinic acid	0.7 mmole/kg.	22.6 \pm 9.1	5658 \pm 1130
β -(4-Hydroxy-2-methoxyphenoxy)lactic acid	1 mmole/kg.	26.3 \pm 4.2	6998 \pm 2889
(4-Hydroxy-2-methoxyphenoxy)acetic acid	1 mmole/kg.	27.2 \pm 3.0	7186 \pm 1666
Mesoinositol hexanicotinate	0.3 mmole/kg.	21.6 \pm 6.6	5717 \pm 804
2,6-Pyridine dimethanol bis-(N-methylcarbamate)	0.8 mmole/kg.	21.8 \pm 6.6	7605 \pm 1560

^a Male rats (Wistar strain), weighing 160–200 g., were used. Each group consisted of five rats. ^b SE = standard error.

of bile in each group (five rats per group) was started 18 hr. after injection of the polyoxyethylene ethers (4, 5).

Assay of Cholesterol—Cholesterol in bile was determined quantitatively by the method of Zak (6).

Bilirubin in Rabbit Bile—Bilirubin concentration in bile was determined by the method of Jendrassik and Cleghorn (7).

Nicotinic Acid, Mesoinositol Hexanicotinate, and 2,6-Pyridine Dimethanol Bis(N-methylcarbamate)—These compounds were commercially available.

β -(4-Hydroxy-2-methoxyphenoxy)lactic Acid and (4-Hydroxy-2-methoxyphenoxy)acetic Acid—The compounds were described in the previous paper (2).

RESULTS AND DISCUSSION

It was described previously (3) that unchanged GGE-MN in blood can be determined when barbituric acid buffer solution instead of ammonia buffer solution is used (8, 9).

When GGE-MN is ingested orally, unchanged GGE-MN and free nicotinic acid as the hydrolysis product of GGE-MN were detected in rabbit plasma (3). In the present work, the blood level of GGE-MN was determined as total drug including unchanged GGE-MN and nicotinic acid liberated from GGE-MN by using an ammonia buffer for the determination of GGE-MN.

GGE-MN seems to be absorbed with pseudo-first-order reaction by passive transport in mice and rats, since the blood level peak is almost proportional to the dose when the logarithm of the blood level is plotted against time from plasma data of GGE-MN (Figs. 1 and 2).

¹ Triton WR-1339, Rohm & Haas Co., Philadelphia, Pa., supplied by Winthrop Laboratories, New York, N. Y.

Figure 4—Mean plasma level of GGE-MN after oral administration of Sample 1 to rabbits at different doses. Key: A, 50 mg./kg.; B, 150 mg./kg.; and C, 250 mg./kg. GGE-MN was screened through 100 mesh and prepared in suspension form with water. Four male rabbits weighing about 2 kg. each were used. Capsule contents were removed and used in water suspension form for ingestion.

To select a proper pharmaceutical formulation of GGE-MN for clinical trials, several formulations were prepared as shown in Table I. Blood levels in rabbits when these pharmaceuticals were administered orally were compared with the blood level when a water suspension of GGE-MN was given, and the results are shown in Figs. 3-6. Formulations of Samples 3 and 4 seemed to be unsuitable, as compared to the water suspension or capsule form. Sample 1 appeared better than Sample 2, because there was less fluctuation in blood level of GGE-MN.

The bile from rabbits was collected under continuous urethan anesthesia, and arterial blood pressure and respiration were recorded on a kymograph. It was ascertained that GGE-MN and GGE have no effect upon arterial blood pressure, respiration, bile flow, and total bile volume excreted for 7.5 hr., as compared to untreated control rabbits.

When 300 mg./kg. of GGE-MN was administered orally to rabbits and rats under continuous anesthesia for 7.5 hr., no GGE-MN was observed in the bile within experimental error, and no variation of bilirubin concentration was recognized compared to control animals.

The effect of GGE-MN, GGE, or the equimolar mixture of GGE and nicotinic acid on cholesterol content in rabbit bile was determined, but it was observed that these three samples had no effect on the cholesterol content in bile.

In previous reports (1, 2), GGE-MN and the metabolites, namely, β -(4-hydroxy-2-methoxyphenoxy)lactic acid and (4-hydroxy-2-methoxyphenoxy)acetic acid, showed hypocholesteremic effect on hypercholesteremia caused by intravenous injection of polyoxyethylene ethers to rats.

In the present work, the effect of GGE-MN and its related compounds or the mixtures on cholesterol content in the bile of rats receiving polyoxyethylene ethers was investigated; the results are shown in Table II. No effect on the cholesterol value in bile was observed when GGE-MN was given orally or intraperitoneally to normal rats.

Compounds that clearly increased the amount of cholesterol excreted in the bile of hypercholesteremic rats receiving polyoxyethylene ethers intravenously were 300 mg. (1 mmole)/kg. of GGE-MN, 0.7 mmole/kg. of nicotinic acid, 0.8 mmole/kg. of 2,6-pyridine

Figure 5—Mean plasma level of GGE-MN after oral administration of Sample 2 to rabbits at different doses. Key: A, 50 mg./kg.; B, 150 mg./kg.; and C, 250 mg./kg. GGE-MN was screened through 100 mesh and prepared in suspension form with water. Four male rabbits weighing about 2 kg. each were used. Capsule contents were removed and used in water suspension form for ingestion.

dimethanol bis(*N*-methylcarbamate),² and 1 mmole/kg. of (4-hydroxy-2-methoxyphenoxy)acetic acid, at 95% confidence limit.

Figure 6—Mean plasma level of GGE-MN after oral administration of Samples 3 and 4 to rabbits. Key: A, Sample 3, corresponded to 150 mg./kg. of GGE-MN; B, Sample 4, corresponded to 50 mg./kg. of GGE-MN; and C, Sample 4, corresponded to 150 mg./kg. of GGE-MN. GGE-MN was screened through 100 mesh and prepared in suspension form with water. Four male rabbits weighing about 2 kg. each were used. A mixture of 20 ml. of water and tablets after disintegration was used for ingestion.

² Anginin, Banyu Pharmaceutical Co. Ltd., Japan.

On the contrary, 0.7 mmole/kg. and 1 mmole/kg. of GGE did not increase the amount of cholesterol excreted in bile.

Other compounds such as 1 mmole/kg. of β -(4-hydroxy-2-methoxyphenoxy)lactic acid, 200 mg./kg. of GGE-MN, 300 mg./kg. of GGE, 1 mmole/kg. of nicotinic acid, 0.3 mmole/kg. of meso-inositol hexanicotinate,³ and the equimolar mixture of GGE and nicotinic acid at 0.7- and 1-mmole/kg. doses increased the amount of cholesterol excreted in bile for some rats but did not alter that for other rats in the same group, compared with that of the control group.

On the other hand, all compounds used showed no effect on the total volume of bile excreted, compared with the control group, at 95% confidence limit.

It is interesting that (4-hydroxy-2-methoxyphenoxy)acetic acid, one of the metabolites of GGE and GGE-MN, has the effect of increasing cholesterol in bile in hypercholesteremia caused by intravenous injection of polyoxyethylene ethers. GGE-MN increased the excretion of cholesterol in bile at 1 mmole/kg., but nicotinic acid, one of the metabolites of GGE-MN, also has similar action at the same dose. Therefore, some question still remains whether the increasing effect of GGE-MN on excretion of cholesterol in bile is due to that of GGE-MN itself and/or to the metabolites of GGE-MN *in vivo*. The data concerned with meso-inositol hexanicotinate and 2,6-pyridine dimethanol bis(*N*-methylcarbamate) were deter-

mined for comparison purposes, since these compounds are now widely being used as hypocholesteremic agents.

Chlorpromazine Metabolism I: Quantitative Fluorometric Method for 11 Chlorpromazine Metabolites

PUSHKAR N. KAUL, MICHAEL W. CONWAY*, MERVIN L. CLARK, and JAMES HUFFINE*

Abstract □ Eleven chlorpromazine metabolites have been reacted with dimethylaminonaphthyl sulfonyl chloride to obtain fluorescent products. The reaction has been standardized and adapted to quantitative determination of nanogram amounts of the metabolites. A procedure for application to biological fluids has been developed. Addition and recovery experiments on urine and plasma indicate that the method is applicable to the study of the pharmacokinetic aspects of chlorpromazine metabolites in human subjects.

Keyphrases □ Chlorpromazine—metabolism □ Metabolites, chlorpromazine—quantitative determination □ 5-Dimethylaminonaphthalene-1-sulfonyl Cl—chlorpromazine metabolites reaction—fluorescence □ TLC—separation, identification □ Fluorometry—analysis

Despite a great deal of work done with chlorpromazine (CPZ), the significance of its biotransformation relative to its therapeutic response is not clear. The pharmacokinetics of CPZ and its metabolites in humans remain largely unexplored, possibly because of the limitations in sensitivity and precision of the analytical methods applied to the study of CPZ metabolism. Only recently (1-5) have the analytical methods been developed that offer desirable sensitivity for quantitating CPZ and its metabolites. However, their adaptation to routine determinations in clinical research is limited because these methods can quantitate only a few of the known metabolites (6).

The metabolites listed in Table I possess primary and secondary amino groups and/or hydroxy groups, all of which are capable of reacting with 5-dimethylaminonaphthalene-1-sulfonyl chloride (DNS, dansyl) to yield fluorescent products. Dansyl has been routinely used as an end-group detector in the study of protein structure; its application for quantitation has, to date, remained limited only to amino acids (7). It has also been reported useful as a reagent for detection of some alkaloids (8).

A preliminary account of the dansylation reaction and separation of the dansylated metabolites of CPZ has already been reported (9). This paper deals with the development and standardization of the reaction between 11 CPZ metabolites and DNS. The method has been adapted to quantitative determinations of nanogram quantities of the metabolites. Addition and recovery experiments on aqueous solutions, urine, and plasma are also included.

EXPERIMENTAL

Materials and Equipment—The following were used: 5-dimethylaminonaphthalene-1-sulfonyl chloride (dansyl, DNS), purity grade¹; acetone, benzene, dichloromethane, dimethyl sulfoxide, di-

¹ Fluke-Buchs, Switzerland.

On the contrary, 0.7 mmole/kg. and 1 mmole/kg. of GGE did not increase the amount of cholesterol excreted in bile.

Other compounds such as 1 mmole/kg. of β -(4-hydroxy-2-methoxyphenoxy)lactic acid, 200 mg./kg. of GGE-MN, 300 mg./kg. of GGE, 1 mmole/kg. of nicotinic acid, 0.3 mmole/kg. of meso-inositol hexanicotinate,³ and the equimolar mixture of GGE and nicotinic acid at 0.7- and 1-mmole/kg. doses increased the amount of cholesterol excreted in bile for some rats but did not alter that for other rats in the same group, compared with that of the control group.

On the other hand, all compounds used showed no effect on the total volume of bile excreted, compared with the control group, at 95% confidence limit.

It is interesting that (4-hydroxy-2-methoxyphenoxy)acetic acid, one of the metabolites of GGE and GGE-MN, has the effect of increasing cholesterol in bile in hypercholesteremia caused by intravenous injection of polyoxyethylene ethers. GGE-MN increased the excretion of cholesterol in bile at 1 mmole/kg., but nicotinic acid, one of the metabolites of GGE-MN, also has similar action at the same dose. Therefore, some question still remains whether the increasing effect of GGE-MN on excretion of cholesterol in bile is due to that of GGE-MN itself and/or to the metabolites of GGE-MN *in vivo*. The data concerned with meso-inositol hexanicotinate and 2,6-pyridine dimethanol bis(*N*-methylcarbamate) were deter-

mined for comparison purposes, since these compounds are now widely being used as hypocholesteremic agents.

^a The test samples of CPZ metabolites were supplied by the National Institute of Mental Health, Bethesda, Md.

oxane, ethanol, and pyridine, all nanograde; various phosphate and carbonate buffer salts, A.R. grade; Eastman 100-μ polyethylene terephthalate TLC plates coated with silica gel without fluorescent indicator; Eastman TLC chambers; and Vortex shakers. A recording Aminco-Bowman spectrofluorometer was used to record the fluorescence spectra, while a Turner model 110 filter fluorometer, fitted with a high sensitivity door, was used to quantitate the solutions. A Turner model 330 spectrophotometer was used for pre-determination of the metabolite concentration range in the biological fluids prior to quantitation *via* the dansylation procedure.

Analytical Method—To 0.003–0.3 μmole of CPZ metabolites in acetone in a small screw-capped graduated glass centrifuge tube were added 0.015 μmole of DNS in acetone and 0.05–5 μmoles of phosphate buffer at pH 12, the total reaction volume being made up with acetone to 1 ml. The tube was capped and incubated at 45° for 2 hr. After cooling to room temperature, 10 μl. of the reaction mixture was spotted on a TLC plate and the chromatogram was developed in the appropriate solvent system (Table II). The individual DNS-metabolite spot was cut out, transferred to a 50-ml. centrifuge tube, and eluted with 10 ml. of ethanol by shaking for 1 min. on a Vortex shaker. The tube was centrifuged at 2000 r.p.m. for 2 min., and the supernatant was decanted for subsequent fluorescence analysis.

Table II—Solvent Systems for TLC Fractionation of DNS-CPZ Metabolite Products and the Corresponding *R_f* Values

System	Products	<i>R_f</i> Values
Benzene-acetone (1:1)	DNS-8-OH CPZ	0.67
	DNS-7-OH CPZ	0.50
	DNS-7-OH CPZ-SO	0.39
	DNS-Cl	0.95

	DNS-Cl	0.92
	DNS-NH ₂	0.26
	DNS-OH	0.00

Proof of Dansylation—A brilliantly fluorescent spot appeared on the developed chromatogram, with a *R_f* value different from that of the DNS and those of the reaction controls. On spraying the chromatogram with the Forrest reagent (10), the DNS-metabolite spot became purple, confirming the presence of a phenothiazine nucleus in the product. Figure 1 shows a typical chromatogram for a few of the DNS-metabolite reaction products.

Characteristics of the Dansylated CPZ Metabolites—Table II includes the solvent systems used to fractionate various groups of the dansylated metabolites and also their corresponding *R_f* values. The spectrofluorescent characteristics are given in Table III. Figure 2 represents the excitation and fluorescence spectra of a few representative metabolite products.

Optimum Conditions of Reaction—The optimum conditions were determined by studying only a few metabolites representing a primary amine, a secondary amine, and a phenol. The dansylation reactions were carried out under different conditions, varying one parameter at a time.

Effect of Temperature and Time—Nor₂ CPZ was reacted in the presence of phosphate buffer at pH 12 with an excess of DNS in acetone at 0, 25, and 45°. The reaction product formed was assayed at varying time intervals. Figure 3 shows the time course of the reaction at the different temperatures. Most of the reaction occurred within the first 30 min. Two hours at 45° or 6 hr. at room tempera-

Table III—Fluorescence Characteristics of the Dansylated Chlorpromazine Metabolites in Ethanol

^a From uncorrected spectra recorded on Aminco-Bowman spectrofluorometer. ^b Numbers in parentheses represent secondary peaks.

Figure 1—TLC on a 100- μ Eastman plate developed with benzene-acetone (9,1), showing separation of some of the DNS-reacted CPZ metabolites. Dansylation reaction mixtures of the metabolites were spotted at A, B, and C, whereas at a, b, and c only the metabolites were spotted. D is the DNS-Cl reagent blank without any metabolite. Key: O, fluorescent, nonreactive to Forrest reagent (F.R.); ⊕, fluorescent, becoming purple when sprayed with F.R.; and ⊙, nonfluorescent but purple when sprayed with F.R.

ture seems to be the practical optimum time-temperature combinations.

Effect of DNS Concentration—Figure 4 shows the formation of the dansylated product of Nor₂ CPZ under varying concentrations of DNS at three different reaction times. It appears that the optimal concentration of DNS on a molar basis is at least 5 times the concentration of the metabolite. In the actual procedure, the amount of DNS used was usually in excess of 6–8 times the molar concentration of the CPZ metabolite(s).

Effect of Hydrogen Ion, Buffer Salt, and Water Concentrations—The compounds Nor₁ CPZ, Nor₂ CPZ, and 7-OH CPZ, selected as representatives of three reactive sites in various groups of CPZ metabolites, were reacted with 6–8 times their concentration of DNS at room temperature for 6 hr. but in the presence of varying hydrogen-ion concentrations. Figure 5 shows the pH-dependent profile of the reaction products. In the optimal reaction procedure, pH 12 was used for the dansylation reaction. Figure 6 represents the influence of the buffer concentration on the dansylation, indicating that at least 0.05 μ mole is required for the reaction and that higher concentrations are without any significant effect. In the absence of any buffer, the reaction is extremely slow. Figure 7 shows that the presence of water in the reaction mixture is critical.

Effect of Organic Solvents—Of several organic solvents used, the reaction proceeded only in relatively polar solvents. Of these, acetone seemed to show an optimum effect on the reaction (Fig. 8). Ethanol and methanol, when used as the reaction medium, gave their own dansylated products which interfered in the TLC fractionation. Alcohols were, therefore, avoided in all procedural steps until after the dansylation reaction. Dimethyl sulfoxide also yielded several additional fluorescent spots.

Effects of Atmosphere and Light—Dansylation of Nor₂ CPZ was carried out in nitrogen, oxygen, and air atmospheres, but no effect was observed on the formation of the reaction products. Reactions run in the dark, in ordinary fluorescent room light, and in UV light also did not show any difference in the product concentration.

Effect of Metabolite Concentration—Figure 9 shows the linear correlation of the fluorescence with the metabolite concentration. The linearity holds over a wide range of concentration.

Stability of Reaction Product—DNS-metabolite products appear to be stable with time for at least 24 hr. in solution. The atmosphere and light conditions do not seem to affect the amine-dansylated metabolites on the TLC, but the phenol-dansylated metabolites appear to be somewhat photosensitive.

Figure 2—Excitation (Ex) and emission (Em) curves of DNS-metabolite products. Key: - -, Nor₁ CPZ; and —, 7-OH Nor₁ CPZ-SO (N-reacted).

Adaptation to Studies on CPZ Metabolism—To apply the dansylation assay to the CPZ metabolites in the biological fluids of humans, it was necessary to develop an isolation and purification procedure for the metabolites prior to the dansylation reaction. For fractionation purposes, most of the CPZ metabolites may be classified into unconjugated and conjugated groups. The existing procedures (11–13) for isolation of these metabolite groups were extensively studied, modified, and adapted to quantitative determination via dansylation.

Procedure for Biological Materials—One-tenth to one milliliter of the biological fluid in a screw-capped centrifuge tube was extracted at pH 10 with 3 ml. of dichloromethane (DCM) for 3 min. and centrifuged. A 2-ml. aliquot of the organic layer was trans-

ferred into another centrifuge tube containing 5 ml. of modified Forrest reagent (5% ferric chloride in 50% sulfuric acid). The mixture was shaken for 1 min. and centrifuged. The lower acid layer was read on a spectrophotometer at 528 mμ, and the concentration of unconjugated metabolites extractable at pH 10 was computed from a predetermined standard curve based on the estimations of known CPZ concentrations by the same method. Although this represents only a few of the determinable metabolites, in any individual subject there should be a definite ratio between these and other CPZ metabolites. It should, therefore, serve as an index of the gross concentration of metabolites in the biological material.

After this predetermination, the biological material was diluted to contain 0.2–20 mcg./ml. of the index group metabolites. A 5-ml. sample in a 50-ml. centrifuge tube was adjusted to pH 10 with an excess addition of solid sodium bicarbonate and a dropwise addition of 6 N sodium hydroxide. It was extracted twice with 10 ml. of DCM for 3 min. each, 9 ml. of the organic phase being removed each time and combined. The combined organic extracts were evaporated to dryness under reduced pressure at low temperature on a rotary vacuum evaporator. The residue containing uncon-

Figure 8—Effect of solvents present in the reaction mixture at 45° on the dansylation of Nor₂ CPZ in 2 hr.

jugated metabolites was dansylated and assayed as described under *Analytical Method*.

The aqueous phase containing the polar conjugated metabolites was quantitatively transferred to a 50-ml. round-bottom flask. Sodium hydroxide solution was added to make the contents 2.5 N with respect to the base. The mixture was refluxed for 1 hr., cooled, and neutralized with HCl to pH 9. It was quantitatively transferred to a 50-ml. centrifuge tube and extracted for 2 min. with 20 ml. of DCM. After centrifugation, an 18-ml. aliquot of the organic phase was evaporated to dryness under reduced pressure and low temperature and was subjected to the dansylation assay.

Addition and Recovery—Known amounts of various representative metabolites of CPZ were added to water and to fresh urine and plasma samples. Aliquots of 5 ml. were subjected to fractionation, described under *Procedure for Biological Materials*, and then assayed by the *Analytical Method*. The addition and recovery data are included in Table IV.

Precision, Blanks, and Specificity—Replicate analyses varied less than $\pm 5\%$ in relative fluorescence whereas the precision of the Turner fluorometer was $\pm 3\text{--}5\%$. A general 10% blank was contributed largely by the TLC plates, but this can be avoided by using self-made plates instead of commercial ones. The urine blanks contributed about $\pm 10\%$, whereas plasma blanks varied from 0–10%. The blanks depend on the position of the DNS-metabolite on the chromatogram, since biological blank controls, particularly of urine, fractionate into several dull spots, some of which may occur at the R_f value of some of the DNS-metabolites. However, the high precision of the method, as revealed by negligible variation between the replicates, makes it feasible to subtract the blanks for concentra-

tion computation purposes. The selective extraction processes and chromatographic fractionations make the dansylation method specific to the CPZ metabolites studied.

DISCUSSION

The reaction between dansyl and the primary or secondary amine metabolites of CPZ may be regarded as a nucleophilic substitution of the S_N2 type, wherein the electron-rich amine nitrogen attacks the partially positive sulfur atom of dansyl chloride, the chloride ion departing as the nitrogen-sulfur bond is being formed. A hydrogen attached to the nitrogen may subsequently come off as a proton to form hydrochloric acid.

The dansylation reaction in absence of any buffer proceeds very slowly. This is understandable, since the acid produced during the reaction, if not buffered, will tend to protonate the amine reactant and thus reduce the nucleophile concentration in the reaction mixture. Buffer concentrations above a certain threshold level did not seem to affect the dansylation rate.

Water appears to be necessary for the optimum reaction rate, possibly because it serves as a medium for the buffer to operate. However, its concentration is critical. In quantities greater than 30% of the reaction mixture volume, water tends to hydrolyze the formed dansylated product. Also, excess water would compete with the nucleophilic metabolite for DNS molecules, decreasing the probability for DNS-metabolite formation.

As a solvent for the reaction medium, acetone appears to be the most suitable among those tested. Alcohols, in general, react with dansyl chloride, yielding highly fluorescent products which interfere in the subsequent chromatographic separation of the reaction mixture. Any alcohol should, therefore, be avoided during the dansylation process.

The dansylation assay method shows a high precision in replicates. The various blanks are within the acceptable range. It is encouraging that plasma gave negligible blanks, and the recoveries from it were better than 80%. A linear correlation graph between the concentration of the metabolites and their dansylated fluorescent products extends over a fairly large concentration range. By decreasing the dansylation reaction volume and by increasing the volume spotted on the TLC plates, the sensitivity of the method can be increased 10–50-fold. This should not only make it possible to quantitate minute amounts of the metabolites but also make feasible the detection of yet unknown trace metabolites of CPZ if any exist. The method is currently being applied to studying the pharmacokinetic aspects of CPZ metabolites in schizophrenic patients.

Effect of pH on Monolayers of Cellulose Acetate Phthalate

JOEL L. ZATZ and BEVERLY KNOWLES

Abstract □ At pH values of 2–4, cellulose acetate phthalate monolayers are uncharged and are arranged in a compact, coherent form. An increase in pH brings about partial ionization and marked changes in monolayer organization. The effects of charge repulsion and increased solvation of charged groups cause marked expansion and decreased stability of cellulose acetate phthalate monolayers. The greatest effect of pH on monolayer properties appears to occur in the vicinity of pH 6.

Keyphrases □ Cellulose acetate phthalate monolayers—pH effect □ pH effects—cellulose acetate phthalate monolayers □ Surface pressure—cellulose acetate phthalate monolayers □ Films, cellulose acetate phthalate—compression effect, area

Many properties of interest of polymer coatings depend strongly on the chemical constitution and structural arrangement of the film-forming agent. A better understanding of the molecular properties of polymers would help in interpreting the behavior of pharmaceutical coatings and in predicting the properties of untested formulations. Studies of monolayers of polymers have provided information on polymer structure (1, 2) and interactions (3). The properties of polymer monolayers have been shown to be related to those of free films and enteric coatings (3, 4). Zatz and Knowles (4) examined monolayers of several cellulose esters on subphases of pH 3 and 6.5. The force–area (π – A) isotherms of cellulose acetate butyrate and cellulose acetate stearate were virtually independent of pH. The π – A curves of cellulose acetate phthalate (CAP), on the other hand, were significantly different at the two pH values. In this communication, further experiments on pH effects in CAP monolayers are described.

EXPERIMENTAL

CAP¹ was purified by precipitation from solution in benzene–ethanol (1:1), using *n*-hexane as the nonsolvent. The polymer mass was washed with *n*-hexane and dried *in vacuo* at 30° to constant weight. The material thus purified contained 18% by weight of combined acetyl and 32% by weight of combined phthalyl. It was free of monomers and moisture. Water was deionized and then distilled in an all-glass still. Organic liquids were of reagent grade and were found free of surface-active contaminants (5). Inorganic materials employed were of reagent grade and were not further purified. The trough of the surface balance was made of Teflon and was cleaned using live steam. Surface pressure was determined by the Wilhelmy plate method, using a roughened platinum plate.

The pH of the subphase was adjusted to the desired value, using HCl for low pH values (2–5) and a mixture of K_2HPO_4 and KH_2PO_4 for high pH values (5–8). Sufficient KCl was then dissolved in the subphase to bring the ionic strength to 0.1, except as otherwise indicated. The results at pH 5 were independent of whether the subphase contained HCl or the phosphate buffers, indicating that the buffering agents did not interact with the monolayer. CAP, dissolved in isopropanol–benzene (1:1), was applied dropwise to the surface by means of an Agla micrometer syringe. Essentially the

Figure 1— π – A curves of monolayers of CAP at various subphase pH values: (1) 2, 3, and 4; (2) 5.1; (3) 5.6; (4) 6.1; and (5) 7.0.

same results were obtained when isopropanol–methylene chloride was employed as the spreading solvent (6). After spreading the polymer, 10 or 15 min. was allowed for equilibration. The rate of compression in all experiments was about 0.02 m²/mg./min. Compression was continued until surface pressure no longer varied with available surface area. This limiting surface pressure was reproducible within 0.5 dyne and was taken to be the collapse pressure of the monolayer. All studies were carried out at room temperature (25.5 ± 0.7°).

RESULTS AND DISCUSSION

The π – A curves for monolayers of CAP as a function of subphase pH are presented in Fig. 1. At subphase pH values of 2–4, the identical π – A curve is obtained, indicating that the film is essentially uncharged over this pH range. The polymer molecules would be expected to have the pyranose rings lying flat at the surface to allow the contact of subphase water molecules with all hydrophilic groups in each ring (7). However, even at low values of surface pressure, the repeating groups are not horizontally oriented. Based on the chemical composition of the polymer, the average formula weight per repeating group was calculated to be 317. Each milligram of polymer contained, therefore, 1.9×10^{18} repeating groups. From the amount of material spread and the surface area, one may calculate the area occupied by each group. At a surface area of

Figure 2—Surface area of CAP as a function of pH at various values of surface pressure: (1) 4 dynes/cm.; (2) 6 dynes/cm.; (3) 8 dynes/cm.; and (4) 10 dynes/cm.

¹ Eastman Organic Chemicals.

Figure 3 — π — A curves of monolayers of CAP at various subphase ionic strengths with pH = 6.5: (1) 0.03; (2) 0.1; and (3) 1.0.

2 dynes/cm., the surface area available to CAP molecules is 0.96 m.²/mg., which is equivalent to 51 Å² per pyranose unit. This is very nearly equal to the area occupied by the unsubstituted, horizontally oriented pyranose ring of cellulose (7) and is clearly too small to allow the more bulky repeating groups of CAP to lie flat at the interface. The rings of CAP are, therefore, tilted from the horizontal. In addition, some ester substituents may be folded over or under the main polymer chain. Examination of Dreiding molecular models shows that, in this way, the effective surface area occupied by each pyranose group may be reduced. These considerations, coupled with the relatively high collapse pressure of CAP compared to monolayers of other cellulose esters (4), suggest that uncharged films of this polymer are rather compact and coherent.

An increase in subphase pH (above 4) causes monolayer properties to become pH dependent. In the expanded region (1) (at surface areas greater than about 0.9 m.²/mg.), surface pressure generally increases with a rise in pH. Collapse pressure decreases over the same pH range. In general, the π — A curves tend to become flatter as pH is increased, so that the monolayers appear to be more expanded.

Above a subphase pH of 4, the monolayers are negatively charged due to ionization of the carboxyl group of the phthalate moiety. Repulsion of like charges would be expected to cause an increase in surface pressure according to the relation:

$$\pi = \pi_0 + \pi_r \quad (\text{Eq. 1})$$

where π is the observed surface pressure, π_0 is the surface pressure of an unionized film, and π_r is the surface pressure component resulting from charge repulsion (8). This theory predicts that, at a given surface pressure, a charged film will always occupy a larger area than an uncharged one. Figure 2 shows the effect of subphase pH on the surface area available to CAP molecules at various values of surface pressure. Up to a surface pressure of about 6 dynes/cm., the expected relation appears to hold (Curves 1 and 2, Fig. 2). At higher surface pressures (Curves 3 and 4, Fig. 2), it does not, indicating that charge repulsion is not the only factor involved.

Changes in the adhesion of the monolayer to the subphase must also be considered (2, 9). Charged groups are strongly attracted to the underlying water molecules as a result of ion-dipole forces. Thus, above a pH of 4, as a result of both solvation of charged groups and repulsion of like charges in the film, the polymer structure is rearranged from the compact, coherent form assumed in the unionized state to a more open, extended conformation. The degree of expansion is dependent upon the degree of ionization and, therefore, upon pH. Compression of the charged monolayers causes a fairly rapid increase in surface pressure at large areas because of the contribution of π_r . As the area available to polymer molecules is reduced, solvation of charges may cause the molecules to assume an "accordion" conformation in which ionized groups are immersed in the subphase as completely as possible. The increase in adhesion reduces film stability and causes the charged films to collapse at lower surface pressures.

Support for this mechanism comes from experiments in which the ionic strength of the subphase was varied. The π — A isotherm of uncharged monolayers of CAP (subphase pH = 3) was independent of ionic strength when the latter was varied over a range of 0.001–1.0. On the other hand, changes in salt concentration had a decided influence on the properties of monolayers of CAP at pH values above 4. The π — A results at a pH of 6.5, under conditions of varying ionic strength, are presented in Fig. 3. As the salt concentration is

Figure 4 — Monolayer collapse pressure and $dA/d\pi$ as a function of subphase pH.

raised, the thickness of the electrical double layer around charges on the monolayer is reduced, thus weakening the effects of charge repulsion. Salting out effects are probably also involved, so that solvation and attraction of the polymer for the subphase are reduced. Therefore, increasing ionic strength should cause the charged CAP monolayer to become more condensed and to collapse at a higher surface pressure. These tendencies are observed in Fig. 4.

Inspection of Fig. 1 reveals that changes in monolayer properties are not a smooth function of pH. Instead, there appears to be a fairly narrow range of pH over which substantial changes in collapse pressure and slope occur. Figure 4 shows that the sharpest decrease in collapse pressure takes place at a pH of about 5.8. In the same figure, the reciprocal of the slope of the condensed portion of each curve, $dA/d\pi$, is plotted versus pH; $dA/d\pi$ is related to the compressibility of the film, which is a measure of its compressional elasticity. The sharpest increase in $dA/d\pi$ occurs at a pH of about 6.2 (Fig. 4). Plots of the area occupied in CAP molecules as a function of pH, at surface pressures at which the monolayers are condensed (Curves 3 and 4, Fig. 2), exhibit breaks around pH 6.0. The greatest effect of pH on monolayers of CAP appears, therefore, to occur in the vicinity of pH 6.

The results of this investigation suggest that complete dissolution of coating material may not be necessary for a drug to be released from a dosage form coated with CAP. In the highly acid environment of the stomach, CAP is unionized and probably quite coherent. In the duodenum, where the pH is approximately 6, ionization of accessible phthalate groups will occur, probably causing expansion and allowing penetration of water and ions. Although the coating may not be completely dissolved, sufficient penetration of water molecules through the coating may bring about disintegration or leaching.

Benzyloxyamines as Possible Inhibitors of Histamine Biosynthesis

GLENN H. HAMOR, DAVID M. BRESLOW*, and GERALD W. FISCH†

Abstract □ The synthesis of some 26 *O*-substituted hydroxylamine derivatives is described. Potent anti-inflammatory activity in the carrageenin-induced rat paw edema test is shown by *m*-nitrobenzyl-oxyamine hydrochloride and by *p*-nitrobenzyl-oxyamine hydrochloride. Moreover, *p*-nitrobenzyl-oxyamine hydrochloride also possesses potent inhibitory activity when tested *in vitro* against the histamine-forming enzyme, specific histidine decarboxylase, thus lending additional support to the theory linking histamine to the inflammatory process. Further evidence is given for the bioisosterism of the nitrobenzene and pyridine moieties. The necessity of a free aminoxy group for anti-inflammatory activity is demonstrated.

Keyphrases □ Benzyloxyamines—synthesis □ Anti-inflammatory activity—benzyloxyamines □ Anorexigenic activity—benzyloxyamines □ Antimalarial activity—benzyloxyamines □ Histidine decarboxylase inhibition—*p*-nitrobenzyloxyamine HCl □ IR spectrophotometry—identification

Histamine, a naturally occurring amine possessing a wide range of potent pharmacologic effects, has been suggested as playing an important part in the mediation of various physiologic functions (1). Histamine has been implicated in the cause of such human diseases as asthma and other allergic disorders, peptic ulcers, and vascular headaches (2). Histamine also has been proposed as a mediator of the inflammatory process (3-5).

Therefore, a drug that effectively inhibits the biosynthesis of histamine in man should be of interest.

both as a tool for physiologic investigations and as a potential therapeutic agent.

Histamine is synthesized in mammalian tissues by enzymatic decarboxylation of the precursor amino acid, histidine. Decarboxylation, being the only enzymic process involved, is rate limiting. In the rat, at least, biosynthesis of histamine is catalyzed by a specific histidine decarboxylase enzyme (6). Therefore, inhibition of histidine decarboxylase activity may result in a depletion of histamine from tissues. Levine and other investigators have reported that the histidine decarboxylase inhibitor, 4-bromo-3-hydroxybenzoyloxyamine (I), inhibits histamine synthesis in rats (6) and in man (7). Previous work has shown 4-thiazolylmethoxyamine (II) and 2-amino-4-thiazolylmethoxyamine (III)

to be potent inhibitors, both *in vitro* and *in vivo*, of histidine decarboxylase (8). In addition, these two thiazole compounds possess preliminary anti-inflammatory activity when tested intragastrically against carrageenin-induced rat paw edema (9). Whitehouse and Skidmore

(10) have shown that a number of anti-inflammatory drugs, such as salicylate, indomethacin, and flufenamic acid, are potent inhibitors of histamine formation through their inhibition of the histidine decarboxylase activity of rat pyloric stomach and fetal rat.

The aims of the present work are the synthesis and structure-activity correlation of various alkoxyamines as histidine decarboxylase inhibitors in relationship to histaminergic mechanisms in inflammation.

4-Thiazolymethoxyamine (II) structurally resembles histamine (IV); the methoxyamine side chain is isosteric with the ethylamine group (11) of histamine, while the thiazole ring is isosteric with the imidazole ring. The thiazole ring (V) is also isosteric with the pyridine moiety (VI) as a result of replacement of the sulfur atom, —S—, by the vinylene grouping —CH=CH— (12). However, pyridine, while showing similari-

ties to thiazole and benzene (replacement of —CH= by —N=), may also resemble nitrobenzene (VII), but now by virtue of similar polar characteristics (13).

Therefore, the nitrobenzyloxyamines described herein are isosteric with both pyridylmethoxyamines and thiazolymethoxyamine. This work, as well as reporting the synthesis of the benzyloxyamines containing a nitro substituent, describes the preparation of a number of additional benzene derivatives containing different functional group substituents. These substituted benzyloxyamines may provide data toward a correlation of chemical structure and anti-inflammatory activity, along with any possible relationships to histidine decarboxylase inhibitory potency.

X = Cl, NO₂, CF₃, etc.

Scheme I

Scheme II

The nine benzyloxyamines synthesized are listed and their physical properties given in Table I. These benzyloxyamines were prepared by the method of McKay *et al.* (14) and Martin *et al.* (15), as modified by Drain *et al.* (16); it consists of the alkylation of *N*-hydroxyphthalimide, followed by hydrazinolysis as shown in Schemes I and II. The 13 *N*-benzyloxyphthalimide intermediate compounds thus synthesized are listed in Table II. *N*-(3-Pyridylmethoxy)phthalimide and *N*-(2-pyridylmethoxy)phthalimide are shown in Table III. Table IV lists 1-(*m*-nitrobenzyloxy)urea and 1-(*p*-nitrobenzyloxy)urea, synthesized by reacting the appropriate nitrobenzyloxyamine hydrochloride with potassium cyanate (Scheme III) according to the method

Scheme III

used by Bauer and Dalalian (18) for the preparation of aryloxyureas (19).

BIOLOGICAL RESULTS

Anti-Inflammatory Screening—Selected compounds have been submitted for pharmacological testing; the preliminary results¹ are shown in Table V. Two of the compounds (Compounds 1 and 2 in Table V) have displayed marked anti-inflammatory activity when

¹ The authors thank Riker Laboratories, Northridge, CA 91324, for performing the pharmacological testing.

^a Reported m.p. 137–138° (14).

tested intragastrically against carrageenin-induced rat paw edema (20). The ED₅₀ of 230 mg./kg. for *m*-nitrobenzyloxyamine hydrochloride (Compound 1) may be compared with an ED₅₀ of approximately 180 for aspirin (9). Furthermore, preliminary testing has shown that *p*-nitrobenzyloxyamine (Compound 2), as well as showing anti-inflammatory activity, possesses potent inhibitor activity of a competitive nature when tested against the histamine-forming enzyme, specific histidine decarboxylase, isolated from fetal rat (21).

The differences in toxicity of the disubstituted aminoxyethyl compounds as related to positions of the two groups on the benzene ring should be noted. The *o*-disubstituted compound (Compound 6) is almost three times as toxic (LD₅₀, mg./kg. i.p. mice) as the *meta*-compound and over four times as toxic as the *p*-di(aminoxyethyl)benzene. The anti-inflammatory activity somewhat parallels the LD₅₀; that is, the *ortho*-compound is the most active, followed by the *meta*- and then the *para*-disubstituted compounds.

Anorexigenic Screening—Several compounds have shown anorexigenic activity in reducing the food intake in rats (Table V) (9). The *o*-di(aminoxyethyl)benzene (Compound 6) is the most active, with an ED₅₀ of 64 mg./kg.

Anticancer Screening—The 10 compounds shown in Table V have been submitted to the Cancer Chemotherapy National Service Center (NSC), National Cancer Institute, for screening against the L-1210 lymphoid leukemia test system (22), and they have the following assigned NSC numbers: Compound 1, Table V, NSC 121170; No. 2, NSC 79411; No. 3, NSC 131325; No. 5, NSC 129221; No. No. 6, 123485; No. 7, NSC 123486; No. 8, NSC 123487; No. 9, NSC 132330; No. 11, NSC 130679; and No. 25, NSC 125363. Preliminary results show these compounds lack any significant antitumor activity. However, *m*-nitrobenzyloxyamine hydrochloride (Compound 1) did prolong the life of L-1210-infected mice 124% (compared with controls at 100%). In general, an increase in survival value of 125% is necessary for further experimental work by NSC.

Antimalarial Screening—The 10 compounds shown in Table V have been submitted to Walter Reed Army Institute of Research for testing for antimalarial activity. Preliminary results indicate a lack of potency, with the exception of *m*-nitrobenzyloxyurea (Compound 25) which is active against the parasite (*Plasmodium gal-linaceum*) in the mosquito (*Aedes aegypti*), giving 100% abnormal oocysts and 100% complete sporozoite suppression at 0.1% con-

centration (but inactive at 0.01 % concentration). However, *m*-nitrobenzyloxyurea was inactive against malaria in chicks (*P. gallinaceum*) and in mice (*P. berghei*).

DISCUSSION

The lack of, or greatly reduced, anti-inflammatory activity of the *m*-chlorobenzyloxyamine hydrochloride (Compound 3) and the other nonnitro-substituted benzyloxyamines gives further evidence for the bioisosterism of the nitrobenzene and pyridine (and thiazole) ring systems. In addition, the lessened activity of *m*-trifluoromethylbenzyloxyamine hydrochloride (Compound 5) as compared to *m*-nitrobenzyloxyamine hydrochloride (Compound 1) is in contrast to reports of the biological equivalence of replacement of NO₂ with CF₃ (23, 24).

The necessity of a free amino group for anti-inflammatory activity may be demonstrated by the essential inactivity of *N*-(*m*-nitrobenzyloxy)phthalimide (Compound 11, Table V). In addition, Schiff base derivatives of *m*-nitrobenzyloxyamine are devoid of anti-inflammatory activity (25). Also, whereas 4-thiazolylmethoxyamine dihydrochloride (II) possesses activity *versus* carrageenin-induced rat paw edema, several nitrogen-substituted Schiff base derivatives are inactive (9). Furthermore, 4-thiazolylmethoxyurea and 1-phenyl-3-(4-thiazolylmethoxy)urea show no *in vitro* inhibition of histidine decarboxylase (8, 19, 26). However, *m*-nitrobenzyloxyurea (Compound 25) and 4-thiazolylmethoxyurea (19) displayed moderate anti-inflammatory activity.

These preliminary results showing histidine decarboxylase inhibitory activity for *p*-nitrobenzyloxyamine hydrochloride (Compound 2) and marked anti-inflammatory activity for *m*-nitrobenzyloxyamine hydrochloride (Compound 1) and for the *para*-isomer lend additional support to the theory linking histamine to the inflammatory process.

Further work will be directed toward synthesis of additional alkoxy amines as possible active site-directed irreversible inhibitors according to the hypothesis of Baker (27, 28). These new inhibitors may be highly specific for the histidine decarboxylase involved in the inflammatory process by virtue of the rigid positioning requirements imposed by: (a) the necessity of a reversible fit within the enzyme activity site (formation of an aldimine bond between the amino group and pyridoxal phosphate displacing the lysyl epsilon-amino

group of the enzyme); (b) fitting an adjacent hydrophobic area; and (c) exoalkylation outside the active site.

As additional data are accumulated, it may be possible to apply regression analysis (29) to clarify the exact hydrophobic, steric, and electronic requirements to accommodate the enzyme active site. Successful elucidation of the enzyme active site may enable the design and synthesis of extremely potent, and highly specific, histidine decarboxylase inhibitors which, hopefully, may find application in the treatment of inflammatory diseases.

EXPERIMENTAL

The syntheses of representative compounds reported in Tables I–IV are described here. All melting points were taken on a Fisher-Johns hot-stage and are uncorrected. Elemental microanalyses were performed by Elek Microanalytical Laboratories, Torrance, Calif. The IR spectra of selected compounds were determined on a Perkin-Elmer infracord apparatus in mineral oil mulls and are in agreement with the assigned structures.

***N*-(*m*-Nitrobenzyloxy)phthalimide (Compound 11)**—In a 500-ml. round-bottom flask, fitted with a reflux condenser and heating mantle, were placed 75 ml. of acetonitrile, 10.5 ml. (0.075 mole) of triethylamine, and 12.4 g. (0.075 mole) of *N*-hydroxyphthalimide.² After heating to effect solution, 13.0 g. (0.075 mole) of α -chloro-*m*-nitrotoluene³ was added, and the solution was refluxed for 2 hr. Upon cooling, filtering the resultant solid, adding excess water to the filtrate to obtain a second crop, and recrystallizing the total product from acetone–water, 16.4 g. (75% yield) of a white crystalline solid, m.p. 186–187°, was obtained.

***m*-Nitrobenzyloxyamine Hydrochloride (Compound 1)**⁴—To a solution of 29.8 g. (0.1 mole) *N*-(*m*-nitrobenzyloxy)phthalimide (Compound 11) in 250 ml. warm anhydrous ethanol was added 5 ml. (0.1 mole) hydrazine hydrate (99%), and the solution was refluxed for 2 hr. The reaction mixture was cooled and the precipitated phthalhydrazide removed by filtration. Addition of excess ethanolic HCl to the filtrate, followed by reduction in volume by evaporation,

gave 16 g. (80%) white solid, m.p. 160–165°. An analytical sample, m.p. 164–166°, was obtained by three recrystallizations from 1-butanol.

O,O'-(*o*-Phenylenedimethylene)bishydroxylamine Dihydrochloride (Compound 6)—To 74 g. (0.45 mole) of *N*-hydroxyphthalimide, dissolved in 175 ml. acetonitrile and 50 ml. (0.36 mole) triethylamine by warming, was added 40 g. (0.15 mole) α,α' -dibromo-*o*-xylene,³ followed by 4 hr. of refluxing. The chilled mixture was filtered and the precipitate washed with cold water to give 64 g. (80%) of the bisphthalimido intermediate (Compound 20), m.p. 282–284°. An analytical sample, m.p. 284–285°, was obtained by two recrystallizations from pyridine.

To 42.8 g. (0.1 mole) of Compound 20 in 300 ml. anhydrous ethanol was added 10 ml. (0.2 mole) hydrazine hydrate (99%), and the mixture was refluxed for 3 hr. The precipitated phthalhydrazide was removed by filtration of the cooled reaction mixture. Addition of excess ethanolic HCl to the filtrate gave 21.6 g. (90% yield) of the desired bisaminooxy compound (Compound 6) as a white solid, m.p. 211–214° dec. An analytical sample, m.p. 222–224° dec., was obtained by four recrystallizations from chlorobenzene-methanol.

***m*-Nitrobenzyloxyurea (Compound 25)**—To 20.5 g. (0.1 mole) *m*-nitrobenzyloxyamine hydrochloride (Compound 1) dissolved in 150 ml. H₂O was added 8.1 g. (0.1 mole) potassium cyanate. The desired urea derivative precipitated out almost immediately and was filtered, washed with cold H₂O, and recrystallized from acetone to give 16.5 g. (78%) of analytically pure, white solid, m.p. 130–131°.

New Method for Assaying Antiapomorphine Activity in Pigeons

W. K. VAN TYLE and A. M. BURKMAN

Abstract □ An electronic monitoring system, which was capable of estimating and recording the intensity of the apomorphine-induced pecking syndrome, was evaluated with regard to its ability to function as an attendant-free assay instrument. Instrument responses were compared with responses derived from a visual recording technique which has been routinely used since 1960. The new monitoring system provides accurate and highly reliable estimates of the desired biological parameters.

Keyphrases □ Apomorphine-induced pecking syndromes, pigeons—assay method □ Pecking syndrome, pigeons—chlorpromazine HCl, methdilazine HCl inhibition □ Monitoring system, electronic—pecking syndrome, pigeons □ Inhibitor potency assay—apomorphine-induced pecking syndrome

Without doubt, the most familiar pharmacological property of apomorphine is its ability to evoke emesis in a variety of animal species. From pharmacodynamic, therapeutic, and toxicological standpoints, the emetic characteristics of the compound have been the subject of greatest attention through the years. On the other hand, interest in the nonemetic activities of apomorphine, particularly in animals refractory to its emetic propensities, has been sporadic, desultory, and largely uninspired. Some of these nonemetic responses are enumerated by Krueger *et al.* in their monumental "The Pharmacology of the Opium Alkaloids" (1).

Among the nonemetic responses to apomorphine is a curious "Zwangspicken" or compulsive pecking in pigeons, which was described by Amsler in 1923 (2). Interest in Amsler's "Zwangspicken" response in pigeons (for whom sublethal doses of apomorphine are *not* notably emetic) remained virtually nonexistent until 1957 when Burkman *et al.* (3) and Koster (4) described, in somewhat greater detail, this apomorphine-induced effect. The response was referred to by Koster as a "feeding hallucination" and by Burkman *et al.*, less imaginatively, as a "pecking syndrome."

Quantitative data describing the characteristics of the syndrome were published, simultaneously and independently, by Burkman (5) and by Dhawan and Saxena (6). Since then the syndrome has attracted increased attention as an example of drug-induced stereotypical behavior. The pecking syndrome is best characterized by a single symptom: a continuous, forceful, repetitive pecking by the pigeon on the floor, walls, and roof of the cage in which it is placed. Although the syndrome has been quantified in terms of intensity (7) and in terms of an all-or-none response (8), the intensity technique is regarded as both more reliable and more efficient than the quantal method. Therefore, the authors have directed most of their efforts toward improving their ability to monitor response magnitude.

The authors have successfully automated this method of quantifying the pecking syndrome and thereby have made what they believe to be a major technical im-

provement. Details relating to the construction of the instrument have been published (9).

This article describes and evaluates the automated instrument method for assessing the potency of apomorphine-inhibiting phenothiazines.

EXPERIMENTAL

Animals—Adult birds (1–2 years of age) of both sexes were housed in individual cages at a room temperature of 20–25° and conditioned to a 12-hr. light cycle. Birds retained for assay were those whose responsiveness to apomorphine HCl had been previously evaluated. Those that did not respond to intramuscularly administered doses of 0.5 mg./kg. were rejected as unsuitable. Thus, birds used in these experiments were *not* randomly selected from a general population, but rather were representative of a stock colony of birds having a high sensitivity to apomorphine.

All drugs used in the assays were dissolved in sterile 0.9% saline and injected intramuscularly.

Determination of Syndrome Intensity: Visual Technique—Each pigeon received the requisite dose of apomorphine HCl and was immediately placed in a wire mesh observation cage 22.9 × 38.1 × 22.9 cm. (9 × 15 × 9 in.). At 5–10-min. intervals, an observer made 1-min. counts of the bird's responses. The duration of observation was determined by the length of the period during which the animal exhibited the pecking syndrome. Since the syndrome was easily interrupted by sudden noises that distracted the bird, it was necessary to conduct the experiments in a sound-attenuated environment. The number of animals

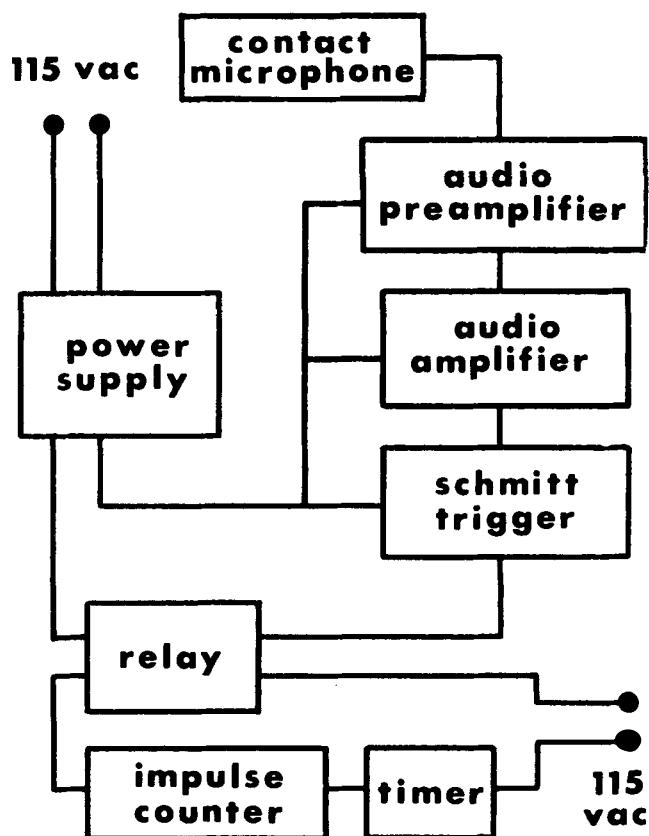

Figure 1—Block diagram of one channel of the pecking syndrome monitor.

Table I—Intensity of Apomorphine-Induced Pecking Syndrome as Determined by Two Monitoring Methods

	Method	
	Visual	Instrument
Number of pigeons	32	32
Mean cumulative response ^a	4395 ± 395	4440 ± 407
Coefficient of variation ^b	0.509	0.519

^a Mean CPR ± standard error. Responses induced by apomorphine HCl, 0.5 mg./kg., i.m. No significant difference could be detected between methods. ^b Ratio of the standard deviation of a CPR sample to the mean CPR of that sample. No significant difference could be detected between methods.

that could be monitored simultaneously depended upon the observer's experience and his ability to make minute counts reliably. Generally, no more than six birds could be effectively monitored by a single person.

Response rate (pecks per minute) plotted against time from injection yielded a curve, whose parameters, suitably computed, provided such information as onset time, duration, peak rate, time-dependent rate changes, and the cumulative pecking response (CPR). The CPR, which has proved to be the most useful expression of response intensity, was determined by measuring the area under the rate-time curve with the aid of a compensating polar planimeter. Using a suitably calibrated instrument, the resulting total area was translated into total pecks, i.e., the CPR.

Determination of Syndrome Intensity: Automated Instrument Technique—The design of the electromechanical CPR monitor was based upon the results of preliminary efforts to adapt an audio-pickup system for continuously recording the sharp, microphonically distinct clicks of the bird's beak as it struck the metal cage (9). The sounds that accompanied the compulsive pecking behavior provided a quantifiable variable which readily lent itself to machine processing.

To monitor apomorphine-induced pecking effectively, each channel of the system required: (a) a sensitive detector to pick up and transmit signals generated by sounds or vibrations developed as a result of the bird's pecking movements, and (b) a means for amplifying the detector signal so that (c) an electromechanical relay and impulse counter could be activated by each discrete pulse. Also essential was the incorporation of a device to improve the instrument's capacity to discriminate between pecking activity and fortuitous noises and movements unrelated to pecking.

The monitor design adopted for use is diagrammed in Fig. 1. The use of a simple contact microphone, bolted to the rear panel of a stainless steel observation cage 22.9 × 38.1 × 22.9 cm. (9 × 15 × 9 in.), served as a transducer. Environmental noises, bird vocalizations, and other air-transmitted sounds were incapable of activating the microphone. The unit, however, was sufficiently sensitive to pick up virtually all desired responses. Signals generated by the microphone were transmitted to a solid-state audiopreamplifier and audioamplifier. A Schmitt trigger, incorporated in the system, is a modified bistable multivibrator, which is widely used as a voltage discriminator in such devices as nuclear radiation pulse height analyzers. It served much the same function here. Input signals above a preset level provided an output signal sufficient always to activate the relay which, in turn, operated the impulse counter. This ensured that clean, artifact-free counts could be obtained. A 12- and 30-v. d.c. regulated power supply provided the energy for operation.

Although the monitor was incapable of being influenced by air-transmitted sounds, loud noises and strong visual stimuli easily distracted the animals under observation. This distraction was reflected in a distortion of the pecking response parameters. Thus, it was still necessary to control the environmental conditions under which responses were monitored. This was most easily accomplished by placing the caged pigeons in a sound-attenuating chamber constructed for that purpose. In addition, the monitor itself was placed in an adjoining room where it could be conveniently examined without disturbing the birds. This precaution further decreased the opportunity for the intrusion of environmental distortions.

Paired-Comparison Experiment—Evaluation of the utility of the pecking syndrome monitor was based on results of two experiments designed to determine the accuracy and reliability of the data supplied by the instrument.

The first experiment involved estimating syndrome intensity for a group of pigeons by recording their responses, using both the visual and instrument methods simultaneously. Thirty-two birds of mixed sex were injected intramuscularly with apomorphine HCl, 0.5 mg./kg., and placed in observation cages. The cages were placed, in turn, in the sound-attenuating chamber, and the monitors were activated. Observation ports allowed the experimenter to see the birds and to make the necessary visual counts. The CPR over its entire duration (about 2 hr.) served as the index of syndrome intensity, and this was determined for each bird by both methods. The conditions of the experiment satisfied the requirements of a "paired-comparison" design; evaluation of the visual and instrument methods was made by examining the magnitude of observed within-animal (between-methods) differences.

Inhibitor Potency Assay—The second experiment was a model assay similar to those repeatedly employed in studies of psycholeptic phenothiazines (10, 11). The apomorphine-inhibiting activities of two compounds, chlorpromazine HCl (CPZ) and methidiazine HCl (MDZ), were determined in terms of their ability to suppress the syndrome evoked by a standard dose of apomorphine HCl. The experiment was designed as a 4-point relative potency assay, utilizing 24 pigeons. Four groups of six birds received, initially, intramuscular injections of 0.5 mg./kg. of apomorphine HCl (1.6 μmole of base/kg.) 8 days prior to the start of the assay. The CPR values obtained served as controls against which the inhibiting influence of the phenothiazines was measured. On the assay day, each group of animals was premedicated with a single high or low dose of either CPZ or MDZ. All doses were expressed in terms of moles of base per kilogram body weight. Fifteen minutes after phenothiazine administration, apomorphine HCl, 0.5 mg./kg., was injected and the CPR was redetermined. Inhibition at each dose level was recorded as percent reduction of the control CPR. For each inhibitor, a log dose-probit response line was constructed, and the relative potency of MDZ was assessed using CPZ as the reference standard.

All activity data were collected by simultaneous use of visual and automated instrument techniques so that comparison could be made between methods.

RESULTS

Paired-Comparison Experiment—The characteristics of syndrome intensity are summarized in Table I. Thirty-two birds supplied two samples of CPR values; a comparison of these samples, in terms of sample means and dispersions about sample means, revealed that no significant difference existed. The computed *t* statistic had an associated *p* > 0.6. The visual and instrument techniques, therefore, provide equivalent estimates of syndrome intensity.

Inhibitor Potency Assay—The results are summarized in Table II. Both methods provided virtually identical estimates of median inhibitory doses (ID₅₀'s), slopes, and relative potency. The parameter estimates were so strikingly similar that a reliable conclusion could be drawn without recourse to further statistical manipulation and testing. No significant differences could be detected between the activity parameters derived from visual and instrument methods.

DISCUSSION

Although the visual technique for quantifying pecking syndrome intensity employed in earlier studies has proved to be highly reliable, its use requires an experienced observer, one who has been trained to make selective, unbiased, and reproducible counts. Even under the best conditions, an observer can usually program the simultaneous visual monitoring of no more than six birds. Under standardized conditions of the phenothiazine assays, the period of observation lasts approximately 2 hr., and the preliminary animal weighings and premedication increase the period to about 2.5 hr. Thus, the number of man-hours required to satisfy the needs of even a comparatively simple 4- or 6-point crossover relative potency assay becomes enormous, and the assay technique has been relatively inefficient in terms of the utilization of an investigator's time.

This kind of inefficiency now seems unnecessary, since the syndrome can be readily quantified by an instrument method which does not require the full and constant attention of the investigator during the recording session. Furthermore, use of the instrument that automatically accumulates and records compulsive pecking

^a Median inhibiting dose (95% confidence limits); in unit of micro-moles of base per kilogram body weight. ^b Slope of the dose-response line ± 95% confidence limits; in units of percent/log dose. ^c Potency of MDZ (95% confidence limits) relative to CPZ.

activity obviates deriving CPR values by curve plotting and area computing manipulations. And, finally, the comparatively unsophisticated device can be fabricated with standard and readily available components.

It seems clear from the results summarized in Tables I and II that the instrument monitor provides data as accurate and as reliable as those provided by the more tedious visual method. The results of the inhibitor potency assay, particularly, demonstrate the utility and applicability of the instrument method for such experiments.

Drug Permeation through Thin Model Membranes I: Development of a Polymeric Model Biomembrane

KARL A. HERZOG and JAMES SWARBRICK

Abstract □ The development of a polymeric nonporous model membrane, containing natural membrane components, and its use in a two-compartment transport cell are reported. Consideration was given to the polymer used to form the polymer matrix, membrane thickness, the amount and type of biological material incorporated, and the effect of nonbiological additives. The effect of these changes on the transport properties of the various membranes were monitored in terms of k_d , the rate of disappearance constant of salicylic acid, from the pH 2.0 compartment of the transport cell. As a result of these studies, a standard model biomembrane was designed, containing 44% ethylcellulose, 44% biological materials, and 12% mineral oil, dry weight of the membrane. From the lack of solvent flux under experimental conditions and the first-order disappearance of salicylic acid, it appears that the polymer membrane mimics the functionality of natural membranes insofar as passive diffusion is concerned.

Keyphrases □ Biomembrane model, polymeric—drug permeation □ Membrane, nonporous—natural membrane components □ Drug absorption, passive—model membranes □ Transport rates—drugs through model membranes

Model membranes have been employed in attempts to develop *in vitro* model systems whose transport characteristics correlate with *in vivo* passive drug absorption. In addition to permitting systematic study of the many variables affecting the *in vivo* process, these model systems also act as a potential tool for assessing the

ability of new medicinal agents to cross the gastrointestinal membranes and similar barriers. Although considerable work has been reported concerning a number of models, significant accomplishments are yet to be made in elucidating the transport process occurring *in vivo* and in producing *in vitro* models that more closely reflect the functionality of biological membranes.

The following properties may be considered desirable in any model system for passive drug absorption:

1. The membrane should be thin, with a low volume ratio of membrane to surrounding aqueous media. This elimination of the membrane "volume" significantly reduces drug retention within the membrane phase.

2. Transport selectivity of the drug(s) in question should be based on solubility in a homogeneous barrier rather than on dialysis through a microporous structure.

3. The membrane should be sufficiently durable to withstand extended experimental procedures without loss of integrity which might lead to changes in the transport characteristics of the membrane.

4. It should be possible to demonstrate a correlation between *in vitro* transport rates and *in vivo* absorption rates.

Model membranes can be conveniently classified into two groups. First, some membranes are essentially bio-

experimental models, whose principal research function has been elucidation of some of the biochemical and biophysical aspects of the ultrastructure of the biological membrane and determination of the role of the constituents in conducting the vital physiological functions accorded to the biomembrane. Such systems are invariably "constructed" on a molecular level, prime examples being monolayers (1), black (bimolecular) lipid membranes (2), and liposomes (3). The second group of model membrane systems are those employed primarily to study transport phenomena. Such systems are of particular relevance to *in vivo* drug-absorption processes. These membrane systems, employed to study this phenomenon on an *in vitro* basis, are termed biotransport models. Many variations of these models were utilized in the preceding decade to study the kinetics of drug transport and the many variables which are held to influence the *in vivo* process.

Biotransport model membrane systems may be divided into natural and artificial (nonliving) systems. The former include goldfish (4) or the everted sac technique (5), which has received recent attention in biopharmaceutical studies (6, 7). Skin sections stripped from hairless mice have been used as model systems to study chloramphenicol transfer (8). There are limitations to all of these approaches, although, understandably, a living system is to be preferred when experimental conditions permit.

Artificial (nonliving) membrane systems fall into two basic categories: those utilizing a liquid barrier and those employing a solid barrier. The liquid membrane system was one of the earliest model membrane systems applied to pharmaceutical research (9-11). The underlying principle of the model is the separation of the two aqueous phases, representing the plasma and the gastrointestinal lumen, by a liquid oil phase which simulates the lipid nature of the biological membrane. Much of the kinetic groundwork was carried out using these models, and their use continues today (12-14).

Procedures applying a solid barrier to separate two aqueous phases are currently being explored, not only by pharmaceutical and medical scientists but also in a wide variety of other disciplines. Whatever the application, the problem of mechanical strength of the membrane becomes significant when a certain cross-sectional dimension is exceeded. When extreme conditions are required to produce the requisite flux, such as in the case of pressurized reverse osmosis in desalination (15) or in pharmaceutical transport studies where the inherent mechanical strength of the particular polymer employed is absent (16), supports of various types are often required to maintain the physical integrity of the barrier. Nonsupported membranes appear to be better suited as biotransport model systems and, consequently, film strength is a necessary criterion upon which to evaluate potential membrane-forming materials.

Based on the mechanism of transport involved, it is possible to distinguish two types of solid barriers. In the first, the permeating molecule can penetrate through pores in the membrane, without actually being in solution within the membrane. The ability to be transported is largely dependent on the relative size of the barrier pore and the penetrant. An example of this

system is dialysis, which has been used in the treatment of drug overdosage and poisoning (17) and in earlier artificial kidneys (18).

The second mechanism is that involving actual solution of the penetrant within the solid membrane. This requisite solubility, when coupled with diffusion, allows permeation across the barrier. Subsequently the penetrant is desorbed from the distal surface. Considering that prior to the solution process, sorption at the proximal membrane surface must occur, these processes parallel a model for liquid permeation proposed by Tuwiner (19). The entire mechanism depends primarily on the ability of the penetrant to dissolve in the membrane. As such, this type of solid barrier better resembles the functionality of the biological membrane with respect to passive diffusion of the uncharged drug species. Included in this category are "solid" barriers formed by the Millipore membrane dip technique, originally conceived by Tobias *et al.* (20, 21) and subsequently used by pharmaceutical investigators (8, 22). The inclusion of this type of barrier is based on the assumptions that the oil-impregnated "channels" of the porous pad constitute the effective membrane with regard to transport and that the size of this channel is much greater than the dimensions of the penetrating molecule. It is through these channels that the intramembrane flux occurs; as a result this model can be considered, along with nonporous polymer barriers, as a partition model system.

When the Millipore model is compared to the three-phase liquid partition models, it is seen that the volume ratio of the liquid phase to the aqueous phases employed has been drastically reduced. Although this diminution is significant, drug retention may still be considerable within the membrane during the time course of transport. Ideally, a model should exhibit negligible capacity for the permeating species. This requirement appears to be most adequately fulfilled by the use of polymeric film-forming agents from which solid, nonporous barriers of quite thin cross section can be made. Two sources exist: commercially prepared films or those extemporaneously formed by the experimenter. An advantage of the latter is that it permits experimental flexibility, especially in terms of membrane composition.

MEMBRANE COMPOSITION

Monoconstituent Membranes—Membranes that consist entirely of film-forming materials, alone or in combination, are termed monoconstituent or pure membranes. Regardless of the method used to produce these membranes, this type of barrier has received the most attention. Water-vapor transmission through polymeric films has been studied both in terms of the free film (23) and when the film is applied to tablets (24). Moisture uptake increased with increasing hydrophobicity of the barrier, and the transmission characteristics of the free film differed from that of the applied film. Permeation studies using polyethylene allowed the computation of apparent diffusion coefficients, permeability constants, and solubility coefficients of six aromatic compounds, the majority of which were nonelectrolytes (25). As an alternative to conventional separation methods of azeotropic binary mixtures of organic liquids, selective diffusion through polymer membranes has been employed by Carter and Jagannadhaswamy (26) as the rationale behind their extraction procedure. Termed pervaporation, the permeating component of the mixture vaporizes on the receiving side of the membrane and is subsequently collected in a cold trap.

Biomedical applications of pure films also have received attention. Extracorporeal hemodialysis efficiency has heretofore been extremely limited for large molecular volume solutes such as urea when employing cellophane-type membranes. Recently, attempts to fabricate a membrane applicable to "hemodialysis," whose mechanism of selectivity is based *not* upon dialysis but upon partition phenomena, have centered around a block copolymer system (27). Furthermore, with the upsurge in plastic packaging of a wide variety of pharmaceutical products, investigations of drug-polymer interactions continue (28), as workers attempt to elucidate the mechanisms of interaction based upon the study of kinetic and thermodynamic parameters.

There have been limited reports concerning drug transfer from one aqueous environment across a polymeric barrier into a second receiving compartment, also aqueous in nature. Johnson (29) used crosslinked thiolated gelatin films to study ionic and nonionic drug diffusion. Rummel *et al.* (30) separated an acid medium from an alkaline medium with several different polymeric membranes and noted that transport was unidirectional, favoring the unionized species. Garrett and Chemburkar (31-33) reported extensive experimentation utilizing dimethylsiloxane polymer sheeting. The silastic membranes proved to be impermeable to ions, and Fick's law was shown to apply for the diffusing species.

Composite Membranes—Flexibility of membrane composition, as an experimental variable, provides considerable potential for investigation. As a consequence, several researchers have attempted to alter the permeation properties of polymer membranes by the addition of compatible materials. Experimentally, this is most often accomplished by incorporating the additives into the membrane solution prior to casting, resulting in a composite membrane. Recently (34) a patent for a paraffin oil additive to polyethylene was awarded. The resultant film was said to have good vapor permeability and was suitable as a packaging material for fresh fruits and vegetables. Dupeyrat and Schreiber (35) studied the electrical properties of an oleic acid-collodion membrane which separated aqueous solutions of electrolytes. These properties were altered when the additive was omitted from the collodion matrix. A lipid-permeable collodion membrane, in which mineral oil was incorporated, was employed to study cholesterol transfer which was then used as a measure of serum lipoprotein-cholesterol complex dissociation (36).

Weatherby (37, 38) was one of the first to construct polymeric membranes comprised of materials distinctly biochemical in nature. He qualitatively demonstrated a relationship between pH of the bathing solution (distilled water was used in the receiving chamber) and the transport of some organic electrolytes. Ionic impermeability was attributed to like-charge repulsion arising from the exposed ionizable groups of the incorporated biochemicals on the membrane surface. Later, Weatherby (39) expanded this original work while employing phospholipids of determined composition. At about the same time, Goldman (40) prepared and studied the electrical characteristics of parlodion (purified collodion) and polystyrene membranes, some of which contained added phospholipid material. More recently, Lakshminarayanaiah (41) studied the resistance and capacitance of parlodion membranes containing stearic acid, phosphatidyl-L-serine, and cholesterol.

The literature does not appear to contain any reports of investigations utilizing a nonporous polymeric barrier, in which are incorporated additives of a biological nature, used expressly for the purpose of studying passive drug transport. Misra *et al.* (16), using collodion as the matrix material, combined lecithin into membranes cast on a mercury substrate and quantitated the permeation of several pharmaceutical substances. Analysis of the transport kinetics using such a model membrane system indicated that salicylic acid did not permeate the membrane in a fashion predicted by the pH-partition hypothesis. Moreover, nonlinearity of a semilogarithmic plot of concentration *versus* time depicting salicylic acid transport in the model system was observed and attributed to adsorption of the acid on the membrane.

It was, therefore, decided to investigate a composite model membrane system for its potential as a model biomembrane which would mimic some of the distinctive qualities of the biological membrane with regard to passive drug absorption. A prime consideration was the design of a membrane that would better fulfill the aforementioned criteria than model systems heretofore utilized. This preliminary report details the various parameters investigated in constructing such a model biomembrane.

Materials—Solutions of lecithin (90% pure, bovine)¹ and cephalin (animal)¹ in chloroform were filtered through Whatman No. 2 filter paper to remove insoluble contaminants. The solvent was evaporated under ambient conditions, and the material collected was stored over a desiccant. The composition of the cephalin was taken to be 15% phosphatidylethanolamine and 85% phosphatidylserine (20). Cholesterol was similarly stored over a desiccant. The polymeric film-forming agents tested included ethylcellulose,² *n*-butyl methacrylate,³ and a vinyl chloride copolymer.⁴ Buffer components (sodium hydroxide, potassium phosphate monobasic, potassium chloride, and hydrochloric acid), salicylic acid,⁵ and the polymer solvents employed were all of reagent grade. Light mineral oil NF⁶ and sodium carboxymethylcellulose⁷ were also used in this study. All chemicals, except where specified, were used as received.

Membrane Formation—Solutions of the chosen polymer (percent weight in volume ratio) and liquid paraffin (percent volume in volume ratio) in chloroform were made to contain twice the concentration desired for each component in the final membrane solution. To 5 ml. of this stock solution were added the requisite amounts of lecithin, cephalin, and cholesterol in chloroform, and the volume was brought to 10 ml. with chloroform.

The membrane was formed by a casting technique. Two milliliters of the solution containing the biological materials and the polymer was introduced into a glass ring (5.5 cm. i.d.) clamped onto a leveled glass plate approximately 12.5 cm. square. No seepage occurred at the ring-plate joint. The solvent was allowed to evaporate under controlled conditions at room temperature. This took 6-7 hr. The resulting polymer film containing the dispersed biochemicals was removed by soaking for 10 min. in distilled water at room temperature. The membrane was allowed to air dry and was stored in a glass culture dish until used.

Transport-Rate Studies—A 50-ml. Plexiglas dialysis cell, similar to that described by Patel and Foss (42) and consisting of two half-cells separated by the model membrane, was employed in the transport-rate studies. The cell was modified by the addition of two sampling ports, each having a 4.0-cm. extension of glass tubing (0.9 cm. i.d.) which permitted sampling while the cell remained submerged in a constant-temperature water bath. The sampling extensions were closed during agitation. The maximum area of contact between the membrane and solution was 11.34 cm.².

Twenty-five milliliters of a pH 7.4 buffer (43), used as the receiving medium, was introduced into one side of the cell. The unexposed surface of the membrane was inspected for leaks. The drug-containing pH 2.0 buffer solution (43) was then added to the other chamber. All solutions were previously equilibrated to 37° except where noted. The cells were immersed in the temperature-controlled water bath at 37° and shaken at 73 strokes/min. At appropriate time intervals, 1-ml. samples were withdrawn from both chambers and diluted with the respective buffer solutions; the absorbance was determined spectrophotometrically at 303 and 298 m μ , the wavelengths of maximum absorbance of salicylic acid in pH 2.0 and pH 7.4 buffer, respectively. The corresponding buffer was employed as the reference in each case. From a predetermined calibration curve, the unknown concentration of the test drug was determined. In most cases, the initial concentration of drug was 300 mg./l.

The apparent rate constant, k_d , for the disappearance of salicylic acid from the chamber buffered at pH 2.0 was obtained from a semilogarithmic plot of the concentration of drug remaining on the pH 2.0 side of the membrane *versus* time. In all cases, the reported rate constant was derived from the statistically determined slope (method of least squares) of such a plot, using the first sample period (not zero time) in the computation. Correlation coefficients were not less than 0.97. Except where specified, triplicate runs were made.

RESULTS AND DISCUSSION

To represent the major biological components of membranes of animal origin (44, 45), two phospholipids, lecithin (phosphatidylcholine) and cephalin (phosphatidylethanolamine and phosphatidylserine), and the neutral lipid cholesterol were chosen. In subsequent discussions, this combination is referred to as the total biological mixture or TBM. The 1:1:2 molar ratio of cephalin, lecithin, and cholesterol, respectively, used in the majority of these initial studies represents a 1:1 molar ratio of *total* phospholipid to cholesterol and is based upon a comparable ratio found in the plasma membrane (46). A recent report (47) demonstrated that these materials are major components of the intestinal membrane and exist therein in this approximate ratio. As will be discussed, consideration was first given to the polymer used to form the supporting matrix. Attention was then directed toward the effect of increasing the TBM, both with and without additives of a nonbiological nature. Finally, the effect on transport rate of varying the ratio of the individual biological membrane components was studied.

Choice of Supporting Matrix—Several film-forming agents were chosen for their potential to create a lipophilic matrix. Only data associated with two of these materials [*n*-butyl methacrylate (BMA) and ethylcellulose (EC), 50 cps.] will be presented here. With BMA, membranes of constant-surface area were cast from a series of dilutions of a stock solution containing BMA (6.0%) and TBM (1.5%) in chloroform. In this manner, the weight of the membrane and hence the thickness varied while holding constant the ratio of polymer to TBM. A similar series of membranes was cast from dilutions of a stock solution containing EC (3.0%) and TBM (0.75%) in chloroform. The rate constants, k_d , for the transport of salicylic acid through these membranes are shown in Fig. 1 as a function of the weight per unit area (equivalent to thickness) of the cast membrane. It is apparent that the change in k_d with thickness was greater with the EC membrane than with the BMA membrane system, the rate constant increasing rapidly with the thinner membranes. The EC films possessed certain other advantages over the BMA mem-

Figure 2—Effect of TBM on the rate of salicylic acid disappearance. Key: ■, matrix solution was EC (1.5%) and MO (0.5%); and ●, matrix solution was EC (1.5%).

branes. The pliability of the BMA film limited its handling qualities and mechanical strength and these, in turn, limited the minimum thickness to which the membrane could be cast. Mechanical strength of the BMA membrane was also sensitive to small changes in TBM concentration. On this basis and because of the higher transport rates of thin EC membranes, all subsequent studies were conducted using this polymer as the film-forming agent.

Effect of TBM on k_d —Increasing amounts of TBM were added to solutions of 1.5% EC in chloroform in an attempt to potentiate transport across the resultant membrane. It was found, however, that above a certain concentration of TBM the aqueous phases in the transport system became turbid due to excessive washout of biological material from the membrane. To ensure that all such material had been removed, it was necessary to prewash the membrane for prolonged periods of time (up to 116 hr.).

To overcome this disadvantage, 0.5% mineral oil (MO) was added to the chloroform solution of EC and TBM prior to casting. The membranes were then prewashed with pH 2.0 and pH 7.4 buffers on their respective sides of the membrane mounted within the transport cell for 3 hr., this now being sufficient time to remove the excess material. The effect of increasing TBM on k_d for membranes with and without MO, is shown in Fig. 2. Several points are apparent. First, the addition of 0.5% MO to the casting solution acts to potentiate the transport rate of salicylic acid. Second, there is a certain capacity of the polymer matrix for TBM in the presence of MO. This is evidenced by the break in the left-hand curve in Fig. 2, indicating the failure of additional TBM to enhance k_d . The breakpoint is equivalent to a membrane containing 44% TBM, expressed as a percentage of the total weight of the dry membrane. It would appear that any TBM in excess of this concentration is removed in the prewash; as a result, k_d remains constant.

As a result of this study, the standard membrane used in all subsequent investigations consisted of 44% EC, 44% TBM, and 12% MO, expressed in terms of the dry weight of the membrane.

Effect of Biochemical Constituent Variation—To study the effect of variations in the three biological components of the membrane on k_d , a series of membranes was studied in which the percentage of lecithin was progressively increased. The remaining TBM requirement was divided equally between cephalin and cholesterol. The TBM was held constant at 44% of the membrane weight, which also contained 44% EC and 12% MO. The data are shown in Fig.

Figure 3—Effect of lecithin as a percentage of TBM on the rate of salicylic acid disappearance. Membrane composition was 44% EC, 44% TBM, and 12% MO.

3, where it is apparent that lecithin has a potentiating effect on the rate of salicylic acid transport. This rate increase may be attributed to the contribution of lecithin to the nonpolar character of the model biomembrane, hence increasing the passage of the lipid-soluble drug species. In contrast to both phosphatidylserine and phosphatidylethanolamine, phosphatidylcholine has a greater alkyl moiety esterified to the common phosphatidic acid backbone. This is consistent with the effect observed with the incorporation of MO into the EC membrane (Fig. 2).

Determination of Solvent Flux—Employing the standard membrane, the effect of hydrostatic and osmotic pressure on solvent flux was investigated. Distilled water was placed on one side of the membrane and dialyzed against an equal volume of a 5% aqueous solution of sodium carboxymethylcellulose (CMC). After 6 days, there was no volume increase in the chamber containing the CMC. In another study, 25 ml. of distilled water was added to one chamber, the second chamber remaining empty. Although the membranes appeared slightly distended after 6 days, there was no evidence of leakage or the appearance of moisture on the distal side of the membrane. These observations lend support to the proposed mechanism for the transport of unionized drug molecules across polymeric barriers, wherein the permeating species moves across the membrane without the aid of the aqueous solvent.

SUMMARY

In summary, a polymeric membrane that incorporates biochemicals representing natural membrane constituents was fabricated by casting. The transport of salicylic acid through such a model followed apparent first-order kinetics and is represented by the disappearance-rate constant, k_d . Additionally, the lack of solvent flux indicates that this solid barrier is nonporous in nature. This property, coupled with approximately 2% salicylic acid retention (48), allows the model biomembrane to mimic the passive diffusion functionality of natural membranes. Lecithin potentiates transport, as does MO, both apparently contributing to the lipophilicity of the barrier.

As a result of these studies, a standard model biomembrane was prepared. The composition of this membrane is 44% EC, 44% TBM, and 12% MO, expressed as dry weight before prewashing. The transport characteristics of the standard membrane are presently being investigated and will be the subject of a future communication.

Chemical Balance as a Rheometer for Biological Fluids

S. S. DAVIS*, B. Warburton*, and J. E. DIPPY†

Abstract □ The chemical balance provides a simple, cheap, and readily available method of assessing the consistency of biological fluids such as sputum. Scale reading at an arbitrary time provides a useful empirical parameter that can be employed in routine testing of clinical samples and in the assessment of mucolytic agents. It also correlates well with data obtained using a conventional cone and plate viscometer. The change of scale reading with time can be analyzed in a fundamental rheological manner using the linear viscoelastic model. The method of measurement is nondestructive and allows repeated measurements to be made on the same sample.

Keyphrases □ Chemical balance—used as rheometer □ Rheometer—chemical balance use □ Sputum—rheological measurements □ Viscosity measurements—viscometer, chemical balance comparison □ Mucolytic agent effect—sputum viscosity

In the past, many attempts have been made to obtain some form of "viscosity" or consistency measurement for complex biological fluids such as sputum and to correlate this with variables such as state of disease, biochemistry, and the action of mucolytic agents. Unfortunately, sputum is not a simple Newtonian

fluid, and its rheological evaluation is beset with many difficulties. These can be summarized as follows (1, 2): (a) limited sample size; (b) highly shear-sensitive structure which is easily destroyed in sample collection or in its preparation for examination; (c) inhomogeneity; (d) material cannot be frozen or homogenized without greatly altering its structure; (e) complex nature of material makes it difficult to obtain fundamental rheological parameters; (f) *in vitro* rheological measurements must be representative of the conditions that exist *in vivo*; and (g) material changes rapidly in consistency after collection due to loss of water and biodegradation.

Using sputum as the representative biological fluid, the authors examined some of the previous attempts to measure consistency (Table I). It is clear that many of the difficulties listed have not been given proper consideration; it is, therefore, not surprising that few reasonable consistency correlations have been obtained. Only in the more recent studies of Hwang *et al.* (1), Denton *et al.* (22), Davis and Dippy (24), and Sturges *et al.* (25) have fundamental rheological param-

Table I—Rheological Evaluation of Sputum

Method and References	Advantages	Disadvantages
1. U-tube viscometer (3-9)	Simple and inexpensive	Variable shear rate; single-point method; destructive; data of doubtful significance; often impossible to obtain meaningful results
2. Falling-sphere viscometer (10)	Same as for No. 1	Same as for No. 1
3. Concentric-cylinder viscometer (5, 6, 8, 11-14)	Different shear rates can be studied (hysteresis effects); non-Newtonian behavior; can be used effectively as comparative method	Destructive; high shear rates that are almost impossible to correlate with <i>in vivo</i> conditions; some instruments only single point; automatic recording instruments are expensive; often impossible to obtain meaningful results
4. Cone and plate viscometer (15-19)	Small sample size; same as for No. 3	Material can be expelled from measuring surface; evaporation; same as for No. 3
5. Perforated disk (2, 8, 20, 21)	Simple and inexpensive; yield effects can be measured	Destructive; measured parameter difficult to interpret in fundamental manner; poorly reproducible
6. Magnetic rheometer (1, 22, 23)	Provides fundamental viscoelastic data, elasticities, viscosities, etc., which can be correlated with <i>in vivo</i> conditions and molecular structure	Complex experimentally; not suitable for routine testing; complex mathematical analysis requiring digital computer
7. Rheogoniometer (oscillation) (24, 25)	Wide frequency range; same as for No. 6	Very expensive, especially when using automatic data-collection method; same as for No. 6
8. Rheogoniometer (creep testing) (24)	Same as for No. 6	Not suitable for samples of low consistency; same as for No. 6

eters been obtained that can be correlated sensibly with mucus structure and cilia transport. In these cases, the linear viscoelastic model was employed as a convenient starting point and the experimental results were interpreted in terms of viscosities, elasticities, and relaxation or retardation times.

In some cases, such as the assessment of mucolytic agents or the routine examination of clinical samples in the clinical laboratory, a detailed viscoelastic treatment is time consuming and probably unnecessary (16). It would rarely warrant the considerable capital outlay needed for setting up the experimental and data analysis procedures. Therefore, an instrument is needed that will satisfy the necessary conditions without being unduly expensive. The basic requirements for this instrument are:

1. It must be capable of dealing with a small sample size, a maximum of a few milliliters.
2. It must be robust and cheap.
3. It must be simple to operate in routine tests by unskilled technical staff.
4. The measurement should be reasonably quick to perform so that large numbers of samples can be examined without delay.
5. It should provide some easily calculated, empirical parameter that will characterize consistency in a rheologically sound manner.
6. The data obtained should also be amenable to further treatment to obtain fundamental quantities such as viscosities and elasticities, should these be required.
7. The test should be nondestructive to enable repetition with the same sample in storage or kinetic experiments.
8. The conditions of test should be such that the derived data describes as well as possible the conditions *in vivo*.

Fortunately, a minor adaptation of the modern chemical balance is suitable for this purpose. This, of course, is standard equipment in nearly all laboratories.

APPARATUS

A conventional chemical balance (Stanton A.D.3) forms the main part of the apparatus (Fig. 1). The essential requirement is some type of illuminated scale that gives readings over the range 0–100 mg. A small glass plate (microscope cover slip) is suspended from one side of the balance and is immersed in the test fluid, which can be conveniently contained in a spectrophotometer cell. The latter is adjusted using a rack and pinion movement, and the whole assembly is enclosed in a thermostated glove-box at required temperature. The final setup is similar in a number of ways to the rising sphere viscometer described by McVean and Mattocks (26) and the commercial Haake Viskowaage viscometer (27).

Operation of the Balance—The glass plate is counterbalanced so that the reading on the illuminated scale is at the 100-mg. mark. The material under test is placed in the cell, and the plate is carefully immersed so that it is in the center of the cell and well below the surface. The vertical position of the cell is then adjusted, if necessary, to correct for buoyancy and to ensure that the balance is once again “zeroed” at the 100-mg. position. A 100-mg. weight is added carefully to the right-hand scale pan, and the change in scale reading with time is followed with a stopwatch.

Theoretical Considerations—From an analysis of the principle of the chemical balance, one can easily show that in the absence of a sample in the cell the balance system can be represented by a mechanical model (Fig. 2A), consisting of a spring (elastic) element and a dashpot (viscous) element arranged in parallel. The spring G_b represents the movement of the balance in response to a weight

Figure 1—Diagram of apparatus. Key: 1, rack and pinion stand; 2, cell and glass plate; 3, mechanical damper of balance; 4, illuminated scale; 5, weight added to this scale pan; and 6, counterbalance arrangement.

placed on the scale pan, and the dashpot η_b represents the mechanical damping of the balance together with friction in the knife edges, etc. G_b will be directly proportional to the sensitivity of the balance. The ratio η_b/G_b is called the retardation time (τ_b).

In rheological terms, this representation is equivalent to a Voigt (Kelvin) solid (28). Material placed in the cell will naturally change the situation, as shown in Fig. 2B–E. The Newtonian fluid (Fig. 2B) and the Voigt solid (Fig. 2D) are trivial cases since similar models in parallel are additive (29); however, the Maxwell

Figure 3—Change in balance scale reading with time for different materials. Key: balance without sample (—), 1. Newtonian fluids (—○—): castor oil ($\eta_s = 8.0 P$), 2; silicone oils ($\eta_s = 1250cS$), 3; ($\eta_s = 3000cS$), 4; ($\eta_s = 60,000cS$), 5; and ($\eta_s = 100,000cS$), 6. Complex materials (—●—): egg white, 7; sputum, 8; and tragacanth mucilage, 9.

liquid (Fig. 2C) and the generalized viscoelastic material (Fig. 2E) provide rather complex models. Nevertheless, it is possible to analyze these, subtract out the inherent contribution of the balance, and thereby represent the behavior of the material in the conventional viscoelastic manner (see *Appendix*). However, as neither stress nor strain is held constant during an experiment, this is not a simple process and, in routine testing, little is to be gained. The change in scale reading (equivalent to a change of strain) with time is an extremely useful, albeit empirical, parameter for studying rheological behavior.

The Newtonian Fluid—The Newtonian fluid (Fig. 2B) provides the simplest possible condition for rheological testing, and it is instructive to examine this in detail. When the 100-mg. weight is placed on the right-hand scale pan, the plate will be moved upward through the test fluid, and the change in strain will be proportional to the reading on the illuminated scale. The strain-time response for a Voigt model can be represented by Eq. 1 (30):

$$\gamma_t = \gamma^\infty(1 - e^{-t/\tau}) \quad (\text{Eq. 1})$$

Figure 4—Calibration of balance viscometer with Newtonian fluids (25°). Viscosity standards: mineral oil ($\eta_s = 14.5 P$); and silicone oils ($\eta_s = 30.9 P$) and ($\eta_s = 129 P$).

where γ_t is the strain at time t , and γ^∞ is the total strain at infinite time. Or, in terms of scale readings, S_t and 100 mg. as the zero:

$$100 - S_t = 100(1 - e^{-t/\tau}) \quad (\text{Eq. 2})$$

which, on rearranging:

$$S_t/100 = e^{-t/\tau} \quad (\text{Eq. 3})$$

Taking logs:

$$2.303 \log S_t - 4.606 = -t/\tau \quad (\text{Eq. 4})$$

$$\log S_t = 2 - t/2.303\tau \quad (\text{Eq. 5})$$

The retardation time will be made up from two contributions, a retardation time associated with the balance (τ_b) and one with the Newtonian sample (τ_s):

$$\tau = \tau_b + \tau_s \quad (\text{Eq. 6})$$

A graph of scale reading against time, in semilog form (Fig. 3), for a Newtonian fluid will be linear with gradient $-1/(2.303\tau)$ and the intercept at the 100-mg. unstressed position. The combined retardation time can easily be calculated.

The τ is defined as the ratio of viscosity to spring modulus for the Voigt model. For the Newtonian fluid in the cell,

$$\tau_s = K_1\eta_s/G_b \quad (\text{Eq. 7})$$

where K_1 is an apparatus constant that will depend on the geometry of the plate and the cell. Substituting in Eq. 6:

$$\tau = \tau_b + K_2\eta_s \quad (\text{Eq. 8})$$

where $K_2 = K_1/G_b$. A graph of τ versus η_s will be linear with gradient K_2 and intercept τ_b . The latter can be obtained by following the movement of the balance when there is no sample in the cell. A calibration curve can thus be obtained using Newtonian fluids of known η_s (Fig. 4).

The viscosity term (η_s) is defined from Newton's law as the ratio of shear stress to shear rate. Shear stress will be directly related to the apparatus geometry. Changing the size of the plate will have a direct effect on the shear stress through an area relationship, and one can write

$$\tau = \tau_b + AK_3 \quad (\text{Eq. 9})$$

where A is the surface area of the plate and $K_3 = K_2\eta_s$.

For a given Newtonian oil, τ will be linearly related to plate area with intercept τ_b and gradient K_3 . However, experimental data plotted in this manner do not pass through the expected intercept, and an end-correction term is evident such that

$$\tau = \tau_b + (A + Ae)K_3 \quad (\text{Eq. 10})$$

It is to be expected that this end-correction value will vary to some extent with the viscosity of the test fluid (31).

Similar experiments with polystyrene spheres also give a linear

Table II—Comparison of Balance Method and Ferranti-Shirley Viscometer for the Effect of Water and Mucolytic Agent^a on the Consistency of Sputum (Contact Time = 20 min.)

Viscometer	Measured Parameter	Percent Reduction in Parameter Compared to Untreated Sputum (Mean & SD)		No. Experiments
Balance	Scale reading at 60 sec.	Water	22.5 ± 12.9	20
		Mucolytic agent	54.3 ± 11.1	20
Ferranti-Shirley	Static yield value	Water	26.2 ± 14.8	10
		Mucolytic agent	55.6 ± 11.1	10
	Dynamic yield value	Water	25.0 ± 12.6	10
		Mucolytic agent	56.1 ± 16.5	10
	Apparent viscosity	Water	22.1 ± 12.4	10
		Mucolytic agent	61.0 ± 14.6	10
	Limiting viscosity	Water	22.8 ± 12.6	10
		Mucolytic agent	60.9 ± 13.7	10

^a Ascoxal-ascorbic acid-hydrogen peroxide-cupric-ion system.

plot between τ and A but without an end correction. This is as expected from theoretical considerations (32, 33) (Fig. 5).

SOME PRACTICAL SYSTEMS

Experiments with a range of Newtonian fluids (Figs. 3 and 4) show that the instrument can be used without modification for viscosities in the range 1–1000 P. Complex non-Newtonian fluids such as sputum do not give linear relations between $\log S$ and time. Instead, the scale reading changes rapidly at short times and then more slowly at long times until it reaches an almost constant value. The same sample of biological fluid can be subjected to repeated measurements with little or no change in the measured $\log S$ versus t curve. The movement of the plate (*i.e.*, the strain) is small and, therefore, the method is essentially a nondestructive test. In practice the sample is usually examined a number of times, and a mean or self-consistent curve is taken as being representative. In repeated measurements the variation in measured scale readings is in the region of 10%, provided that care is taken in centering the plate in the cell well below the surface.

The sensitivity of the balance can be controlled by the counterbalance arrangement above the fulcrum of the balance. Theoretically, there is no reason why the counterbalance should not be set so that the fulcrum and center of gravity are coincident to provide the experimental conditions for pure creep (constant stress). However, experimentally the system would be mechanically unstable. The retardation time of the balance is directly related to the sensitivity, and the range on the illuminated scale can be changed if required using the counterbalance arrangement.

As an alternative to the full viscoelastic treatment for complex materials (see *Appendix*), the scale reading at an arbitrary time or the limiting scale reading as t becomes large is a suitable parameter for use in comparative experiments. For linear viscoelastic materials, the former is very similar to a compliance at arbitrary time measured from a creep curve. This is a popular approach in studies on polymer solutions and pharmaceutical systems (34, 35). In many cases, little difference exists between the two suggested parameters at times greater than 40 sec.

COMPARISON OF BALANCE METHOD WITH FERRANTI-SHIRLEY VISCOMETER

The results obtained with the balance were compared with those from the conventional Ferranti-Shirley cone and plate viscometer (28) for measurements on the consistency of sputum (Table II). The scale readings at an arbitrary time of 60 sec. were chosen for the balance experiments and compared with four rheological parameters obtained from the sputum rheogram off the Ferranti-Shirley viscometer. The rheological parameters were: (a) static yield value—minimum shear stress necessary to cause the unsheared material to flow (dyne cm.⁻²); (b) dynamic yield value—minimum shear stress required to keep the sample in flow once it has been sheared (dyne cm.⁻²); (c) apparent viscosity—ratio of shear stress to shear rate at the highest shear rate (poise); and (d) limiting viscosity—reciprocal of the gradient of the down-curve of the hysteresis loop (poise).

The comparison was made on the basis of percent reduction in rheological parameter upon addition of water or a mucolytic agent¹ as compared to an untreated sample. In all cases, the standard deviations about the mean are large due to considerable biological variation. Nevertheless, statistical analysis (16) shows that the results are valid and can be used in a comparative manner. The agreement between the two methods, balance and Ferranti-Shirley viscometer, is extremely satisfactory, especially when one considers that two different measurement principles are used. There is a slightly better correlation between the balance method and the two yield values from rheograms than with viscosities. This is as expected, because yield values can be considered as an estimate of solidlike structure in a material and will, therefore, be closer in physical nature to scale readings obtained in a nondestructive test than viscosity values calculated after a material has been broken down by shear.

KINETIC EXPERIMENTS

Besides having the great advantage of inexpensiveness, the balance method is also almost nondestructive and the same sample can be examined a number of times. Therefore, kinetic experiments can be performed, provided that the kinetic process proceeds at a rate whereby little change occurs in the consistency of the sample during the period of measurement. Figure 6 shows the effect of contact time for the mucolytic agent on the $\log S$ versus t curves of sputum. To obtain similar information with the Ferranti-Shirley viscometer, fresh samples have to be loaded for each measurement. This introduces sampling errors. The percentage reduction in consistency with mucolytic contact time is shown in Fig. 7. Once again the agreement between the two different methods of evaluation is satisfactory.

APPENDIX

Calculation of Viscoelastic Parameters—The rheological behavior of biological fluids can often be examined in a fundamental manner, using the linear viscoelastic model as a convenient starting point (1, 24). It can be used effectively in the present case, provided the strain response of the material is small and it is behaving in a linear viscoelastic manner (37). The behavior of the balance system will be superimposed upon the model and will contribute G_b and η_b , respectively, to the elasticity and viscosity of the total system (Fig. 8, System I). The material under examination can be represented by a subsystem consisting of a series of Voigt elements (G_{sr} , η_{sr}) with or without a final series viscosity ($\eta_{s(0)}$). Moreover, the total combined system can be represented by the series Voigt system in Fig. 8, System II; in general, Systems I and II are entirely equivalent over a wide range of time (in creep testing) or frequency (in oscillatory testing) (29).

The problem is to evaluate the material subsystem in System I. This may be achieved by employing an intermediate hypothetical

¹ Ascoxal, Astra-Hewlett Ltd., Watford, England.

Figure 6—Effect of contact time of the mucolytic agent on the consistency curves for sputum (repeated measurements on same sample). Mucolytic contact time (min.): ●, 0 (control with water); ○, 5; ■, 10; □, 15; ▲, 20; △, 30; and ▼, 40.

oscillatory experiment of wide frequency range. The steps in the analysis are as follows:

1. Conventional creep curve analysis is used to evaluate the viscoelastic models in System II (30, 38).
2. From the models produced by this procedure, the frequency response over a wide range of frequency is then evaluated using the following equations (29):

$$J'(\omega) = \sum_{r=1}^n J_r \left(\frac{1}{1 + \omega^2 \tau_r^2} \right) \quad (\text{Eq. A1})$$

$$J''(\omega) = \sum_{r=1}^n J_r \left(\frac{\omega \tau_r}{1 + \omega^2 \tau_r^2} \right) \quad (\text{Eq. A2})$$

3. The complex modulus is then computed from the complex compliance over a similarly wide frequency range. Since

$$G^*(\omega) = 1/J^*(\omega) \quad (\text{Eq. A3})$$

$$G^*(\omega) = G'(\omega) + iG''(\omega) = 1/[J'(\omega) + iJ''(\omega)] \\ = \frac{J'(\omega) - iJ''(\omega)}{[J'(\omega)]^2 + [J''(\omega)]^2} \quad (\text{Eq. A4})$$

4. After Step 3 is completed, the total arrangement can be con-

Figure 7—Change in consistency with contact time for the action of the mucolytic agent on sputum. Comparison of balance rheometer and Ferranti-Shirley viscometer. Key: ○, balance (calculated from scale reading at 60 sec.); and ●, Ferranti-Shirley viscometer [mean value from change in four rheological parameters (Table II)].

sidered equivalent to System I. The contribution of the balance $G_b' + iG_b''$ is known:

$$G_b' = G_b \quad (\text{Eq. A5})$$

$$G_b'' = \omega \eta_b \quad (\text{Eq. A6})$$

and, therefore, can be subtracted from the total complex modulus to give that of the subsystem in System I, using Eqs. A5 and A6:

$$G_s'(\omega) = G'(\omega) - G_b'(\omega) \quad (\text{Eq. A7})$$

$$G_s''(\omega) = G''(\omega) - G_b''(\omega) \quad (\text{Eq. A8})$$

5. The complex compliance of the subsystem can then be calculated:

$$J_s'(\omega) + iJ_s''(\omega) = \frac{G_s'(\omega) - iG_s''(\omega)}{[G_s'(\omega)]^2 + [G_s''(\omega)]^2} \quad (\text{Eq. A9})$$

6. The values of $J_s'(\omega)$ and $J_s''(\omega)$ can finally be used to calculate either a line spectrum or continuous spectrum of viscoelastic behavior for the material (37).

SYMBOLS

- A = surface area, cm.²
 A_e = end correction, cm.²
 G_b = elastic contribution (shear modulus) associated with balance, dyne cm.⁻²

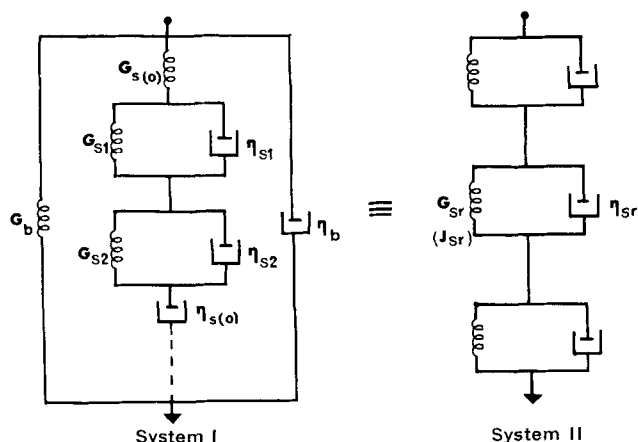

Figure 8—Models for calculating viscoelastic data.

G_{sr} = shear modulus of test sample, Voigt unit r , dyne cm^{-2}
 $G'(\omega)$ = real part of total complex modulus, at frequency ω rad. sec^{-1}
 $G''(\omega)$ = imaginary part of total complex modulus, at frequency ω rad. sec^{-1}
 $G^*(\omega)$ = complex modulus [= $G'(\omega) + iG''(\omega)$]
 J_{sr} = compliance of test sample, Voigt unit r , $\text{cm}^2 \text{ dyne}^{-1}$
 $J'(\omega)$ = real part of complex compliance, at frequency ω rad. sec^{-1}
 $J''(\omega)$ = imaginary part of complex compliance, at frequency ω rad. sec^{-1}
 $J^*(\omega)$ = complex compliance [= $J'(\omega) + iJ''(\omega)$]
 K_n = apparatus constants
 S = scale reading
 i = $\sqrt{-1}$
 t = time
 γ = strain
 η_s = viscosity of Newtonian fluid, poise
 η_b = viscous contribution associated with balance, poise
 η_{sr} = viscosity of test sample, Voigt unit r
 $\eta_{s(0)}$ = viscosity of uncoupled Newtonian dashpot in viscoelastic model
 τ = total retardation time, sec.
 τ_b = retardation time of balance, sec.
 τ_s = retardation time for Newtonian fluid in apparatus
 τ_r = retardation time for Voigt unit r (= η_r/G_r)
 ω = frequency, rad. sec^{-1}

Kinetics of the Decomposition of a Mannich Base

J. A. MOLLICA, J. B. SMITH, I. M. NUNES, and H. K. GOVAN

Abstract □ The elimination reaction of 3-(4-*o*-methoxyphenyl-1-piperazinyl)-4'-morpholinopropiophenone dihydrochloride (Su 17595A) was studied over the pH range of 1–10. It appears that only the unprotonated form of the Mannich base undergoes elimination in the pH range of 3–10. The observed rate constant for elimination as a function of pH corresponds well with the dissociation curve for the compound. The value $k_1 = 7.15 \times 10^{-2} \text{ min}^{-1}$ (60°) was obtained for the specific rate constant for elimination. The elimination reaction is reversible, and the extent of reaction is also a function of pH because the reverse reaction, the addition of 1-(*o*-methoxyphenyl)-piperazine to 4'-morpholinoacrylophenone, proceeds only with the unprotonated amine. The reaction does not remain at equilibrium, because competitive (*e.g.*, desaminomethylation) and/or consecutive (*e.g.*, hydration and dimerization) reactions also can occur. In strong acid solution, the elimination of the protonated form is acid catalyzed.

Keyphrases □ Mannich base—decomposition kinetics □ 3-(4-*o*-Methoxyphenyl-1-piperazinyl)-4'-morpholinopropiophenone dihydrochloride—elimination reaction □ TLC—separation □ NMR spectroscopy—structure

An increasing number of publications have appeared on the synthesis of Mannich bases with potential therapeutic application, and a recent review in this journal discussed the mechanistic and technological considerations of the Mannich reaction (1). Although it has been long recognized that Mannich bases can be decomposed by steam distillation to yield an amine and an α,β -unsaturated ketone, few studies investigating this reaction in detail have been reported. Some workers have studied the elimination of β -morpholinopropiophenone over the pH range of 5.6–9 in their studies on the application of polarography to reaction kinetics (2–4).

Riviere (5), in his studies on the reversibility of the Mannich reaction, found that three processes may occur, depending upon the reaction conditions: (a) desaminomethylation or reverse Mannich reaction; (b) deamination or elimination; and (c) if a free amine is added to the reaction, amine exchange between the β -amino ketone and the amine.

Angeloni and Tramontini (6) and Andrisano *et al.* (7), in their studies on Mannich bases, investigated the decomposition of β -aminoketone hydrochlorides in boiling water and reported that the reaction follows pseudo-first-order kinetics under these conditions.

Koshy and Mitchner (8) reported on the acid-catalyzed hydrolysis of 2-(4-phenyl-1-piperazinyl methyl)-cyclohexanone hydrochloride (MA 1050). The reaction was studied over the pH range 1.1–5.5 and was found to be pseudo-first-order in nature and specific acid and general base catalyzed.

In this article the authors report on the decomposition reaction over the pH range of 1–10 for the Mannich base 3-(4-*o*-methoxyphenyl-1-piperazinyl)-4'-morpholinopropiophenone dihydrochloride (Su 17595A). This reaction is novel and interesting. Although simple

pseudo-first-order kinetics were expected according to several reports (2–4, 6, 8), (at pH values less than the pKa), the authors did not observe them.

EXPERIMENTAL

Materials—Su 17595A, m.p. 208–211° dec., was used.¹ Purity of the compound was determined by phase-solubility analysis and by nonaqueous titration with perchloric acid in the presence of mercuric acetate. All material used in the kinetic studies had a minimum purity of 99% by both methods. 4'-Morpholinoacrylophenone, m.p. 88°, was prepared by elimination from 3-dimethylamino-4'-morpholinopropiophenone. The NMR spectrum had bands at 3.30 and 3.84 (8H, 2 multiplets); 6.90 and 7.90 (4H, 2 doublets); and the acrylic hydrogens at 5.8, 6.4, and 7.2.

Anal.—Calcd. for $C_{13}H_{13}NO_2$: C, 71.92; H, 6.95; N, 6.44. Found: C, 71.72; H, 6.93; N, 6.42. This material was used to confirm the reaction product found in solution and to check the specificity of the assay procedure.² The 1-(*o*-methoxyphenyl)-piperazine dihydrochloride, m.p. 220° dec., had a single trace impurity by TLC. All other chemicals used were of reagent grade.

Buffers—Reagent grade chemicals were used in the preparation of all buffer solutions. Solutions were prepared at an ionic strength of 0.1 or were adjusted to an ionic strength of 0.1 with potassium chloride. The following buffers were used: pH 1–2, hydrochloric acid; pH 3, formate; pH 4–6, acetate; pH 6–8, phosphate; and pH 9–10, borate.

Ionization Constants—The pKa values of Su 17595A were determined spectrophotometrically and potentiometrically. Spectrophotometric determination of the dissociation constants was conducted according to the procedure of Albert and Serjeant (9).

The values obtained spectrophotometrically at 25° are $pK_{a2} = 1.04$ and $pK_{a1} = 6.54$. A pK_{a1} of 6.7 was determined at 25° by potentiometric titration with NaOH in water. A pKa of 9.0 was determined for 1-(*o*-methoxyphenyl)-piperazine at 25° by potentiometric titration with NaOH in water.

Equipment—The pH values were measured with a Radiometer model 25 SE meter using a K401 calomel electrode and a G202B glass electrode. The meter-electrode system was standardized against the standard buffers recommended by Bates (10). Standardization of the meter and determination of pH values were carried out at 60°. Potentiometric titrations to determine substance purity and ionization constants were performed with a Radiometer titrator type TTT1a and titrator type SBR2c. Spectrophotometric measurements were made on a Beckman model DU, and spectra were obtained with a Cary model 11 or 14 spectrophotometer. Constant-temperature baths were maintained at $60 \pm 0.05^\circ$.

Assay Development and Kinetic Procedure—Su 17595A can be determined by UV absorbance at 330 m μ . The 1-(*o*-methoxyphenyl)-piperazine has no absorbance at this wavelength; however, the 4'-morpholinoacrylophenone does absorb at 330 m μ and it is necessary to separate it from Su 17595A. An extraction procedure utilizing CCl_4 - $CHCl_3$ (4:1) and 0.1 N H_2SO_4 was employed; the 4'-morpholinoacrylophenone is quantitatively extracted into the organic phase and the Su 17595A remains in the aqueous phase. Recovery studies of Su 17595A in mixtures containing up to a twofold excess of 1-(*o*-methoxyphenyl)-piperazine show that this decomposition product does not interfere in the extraction procedure. Recovery tests using up to a twofold excess of 4'-morpholinoacrylophenone show the unsaturated ketone to be completely extracted into the organic phase.

¹ The synthesis of compounds of this class has been reported by Dr. G. de Stevens, South African patent 6705,794(1968).

² The authors thank Dr. J. Bishop for providing this compound.

Figure 1—Concentration of Su 17595A as a function of time at various pH values. $T = 60^\circ$.

Figure 2—Concentration versus time plots for the initial loss of Su 17595A at several pH values. $T = 60^\circ$; $C_0 = 4.15 \times 10^{-4}$ M.

Figure 3—Concentration versus time plots for the initial loss of Su 17595A and the attainment of equilibrium at several pH values. $T = 60^\circ$; $C_0 = 4.15 \times 10^{-4}$ M.

The following procedure was utilized throughout the study: a 20-mg. sample of Su 17595A was accurately weighed and transferred to a 200-ml. volumetric flask. To this was added 100 ml. of a buffer which had been equilibrated at 60° . The solution was rapidly mixed and placed in the 60° bath. A 5.0-ml. aliquot was transferred into a 125-ml. separator containing 15 ml. of the $\text{CCl}_4\text{-CHCl}_3$ solvent, 25 ml. of 0.1 N H_2SO_4 , and sufficient 1 N H_2SO_4 to adjust the pH of the aqueous phase to a value of 1. The solution was cooled to room temperature to stop the reaction. The solution was shaken and the organic phase discarded. The extraction was repeated with three additional 15-ml. portions of $\text{CCl}_4\text{-CHCl}_3$; the aqueous layer was then filtered through cotton into a 50-ml. volumetric flask. The funnel was washed with two 5-ml. portions of 0.1 N H_2SO_4 , and these washings were added to the volumetric flask. The solution was

diluted to volume with 0.1 N H_2SO_4 , and the absorbance was determined at $330 \text{ m}\mu$ against a 0.1 N H_2SO_4 blank.

Rate constants ($k_1^{\text{obsd.}}$) were obtained from the initial slopes of plots of $\log [\text{Su 17595A}]$ versus time and, in those instances where "equilibrium" was obtained, also from plots of

$$\log \left[\frac{1 - (1 - f_e)(1 - f)}{(1 - f) - (1 - f_e)} \right] \text{ versus } t$$

where f is the fraction reacted at the time t , and f_e is the fraction reacted at equilibrium.

RESULTS AND DISCUSSION

The concentration versus time plots obtained were not amenable to simple interpretation. Figure 1 depicts the type of data obtained over a 5-day period. The reaction, in at least the intermediate pH region, appeared to approach a state of "quasiequilibrium," and the extent of reaction appeared to be a function of pH. Figures 2 and 3 show the initial loss of Su 17595A in the pH range of 4-9.

A mechanism consistent with such data indicates that only the unprotonated form of the Mannich base undergoes elimination and that only the unprotonated amine undergoes conjugate addition to the α,β -unsaturated ketone in the reverse reaction. It has been suggested (4) that in intermediate pH ranges, the elimination proceeds through intramolecular catalysis (Scheme I).

Analogous pathways, one of which incorporates a molecule of water, have been formulated using the two transition states, I and II.

Figure 4—Plot of $\log k_1^{\text{obsd.}}$ versus pH for elimination of Su 17595A. The points are experimental, and the solid line is a theoretical fit using the values in the text.

These two transition states would also give rise to the same products, and all three are kinetically indistinguishable.

The rate of loss of Su 17595A in accord with Scheme I can be expressed as follows:

$$-d[\text{MB}_i]/dt = \frac{k_1[\text{MB}_i]}{1 + [\text{H}^+]/K_1} - \frac{k_{-1}[\text{MAP}][\text{MPP}]}{1 + [\text{H}^+]/K_3} \quad (\text{Eq. 1})$$

where $[\text{MB}_i]$ = stoichiometric concentration of Su 17595A, $[\text{MPP}]$ = stoichiometric concentration of 1-(*o*-methoxyphenyl)-piperazine, $[\text{MAP}]$ = concentration of 4'-morpholinoacrylophenone, and the constants are as defined in Scheme II:

Scheme II

where

and K_1 , K_2 , and K_3 are the acid-dissociation constants; and k_1 and k_{-1} are rate constants for the forward reaction and reverse reaction, respectively.

The rate constant for the forward reaction (elimination reaction), $k_1^{\text{obsd.}}$, is given by the following equation:

$$k_1^{\text{obsd.}} = \frac{k_1}{1 + [\text{H}^+]/K_1} \quad (\text{Eq. 2})$$

Figure 4 gives a plot of $\log k_1^{\text{obsd.}}$ versus pH for the forward reaction.

Figure 5—Plot relating the fraction decomposed (f_e) to pH. The points are experimental, and the solid line is the theoretical line according to Eq. 3, using the following values: $K_1 = 2.6 \times 10^{-7}$, $K = 1.5 \times 10^{-5}$, $K_3 = 4 \times 10^{-9}$, and $C_0 = 4.15 \times 10^{-4}$ M.

The solid line is drawn according to Eq. 2 using the values $k_1 = 7.15 \times 10^{-2} \text{ min}^{-1}$, which is the average value calculated from the observed rate constants, and $K_1 = 2.6 \times 10^{-7}$, the dissociation constant, determined as described in the *Experimental* section. The experimental points, as can be seen, are in excellent agreement with the theoretical line.

If Eq. 1 is operative and the predominant pathway for the reaction is as outlined, then at equilibrium one could write:

$$\frac{f_e^2}{1 - f_e} = \frac{K}{C_0} \cdot \frac{K_1}{K_3} \cdot \frac{[K_3 + [\text{H}^+]]}{[K_1 + [\text{H}^+]]} \quad (\text{Eq. 3})$$

where f_e = fraction of Su 17595A decomposed at equilibrium, $K = k_1/k_{-1}$, K_1 and K_3 are as described previously, and C_0 = initial concentration of Su 17595A $[M]$.

The extent of reaction was estimated from plots such as are given in Figs. 2 and 3, and the "equilibrium" values were plotted as a function of pH. As can be seen in Fig. 5, the values obtained from the initial plateau are in excellent agreement with the theoretical line according to Eq. 3. This lends further support to the hypothesis that at least the initial loss is primarily by this pathway.

The authors are not able to identify or isolate the amino alcohol,

in the reaction mixture. This would be the expected product of desaminomethylation or reverse Mannich reaction and has been reported by Riviere (5). The β -keto alcohol, which can arise from

the hydration of the α,β -unsaturated ketone, was detected in the reaction mixtures. The hydration and/or polymerization of the α,β -unsaturated ketone are the most likely driving forces which shift the equilibrium of the reaction.

Figure 6—Concentration versus time plots for the loss of Su 17595A in acidic solution. $T = 60^\circ$; $C_0 = 4.15 \times 10^{-4}$ M.

A kinetically equivalent scheme would be a bimolecular reaction involving hydroxide-ion catalysis of the protonated Mannich base. However, this would require a specific rate constant greater than $10^{-5} \text{ M}^{-1} \text{ min}^{-1}$, and one would expect significant buffer catalysis which was not observed.

In stronger acid solution ($\text{pH} < 2$), a mechanism consistent with the data could be as shown in Scheme III.

If there are no competitive or consecutive reactions, all equilibria shown in Scheme II would have to be satisfied. According to Eq. 1, even in solutions at $\text{pH} 6$ where the amine, 1-(*o*-methoxyphenyl)-piperazine, is completely protonated, the reaction does not go to completion. This can be seen in Fig. 6 where even at $\text{pH} 1-2$, 10–20% is still remaining at 10 days. (Equation 3 predicts a maximum of 80% degradation if only elimination is considered.)

SUMMARY

1. Over a wide range of pH values, the principle route of decomposition appears to be elimination from the unprotonated Mannich base. These data are in excellent agreement with a theoretical curve constructed using the dissociation constant of the Mannich base.

2. This hypothesis is given further support in that the reversibility of the reaction is pH dependent and the extent of reaction can be correlated with the dissociation constant of the Mannich base. The reverse reaction, addition of the amine to the α,β -unsaturated

Scheme III

ketone, can be correlated with the dissociation constant of 1-(*o*-methoxyphenyl)-piperazine.

3. Other pathways, such as desaminomethylation, are undoubtedly operative to a small extent as well as a bimolecular pathway for the elimination. The reaction is driven past equilibrium due to consecutive reactions of the α,β -unsaturated ketone such as hydration and dimerization.

4. In strong acid solution, hydrogen-ion catalysis of both the singly and doubly protonated forms ($\text{p}K_2 = 1.04$) is undoubtedly the major pathway.

Kinetics of Elimination of Optical Isomers of Mandelic Acid and Effect of Probenecid on Their Elimination Kinetics in Humans

JANARDAN B. NAGWEKAR* and HARRY B. KOSTENBAUDER†

Abstract □ Kinetics of metabolism and urinary excretion of the optical isomers of mandelic acid have been studied in three human subjects, and the rate constants have been determined for a model consisting of parallel apparent first-order processes for excretion of intact mandelic acid and metabolism to benzoylformic acid. The kinetic studies revealed no significant difference in the rate of urinary excretion of L-(+)- and D-(-)-mandelic acid, but there was a difference in the rate of metabolism of these two isomers in the subjects. The rate constant for metabolism of L-(+)-mandelic acid was approximately twice that for the metabolism of D-(-)-mandelic acid. The inhibitory effect of probenecid on urinary excretion of the optical isomers of mandelic acid suggests that both isomers are involved in active renal tubular secretion.

Keyphrases □ Mandelic acid optical isomers—elimination kinetics □ Probenecid effect—mandelic acid optical isomers elimination □ Metabolism—mandelic acid optical isomers □ GLC—analysis

Although metabolism and urinary excretion of mandelic acid have been the subjects of considerable investigation in both humans and lower animals for more than 50 years, there has been no previous study of the kinetics of these processes. Schotten (1), Knoop (2), Neubauer and Fisher (3), and Quick (4) showed that mandelic acid fed to dogs was excreted unchanged in the urine. Similar observations were made in humans by Rosenheim (5). However, Wrede (6), Scholz (7), and Montenbruck (8) claimed that mandelic acid undergoes significant biotransformation both in man and dogs. Prior to 1938 the urinary excretion of only the racemic mandelic acid was studied, but Wrede (6), Scholz (7), and Montenbruck (8) also investigated the excretion of the individual optical isomers of mandelic acid. Montenbruck (9) extensively investigated the fate of individual optical isomers of mandelic acid in man. He found that 65% of the administered dose of L-(+)-mandelic acid was excreted in the urine as intact dextrorotatory mandelic acid, 14% as benzoylformic acid, and 7% as levorotatory phenylaminoacetic acid. From his studies with D-(-)-mandelic acid, Montenbruck observed that 73% of the administered dose was excreted as intact levorotatory mandelic acid, 7% as benzoylformic acid, and only traces as levorotatory phenylaminoacetic acid. Montenbruck also suggested that benzoylformic acid formed in the body by oxidation of either optical isomer of mandelic acid was oxidized to yield about 2% benzoic acid.

Gary and Smith (10) investigated the urinary excretion of racemic mandelic acid in decerebrate cats, and they reported that the initial urine samples showed a preponderance of levorotatory mandelic acid and that the later urine samples contained mainly the dextrorotatory mandelic acid. Similar differing excretion of

optical isomers of mandelic acid was also observed in humans by Klingmüller and Brune (11), who reported that 74% of the administered dose of mandelic acid appeared in the urine in 24 hr., regardless whether the drug was administered orally or intravenously. Neish (12) reported that 13% of the administered dose of racemic mandelic acid was excreted in the urine as benzoylformic acid within 24 hr.

All these investigators used a polarimetric method to determine mandelic acid excreted in the urine. This method, however, was shown to exhibit an error as high as 15% (13). Other analytical methods reported for mandelic acid include gravimetric (13), iodometric (14), polarographic (15), and cerimetric (16). With the exception of the gravimetric method, these procedures involve conversion of mandelic acid to benzaldehyde and are not convenient for estimation of intact acid excreted in the urine. Williams (17) demonstrated that mandelic acid can be separated from urinary aromatic acids by gas chromatography on an 8% ethylene glycol adipate column.

The isomers of many optically active drugs are known to show differences in the extent of their metabolism and in the pharmacological responses they elicit upon administration to humans. These differences could be attributed to their different rates of absorption, metabolism, and urinary excretion. Since a significant fraction of an oral dose of mandelic acid is excreted in the urine as intact drug, this compound provides a convenient model for the investigation of possible differences in the rates of metabolism and urinary excretion. Also, many organic acids are actively secreted (18) by the renal

Figure 1—Calibration curve for methyl ester of mandelic acid. Conditions: range, 10; attenuation, 64×; injection port temperature, 220°; column temperature, 180°; detector temperature, 250°; and helium flow, 80 ml./min.

tubules; therefore, it is conceivable that this active transport might also show specificity with respect to the optical isomers of this model compound.

The specific objectives of the present study were to: (a) develop a gas chromatographic procedure that allowed the determination of both intact mandelic acid and its metabolites; (b) utilize the urinary excretion data to study the kinetics of, and determine the rate constants for, metabolism and urinary excretion of individual optical isomers of mandelic acid for the purpose of determining any differences in the metabolism and urinary excretion of the respective isomers in humans; and (c) determine the effect of probenecid on the excretion kinetics of the individual isomers of mandelic acid as a test for difference in active renal tubular transport for the two isomers.

EXPERIMENTAL

Materials—The following were used: L-(+)-mandelic acid,¹ recrystallized, m.p. 132–133°, $[\alpha]_D^{25} + 153^\circ$; D-(–)-mandelic acid,¹ recrystallized, m.p. 132–133°, $[\alpha]_D^{25} - 154^\circ$; benzoylformic acid,¹ m.p. 64°; benzoic acid USP,¹ m.p. 122°; and probenecid (500 mg).²

Apparatus—The gas chromatograph (F & M model 810) was equipped with a hydrogen-flame detector. The column used was a copper tube, 1.83 m. (6 ft.) long and 0.63 cm. (0.25 in.) outside diameter, packed with diatomaceous earth³ coated with 8% ethylene glycol adipate. Helium was used as the carrier gas. A Beckman model G pH meter was used for all pH determinations.

Subjects and Test Procedures—Three, apparently healthy, male adult volunteers participated in this study. Each subject, after overnight fasting, ingested a given dose of an appropriate isomer of mandelic acid, dispensed in hard gelatin capsules, with about 250 ml. water. The subject was advised against eating anything for at least 2 hr. after ingesting the drug, but no dietary restrictions were imposed. Each subject collected a blank urine sample prior to ingestion of the drug. Following the ingestion of mandelic acid, urine was collected quantitatively at an interval of 1 hr. for 6 hr., at 2-hr. intervals up to 12 hr., and at longer intervals up to 48 hr. The urine samples were allowed to attain room temperature; then volume and pH were measured, and the samples were stored in the refrigerator until the time they were analyzed. No attempt was made to control the pH of urine during excretion studies. The pH of urine generally remained about 6 ± 0.5 throughout the study. Each subject ingested each of the isomers of mandelic acid in separate studies, generally after an interval of 1 week.

When the studies were carried out with probenecid, the subject ingested 1 g. of an appropriate isomer of mandelic acid after overnight fasting and collected urine quantitatively every hour for 5 or 6 hr. At the end of this period, immediately after collecting the urine sample, the subject ingested a hard gelatin capsule containing a powdered, 250 or 500 mg., probenecid tablet. The subject was advised to eat a light breakfast 2 hr. after ingestion of the dose of mandelic acid and was also advised against eating anything for at least 1 hr. after ingesting the dose of probenecid. Hourly urine samples were collected for another 5 or 6 hr. after ingestion of the probenecid, and subsequent urine samples were collected at longer intervals of time for 36–48 hr. The volume and pH of urine samples were recorded in the usual manner.

Analytical Method—Prior to analysis, urine samples were removed from the refrigerator and allowed to attain room temperature. An appropriate volume of each urine sample was pipetted into a suitable separator, 2.5 ml. of 5 N HCl was added to it, and mandelic acid and its metabolites were completely extracted with ether. The volume of the ether used for each of four extractions was about twice the volume of the aqueous phase. Each of the ether extracts was transferred to a 50-ml. beaker, and the ether was evaporated on a water bath at 55°. The residue was dissolved in 2 ml. methanolic sulfuric acid reagent (30 ml. concentrated sulfuric

acid diluted to 200 ml. with anhydrous methanol) and transferred quantitatively to a 25-ml. glass-stoppered volumetric flask. The beaker was rinsed with two additional 2-ml. volumes of the reagent to transfer quantitatively the residue from the beaker to the flask. The flask was then stoppered, and the bulb of the flask was half-immersed in an oil bath at 75°, leaving the rest of the flask exposed to the atmosphere to serve as an air condenser for the methanol. After refluxing for 2 hr., the contents of the flask were cooled to room temperature, diluted with 5 ml. of distilled water, and transferred quantitatively to a 60-ml. separator with the aid of 20 ml. ether. After shaking and equilibration, the ether layer was transferred to a 50-ml. beaker and evaporated on a water bath at 55°. The aqueous alcoholic layer was further extracted three times with 20-ml. portions of ether, and the ether extracts were treated as described previously. The evaporation of ether was discontinued when approximately 0.3 ml. solution remained in the beaker. The residue was quantitatively transferred to a graduated test tube by rinsing the beaker with small portions of anhydrous methanol, and volume was adjusted to 5 ml. One microliter of this solution was injected onto the gas chromatographic column. The conditions employed for the gas chromatographic analysis were similar to those described elsewhere (19).

Blank urine samples of all participants in these excretion studies were treated in exactly the same manner as the other samples, and 1 μ l. of the methanol extract was injected onto the column.

Fifty-milliliter solutions, each containing 10, 25, 40, or 50 mg. of mandelic acid, were prepared in distilled water; the solution was adjusted to about pH 2 with hydrochloric acid. These samples were extracted with ether, the acid esterified with the methanolic sulfuric acid reagent, and prepared for gas chromatographic analysis in the same manner as the urine samples. These samples were prepared to construct a calibration curve for mandelic acid (Fig. 1).

RESULTS AND DISCUSSION

Gas Chromatographic Method for Quantitative Determination of Mandelic Acid and Its Metabolites—To render them suitable for gas chromatographic analysis, carboxylic acids are routinely converted to their methyl esters. Various agents reported for methylating carboxylic acids include diazomethane (17, 19, 20), BF_3 -methanol (21–23), and dry methanolic HCl (24). Prior to the use of diazomethane as an esterifying agent of mandelic acid and its metabolites for their gas chromatographic analysis by Kamienny *et al.* (19) and Randinitis *et al.* (20), the method described here was used to esterify the acids. Considering the simplicity of preparation and use of dry methanolic HCl, this method was employed to esterify mandelic acid, but the low yield of the ester under the conditions employed necessitated development of another suitable reagent, namely, dry methanolic sulfuric acid. As evidenced in Fig. 1, 2 hr. of refluxing mandelic acid with this reagent offered a reproducible yield of the ester.

The gas chromatograms obtained for blank urine samples of all the participants of these excretion studies revealed complete absence of a peak at that retention time (12.2 min.) where the peak for methyl mandelate appears. Small peaks appeared at retention times between 4 and 6 min. This situation afforded an effective means of estimating benzoylformic acid, the principal metabolite of mandelic acid, which was previously identified by forming a 2,4-dinitrophenylhydrazone derivative in the urine samples voided after ingesting mandelic acid (12). Benzoylformic acid was prepared for gas chromatographic analysis in the same manner as mandelic acid, and a standard calibration curve was constructed. The retention observed for methyl benzoylformate was 8.2 min.

The blank urine sample treated with methanolic sulfuric acid rarely showed a peak at a retention time of 2.2 min., but the urine samples voided after ingesting mandelic acid and treated with the reagent often showed a peak at this retention time. Since methyl benzoate⁴ exhibits a peak at this retention time, such a peak in a chromatogram was attributed to benzoic acid, which appears in the urine as the ultimate oxidation product of mandelic acid. A standard curve was also constructed for methyl benzoate.

Mandelic acid and its metabolites are thus extracted together from a urine sample and are esterified in a single esterification step with the methanolic H_2SO_4 reagent. Finally, when the ester extract

C ^b	1000	250	712	180	11	21.0	903

^a The percentage is based on the total amount of mandelic acid recovered in the urine. ^b The subject inadvertently drank milk along with mandelic acid, which may account for incomplete recovery of mandelic acid. ^c Probenecid was administered 4.5 or 6 hr. after the ingestion of mandelic acid (Fig. 2).

is injected onto the polar column, the esters are separated on the column due to the difference in their polarity. Thus, a single injection of the sample makes the quantitative determination of intact mandelic acid and its metabolites possible, as previously shown (19). The area under the response curve for each of the respective acids was directly proportional to its concentration. The area under the response curve was calculated by the trapezoidal rule (25).

To determine accurately the amount of mandelic acid and its metabolites present in the urine samples, calibration curves of concentration *versus* area under the response curve for the respective acids were constructed each time the urine samples were analyzed. This analytical procedure produced results accurate to $\pm 5\%$.

Model for Excretion Kinetics of Mandelic Acid and Determination of Rate Constants—The recovery of the administered dose of each optical isomer of mandelic acid was complete in the majority of the studies (Table I). Preliminary data obtained for excretion of intact mandelic acid following the oral administration of the respective isomer indicated that the elimination of the acid proceeded by an apparent first-order process. From the information thus obtained about the fate of mandelic acid in the human subjects, Scheme I was formulated to describe a kinetic scheme for metabolism of mandelic acid and its metabolites after absorption of drug and attainment of apparent equilibrium between the drug in blood and the drug in other fluids of distribution. In this scheme, M, BFA,

BA, and CBA are the respective amounts of mandelic acid, benzoylformic acid, benzoic acid, and conjugates of benzoic acid in the body at any time; Me, BFAe, BAe, and CB Ae are the amounts of the respective compounds excreted in the urine at any time; and k_i ($i = 1 \dots 7$) represents apparent first-order rate constants for the respective processes indicated in the model. From 0 to 2% of the administered dose of D-(–)-mandelic acid and from 1 to 2% of the administered dose of L-(+)-mandelic acid were recovered in the urine as benzoic acid. Although glycine or glucuronic acid conjugates of benzoic acid are likely to be formed in the body (26), the extent of conjugation is considered negligible, since the amount of benzoic acid formed in the body is very small. Therefore, the conjugation step in the model is indicated by a broken line.

One primary purpose of the present studies was to determine the rate constants for metabolism and urinary excretion of the optical

isomers of mandelic acid from the urinary excretion data. Therefore, the following differential equations were considered:

$$dMe/dt = k_1M = k_1M_T e^{-k(t-T)} \quad (\text{Eq. 1})$$

$$\log \Delta Me/\Delta t = \log k_1M_T - k(t-T)/2.303 \quad (\text{Eq. 2})$$

where $\Delta Me/\Delta t$ is the rate of urinary excretion of intact mandelic acid (mg./hr.); k , which is equal to $k_1 + k_2$, is the overall rate constant for disappearance of the drug from the body [referred to in recent literature as the disposition-rate constant (26)]; k_1 is the fraction of k attributable to processes leading to urinary excretion of intact drug; k_2 is the fraction of k attributable to processes leading to conversion of mandelic acid to the primary metabolite, benzoylformic acid; M_T is the amount of intact mandelic acid in the body at time T after oral administration of the drug; and T is the time period (hours) during which apparent complete absorption of drug occurred from the gastrointestinal tract and at the time, T , excretion of the drug became apparent first-order. The $\log \Delta Me/\Delta t$ was plotted against t and the rate constant, k , determined from the resulting straight line (least squares) obtained for the data after T hr. The T was generally less than 2 hr. in Subjects A and B, but it was 3–4 hr. in Subject C, who inadvertently drank milk along with the drug (Fig. 2). The time t in Figs. 2 and 3 represent the mid-points of the urinary collection intervals. The values of k_1 and k_2 were determined as follows:

$$k_1 = k \cdot f \quad (\text{Eq. 3})$$

$$k_2 = k - k_1 \quad (\text{Eq. 4})$$

$$f = \frac{Me_\infty}{Me_\infty + BFAe_\infty + BAe_\infty} \quad (\text{Eq. 5})$$

where Me_∞ , $BFAe_\infty$, and BAe_∞ are the equivalent amounts of mandelic acid excreted in the urine as intact mandelic acid, benzoylformic acid, and benzoic acid during 48 hr., the experimental infinite time.

Comparison of Rate Constants for Metabolism and Urinary Excretion of Optical Isomers of Mandelic Acid—Comparison of data for the isomers of mandelic acid, as illustrated in Table II, indicates no significant differences in values of k and k_1 . However, the value of k_2 in all subjects is found to be greater for L-(+)-mandelic acid than for D-(–)-mandelic acid. Table I also indicates that in all subjects the recovery of the metabolites for L-(+)-mandelic acid was about twice the recovery of metabolites observed for D-(–)-mandelic acid. Clearly, k_2 is a hybrid rate constant, involving processes of distribution as well as a specific rate of conversion of intact drug to benzoylformic acid at the metabolic site. However,

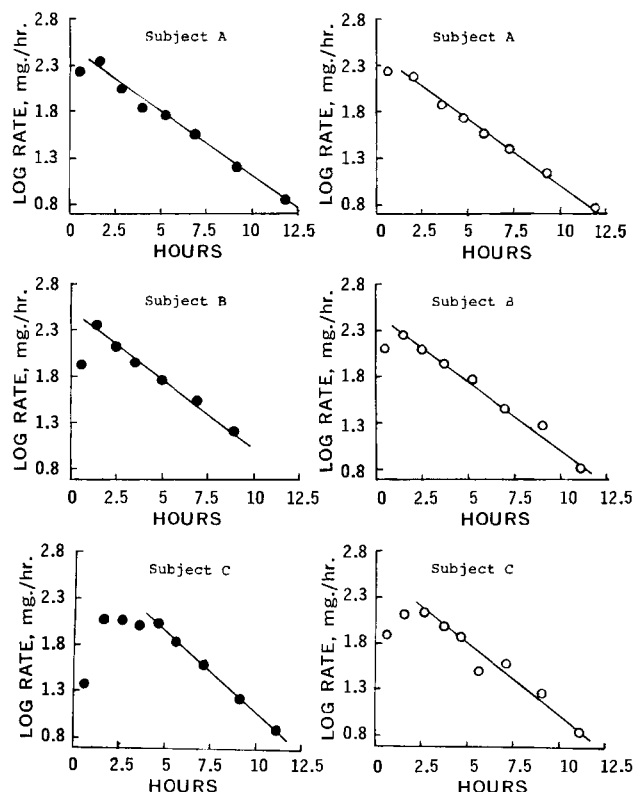

Figure 2—Apparent first-order urinary excretion of D-(–)-mandelic acid (●) and L-(+)-mandelic acid (○) in Subjects A, B, and C. The prolonged periods for absorption of mandelic acids reflected in the plots of Subject C are probably caused by milk inadvertently drunk by the subject along with mandelic acid.

since L-(+)- and D-(–)-mandelic acid have similar physical properties, if it is assumed that distribution within the body is accomplished primarily by processes other than active transport, it is probable that differences in k_2 for the two isomers do, in fact, represent differences in the rate at which intact drug is transformed at the metabolic site. It may then be concluded that, while the oxidative enzyme(s) show apparent differential affinity for the optical isomers of mandelic acid, the tubular “carrier” system does not show similar differential affinity for renal tubular secretion of these isomers in humans. The evidence indicating that both isomers of mandelic acid are involved in renal tubular secretion is presented in a later section.

Comparison of Quantitative Aspects of the Fate of Mandelic Acid Observed in Present Studies with Those Reported by Others—After the oral ingestion of L-(+)-mandelic acid, since the urine, following its exhaustive extraction with ether, exhibited levorotatory activity upon polarimetric examination, Montenbruck (9) assumed that the levorotation was caused by 7% (–)-phenylaminoacetic acid formed from mandelic acid in the human subject and eventually excreted in the urine. Furthermore, he reported that only traces of phenylaminoacetic acid were formed from D-(–)-mandelic acid, since he did not encounter similar observation in the urine collected following the oral ingestion of mandelic acid. In these studies the equivalent amount of either isomer of mandelic acid recovered from the urine as intact mandelic acid and benzoylformic acid was about 80% of the administered dose. However, the data presented in Table I indicate that the urinary recovery of either isomer of mandelic acid is practically complete (97–103% of the ingested dose) in most studies in Subjects A and B. Similar observation was also made by Kamienny *et al.* (19) in their studies with D-(–)-mandelic acid. Therefore, if (–)-phenylaminoacetic acid was formed from L-(+)-mandelic acid in the body, as suggested by Montenbruck (9), it was assumed to be negligible and no attempt was made to identify it.

Although the total urinary recovery of the administered dose of each mandelic acid isomer reported by Montenbruck (9) was less than that observed in the present study, a fairly good agreement is noted in these studies between the fractions of the dose of mandelic

Figure 3—Effect of probenecid on the urinary excretion of the optical isomers of mandelic acid (M.A.) in Subject B. The arrow indicates the time at which probenecid was ingested by the subject. The numbers in parentheses represent the doses of the corresponding compounds. The isomer of mandelic acid was ingested at zero time.

acid obtained as its metabolites (benzoylformic acid and benzoic acid). The extent of metabolism is indeed found to be greater for L-(+)-mandelic acid than for D-(–)-mandelic acid, and the urinary recovery of the former in the intact form is less than that of the latter. As shown by Montenbruck (9), not more than 2.3% of the administered dose of L-(+)-mandelic acid was obtained as benzoic acid in the present studies.

In their studies, Kamienny *et al.* (19) noted that the extent of metabolism of the administered dose of D-(–)-mandelic acid to benzoylformic acid was 10–15% in two of the three human subjects and 14–22% in the third subject. Subject B, who participated in those studies, was the same Subject B who participated in the present studies, and yet the subject was found to metabolize 6–8% of the administered dose of D-(–)-mandelic acid to benzoylformic acid in the present study (Table I) in contrast to 11–13% in the Kamienny *et al.* studies (19). The overall elimination rate constants observed for D-(–)-mandelic acid in Subject B prior to the administration of probenecid in the inhibitory studies were $33–36 \times 10^{-2} \text{ hr}^{-1}$ (Table III), while in the Kamienny *et al.* studies (19) the overall elimination rate constants observed for D-(–)-mandelic acid in Subject B prior to the administration of sulfonamides were $44–46 \times 10^{-2} \text{ hr}^{-1}$. Furthermore, the two studies with D-(–)-mandelic acid (without probenecid and with 250 mg. probenecid) in Subject B were carried out 5 years ago (Table I); the studies with the same compound in the same Subject B were carried out by Kamienny *et al.* (19) 2 years ago, and the study with the same compound (with 500 mg. probenecid) in the same Subject B was carried out recently (Table I).

In retrospect, it is correctly recollected that, while Subject B was generally resting during the first 10–12 hr. of urine collection for the studies reported in Table I, he was ambulatory during the similar urine-collection period reported in the Kamienny *et al.* studies (19). Recently, Schmidt and Roholt (27) demonstrated that the initial plasma levels of benzylpenicillin following the intramuscular administration to the human subjects were higher when they were ambulatory than when they were resting in bed. Subjecting these data reported by Schmidt and Roholt to pharmacokinetic analysis, Levy (28) observed that, although the increase in the average rate

Table II—Apparent First-Order Rate Constants for Overall Elimination (k), for Processes Leading to Urinary Excretion (k_1), and for Processes Leading to Metabolism (k_2) of Optical Isomers of Mandelic Acid in Humans

Subject	k , hr. ⁻¹ ($\times 10^2$)	k_1 , hr. ⁻¹ ($\times 10^2$)	k_2 , hr. ⁻¹ ($\times 10^2$)
D-(−)-Mandelic Acid			
A	31.78	29.02	2.76
B	31.68	29.02	2.66

B ^a	37.53	29.76	7.77
C	37.24	29.94	7.30
C ^a	37.90	29.94	7.96

^a The rate constants presented for these subjects were determined from the urinary excretion data obtained prior to the administration of probenecid (Fig. 3). The reason for utilizing these data is explained in the text.

constant for overall elimination of the drug was only 1.1-fold, such an increase in the average rate constant for metabolism of the drug was 2-fold in the subjects when they were ambulatory. Therefore, the greater extent of the metabolism of D-(−)-mandelic acid noted by Kamienny *et al.* (19) for Subject B and others possibly was due to their ambulatory state during the study. Subject C (Tables I and II) was generally ambulatory during the studies, and this probably was a significant factor for the considerably higher rate of metabolism in Subject C than in Subjects A and B, especially in the study of D-(−)-mandelic acid. Further studies will be carried out for L-(+)-mandelic acid to determine the effect of an ambulatory state of the subjects during such studies.

Effect of Probenecid on Urinary Excretion of Optical Isomers of Mandelic Acid—Since probenecid is known to inhibit the renal tubular secretion of a large number of organic anions (18), studies were carried out to determine if probenecid is able to decrease the rate of urinary excretion of the optical isomers of mandelic acid. It was thought that such studies would reveal whether or not these compounds are involved in renal tubular secretion. In the event the optical isomers of mandelic acid are involved in renal tubular secretion, and their tubular secretion is suppressed by probenecid, it was further thought that the extent of inhibitory effect of probenecid on the urinary excretion of the compounds might indicate if the renal tubular transport carrier system shows differing affinity for the compounds.

As shown in Fig. 3 and Table III, the inhibitory effect of probenecid on the urinary excretion of each isomer of mandelic acid becomes evident. The rate constant (k) for overall elimination of an optical isomer in the absence of probenecid was calculated from the slope of the straight line (least squares) for the data obtained after the postabsorptive and postequilibrative period, but prior to the administration of probenecid. The modified rate constant (kp) for overall elimination of the optical isomer in the presence of probenecid was calculated from the slope of the straight line (least squares) of its excretion data obtained following the oral administration of probenecid. However, since the rate of excretion of the isomer at the 1st hr. after the oral administration of probenecid (Fig. 2) is unlikely to represent the excretion rate of the isomer in the period of postabsorption and postequilibration of probenecid in the body, it is excluded when constructing the least-squares straight line for the subsequent urinary excretion data to calculate the modified rate constant kp . The values of R obtained from the ratio k/kp are listed in Table III. The values of R are used as the index of the inhibitory effect of probenecid on the urinary excretion of the optical isomers of mandelic acid for the following reason.

It is noted from the summary of urinary excretion recovery data (Table I) that the recovery of the administered dose of the optical isomers of mandelic acid in the studies involving probenecid was generally complete and that the extent of metabolism of the isomers of mandelic acid in these studies was comparable to that observed

Table III—Rate Constants for Overall Elimination of Optical Isomers of Mandelic Acid Determined in Humans before (k) and after (kp) Oral Administration of Probenecid, and the Index of Inhibitory Effect ($R = k/kp$) of Probenecid on the Urinary Excretion of Optical Isomers of Mandelic Acid

Subject	Mandelic Acid Dose, mg.	Probenecid Dose, mg.	k , hr. ⁻¹ ($\times 10^2$)	kp , hr. ⁻¹ ($\times 10^2$)	R
D-(−)-Mandelic Acid					
B	1015	250	33.39	20.22	1.65
B	1420	500	38.46	25.27	1.52
L-(+)-Mandelic Acid					
B	1000	250	39.84	24.87	1.60
B	972	250	38.13	26.48	1.44
B	1545	500	37.53	25.81	1.45
C	1000	250	37.90	27.42	1.38

in absence of probenecid. The extent of metabolism of the isomers of mandelic acid appears unaffected in the presence of probenecid, since probenecid was administered to the subject 4.5 or 6 hr. after the administration of mandelic acid, during which period 80–85% of the administered dose of mandelic acid was eliminated. Therefore, even if the extent of metabolism of mandelic acid had probably increased in the presence of probenecid, the slight increase in the amount of metabolite due to the remaining dose (15–20% of the administered dose) of mandelic acid in the body is unlikely to become apparent when the total amount of metabolite due to the entire dose of mandelic acid is considered. Differences in the overall elimination rate constants (k and kp) observed in the inhibitory studies appear to be primarily attributable to the differences in the urinary excretion rate.

It is further concluded that the decrease in the rate of urinary excretion of the isomers of mandelic acid in the presence of probenecid is due to the decrease in the rate of secretion of the compounds caused by probenecid. The inhibitory studies described here were carried out primarily in Subject B; only one study was carried out in Subject C. Judging from the values of kp or R (Table III) determined for each isomer of mandelic acid, it does not appear that probenecid decreases the excretion rate of one isomer to a significantly greater extent than that of the other isomer at the dosage levels of the substrate compounds (mandelic acid isomers) and the inhibitor (probenecid) employed in the present study.

As already pointed out, the extent of metabolism of the optical isomers of mandelic acid remained apparently unaffected in the studies involving probenecid (Table I). Furthermore, the rate constants (k) determined for overall elimination of each optical isomer of mandelic acid in the studies involving probenecid (Table III) are found to be similar to those obtained for the isomers in the studies that did not involve probenecid (Table II). Therefore, the urinary excretion data obtained for each optical isomer of mandelic acid in the inhibitory studies (prior to the administration of probenecid) are utilized to determine the apparent rate constants, k_1 and k_2 , of the respective isomers. The values of the rate constants thus determined are included in Table II, because these results may be considered as the results of the additional studies performed by the subjects in support of the results obtained in the studies involving only the respective isomer of mandelic acid.

In conclusion, it appears that, in humans, the “carrier” system responsible for renal tubular secretion of mandelic acid shows no apparent stereospecificity for the optical isomers of mandelic acid, as does the oxidative enzyme system for their metabolism.

Effect of Vehicles on Metabolism of Serotonin and Imipramine

BENG T. HO, VICENTE ESTEVEZ, and WILLIAM M. McISAAC

Abstract □ Effects of different vehicles on excretion and metabolism of serotonin and imipramine were studied. Rats receiving serotonin-¹⁴C in dimethyl sulfoxide or propylene glycol excreted radioactivity in the urine slower and in lesser amounts than when water was the vehicle. However, the urinary excretion of radioactivity by rats administered a single dose of imipramine-¹⁴C was the same for the three vehicles over a period of 72 hr. Dimethyl sulfoxide and propylene glycol caused not only an increase in the amount of urinary 5-hydroxytryptophol and *N*-acetylserotonin, but also an increase in the conjugated form of these two metabolites as well as that of 5-hydroxyindoleacetic acid. These two nonaqueous vehicles caused a diminished demethylation of imipramine when compared to the water vehicle.

Keyphrases □ Serotonin-¹⁴C metabolism—vehicle effect □ Imipramine-¹⁴C metabolism—vehicle effect □ Metabolism—serotonin-¹⁴C, imipramine-¹⁴C □ Paper chromatography—autoradiographic analysis □ Scintillometry—analysis

An aqueous solvent is the most common vehicle for the administration of drugs for pharmacological studies in animals. However, other solvents are also frequently used, such as propylene glycol and dimethyl sulfoxide (DMSO). DMSO is a powerful solvent with a remarkable ability to alter membrane permeability, and its function as a carrier for many substances has been demonstrated by a number of investigators.

Recently, effects of DMSO on the uptake of ¹⁴C-pemoline (1, 2), ¹⁴C-urea, and ¹⁴C-sucrose (3) by the rat brain have been reported. This study is to determine the difference in effects of water and these two organic solvents as vehicles on the metabolism of two ¹⁴C-

labeled centrally acting agents, serotonin and imipramine.

MATERIALS AND METHODS

Labeled Compounds—Serotonin-2-¹⁴C creatinine sulfate¹ and imipramine-¹⁴C hydrochloride² were used.

Animals and Doses—Male Sprague-Dawley rats, weighing between 180 and 220 g., were used. The compounds were dissolved separately in water, DMSO, and propylene glycol and were administered intraperitoneally to groups of three animals in a dose of 20 mg./kg. (0.5 ml./rat; 1 μ C./rat).

Collection of Urine and Fecal Samples—After the administration of the compound, animals were kept in metabolism cages. Urine samples were collected at intervals of 2, 3, 4, 8, 12, and 24 hr. and then at every 24-hr. interval up to 6 days. In some cases the collection was extended beyond 6 days, as indicated in the results. Toluene was added to the collection tube to prevent any bacterial growth. Fecal samples were collected every 24 hr. for several days. All samples were immediately frozen until assayed.

Determination of Radioactivity—Radioactivities were measured with a Nuclear Chicago liquid scintillation spectrometer, model 725. The scintillation fluid was composed of 4 g. of PPO, 50 mg. of POPOP, and 70 g. of naphthalene/l. of toluene. All determinations were performed in duplicate and were corrected to 100% efficiency by the channels ratio method (4) and for recovery of radioactivity.

The urine sample (0.1 ml.) was mixed with 3 ml. of methanol in a counting vial, and the radioactivity was then measured with 15 ml. of the scintillation fluid.

For measuring the radioactivity in feces, 0.1 ml. of 20% water homogenate in a counting vial was treated with 1.0 ml. of 10% hydrogen peroxide in methanol. The mixture was heated at 45° to al-

most dryness, treated with 3 ml. of methanol, and 1 hr. later again treated with 15 ml. of the scintillation fluid.

Enzymatic Hydrolysis of Conjugates—Urine was adjusted to pH 5.5 and incubated overnight with β -glucuronidase and sulfatase³ in sodium acetate buffer, pH 5.5, at 37°.

Chromatography of Urine Sample—Hydrolyzed and unhydrolyzed urine samples from the ^{14}C -serotonin experiment were applied on Whatman 3MM paper and developed in the system of *n*-butanol-acetic acid-water (120:30:50) using the descending technique. The radioactive spots were located by autoradiography of the paper chromatograms with Kodak no-screen X-ray film and eluted by methanol. The eluates were rechromatographed on silica gel G pre-coated glass plates⁴ in the solvent ethyl acetate (5). Serotonin and its metabolites were identified against standards and by their R_f values, UV fluorescence, and color reactions with Ehrlich's reagent. For quantitation, radioactive spots on paper or glass plate were cut out or scraped off and transferred to counting vials; the radioactivity was measured after addition of 3 ml. of methanol and 15 ml. of the scintillation fluid.

Urine samples from the imipramine- ^{14}C experiment were chromatographed on silica gel G pre-coated TLC plates in the solvent

Figure 3—Cumulative excretion of radioactivity in rat feces following intraperitoneal injection of serotonin- ^{14}C . Key: O—O, in water; ●—●, in DMSO; and X—X, in propylene glycol.

system of chloroform-methanol (90:10) (6). Imipramine and desimipramine were detected by spraying the plates with iodoplatinate reagent.⁵

RESULTS AND DISCUSSION

Excretion—Urine levels of radioactivity after the intraperitoneal administration of serotonin- ^{14}C were less when the compound was administered in DMSO or propylene glycol than when administered in water. After 24 hr., 98% of the given dose was excreted when the aqueous solution was used, whereas only 75 and 67% of the injected radioactivity were recovered respectively when DMSO and propylene glycol were the vehicles (Fig. 1). However, in rats injected

⁵ This reagent was found to be useful in detecting imipramine and desimipramine in less than 1-mcg. quantities, giving a pinkish color.

Figure 4—Cumulative excretion of radioactivity in rat feces following intraperitoneal injection of imipramine-¹⁴C. Key: O—O, in water; ●—●, in DMSO; and X—X, in propylene glycol.

Figure 5—Distribution of metabolites in 24-hr. rat urine following intraperitoneal injection of serotonin-¹⁴C. Key: A, in water; D, in DMSO; P, in propylene glycol; 5-HT, unchanged serotonin recovered; 5-HIAA, 5-hydroxyindoleacetic acid; 5-HTOL, 5-hydroxytryptophol; and N-Ac-5-HT, N-acetylserotonin. Values shown at the top of each column represent ratio of the conjugated form to the free form for each metabolite.

with imipramine-¹⁴C, urinary excretion of radioactivity was the same (approximately 33%) over a period of 72 hr., regardless of which of the three vehicles was used (Fig. 2).

Rats receiving serotonin or imipramine in the two nonaqueous solvents showed higher excretion of radioactivity in feces than when the aqueous solution was used (Figs. 3 and 4).

Metabolism—The urinary metabolites of serotonin-¹⁴C recovered in the first 24 hr. after administration are shown in Fig. 5. Both DMSO and propylene glycol doubled the urinary excretion of 5-hydroxytryptophol and N-acetylserotonin over that with the aqueous vehicle (Fig. 5 and Table I). A similar alternation of metabolic pathways of serotonin by ingestion of ethanol has been reported (7).

In this study, the cause for the increased urinary 5-hydroxytryptophol and N-acetylserotonin remains to be determined. The latter could have resulted from a blockage of the oxidative pathway by DMSO and propylene glycol; these two solvents were found to inhibit monoamine oxidase *in vitro*.⁶ It has been postulated that DMSO could alter secondary and tertiary structures of proteins by substituting the protein-bound water, and this could cause a partial loss of enzyme activity (8, 9).

⁶ During the assay for inhibitors of monoamine oxidase, the solvents DMSO and propylene glycol were found to be weak inhibitors of bovine liver monoamine oxidase with I_{50} equal to 1.12 and 0.41 M, respectively.

Table I—Effects of Vehicles on Percent^a Distribution of Metabolites in 24-hr. Urine of Rats Administered Intraperitoneal Dose (20 mg./kg.) of Serotonin-¹⁴C

Vehicle	Percentage ^a Urinary Metabolites of Serotonin			
	5-HT ^b	5-HIAA ^b	5-HTOL ^b	N-Ac-5-HT ^b
Water	12.6	70.8	10.6	5.9
DMSO	8.3	63.6	18.0	10.0
Propylene glycol	13.7	53.1	23.0	10.1

^a For a direct comparison of the distribution of serotonin metabolites in the 24-hr. urine with the three vehicles, the total excreted radioactivity in the individual case was corrected to 100%. ^b Key: 5-HT, unchanged serotonin recovered; 5-HIAA, 5-hydroxyindoleacetic acid; 5-HTOL, 5-hydroxytryptophol; and N-Ac-5-HT, N-acetylserotonin.

Table II—Effect of Vehicles on the Ratio of Desimipramine to Imipramine in Urine of Rats Administered Imipramine-¹⁴C (20 mg./kg. i.p.)

Urine Collection, hr.	Ratio of Desimipramine to Imipramine		
	Water	DMSO	Propylene Glycol
0-4	11.33	2.73	5.19
4-8	9.57	6.66	6.57
8-24	10.08	9.25	11.96

An increase in the conjugated form of the three metabolites, especially 5-hydroxytryptophol and N-acetylserotonin, was also observed with both DMSO and propylene glycol (Fig. 5). In this aspect, the latter solvent was more effective than the former.

Table II lists the ratio of desimipramine to imipramine in the urinary excretion. When water was the vehicle, this ratio was held constant throughout the intervals of 4, 8, and 24 hr. With DMSO and propylene glycol as the two vehicles, the low ratios in the first 4 hr. indicated a diminished demethylation of imipramine, particularly for DMSO. It is possible that the two nonaqueous solvents inhibit the demethylation enzyme, and this is currently under study.

Extraction of Morphine Enhanced by Addition of *N*-Methyl-3-piperidyl-(*N'**N'*)-diphenylcarbamate

RAMSES HAKIM and JAMES M. FUJIMOTO

Abstract □ The extractibility of morphine (N - $^{14}\text{CH}_3$) into chloroform from aqueous solution was enhanced to completeness by adding *N*-methyl-3-piperidyl-(*N'**N'*)-diphenylcarbamate under the following conditions: ratio of *N*-methyl-3-piperidyl-(*N'**N'*)-diphenylcarbamate-morphine between 40:1 and 200:1, with morphine concentration no greater than 30 mcg./ml. and the pH between 6.8 and 10. This high extractibility was decreased by concentration of morphine greater than 30 mcg./ml. and by addition of dihydromorphinone, apomorphine, nalorphine, cyclazocine, and naloxone. Thebaine, codeine, methadone, meperidine, levorphanol, dextrophan, and levallorphan did not affect the extractibility. The same qualitative relationships were obtained by using carbon tetrachloride instead of chloroform as the solvent.

Keyphrases □ Morphine (N - $^{14}\text{CH}_3$) extraction enhancement—*N*-methyl-3-piperidyl-(*N'**N'*)-diphenylcarbamate □ *N*-Methyl-3-piperidyl-(*N'**N'*)-diphenylcarbamate—morphine (N - $^{14}\text{CH}_3$) interaction □ Countercurrent distribution—analysis □ TLC—analysis □ Scintillometry—analysis

The effect of SK & F 525A and *N*-methyl-3-piperidyl-(*N'**N'*)-diphenylcarbamate (MPDC) on the renal metabolism and tubular transport of morphine in the chicken has been recently reported (1). The present investigation concerns the unusual chemical interaction that occurs between morphine and MPDC. The rationale for embarking on this study is found in the preliminary observation that when MPDC was infused along with radioactive morphine into the saphenous vein of the chicken, the free morphine excreted in the urine was more extractible into chloroform than when no MPDC was given (1). Since addition of MPDC directly to urine containing radioactive morphine produced the same increase in extractibility, it was evident that a chemical interaction was occurring between MPDC and morphine. In the present study, the authors examined and characterized the factors involved in pro-

Figure 1—Left panel is the countercurrent distribution analysis of ^{14}C -morphine. Key: —, experimental; and . . . , theoretical. Right panel is the countercurrent distribution analysis of ^{14}C -morphine with 10 mcg./ml. MPDC added. Stationary phase, pH 8.5 buffer; mobile phase, chloroform; volume of each phase, 3 ml.

Figure 2—Extraction of ^{14}C -morphine into chloroform from buffers at different pH's. Key: . . . , ^{14}C -morphine extraction in absence of MPDC; and —, ^{14}C -morphine extraction in presence of 5 mcg./ml. of MPDC. Volume of each phase was 3 ml.

ducing this unusual interaction between the two bases. Other narcotic analgesics and antagonists also were tested. A preliminary report on these studies has appeared (2).

EXPERIMENTAL

Materials—Morphine- N - $^{14}\text{CH}_3$ hydrochloride,¹ specific activity 17 mc./mmole, was dissolved in distilled water to make a 0.01 $\mu\text{c.}/\text{ml.}$ solution. MPDC HCl² was used. The solvents used, chloroform, carbon tetrachloride, methylene chloride, ethylene dichloride, ethyl acetate, *n*-butanol, and ethyl ether, were reagent grade (Baker analyzed).

Countercurrent Distribution Analysis—Characterization of ^{14}C -morphine and separation of the ^{14}C -morphine MPDC reaction products were accomplished by using the solvent system previously used for separation of morphine from morphine metabolites in urine samples (1, 3, 4). The solvent system consisted of a sodium bicarbonate (2 g./l.) buffer, pH 8.3–8.5, equilibrated with chloroform. The ^{14}C -morphine, along with MPDC, was added to the system in the buffer phase. Equal volumes of buffer-to-chloroform phases were used; chloroform, the mobile phase, was transferred manually with a syringe equipped with a long needle. One milliliter of each phase was plated and counted in a Tracerlab low background counting system (efficiency of counting was 10% at infinite thinness). Countercurrent analyses were also done with buffers at pH 3; in these instances, sodium phosphate (3 g./l.) buffers were used.

² Lakeside Laboratories.

Figure 3—The extraction of ^{14}C -morphine into chloroform from pH 8.3–8.8 buffer to which 6 (●), 12 (○), 18 (Δ), 30 (▲), and 80 (×) mcg./ml. morphine and 0–120 times these concentrations of MPDC were added.

Chromatographic Studies—TLC on Gelman silica gel fiberglass sheets (TLC type SG) was performed with a solvent system consisting of benzene–dioxane–ammonium hydroxide, 5:5:0.1 (v/v/v). The nonradioactive compounds were visualized either by spraying the chromatogram with iodoplatinate reagent (5) or by spraying with sulfuric acid followed by charring the TLC on a hot plate. Radioactive components on the TLC were detected by passing the chromatogram through a 4-pi scanner (Tracerlab).

RESULTS AND DISCUSSION

Countercurrent Distribution of ^{14}C -Morphine with and without MPDC Added—In Fig. 1 the countercurrent analyses performed at pH 8.5 for ^{14}C -morphine are shown to be markedly affected when 10 mcg./ml. of MPDC was added. This addition of MPDC shifted the peak for ^{14}C -morphine from Tube 3 to Tube 8, demonstrating that an increase in the extractibility of ^{14}C -morphine occurred. Although the preliminary observation was that MPDC added to urine containing ^{14}C -morphine altered the extraction of the morphine (1), the present experiment demonstrated that the effect could be obtained in solutions without the presence of urine.

Extractibility of ^{14}C -Morphine with and without Addition of MPDC—Effect of pH—A single-extraction procedure was used to expedite the study of several parameters. The extraction of ^{14}C -morphine into chloroform (Fig. 2) was maximal at pH 8.3–9; outside this pH range, extraction decreased. Chloroform in the absence of MPDC, even under optimal pH conditions, did not extract over 50% of the ^{14}C -morphine. These data on extraction of morphine with chloroform agree with expectations from the literature (6). Addition of MPDC increased the extraction of ^{14}C -morphine to beyond 90% in the pH range 7.5–10.

Effect of Concentration of MPDC and Morphine—To study the stoichiometric relationship, a series of experiments was done by adding different concentrations of MPDC and carrier morphine to a

Figure 4—The extraction of ^{14}C -morphine into carbon tetrachloride from pH 8.3–8.8 buffer to which 6 (●), 12 (○), 18 (Δ), and 30 (▲) mcg./ml. morphine and 0–80 times these concentrations of MPDC were added.

^a A mixture containing 2.5 ml. of each organic solvent.

constant amount of ^{14}C -morphine. For example, in Fig. 3 if the curve corresponding to 6 mcg./ml. of morphine is examined, the ^{14}C -morphine extraction was less than 50% initially in the absence of MPDC. When the MPDC concentration was increased to between 40 and 120 times the morphine concentration of 6 mcg./ml., the ^{14}C -morphine extraction was greater than 96%. Each curve in the figures should be examined in this manner, since the figures contain a large mass of data. In the range of 6–30 mcg. of carrier morphine, addition of up to 40 times as much MPDC generally increased the extraction. Increasing the relative concentration of MPDC beyond 40 had a detrimental effect on extraction of ^{14}C -morphine, especially at the 18- and 30-mcg. concentrations of morphine. At 80 mcg./ml. of carrier morphine, the extraction decreased from a control value of 46% (with no MPDC) down to 2% when MPDC was 120 times this morphine concentration. At no time was the extraction better than the control value in this situation. This decrease in extraction, as well as the increase in extraction effected by MPDC at lower concentrations of carrier morphine, indicated that chemical interaction was occurring between MPDC and morphine.

Effect of Different Solvents—As shown in Table I, a number of solvents were tested for ability to extract ^{14}C -morphine in the presence and absence of MPDC and carrier morphine. For these situations, no change in extraction of ^{14}C -morphine was seen when the solvents were ethyl acetate, hexane, methylene chloride, ethylene chloride, and ethyl ether. Butanol appeared to be a special case in which extraction was decreased by adding MPDC and carrier morphine. This case was not studied any further. On the other hand, carbon tetrachloride showed an increase in extraction of ^{14}C -mor-

Figure 5—The effect of various narcotics and antagonists on the extraction of ^{14}C -morphine into 5 ml. chloroform from 5 ml. of pH 8.5 buffer in the presence of MPDC. The concentration of morphine (○), dihydromorphinone (×), nalorphine (Δ), and thebaine (●) is read from the abscissa. The concentration of MPDC was always 40 times the drug concentrations. Codeine, methadone, meperidine, dextrophan, and levallorphan gave the same results as thebaine.

Figure 6—The effect of various narcotics and antagonists on the extraction of ^{14}C -morphine into 5 ml. carbon tetrachloride from 5 ml. of pH 8.5 buffer in the presence of MPDC. The MPDC concentration was always 20 times that of the drugs. The other designations were as in Fig. 5: O, morphine; X, dihydromorphinone; Δ, nalorphine; ▲, naloxone; and ●, thebaine, codeine, methadone, meperidine, dextrophan, and levallorphan.

phine from 8 to 87% by addition of MPDC. But, addition of 10 mcg./ml. of morphine caused the extraction to drop to 35%. Thus, carbon tetrachloride was similar in a qualitative sense to the studies with chloroform as the solvent. Chloroform or carbon tetrachloride added to an equal volume of ethylene dichloride, a solvent that showed no effect to addition of MPDC and morphine, still produced the same phenomenon. Considerable increases in extraction occurred beyond that of ethylene dichloride alone.

The extraction of ^{14}C -morphine from sodium bicarbonate buffer, pH 8.5, was examined (Fig. 4) with carbon tetrachloride used in place of chloroform (Fig. 3). The extraction of ^{14}C -morphine into carbon tetrachloride was almost complete (over 90%) for solutions containing 6 and 12 mcg./ml. of carrier morphine and up to 80 times these respective concentrations of MPDC. Beyond these concentrations of morphine and MPDC, extraction of ^{14}C -morphine decreased. The general conclusions were the same as for the results given in Fig. 3 with chloroform as the solvent. Namely, MPDC was interacting with morphine.

Figure 7—Reextraction of radioactive product (—) and MPDC (···) from chloroform into buffers of different pH's. ^{14}C -Morphine and MPDC (in 1:40 molar ratio) were extracted from pH 8.5 buffer into chloroform. This chloroform was then shaken with an equal volume (5 ml.) of buffer. The percent extraction was calculated for this last step.

Figure 8—Countercurrent distribution at pH 3 of material reextracted from chloroform and analyzed for (A) ^{14}C -activity and (B) MPDC. MPDC was determined by UV absorption spectrometry.

Effect of Other Drugs in Extraction of ^{14}C -Morphine—Investigations of the effects of other narcotic analgesics and antagonists on this interaction of morphine with MPDC are shown in Figs. 5 and 6. There were two types of effects. One group of drugs had no effect; this group included thebaine, codeine, methadone, meperidine, dextrophan, and levallorphan. The other group depressed ^{14}C -morphine extraction and included morphine itself, nalorphine, and dihydromorphinone. Apomorphine at 50 mcg./ml. also belonged in the latter group, but only this one concentration was tested. The same kind of grouping into two types is seen in Fig. 6, where carbon tetrachloride was used as the solvent instead of chloroform. The first group consisted of the same drugs in which no effect was found. The second group consisted again of morphine, nalorphine, dihydromorphinone, apomorphine (one concentration of 20 mcg./ml., not shown), and, in addition, naloxone. It is evident from the experiments (Figs. 5 and 6) that certain drugs affect the interaction of MPDC with ^{14}C -morphine, and some structural specificity exists in this interaction. Dihydromorphinone, morphine, nalorphine, and naloxone all possess the phenolic OH and either an alcoholic OH or keto group at position 6. It is interesting to note that two were agonists (morphine and dihydromorphinone) and two were antagonists (nalorphine and naloxone), but there appeared to be little relationship to pharmacologic potency. At first, it appeared that the morphine-MPDC system would provide an *in vitro* approach for preliminary screening for narcotic analgesics and antagonists. However, some important compounds known to have pharmacologic activity would have been missed.

Reextraction of ^{14}C -Morphine and MPDC from Chloroform into Buffers of Different pH's—The chloroform phase containing the ^{14}C and MPDC was extracted with buffers of different pH's. Figure 7 shows that the radioactive material presumably present as a complex with MPDC was extractable back into acid buffers. This curve, which might be thought of as an inverse plot of the extraction of ^{14}C -

Figure 9—TLC on Gelman silica gel fiberglass sheets. On the left the chromatogram shows (a) morphine, (b) MPDC, (c) chloroform extract at pH 8.5 containing morphine and MPDC, and (d) Tube 0 pH 3 buffer phase of countercurrent distribution analysis performed in Fig. 8.

Figure 10—UV spectrum of the ^{14}C -morphine-MPDC product (—) from Tube 0 of the countercurrent distribution at pH 3.0 (Fig. 8 and *d* in Fig. 9); morphine (· · ·) at pH 3, MPDC (---) at pH 3, and morphine and MPDC together (— · —) in pH 3 buffer where no chloroform extraction was involved.

morphine in the presence of MPDC from buffer into chloroform, was not identical to the results derivable from Fig. 2. For the experiment shown in Fig. 7, transfer of radioactive material from chloroform back to buffer required lower pH's than the transfer of ^{14}C -morphine from buffer to chloroform (Fig. 2). Extraction of ^{14}C -morphine in the absence of MPDC into chloroform and re-extraction of this morphine from chloroform into the buffer showed the same type of hysteresis. Occurrence of such hysteresis militated against a clearcut interpretation of these results from the reextraction experiments. Figure 7 includes a further experiment, in which the reextraction into the buffer of the MPDC portion from the morphine-MPDC chloroform solution was measured. Since the amount of MPDC was large relative to morphine (40:1 molar ratio), it was possible to measure MPDC by UV spectrometry. The data show that at a 2–6 pH range, MPDC was not extracted from chloroform into buffer to the same proportion that the radioactive material was extracted.

The practical consequence of the information derived from Fig. 7 was that it was possible to separate the radioactive material from the excess MPDC in the chloroform by adjusting the aqueous phase

to pH 3. These conditions were employed in performing the countercurrent distribution analysis given in Fig. 8. As expected, the radioactive material that peaked in Tube 1 was clearly separated from the MPDC that peaked in Tube 8. Since free ^{14}C -morphine itself would have peaked in Tube 0, the peak for the radioactive material in Tube 1 of the present experiment indicated that the radioactive material was not free ^{14}C -morphine. Therefore, attempts were made to characterize this material further.

TLC of the material from the aqueous phase of Tubes 0 and 1 of the countercurrent fractionation is shown in Fig. 9. The results indicated that this material was a single component with an R_f of 0.83, both by iodoplatinate reaction and by radioactivity. It was different from MPDC or morphine. The TLC for *c* is for a 40:1 mixture of MPDC-morphine in pH 8.5 buffer extracted with chloroform and the chloroform spotted. In this case, both the material corresponding to *d* and excess MPDC were present as expected.

UV absorption spectra were obtained from these same materials (Fig. 10). The spectrum of the material in Tube 0 of the countercurrent distribution analysis was not characteristic of either morphine or MPDC. Also, this spectrum was different from a spectrum obtained by simple addition of morphine and MPDC spectra. A spectrum obtained experimentally by having both MPDC and morphine together in a buffer at pH 3 given in the figure was also different from that for the material in Tube 0. Thus, the results from the TLC and the UV spectral studies supported the idea that some sort of "complex" was formed between morphine and MPDC. This complex acted as a single entity with its own characteristics. Efforts to crystallize this material have not been successful.

Characterization of Tablet Surfaces by Their Critical Surface-Tension Values

S. W. HARDER, D. A. ZUCK, and J. A. WOOD

Abstract □ Experiments were conducted to determine the critical surface-tension (γ_c) values of a range of acetylsalicylic acid tablets in combination with various adjuvants. A telemicroscope was used to measure the contact angle (θ) as test liquids with known surface tensions (γ_L) advanced across the tablet surface. The cosine of the contact angles ($\cos \theta$) were plotted as a function of the γ_L of the test liquids. Straight-line extrapolation to $\cos \theta = 1$ resulted in γ_c values for each particular type of tablet. These values were determined for each group of tablets, using different sets of test liquids. The γ_c values obtained by this method indicated that pure acetylsalicylic acid tablets presented a surface with intermediate activity, having a γ_c value of about 31 dynes/cm. The addition of a lubricant like magnesium stearate presented a surface richer in $-\text{CH}_3$ and $-\text{CH}_2-$ groups, resulting in a lower value, whereas the addition of adjuvants such as starch, cellulose, and talc resulted in surfaces richer in $=\text{O}$ and $-\text{OH}$, causing an increase in the γ_c values. Increased γ_c values result in increased wetting by the coating solution and in an increased bonding force between the tablet surface and the polymer film coating after the solvent has evaporated. Characterization of the tablet surface should eliminate some of the guesswork involved in developing an adequate film coating for a particular type of medicinal tablet.

Keyphrases □ Tablet surfaces—characterization □ Critical surface-tension values—tablet surface characterization □ Telemicroscopy—liquid, tablet surface contact-angle measurement □ Adjuvant effect—liquid, tablet surface contact angle

The strength of the adhesive bond between a film coating and a solid surface, as well as the uniformity of the coating, is influenced by surface energy forces acting at and across an interface (1-4). It is, therefore, important to understand the energy forces present at the surface of a tablet and to be able to characterize a tablet according to the cohesive energy density (CED) of its surface. Knowledge of the forces operative at the tablet surface will assist in prediction of the degree of bonding and permit the design of coating solutions, resulting in optimum utilization of these forces to obtain adequately bonded and uniform film coatings. Preliminary tests indicated that there is a certain amount of correlation between the critical surface-tension values and film-coating characteristics such as degree of adhesion and film texture (5).

Although no direct method of measuring solid surface energy has yet been found, critical surface-tension

(γ_c) values do represent an indirect approach to the characterization of solid surfaces according to their CED.

In the articles cited in the previous paper (5), γ_c values were determined using a selection of pure liquids with surface tensions in the range necessary for the determination of these values. Some investigators did use liquids of a homologous series in an effort to overcome variations in contact angles due to specific interactions. Since it is not always possible to find a homologous series with surface tensions in the required range, a decision was made to use series of high and low surface-tension liquid mixtures. These could be prepared as series of solutions with similar physical-chemical properties and with a gradual gradation of surface-tension values. Other investigators (6-11) have also used such mixtures of high and low surface-tension liquids to determine the γ_c of a variety of surfaces.

In the present study, two series of mixtures of solvents with high and low surface tensions were used to characterize the surfaces of various tablets. The methanol-water series and the 1-butanol-formamide series represent two such systems, with both polar and dispersion forces operative and a range of surface-tension values suitable for determining the γ_c values of the solid surfaces under investigation. This study consists of observations on the validity of such characterizations

and on possible reasons for differences in γ_c values when different series of test liquids are used.

Modifications have been made in the procedure previously used in an effort to get more reproducible results. In the previous work, the contact angles reported were measurements made as soon as possible after a single drop was placed on the tablet surface. Because of the porous nature of the tablet, considerable difficulty was experienced in obtaining true initial contact-angle readings that actually reflected the surface energy of a particular tablet surface. In this paper, the contact-angle data reported are the results of successive contact-angle readings as the test liquid was being continuously applied and advanced across the surface of the tablet. This method ensured that the

angles of contact measured were advancing contact angles. Also, the mean contact-angle value for a tablet surface obtained from successive measurements as the liquid advances across the tablet surface is a more accurate measure of the surface energy of that tablet. It is not as prone to distortion due to heterogeneity and tablet imperfections, as is a single measurement on one discreet drop made some time after the drop is placed on the tablet surface.

EXPERIMENTAL

Materials—Tablets were prepared using a pure granular amorphous acetylsalicylic acid (ASA) with adjuvants as indicated (Table I). The tablets were prepared on a single-punch tablet machine using 1.27-cm. (0.5-in.) flat faced punches.

The two series of test liquids were mixtures of absolute methanol¹-water² and 1-butanol³-formamide.³ Table II indicates the surface tensions and compositions of the test liquids.

Surface-Tension Measurements—The surface tensions of the test liquids were determined with a Fisher Tensiometer.⁴ Each recorded measurement is the mean of at least 10 trials, corrected for ring dimension and density of the liquid.

Contact-Angle Measurements—The apparatus used to measure the contact angles consisted of a horizontal telemicroscope⁵ fitted with an erecting adapter, a protractor eyepiece (eyepiece 10X), and an objective lens (objective 2.8X) with a ring light. A further diffuse light source in the form of a microscope light was mounted behind the sample.

The sample holder consisted of a glass microscope slide mounted horizontally on a mechanical microscope stage fitted with a micrometer.

The test liquids were delivered onto the tablet surface by means of a 1-ml. glass syringe mounted in a horizontal position, fitted with a 21-gauge stainless steel needle bent in a 90° curve and containing a polyethylene tubing⁶ insert protruding from the end. The syringe piston was driven by a syringe pump⁷ set to deliver between 0.0355

and 0.0450 ml./min. Figure 1 shows a schematic arrangement of the apparatus.

The contact angles were measured at approximately 10-sec. intervals as the test liquid advanced across the tablet surface. Prior to testing, the tablet surface was wiped on a clean paper towel and brushed with a camel hair brush to remove any materials or loose powder which might have contaminated the surface and could affect the contact angle.

Figure 2 shows a view of the contact angle through the telemicroscope.

All experimental work was carried out in a controlled environment at 20° and 45% relative humidity.

RESULTS

Mean contact angles were determined for the six sets of tablets indicated in Table I, using the relevant members of the series of test liquids indicated in Table II. Each contact angle reported is the mean of approximately 100 readings. Ten readings were made on each of 10 tablets. The mean contact angle and standard deviation

($\theta \pm SD$) of each set were calculated. Tables III and IV are a tabulation of the contact-angle data obtained.

Figures 3-8 show graphically the results when $\cos \theta \pm SD$ is plotted against the surface tension of the test liquid applied to the surface. A linear regression analysis was used to determine the best line through the points, the slope of the line, the degree of correlation, an estimate of critical surface tension (extrapolate to $\cos \theta = 1$), and the error of the estimate. Table V shows a summary of these results.

DISCUSSION

The degree of correlation between surface tension of the test liquids and contact angle is especially good for the tests carried out with the methanol-water solutions. Between 95 and 99% of the variation in contact angle can be attributed to the variation in surface tension of the test liquid.

Although the γ_c values obtained by the use of one test liquid fall within the error of the estimate of the γ_c value obtained by using the

other test liquid, there is an indication that for the tablets with a higher surface energy, a higher γ_c value is obtained when methanol-water contact-angle data are used. It would appear that the γ_c value obtained for a particular tablet is dependent on the type of test solution employed.

The slopes of the curves for methanol-water in all cases are greater than the slopes of the curves for the 1-butanol-formamide solutions. This indicates that changing the concentration of the methanol-water solution so as to increase its surface tension by a fixed amount would cause a greater deterioration in the wetting properties than would be caused by a similar increase in the surface tension of the 1-butanol-formamide solution.

A straight-line relationship between $\cos \theta$ and the surface tension of the liquid as $\cos \theta \rightarrow 1$ has been assumed. One is aware that the overall relationship is not linear, but the part of the curve $\cos \theta$ between 0.7 and 1.0 so closely approximates a straight line that it is felt that this approach is valid. The high degree of correlation, despite the considerable variation in $\cos \theta$ values across a tablet surface and between tablets with the same composition, seems to justify this approximation. The results published by Dann (12) for ethanol-water mixtures on a pure hydrocarbon surface such as paraffin and on surfaces with both polar and nonpolar forces such as poly(ethylene terephthalate) and poly(methylmethacrylate) yield curves that very nearly approximate straight lines between $\cos \theta$ values of 0.7-1. The error introduced by this assumption would be well within the error due to variation in contact-angle measurements, which he puts at $\pm 3^\circ$ in his work on polar polymers.

The surface tension of an organic compound can be estimated

Figure 6—Tablets of acetylsalicylic acid with 5% microcrystalline cellulose; $\cos \theta$ versus γ_L plots of two liquid series. Key: \square , 1-butanol-formamide; and \odot , methanol-water.

from its chemical structure using parachor values (13). The estimated surface tension of acetylsalicylic acid using this method is 34.0 ± 1.7 dynes/cm. This value is fairly close to the estimates obtained from γ_c value data, 30.7 ± 0.8 dynes/cm, and 29.8 ± 0.9 dynes/cm. The discrepancy may well be due to an imbalance of polar and dispersion forces between the tablet surface and the test liquids used.

The addition of magnesium stearate considerably reduces the γ_c of the tablet surface. The slopes of both lines, $\cos \theta$ versus γ_L for methanol-water and 1-butanol-formamide, become steeper (more negative) by the addition of magnesium stearate to the acetylsalicylic acid. This signifies increasingly poorer wetting properties as the surface tension of the test liquids in contact with the tablet surface is increased.

The addition of talc does not significantly affect the γ_c of the tablet surfaces, although it does alter the slopes of the curves so that the curves do not intersect as they do for pure acetylsalicylic acid. The significance, if any, of these changes has not yet been established.

Figure 7—Tablets of acetylsalicylic acid with 10% starch; $\cos \theta$ versus γ_L plots of two liquid series. Key: \square , 1-butanol-formamide; and \odot , methanol-water.

Table V—Summary of Data Analysis from Plots, $\cos \theta$ versus γ_L

Tablet Composition	Methanol-Water Data			1-Butanol-Formamide Data		
	Estimate γ_c , dynes/cm.	Slope	Correlation	Estimate γ_c , dynes/cm.	Slope	Correlation

The addition of microcrystalline cellulose and starches results in surfaces somewhat richer in hydroxyl groups, a consequent higher surface energy, and a surface more prone to polar bonding with polar materials. The experimental γ_c values are increased by the addition of these materials. The fact that for all three tablets the γ_c values obtained with the more polar methanol-water test liquids are greater than that obtained with the 1-butanol-formamide test liquids tends to indicate greater interaction of polar forces.

The attractive forces present in the surface layers and the extent and manner of interaction of these intermolecular forces have been discussed by Dann (12). When a liquid (L), with a surface tension (γ_L) made up of components (γ_L^W) due to dispersion forces and (γ_L^P) due to polar forces, is in contact with a surface made up of saturated hydrocarbons (S) where the surface tension (γ_S) is due to dispersion forces only ($\gamma_S = \gamma_S^W$), the relationship between the contact angle (D) the liquid makes with the hydrocarbon surface is given by the Good-Girifalco-Fowkes-Young equation (14):

$$\cos \theta = 2\sqrt{\gamma_S^W} \left(\frac{\sqrt{\gamma_L^W}}{\gamma_L} \right) - 1 \quad (\text{Eq. 1})$$

If the surface has both dispersion forces and polar forces present and the polar forces are mainly due to hydrogen bonding whose interaction across the interface can also be expressed by a geometric

Figure 8—Tablets of acetylsalicylic acid with 10% starch USP; $\cos \theta$ versus γ_L plots of two liquid series. Key: \square , 1-butanol-formamide; and \circ , methanol-water.

mean relationship, then Eq. 1 becomes:

$$\cos \theta = 2\sqrt{\gamma_S^W} \left(\frac{\sqrt{\gamma_L^W}}{\gamma_L} \right) + 2\sqrt{\gamma_S^P} \left(\frac{\sqrt{\gamma_L^P}}{\gamma_L} \right) - 1 \quad (\text{Eq. 2})$$

Since γ_L and $\cos \theta$ are measurable, γ_S^W for paraffin is known to be 25.5 dynes/cm. (12). Moreover, since $\gamma_L = \gamma_L^W + \gamma_L^P$, the polar and dispersion forces operative in a liquid with mixed attractive forces can be determined (14). The same method could be applied to solid surfaces with mixed attractive forces to determine the individual polar and dispersion forces operative. A knowledge of the breakdown of these forces would permit adjustment of either or both the solid surface or the liquid applied to yield a balanced interface with optimum interaction and, therefore, optimum adhesion. It would also permit the intelligent application of the Zisman technique (15) in determining γ_c values of solid surfaces with mixed attractive forces.

By examining Eq. 2, one sees that if γ_S and γ_L are constant and $\gamma_S^W > \gamma_S^P$, an increase in the γ_L^P will cause a comparable decrease in the γ_L^W and an overall decrease in $\cos \theta$, i.e., a larger contact angle. This would account for the difference in slopes of the plots of $\cos \theta$ versus γ_L for the two different test liquid series.

The extent to which the γ_c values obtained represent the surface energies or attractive forces in the tablet surfaces depends on the extent to which the polar and dispersion forces in the test liquid balance the polar and dispersion forces in the solid surface, since $\cos \theta \rightarrow 1$ when the test liquid only just wets the surface. Figure 9, taken from Dann (12), illustrates the effects of an unbalanced system. A solid surface, which yields a γ_c^W of 39 dynes/cm. when determined using a nonpolar liquid with only dispersion forces interacting, will yield a critical surface tension with a polar series of liquids (γ_c^{PL}), similar to the 1-butanol-formamide, of 31 dynes/cm. When an even more polar series of liquids, ethanol-water, similar to the methanol-water, is used, an even lower γ_c^{PL} value of 26 dynes/cm. is obtained. The use of highly polar liquid series to determine the

Figure 9—Critical surface-tension conversion curves. Key: A, hydrocarbon liquid series with dispersion forces only; B, liquid series with moderate polar forces; and C, ethanol-water series with greater polar forces.

surface energy level of surfaces with only moderate polar forces would result in a very misleading estimate of at least the dispersion forces present in that surface.

CONCLUSIONS

It is possible to characterize tablet surfaces according to their CED by using contact-angle data and applying a modification of the Zisman (15) technique. However, caution must be exercised in the interpretation of the γ_c values obtained. Particular attention should be paid to the possible effects of unbalanced polar and dispersion forces between the test liquids and surfaces investigated.

The surface energy of a tablet, as well as the types of forces present, can to some extent be predicted by studying the types of chemical components that would be present at the surface.

More work needs to be done in determining the presence and relative roles of polar and dispersion forces as they influence wetting, contact-angle data, adsorption, and adhesion.

A knowledge of the types of forces acting across the interface between the tablet surface and a film coating, their relative intensities, and the degree of interaction should greatly advance the understanding of processes involved in the formation of an adequate film coating.

Rotating-Flask Method for Dissolution-Rate Determinations of Aspirin from Various Dosage Forms

HOWARD WEINTRAUB* and MILO GIBALDI

Abstract □ The dissolution of aspirin from different commercial dosage forms was evaluated by the rotating-flask method, and the data were correlated with previously reported absorption data. Regardless of agitation intensity, over a range from 0.9 to 2.4 r.p.m., dissolution rate was found to decrease in the following order: buffered tablets > plain tablets > timed-release tablets. The data were linearized by means of log-normal probability plots and interpreted accordingly. Aspirin dissolves from the buffered tablet about twice as rapidly as from the plain tablet and about eight times as rapidly as from the timed-release tablets. Once disintegration and deaggregation take place, the dissolution of aspirin from the capsule formulation proceeds as rapidly as from the buffered tablet. Surfactant decreased the dissolution rate of aspirin from certain formulations, in contrast to the enhanced dissolution effects observed using the beaker method where mound formation occurred. Excellent single- and multiple-quantitative correlations were observed between the dissolution data and absorption data in man.

Keyphrases □ Aspirin in dosage forms—dissolution rates □ Dissolution rates—aspirin dosage forms □ Surfactant effect—aspirin dissolution from dosage forms □ Rotating-flask method—dissolution-rate determination

A number of methods designed to measure the dissolution rate of drugs from solid dosage forms are presently available (1, 2). Interest has been particularly focused on the beaker method (3) and its variants, including the rotating-basket assembly (4) and the flask and stirrer method (5), since these methods have

consistently provided data which permit some correlation with *in vivo* data (5-8).

A shortcoming of the beaker method is observed at relatively low agitation intensities, *i.e.*, <40-50 r.p.m., where the geometry of the system combined with the nature of the agitation forces the granules or particles into a mound at the bottom of the flask or beaker. The mound is more or less compact, depending upon the formulation of the dosage form, and may or may not present a markedly reduced surface area to the dissolution medium. This problem was exemplified by Levy *et al.* (6), who were concerned with the quantitative correlation of dissolution data with the gastrointestinal absorption in man of aspirin from different types of dosage forms. Clinical studies indicated that aspirin was absorbed about three times more rapidly from "plain tablets" of the drug than from a timed-release preparation. Dissolution data obtained at 50 r.p.m. gave virtually perfect correlation with respect to differences between the two dosage forms observed *in vivo*, but the dissolution rate of the drug from the plain tablet was about twice the absorption rate of the drug from the same dosage form. At 45 r.p.m., where the dissolution rate of aspirin from the plain tablet was comparable to the absorption rate of drug from this dosage form, there was only a 50% difference between the timed-

surface energy level of surfaces with only moderate polar forces would result in a very misleading estimate of at least the dispersion forces present in that surface.

CONCLUSIONS

It is possible to characterize tablet surfaces according to their CED by using contact-angle data and applying a modification of the Zisman (15) technique. However, caution must be exercised in the interpretation of the γ_c values obtained. Particular attention should be paid to the possible effects of unbalanced polar and dispersion forces between the test liquids and surfaces investigated.

The surface energy of a tablet, as well as the types of forces present, can to some extent be predicted by studying the types of chemical components that would be present at the surface.

More work needs to be done in determining the presence and relative roles of polar and dispersion forces as they influence wetting, contact-angle data, adsorption, and adhesion.

A knowledge of the types of forces acting across the interface between the tablet surface and a film coating, their relative intensities, and the degree of interaction should greatly advance the understanding of processes involved in the formation of an adequate film coating.

Rotating-Flask Method for Dissolution-Rate Determinations of Aspirin from Various Dosage Forms

HOWARD WEINTRAUB* and MILO GIBALDI

Abstract □ The dissolution of aspirin from different commercial dosage forms was evaluated by the rotating-flask method, and the data were correlated with previously reported absorption data. Regardless of agitation intensity, over a range from 0.9 to 2.4 r.p.m., dissolution rate was found to decrease in the following order: buffered tablets > plain tablets > timed-release tablets. The data were linearized by means of log-normal probability plots and interpreted accordingly. Aspirin dissolves from the buffered tablet about twice as rapidly as from the plain tablet and about eight times as rapidly as from the timed-release tablets. Once disintegration and deaggregation take place, the dissolution of aspirin from the capsule formulation proceeds as rapidly as from the buffered tablet. Surfactant decreased the dissolution rate of aspirin from certain formulations, in contrast to the enhanced dissolution effects observed using the beaker method where mound formation occurred. Excellent single- and multiple-quantitative correlations were observed between the dissolution data and absorption data in man.

Keyphrases □ Aspirin in dosage forms—dissolution rates □ Dissolution rates—aspirin dosage forms □ Surfactant effect—aspirin dissolution from dosage forms □ Rotating-flask method—dissolution-rate determination

A number of methods designed to measure the dissolution rate of drugs from solid dosage forms are presently available (1, 2). Interest has been particularly focused on the beaker method (3) and its variants, including the rotating-basket assembly (4) and the flask and stirrer method (5), since these methods have

consistently provided data which permit some correlation with *in vivo* data (5-8).

A shortcoming of the beaker method is observed at relatively low agitation intensities, *i.e.*, <40-50 r.p.m., where the geometry of the system combined with the nature of the agitation forces the granules or particles into a mound at the bottom of the flask or beaker. The mound is more or less compact, depending upon the formulation of the dosage form, and may or may not present a markedly reduced surface area to the dissolution medium. This problem was exemplified by Levy *et al.* (6), who were concerned with the quantitative correlation of dissolution data with the gastrointestinal absorption in man of aspirin from different types of dosage forms. Clinical studies indicated that aspirin was absorbed about three times more rapidly from "plain tablets" of the drug than from a timed-release preparation. Dissolution data obtained at 50 r.p.m. gave virtually perfect correlation with respect to differences between the two dosage forms observed *in vivo*, but the dissolution rate of the drug from the plain tablet was about twice the absorption rate of the drug from the same dosage form. At 45 r.p.m., where the dissolution rate of aspirin from the plain tablet was comparable to the absorption rate of drug from this dosage form, there was only a 50% difference between the timed-

Figure 1—Cumulative percent dissolved from aspirin dosage forms in 0.1 N HCl at 0.9 r.p.m. Key: ●, buffered tablets; ○, plain tablets; and △, timed-release tablets.

release preparation and the plain tablet, in contrast to the threefold difference observed *in vivo*. At still lower agitation rates, aspirin dissolved more rapidly from the timed-release tablets than from the plain tablets. In an attempt to overcome this problem, the rotating-flask method (9) was devised.

The philosophy underlying the development of the method is in keeping with that embodied in the development of the beaker method (3). "For tablets and other solid oral dosage forms, low intensities of agitation are highly desirable and more likely to allow distinguishing formulations and products and correlating results with *in vivo* data" (2). But at the same time, the hydrodynamics of the rotating-flask method effectively preclude mound formation, which is considered to be physiologically unrealistic. The present report concerns the evaluation of aspirin dissolution from different types of commercial dosage forms by means of this method and the correlation of these data with previously reported (6, 10) absorption data.

EXPERIMENTAL

Dosage Forms—The following were used: (a) rapidly disintegrating tablets, each containing 650 mg. aspirin as microencapsulated particles (timed-release tablets); (b) rapidly disintegrating tablets, each containing 325 mg. aspirin (plain tablets); (c) rapidly disintegrating tablets, each containing 325 mg. aspirin and alkaline additives (buffered tablets); and (d) capsules, each containing 325 mg. aspirin (capsules). Each dosage form was purchased from retail outlets.

Dissolution-Rate Determination—*In vitro* dissolution rates were determined at 37° by the rotating-flask method (9). The dissolution medium consisted of 400 ml. of 0.1 N HCl. In certain experiments, 0.01 % polyoxyethylene (23) lauryl ether¹ was added to the medium.

Table I—Comparison of Aspirin Dissolution from Commercial Dosage Forms at Various Experimental Conditions

Experimental Conditions and Dosage Forms	Median Time, ^a min.	Dissolution Interval, ^b min.	SD ^c

^a Time required to dissolve 50% of the dose. ^b Time required to dissolve 84% of the dose minus the time required to dissolve 16% of the dose. ^c Log (time required to dissolve 50% of the dose) - log (time required to dissolve 16% of the dose), or log (time required to dissolve 84% of the dose) - log (time required to dissolve 50% of the dose). ^d 0.01 % Polyoxyethylene (23) lauryl ether.

Rotation was provided by a constant-speed motor² coupled to a series of gears and was varied from 0.9 to 2.4 r.p.m. A minimum of five determinations was made with each dosage form at a given rate of rotation, with the exception of the timed-release tablets where three determinations were made.

At frequent intervals after the introduction of the dosage form into the flask, rotation was briefly halted, a 1-ml. sample was taken by means of a filter pipet, and rotation was initiated once again. Elapsed time was considered to be the time during which the flask was actually rotating. Preliminary studies with the most rapidly dissolving aspirin dosage form indicated that intermittent sampling had no significant effect on the dissolution profile.³

Each sample was made alkaline by addition of 1 ml. 1 N NaOH and hydrolyzed for 1 hr. at 100°. Following hydrolysis, the pH of each sample was adjusted to pH 1 with concentrated HCl, and the samples were assayed spectrophotometrically⁴ at 302.5 mμ for salicylic acid.

RESULTS AND DISCUSSION

Figure 1 is a plot of the cumulative amount (expressed as percent of dose) of aspirin dissolved as a function of time from three of the dosage forms at an agitation intensity of 0.9 r.p.m. The ranking observed—*viz.*, buffered tablet > plain tablet > timed-release tablet, agrees with the findings of Levy *et al.* (6). The same rank order was observed at 1.2 and 2.4 r.p.m. The initial dissolution profile of aspirin from the capsule was comparable to that observed with the plain tablet, but the time required to dissolve 80–90% of the capsule dose was considerably less than that observed with the plain tablet and, in fact, compared favorably with findings from the buffered tablet. Therefore, it was difficult to compare the dissolution of aspirin from the capsule with the data from the other dosage forms.

The interpretation of the percent dissolved–time plots adopted in this study was based on the graphical methods suggested by Wagner (11). He demonstrated that under sink conditions, the per-

cent dissolved to time T from a solid is equal to the percent of surface area generated to time T of total surface generated. Wagner proposed that the properties of the distribution of surface area available for dissolution from a capsule or tablet dosage form are similar to those of a log normal and log logistic distribution. Hence, one could plot the cumulative percent dissolved values on the probability scale (ordinate) *versus* the corresponding time values on the logarithmic scale (abscissa). If the data are described by this particular distribution function, then the points should describe a straight line. An estimate of the median dissolution time may be obtained by reading the time corresponding to the 50% point, and an estimate of the standard deviation (SD) may be obtained from the 16, 50, and 84% points by appropriate conversion of the time values to their logarithms. In the present report the difference, in units of time, between the 16 and 84% points is termed the dissolution interval.

The percent dissolved-time data obtained with the various dosage forms, with and without surfactant in the dissolution medium, at various agitation intensities were well described in each

Figure 3—Relationship between percent aspirin dissolved from buffered tablets and percent aspirin absorbed from this dosage form to the same time T . Dissolution data obtained in 0.1 N HCl at 0.9 r.p.m.

case by log-normal probability plots. Examples are shown in Fig. 2, using dissolution data obtained at 2.4 r.p.m. The critical parameters used to describe the dissolution data for all dosage forms under various experimental conditions are summarized in Table I.

As expected, for a given dosage form both the median time and dissolution interval decrease with an increase in agitation intensity; with the exception of the capsule data, the standard deviation increases with increasing agitation. Regardless of agitation intensity, the median time increases in the following order: buffered tablet < plain tablet < capsule < timed-release tablet. Comparison of the dissolution interval data suggests that aspirin dissolves from the buffered tablet about twice as rapidly as from the plain tablet and

Figure 2—Log-normal probability plots of dissolution data from aspirin dosage forms in 0.1 N HCl at 2.4 r.p.m. Key: ○, buffered tablets; □, plain tablets; and Δ, timed-release tablets.

Figure 4—Relationship between percent aspirin dissolved and percent aspirin absorbed to the same time T . Dissolution data obtained in 0.1 N HCl with 0.01% polyoxyethylene (23) lauryl ether at 0.9 r.p.m. Key: ●, buffered tablets; ○, plain tablets; and △, timed-release tablets.

about eight times as rapidly as from the timed-release tablet. Ratios of dissolution intervals are reasonably constant over the entire range of agitation intensities. The dissolution interval for the capsule was comparable to that of the buffered tablet. These observations suggest that disintegration and deaggregation of the capsule contents require a greater time than for similar events to occur with the plain and buffered tablets; but once these processes take place, the dissolution of aspirin from the capsule formulation proceeds as rapidly as from the disintegrated buffered tablet formulation.

The influence of 0.01% nonionic surfactant on the dissolution rate of aspirin from the various dosage forms at 0.9 r.p.m. is also summarized in Table I. Addition of the surfactant results in a considerable increase in the median time and dissolution interval for both the plain and buffered tablets but is without effect on the dissolution of aspirin from the capsule and timed-release formulations. In a previous report (12) concerned with dissolution of aspirin from the capsule and buffered tablet dosage forms using the flask and stirrer method, it was observed that 0.01% polyoxyethylene (23) lauryl ether had no effect on the dissolution of aspirin from the capsule but markedly decreased the median dissolution time for the buffered tablet. In the judgement of the present authors, the qualitatively different effects of the surfactant on the dissolution of aspirin from the buffered tablet, using the beaker method and rotating-flask method, are attributable to mound formation in the former and its absence in the latter.

In the beaker method, the disintegrated buffered tablet granules apparently form a rather compact mound at the bottom of the flask and give rise to a "porous plug" which the dissolution medium finds difficult to penetrate. The surfactant enhances pore penetration ostensibly by reducing the contact angle and thereby increases the effective surface area and, in turn, the dissolution rate. Since the rotating-flask method does not give rise to a mound or porous plug, one anticipates that the surfactant would not enhance the dissolution rate. This was indeed the case. The decreased dissolution rate of aspirin from the plain and buffered tablets which was observed in the presence of the surfactant may be due to a dewetting phenomenon and subsequent aggregation of the particles (13).

In a preliminary communication (9), the authors reported that the aspirin-dissolution data for the plain, buffered, and timed-release tablets obtained with the rotating-flask method provided an excellent quantitative correlation with previously reported *in vivo* absorption data (6, 10) on the same dosage forms. This type of an-

alysis was extended, and comparisons of *in vivo* and *in vitro* data were made for the individual dosage forms as well as for the three dosage forms simultaneously under various experimental conditions. Figure 3 is an example of a single correlation. Excellent linearity is observed when the percent of dose dissolved in time T from a buffered tablet in 0.1 N HCl at 0.9 r.p.m. is plotted as a function of the percent absorbed to time T in man. The slope of the line is 1.32, and the correlation coefficient is > 0.99 . Figure 4 shows the best example of a multiple correlation. Dissolution data were obtained in 0.1 N HCl with surfactant at 0.9 r.p.m. The slope of the least-squares line is 0.99, and the correlation coefficient is 0.98.

Table II summarizes the analysis for *in vivo-in vitro* correlation and includes the least-squares slope and intercept for the equation:

$$(\% \text{ dissolved to time } T) = b(\% \text{ absorbed to time } T) + a \quad (\text{Eq. 1})$$

as well as the correlation coefficient. The latter values were computed according to Mather (14) for interclass correlation where both variables are normally distributed. In all but two cases, the correlation coefficient was greater than 0.90 and in all cases the correlation coefficient was highly significant ($p < 0.005$).

Based on the *in vivo-in vitro* correlations obtained with the aspirin dosage forms, it would appear that the rotating-flask method offers certain advantages over the beaker methods currently in use. However, before any *in vitro* dissolution method can be relied upon as an index of physiologic availability or *in vivo* absorption rate, more retrospective testing is required.

Theoretical Approach to Sustained-Release Multiple-Dose Therapy: Noncumulative Attainment of Desired Blood Level

JOSEPH R. ROBINSON* and STUART P. ERIKSEN†

Abstract □ Equations are presented to allow calculation of doses and dosing interval for multiple-dose therapy of sustained-release dosage forms. Both zero- and first-order release of drug from the dosage form are considered in developing these equations. Although special problems are associated with multiple dosing of sustained-release dosage forms because of their unique design, application of the appropriate equations yields relatively uniform blood levels of drug.

Keyphrases □ Sustained-release products—multiple-dose therapy □ Equations—doses, dosing intervals, calculation □ Blood levels—noncumulative multiple-dose therapy □ Theoretical approach—noncumulative blood levels, sustained-release therapy

Considerable effort has been expended in the mathematical development of dosage regimens for multiple dosing of nonsustained-release dosage forms (1-7). In recent work (7), the authors developed equations to allow calculation of doses and dosing intervals to produce and maintain a desired blood level (noncumulative approach). Surprisingly, the problem of multiple dosing with sustained-release dosage forms has not been considered. In the present work, equations are presented which will allow a rational (and hopefully pragmatic) approach to such therapy.

MODEL USED

A simple four-compartment model was used throughout this study (Scheme I). All of the customary assumptions of pharmacokinetics with respect to exponential rate processes, constants, etc., as well as the validity of the model are assumed in this study (see *References 1a* and 7 for a discussion of these points).

ELEMENTARY REGIMEN

The elementary regimen design, using two units initially followed by one unit each elimination half-life later, was found to be only very approximately valid for oral nonsustained-release products, as reported in another paper (7). Simple extension of this elementary concept from nonsustained- to sustained-release dosage forms suggests that for a sustained-release dosage form, which is designed to

Scheme I—Model used in development and evaluation of sustained-action equations

provide flat blood levels over a full treatment period, the dosing frequency, $\tau_{\text{sust.}}$, should be

$$\tau_{\text{sust.}} = h + t_{1/2 \text{ elimination}} \quad (\text{Eq. 1})$$

where h is the number of hours of desired sustained effect for which one dose of the sustained-release dosage form has been designed, and $t_{1/2 \text{ elimination}}$ is the elimination half-life of the drug. Similar, but more severe, problems than those encountered with nonsustained medications are encountered here. The solution to these problems depends somewhat upon the mathematics to describe the release of drug from the dosage form, i.e., zero- or first-order release, but in general involves corrections for the same difficulties present in non-sustained multiple-dose therapy, i.e., accumulation of drug in the body.

As in any therapy, the interest of both the patient and the physician is safe, but rapid, and maintained relief. A therapy dependent upon accumulation does not achieve this goal. The desired sustained-action product should rapidly attain and maintain the desired blood or tissue level of drug. All subsequent doses must be designed and taken to reach the plateau blood level established by the first dose.

The theoretical concepts behind the design of a single sustained-action dosage form have been reported (8-10). This earlier work was designed to produce the optimum blood picture for one administered dose. While identical concepts are involved when multiple doses are to be administered, slight alterations must be made to eliminate the undesired accumulation effect.

SATISFACTORY SUSTAINED-ACTION PATTERN

The nonsustained-action definition of "satisfactory therapeutic blood level patterns" (7), i.e., a rapid rise to a peak suitable to produce the desired biological action followed by a regular rise and fall between constant values, must be altered slightly for sustained-action dosage forms. Satisfactory blood level patterns, for

ELEMENTARY REGIMEN

The elementary regimen design, using two units initially followed by one unit each elimination half-life later, was found to be only very approximately valid for oral nonsustained-release products, as reported in another paper (7). Simple extension of this elementary concept from nonsustained- to sustained-release dosage forms suggests that for a sustained-release dosage form, which is designed to

Scheme I—Model used in development and evaluation of sustained-action equations

provide flat blood levels over a full treatment period, the dosing frequency, $\tau_{\text{sust.}}$, should be

$$\tau_{\text{sust.}} = h + t_{1/2 \text{ elimination}} \quad (\text{Eq. 1})$$

where h is the number of hours of desired sustained effect for which one dose of the sustained-release dosage form has been designed, and $t_{1/2 \text{ elimination}}$ is the elimination half-life of the drug. Similar, but more severe, problems than those encountered with nonsustained medications are encountered here. The solution to these problems depends somewhat upon the mathematics to describe the release of drug from the dosage form, i.e., zero- or first-order release, but in general involves corrections for the same difficulties present in non-sustained multiple-dose therapy, i.e., accumulation of drug in the body.

As in any therapy, the interest of both the patient and the physician is safe, but rapid, and maintained relief. A therapy dependent upon accumulation does not achieve this goal. The desired sustained-action product should rapidly attain and maintain the desired blood or tissue level of drug. All subsequent doses must be designed and taken to reach the plateau blood level established by the first dose.

The theoretical concepts behind the design of a single sustained-action dosage form have been reported (8-10). This earlier work was designed to produce the optimum blood picture for one administered dose. While identical concepts are involved when multiple doses are to be administered, slight alterations must be made to eliminate the undesired accumulation effect.

SATISFACTORY SUSTAINED-ACTION PATTERN

The nonsustained-action definition of "satisfactory therapeutic blood level patterns" (7), i.e., a rapid rise to a peak suitable to produce the desired biological action followed by a regular rise and fall between constant values, must be altered slightly for sustained-action dosage forms. Satisfactory blood level patterns, for

Figure 1—Simulated blood level patterns produced with an adequately designed "zero-order released" sustained-action dosage form. Curve A (lower curve) is one dosage unit initially followed by one dosage unit every $\tau_{\text{sust.}}$ hr.; Curve B (upper curve) is two dosage units initially followed by one every $\tau_{\text{sust.}}$ hr. Both curves utilize $\tau_{\text{sust.}}$ as calculated from Eq. 1.

this purpose, will be produced by dosages and regimens yielding a rapid rise to blood levels suitable to produce the therapeutic effect, maintained at that level for a desired length of time, and followed at regular intervals by suitable doses to reestablish and maintain the same blood levels. The equations required will be discussed according to the type of release produced by the dosage form used, i.e., zero- or first-order release.

DRUGS RELEASED BY ZERO-ORDER PROCESSES

Calculation of Doses Required—The second dose of a sustained-release dosage form,¹ administered at time $\tau_{\text{sust.}}$ (using Eq. 1) after the start of therapy, produces blood levels similar to those shown in Fig. 1. Because of their unique design, sustained-release dosage forms are unable to maintain any blood level but the one for which they were designed (B_d). The dosage regimen, where a single sustained-release dose is taken after two initial ones, produces a slow drop of the blood level down to that value for which the single dose was designed. Single doses administered one after the other produce accumulation.

The immediately available portion of the second and subsequent sustained-action doses must be corrected to obtain the optimum flat blood level pattern for which these dosage forms are designed. For the initial dose, the maintenance portion (D_m) is prepared according to standard equations (8):

$$D_m = R \times h \quad (\text{Eq. 2})$$

where $R = k_d B_d$ and is the zero-order availability rate of drug from the dosage form, h is the selected time of sustained action for one dose, k_d is the elimination constant,² and B_d is the desired amount of drug in the blood, all ascertained from the pharmacokinetics of single, nonsustained doses. The immediately available portion (D_1), when both the immediate and maintenance portions begin release of drug from time zero, is normally calculated to be (8):

$$D_1^{\text{corr.}} = D_1 - R t_p \quad (\text{Eq. 3})$$

where D_1 is the nonsustained dose required to obtain the desired peak blood level of B_d , and $R t_p$ is the correction on the initial dose necessary due to supply of drug from the maintenance portion over the time period zero to peak time (8). For any subsequent sustained-action dose, however, the immediately available portion must be decreased to take into account that the desired blood level

(B_d) has decreased to $N B_d$ by the time of the next dose [the fraction N is defined as the fraction of the peak height (B_d) to which the blood level is allowed to drop before the next dose is administered]. Thus, the optimum dose for the subsequent doses, $D_2^{\text{corr.}}$, can be estimated to be

$$D_2^{\text{corr.}} \dots n \cong (1 - N) D_1 - R t_p \quad (\text{Eq. 4})$$

using the approximations developed in earlier work (7, 8). It is apparent that if the half-life time is used

$$D_2^{\text{corr.}} \cong \frac{1}{2} D_1 - R t_p \quad (\text{Eq. 4a})$$

To offer a complete picture, if a dosage form involving a delayed start of maintenance dose is used (8):

$$D_2 \dots n \cong (1 - N) D_1 \quad (\text{Eq. 5})$$

Calculation of Dosing Interval—The calculation of $\tau_{\text{sust.}}$, the treatment time for the zero-order release dosage form, involves a sum of the time to empty the dosage form (h) and the time for the blood level to drop to one N th of the plateau value:

$$\tau_{\text{sust.}}^0 = h + \frac{2.3}{k_d} \log \left(\frac{1}{1 - N} \right) + \Delta t \quad (\text{Eq. 6})$$

where the first two terms are the general expression for which Eq. 1 is the example at $N = 1/2$. The Δt term is a correction for drug being absorbed from the gut after the moment (h) where the dosage form has ceased to yield drug (7).

The correctness of Eq. 1 assumes that the dosage form is completely empty (probably true) and that all absorption ceases at the moment h . Under these circumstances, the drop of the blood level to one N th of the plateau value requires a time equal to $2.3/k_d \log [1/(1 - N)]$ time units. The time error involved in making the assumption that all absorption ceases at the moment h for oral dosage forms can be estimated to be Δt , where Δt is the horizontal distance between that "no absorption line" and the "eventual elimination line," as shown in Fig. 2. It can be shown mathematically that the time error is identical to that previously derived for nonsustained forms (7).

At the moment that the dosage form is empty, h , the concentration in the gut is G_h , where $G_h = k_d B_d / k_a$. The equality of the rate of absorption, $k_a G_h$, and the rate of loss from the blood, $k_d B_d$, is a requirement for sustained action. From that time on, the blood level is

$$B = B_d e^{-k_d t} + \frac{G_h k_a}{k_a - k_d} (e^{-k_d t} - e^{-k_a t}) \quad (\text{Eq. 7})$$

Substituting $k_d B_d$ for $G_h k_a$,

$$B = B_d \left[e^{-k_d t} + \frac{k_d}{k_a - k_d} (e^{-k_d t} - e^{-k_a t}) \right] \quad (\text{Eq. 8})$$

The eventual elimination line for such a dosage (letting $e^{-k_a t} \rightarrow 0$) is described by the equation:

$$B = B_d e^{-k_d t} \left(\frac{k_a}{k_a - k_d} \right) \quad (\text{Eq. 9})$$

This equation is identical to the similar eventual elimination line described for a nonsustained dose (7). The time error, Δt , is therefore again described by the equation previously reported (7):³

$$\Delta t = \frac{2.3}{k_d} \log \left(\frac{k_a}{k_a - k_d} \right) \quad (\text{Eq. 10})$$

One precisely designed sustained-action dose, followed at intervals of $\tau_{\text{sust.}}^0$ by corrected sustained-action follow-up doses, will produce

³ The derivation of this equation involves setting the equations describing the blood level of an intravenous injection and an oral dose (Eq. 9) equal and solving for the time difference between them, i.e.,

$$B e^{-k_d t_1} = \frac{B k_a}{k_a - k_d} e^{-k_d t_2}$$

$$t_2 - t_1 = \Delta t = \frac{2.3}{k_d} \log \left(\frac{k_a}{k_a - k_d} \right)$$

¹ Sustained-action dosage forms, as used here, mean a system composed of an immediately available portion plus a sustaining or maintenance portion.

² The terms elimination and absorption refer specifically to the mathematical model considered and are so termed only for purposes of comprehension. From the standpoint of dosage form design, the only constants of concern are those describing the rise of drug concentration (or amount) in the tissue measured (blood in these discussions) and the decrease of that concentration (or amount). For a simple model, these may be called absorption and elimination constants, k_a and k_d , but they are only related to the actual constants for the physiologic processes of absorption and excretion or metabolism.

Figure 2—Computer-drawn construction showing the development of the Δt correction for sustained-action dosage forms.

the blood level patterns shown in Figs. 3 and 4. While the impractical method of administering a different dosage unit initially ($D_1^{\text{corr.}}$ and then $D_2^{\text{corr.}}$) produces the fastest rise to B_d , the use of the same corrected second dose at each interval of $\tau_{\text{sust.}}^0$ hr. achieves essentially the same result. Figure 4 shows the computer-drawn curves for a sustained-release penicillin product using zero-order release procedures and the constants of Juncher and Rasschou (11); quite acceptable sustained action is demonstrated.

DRUGS RELEASED BY FIRST-ORDER PROCESSES

Calculation of Doses Required—For the initial dose, the maintenance portion (D_m) is prepared according to standard procedures (8):

$$D_m = \frac{k_d}{k_r} B_d \quad (\text{Eq. 11})$$

where $k_r = k_d e^{-k_d h}$ and is the first-order availability rate of drug from the dosage form. The immediately available portion (D_1), when both the immediate and maintenance portion begin release at time zero, can be calculated using Eq. 12:

$$D_1^{\text{corr.}} = D_1 - k_r D_m t_p \quad (\text{Eq. 12})$$

As with the zero-order case, a correction is applied for the amount of drug contributed by the maintenance portion from time zero to the peak time (8).

Subsequent doses require correction for the immediately available portion:

$$D_2^{\text{corr.}} \dots n = (1 - N)D_1 - k_r D_m t_p \quad (\text{Eq. 13})$$

Figure 3—Simulated blood level patterns for multiple sustained-release therapy. Curve A is initial dose unit of ($D_1 + D_m$) and subsequent dose units of $[(1 - N)D_1 + D_m]$ every $\tau_{\text{sust.}}$ hr.; Curve B is repeated dosings with $[(1 - N)D_1 + D_m]$ every $\tau_{\text{sust.}}$ hr.

Figure 4—Computer-drawn blood level patterns for a zero-order sustained-release penicillin product, using the pharmacokinetic constants of Juncher and Rasschou (11), calculated for a blood level of 47.65 units, $k_a = 4.3 \text{ hr.}^{-1}$, $k_d = 0.852 \text{ hr.}^{-1}$, $R = 40.5$, $D_1^{\text{corr.}} = 51.2$, and $D_2^{\text{corr.}} = 25.6$.

If the maintenance dose has a delayed start, the equation is

$$D_2 \dots n = (1 - N)D_1 \quad (\text{Eq. 14})$$

Calculation of Dosing Interval—The second and subsequent doses of a dosage form whose maintenance portion releases drug by a first-order process must be corrected in a manner similar to zero-order dosages to prevent excessive peaking. The frequency of therapy, however, plays a larger part in first-order release therapy, because after the designed sustained-release time, h , has passed, considerable drug is still available and is being released from the dosage form. First-order release forms achieve their action through small release constants, k_r , and relatively large maintenance doses, D_m (8). The blood level very rapidly becomes controlled by the dosage form release constant, so that

$$B = \frac{D_m k_r}{(k_d - k_r)} e^{-k_r t} \quad (\text{Eq. 15})$$

after the immediately available portion of the dosage form is no longer contributing to the blood picture. This is the equation for the "eventual elimination line" of such a dosage form (Fig. 2).

The time error (Δt_1), resulting from assuming immediate cessation of absorption and that the blood level decreases in a manner based solely on k_d , is then

$$\Delta t_1 = \frac{2.3}{k_r} \log \left(\frac{k_d}{k_d - k_r} \right) \quad (\text{Eq. 16})$$

making the dosing interval for first-order release dosage forms

$$\tau_{\text{sust.}}^1 = h + \frac{2.3}{k_r} \log \left(\frac{1}{1 - N} \right) + \Delta t_1 \quad (\text{Eq. 17})$$

Figure 5—A "practical" solution to sustained-action for penicillin ($k_a = 4.3 \text{ hr.}^{-1}$, $k_d = 0.852 \text{ hr.}^{-1}$) with a first-order release dosage form. Curve A is a computer-simulated blood level diagram for a 0.024-g. dose. Curve C is the diagram for a single sustained-action dose, the parameters calculated as described in earlier work ($D_1^{\text{corr.}} = 0.024 \text{ g.}$, $D_m = 81 \text{ g.}$, $k_r = 0.00174 \text{ hr.}^{-1}$). Curve B is the "practical, multiple sustained-release dosage method" described here ($D_1^{\text{corr.}} = 0.013 \text{ g.}$, $D_m = 0.488 \text{ g.}$, $k_r = 0.028 \text{ hr.}^{-1}$).

Table I—Required Equations for Design of Sustained- and Nonsustained-Release Dosage Forms

Term	Nonsustained	Zero-Order Sustained	First-Order Sustained
D_1	D	D	D
$D_1^{\text{corr.}}$	—	$D_1 - R t_p$	$D_1 - k_r D_m t_p$
$D_2 \dots n$	$(1 - N)D$	$(1 - N)(D_1)$	$(1 - N)D_1$
$D_2 \dots n^{\text{corr.}}$	—	$(1 - N)D_1 - R t_p$	$(1 - N)D_1 - k_r D_m t_p$
D_m	—	$R \cdot h$	$\frac{k_d}{k_r} B_d$
R or k_r	—	$R = k_d B_d$	$k_r = k_d e^{-k_d h}$
τ or $\tau_{\text{sust.}}$	$t_p + \Delta t$	$h + \Delta t$	$h + \Delta t_1$
	$+ 2.3 \log \left(\frac{1}{1 - N} \right) \left(\frac{1}{k_d} - \frac{1}{k_a} \right)$	$+ \frac{2.3}{k_d} \log \left(\frac{1}{1 - N} \right)$	$+ \frac{2.3}{k_r} \log \left(\frac{1}{1 - N} \right)$
Δt or Δt_1	$\frac{2.3}{k_d} \log \left(\frac{k_a}{k_a - k_d} \right)$	$\frac{2.3}{k_d} \log \left(\frac{k_a}{k_a - k_d} \right)$	$\frac{2.3}{k_r} \log \left(\frac{k_d}{k_d - k_r} \right)$

For the design of sustained-release dosage forms intended to be administered in more than one dose, a summary of the required equations is shown in Table I and a glossary of terms is given in Table II. For comparison, the equations required for nonsustained-release dosage forms are also shown.

PRACTICAL DESIGN OF DOSAGE FORMS

Because therapy with sustained-action dosage forms is for the benefit of the patient, not every treatment frequency is equally convenient, nor are varying dosage schedules. From a pragmatic point of view, the dosage units must be all the same or, at most, simple fractions of the first dose. In addition, treatment frequency must be constant and, by convention, be held to a very few values.

Nonsustained-Action Forms—Nonsustained-action forms are commonly administered at intervals of one, two, three, or four per day. The dosage multiples represent the only variable available to the formulator for maintaining an even series of blood level peaks and valleys.

The frequency of treatment equation (τ , see Table I) may be solved for N using $\tau = 6, 8, 12$, and 24 hr. (7). Any simple, even fraction approximating N will enable the initial and subsequent dose ratios to be calculated (if $N = 0.75$ or $3/4$, the initial dose represents three units and the subsequent doses one unit).

Sustained-Action Forms—Zero-Order Release—The dosing interval contains only the sustained-action time, h , as an adjustable variable. Since $\tau_{\text{sust.}}$ for sustained-action forms is normally limited to 12 or 24 hr., h can have but two possible values for any drug. Using a selected value for $\tau_{\text{sust.}}$, the resulting value of h may be used to calculate the remaining factors.

The size of the total dose is customarily limited to 0.5 g. for one dosage unit (an administered dose could, of course, be two units).

Thus, because $D_m = R \times h$ where R is fixed by the desired blood level and the elimination constant,

$$D_m = 0.5 - (1 - N)D_1 \quad (\text{Eq. 18})$$

$$h^* = (\text{desired } h) = D_m/R \quad (\text{Eq. 19})$$

$\tau_{\text{sust.}}^0$ = selected value that produces a calculated

value of h closest to h^* (Eq. 20)

$$\text{subsequent } D_2 \dots n = (1 - N)D_1 \quad (\text{Eq. 21})$$

Note that several values of N may be tried; larger values decrease the valleys and decrease the subsequent $D_2 \dots n$, smaller ones increase them.

First-Order Release—Since the total dose is again limited to approximately 0.5 g. and $\tau_{\text{sust.}}$ is again constrained to 12 or 24 hr., the required parameters are calculated from these points:

$$D_m = 0.5 - (1 - N)D_1 \quad (\text{Eq. 22})$$

$$k_r = k_d \frac{B_d}{D_m} \quad (\text{Eq. 23})$$

$$h^* = (\text{desired } h) = \frac{2.3}{k_d - k_r} \log \left(\frac{k_d}{k_r} \right) \quad (\text{Eq. 24})$$

$$h = \tau_{\text{sust.}}^1 - \frac{2.3}{k_r} \log \left(\frac{1}{1 - N} \right) - \Delta t \quad (\text{Eq. 25})$$

and $\tau_{\text{sust.}}^1$ is selected as 12 or 24 to produce a calculated value of h as close as possible to h^* . Several values of N should be tried. Then,

$$D_1^{\text{corr.}} = D_1 - k_r D_m t_p \quad (\text{Eq. 26})$$

Calculation of sustained-action dosage forms, based on this pragmatic approach, will not produce the optimum in blood level patterns. Unfortunately, however, to obtain the optimum blood level pattern with these nonideal availability kinetics, very large maintenance doses may be required (especially if k_d is large). Within the limits of practical oral dosages, the "practical approach" produces the only satisfactory dosage form. The difference between the blood level pattern for the optimum and the practical design is shown in Fig. 5 for a drug with a large k_d .

Satisfactory sustained- and nonsustained-release dosage forms can be designed with relatively simple equations. The equations provided in this report are based on simple models and are intuitively correct. They have been derived completely so that the assumptions involved are apparent.

Table II—Glossary of Terms Used

Symbol	Definition
D	Equals the 100% available oral dose required to produce the desired blood level peak, B_d
R or k_r	Zero- and first-order dosage form availability constants
t_p	Time after administration for peak blood level to occur
N	Fraction of peak or sustained blood level present at the time when the next dose is administered
h	Designated sustained action for one dose, or the time to "empty" the dosage forms
D or $D^{\text{corr.}}$	Immediately available dose (D) and corrected dose ($D^{\text{corr.}}$), with the subscript referring to the dose number
D_m	Maintenance dose
$\tau_{\text{sust.}}$	Dosing interval for sustained-action dosage forms: $\tau_{\text{sust.}}^0$ (zero order), $\tau_{\text{sust.}}^1$ (first order)
k_a, k_d	Absorption and elimination constants for the drug involved

Metabolism of Flurazepam, a Benzodiazepine, in Man and Dog

MORTON A. SCHWARTZ and EDWARD POSTMA

Abstract □ The metabolism of ^{14}C -flurazepam hydrochloride, 7-chloro-1-(2-diethylaminoethyl)-5-(2-fluorophenyl)-1,3-dihydro-2H-1,4-benzodiazepin-2-one- $5\text{-}^{14}\text{C}$ dihydrochloride, was studied in a dog administered oral and intravenous 2-mg./kg. doses and in two human subjects who each received a 28-mg. oral dose. In both species, evidence was obtained for rapid and essentially complete absorption followed by a rapid elimination of plasma flurazepam. Biotransformation of the drug was rapid and virtually complete in man and dog. Pathways of biotransformation were similar in both species. All the metabolites identified either showed some alteration in the N_1 -diethylaminoethyl moiety or lacked the N_1 -substituent altogether. The major metabolite in the dog was a carboxylic acid, the N_1 -acetic acid analog of flurazepam. In man, the analogous alcohol (the N_1 -ethanol analog) predominated.

Keyphrases □ ^{14}C -Flurazepam HCl metabolism—humans, dogs □ Metabolites, flurazepam HCl—isolation, identification □ Urinary, fecal excretion— ^{14}C -flurazepam □ Plasma levels— ^{14}C -flurazepam □ TLC—separation □ UV spectrophotometry—analysis □ Scintillometry—analysis

The synthesis (1) and the pharmacology (2) of flurazepam hydrochloride,¹ 7-chloro-1-(2-diethylaminoethyl)-5-(2-fluorophenyl)-1,3-dihydro-2H-1,4-benzodiazepin-2-one dihydrochloride, have been reported as well as the clinical use of this compound (also designated Ro 5-6901) as a hypnotic (3, 4).

In a previous report (5), the isolation by TLC and the characterization by high-resolution mass spectrometry of five urinary metabolites from the dog and one human urinary metabolite were described. The structures of these metabolites are shown in Table I, together with those of flurazepam, the 3-hydroxy derivative of flurazepam (F-3-OH), and Compound III. While neither of the latter two compounds had been detected as metabolites, F-3-OH was of interest as a reference compound to test for 3-hydroxylation of intact drug, and Compound III was a likely metabolic precursor of metabolites III-OH and IV. All the compounds of Table I, except the incompletely characterized III-OH, have been synthesized (6).

The synthesis of ^{14}C -labeled flurazepam hydrochloride allowed for a study of the disposition of this drug in terms of absorption, distribution, biotransformation, and excretion.

EXPERIMENTAL

Labeled Compound and Counting of ^{14}C -Flurazepam- $5\text{-}^{14}\text{C}$ hydrochloride² was diluted with unlabeled compound to a specific activity of 3.12 $\mu\text{C}/\text{mg}$. flurazepam base for the dog studies and 2.10 $\mu\text{C}/\text{mg}$. base for the human studies. Before administration to the human subjects and the dog, the labeled drug was shown to be radiochemically pure by TLC with System A (described later).

All samples were counted in a Nuclear-Chicago Corp. Mark I liquid scintillation spectrometer equipped with a ^{138}Ba external standard; the external standard-channels ratio technique was used to determine counting efficiency. Aliquots of urine and extracts of both urine and plasma were counted in Phosphor I (7), while plasma (0.2–1.0 ml.) and silica gel segments from chromatoplates were counted as suspensions in Phosphor II (7) which contained a thioxotropic gel. The ^{14}C in aliquots of 50% ethanol homogenates of feces was determined by the Schoniger combustion, carbon dioxide trapping, and counting procedures of Kelly *et al.* (8).

Dog Studies—A nonfasted 13-kg. male dog (beagle) was first given an oral dose of 2 mg./kg. of ^{14}C -flurazepam HCl in a gelatin capsule. Two months later, it was given the same dose as a solution in 2.6 ml. of physiological saline by rapid intravenous injection. Urine and feces were collected until the excretion of radioactivity reached the limits of detection. Blood (10 ml., heparinized) was drawn at 0, 1, 2, 3, 4, 7, 12, and 24 hr. after oral dosing and at 0, 5, 15, and 30 min., and 1, 2, 3, 4, 7, 11, and 24 hr. after intravenous dosing of the dog.

For fractionation of the plasma radioactivity, aliquots (0.2–0.5 ml.) of plasma were brought to 1 ml. with water, mixed with 1 ml. of 0.5 M borate buffer, pH 9.0, and extracted twice with 5 ml. of ether. This procedure quantitatively removed flurazepam (9). The aqueous phases were adjusted to pH 7.0 and were extracted twice with 5 ml. of ether and then twice with 5 ml. of ethyl acetate. Finally, the aqueous phases were brought to pH 3.0 and again extracted twice with 5 ml. of ethyl acetate. These extracts were concentrated and counted.

The urinary radioactivity was fractionated in a similar manner. Aliquots (10 ml.) of urine were extracted twice with equal volumes of ethyl acetate at various pH's before incubation at pH 5.5 and 37° for 3 hr. with a commercial preparation³ containing β -glucuronidase

Table I—Flurazepam and Metabolites

Compound Designation	R ₁	R ₂	Metabolic Status from Previous Work (5)
Flurazepam	—CH ₂ CH ₂ N(C ₂ H ₅) ₂	H	Intact drug
F-3-OH	—CH ₂ CH ₂ N(C ₂ H ₅) ₂	OH	Not found in urine
I	H	H	Urinary metabolite in dog
I-DE ^a	—CH ₂ CH ₂ NC ₂ H ₅	H	Urinary metabolite in dog
II	—CH ₂ CH ₂ NH ₂	H	Urinary metabolite in man and dog
III	CH ₂ CH ₂ OH	H	Not found in urine
III-OH ^b	H	H	Urinary metabolite in dog
IV	H	OH	Urinary metabolite in dog

^a DE signifies that this compound is the desethyl derivative of I. ^b Compound III-OH was not completely characterized; mass spectral analysis indicated the addition of a phenolic group to Compound III.

and sulfatase; they were reextracted at pH 7.0 after incubation. This incubation previously yielded maximum hydrolysis of benzo-diazepine conjugates (7). Further details of these extractions are included with the results in Table II. Fecal homogenates in 50% ethanol were first evaporated to remove the ethanol before two extractions at pH 9.0 with an equal volume of ether.

Human Study—Two women, H-17 and H-18, were each given 28.0 mg. of labeled flurazepam hydrochloride (specific activity of 3.90×10^6 d.p.m./mg.) in a gelatin capsule. H-17, a 57-year-old hypertensive weighing 91 kg., was treated with 50 mg. of hydrochlorothiazide per day before and during the study. H-18, 61 years old and weighing 73 kg., suffered from labile hypertension but was normotensive during the study and required no therapy.

Both subjects were given a glass of water every 2 hr. during the 1st day to promote diuresis; intervals of urine collection were 0–2, 2–4, 4–6, 6–9, 9–12, and 12–24 hr. and daily thereafter until the end of the study. Feces were collected as daily pools. Oxalated blood (10 ml.) was drawn at 0, 1, 2, 4, 7, 12, and 24 hr. and at 24-hr. intervals thereafter. Aliquots of plasma were extracted at pH 9.0 with ether, as described for dog plasma, and the extracts were counted. Aliquots of urine were serially extracted at pH 9.0 with ether, at pH 7.0 with ethyl acetate before and after treatment with the β -glucuronidase-sulfatase preparation, and finally at pH 3.0 with ethyl acetate; equal volumes of solvent were used twice for each extraction. The extracts were evaporated to dryness, and the residues were dissolved in 5 ml. of ethanol; aliquots were counted and, if sufficient ¹⁴C was present, were examined by TLC.

Separation and Estimation of Drug and Metabolites—The technique used previously (7) involves the determination of the amount of chromatographed radioactivity that migrates on two-dimensional TLC as an authentic reference compound. Internal reference compounds chromatographed with extracts of plasma, urine, and feces included flurazepam, F-3-OH HCl, I 2HCl, I-DE 2HCl, II HCl, III, and IV. Also used as a reference compound was the dehydrated derivative of I-DE which was shown (5) to be an artifact arising on TLC of I-DE; any ¹⁴C separated as this compound was considered to have been present in the biological media as I-DE. The recovery of plasma ¹⁴C-flurazepam on extraction and TLC was estimated at roughly 90%.

Silica gel containing a fluorescent indicator⁴ was used for TLC, together with the following solvent systems: System A, ethyl acetate-ethanol-concentrated ammonia (95:5:0.5); System B, isopropanol-ethanol-concentrated ammonia (90:10:1); System C, benzene-ethyl acetate-ethanol-concentrated ammonia (80:20:10:0.2); System D, chloroform-acetone-concentrated ammonia (80:20:1); System D', chloroform-acetone-concentrated ammonia (95:5:0.1); System E, benzene-*n*-butanol-methanol-water (1:1:2:

1); System F, benzene-methanol-acetic acid (90:10:1); System G, heptane-chloroform-ethanol (10:10:2.5); System G', heptane-chloroform-ethanol-concentrated ammonia (50:50:25:1); System H, benzene-*n*-butanol (90:10); System I, methylene chloride-*n*-butanol (90:10); System J, heptane-ethyl acetate-ethanol-concentrated ammonia (50:50:5:0.2); and System K, heptane-benzene-ethanol (5:5:2).

In many instances, these solvent systems were used as pairs for two-dimensional TLC. For example, System AC signifies that the chromatoplate was developed first in A and then, after being turned 90°, in C. Compounds were located on the plates under shortwave UV light.

Metabolites of II HCl in the Dog—The biotransformation in the dog of unlabeled metabolite II was studied to elucidate further the pathways of flurazepam metabolism. Three milliliters of plasma separated from blood drawn 1, 2, and 3 hr. following oral administration of 22 mg./kg. of II HCl in a gelatin capsule was combined and extracted at pH 9.0 with ethyl acetate. The extracted metabolites were separated by TLC. Urine excreted the day before and the day after the intravenous administration in propylene glycol-water (1:1) of 6 mg./kg. of II HCl was separately extracted by the Series 2 procedure of Table II. The extracts were dried over anhydrous sodium sulfate, concentrated, and examined by TLC. Identification was accomplished by the demonstration that the metabolite and an authentic reference compound migrated as a single compound.

RESULTS

Metabolism in the Dog—Excretion of Labeled Drug and Metabolites—The radioactivity excreted after the oral and intravenous administration of ¹⁴C-flurazepam hydrochloride is shown in Table III. After each route of administration, roughly the same amount of ¹⁴C was excreted in the feces as in the urine during the 1st day. Fecal excretion of ¹⁴C was significant for the first 3 days, and the total amount excreted exceeded that found in the urine. These findings suggest that a considerable secretion of labeled material into the gastrointestinal tract occurred. The feces excreted in the first 2 days after intravenous drug administration were analyzed by ether extraction at pH 9.0 and TLC of the extracts with System DB. No flurazepam was detected in this extract. While I-DE and IV were found, the fecal excretion of each was less than 1% of the dose. The remaining fecal radioactivity remained unidentified.

The composition of the urinary radioactivity was first studied by solvent extraction. The results of three separate series of extractions of urine from the orally treated dog (Table II) demonstrated the following: (a) no more than 5% of the urinary ¹⁴C, that extracted at pH 9.0, could be intact drug; (b) roughly 60% of the urinary metabolites was acidic (the Series 3 extraction ruled out the possibility that the ¹⁴C removed at pH 1.0 and 3.0 in the first two extraction

⁴ Mallinckrodt Silicar 7-GF-5.

Table II—Extractability of the Radioactivity Excreted by a Dog in the 0-36-hr. Urine after Oral and Intravenous Doses of ^{14}C -Flurazepam HCl^a

Serial Extraction with Ethyl Acetate ^b	Percent of Urinary ^{14}C Extracted—

acetate under any condition listed in Table II. It is also evident from Table II that the urine from the intravenously treated dog contained metabolites similar in extractability to those excreted after oral drug administration.

To identify the acidic metabolites, 180 ml. of the 0-36-hr. urine from the orally treated dog was extracted according to Series 2, Table II. At pH 3.0, 57.4% of the urinary ^{14}C was extracted. TLC of the concentrated extract with System H yielded a UV-absorbing band at R_f 0.3-0.4, which was associated with roughly 80% of the chromatographed radioactivity. This labeled component was eluted from the silica gel, and an aliquot of the concentrated ethanol eluate was rechromatographed with System I alongside authentic 2-[7-chloro-5-(2-fluorophenyl)-1,3-dihydro-2-oxo-2H-1,4-benzodiazepin-1-yl]acetic acid (Compound V). Compound V was chosen as the reference compound because the analogous alcohol, II, was a known urinary metabolite of flurazepam hydrochloride in the dog (5). The labeled metabolite migrated as a single band (R_f 0.75), which contained 94% of the ^{14}C chromatographed with System I and did not separate from authentic V. Although TLC with System I of greater amounts of labeled material yielded a diffuse band, this diffuse component, after elution from the silica gel, and authentic V were shown by high-resolution mass spectral analysis⁵ to be identical. It was estimated that roughly 45% of the urinary ^{14}C was present as V.

Although this new metabolite was quantitated successfully in plasma extracts by two-dimensional TLC, this technique could not be used with extracts of urine because of excessive tailing. It was, therefore, necessary to convert metabolite V into its methyl ester prior to TLC. Freshly prepared diazomethane (10) was added in excess to the urinary extract and, after standing 15 min. at room temperature, the solution was evaporated to dryness and the residue dissolved in ethanol. Authentic V was found to be completely esterified under these conditions.

The urinary excretion of drug and metabolites, quantitated by solvent extraction and TLC, is summarized in Table IV. After oral administration, no flurazepam was detected in the urine; the major metabolite was V, while lesser amounts of conjugated IV and free I-DE were excreted. The same three metabolites were excreted after intravenous drug administration in amounts similar to those found after oral dosing. In addition, the excretion of small amounts of intact drug (0.2% of the dose), Compound I, and conjugated II was

Figure 1—Plasma levels of flurazepam-derived ^{14}C and labeled metabolites in a dog given an intravenous dose of 2 mg./kg. of ^{14}C -flurazepam hydrochloride. The concentrations of plasma total ^{14}C (○—○), the ^{14}C extracted at pH 9.0 into ether (●—●), and the ^{14}C extracted at pH 3.0 into ethyl acetate (■—■) are expressed as microgram equivalents flurazepam per milliliter of plasma; the concentrations of flurazepam (X—X), III (▲—▲), and V (□—□) are expressed as micrograms per milliliter of plasma. The basic metabolites were quantitated by TLC of the pH 9.0 ether extract in System DB; the acidic metabolite V was quantitated by TLC of the pH 3.0 ethyl acetate extract in System EF. N.M. = not measurable.

⁵ Performed by F. M. Vane, Physical Chemistry Department, Hoffmann-La Roche Inc., Nutley, NJ 07110

Figure 2—Plasma levels of flurazepam-derived ^{14}C and labeled metabolites in a dog given an oral dose of 2 mg./kg. of ^{14}C -flurazepam hydrochloride. The concentrations of plasma total ^{14}C (O--O), the ^{14}C extracted at pH 9.0 into ether (●--●), and the ^{14}C extracted at pH 3.0 into ethyl acetate (■--■) are expressed as microgram equivalents flurazepam per milliliter of plasma; the concentrations of III (Δ--Δ), I-DE (Δ--Δ), IV (+--+), and V (□--□) are expressed as micrograms per milliliter of plasma. The metabolites were quantitated by TLC as described in the legend of Fig. 1. N.M. = not measurable.

seen only after intravenous drug administration. Although not shown in this table, no excretion of F-3-OH, either as a free or conjugated metabolite, was found.

Plasma Levels of Drug and Metabolites—The plasma levels of undifferentiated ^{14}C and of specific labeled compounds following the intravenous administration of ^{14}C -flurazepam hydrochloride are shown in Fig. 1. Intact drug was the major labeled compound extracted at pH 9.0, and its rapid biexponential elimination was characterized by half-lives of 11 min. and 1.4 hr. In addition, its apparent volume of distribution in terms of the central compartment of a two-compartment open system was calculated (11) to be 44.2 l. or 340% of body weight, a value indicating extensive tissue uptake of drug. Compound III was found in the same extract as flurazepam, but its plasma levels remained below 0.01 mcg./ml. At 5 min., the

Table IV—Urinary Excretion of Drug and Metabolites by a Dog after Oral and Intravenous ^{14}C -Flurazepam Hydrochloride

Urinary Components	Amount Excreted

Unknown	6.4	2.1	8.5	2.3
Polar nonconjugates				
Unknown	20	6.6	31.0	8.5

^a The urinary excretion of metabolites in 36 hr. is shown; over 90% of the total urinary ^{14}C excreted was excreted in this time interval. The appropriate extracts of Series 2, Table II, were used for the quantitation of the basic and conjugated metabolites. Basic metabolites were separated by TLC with System AC, while both Systems AC and BD were used to separate the deconjugated metabolites. The amount of acidic metabolite was estimated during its isolation. The "polar nonconjugates" represent the nonextractable ^{14}C of Series 2, Table II. ^b The total urinary excretion of drug and metabolites is shown. Each urine collected during the first 3 days was analyzed by solvent extraction (Series 2, Table II) and TLC. Basic and deconjugated metabolites were separated by TLC with System DB, while the acidic metabolite was esterified with diazomethane and separated in two one-dimensional systems, G and D'.

acidic metabolite (V) was present at a plasma level of 0.041 mcg./ml.; at 1 hr., it reached a peak level of 0.12 mcg./ml. Since no appreciable amounts of intact drug were found in the urine and feces, it appears that the rapid elimination of plasma flurazepam resulted from tissue uptake and rapid biotransformation.

These two processes were also apparently responsible for the absence of detectable plasma levels of drug after oral administration. As shown in Fig. 2, the highest level of plasma ^{14}C was observed at 1 hr., suggesting that rapid absorption had occurred. But even at this early time the major portion of the plasma radioactivity resided in acidic metabolites. Metabolite V accounted for over 70% of the acidic metabolite fraction of 1, 2, 3, and 4-hr. plasma, and its levels fell rapidly from 0.43 mcg./ml. with a half-life of 0.76 hr. Also found in the plasma were relatively low concentrations of I-DE, III, and IV.

Metabolism of II HCl—Intact II and Compound III were both identified in the ethyl acetate extract of dog plasma by TLC with Systems D and J. In the urine, both free and conjugated II were found (System DB), while the presence of conjugated IV was demonstrated with Systems AD and G'B. The acidic Compound V was also shown to be a urinary metabolite by formation of its methyl ester and subsequent TLC with System GK.

Figure 3—Cumulative urinary excretion of radioactivity by Subject H-17 (O--O) and Subject H-18 (X--X) following an oral dose of 28 mg. of ^{14}C -flurazepam hydrochloride.

Figure 4—Falloff of ^{14}C levels expressed as microgram equivalent flurazepam per milliliter in plasma (○) and ether extracts of plasma (□) of Subject H-17 and in plasma (●) and ether extracts of plasma (■) of Subject H-18.

Administered II was apparently biotransformed *via* two pathways. One involved the removal of the *N*-ethanol moiety to give plasma III; this was subsequently hydroxylated at C-3 to form IV which, as a conjugate, was excreted in the urine. The second pathway involved oxidation of the alcohol moiety of II to form the carboxylic acid, V, which was found in the urine.

Metabolism in Man—The cumulative excretion of radioactivity in urine and feces was almost the same for both subjects. More than half of the administered ^{14}C was excreted by each subject in the urine during the 1st day; each excreted a total of 81% of the dose in the urine, with 9% of the dose excreted in the feces by H-17 and 8% of the dose so excreted by H-18. The similarity of the excretion of urinary radioactivity for both subjects is clear from Fig. 3, which shows the cumulative excretion of urinary ^{14}C as a function of time.

In the plasma, the highest levels of total radioactivity, 0.24 mcg. equivalents of flurazepam per ml. for H-17 and 0.34 mcg. equivalents/ml. for H-18, were seen at 1 hr. (Fig. 4). These early peak levels indicated that absorption of labeled drug had been rapid. While the levels of ether-extracted radioactivity were markedly lower than those of total ^{14}C , the falloff of this extracted radioactivity closely paralleled that of total plasma ^{14}C in each subject.

Only in the plasma samples containing the highest levels of ^{14}C was it feasible to search for drug and metabolites. As seen in Table V, intact flurazepam was detected only in the 1-hr. plasma of H-17. Furthermore, intact drug in these early samples accounted for roughly 1% or less of the total plasma ^{14}C shown in Fig. 4. In view of the evidence for rapid absorption of labeled drug, this finding indicates that the absorbed drug was rapidly biotransformed into metabolites. With respect to the plasma metabolites identified

(Table V), II was the major metabolite in both subjects at 1 hr. while roughly equivalent levels of II, III, and I were found at 2 hr. In addition, trace levels of I-DE and IV were found in the plasma, while F-3-OH was not detected and 33–47% of the extracted ^{14}C was not identified.

The nature of the urinary radioactivity was investigated with pooled urine (0–4 days) representing over 90% of the total urinary ^{14}C eliminated by each subject. Only 15% (H-17) and 11% (H-18) of the urinary ^{14}C was extractable as intact drug and/or basic metabolites (Table VI). The major portion, 49% in each subject, was extracted at pH 7.0 after β -glucuronidase-sulfatase treatment; *i.e.*, it was apparently excreted as glucuronide and/or sulfate conjugates. Less than 7% of the excreted radioactivity represented acidic metabolites extractable at pH 3.0, and roughly 20% was comprised of polar nonextractable compounds.

The composition of the urinary radioactivity extractable directly at pH 9.0 and, following β -glucuronidase-sulfatase treatment, at pH 7.0 is shown in Table VII. While no intact drug was found, both subjects excreted I and I-DE as unconjugated metabolites. The major urinary metabolite was conjugated II, which accounted for 25% of the dose in H-17 and 22% of the dose in H-18. A small amount of conjugated IV was also excreted by both subjects.

The rate of excretion of metabolites was studied in H-18. The unconjugated and conjugated metabolites of each urine specimen collected during the first 4 days were extracted as described previously, and the metabolites of each extract were separated and quantitated by TLC with System DB. The total urinary excretion of each metabolite in milligrams was readily estimated (I, 0.21; I-DE, 0.76; II, 4.69; and IV, 0.30), and the amount of each compound remaining to be excreted was plotted as a logarithmic function of time (Fig. 5) to

Table V—Composition of the Plasma Radioactivity Extractable at pH 9.0 into Ether following Oral ^{14}C -Flurazepam Hydrochloride Administration to Two Subjects

Compound	Plasma Concentration, mcg./ml. ^a			
	H-17		H-18	
	1 hr.	2 hr.	1 hr.	2 hr.
Flurazepam	0.004	N.S.	N.S.	N.S.
II	0.014	0.013	0.020	0.009
III	0.005	0.008	0.010	0.010
I	0.003	0.008	0.012	0.010
I-DE	N.S.	0.004	0.004	0.004
IV	0.003	N.S.	N.S.	0.004
F-3-OH	N.S.	N.S.	N.S.	N.S.
Unaccounted ^b	0.014	0.027	0.041	0.028

^a The distribution of the ether-extracted ^{14}C was determined by two-dimensional TLC (System DB), using the compounds listed in the table as internal standards. Limit of sensitivity for each compound was roughly 0.003 mcg./ml. plasma; N.S. indicates that levels of ^{14}C were below 10 c.p.m. above background. ^b The ^{14}C unaccounted for is expressed as microgram equivalent flurazepam/milliliter.

Table VI—Extraction of the Radioactivity in 0–4-Day Pooled Urine^a from Subjects H-17 and H-18

Serial Extraction	Radioactivity Extracted—Subject			
	H-17		H-18	
	(% of Urinary ^{14}C)	(% of Dose)	(% of Urinary ^{14}C)	(% of Dose)
pH 9.0, ether	15.0	11.1	10.9	8.4
pH 7.0, ethyl acetate	2.6	1.9	2.5	1.9
After β -glucuronidase-sulfatase treatment				
pH 7.0, ethyl acetate	49.0	36.3	49.2	37.9
pH 3.0, ethyl acetate	4.1	3.0	6.1	4.7
Remaining aqueous	21.1	15.6	17.7	13.6
Recovery	91.8		86.4	

^a The 0–4-day urine pool represented the excretion of 74% of the administered ^{14}C dose by H-17 and 77% of the dose by H-18.

Figure 5—Urinary excretion of metabolites by Subject H-18. The milligrams of I ($\square - \square$), I-DE ($\times - \times$), II ($\circ - \circ$), and IV ($\Delta - \Delta$) remaining to be excreted are plotted logarithmically as a function of time. (Metabolites II and IV were excreted as conjugates.) The half-life in hours for each rate [with rate (a) obtained by the "residuals" method] was:

I		I-DE	II		IV
(a)	(b)		(a)	(b)	
2.0	11	17	2.5	17	42

give the pseudo-first-order elimination rates expressed as half-lives in the legend. The major urinary metabolite, conjugated II, was eliminated biexponentially at rates characterized by half-lives of 2.5 and 17 hr. Metabolite I was also eliminated biexponentially at similar rates. Both I-DE and conjugated IV were eliminated mono-

exponentially; the latter metabolite exhibited a long lag period before appreciable excretion occurred and had the longest half-life.

DISCUSSION

The evidence presented indicated that in both man and dog the rate of labeled drug absorption was relatively fast. Furthermore, the dog excreted more of the labeled dose in the urine after oral ^{14}C -flurazepam administration than after intravenous administration, and the human subjects excreted over 80% of the oral dose in the urine. These findings suggest that absorption was fairly complete in both species.

Since orally administered flurazepam hydrochloride was not excreted intact by dog or man, it is clear that the drug was eliminated solely by biotransformation. Evidence for the elimination being a rapid process was provided by the fact that, in the intravenously injected dog, drug disappeared rapidly from the plasma exhibiting a biexponential decline with half-lives of 11 min. and 1.4 hr. Furthermore, in both species, metabolites predominated even in the earliest plasma samples. The rapid biotransformation, together with tissue uptake of intact drug, appeared to be responsible for keeping plasma flurazepam below measurable levels after oral administration to man or dog.

The postulated pathways of flurazepam biotransformation are shown in Scheme I. Flurazepam was metabolized by successive *N*-dealkylation to yield I and I-DE, both of which were excreted in the urine by man and dog. The dog produced V as a major metabolite of plasma and urine and II as a minor urinary metabolite. It is likely that both arose from the same precursor, an aldehyde formed by oxidative deamination of I-DE. In the dog, oxidation of the aldehyde was preferred and V was the dominant metabolite; in man the reduction to II, which was excreted as the major urinary metabolite in the form of a conjugate, was the preferred pathway.

The study of the metabolism of II in the dog revealed that III was formed by removal of the $\text{N-CH}_2\text{CH}_2\text{OH}$ group, a pathway shown in Scheme I. Since III was also a metabolite of flurazepam in man and dog and has not been shown to be formed exclusively *via* II as the intermediate, possible pathways (broken arrows) leading from flurazepam, I, and I-DE are also shown.

The 3-hydroxy derivative of flurazepam, F-3-OH, was not found as a metabolite in either man or dog, suggesting that metabolic attack at the N-1 side chain was preferred over 3-hydroxylation of intact drug. Therefore, the conjugated IV found in the urine of both species probably was formed *via* a pathway in which *N*-dealkylation preceded 3-hydroxylation, thus indicating that III was the immediate precursor of IV. Scheme I also shows III-OH, the incompletely characterized phenolic metabolite previously found (5) as a urinary conjugate in a dog chronically treated with flurazepam, arising from III. Although this metabolite may have been excreted in the present experiments in very small amounts, it definitely was not a significant metabolite in man or dog following single doses of flurazepam.

The three ether-extractable metabolites present in human plasma in greatest amounts were I, II, and III. I and conjugated II were excreted fairly rapidly in the urine, while III was not excreted *per se* but was biotransformed to IV. Conjugated IV did not appear in the urine in any appreciable amounts until the 2nd day, and it was excreted relatively slowly. This suggests that the conversion of III to IV may be slow and that III, on repeated administration of flurazepam, may tend

Table VII—Estimation by Two-Dimensional TLC of the Conjugated and Unconjugated Urinary Metabolites of Subjects H-17 and H-18

Source of 0-4-Day Urine	Metabolite Form	Flurazepam	Urinary Excretion of Drug and Metabolites in Percent of Administered Dose ^a					Unaccounted for
			I	I-DE	II	III	IV	
Subject H-17	Unconjugated	N.D. ^b	0.4	1.3	N.D.	0.5	N.D.	9.0
	Conjugated	N.D.	N.D.	0.8	25.0	N.D.	0.9	9.6
Subject H-18	Unconjugated	N.D.	1.2	4.1	N.D.	N.D.	N.D.	3.1
	Conjugated	N.D.	N.D.	N.D.	22.0	N.D.	1.5	14.4

^a The values presented were based on the average distribution of ^{14}C on two-dimensional TLC in at least two systems. The "pH 9.0, ether" extract of H-18 was chromatographed in Systems DB and AD; the other extracts were each chromatographed in Systems DB, AD, and DC. ^b N.D. indicates that the compound was not detectable. The detection limits were 0.2% of the dose for unconjugated metabolites and 0.8% of the dose for conjugated metabolites. Compound F-3-OH was also used as an internal reference compound but was not detected as a metabolite in any of the extracts.

Scheme I—Postulated pathways of flurazepam metabolism in man and dog. The compound shown in parenthesis was not detected but is a presumed intermediate which would result from oxidative deamination of I-DE. The pathways labeled "dog" denote that the resulting metabolites were definitely established solely in the dog

toward higher plasma concentrations. Further studies are required to test this supposition.

Interaction of Nitrogen Dioxide with Cholesterol Monomolecular Films: Effect of Initial Surface Pressure, Time of Exposure, and Concentration of Nitrogen Dioxide

AIDA M. KAMEL, ALVIN FELMEISTER, and NORMAN D. WEINER*

Abstract □ The interaction of NO_2 with cholesterol monomolecular films was studied as a function of the initial surface pressure, time of exposure, and concentration of NO_2 . A condensation of the cholesterol films was observed that increased with the time of exposure and concentration of the NO_2 . This effect apparently was due to the loss of cholesterol from the interface. A percent apparent loss of cholesterol was calculated. Films exposed at an initial surface pressure of 7 dynes/cm. exhibited a greater percent apparent loss of cholesterol than did those exposed at 0 dyne/cm. An explanation for these results based on the orientation of the cholesterol at the interface is offered, and the possible biological relevance of this work is considered.

Keyphrases □ Cholesterol monomolecular films—nitrogen dioxide interaction □ Films, cholesterol—initial pressure, exposure time effects □ Nitrogen dioxide, concentration effect—cholesterol film interaction □ Colorimetric analysis—spectrophotometer

Recently, the authors reported the interaction of a series of phospholipid films with the air pollutant nitrogen dioxide (1, 2). The data demonstrated that the unsaturated fatty acid moieties of phospholipids are sensitive to attack by NO_2 . Similar results were reported *in vivo* by Thomas *et al.* (3), who postulated that some observed effects of air pollutants may be directly attributable to the interaction of NO_2 with unsaturated lipids.

Since cholesterol also is an important component of cell membranes, it was of interest to examine the interaction of NO_2 with cholesterol monomolecular films. In this study the effect of time of exposure, NO_2 concentration, and the physical state of the cholesterol film, as influenced by the initial surface pressure, were investigated.

EXPERIMENTAL

Materials and Equipment—Chromatographically pure cholesterol was obtained,¹ and spectroscopic grade hexane was used to prepare the cholesterol solutions. All other chemicals were of reagent grade. Previously deionized water was distilled from an all-glass still prior to use.

A mixture of 0.5% NO_2 (99.5% pure)² and 99.5% research grade nitrogen was used. The gas mixture was allowed to pass through a flow meter at a fixed rate and directed into a short length of perforated Teflon tubing which was affixed to the underside of an acrylic resin³ trough cover as previously described (1). This served to maintain the desired gaseous atmosphere over the film.

The film balance used to study the surface pressure–surface area (π - A) characteristics of the film has been described previously (1). Surface pressures were measured by the Wilhelmy plate method (4).

Methods—Solutions of cholesterol in hexane were spread on a 0.065 *M* phosphate buffer at pH 7.0, and the gas was allowed to flow over the film for a fixed period of time. At the end of the time

period, the flow of gas was discontinued; any NO_2 remaining over the surface was removed by use of the exhaust fan in the hood, in which the film-balance unit was set. Manual compression of the film was then initiated, and surface pressure readings were obtained at various film areas.

The concentration of the NO_2 over the subphase during exposure was determined as follows. At periodic intervals during each experiment, 10-ml. samples of the atmosphere under the acrylic resin cover were drawn into a gastight Hamilton syringe containing 10 ml. of NO_2 -absorbing solution. The color of the absorbing solution was permitted to develop for 15 min., and the absorbance was measured at 550 $\text{m}\mu$ using a Spectronic-20 spectrophotometer. The concentration of NO_2 was determined from a standard nitrite curve (5).

RESULTS AND DISCUSSION

Effect of Concentration and Time of Exposure to NO_2 —Figure 1 shows the π - A curves obtained after exposure of a cholesterol film (at an initial pressure of 0 dyne/cm.) to 175 ± 25 p.p.m. of NO_2 for various time periods. Under these conditions the condensation effects increased with the time of exposure up to 60 min. Exposure for periods longer than 60 min. had no further effect on the shape or position of the π - A curve. A similar limiting effect was observed also when the film was exposed at an initial surface pressure of 7 dynes/cm. Additional experiments were conducted at both

initial pressures using a concentration of 95 ± 20 p.p.m. of NO_2 . In these cases, maximum condensation was observed after a 90-min. exposure.

The reason for this limiting effect could not be explained on the basis of the data obtained in this study. However, Bergstrom and Wintersteiner (6) previously reported such a limiting effect during the autoxidation of aqueous dispersions of cholesterol, which they attributed to an inhibitory effect exerted by the oxidation products. A maximum loss of 70% of the cholesterol was reported by these workers, which corresponds to the maximum percentage losses observed under varying conditions in the present study.

The effect on the π -A curves of films exposed at zero initial pressure for 60 min. to different concentrations of NO_2 is shown in Fig. 2. The condensation effect clearly increases with increasing concentration of NO_2 . When films were exposed at an initial pressure of 7 dynes/cm. for the same period of time, the results were essentially the same.

The apparent condensation effect observed in these experiments appears to be due, at least in part, to an NO_2 -cholesterol interaction. This reaction, in turn, results in the formation of relatively polar products and in their subsequent desorption or dissolution. This effect can be represented by the percent apparent loss (PAL) of cholesterol calculated from the following equation:

$$\text{PAL} = (1 - A'/A) 100 \quad (\text{Eq. 1})$$

where A and A' are the area/molecule of cholesterol at 30 dynes/cm. before and after exposure to NO_2 , respectively. PAL is not the actual percent loss of cholesterol from the surface, but rather a com-

Figure 3—Rate of loss of cholesterol from films at an initial surface pressure of 0 dyne/cm. exposed to various concentrations of NO_2 . Key: \circ , 25 ± 10 p.p.m.; \square , 95 ± 20 p.p.m.; and \triangle , 175 ± 25 p.p.m.

Figure 4— π -A curves of cholesterol films at various initial surface pressures exposed to 175 ± 25 p.p.m. NO_2 for 35 min. Key: \circ , control; \bullet , 0 dyne/cm.; and \square , 7 dynes/cm.

plex function which takes into account such factors as desorption, dissolution, changes in molecular orientation, and chemical modification of the cholesterol molecules. However, PAL is a useful means of comparing the effects of NO_2 concentration and initial surface pressure on the stability of NO_2 -exposed cholesterol monomolecular films.

The curves shown in Fig. 3 were constructed from the calculated values of PAL of cholesterol from films exposed at an initial pressure of 0 dyne/cm. to 25 ± 10 , 95 ± 20 , and 175 ± 25 p.p.m. of NO_2 for periods of time ranging from 20 to 90 min.

The rate of loss of cholesterol appears to be dependent on the concentration of NO_2 and independent of the amount of cholesterol remaining in the films up to the time at which the limiting effect is observed.

Figure 5—Rate of loss of cholesterol as a function of NO_2 concentration for films at an initial surface pressure of 0 dyne/cm.

Effect of Initial Surface Pressure—Figure 4 shows the π - A curves of cholesterol films at initial surface pressures of 0 and 7 dynes/cm. prior to and following a 35-min. exposure to 175 ± 25 p.p.m. nitrogen dioxide.

Exposure to NO_2 , in the case of the film adjusted to an initial surface pressure of 7 dynes/cm., resulted in a steady decrease in pressure, reaching a value of zero in about 20 min. Furthermore, following a 35-min. exposure to NO_2 , the film exposed at this higher surface pressure exhibited a greater PAL of cholesterol.

The orientation of cholesterol molecules in a monomolecular film is markedly influenced by the surface pressure of the film. At zero pressure the molecules would be expected to be essentially flat on the surface, occupying relatively large areas. At 7 dynes/cm., the cholesterol molecules are closely packed and occupy an area that indicates they are in a vertical position with the 3-hydroxy groups anchored in the subphase. Thus, at zero pressure, both polar sites of the cholesterol molecule (*i.e.*, the 3-hydroxy group and the 5-6 double bond) would likely be associated with the aqueous subphase. At 7 dynes/cm., only the 3-hydroxy group would be associated with the subphase, while the double bond would be in the gas phase.

Since the PAL of cholesterol upon exposure to NO_2 is greater when the molecules are in the vertical position, it appears that association of both polar sites with the subphase inhibits the oxidation of cholesterol by NO_2 . Such a postulation is supported by Altshuller and Cohen (7), who reported that the oxidation of olefins by NO_2 occurred in the gas phase along with some nitration, while little or no oxidation was observed (though nitration did occur) in the aqueous phase reaction.

CONCLUSIONS

While it appears that the rate of loss of cholesterol from a monomolecular film is dependent on the concentration of NO_2 , the rate of loss at levels of NO_2 normally found in polluted air (≈ 0.5 p.p.m.) would be very slow. Thus, only at relatively high levels of NO_2 would the loss of cholesterol be significant, even over several hours. This can be seen from the extrapolated portion of the plot in Fig. 5 of the rate of loss of cholesterol *versus* the concentration of NO_2 .

Whether these results can be related to the effect of NO_2 on cell membranes or to the *in vivo* exposure of humans or animals to NO_2 has not been established. However, the work of Steadman *et al.*

(8), in which animals were exposed to wide ranges of concentrations of NO_2 for varying periods of time, does show some correlation. These workers noted that animals exposed to NO_2 concentrations of 70 p.p.m. for 8 hr. suffered pulmonary edema and vascular congestion with high mortality rates. On the other hand, exposure to a concentration of 0.5 p.p.m. even for as long as 90 consecutive days produced no apparent untoward effects. Thus, it may be that the loss of cholesterol from surface films, which would be very slow at a NO_2 concentration of 0.5 p.p.m. and relatively fast at a concentration of 70 p.p.m., gives some indication of the loss of this essential lipid from cell membranes and of the observed clinical effects of NO_2 .

Crystal Pseudopolymorphism of Cephaloglycin and Cephalixin

RALPH R. PFEIFFER, K. S. YANG, and MARY ANN TUCKER

Abstract □ The systematic investigation of the crystallization of cephaloglycin and cephalixin leads to a better understanding of the part that pseudopolymorphic crystal transitions play in the analysis, processing, and formulation of these and many other pharmaceutical compounds. The employment of solubility *versus* solvent composition diagrams to detect various crystal forms of compounds is discussed. This appears to be a convenient and sensitive method for detecting new crystalline phases. It should find application whenever crystallizations are performed with more than one solvent, and particularly when instability of the compound at elevated tempera-

tures prevents the use of conventional thermal methods or when poor crystal development limits the use of microscopic methods. Interpretation of vapor pressure-composition relationships for various crystal forms of these compounds points to the advisability of obtaining such data for all pharmaceutical solids.

Keyphrases □ Crystal pseudopolymorphism—cephaloglycin, cephalixin □ Cephaloglycin, cephalixin—pseudomorphic crystallization □ UV spectrophotometry—analysis □ X-ray powder diffraction—analysis □ NMR spectroscopy—analysis

It is the responsibility of the pharmaceutical chemist to become familiar with the crystallizing properties of drugs in order to control the crystal form, habit, size, size distribution, degree of crystallinity, and state of aggregation of the drug particles. These parameters often determine the acceptability of bulk properties

(mixing, tableting, filling, dusting, *etc.*) and pharmaceutical performance (dissolution, biological availability, chemical and physical stability, suspendibility, rheology, *etc.*). Haleblan and McCrone (1) adequately documented the broad aspects of this argument in a recent review article on polymorphism, wherein they

Effect of Initial Surface Pressure—Figure 4 shows the π - A curves of cholesterol films at initial surface pressures of 0 and 7 dynes/cm. prior to and following a 35-min. exposure to 175 ± 25 p.p.m. nitrogen dioxide.

Exposure to NO_2 , in the case of the film adjusted to an initial surface pressure of 7 dynes/cm., resulted in a steady decrease in pressure, reaching a value of zero in about 20 min. Furthermore, following a 35-min. exposure to NO_2 , the film exposed at this higher surface pressure exhibited a greater PAL of cholesterol.

The orientation of cholesterol molecules in a monomolecular film is markedly influenced by the surface pressure of the film. At zero pressure the molecules would be expected to be essentially flat on the surface, occupying relatively large areas. At 7 dynes/cm., the cholesterol molecules are closely packed and occupy an area that indicates they are in a vertical position with the 3-hydroxy groups anchored in the subphase. Thus, at zero pressure, both polar sites of the cholesterol molecule (*i.e.*, the 3-hydroxy group and the 5-6 double bond) would likely be associated with the aqueous subphase. At 7 dynes/cm., only the 3-hydroxy group would be associated with the subphase, while the double bond would be in the gas phase.

Since the PAL of cholesterol upon exposure to NO_2 is greater when the molecules are in the vertical position, it appears that association of both polar sites with the subphase inhibits the oxidation of cholesterol by NO_2 . Such a postulation is supported by Altshuller and Cohen (7), who reported that the oxidation of olefins by NO_2 occurred in the gas phase along with some nitration, while little or no oxidation was observed (though nitration did occur) in the aqueous phase reaction.

CONCLUSIONS

While it appears that the rate of loss of cholesterol from a monomolecular film is dependent on the concentration of NO_2 , the rate of loss at levels of NO_2 normally found in polluted air (≈ 0.5 p.p.m.) would be very slow. Thus, only at relatively high levels of NO_2 would the loss of cholesterol be significant, even over several hours. This can be seen from the extrapolated portion of the plot in Fig. 5 of the rate of loss of cholesterol *versus* the concentration of NO_2 .

Whether these results can be related to the effect of NO_2 on cell membranes or to the *in vivo* exposure of humans or animals to NO_2 has not been established. However, the work of Steadman *et al.*

(8), in which animals were exposed to wide ranges of concentrations of NO_2 for varying periods of time, does show some correlation. These workers noted that animals exposed to NO_2 concentrations of 70 p.p.m. for 8 hr. suffered pulmonary edema and vascular congestion with high mortality rates. On the other hand, exposure to a concentration of 0.5 p.p.m. even for as long as 90 consecutive days produced no apparent untoward effects. Thus, it may be that the loss of cholesterol from surface films, which would be very slow at a NO_2 concentration of 0.5 p.p.m. and relatively fast at a concentration of 70 p.p.m., gives some indication of the loss of this essential lipid from cell membranes and of the observed clinical effects of NO_2 .

Crystal Pseudopolymorphism of Cephaloglycin and Cephalixin

RALPH R. PFEIFFER, K. S. YANG, and MARY ANN TUCKER

Abstract □ The systematic investigation of the crystallization of cephaloglycin and cephalixin leads to a better understanding of the part that pseudopolymorphic crystal transitions play in the analysis, processing, and formulation of these and many other pharmaceutical compounds. The employment of solubility *versus* solvent composition diagrams to detect various crystal forms of compounds is discussed. This appears to be a convenient and sensitive method for detecting new crystalline phases. It should find application whenever crystallizations are performed with more than one solvent, and particularly when instability of the compound at elevated tempera-

tures prevents the use of conventional thermal methods or when poor crystal development limits the use of microscopic methods. Interpretation of vapor pressure-composition relationships for various crystal forms of these compounds points to the advisability of obtaining such data for all pharmaceutical solids.

Keyphrases □ Crystal pseudopolymorphism—cephaloglycin, cephalixin □ Cephaloglycin, cephalixin—pseudomorphic crystallization □ UV spectrophotometry—analysis □ X-ray powder diffraction—analysis □ NMR spectroscopy—analysis

It is the responsibility of the pharmaceutical chemist to become familiar with the crystallizing properties of drugs in order to control the crystal form, habit, size, size distribution, degree of crystallinity, and state of aggregation of the drug particles. These parameters often determine the acceptability of bulk properties

(mixing, tableting, filling, dusting, *etc.*) and pharmaceutical performance (dissolution, biological availability, chemical and physical stability, suspendibility, rheology, *etc.*). Haleblan and McCrone (1) adequately documented the broad aspects of this argument in a recent review article on polymorphism, wherein they

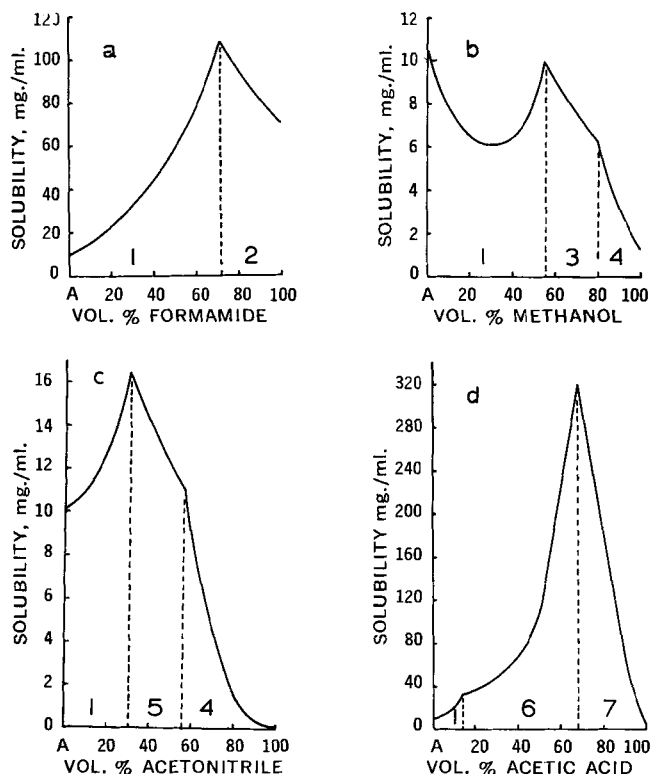

Figure 1—Solubility of cephaloglycin in binary solvent mixtures at 25°. A = water in all cases. Arabic numerals refer to solid phases in Table I.

also discussed thoroughly the preparation and characterization of true polymorphic¹ crystal forms by thermal methods. The related and equally pertinent phenomenon of pseudopolymorphism, *i.e.*, modification caused by inclusion of solvent in the crystal structure, apparently has received no such general treatment in the pharmaceutical literature, although many specific cases of pseudopolymorphism in drugs have been reported (2-4).

This article suggests some new approaches to the study of pseudopolymorphic crystal transformations as they apply to pharmaceutical manufacturing practice. As a case in point, it reports the crystallizing properties of the antibiotics cephaloglycin (I) (5) and cephalixin (II) (6), both of which occur in a wide variety of solvated crystal forms.

EXPERIMENTAL

Reagents—The cephaloglycin and cephalixin each had a microbiological potency (5, 6) of >970 mcg./mg.; phase-solubility analysis in water indicated a purity of $97 \pm 1\%$. (Both analyses were corrected for volatile components.)

Solvents and other chemicals were reagent grade and were taken from freshly opened packages without further purification.

Equilibration with Solvents—Finely ground cephaloglycin (dihydrate) or cephalixin (monohydrate) was suspended and equilibrated at 25° in a variety of solvents and solvent mixtures. In a typical experiment, 11 tubes, containing a total of 5 ml. of two miscible solvents in ratios ranging from 1:0 to 0:1, were prepared. A quantity of the compound, sufficient to ensure the presence of a

substantial amount of solid phase throughout the equilibration period, was added to each tube. Three hours of shaking on a vibrating mixer,² with occasional manual stirring to disperse any lumps, proved satisfactory for the present purpose. The tubes were then centrifuged, and the clear supernates were analyzed spectrophotometrically at 260 mμ for dissolved cephaloglycin or cephalixin. A preliminary solubility *versus* solvent composition diagram was constructed from the data. The crystals, wet with mother liquor, were examined under a polarizing microscope and by X-ray powder diffraction to detect changes in the solid phase.

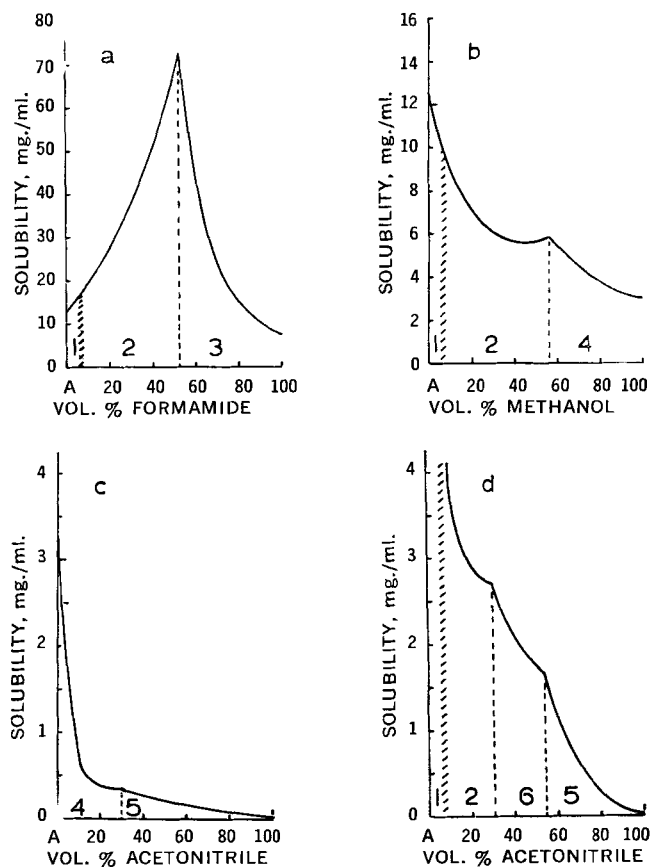

Figure 2—Solubility of cephalixin in binary solvent mixtures at 25°. A = water in Sections a, b, and d. A = methanol in Section c. Arabic numerals refer to solid phases in Table II.

¹ True crystal polymorphism involves forms of identical chemical composition. Thus, a compound may exhibit pseudopolymorphism by forming variously solvated crystals; each of these solvates (including the unsolvated form) may exhibit polymorphism.

Figure 3—(a) Stability zones of cephaloglycin crystal forms in mixtures of water-methanol-glacial acetic acid. The broken line indicates the compositions used in Section b. (b) Typical solubility diagram (also Fig. 1, Section d) used to locate zone boundaries in Section a. A = 75% methanol-water. Points m and n correspond in the two sections. Arabic numerals refer to solid phases in Table I.

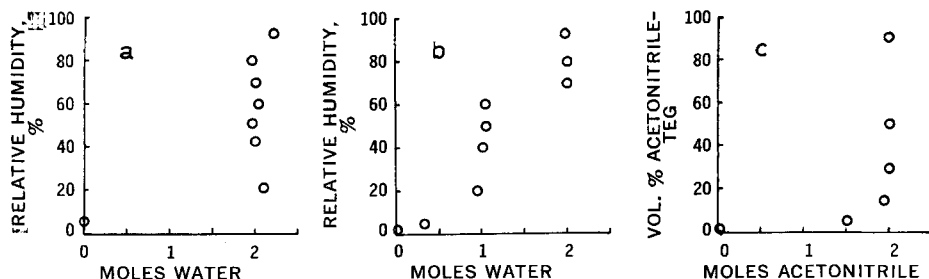

Figure 4—Crystal-vapor equilibria: a, cephaloglycin-water; b, cephalixin-water; and c, cephalixin-acetonitrile. The ordinate in Section c describes the volume composition of acetonitrile-triethylene glycol (TEG) used to provide a range of acetonitrile vapor pressures whose exact magnitude was not determined.

Preparation of Pure Reference Phases—To obtain the various crystalline phases in a homogeneous form, each phase was crystallized from the totally dissolved state. A solution (about 10% w/v) of the antibiotic in the appropriate solvent mixture, *i.e.*, a composition that had yielded a new solid phase in the equilibration, was prepared by acidification with an amount of concentrated hydrochloric acid³ equivalent to the amount of solute. Precipitation of the zwitterion in the desired crystal form was then effected by slow addition of an equivalent amount of concentrated ammonium hydroxide.³ The resulting crystals were removed by filtration and dried under conditions that would not disrupt the crystal stoichiometry (see *Discussion*). Analysis by selected methods followed. These methods always included X-ray powder diffraction and some of the following methods: elemental analysis, thermogravimetry, titration, spectrophotometry (NMR and UV), and specific analysis for water (Karl Fischer).

Determination of Solubility versus Solvent Composition Diagrams—The solubility determinations were repeated under the earlier conditions but using the proper equilibrium solid phases at the start of the individual equilibrations. In this way the solubility *versus* composition curve for each solid phase could be obtained over its entire stability range without relying on phase transformations. The equilibrium diagrams in Figs. 1 and 2 were constructed using the nonoverlapping parts of these curves. It was found that the same solubility information (agreement within 5%) could be obtained by using admixtures of two appropriately chosen solid phases for equilibrations near transition points. This procedure was used to obtain the information in Fig. 3. It was assumed that the stable (least soluble) phase was essentially controlling the solubility, even in the presence of unconverted metastable crystals.

Equilibration with Vapor—Vapor equilibration chambers were made from 5-lb. ointment jars with tight fitting lids. Each jar contained about 500 ml. of a constant vapor pressure slurry. Water vapor pressures were determined with electric hygrometer⁴ sensors. In one study, the jars contained 200 ml. of acetonitrile and triethylene glycol mixed in various ratios, thus providing atmospheres covering a wide range of acetonitrile vapor pressures. Previously analyzed samples of about 1 g., spread thinly in open weighing dishes, were set on trivets within the jars. The dishes were covered and weighed daily for 1 week, although constant weight was achieved

after 2 or 3 days. Samples showing significant gain or loss in weight were checked for phase changes by X-ray diffraction. All changes in solvent content or phase identity were found to be reversible upon subsequent exposure of the samples to the appropriate atmospheres.

RESULTS AND DISCUSSION

Because cephaloglycin and cephalixin were each observed to occur in many solvated crystal forms (Tables I-IV), and often in widely varying mixtures of these forms, a systematic study of the crystallizing properties of these compounds was undertaken. The properties of the pure crystalline components under equilibrium conditions were first explored. Mixtures of these components resulting from kinetic factors are subsequently considered.

Crystal-Solution Equilibria—The solubility diagrams resulting from this study (Figs. 1 and 2) provide a clear indication of not only the existence of multiple crystalline forms of cephaloglycin and cephalixin but also the ranges of solvent compositions in which the various forms are stable.

When considering crystal transformations that occur with changes

Table I—Some Solvated Crystal Forms of Cephaloglycin

Moles Solvent/Moles Cephaloglycin ^a	Method ^b
1. 2H ₂ O	a, b, c, d, e, f, g
2. Formamide	a, b, e, f
3. Methanol · H ₂ O	a, b, c, e, f, g
4. Unsolvated (anhydrate)	a, b, c, e, f, g
5. Acetonitrile · H ₂ O	a, b, d, e, f
6. Acetic acid · H ₂ O	a, b, c, e, f, g, h
7. 2 Acetic acid	a, b, e, f, g, h
8. Acetic acid · methanol	a, b, e, f
9. Ethanol · H ₂ O	a, b, e
10. N-Methylformamide	a, b, i

^a Arabic numerals correspond to phases in Figs. 1 and 3. ^b Compositions were determined by: a, uniqueness of X-ray powder diffraction pattern; b, Karl Fischer water; c, thermogravimetric analysis; d, vapor pressure-composition diagram; e, UV spectrophotometry; f, NMR spectrometry; g, elemental analysis; h, titration; and i, qualitative stoichiometry only. The quantitative results confirmed the stated compositions to ± 0.1 mole solvent. All forms, when recrystallized from water, had retained the X-ray diffraction properties of the starting material, indicating that no chemical modification of the antibiotic had occurred.

³ Possible effects caused by the water and salt thus introduced were ignored.

in solvent composition, it is helpful to recall that the changing solubility values along a smooth curve refer to an equilibrium between a solid phase of definite, unchanging composition and a solution of changing properties. The proportions of the variously solvated, aggregated, and charged solute species in solution vary with and are determined by the composition of the solvent. At equilibrium, the concentration of solute in solution, *i.e.*, the solubility, may vary as the solvent changes, but the activity of the crystallizing molecular species remains constant, *i.e.*, equals that of the crystalline form present. When individual solubility *versus* solvent composition curves of several available crystal forms cross one another to give a peak or cusp, a phase transition point is revealed. At such points the two solid phases represented by the separate curves have the same solubility and may therefore coexist at equilibrium. At other compositions, the respectively more soluble phase is necessarily metastable with respect to the less soluble one.

Phase Relationships in Ternary and Quaternary Solvent Mixtures

—The compositions of 3-solvent mixtures in which the various

crystal forms of a compound are stable can be conveniently represented by a triangular diagram such as the one presented in Fig 3a for cephaloglycin in water-methanol-glacial acetic acid. Each edge of the triangle was marked with the zone boundaries determined earlier in the respective binary solvent mixtures (Figs. 1b and 1d), and the positions of boundaries within the triangle were located by determining solubilities in series of appropriately chosen ternary solvent mixtures and interpreting the resulting curves in the manner described earlier (Fig. 3b).

Occasionally, a ternary mixture of solvents serves as a recrystallizing solvent, with a fourth miscible liquid acting as the antisolvent. The phase relationships, or stability zones, of solute crystals in such a system can be analogously represented by a triangular pyramid.

Doubly Solvated Crystals—Both cephaloglycin and cephalixin display the ability to crystallize with simultaneous stoichiometric inclusion of two solvents in the crystal lattice. The existence and identity of these phases are evident from their unique and uniform microscopic appearance, their X-ray pattern, the solubility diagram, and the various analyses of the crystals (Tables I–IV).

Crystal-Vapor Equilibria—One cause of erratic changes in the properties of powders is their physical interaction with solvent vapors. In the interests of crystal stability, therefore, the vapor composition of the environment, especially with regard to water vapor, must be given due consideration throughout the history of a powder, and the quantitative equilibrium relationships between crystal and vapor phases must be determined.

Vapor pressure *versus* composition diagrams of the kind presented for cephaloglycin–water, cephalixin–water, and cephalixin–acetonitrile (Fig. 4) delimit the vapor pressure range over which a solvated crystal is stable after isolation from the mother liquor. These diagrams also reveal the true stoichiometry of the solvated crystals.

Multiple Hydrated Forms—When a compound exists in several hydrated crystal forms at one temperature, as is clearly the case

^a See Table III for explanation of symbols and experimental conditions.

with cephalexin (Fig. 4b), the relative humidity *versus* composition diagram indicates the exact relative humidity that marks the transition from one form to another. Thus, cephalexin crystallized from water at room temperature is separated from solution as the dihydrate but converts to the monohydrate when the relative humidity is below 70%.

The Desolvated Crystal—Cephalexin·2 acetonitrile (Tables II and IV) serves as an example of what the authors believe to be a widely occurring but often undetected or improperly described case in powder technology, *viz.*—the “desolvated” crystal. This crystal is solvated stoichiometrically while in equilibrium with saturated solution; but when isolated and dried under ordinary conditions, it loses all except small mole fractions of solvent from the crystal lattice without thereby converting to another form (Fig. 4c). It is in this condition that the compound is commonly analyzed for the first time. When subsequently exposed to ambient atmospheres, the desolvated crystal takes up limited amounts of moisture, the water molecules presumably occupying lattice vacancies left by the original solvent. This water can be removed by drying or it can be displaced by exposing the crystal to vapor of the original solvent. In the latter case, the crystal returns to its native stoichiometric composition. All these changes may occur reversibly and without significant changes in the lattice, as evidenced by the X-ray powder diffraction pattern.⁵ It is, therefore, proper in such

cases to refer to a “desolvated” crystal, *e.g.*, “desolvated acetonitrilate crystal,” “desolvated methanolate crystal,” *etc.* This is necessary to differentiate it from a truly unsolvated unique structure (anhydrate), which would have different physicochemical properties despite having a chemical composition virtually identical to that of the desolvated crystal.

The authors have also observed the partial desolvation of the doubly solvated crystals listed in Tables I and II, but have not studied these more complex vapor-composition relationships.

The proper handling of solvated crystals to assure the maintenance of their stoichiometry for purposes of analysis should be evident from this discussion. Such crystals should always be isolated from the mother liquor and blotted free of liquid. To avoid exposure to atmospheres differing from that above the saturated mother liquor, well-sealed containers with a minimum of void space should be used for storage. Temperature changes should also be avoided.

Mixtures and Achievement of Equilibrium—While the results in this study lend themselves particularly well to interpretation by equilibrium principles, the authors realize that in studying other systems, kinetic barriers may be encountered that prevent the practical achievement of equilibrium, leading to highly variable mixtures.

Failure to observe equilibrium in laboratory experiments should, therefore, be regarded as highly pertinent to everyday industrial product variability. To be sure, it is sometimes desirable to deliberately make nonequilibrium forms, or even to reproducibly halt crystal transformations at a given stage. In any event, it is necessary to characterize all the available crystal forms to evaluate properly the role of crystal transformations in a pharmaceutical process.

⁵ In some cases of crystal desolvation, the diffraction intensities of one or two planes are particularly sensitive to the solvent content of the crystals; in other cases, the loss of solvent is accompanied by a general loss of diffraction sharpness or by slight changes in the unit cell constants (2). However, the X-ray powder diffraction pattern retains its value in identifying the unique origin of the solid phase.

Influence of Several Autonomic Drugs on Sodium Nitroprusside and Oxotremorine-Induced Hypothermia in Immature and Mature Mice

DAVID H. BURKE* and DAVID E. MANN, Jr.

Abstract □ Sodium nitroprusside and oxotremorine each produced body temperature depression that was independent of age. Atropine inhibited oxotremorine hypothermia in both age groups, but was ineffective in modifying thermal responses to nitroprusside in both age categories. Pilocarpine administration did not alter oxotremorine activity at either age level, while nitroprusside hypothermia was enhanced and partially reversed, respectively, in immature and mature mice. Nicotine and tetraethylammonium chloride were unable to modify hypothermia produced by oxotremorine and nitroprusside in adult mice. Nicotine enhanced nitroprusside hypothermia in 10-day-old mice, while temperature depression due to oxotremorine was unaffected in the same age group. Administration of tetraethylammonium chloride to immature animals treated with oxotremorine and nitroprusside resulted in greater temperature depression. Chlorpromazine, which produced no change in oxotremorine or nitroprusside hypothermia in 10-day-old mice, partially blocked oxotremorine-induced hypothermia in mature animals; the weak parasympatholytic phenothiazine produced no significant difference in hypothermia when given prior to nitroprusside in the adult group.

Keyphrases □ Hypothermia, mice—sodium nitroprusside, oxotremorine induced □ Oxotremorine, sodium nitroprusside-induced hypothermia—autonomic drugs effect □ Autonomic drugs effect—oxotremorine, sodium nitroprusside-induced hypothermia □ Age of mice, effect—induced hypothermia

The mammalian body "thermostat," because of its vast complexity, is susceptible to the action of various drugs and agents, particularly those that mimic or interfere with neurotransmitter substances. Oxotremorine, the active metabolite of tremorine, was shown to produce hypothermia in rodents through a central cholinergic mechanism (1, 2).

Age has been shown to modify the effects of certain centrally acting drugs in rats (3, 4). These animals are born functionally immature with poorly developed nervous systems. Bagdon and Mann (5) demonstrated the age factor in mice with the drug chlorpromazine. The hypothermia normally seen in mature mice in

response to chlorpromazine administration was reversed in immature animals to marked hyperthermia.

During routine screening procedures in this laboratory, it was discovered that sodium nitroprusside induces a pronounced fall in the body temperature of mice. It was the purpose of this investigation, therefore, to compare the hypothermia caused by oxotremorine with that induced by sodium nitroprusside with respect to alteration by several autonomic drugs in order to ascertain the mechanism of action and to observe the effects of age on the thermic response.

EXPERIMENTAL

Young (10-day-old) and adult male mice (1398) of the Huntington Farms (HTF) strain were utilized in this investigation.

The drugs employed were as follows: oxotremorine,¹ sodium nitroprusside,² atropine sulfate,³ pilocarpine nitrate,³ nicotine,⁴ tetraethylammonium chloride,⁵ and chlorpromazine hydrochloride.⁶ All solutions were freshly prepared with sterile water distilled in the laboratory.

A model 43 Telethermometer equipped with a No. 402 probe⁷ was used for obtaining oral and rectal temperatures. The animals were kept at a constant environmental temperature of 23–24°C for 24 hr. prior to and including the time of the experimental course.

All injections were given as a fixed dose in a volume of 0.05 ml. for immature mice and 0.25 ml. for mature mice. Calculation of doses for the immature mice was based upon an average weight of 4.5 g. obtained from preliminary experiments in this laboratory. Mature male mice, weighing from 20 to 25 g., received doses calculated on the basis of 22.5 g./mouse.

The agonists with their concentration and dose were: oxotremorine (0.0045%; 0.5 mg./kg.) and sodium nitroprusside (0.045%; 5 mg./kg.).

^a Temperature 15 min. after antagonist injection. ^b Temperature 15 min. after agonist injection. ^c Antagonist-agonist temperature difference. ^d Sodium nitroprusside or oxotremorine. ^e Sodium nitroprusside. ^f Oxotremorine.

Concentrations and doses of the antagonists used in the experiment were: atropine sulfate (0.045%; 5 mg./kg.), pilocarpine nitrate (0.0009%; 0.1 mg./kg.), nicotine (0.0023%; 0.25 mg./kg.), tetraethylammonium chloride (0.0023%; 0.25 mg./kg.), and chlorpromazine hydrochloride (0.009%; 1 mg./kg.).

The animals were grouped according to age and treatment regimen. Experiments were performed at the same time each day to minimize temperature variation.

Groups of 12 animals were weighed individually on a triple-beam Ohaus balance, and their weights were recorded at the start of the experiment. Immediately following weight determination, the animals were confined singly in beakers for a 2-hr. period, during which food and water deprivation was accomplished to preserve metabolic stability. Following the 2-hr. conditioning period, oral (immature) and rectal (mature) temperatures were recorded. In the younger mice, oral temperatures were noted because their small size did not permit taking rectal temperatures without extreme discomfort to the animal. Subcutaneous administration of the antagonist occurred immediately after initial temperature recordings, whereupon the mice were returned to their containers for 15 min. At the end of this period, temperatures were again noted and the agonist was injected intraperitoneally.

Fifteen minutes after the latter challenge, final temperatures were recorded. Control animals were subjected to an identical treatment procedure with the exception that either antagonist or agonist was replaced with saline.

In the comparison of mean temperature changes (*i.e.*, temperature before and after administration of agonist), statistical significance was determined by the use of Student's *t* distribution. Temperature differences were considered to be significant at the probability level of 5% or less. Temperature alterations attributed to antagonist or agonist were ascertained through a comparison with their saline counterparts. Antagonist effect on agonist hypothermia was determined through comparison of saline-agonist with antagonist-agonist treatments.

RESULTS AND DISCUSSION

The effects of sodium nitroprusside on the body temperature of mature male and immature (mixed sex) albino mice at a dosage level of 5 mg./kg. are outlined in Tables I and II. Temperature changes attributed to the agonist were significant for both age groups, with probability levels reaching 99.9%. In 107 mature mice, sodium nitroprusside caused an average temperature depression

of 3.38°, while 91 immature animals exhibited a mean decrease in body temperature of 1.09°.

At the dosage level of 0.5 mg./kg., oxotremorine gave mean drops of 3.55 and 1.52°, respectively, in 114 mature and 103 immature albino mice. Again, these temperature changes were significantly different from the controls at the probability level of 99.9%.

A paucity of information exists in the literature with respect to age variation for oxotremorine. Bowman and Osuide (6) have shown the hypothermic action of tremorine to be independent of age in 4-day-old chicks. It has been shown in this investigation that the intraperitoneal administration of oxotremorine elicited body temperature depression for both age groups.

Subcutaneous injections of atropine sulfate (5 mg./kg.) produced a significant decrease from control values in the body temperature of mature animals (Table III). This 0.21° drop was probably mediated through the ganglionic blocking ability of the alkaloid (7). When this agent was administered prior to sodium nitroprusside, a significant increase in hypothermia (0.28°) was realized. These results indicate that the increased hypothermia was representative of positive summation (agonist plus antagonist).

Ten-day-old mice responded to the action of atropine in a manner similar to that of the mature group (Table IV). A temperature depression, which was 0.32° lower than the saline control value of +0.22°, was significant at the 95% probability level. Temperature depression brought about by the combination of atropine and sodium nitroprusside in this age group was not significantly dif-

ferent from saline-sodium nitroprusside treatment. The lack of positive summation for atropine and this agonist indicates that nitroprusside may block the gangliolytic action of atropine. On the other hand, atropine may produce a partial blockade of nitroprusside hypothermia.

From the results in Table III, it can be seen that pilocarpine, when injected subcutaneously at a dosage level of 0.1 mg./kg., was not significantly different from saline on the body temperature of the older animals. In mature mice, this cholinomimetic agent was able to reverse partially the hypothermic action of sodium nitroprusside at the probability level of 99% (Table III). It is possible that this antagonism was carried out through the capacity of pilocarpine to stimulate sympathetic ganglia and to release catecholamines from the adrenal medulla (8).

As observed in mature animals, oral temperature changes in the pilocarpine-treated juveniles were not different from the saline-treated control group, yet this diaphoretic agent was able to augment the hypothermic action of sodium nitroprusside (Table IV). It is, therefore, concluded from the results of this investigation that the effect of pilocarpine on sodium nitroprusside hypothermia varies according to age; slight antagonism occurs in the mature group, while the immature animals show hypothermic enhancement.

In adult mice treated with nicotine (0.25 mg./kg.), no significant effect was noted. As shown in Table III, nicotine was not able to modify hypothermia produced by sodium nitroprusside.

In Table IV, nicotine has been shown to produce a rise in the body temperature of 10-day-old mice at the dosage level of 0.25 mg./kg. In 30 animals treated with this compound, a mean elevation of 0.5° was observed, which was significant at the 99.9% probability level. When administered 15 min. before sodium nitroprusside, this agent approximately doubled agonist-induced temperature depression. The possibility exists that the agonist drug may have inhibited nicotine pyresis in these animals. It is proposed that the immature mammalian thermoregulatory system modifies the effect of nicotine on sodium nitroprusside temperature reduction.

Tetraethylammonium chloride administration, at a dosage level of 0.25 mg./kg., resulted in no alteration of the thermoregulatory ability of adult mice. When administered prior to sodium nitroprusside, a very slight temperature inhibition of borderline significance was observed. In young animals of this species, tetraethylammonium chloride produced a significant rise in body temperature, amounting to 0.47°. As observed with nicotine, this ganglionic blocking agent further enhanced the temperature depression of sodium nitroprusside; again, the possibility exists that the agonist drug may have inhibited the hyperthermia caused by tetraethylammonium chloride.

It is probable that nicotine and tetraethylammonium chloride act in the same fashion because they both produced qualitatively similar responses when administered alone or prior to sodium nitroprusside. It was reported that these two compounds have in common an ability to stimulate the release of epinephrine from the adrenal medulla (9). It is possible that these agents may produce hyperthermia in young animals through this mechanism and that the administration of sodium nitroprusside inhibits this response. Potentiation of nitroprusside hypothermia may result from inhibition of sympathetic ganglia in the presence of a poorly developed thermoregulatory system.

Chlorpromazine hydrochloride has been shown to achieve a temperature deficit of 1.28° in the mature age group. These results agree with those of Kopera and Armitage (10), who demonstrated the ability of chlorpromazine to cause hypothermia in mice. From the results given in Table III, it can be seen that either nitroprusside blocked the temperature effects due to chlorpromazine or the latter agent caused a partial reversal of nitroprusside hypothermia. Chlorpromazine did not alter the body temperature in young animals and failed to alter the action of nitroprusside.

Tables V and VI show that the effect of atropine sulfate on oxotremorine temperature depression is similar for both age groups. In both cases, a complete inhibition of oxotremorine hypothermia occurred and was significant at the probability level of 99.9%. Lomax and Jenden (11) blocked the hypothermic response of oxotremorine in rats with atropine. The observations of these investigators have been confirmed by this study.

The administration of pilocarpine nitrate (0.1 mg./kg.) 15 min. prior to oxotremorine caused a very slight enhancement of agonist hypothermia in both age groups; it was of borderline significance

in each case (Tables V and VI). Therefore, the effect of age was not demonstrated for pilocarpine modification of oxotremorine hypothermia.

Oxotremorine-induced temperature drops were not modified by the prior administration of nicotine in mature mice. The immature animals showed no significant change in agonist hypothermic response when treated with oxotremorine in combination with nicotine. Because nicotine caused hyperthermia in immature mice (Table VI), it is possible that oxotremorine inhibited this rise in temperature. Conversely, nicotine could have enhanced oxotremorine hypothermia (negative summation).

Age has been shown to modify effects of tetraethylammonium chloride on oxotremorine-induced temperature depression. In the older group of mice, the administration of tetraethylammonium chloride did not affect the hypothermia caused by oxotremorine. Everett *et al.* (12) demonstrated that this antagonist was ineffective in blocking the temperature-lowering effect of tremorine in mice. These results lend support to their claim that the hypothermic action of tremorine is central in origin. A slight increase in the agonist hypothermic response was noted in immature mice after the administration of tetraethylammonium chloride (Table VI). A significant difference was present at the probability level of 95%. Oxotremorine may also inhibit the thermogenic effect of tetraethylammonium chloride in this age group.

A partial blockade of oxotremorine activity by chlorpromazine was observed in the mature group, which was probably caused by the weak parasympatholytic effect of the phenothiazine (13, 14). Conversely, it is also possible that oxotremorine may have interfered with the hypothermia elicited by chlorpromazine. Preadministration of chlorpromazine in the younger animals produced no change in the hypothermia due to oxotremorine. The effect of chlorpromazine on oxotremorine-induced hypothermia has thus been shown to be modified by age.

Although the means by which sodium nitroprusside causes a fall in body temperature has not been elucidated as a result of this study, a comparison of its activity with that of the centrally acting oxotremorine in the presence of various autonomic drugs in mature mice has provided strong evidence for a different mechanism of action. While the administration of atropine resulted in a complete blockage of oxotremorine-induced depression of body temperature, no such inhibition was observed with sodium nitroprusside following the parasympatholytic agent. On the other hand, pilocarpine failed to modify oxotremorine hypothermia, whereas this parasympathomimetic partially inhibited nitroprusside hypothermia.

SUMMARY AND CONCLUSIONS

1. Sodium nitroprusside and oxotremorine each produced a hypothermic response that was independent of age in the mouse.
2. The effect of atropine on oxotremorine-induced hypothermia appeared to be uninfluenced by age. In both cases, a complete inhibition of agonist hypothermia occurred.

3. The prior administration of atropine enhanced sodium nitroprusside-induced hypothermia, indicating the existence of positive summation in the mature group. This antagonist was unable to alter nitroprusside hypothermia in immature animals. Nitroprusside may block atropine-induced changes.

4. Pilocarpine effects on oxotremorine-induced hypothermia were unaffected by age.

5. The action of pilocarpine on sodium nitroprusside-induced hypothermia was age related, because slight antagonism occurred in the mature group while immature animals showed hypothermic enhancement.

6. The influence of nicotine on sodium nitroprusside-induced hypothermia was affected by age. Agonist hypothermia was not modified in the mature group; hypothermia was enhanced in the immature group. Nicotine pyresis may be antagonized in the younger group.

7. Oxotremorine temperature depression was not modified by nicotine in mature mice. In the immature animals, this agonist may have inhibited nicotine hyperthermia; conversely, nicotine may have enhanced oxotremorine hypothermia (negative summation).

8. Tetraethylammonium chloride produced effects on sodium nitroprusside hypothermia which were qualitatively similar to those of nicotine. It has been suggested that these antagonistic drugs act in a comparable manner.

9. Age was shown to modify the effect of tetraethylammonium chloride on oxotremorine-induced temperature depression. Agonist hypothermia was not affected by tetraethylammonium chloride in the mature group. Slight enhancement was shown in the immature animals. Oxotremorine may have inhibited tetraethylammonium chloride hyperthermia.

10. Sodium nitroprusside-induced hypothermia was not affected by chlorpromazine in the immature age group. In the mature animals, either nitroprusside blocked chlorpromazine hypothermia or the latter agent partially reversed nitroprusside hypothermia.

11. Chlorpromazine demonstrated no effect on oxotremorine-induced hypothermia in the immature animals. Partial antagonism was noted in the mature group. Oxotremorine may have inhibited chlorpromazine-induced hypothermia.

12. Evidence has been provided that oxotremorine and sodium nitroprusside each produce hypothermia in mature mice *via* a different mechanism. The parasympathomimetic agent, pilocarpine, did not alter oxotremorine-induced hypothermia, while this drug partially inhibited that of sodium nitroprusside. Conversely, atropine inhibited hypothermia attributed to oxotremorine but failed to modify that of nitroprusside.

Potentiometric Titration of Allantoin in Cream Formulations

D. J. WEBER* and J. W. HIGGINS†

Abstract □ An analytical procedure is described which uses a rapid partition chromatographic separation of intact allantoin from cream formulations. The allantoin content is measured by potentiometric titration in a mixed solvent system. Accuracy and precision data are presented, and good results are obtained with commercial preparations.

Keyphrases □ Allantoin cream formulation—analysis □ Column chromatography—separation □ Potentiometric titration—analysis

The current methods of analysis of allantoin involve hydrolysis and quantification of the resulting glyoxylic acid (1–3) or urea (3–5). These procedures are deficient for the analysis of residual allantoin, since they measure urea or glyoxylic acid which are the products of normal allantoin degradation (6). Using these methods of analysis after preliminary isolation of allantoin from its degradation products requires a difficult separation step. Other procedures use paper chromatography (7) or paper electrophoresis (5, 7), which are rather slow and have been applied only to urine samples. A TLC separation and UV assay of allantoin at 220 $m\mu$ was reported for creams and lotions (8), but data on samples were not included and the molar absorptivity is only about 1200.

This report describes an assay for allantoin in cream formulations based on a partition chromatographic separation of allantoin from interfering substances and potentiometric titration of the allantoin with alkali. Those substances, which are eluted with the allantoin, are either nontitratable or have acid-dissociation constants sufficiently different from allantoin to permit its analysis.

EXPERIMENTAL

Apparatus—The following were used: recording pH meter¹ equipped with a glass-reference combination electrode² and a magnetic stirrer;³ a motorized, constant-speed syringe buret⁴ to deliver the titrant; and a glass chromatographic column, 30 × 2 cm.

Reagents—The following were used: sodium hydroxide, 0.1 *N* solution standardized potentiometrically against primary standard potassium biphthalate; acetone, A.R.; acid-washed diatomaceous earth;⁵ ethyl acetate, A.R.; ethyl ether, A.R.; glass wool; and *p*-dioxane.⁶ Allantoin⁷ was used as received.

Preparation of Solvent Mixtures—Ethyl acetate (200 ml.) and water (20 ml.) were combined in a separator and shaken to equilibrate. The layers were allowed to separate. The water phase (lower)

serves as the stationary phase in the column and for sample preparation. The ethyl acetate layer serves as the organic mobile phase for column elution.

Ether saturated with water was prepared by adding 25 ml. of water to 100 ml. of ethyl ether and separating after equilibration. The aqueous phase was discarded.

Column Preparation—To 4 g. of acid-washed diatomaceous earth, 3.5 ml. of stationary phase is added and mixed thoroughly. This material is added in portions to a 2-cm. i.d. chromatography column containing a pledget of glass wool at the bottom. The column is tapped on a wooden block after each addition of support until it is compact. The column is then tamped semifirmly with a column-packing rod to a length of 5.6 cm. The column is washed with 50 ml. of water-saturated ethyl acetate.

Preparation of Artificial Sample—A placebo batch of Cream E, containing all ingredients except allantoin, was prepared. Allantoin was added to samples of this placebo cream, lightly heated, mixed to give a homogeneous mix, and then rapidly cooled. The samples were put into beakers, sealed with Parafilm to avoid evaporation, and stored at room temperature for 4 days before being analyzed.

Procedure—Accurately weigh a quantity of sample equivalent to about 25 mg. of allantoin into a 50-ml. beaker, and add 1.5 g. of acid-washed diatomaceous earth. Mix thoroughly with a spatula and then add 0.5 ml. of stationary phase and mix thoroughly again. Add the sample preparation to the prepared column and tamp semifirmly. Place a pledget of cotton on top of the sample, and elute the column with 100 ml. of mobile phase. Allow the ethyl acetate mobile phase to run just below the surface of the diatomaceous earth, add 5 ml. of ethyl ether (water saturated), and again allow this to run just below the surface. Add an additional 25 ml. of ethyl ether (water saturated) and allow the column to run dry. Discard all solvent eluted. Strip the allantoin from the column by eluting with 40 ml. of deionized water. Only the water is collected into a 150-ml. beaker. The boundary between the residual ethyl ether on the column and the water eluate containing the allantoin is easily determined by the initially cloudy nature of the water eluate.

Table I—Solvent Effect of the pK_a' of Allantoin, Triethanolamine, and Glyoxylic Acid

Substance	H_2O	pK_a'			
		Dioxane- H_2O		Acetone- H_2O	
		1:2	2:1	1:2	2:1
Allantoin	8.01	9.13	10.38	8.75	9.91
Triethanolamine	7.66	7.52	7.33	7.25	7.10
Glyoxylic acid	3.50	Reaction	Reaction		4.98

Collect all eluent until the column runs dry. Add 70 ml. of acetone to the 30–35 ml. of eluate collected and potentiometrically titrate the sample with standard 0.1 *N* NaOH to an apparent pH of 11.5–12.0. Usually, two inflections are observed, one near pH 8 and the other near pH 11. Calculate the milligrams of allantoin per gram of sample by substituting the observed values into the following equation:

$$\frac{V \times N \times 158.12}{(\text{sample wt., g.})} = \text{mg. allantoin/g. sample} \quad (\text{Eq. 1})$$

where *V* is the milliliters of titrant consumed between the two inflections, *N* is the normality of the titrant, and 158.12 is the equivalent weight of allantoin.

DISCUSSION

Potentiometric Titration of Allantoin—The potentiometric titration curves of allantoin in water and 66% acetone–water are shown in Fig. 1. The equivalence points, although short, are distinct and analytically useful. Many cream samples were found to contain a basic emulsifying agent such as triethanolamine, which was eluted from the column with the allantoin and interfered with its titration in a purely aqueous solvent system. The addition of acetone or dioxane to the aqueous solution caused a large increase in the pK_a' of allantoin and a smaller decrease in the pK_a' of the amine. These shifts are due to the combined effects of a lower solvent dielectric constant and changes in the solvation sphere of the molecules (9). The effects of different solvents on the pK_a' of allantoin, triethanolamine, and glyoxylic acid are given in Table I. Dioxane has a lower dielectric constant than acetone and, therefore, produced a greater separation in pK_a' of allantoin and triethanolamine than was found for acetone. The titration curve of allantoin plus triethanolammonium ion in 66% acetone–water is given in Fig. 1. Glyoxylic acid, a natural degradation product of allantoin, reacted very rapidly with a substance in the *p*-dioxane to give a product which interfered with the titration of allantoin. This problem was avoided by using acetone as the solvent. Dioxane, besides containing material reactive to glyoxylic acid, also contains small amounts (9.6×10^{-4} meq./ml.) of an acid substance which also interferes with the titration of allantoin.

Partition Column Separation of Allantoin—The partition coefficient of allantoin estimated from the ratio of its solubility in ethyl acetate to its solubility in water is 3×10^{-3} . Therefore, in an aqueous stationary phase the allantoin is essentially immobile and is easily separated from nearly all excipients after sufficient ethyl acetate mobile phase has been passed through the column. Those excipients that are not separated are either not titratable or have a sufficiently different pK_a' to allow differentiation using a mixed solvent system.

Table II—Elution of Allantoin^a from Partition Column with Water

Table III—Accuracy Data for the Assay of Allantoin in Creams^a

Sample	Placebo Weight, g.	Allantoin Added, mg.	Theoretical Allantoin, meq.	Observed Allantoin, meq.	Theory, % ^b
1	1.5253	28.20	0.1783	0.1792	100.50
2	1.4829	30.25	0.1912	0.1897	99.21
3	1.5842	29.82	0.1885	0.1885	100.00
4	1.4417	32.50	0.2055	0.2001	97.37
5	1.4045	29.46	0.1850	0.1862	100.64
6	1.3810	36.20	0.2289	0.2280	99.60
7	1.6279	31.14	0.1969	0.1941	98.57
8	1.6254	30.13	0.1905	0.1908	100.15

^a Samples were prepared by the addition of allantoin to a placebo cream. ^b The mean percent recovery is 99.51%, and the 95% confidence interval is $\pm 1.07\%$.

The apparent partition coefficient on a chromatographic column has been shown (10) to be a function of the stationary phase volume. The present assay uses a column with a ratio of milliliters of stationary phase to grams of support of 0.875. To maintain equilibrium conditions and produce a satisfactory elution pattern, it was found useful to add water to the sample preparation sufficient to give a ratio of aqueous phase to grams of support close to 0.875. This produced a satisfactory elution pattern (Table II). Excellent analytical results were obtained with flow rates as high as 5 ml./min.

The function of the ethyl ether wash is to remove residual ethyl acetate from the column. Any ethyl acetate present during the titration of allantoin interferes due to its rapid hydrolysis. This rapid hydrolysis was indicated by the fact that when the titration was stopped at high pH values (greater than 8), the pH began to drift toward lower values.

Accuracy and Precision—Accuracy data for the assay of allantoin added to placebo samples of Cream E are given in Table III. The data indicate that both the accuracy and precision of the analysis are excellent. The results of repeated analysis of a commercial sample of Cream E are given in Table IV. The 95% confidence interval is nearly the same as was calculated for the data of Table III. This suggests that the samples prepared for the accuracy study are truly representative of commercial creams and that the data in Table III are valid estimates of the accuracy of the assay.

The results of the analysis of a variety of commercial creams are given in Table V. The assay gave acceptable results in every case, and repeat assays of Products A and D showed good precision.

It has been shown (6) that under conditions of temperature and pH that would be expected in cream formulations, the products of allantoin hydrolysis are allantoic acid and then urea and glyoxylic acid. Potentiometric titration of mixtures of allantoin, glyoxylic acid, and triethanolammonium chloride and allantoin plus allantoic acid in 66% acetone–water gave allantoin recoveries of 100.3 and 100.0%, respectively. These results demonstrate that no interference is caused by these compounds.

Alkaline hydrolysis of allantoin (1.5×10^{-3} *M* NaOH at 80° for 30 min.), acidification, and then analysis showed a loss of allantoin of 10.5%. If ammonium ion had been produced, the recovery of allantoin would have been greater than 100% since urea, an initial hydrolysis product of allantoin, gives two molecules of ammonium ion when it hydrolyzes. The pK_a' of the allantoin from the hydrolyzed sample was 9.95, in excellent agreement with the value 9.91 previously determined.

Table IV—Precision Data for Assay of Allantoin

Sample ^a	Sample Weight, g.	Observed Concentration, mg./g.	Formula Strength, % ^b
1	1.2765	20.28	96.57
2	1.4072	20.53	98.10
3	1.4026	20.42	97.24
4	1.3113	19.97	95.10
5	1.5625	20.28	96.57
6	1.2270	20.54	98.10

^a All samples are from a single tube of Cream E. ^b The mean percent formula strength is 96.9% and the 95% confidence interval is $\pm 1.18\%$.

Table V—Assay Results for Allantoin in Commercial Creams

Product	Sample Weight, g.	Weight Allantoin/g. Cream, mg.	Label Strength, %
A	1.1495	18.6	93.0
A	1.0523	18.4	92.0
B	1.0670	20.9	104.5
C	0.9141	20.2	101.0
D	3.2041	2.44	97.6
D	3.3492	2.47	98.8
E	1.2765	20.28	96.57

Chromatography and potentiometric titration of a mixture of allantoin and ammonium chloride showed that the ammonium ion is eluted with the allantoin and interferes with the quantification of allantoin in the titration. However, since no significant production of ammonia from allantoin in creams occurs, this causes no problem in the assay. Precipitation of ammonium ion from equimolar allantoin-ammonium-ion mixtures using sodium tetraphenyl borate was 96% effective in removing the ammonium-ion interference and resulted in 103% apparent recovery of allantoin. Smaller amounts of ammonium ion gave correspondingly smaller interferences.

NMR Analysis of Mestranol Bulk Drug

HAJRO W. AVDOVICH, MARTHA BOWRON, and BRUCE A. LODGE

Abstract □ A double assay procedure for mestranol is described. The method is based upon measurement of the NMR spectrum of mestranol in pyridine, using diphenylacetic acid as an internal standard. The signals chosen are those from the methoxyl and ethinyl groups. Three commercial lots of the steroid were studied, and a TLC study of each lot is described. The impurities are tentatively identified.

Keyphrases □ Mestranol bulk drug—analysis □ TLC—separation □ Potentiometric titration—analysis □ NMR spectroscopy—analysis

The synthetic oral estrogen mestranol (17 α -ethinyl-3-methoxyestra-1,3,5(10)-trien-17 β -ol) is now in widespread use, chiefly as a component of oral contraceptive preparations. At present, the only official assay (1) for the raw material is a potentiometric titration. Other methods reported in the literature are colorimetric (2-4), UV (5-7), GLC (4, 6, 8, 9), TLC (7), and fluorometric (4, 10-12).

Mestranol lends itself very well to quantitative analysis by means of NMR spectroscopy, since the signals from the protons of both the ethinyl and methoxyl groups are single sharp peaks. With a suitable choice of solvent, these peaks appear in a region of the spectrum that is unaffected by signals from other protons.

The effect of solvents on the chemical shift of acetylenic protons is well documented (13). In particular, addition of pyridine to a dilute solution of a monosubstituted acetylene in carbon tetrachloride can result in deshielding of up to 1 p.p.m. of the acetylenic proton (14). Such significant deshielding is due to the fact that acetylenic compounds can form weak hydrogen bonds with molecules containing electronegative centers, such as acetone, acetonitrile, and pyridine (14-16).

Since the impurities present in mestranol bulk drug might interfere with either the signal from the ethinyl group or that from the methoxyl group, a study of the assayed samples was made by means of TLC.

EXPERIMENTAL

Spectra were obtained at 60 Mc.p.s., using a Varian A-60A analytical NMR spectrometer. A sweep time of 50 sec. for a chart width of 500 c.p.s. was used for all integrals. A r.f. power of 0.25 mG. (nominal dial setting) gave the maximum integral amplitude (17) and was used for the integrations. Tetramethylsilane in chloroform was used as an external reference to measure chemical shifts.

Assay Procedure—NMR—Approximately 200 mg. of mestranol and 150 mg. of pure diphenylacetic acid (DPAA) were accurately weighed and dissolved in the minimum amount of pure pyridine (approximately 0.5 ml.). The NMR spectrum was obtained in the usual manner and integrated five times in each direction through the region of interest.

Potentiometric Titration—Approximately 200 mg. of mestranol,

Table V—Assay Results for Allantoin in Commercial Creams

Product	Sample Weight, g.	Weight Allantoin/g. Cream, mg.	Label Strength, %
A	1.1495	18.6	93.0
A	1.0523	18.4	92.0
B	1.0670	20.9	104.5
C	0.9141	20.2	101.0
D	3.2041	2.44	97.6
D	3.3492	2.47	98.8
E	1.2765	20.28	96.57

Chromatography and potentiometric titration of a mixture of allantoin and ammonium chloride showed that the ammonium ion is eluted with the allantoin and interferes with the quantification of allantoin in the titration. However, since no significant production of ammonia from allantoin in creams occurs, this causes no problem in the assay. Precipitation of ammonium ion from equimolar allantoin-ammonium-ion mixtures using sodium tetraphenyl borate was 96% effective in removing the ammonium-ion interference and resulted in 103% apparent recovery of allantoin. Smaller amounts of ammonium ion gave correspondingly smaller interferences.

The NMR spectrum was obtained in the usual manner and integrated five times in each direction through the region of interest.

Potentiometric Titration—Approximately 200 mg. of mestranol,

Figure 1—NMR spectrum of mestranol in deuteriochloroform.

accurately weighed, was dissolved in 40 ml. of tetrahydrofuran. To the solution was added 10 ml. of 5% silver nitrate solution, and the mixture was titrated with 0.1 N sodium hydroxide, the end-point being determined potentiometrically.

TLC was carried out on silica gel GF plates of 0.25-mm. thickness. The developing mixture was benzene-methanol (19:1), and spots were detected by spraying with concentrated sulfuric acid and heating for 20 min.

Figure 2—Partial NMR spectrum of mestranol plus DPAA in pyridine.

Figure 3—Partial NMR spectrum of estrone-3-methyl ether in pyridine.

Calculation—NMR—

$$\text{Wt. of mestranol (mg.)} = \frac{\text{E.W. mestranol}}{\text{E.W. DPAA}} \times \frac{I \text{ mestranol}}{I \text{ DPAA}} \times \text{wt. DPAA (mg.)} \quad (\text{Eq. 1})$$

where E.W. is the molecular weight of the substance divided by the number of protons corresponding to the signal chosen for the assay, and I is the integral height.

Potentiometric Titration—

$$\text{Wt. of mestranol (mg.)} = 31.04 \times \text{number of ml. 0.1 N sodium hydroxide} \quad (\text{Eq. 2})$$

RESULTS AND DISCUSSION

NMR spectroscopy, based on the 60-Mc.p.s. spectrum, has been shown (18) to be of value in the analysis of meprobamate and chemically related substances. Information has been presented (19) demonstrating the use of NMR in the quantitative analysis of synthetic corticosteroids of the 1,4-dien-3-one type.

The NMR spectrum of mestranol in deuteriochloroform (Fig. 1) possesses signals at 6.27 τ (3 protons, due to the 3-methoxy group) and at 7.44 τ (1 proton, due to 17 α -ethinyl group). The signal from the methoxyl protons is in an isolated region of the spectrum and is thus available for use in quantitative analysis. The ethinyl proton

Table I—Analysis of Mestranol Bulk Drug by NMR and Potentiometric Titration

	NMR				Potentiometric Titration—	
	Percent Found, Based on Ethinyl Protons	Mean	Percent Found, Based on Methoxyl Protons	Mean	Percent Found	Mean
Lot A	99.0 98.8	98.9	101.8 100.5	101.2	99.6 99.2	99.4
Lot B	99.6 100.4 100.3	100.1	101.1 101.0 100.9	101.0	101.4 100.6 102.2	101.4
Lot C	99.9 99.2 99.7	99.6	100.1 100.6 101.3	100.3	98.6 98.4 98.2	98.4

Figure 4—Schematic TLC chromatogram of three commercial lots of mestranol and likely impurities. Key: A–C = samples, D = 17 β -ethinylestradiol, E = estradiol, F = estrone-3-methyl ether, G = estrone, and H = estradiol-3-methyl ether. The adsorbent is silica gel GF, 0.25 mm.; the solvent is benzene-methanol (19:1).

signal is not suitable, however, since it is surrounded by a large number of other signals. On the other hand, in the NMR spectrum of mestranol in pyridine (Fig. 2), the methoxyl proton signal is very slightly shielded (6.33 τ), but the ethinyl proton signal is significantly deshielded (6.80 τ) and is isolated from all other signals, thus making it suitable for use in quantitative analysis. Therefore, using pyridine as the solvent, two simultaneous independent determinations can be carried out on the same molecule. The signal at 4.62 τ (Fig. 2) is due to the methine proton of the internal standard, DPAA.

Mestranol is synthesized from estrone via estrone-3-methyl ether (20); both of these are, therefore, likely to occur as impurities. Other possible foreign related steroids in the final raw material are estradiol, estradiol-3-methyl ether, and 17 α -ethinylestradiol. Of these, two (estrone-3-methyl ether and estradiol-3-methyl ether) interfere with the signal from the methoxyl protons of mestranol, and one (17 α -ethinylestradiol) interferes with the signal from the ethinyl proton. Figure 3 shows a partial NMR spectrum of estrone-3-methyl ether in pyridine, with the signal from the methoxyl protons, at 6.3 τ , being in exactly the same position as the corresponding signal in mestranol (Fig. 2).

Figure 4 shows a schematic representation of the results of a TLC study of the three commercial lots investigated, together with the most likely impurities. Lot A contained significantly more methoxyl than ethinyl impurities, together with some estrone, which would not be detected by either the NMR or the BP potentiometric method (1). Lot B contained rather more methoxyl than ethinyl impurities, together with some estradiol, which again would not be detected. Lot C contained a trace of 17 α -ethinylestradiol but no methoxyl impurities; in addition, there was a very faint but diffuse spot, close to the origin, which was not identified.

Results obtained from the analysis of the samples are shown in Table I. The potentiometric titration (1) is essentially an estimation of ethinyl protons, since the alkyne is treated with silver nitrate, liberating nitric acid which is determined by titration with standard alkali. Therefore, the results obtained from the NMR ethinyl proton signal should agree with those obtained by titration. The results from Lot A are in good agreement; the results from Lots B and C differ by 1.3 and 1.2%, respectively. The NMR method gives an average deviation of $\pm 0.6\%$ (19); the accuracy of the titration method was not determined, but if it is no worse than the NMR procedure, the results obtained from the ethinyl protons by the two techniques are not significantly different.

Of immediate interest in the NMR method is a comparison of the pairs of results. For pure mestranol, the results should be identical (within the experimental limits $\pm 0.6\%$). In the case of Lots B and C, the results are in good agreement. The results obtained from Lot

A, however, show a difference of 2.3%, the methoxyl signal giving the higher answer. This is probably because this sample contained both estrone-3-methyl ether and estradiol-3-methyl ether as impurities in amounts which appeared, from TLC, to be significantly greater than the amount of 17 α -ethinylestradiol present. Therefore, the result would be expected to be biased by an increase in the methoxyl signal.

The NMR procedure as described offers an attractive alternative assay for mestranol bulk drug. Simultaneous independent answers, from two different and isolated functional groups in the same molecule, act as a built-in check for the procedure.

Fluorometric Determination of Reserpine and Related Compounds by Reaction with Vanadium Pentoxide

TIBOR URBÁNYI and HENRY STOBER*

Abstract □ A rapid and fairly specific fluorometric procedure has been developed for the routine quantitative determination of reserpine and its derivatives alone and in tablet formulations. The method is based on the formation of fluorescence induced by the oxidation of reserpine with a reagent containing vanadium pentoxide in phosphoric acid. The oxidation product exhibits a greenish-yellow fluorescence, with the maximum around 500 m μ in an acidic alcoholic solution. The dependence of the intensity of fluorescence upon the nature of the solvent, reagent concentration, and other parameters is discussed. The fluorogen developed follows Beer's law over a very wide range, from 0.004 to 2 mcg./ml. of sample solution. The advantages and disadvantages of the proposed method are discussed, and the applicability in different formulations is demonstrated.

Keyphrases □ Reserpine and derivatives in tablets—determination □ Vanadium pentoxide—reserpine reaction—fluorescence □ Phosphoric acid effect—reserpine—vanadium pentoxide fluorogen □ Fluorometry—analysis

Since the isolation of reserpine¹ from the various Rauwolfia roots was completed, its double therapeutic effect as an antihypertensive and a tranquilizer has been recognized. When the usefulness of the reserpine as an effective human medicine was realized, Szalkowski and Mader (1) developed a quantitative method for its

determination. This method underwent many modifications (2, 3) which, however, did not alter the methodology of the original procedure significantly.

In recent years, photometric methods (4) have been introduced for the quantitative determination of reserpine. These methods are based on reactions with suitable reagents resulting in the formation of chromophores or fluorogens, which can be measured by colorimetric or fluorometric techniques. Colorimetric measurements (5) are applied mostly for pharmaceutical formulations where the sensitivity of the determination is not critical. Fluorescence determinations are used for reserpine in feeds and biological materials (6), where extremely sensitive and selective methods are required. A direct UV method (7) is frequently used for the determination of reserpine and has the advantage of speed of assay where the concentration of reserpine is high enough for UV absorption. Column chromatographic methods (8) are highly specific and fairly sensitive, but they are time consuming. TLC methods (9) are often used for the separation of the active alkaloids, but these methods are primarily qualitative rather than quantitative.

The development of a specific method for the determination of reserpine is difficult because of its structural similarity to other active alkaloids isolated from the Rauwolfia root. The greenish-yellow color produced

using the general nitrite procedure for reserpine is specific for alkaloids having a 2,3,4,9-tetrahydro-7-methoxy-1*H*-pyrido[3,4-*b*]indole group (10) with the following structural formula (I):

It was observed that when reserpine was exposed to intense light, air, or oxidizing agents, a greenish-yellow colored compound was produced (11). This compound is identical with the reaction product obtained from the nitrite procedure and was identified by several authors (11, 12) as 3-dehydroreserpine, a first-step oxidation product of reserpine. Among many oxidative reagents, the official method in Pharmacopeia Belgique IV (13) is the sulfovanadic acid, which produces a greenish-yellow color with reserpine in acetone solution.

In the USP and NF, the official method is the nitrite procedure in the presence of hydrochloric acid. The chromophores produced by these different reagents are

Figure 1—Rate of formation of fluorogen with vanadium pentoxide in different solvents.

Figure 2—Plot of fluorescence of alcoholic solutions against concentrations.

alike and are measured colorimetrically at the absorption maximum at about 390 $m\mu$. The greenish-yellow color recommended by the official procedure permits the determination of reserpine by fluorescence measurements, since the fluorescent product increases the sensitivity for the determination of reserpine.

The goal of this study was to develop a fluorescence method which would be as sensitive or better than that of the nitrite procedure and, with its simplicity, would improve the precision of the official method. The proposed method is based on the formation of a greenish-yellow fluorogen with vanadium pentoxide in phosphoric acid in alcohol or with an aqueous ethanolic solution of reserpine. On the basis of these observations, the method described can be adopted for the reserpine determination of the single-tablet assay, where extremely high sensitivities are desired. The optimal reaction conditions and the characteristics of the fluorescent species are presented.

EXPERIMENTAL

Reagents and Solutions—Concentrated phosphoric acid was saturated with reagent grade vanadium pentoxide by mechanical

shaking for approximately 1 or 2 hr. The solution was filtered through a medium-porosity sintered-glass funnel. The saturated solution contained about 0.8 mg. of vanadium pentoxide/ml. This reagent was quite stable and could be stored for a long period without any changes in composition; alcohol USP was used as solvent.

Apparatus—An Aminco SPF-125 spectrophotofluorometer, equipped with variable slit controls and a mercury lamp for the light source, and an Aminco-Bowman recording spectrophotofluorometer with xenon lamp for the light source were used for the measurements.

Preparation of Standard Solution—A solution containing 1 mcg./ml. of USP reserpine reference standard in alcohol USP was prepared.

Preparation of Assay Solution—A reserpine solution of 1 mcg./ml. in alcohol USP was prepared. To facilitate the dissolution of reserpine from the tablet mass, a sonifier bath was employed.

Procedure—Into a 25-ml. volumetric flask, pipet 10 ml. of assay

Figure 3—Plot of the $\log F_{\infty} - F_t$ of reserpine treated with varying amounts of vanadium pentoxide per 0.5 ml. H_3PO_4 against time. Reserpine concentration = 0.01 mg./10 ml.

solution and 0.5 ml. of reagent. Mix well and let the solution stand about 10–15 min. At the same time, pipet standard solutions into separate 25-ml. volumetric flasks containing 6, 8, and 10 mcg. of reserpine in 10 ml.; add 0.5 ml. of reagent solution to each flask, and mix well. After the standing time, set the activation slit control at 2 mm. and the emission slit control at 4 mm. at full sensitivity, and set the percent full scale setting at 100 of the instrument. Measure the fluorescence of the standard and sample solutions at 495 $m\mu$ with the activation wavelength of 365 $m\mu$, using a 1-cm. fluorescence cell.

DISCUSSION

The most frequently reported quantitative method for the determination of reserpine and its related compounds, alone or in formulations, is still the nitrite procedure. The use of colorimetric or fluorometric determinations depends on the concentration of reserpine in the product to be analyzed, since the species assayed in both instances are identical. The colorimetric or fluorometric procedures currently used are fairly complicated (using several reagents and extractions). A simpler procedure requiring a single reagent and fewer associated steps with possibilities of automation would be desirable.

It is well known that reserpine can be fairly easily oxidized to a fluorescent product in acid solution using suitable oxidants. Several oxidizing reagents such as ceric compounds, peroxides, selenium dioxide, permanganates, periodates, and vanadium salts and its oxides were tested in these laboratories. Because the oxidation of

^a These assays were performed on chloroform extracts obtained by the official nitrite procedure. An aliquot of the chloroform extract was evaporated to dryness, the residue dissolved in ethanol, and the resultant solution assayed by the vanadium pentoxide procedure. The nonstarred results are based on analysis by vanadium pentoxide without prior extraction.

Figure 5—3-Dehydroreserpine treated with vanadium pentoxide reagent. (The base line for Spectrum B was displaced for visual convenience.)

reserpine occurs in acid solution, the effect of different inorganic and organic acids on the oxidants was tested. Ceric compounds dissolved in mineral acids produced fluorescence with reserpine in alcoholic solution; however, the usefulness of this reagent was impaired by a rapidly forming precipitate in the solution. The other oxidants mentioned failed to produce significant fluorescence with reserpine, regardless of the acid or solvent used for the dissolution.

The dissolution of the pure substance or the tablet mass was carried out in alcoholic solutions. Appreciable fluorescence was observed when an alcoholic solution of the reserpine was treated with a saturated solution of vanadium pentoxide in concentrated phosphoric acid. The fluorescence yields of reserpine with vanadium pentoxide were considerably inhibited when the vanadium pentoxide was dissolved in mineral acids other than phosphoric acid. Table I illustrates the fluorescent intensity of reserpine obtained with saturated vanadium pentoxide in different acids. It is evident from these data that the maximum fluorescent intensity was achieved with phosphoric acid. The phosphoric acid reagent also proved to be more stable. From these observations it was obvious that the optimum concentration of the reagent should be investigated. The volume and the concentration of the sample solution were kept constant. The optimal fluorescent intensity was achieved using 0.25-0.5 ml. of reagent, and the data for these observations are presented in Table II. The effect of phosphoric acid upon the production of fluorescence was investigated by maintaining the reserpine and the reagent concentration constant. These data are presented in Table III and show that the variation of the phosphoric acid concentration insignificantly influenced the fluorescent intensity of the recommended assay.

During this investigation it also was observed that the fluorescence measurements were not only affected by the oxidation reagent but that the rate of oxidation was substantially affected by the solvents used in dissolution. From Fig. 1 it is apparent that the reaction proceeds most rapidly in alcohol USP but with less fluorescent intensity than in ethanolic water solutions that were tested for suitability with respect to automated procedures. This difference can be explained by the quenching effect, since the reagent imparts a slight yellow color in alcohol USP. However, this yellow color can be significantly decreased upon the addition of water. Ethanolic solutions of reserpine containing various amounts of water were analyzed by this procedure. The data presented in Table IV indicate that with 25% water, maximum fluorescence was produced. With aqueous ethanolic solution, a very faint straw-yellow color was observed; however, the fluorescence for reserpine in this solution was approximately 10-15% higher than in alcohol USP alone. Since the rate of fluorescence development is faster in alcohol USP, the slight decrease due to quenching can be overcome if one allows the

fluorescence to develop in alcohol USP and then, after a suitable time, dilutes the solution to a desired volume with water.

Almost the same quenching effect as in the case of alcohol was observed when a large excess of phosphoric acid was employed for the assay. A maximum fluorescence was obtained upon addition of 0.5 ml. reagent and 0.5-1.5 ml. of phosphoric acid to 12 ml. of an ethanolic solution containing 1 mcg. reserpine/ml. These data indicate the optimum reaction conditions and the most stable fluorescence species. To determine the validity of the reaction using optimum conditions, the fluorescent intensity was plotted against the concentration of reserpine (Fig. 2). The linear plots obtained by this procedure indicate that the method is reliable. The fluorescence species appears to be stable in solution for a period of several hours. This procedure would be suitable for the determination of reserpine, alone and in tablet formulations.

Reserpine and syrosingopine² are fairly soluble in alcohols; tablets containing these active ingredients were extracted with alcoholic solutions. The results obtained for reserpine and syrosingopine tablets, using the new vanadium pentoxide procedure, are presented in Table V. The data were compared with the results obtained by the official nitrite procedure. The proposed new vanadium pentoxide method without an extraction procedure fails to distinguish the possible degradation products, such as reserpic acid, from the parent compound. To determine the amount of reserpic acid, the citric acid extracts remaining from the analysis of syrosingopine tablets by the nitrite procedure were subjected to the vanadium pentoxide method. Approximately 0.4% of fluorescent material based on syrosingopine was found in the citric acid extract. The differences between the extracted and nonextracted analyses indicate, therefore, that the reserpic acid concentration is negligible in comparison with the experimental error of the method. The reproducibility of the method according to the new procedure is presented in Table VI.

After a practical determination of reserpine by fluorescence measurements, an attempt was made to determine if the reaction products from the nitrite and vanadium pentoxide methods were identical. Haycock *et al.* (12) studied the kinetics of nitrous acid-induced fluorescence and suggested that the fluorescent product in reserpine by nitrous acid is a two-step reaction which can be explained by Scheme I:

^a Analysis of 0.25-mg. reserpine tablets.

A linear relationship was obtained by plotting the logarithm of unreacted reserpine expressed as $F_{\infty} - F_t$, where F_{∞} is the final fluorescence of the solution and F_t the fluorescence at time t , versus the time required for fluorescence development with nitrous acid. A plot of this type is linear for several different concentrations of nitrite reagent and indicates first-order kinetics with respect to reserpine concentration. Preliminary data of this type have been obtained for the fluorescence produced by the reaction of reserpine with vanadium pentoxide reagent. A plot of the logarithm of $F_{\infty} - F_t$ versus time for different concentrations of vanadium pentoxide produces straight lines, indicating an apparent first-order reaction with respect to reserpine concentration as in the nitrite case (Fig. 3).

To establish that the fluorescent species is the same, 3-dehydroreserpine was synthesized from reserpine, and the synthesized product was compared with the fluorescent species produced by vanadium pentoxide reagent. Satisfactory combustion analysis was obtained for the synthesized product, and the TLC data indicated only a few trace impurities. The activation and fluorescence spectra of 3-dehydroreserpine in the presence and absence of vanadium pentoxide reagent were essentially identical to that of reserpine treated with vanadium pentoxide reagent (Figs. 4 and 5). Since the spectra were generated by an Aminco-Bowman spectrophotofluorometer, the activation and fluorescence maxima show slight differences in wavelengths from those obtained on SPF-125. This difference between the Aminco-Bowman and SPF-125 is most likely due to the difference in sources for the two instruments. The spectra were generated in ethanol and aqueous alcoholic solutions. The fluorescence yields of reserpine treated with vanadium pentoxide reagent were 106% based on the fluorescence obtained from an equimolar amount of 3-dehydroreserpine treated similarly. Some fluorescence quenching is observed for 3-dehydroreserpine treated with reagent compared to a solution of 3-dehydroreserpine treated with phosphoric acid only.

An attempt was made to isolate the fluorescent species of reserpine generated by vanadium pentoxide reagent by making the reaction mixture basic with sodium hydroxide and extracting with chloroform. Approximately 250 mcg. of reserpine was allowed to react with vanadium pentoxide reagent for several hours. The reaction mixture was made basic with sodium hydroxide, diluted to 100 ml. with water, and extracted with chloroform. The chloroform extract was evaporated to dryness, and the residue was taken up in ethanol. The UV spectrum of this solution did not compare well to the UV spectrum of 3-dehydroreserpine in ethanol, but it was practically identical to that obtained for 3-dehydroreserpine treated with vanadium pentoxide reagent and extracted as described.

Rather than indicating a fluorescent species other than 3-dehydroreserpine, the different UV spectra obtained for 3-dehydroreserpine in the absence of vanadium pentoxide and after extraction from a basic solution containing vanadium pentoxide might possibly be explained by the formation of an extractable complex between 3-dehydroreserpine and a vanadium species.

The authors feel that the proposed method, with its simplicity and efficiency, would provide a suitable procedure for the routine analysis of reserpine and may contribute to the progress of an automated technique for reserpine.

CONCLUSION

A new fluorometric method has been developed for the determination of reserpine and related compounds in bulk and tablet formulations. The proposed method is based on the formation of a fluorogen with vanadium pentoxide. The intensity of the fluorogen was significantly increased when the reagent was saturated in phosphoric acid. This method, with its simplicity and rapidity, can be used for the quantitative determination of reserpine. The possible formation of 3-dehydroreserpine as the fluorescent product was postulated, and the optimum reaction conditions, were evaluated. Since the mechanism of the reaction is not completely evident and is strongly dependent on the reagent and the acid used for the reaction, these parameters will be the subject of a further investigation.

Quantitative Analysis and Stability of 5(or 4)-[3,3-Bis(2-chloroethyl)-1-triazeno]imidazole-4(or 5)-carboxamide in Acidic Aqueous Solutions

DAVID S. DRESBACK and JOSEPH F. GALLELLI

Abstract □ Methods of quantitative analysis by UV spectrophotometric, colorimetric, and ionic chloride determination are reported for 5(or 4)-[3,3-bis(2-chloroethyl)-1-triazeno]imidazole-4(or 5)-carboxamide (NSC-82196) in the presence of its degradation products. With the exception of the ionic chloride method of analysis of samples exposed to light, all three methods showed good agreement for stability studies of NSC-82196 in acidic aqueous solutions exposed to light and dark and stored at 25°. A sterile lyophilized hydrochloride salt of NSC-82196 for parenteral use, reconstituted with water for injection, was found to have a $t_{1/2}$ = 150 min. at 25° and $t_{1/2}$ = 65 hr. at 4°.

Keyphrases □ 5(or 4)-[3,3-Bis(2-chloroethyl)-1-triazeno]imidazole-4(or 5)-carboxamide—quantitative analysis, stability □ TLC—separation □ UV spectrophotometry—analysis □ Colorimetric analysis—spectrophotometer □ Ionic chloride determination—analysis

5(or 4)-[3,3-Bis(2-chloroethyl)-1-triazeno]imidazole-4(or 5)-carboxamide (NSC-82196) is a promising anti-leukemic agent. It has been shown to be superior, in the murine leukemia L-1210 system, to 5(or 4)-[3,3-dimethyl-1-triazeno]imidazole-4(or 5)-carboxamide (NSC-45388), an analog of similar structure presently in clinical trials (1).

A sterile lyophilized hydrochloride salt of NSC-82196, for parenteral use, was prepared by the Pharmaceutical Development Service. Since the drug is extremely unstable in aqueous solutions, adequate assay procedures were needed to determine the potency and stability of the formulated dosage form.

NSC-82196 is an analog belonging to a series of dialkyltriazenoimidazoles that undergoes rapid decomposition in aqueous acidic solutions. The resulting degradation products have been reported to be "transformation" product (NSC-112970) (II) and 2-azahypo-

Figure 1—UV spectra of NSC-82196, NSC-112970, and NSC-22419 in pH 2.31 phosphate buffer.

xanthine (NSC-22419) (III) (2–4). The formation of NSC-22419 is preceded by the photodegradation of NSC-82196 to an intermediate 5-diazoimidazole-4-carboxamide (IV), which cyclizes by intramolecular coupling to NSC-22419 (3–5).

Loo and Stasswender (6) reported a colorimetric method of assay suitable for intact NSC-82196. A UV spectrophotometric assay has also been reported which is specific for the degradation products, NSC-112970 and NSC-22419, as well as NSC-82196 (2). Adaptations of these two methods were used in this study to assay intact NSC-82196. Since one chloride ion is liberated for each molecule of transformation product formed, an ionic chloride method of assay was also used to follow the degradation of NSC-82196. Stability studies were performed to correlate all three methods of assay and to outline limitations, if any. The stability of a reconstituted, lyophilized, parenteral dosage form was determined under various conditions of light and dark at 25 and 4°.

EXPERIMENTAL

Reagents—The following were used: 5(or 4)-[3,3-bis(2-chloroethyl)-1-triazeno]imidazole-4(or 5)-carboxamide,¹ transformation product² (m.p. 209° dec.), and 2-azahypoxanthine monohydrate³ [m.p. 208–209° (explosive), darkens at 150°]. 5-Diazoimidazole-4-carboxamide³ was synthesized according to the method of Shealy

¹ Prepared by Parke, Davis & Co., Detroit, Mich., and obtained from the Drug Development Branch, Cancer Chemotherapy, National Service Center, NCI, Bethesda, Md.; m.p. 208° dec., darkens at 150°, purity determined from IR spectrum and ionic chloride determination.

³ Elemental analysis—Calcd.: C = 35.04%, H = 2.21%, N = 51.09%; Found: C = 35.01%, H = 2.17%, N = 50.74%. Elemental analysis was performed by Microanalytical Laboratory, National Institute of Allergy and Infectious Diseases, NIH, Bethesda, Md.

Figure 2—Verification of stoichiometry of NSC-82196 hydrolysis at pH 2.31 phosphate buffer and 25° in light (---) and dark (—). Key: O, NSC-82196; ●, NSC-112970; ○, NSC-22419; and ■, NSC-112970 plus NSC-22419.

et al. (5) [m.p. 199° (explosive), darkens at 149–150°]. Sterile lyophilized hydrochloride salt of NSC-82196 for injection, 100 mg./vial;⁴ *N*-(1-naphthyl)-ethylenediamine dihydrochloride (Bratton-Marshall reagent), 3% in distilled water; 0.2 *M* phosphate buffer, pH 2.31; gelatin reagent;⁵ and silica gel GF thin-layer plates⁶ were also used. All other chemicals were of reagent grade.

Apparatus—The following were used: Cary model 11 recording spectrophotometer; UV lamp (longwave),⁷ maximum intensity at 366 mμ; Aminco chloride titrator, model 4-4433;⁸ IBM 1620 computer;⁹ Beckman zeromatic pH meter; Desaga TLC apparatus;¹⁰ Beckman IR-5A spectrophotometer; constant-temperature water bath (±0.1°); and Thomas-Hoover capillary melting-point apparatus.

Colorimetric Assay—To a 10-ml. volumetric flask was added 0.2 ml. of freshly prepared 3% Bratton-Marshall reagent followed by 20–110-mcg. portions of NSC-82196. The flask was rapidly brought to volume with pH 2.31 phosphate buffer and mixed in subdued light. Approximately one-half of the solution was removed and placed in the dark. The other half was irradiated with a longwave UV lamp for 30 min. The lamp was positioned approximately 8 cm. from the center of the solution in the 10-ml. volumetric flask. The absorbance of both fractions was measured on a Cary 11 recording spectrophotometer at 520 mμ, using a phosphate buffer as the blank. A blank of the reagents alone, without NSC-82196, was also treated in the same manner, and its absorbance was recorded at 520 mμ.

Ionic Chloride Assay—A sample portion was taken, diluted if necessary, and titrated on an Aminco chloride titrator at one of the three titration speeds. The titrator can accurately determine a minimum of 9 mcg. of chloride ion in a sample. Accuracy was better

than 0.1% and reproducibility was ±1%, with the entire determination taking less than 2 min. to perform.

UV Spectrophotometric Assay—Sample solutions from 1 to 2 mg./100 ml. in pH 2.31 phosphate buffer were read on the Cary 11 recording spectrophotometer from 400 to 225 mμ. Absorbances at 326, 278, and 236 mμ were recorded. Calculations were made with an IBM 1620 computer, using simultaneous equations with three equations and three unknowns.

TLC—TLC for qualitative studies was carried out on activated layers of silica gel GF₂₅₄, 250 μ thick, in two systems: water (saturated with *n*-butanol)–glacial acetic acid (4:1) and *n*-butanol–glacial acetic acid–water (4:3:3). All TLC was done at room temperature. The quantity of the compounds applied on TLC varied from 5 to 60 mcg. The limits of detection for each of the compounds were: NSC-82196, 0.5 mcg.; NSC-112970, 2 mcg.; and NSC-22419, 0.5 mcg. Spots were detected by UV quenching, I₂ vapor, aqueous 0.2% Bratton-Marshall reagent spray, and concentrated H₂SO₄ spray followed by heating.

Kinetic Studies—The degradation of NSC-82196 was monitored by the UV, colorimetric, and ionic chloride methods of assay. Various portions of NSC-82196 (depending upon the assay method used) were dissolved in pH 2.31 phosphate buffer¹¹ in 50-ml. volumetric flasks. The solutions were brought to volume at the temperature of the bath. The flasks were then immersed to 90% of their length in the thermostatically controlled bath at 25 ± 0.1° and exposed to the light and dark. The light samples were exposed to two fluorescent bulbs,¹² placed 15 cm. from the center of the volumetric flasks in the bath. At appropriate time intervals, portions were withdrawn for assay.

Stability of Parenteral Product—Amber glass vials of a lyophilized product were each reconstituted with 20 ml. of water for injection and stored in light and dark at 25° and in dark at 4°. All vials were reconstituted with water for injection at 25°. Sample portions

¹¹ A 0.2 *M*, pH 2.31 phosphate buffer was chosen for the kinetic and stability studies because the parenteral formulation used in clinical trials, when reconstituted with water for injection, is pH 2.3. Also, samples below pH 2.5 were found to be in an optimum stability range as seen with the data on the effect of pH on stability reported by the University of Michigan (2). Since the authors were trying to mimic conditions of the actual formulation, pH 2.3 was chosen for the study.

Table I—Results of UV Analyses of Three Mixtures of NSC-82196, NSC-112970, and NSC-22419 in pH 2.31 Phosphate Buffer

Mixtures	Added, mg./100 ml.	Found, mg./100 ml.	Error, %
NSC-82196	1.7380	1.7318	0.8
NSC-112970	1.0450	1.0678	2.2
NSC-22419	1.1360	1.0877	4.2
NSC-82196	0.6440	0.6574	2.0
NSC-112970	0.9280	0.9250	0.3
NSC-22419	0.8180	0.7711	5.7
NSC-82196	0.9111	0.9010	1.1
NSC-112970	0.7651	0.7530	1.6
NSC-22419	0.9121	0.9311	2.1

were withdrawn at appropriate time intervals and assayed by the UV method.

RESULTS AND DISCUSSION

TLC Studies—TLC confirmed the presence of NSC-22419 and NSC-112970 as degradation products of NSC-82196 in acidic aqueous media. The decomposition products had R_f values identical to authentic NSC-22419 and NSC-112970. However, only trace amounts of NSC-22419 were found in samples degraded in the dark, while large amounts of NSC-22419 were found in samples degraded with longwave UV light. No attempt was made to confirm the presence of the photodecomposition product, 5-diazoimidazole-4-carboxamide, because of its small buildup and concentration.

UV Method of Assay—The UV method of assay was specific for NSC-82196 and its decomposition products NSC-22419 and NSC-112970. Table I shows the results of three separate trials assay-

Table II— a Values (at pH 2.31) for NSC-82196, NSC-112970, and NSC-22419 at Three Wavelengths Used in the UV Assay

Mixtures	326 m μ	278 m μ	236 m μ
NSC-82196	635.2	230.3	252.0
NSC-112970	250.2	112.2	412.5
NSC-22419	000.0	263.8	255.0

ing mixtures of all three authentic materials. Figure 1 shows the UV spectrum of all three components in pH 2.31 phosphate buffer.

The λ_{\max} used for the calculations were 278 m μ (NSC-22419), 236 m μ (NSC-112970), and 326 m μ (NSC-82196).¹³ The a values at pH 2.31, used to calculate the final formulas using simultaneous equations, are seen in Table II. All calculations were based on three components only.

Colorimetric Assay—Intact NSC-82196 follows Beer's law over the concentration range 1–12 mcg./ml. The a value was found to be $937.5 \pm 1.4\%$. At low concentrations, less than 3 mcg./ml., the λ_{\max} of the solution was seen to shift from 520 to 525–526 m μ . Samples of intact NSC-82196 developed for 30 min. in the dark

Figure 4—Semilogarithmic plot of fraction NSC-82196 remaining versus time for reconstituted parenteral product at 25° in light (O) and dark (●).

¹³ The wavelength of 209 m μ for NSC-22419 recommended by the University of Michigan group (2) for quantitation could not be used in this laboratory due to limitations of the Cary 11 recording spectrophotometer.

Figure 5—Semilogarithmic plot of fraction NSC-82196 remaining versus time for reconstituted parenteral product at 4° in dark.

demonstrated zero absorbance, thus indicating that no 5-diazoimidazole-4-carboxamide was formed in the absence of light. If diazoimidazole carboxamide was found, it would be indicative of what was already present at the time the sample was taken. Therefore, subtraction of the sample's absorbance from the irradiated sample's absorbance is necessary to obtain the corrected absorbance of the remaining intact NSC-82196 in the sample. This procedure is necessary since in a stability study with rigorous lighting conditions, a buildup of 5-diazoimidazole-4-carboxamide is expected.

Kinetic Studies—Apparent adherence to stoichiometry during the course of the reaction of NSC-82196 in acidic aqueous solution with time using the UV assay method is seen in Fig. 2. Samples exposed to light showed a significant amount of NSC-22419 formation. Table III shows the rate constants and half-lives obtained by the assay methods used. Figure 3 is a semilogarithmic plot of fraction NSC-82196 remaining versus time for all assay methods. With the exception of the ionic chloride method for light-stored samples, all assay methods used indicated that the degradation of NSC-82196 followed apparent first-order kinetics. All chloride calculations were based on the premise that NSC-82196 was degrading solely to NSC-112970; thus the chloride method would be expected to be invalid if anything other than NSC-112970 was being formed.

It can be seen in Fig. 3 that an error can be introduced if one does not account for existing 5-diazoimidazole-4-carboxamide at any given time when using the colorimetric method. The presence of a significant amount of the diazo compound also would be expected to introduce error into the UV results, since the UV calculations

Table III—First-Order Rate Constants and $t_{1/2}$ Values for Degradation of NSC-82196 in Phosphate Buffer at pH 2.31, 25.0°, in Light and Dark

Assay Method Used	Light		Dark	
	$k \text{ min.}^{-1} \times 10^3$	$t_{1/2} \text{ min.}$	$k \text{ min.}^{-1} \times 10^3$	$t_{1/2} \text{ min.}$
Colorimetric corrected	7.90 ± 3.13%	87.8	5.46 ± 4.3%	126.9
Colorimetric noncorrected	6.14 ± 3.12%	112.9	5.46 ± 4.3%	126.9
Chloride	Invalid		5.59 ± 2.8%	123.9
UV	7.75 ± 3.9%	89.5	5.30 ± 5.1%	130.7

allow for three components only in the system. In this study the amount of diazo compound existing at a given time in light samples was small (there was a maximum amount of 10% at $t_{1/2}$) and was calculated to result in less than 3% error in the concentration of NSC-82196 in a solution at $t_{1/2}$ by the UV method of assay.

Stability of Parenteral Product—Figures 4 and 5 are the semi-logarithmic plots for the reconstituted parenteral product at 25 and 4°, respectively. No difference in stability of NSC-82196 was noted between those samples stored in light or dark at 25°, presumably due to the drug being stored in the amber glass vials.

The pH was found to change considerably in this unbuffered system. It is likely that the pH lowering causes apparent variance from first-order kinetics in both cases, since the drug in general has been reported to be more stable in acidic aqueous media (2). Also, water at 25° was used to reconstitute the 4° sample; thus a faster degradation rate would be expected in the first few minutes (Fig. 5) until the system actually comes to 4°.

The purpose of this experiment was to mimic conditions the product would actually encounter in clinical use. Therefore, the results are different than would be predicted from a controlled stability study carried out in a buffer system at constant pH. The apparent half-life of the parenteral product is approximately 150 min. at 25° and 65 hr. at 4°

CONCLUSIONS

Good agreement was found between the UV and colorimetric methods of assay. The University of Michigan's UV method of assay was found to be quite specific for NSC-82196 and its decomposition products, NSC-22419 and NSC-112970, but does not include the decomposition product 5-diazoimidazole-4-carboxamide. The University of Michigan group did not conduct their studies of the drug in light. Since the diazo compound is a photo-degradation product of the drug, no allowances were made for it in the UV method of assay. However, as mentioned previously, even when there was a buildup of diazo compound to a maximum of 10% at $t_{1/2}$ in the light, this resulted in an error of 3% in the concentration of NSC-82196.

Values obtained from the colorimetric method would also be in error if any 5-diazoimidazole-4-carboxamide was present as a degradation product and not accounted for, as seen in Table III. Therefore, correction of the colorimetric method, as reported by Loo and Stasswender (6), is definitely needed in a study with rigorous lighting conditions where the buildup of diazo compound, although small, does occur.

The chloride method was found in agreement with the other two methods of assay when used for stability studies in which NSC-112970 was the only degradation product (samples protected from light). The chloride method is of no value in determining the absolute amount of NSC-82196 remaining in the sample because it is not specific for intact NSC-82196. Also, obvious problems arise if one attempts to use the chloride method to follow the stability of a hydrochloride salt of NSC-82196. Thus the chloride method is not recommended due to these serious limitations. By protecting the solutions from light, it appears that the 5-diazoimidazole-4-carboxamide formation can be inhibited. The degradation of the reconstituted parenteral product did not appear to follow first-order kinetics, possibly due to the pH decrease which accompanies the degradation. The apparent $t_{1/2}$ was 150 min. for amber glass vials

of the reconstituted hydrochloride salt of NSC-82196 stored at 25° in dark or light. The apparent $t_{1/2}$ was 65 hr. for the same vials stored at 4° in the dark.

Automated Dual Extraction Procedure for Analysis of Phenmetrazine Hydrochloride Tablets

S. AHUJA, C. SPITZER, and F. R. BROFAZI

Abstract □ An automated method of analysis, based on dual extraction of phenmetrazine hydrochloride, has been developed for analysis of phenmetrazine hydrochloride tablets. The method requires use of a continuous digester along with other more familiar modules of an automatic analyzer. A total of 520 individual tablets was analyzed by this method. Of all the tablets analyzed, 99.8% were within $\pm 10\%$ of the indicated dosage and 100% were within $\pm 15\%$ of the indicated dosage.

Keyphrases □ Phenmetrazine HCl tablets—analysis □ Automated extraction procedure—phenmetrazine HCl analysis □ Diagram—automated system, phenmetrazine HCl analysis □ UV spectrophotometry—analysis

Automated analytical methods have been limited generally to dissolution and/or extraction of active ingredients from the formulation, filtration, and dilution to suitable concentration for analytical determinations. Manual methods involving evaporation of the organic solvent, followed by dissolution of the residue in suitable aqueous solvents, have been considered difficult to automate. One semiautomated approach to the solution of this problem has been reported by Feller *et al.* (1) for analysis of ethopabate in poultry feeds. This approach should provide a valuable means of automating pharmaceutical methods of analysis, where such extractions are frequently used.

A variety of manual methods (2–9) has been used for analysis of phenmetrazine hydrochloride.¹ For several years, a manual dual-extraction procedure (9) has been used in the authors' laboratories for analysis of 25-mg.

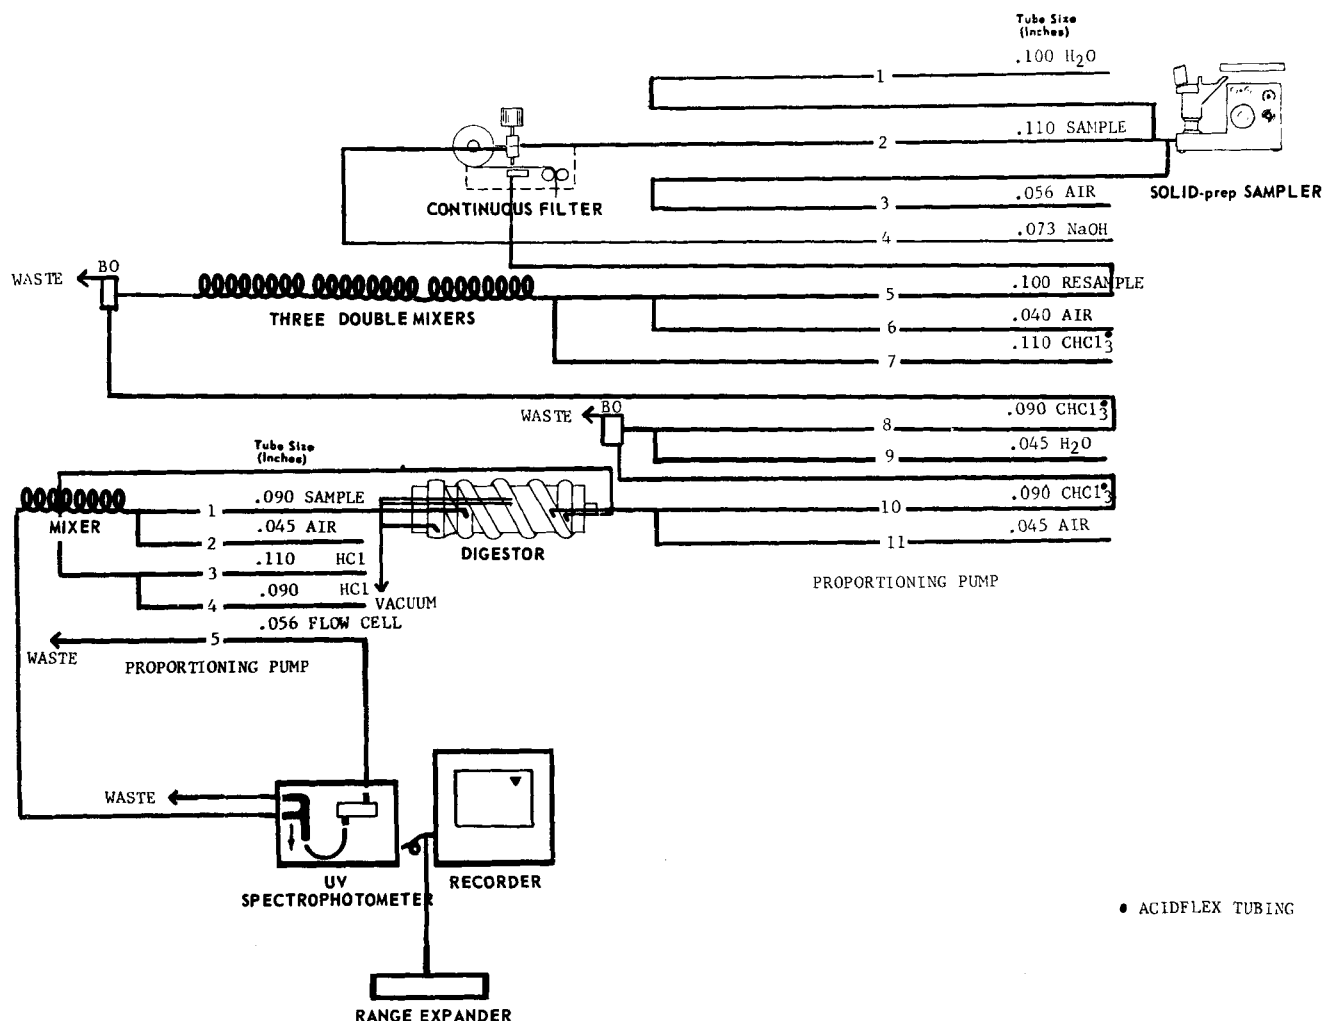

Figure 1—Flow diagram of the analytical system.

is fed into the continuous digester where chloroform is evaporated in a heated rotating helix, with subsequent solution of the residue in the dilute hydrochloric acid. A portion of the dilute hydrochloric acid solution is sampled on the other end of the rotating helix (the rest of the sample and chloroform are sent to waste) and passed through a mixing coil; its absorbance is determined at 256 $m\mu$ in a 15-mm. tubular flow cell with the range expander set at the 2 \times setting. Standards are run at various intervals to provide a means for calculation of sample concentration and to check any instrumental fluctuations.

RESULTS AND DISCUSSION

Tablets are initially extracted with water instead of the dilute hydrochloric acid (4 in 100) used in the manual method. The latter solvent was undesirable for use with the automatic analyzer. After investigating various alternate solvents, it was found that water was the solvent of choice because of its greater suitability for further extractions.

In the manual method, 50% NaOH w/v solution is used for alkalization of dilute hydrochloric acid (4 in 100) prior to chloro-

form extraction. The use of such a strong alkaline solution was considered neither desirable nor necessary in the automated method. A much lower concentration, such as a 1% w/v NaOH solution, was found very suitable for alkalization in the automated method.

Beaded mixing coils are generally used for liquid/liquid extraction in automated methods. For this work, these coils were found unusable because they yielded very heavy emulsions which could not be resolved. This problem was solved by using three mixing coils in a row along with two separators. The first separator provides the separation of chloroform from the aqueous phase. In the second separator, chloroform is washed with water, whereby emulsion problems are completely eliminated.

Table II—Comparison of Results Obtained by Automated and Manual Methods

Sample	Phenmetrazine Hydrochloride, mg.		
	Automated Method	Manual Method	Deviation, mg.
A	25.0	25.3	-0.3
B	24.8	24.8	0.0
C	24.3	24.0	+0.3
D	23.8	23.9	-0.1
E	24.4	25.1	-0.7
F	24.7	24.3	+0.4

H	25.1	24.7	+0.4
I	24.5	24.6	-0.1
J	24.6	24.5	+0.1
Average	24.6	24.6	± 0.3

Figure 2—Typical recording of phenmetrazine tablets, 25 mg.

Figure 3—Histogram of phenmetrazine tablets, 25 mg.

The second extraction step, involving reextraction of phenmetrazine into dilute hydrochloric acid (4 in 100) from chloroform, is automated by the use of the continuous digester. This is accomplished in a heated rotating helix. The chloroform and the dilute hydrochloric acid are introduced in such a proportion as to create thin layers of both of these phases. The organic phase is volatilized by heat and vacuum (which is applied on the other end), and the aqueous acid phase is aspirated into the automated system and processed as shown in Fig. 1. The use of the continuous digester provides increased sensitivity (1) and eliminates the emulsification problems commonly encountered in manual liquid/liquid extraction methods.

A linear relationship was observed between the concentration of phenmetrazine hydrochloride and absorbance in the range of concentration studied. The precision and recoveries obtained by the method were checked by running "synthetic" formulations (prepared in a manner similar to the commercial formulation). The percentage recovery results on the synthetic formulation are shown in Table I. No significant interference from the excipients was observed when placebos of this formulation were run by this method.

A typical recording is shown in Fig. 2. The average of 10 individual tablets compared favorably with the results obtained manually (Table II), thus suggesting that the automated method provides an acceptable alternate means of assaying phenmetrazine hydrochloride in phenmetrazine hydrochloride tablets.

To study tablet-to-tablet variation, a very large number of individual tablets was analyzed by these methods. The tablets used were selected randomly from several production batches to obtain a good overall picture of tablet-to-tablet variation. The distribution of dosage in these tablets is presented in the form of a histogram (Fig. 3). Of all the tablets analyzed, 99.8% were within $\pm 10\%$ of the indicated dosage and 100% were within $\pm 15\%$ of the indicated dosage ($\pm 15\%$ is the present limit in the NF for content uniformity of tablets).

Complexes of Ergot Alkaloids and Derivatives V: Interaction of Methysergide Maleate and Caffeine in Aqueous Solution

M. A. ZOGLIO* and H. V. MAULDING

Abstract □ Evidence of complex formation between methysergide maleate and caffeine is presented, utilizing solubility and vapor pressure osmometer information. The effect of this interaction on the rate of dissolution and partitioning-rate behavior of methysergide maleate has been measured. The absorption consequences of this interaction as implied from the *in vitro* studies are presented.

Keyphrases □ Methysergide maleate, caffeine complexes—interactions in aqueous solutions, effect on dissolution, partition rates □ Vapor pressure osmometry—complex formation data, methysergide maleate, caffeine □ Ergot alkaloids, derivatives—complexes, methysergide, caffeine

The successful utilization of complexing phenomena to enhance the absorption of proteinaceous ergot alkaloids (1, 2) prompted an investigation into the possible interaction of a synthetic nonproteinaceous ergot alkaloid with caffeine. The drug, methysergide maleate,¹ (+)-9,10-didehydro-*N*-[1-(hydroxymethyl)propyl]-1,6-dimethylergoline-8 β -carboxamide maleate, was studied with caffeine in aqueous media, utilizing changes in apparent solubility and vapor pressure osmometry to detect complexation. After establishing an interaction, the pH dependency of the interaction was examined. Studies of the consequence of the interaction on *in vitro* dissolution and partition rates were undertaken to gain some insight into potential *in vivo* absorption effects.

EXPERIMENTAL

Materials—Methysergide maleate² (mol. wt. 469.54) showed only trace contaminants when subjected to TLC. Anhydrous caffeine powder USP,³ m.p. 238°, was utilized in this study.

Reagent grade chloroform⁴ was employed in the partitioning-rate studies. A pH 6.65 buffer was made by dissolving 13.6 g. KH_2PO_4 in 500 ml. water, adjusting the pH with concentrated KOH, and diluting to 1 l. (ionic strength 0.2).

The pH measurements were made on a Metrohm pH meter, and spectrophotometric data were obtained from a Cary model 14 spectrophotometer.

Solubility Studies—Methysergide maleate, 1.5 g., was placed in watertight, amber, screw-capped vials (50 ml.) containing 10 ml. of either distilled water, 0.1 *M* pH 6.65 phosphate buffer, or 0.1 *N* HCl, and varying quantities of anhydrous powdered caffeine were added. The vials were clamped onto the edge of metal disks (15-cm. diameter) mounted on a motor-driven shaft and rotated vertically at 6 r.p.m. in a constant-temperature bath, 30 \pm 0.1°. After 24 hr., samples were taken using pipets with filters attached and were analyzed for methysergide maleate by UV spectrophotometry (325 m μ).

Figure 1—Apparent solubility changes for methysergide maleate as a function of added caffeine. Key: ●, 0.1 *N* HCl, pH = 1.25; ○, distilled water; and ▲, 0.1 *M* phosphate buffer, pH = 6.65.

Vapor Pressure Osmometry—A model 301A Mecrolab (Hewlett-Packard) vapor pressure osmometer was employed in these studies. The instrument was calibrated using solutions of raffinose in distilled water. Forty-eight hours was allowed for thermal equilibration before measurements were taken. Samples were inserted into the chamber containing the thermistor beads 3 hr. prior to reading. Solutions were prepared from the same lot of deionized distilled water. The reservoir of water used in the measuring chamber was also taken from this lot and changed after each series of five readings with subsequent reequilibration of the instrument.

Partitioning Studies—A solution was prepared by placing methysergide maleate, 100 mg., in 950 ml. of pH 6.65 phosphate buffer, stirring magnetically for 30 min. to 1 hr., and filtering (Whatman No. 1 filter paper) into a flask immersed in a water bath maintained at 30°. Finally, pH 6.65 buffer was added to make 1 l. of solution. Five hundred milliliters of this solution was kept, and 500 ml. had caffeine (5 g.) added to it.

Fifteen milliliters of the freshly prepared aqueous phase—either with or without xanthine—was added carefully to 15 ml. chloroform in screw-capped vials (50 ml.). The vials were sealed and rotated at 6 r.p.m. in a 30 \pm 0.1° water bath. Five-milliliter samples were taken at 3, 5, 7, 9, 11, 13, and 15 min. from the aqueous phase and analyzed for methysergide maleate by UV spectrophotometry.

Dissolution Rates—A 6- or 25-r.p.m. stirrer motor, fitted with a 2.54-cm. propeller blade placed 4 cm. from the bottom of an 800-ml. beaker containing 500 ml. 0.1 *N* HCl solution, was employed for these determinations. Methysergide maleate, 50 mg., or the alkaloid in combination with caffeine, prepared by mixing 50 mg.

alkaloid with 5 g. caffeine in a mortar, was placed into the stirred solution from a height of about 1.5 cm. The temperature was maintained at $37 \pm 0.1^\circ$ by immersing the beaker in a constant-temperature bath. Samples were withdrawn periodically for UV analysis of methysergide maleate.

RESULTS AND DISCUSSION

Methysergide maleate showed some unexpected changes in apparent solubility when combined with caffeine. The intact proteinaceous alkaloids previously studied (1-3) had all required high ratios of xanthenes to effect solubilization, demonstrated a pH dependency for complexation, and gave nonlinear changes in solubility as a function of added caffeine. Methysergide maleate (Fig. 1) shows a linear dependency of apparent solubility upon the amount of caffeine added. This has been suggested to imply a 1:1 relationship between the two compounds (4, 5). These changes are apparently pH-independent because the slopes are parallel. Their displacement only reflects the variation of inherent methysergide solubility at different pH values. The difference in behavior of this ergot alkaloid derivative indicates that the cyclic polypeptide moiety present in the naturally occurring alkaloids plays an important role in their complexing behavior.

As further evidence of interaction, vapor pressure osmometry studies were performed in a manner similar to that described by Goyan and Borazan (6). These measurements differ from those of Goyan and Borazan in that the units are not expressed in ohms but rather in arbitrary units of resistance change. Since the studies were used solely to determine interaction, the units read from the instrument, which are proportional to the resistance change in ohms, were found to be sufficient.

In Fig. 2, there are two noteworthy observations. First, note the evidence of interaction from the decreased values of ΔR when solutions of caffeine in 0.01 M methysergide are compared to expected values. These lower values of ΔR reflect a change in the colligative properties indicative of association of molecules. Second, the breaks in the continuity of the curves appear to support the suggestion that these inflections relate in some manner to the nature of the interaction. The complexing capacity number, as indicated by Fig. 2, is approximately 3.0, which is close to the value found for sodium salicylate-caffeine interaction (6). Although the significance

Figure 3—Methysergide maleate-caffeine (1:100 w/w ratio). Partitioning-rate experiment in pH 6.65 0.1 M phosphate buffer. Key: ●, methysergide maleate in the presence of caffeine; and □, methysergide maleate.

of complexing capacity numbers has not yet been well established, the indication here is that the methysergide maleate-caffeine and sodium salicylate-caffeine interactions are related in some manner.

After establishing an interaction, the effect of this interaction on parameters related to drug absorption was studied. The effect of the interaction on dissolution rate, which had been quite dramatic in previous studies (1-3), was negligible for methysergide maleate. Since the drug has a greater inherent solubility than the ergot alkaloids, an attempt to demonstrate dissolution enhancement by slowing the stirrer speed to 6 r.p.m. was tried but was unsuccessful. The partitioning behavior, which had paralleled *in vivo* absorption effects (2, 3), also was negligible for caffeine-methysergide maleate combinations (Fig. 3). The *in vitro* studies, therefore, suggest that the stronger interaction demonstrated in this study is possibly a deleterious factor when attempting absorption enhancement through the use of complexing agents.

Substituted Benzamides with Potential CNS-Depressant and Hypotensive Activity

W. D. ROLL

Abstract □ A series of 14 *N*-alkyl, *N*-aryl, and *N*-aralkyl analogs of *N*-cyclohexyl nitrobenzamide has been synthesized and characterized. The compounds have been studied for their ability to depress the spontaneous motor activity of mice and for their hypotensive activity in rats. Four of the compounds, which are structurally characterized by small alkyl groups attached to the amide nitrogen and a *p*-nitro group, showed the greatest CNS-depressant activity. The hypotensive action of these compounds paralleled their depressant action.

Keyphrases □ Nitrobenzamide, *N*-cyclohexyl—synthesis, *N*-alkyl, *N*-aryl, *N*-aralkyl analogs; evaluation, CNS-depressant activity □ CNS-depressant activity—synthesis, pharmacological evaluation of *N*-cyclohexyl nitrobenzamide analogs.

In previous publications (1, 2) the synthesis and pharmacological evaluation of two series of ring-substituted benzamides of *N*-(β -cyanoethyl)- and *N*-(β -hydroxyethyl)-*N*-cyclohexylamine were reported. The biological activity of these compounds was studied in mice and rats for their effect on spontaneous motor activity and blood pressure. They were found to exert a depressant action on the spontaneous activity of mice at a 4–5-mg./kg. dosage level and to effect a prolonged reduction in blood pressure of normotensive rats at this dosage. Of the β -cyanoethyl analogs, the most active compounds were the *p*-chlorobenzamides and *p*-methoxybenzamides.

This paper reports a convenient synthesis and preliminary pharmacological evaluation for a series of amides of *m*-nitro- and *p*-nitro-substituted benzoic acids represented by the formula (I):

To study the *in vivo* effects of the test compounds, C₃H mice weighing between 20–25 g. were used. All test compounds were dissolved in propylene glycol and administered orally and intraperitoneally. Dose-response curves were obtained using eight mice (rats) at each of four dosage levels, and the median effective dose (ED₅₀) was calculated.

Concurrent with the toxicity range studies in mice and rats, careful gross observation of the intact animals was made at several dosage levels, and signs of CNS depression (decreased spontaneous motor activity, *etc.*) were noted. The general type of pharmacological activity encountered in these compounds was predominantly evinced by their effects on the CNS.

At a dose of 5 mg./kg., *i.p.*, the test compounds caused sedation without sleep in mice and rats. The animals developed a persistent state of tranquility

7	48.3	30.2	20.0	5.1	0.0

alert to attention. The animals walked normally and their movements were coordinated. Respiration was reduced and somewhat irregular during the 1st hr. following administration. In comparison to control animals, urination and defecation seem to be suppressed, which may be indicative of antispasmodic activity. Side reactions such as tremors were not noted in this study. The test compounds potentiated the sedative activity of barbiturates (amobarbital, pentobarbital, and secobarbital) and reserpine.

The most active compounds were Compounds 1, 3, 5, and 7 (Tables I and II). The *p*-nitro analogs were generally more potent depressants than the *m*-nitro derivatives, except those compounds where R' (Table III) contained an aromatic ring (Compounds 11–14). Analogs where R' was small (C₁–C₃) had the greatest CNS-depressant and blood pressure-depressor activity. Compounds that contained an OH functional group at R' (Compounds 7, 8, 13, and 14) had a shorter duration of action. In all cases, the compounds' relative depressor activity paralleled their depressant activity (Table II).

PHARMACOLOGICAL RESULTS

Spontaneous Activity—The depressant activity of the test compounds was determined in mice with actophotometers.¹ The total body movements of single animals were measured at 15-min. intervals for a period of 1 hr. The mice were placed in the photocell unit immediately after intraperitoneal administration of the test compounds. Eight animals were used to study the effect of each compound at each dosage level, and the mean activity of each series of test animals was compared with the mean activity of a comparable number of control animals to ascertain the percent reduction in activity.

Hypotensive Activity—Indirect blood pressure measurements were performed using a photoelectric tensometer.¹ The test compounds were administered intraperitoneally to normotensive Wistar rats, and the systolic blood pressure was determined for a period of 2 hr. The mean response of eight test animals was used to determine the percent reduction in blood pressure produced by each test compound.

^a Purified by chromatography (eluted by petroleum ether) on silica gel. TLC showed single spot.

EXPERIMENTAL

Melting points were determined using a Mettler FP-1 melting- and boiling-point apparatus. Analyses for carbon and hydrogen were obtained with a Coleman C-H analyzer; IR spectra were obtained with a Perkin-Elmer spectrophotometer model 137-B in KBr, and UV spectra were obtained with a Coleman model 124 Hitachi double-beam grating spectrophotometer. IR and UV spectra were as expected.

General Method of Preparation of Amides—Equimolecular amounts of *m*- and *p*-nitrobenzoyl chloride and *N*-substituted cyclohexylamine (Abbott Laboratories, North Chicago, Ill.) were dissolved in purified dimethylacetamide. The nitrobenzoyl chloride solution was then added to a cooled, well-stirred mixture of the substituted cyclohexylamine solution and triethylamine (Scheme I). When the addition of the acyl chloride solution was completed, the crude substituted benzamide was precipitated by the addition of ice water and collected on a filter. The crude product was recrystallized from EtOH/H₂O or Skelly Solve C/Skelly Solve B to give the pure compounds listed in Table III.

Cactus Alkaloids VIII: Isolation of *N*-Methyl-3,4-dimethoxy- β -phenethylamine from *Ariocarpus fissuratus* var. *fissuratus*

D. G. NORQUIST and J. L. McLAUGHLIN

Abstract \square *Ariocarpus fissuratus* var. *fissuratus* (Engelmann) K. Schumann, commonly known as living rock, chaute, peyote, sunami, or dry whiskey, has an interesting history of folkloric medicinal uses. In previous phytochemical studies the alkaloids, hordenine and *N*-methyltyramine, have been identified in both the *fissuratus* and *lloydii* varieties of the species. In the present investigation, a new alkaloid was crystallized from the nonphenolic alkaloid fractions and identified as *N*-methyl-3,4-dimethoxy- β -phenethylamine HCl. This compound has previously been reported in three other cactus species.

Keyphrases \square *N*-Methyl-3,4-dimethoxy- β -phenethylamine—*isolation from Ariocarpus fissuratus* \square *Ariocarpus fissuratus*—*N*-methyl-3,4-dimethoxy- β -phenethylamine isolation \square Alkaloids, cactus—*isolation, identification of constituents*

Several authors have reported that the cactus, *Ariocarpus fissuratus* (Engelmann) K. Schumann, has had various folkloric medicinal uses among the Indians of Mexico and the southwestern United States (1–4). Sometimes known as living rock, chaute, sunami, and pezuña de venado, the additional common names of peyote, peyote cimarron, and dry whiskey suggest a use similar to that of *Lophophora* (5, 6). References to the intoxicating and stimulating attributes of the plant are especially interesting (2–4). Heffter (1) in 1894 isolated hordenine from *A. fissuratus* var. *fissuratus*, and McLaughlin (7) recently identified hordenine and *N*-methyltyramine in both the *fissuratus* and *lloydii* varieties of the species.

In the present investigation the nonphenolic alkaloids were resolved from the phenolics, hordenine and *N*-methyltyramine, by use of an anion-exchange resin. TLC analysis of the nonphenolic fraction identified the major constituent as *N*-methyl-3,4-dimethoxy- β -phenethylamine. After acid-base partitioning, this alkaloid was easily crystallized from the nonphenolic fraction as the hydrochloride. Several recrystallizations resulted in a product which gave a comparable melting point and no mixed melting-point depression with synthesized *N*-methyl-3,4-dimethoxy- β -phenethylamine HCl. IR spectra of the isolated and the synthetic compounds were indistinguishable.

Agurell (8) has recently identified traces of this new cactus alkaloid in *Coryphantha macromeris* (Engelmann) Britton and Rose var. *runyonii* L. Benson and has crystallized the compound from extracts of *Echinocereus merkeri* Hildmann (9). Speir *et al.* (10) have also recently crystallized this alkaloid from *Ariocarpus trigonus* (Weber) K. Schumann. A single pharmacological study (11) has indicated that *N*-methyl-3,4-dimethoxy- β -phenethylamine has slight activity in the depletion of cardiac norepinephrine, but the reputed stimulating or intoxicating activities of the plant are

not likely attributable to this compound, especially in view of its low concentration in the plant.

EXPERIMENTAL

Living plants of *A. fissuratus* var. *fissuratus* were purchased¹ and matched the latest taxonomic descriptions (12). Sample plants are being maintained as greenhouse specimens.² The fresh plants were sliced, dried in a forced-air oven at 48°, and ground through a 6-mm. screen in a Wiley mill.

In a large continuous-extraction apparatus, 5.28 kg. of the plant material was defatted, basified, and extracted with chloroform; the residues from the chloroform extracts were purified, essentially as previously described (13), to produce a mixture of crude alkaloids. This mixture was separated into phenolic and nonphenolic fractions by the use of an anion-exchange resin (14). TLC of the nonphenolic fraction, using methods and solvent systems previously described (10), identified *N*-methyl-3,4-dimethoxy- β -phenethylamine as the major constituent.

The residue of the nonphenolic alkaloid fraction was dissolved in about 20 ml. of 1 *N* HCl, filtered, and extracted twice with equivalent volumes of both chloroform and ethyl ether. After basification of the aqueous solution to pH 9.5 with concentrated ammonium hydroxide, the alkaloids were extracted into chloroform through several partitionings. The chloroform residue was dissolved in absolute ethanol and acidified with 5% HCl (w/w) in absolute ethanol. The acidified solution was condensed under a stream of nitrogen to about 2 ml., ethyl ether was added to produce cloudiness, and the solution was placed in a freezer (–12°) to induce crystallization. The crystals were recovered by vacuum filtration and recrystallized 5 times from absolute ethanol-ethyl ether to a constant melting point (m.p. 139–140°; yield 186 mg., 0.004% of the dried material). A mixed melting point with synthetic *N*-methyl-3,4-dimethoxy- β -phenethylamine HCl (10) was not depressed, and the IR spectra (KBr pellets) of these compounds were essentially identical.

Effects of Mefruside on Renal Hemodynamics

JAMES H. LUDENS* and HAROLD E. WILLIAMSON†

Abstract □ Mefruside, a natriuretic drug similar in structure to furosemide, was examined for activity on renal hemodynamics in the dog. This agent, when administered at 10 mg./kg. i.v., increased renal vascular resistance and decreased renal blood flow. Blood pressure and the rate of glomerular filtration were not affected. Mefruside differs from furosemide in its action on renal hemodynamics, inasmuch as furosemide decreases renal vascular resistance and increases renal blood flow.

Keyphrases □ Mefruside—effects on renal hemodynamics □ Renal dynamics—mefruside, effects

Mefruside {4-chloro-3-sulfonamido-1-[*N*-methyl-*N*-(2'-methyl-2'-tetrahydrofurylmethyl)]-benzenesulfonamide} (I) is a new orally active natriuretic (1). Structurally, this agent is similar to furosemide (II). In

addition to natriuretic activity, furosemide also affects renal hemodynamics to enhance renal blood flow (2-5). The purpose of this study was to determine if mefruside also enhances renal blood flow.

EXPERIMENTAL

Mongrel dogs, weighing 13-16 kg., were anesthetized with sodium pentobarbital, 30 mg./kg. A tracheal cannula was inserted to ensure free passage of air. The kidney to be utilized was exposed by a flank incision, and the renal artery was cleared of the surrounding tissue. A flow transducer (Carolina Medical Electronics model EMP-411, lumen size, 11-mm. circumference) was placed around the exposed renal artery, and renal blood flow was monitored with a square-wave electromagnetic flowmeter (Carolina Medical Electronics model 321). The flowmeter was adjusted to zero flow by briefly occluding the renal artery distal to the flow transducer. Blood pressure was monitored from the carotid artery. Both blood

Table I—Effect of Mefruside (10 mg./kg.) on Renal Hemodynamics

	Control ^a	Mefruside ^b	Difference ^c
Renal blood flow, ml./min.	174	158	-16 ± 4 ^d
Blood pressure, mm. Hg	142	140	-2 ± 2
Renal vascular resistance, mm. Hg/ml./min.	0.84	0.92	0.08 ± 0.02 ^d
Sodium excretion, μeq./min.	124	424	300 ± 53 ^d
Inulin clearance, ml./min.	30	30	0 ± 3

^a Control values represent values taken immediately prior to mefruside administration. ^b Mefruside values represent values taken 10 min. after drug administration. ^c Difference from control ± S.E. ^d Indicates a significant difference, $p < 0.05$, $n = 4$.

flow and blood pressure were recorded on a Beckman recorder. A solution containing 0.9% NaCl and 0.4% inulin was infused into the right femoral vein at a rate of 0.25 ml./kg./min. for at least 30 min. before and throughout the entire experiment. Mefruside was dissolved in saline using sodium bicarbonate. The drug was given intravenously *via* the right femoral vein.

Urine samples from the exposed kidney were obtained from a renal pelvic catheter introduced into the ureter by way of the retroperitoneal incision. Although urine samples were collected only from the kidney to which blood flow was measured, the other ureter was cannulated *via* a midline incision to ensure free urine flow from the contralateral kidney. Blood samples were obtained from the right femoral artery.

Urine and plasma inulin concentrations were determined by the method of Shreiner (6). Sodium concentrations were determined with a Coleman flame photometer. All data were analyzed with Student's *t* test paired comparisons (7). A *p* value less than 0.05 was used as the level of significance.

RESULTS AND DISCUSSION

Mefruside (10 mg./kg. i.v.) produced a significant decrease in renal blood flow of 16 ml./min. as renal vascular resistance was increased significantly (Table I). These effects were transient. They were maximal about 10 min. after drug administration and returned to control levels by 20 min. after drug administration. Blood pressure was not altered by the drug. Mefruside had no effect on inulin clearance. Sodium excretion was increased from 124 to 424 μeq./min. upon drug administration. The natriuretic action was still present 60 min. after drug administration when the experiments were ended. A lower dose of the drug (2 mg./kg. i.v.) did not produce a significant change in renal vascular resistance or renal blood flow.

Urine and plasma inulin concentrations were determined by the method of Shreiner (6). Sodium concentrations were determined with a Coleman flame photometer. All data were analyzed with Student's *t* test paired comparisons (7). A *p* value less than 0.05 was used as the level of significance.

RESULTS AND DISCUSSION

Mefruside (10 mg./kg. i.v.) produced a significant decrease in renal blood flow of 16 ml./min. as renal vascular resistance was increased significantly (Table I). These effects were transient. They were maximal about 10 min. after drug administration and returned to control levels by 20 min. after drug administration. Blood pressure was not altered by the drug. Mefruside had no effect on inulin clearance. Sodium excretion was increased from 124 to 424 μeq./min. upon drug administration. The natriuretic action was still present 60 min. after drug administration when the experiments were ended. A lower dose of the drug (2 mg./kg. i.v.) did not produce a significant change in renal vascular resistance or renal blood flow.

The results show that mefruside does possess renal hemodynamic properties but that they are not similar to the renal hemodynamic properties of furosemide. Furosemide decreases renal vascular resistance and thereby enhances renal blood flow (2-5). In contrast, mefruside (10 mg./kg. i.v.) increases renal vascular resistance and thereby decreases renal blood flow. The effect of mefruside on renal blood flow is more like that of the thiazide agents which also increase renal vascular resistance and decrease renal blood flow (2, 8).

1-(3,4-Dimethoxyphenyl)-2-propanol Effect on Conditioned Avoidance Response in the Rat

C. F. BARFKNECHT, J. M. MILES, and J. L. LESENEY

Abstract □ The compound, 1-(3,4-dimethoxyphenyl)-2-propanol, was found to prolong latency times initially in a conditioned avoidance response test in rats. It was found to be a CNS depressant in mice. The structural implications of this action, plus the relationship between 1-(3,4-dimethoxyphenyl)-2-propanol and psychotomimetic amphetamines, are discussed.

Keyphrases □ 1-(3,4-Dimethoxyphenyl)-2-propanol—effect on conditioned avoidance response, rat □ Psychotomimetic agents—3,4-dimethoxyamphetamine oxygen analog, pharmacological screening

The literature contains a report indicating that the oxygen analog of mescaline, namely, 3,4,5-trimethoxyphenylethanol (TE), may be psychotomimetic (1). TE was isolated as a product of mescaline metabolism. When it was injected intravenously into rabbits, a mild mescalinelike action was observed.

In structure-activity relationship studies on mescaline, certain methoxylated amphetamines were found to be more potent than mescaline (2). If conversion from β -phenylethylamine to phenylisopropylamine can enhance the potency of psychotomimetics, then a similar logic possibly could be applied to the oxygen analogs of these psychotomimetics. One could anticipate that any mescalinelike actions would be more pronounced in 1-phenyl-2-propanols than in 2-phenylethanol. This paper reports the results of a study on the effect of 1-(3,4-dimethoxyphenyl)-2-propanol (DP), which is the oxygen analog of the psychotomimetic agent 3,4-dimethoxyamphetamine, on conditioned avoidance response (CAR) in the rat.

RESULTS AND DISCUSSION

Although the synthesis of DP was reported in the literature (3), no pharmacological information on the compound could be found.

Initially the effect of DP on CAR in rats was studied. The evaluation of drug action on CAR has been exploited widely. This technique has been especially valuable for the evaluation of psychotomimetics (4).

To determine whether DP is producing an effect similar to mescaline or 3,4-dimethoxyamphetamine (3,4-DMA), the effects of these drugs at various dosages on a running response in conditioned male rats were determined. Each drug was given in three dosage levels ("effective dose," one quarter the effective dose, and four times the effective dose) to groups of six rats. Figures 1 and 2 show the mean reaction time for each trial during the drug sessions for each dosage level of mescaline and 3,4-DMA. That the profile of 3,4-DMA is not completely analogous to mescaline may be due to the amphetamine structure present in 3,4-DMA. CNS stimulation caused by amphetamine would be expected to counteract the increased reaction times. Figure 3 shows the enhanced performance caused by amphetamine sulfate relative to placebo. The lower dose was more effective.

Since 3,4-DMA is expected to be a poorer stimulant than amphetamine itself (*i.e.*, require a much larger dose to cause the same effect), the greatest variation from the mescaline profile would be expected at the higher doses. The large variation between reaction times of adjacent trials is observed in both mescaline and 3,4-DMA, which suggests that this is a characteristic feature of the behavior disruption caused by these agents.

Figure 4 shows the effects of DP. The overall profile of the drug session is substantially different from any of the other drugs tested. When it became clear that DP was different, it was subjected to a more conventional pharmacological screening. In mice intraperitoneally it was a CNS depressant [$ED_{50}(\text{sleep}) = 150 \text{ mg./kg.}$; $LD_{50} = 650 \text{ mg./kg.}$] (5). This pharmacological action of DP is not unexpected in light of the report that acetophenones and other phenones and their corresponding alcohols exhibit depressant effects (6). Thus, DP may be viewed as a structural isomer of these phenones and alcohols.

The data presented here suggest that a reevaluation of the pharmacological effects of TE is required.¹ A detailed study of the structure-activity relationships and the mechanism of action of ring-substituted phenyl-2-propanols, phenyl-2-propanones, and chemi-

¹ Preliminary, unpublished studies indicate that TE has a CNS-depressant effect, $ED_{50}(\text{sleep}) > 650 \text{ mg./kg. i.p. in mice.}$

The results show that mefruside does possess renal hemodynamic properties but that they are not similar to the renal hemodynamic properties of furosemide. Furosemide decreases renal vascular resistance and thereby enhances renal blood flow (2-5). In contrast, mefruside (10 mg./kg. i.v.) increases renal vascular resistance and thereby decreases renal blood flow. The effect of mefruside on renal blood flow is more like that of the thiazide agents which also increase renal vascular resistance and decrease renal blood flow (2, 8).

1-(3,4-Dimethoxyphenyl)-2-propanol Effect on Conditioned Avoidance Response in the Rat

C. F. BARFKNECHT, J. M. MILES, and J. L. LESENEY

Abstract □ The compound, 1-(3,4-dimethoxyphenyl)-2-propanol, was found to prolong latency times initially in a conditioned avoidance response test in rats. It was found to be a CNS depressant in mice. The structural implications of this action, plus the relationship between 1-(3,4-dimethoxyphenyl)-2-propanol and psychotomimetic amphetamines, are discussed.

Keyphrases □ 1-(3,4-Dimethoxyphenyl)-2-propanol—effect on conditioned avoidance response, rat □ Psychotomimetic agents—3,4-dimethoxyamphetamine oxygen analog, pharmacological screening

The literature contains a report indicating that the oxygen analog of mescaline, namely, 3,4,5-trimethoxyphenylethanol (TE), may be psychotomimetic (1). TE was isolated as a product of mescaline metabolism. When it was injected intravenously into rabbits, a mild mescalinelike action was observed.

In structure-activity relationship studies on mescaline, certain methoxylated amphetamines were found to be more potent than mescaline (2). If conversion from β -phenylethylamine to phenylisopropylamine can enhance the potency of psychotomimetics, then a similar logic possibly could be applied to the oxygen analogs of these psychotomimetics. One could anticipate that any mescalinelike actions would be more pronounced in 1-phenyl-2-propanols than in 2-phenylethanol. This paper reports the results of a study on the effect of 1-(3,4-dimethoxyphenyl)-2-propanol (DP), which is the oxygen analog of the psychotomimetic agent 3,4-dimethoxyamphetamine, on conditioned avoidance response (CAR) in the rat.

RESULTS AND DISCUSSION

Although the synthesis of DP was reported in the literature (3), no pharmacological information on the compound could be found.

Initially the effect of DP on CAR in rats was studied. The evaluation of drug action on CAR has been exploited widely. This technique has been especially valuable for the evaluation of psychotomimetics (4).

To determine whether DP is producing an effect similar to mescaline or 3,4-dimethoxyamphetamine (3,4-DMA), the effects of these drugs at various dosages on a running response in conditioned male rats were determined. Each drug was given in three dosage levels ("effective dose," one quarter the effective dose, and four times the effective dose) to groups of six rats. Figures 1 and 2 show the mean reaction time for each trial during the drug sessions for each dosage level of mescaline and 3,4-DMA. That the profile of 3,4-DMA is not completely analogous to mescaline may be due to the amphetamine structure present in 3,4-DMA. CNS stimulation caused by amphetamine would be expected to counteract the increased reaction times. Figure 3 shows the enhanced performance caused by amphetamine sulfate relative to placebo. The lower dose was more effective.

Since 3,4-DMA is expected to be a poorer stimulant than amphetamine itself (*i.e.*, require a much larger dose to cause the same effect), the greatest variation from the mescaline profile would be expected at the higher doses. The large variation between reaction times of adjacent trials is observed in both mescaline and 3,4-DMA, which suggests that this is a characteristic feature of the behavior disruption caused by these agents.

Figure 4 shows the effects of DP. The overall profile of the drug session is substantially different from any of the other drugs tested. When it became clear that DP was different, it was subjected to a more conventional pharmacological screening. In mice intraperitoneally it was a CNS depressant [$ED_{50}(\text{sleep}) = 150 \text{ mg./kg.}$; $LD_{50} = 650 \text{ mg./kg.}$] (5). This pharmacological action of DP is not unexpected in light of the report that acetophenones and other phenones and their corresponding alcohols exhibit depressant effects (6). Thus, DP may be viewed as a structural isomer of these phenones and alcohols.

The data presented here suggest that a reevaluation of the pharmacological effects of TE is required.¹ A detailed study of the structure-activity relationships and the mechanism of action of ring-substituted phenyl-2-propanols, phenyl-2-propanones, and chemi-

¹ Preliminary, unpublished studies indicate that TE has a CNS-depressant effect, $ED_{50}(\text{sleep}) > 650 \text{ mg./kg. i.p. in mice.}$

cally related compounds is underway and will be the subject of a future communication.

EXPERIMENTAL

An A-584 automatic shuttlebox system² was used to measure a running response in male, 70–100-day-old, hooded rats.

Training—Each animal was required to cross from one side to the other in response to a conditioned stimulus (a buzzer, 5 sec.). At the end of this time, the unconditioned stimulus (electric shock, 1.0 mamp., maximum time = 15 sec.) was administered if the animal had failed to cross. The trial ended when the animal made the cross or when a total of 20 sec. had elapsed. After a 40-sec. intertrial interval, the sequence was repeated. Each rat received 20 trials per day until

² Lafayette Instrument Co., Lafayette, Ind.

it attained 90% avoidance of unconditioned stimulus on that day or until it had received 200 trials. Rats failing to reach the criterion were discarded. Those attaining 90% avoidance were dosed with drugs (randomly selected) the following day.

Drug Session—The day following attainment of criterion the rat was injected with a saline solution of a drug intraperitoneally and immediately placed in the shuttlebox. A series of 140 trials was given, and the data (escape or avoidance and reaction time) were automatically recorded. With the exception of extremely unruly subjects, the rats were completely isolated during the entire drug session. After the drug day, the rats were discarded.

Some animals died during the drug sessions with mescaline hydrochloride at 25 mg./kg. (after Trials 77, 87, and 97) and at 100 mg./kg. (after Trials 60, 61, and 68), and with 3,4-DMA hydrochloride at 12.5 mg./kg. (after Trial 53) and at 50 mg./kg. (after Trials 66, 67, and 73). The animals were not considered in the computation of mean reaction times after death.

Preparation of Ethyl Diphenamate in Ethanol Using Potassium Diphenimide and 2-Chloroethanol

Keyphrases ☐ Ethyl diphenamate—synthesis ☐ *N*-(2-Hydroxyethyl)-diphenimide synthesis—literature correction ☐ NMR spectroscopy—structure

Sir:

The preparation of *N*-(2-hydroxyethyl)-diphenimide (III, Scheme I) was reported in 1952 by Demers and Jenkins (1). The approach taken in preparing this compound involved the reaction of potassium diphenimide (I) with 2-chloroethanol (II) in ethanol (1). Since this route of synthesis had been used successfully by Moore and Rapala (2) in the preparation of a series of dialkyl-aminoalkyl phthalimide derivatives, it appeared unlikely that a product other than that reported (III) would be obtained. Elemental nitrogen analysis of Compound III reported by these workers was well within experimental error.

In 1963, Jenkins *et al.* (3) reported that during the attempted synthesis of a series of dialkylaminoalkyl diphenimide hydrochloride salts, using a similar procedure to that reported by Demers and Jenkins (1), the corresponding hydrochloride salts of ethyl diphenamate were formed rather than the diphenimide derivatives. The similar chemical nature of the alkylating species in these reactions prompted us to repeat

Scheme I

the work of Demers and Jenkins to determine if Compound III had actually been obtained.

The results of our work, which we report at this time, shows that Demers and Jenkins did not prepare *N*-(2-hydroxyethyl)-diphenimide (III) as reported but instead obtained ethyl diphenamate (IV).

Identification of Compound IV was established as follows: (a) an NMR spectrum showed peaks at 6.83–8.00 δ (m, 8, Ar), 6.08 δ (b.s., NH₂), 4.09 δ (q, CH₂),

it attained 90% avoidance of unconditioned stimulus on that day or until it had received 200 trials. Rats failing to reach the criterion were discarded. Those attaining 90% avoidance were dosed with drugs (randomly selected) the following day.

Drug Session—The day following attainment of criterion the rat was injected with a saline solution of a drug intraperitoneally and immediately placed in the shuttlebox. The similar chemical nature of the alkylating species in these reactions prompted us to repeat

Scheme I

the work of Demers and Jenkins to determine if Compound III had actually been obtained.

The results of our work, which we report at this time, shows that Demers and Jenkins did not prepare *N*-(2-hydroxyethyl)-diphenimide (III) as reported but instead obtained ethyl diphenamate (IV).

Identification of Compound IV was established as follows: (a) an NMR spectrum showed peaks at 6.83–8.00 δ (m, 8, Ar), 6.08 δ (b.s., NH₂), 4.09 δ (q, CH₂),

Scheme II

and 1.02 δ (t, CH₃); and (b) a mixed melting-point determination of the product prepared by the method of Demers and Jenkins (1) with a sample of ethyl diphenamate prepared by reacting ethyl diphenoyl chloride with ammonia showed no depression, and single melting-point determinations and NMR spectra were identical within experimental error.

Ethyl Diphenamate (IV)—(a) This was prepared following the procedure of Demers and Jenkins (1), m.p. 93° (lit 93°).

Anal.—Calcd. for N¹: 5.20. Found: 5.19.

(b) Items prepared by reacting ethyldiphenoylchloride with ammonia as follows. Approximately 74 mmoles of ethyl diphenoyl chloride was prepared in a manner reported by Demers and Jenkins (1), except that the final product was not isolated following the 8-hr. reflux period because of its hygroscopic nature. Instead the solvent was first removed *in vacuo*, and three successive 10-ml. portions of benzene were then added to the residue and each stripped off in a like manner to remove unreacted thionyl chloride, solvent, and HCl. The residue was dissolved in 200 ml. of anhydrous ether and cooled in a dry ice bath. Ammonia was then bubbled slowly into the mixture for several minutes (Scheme II). A white precipitate (NH₄Cl and ethyl diphenamate) formed immediately and was collected. The solid was triturated with water to remove the NH₄Cl. The remaining solid (ethyl diphenamate) was collected and recrystallized from alcohol and water. Yield 95%, m.p. 89–90°, NMR spectrum identical to that obtained in (a).

Evidence for Capacity-Limited Biotransformation of Sulfanilamide

Keyphrases ☐ Sulfanilamide—capacity-limited biotransformation ☐ Biotransformation, sulfanilamide—rate limited ☐ Dose dependence—sulfanilamide half-life

Sir:

Blood as well as lymph concentrations of various agents were determined following intravenous administration in recent studies concerned with the influence of plasma protein binding on rate of drug distribution to the body (1). Among these agents were several sulfonamides. The data obtained with sulfanilamide appeared to indicate that the fraction of unmetabolized drug increased with increasing dose. Subsequent to the recently presented evidence that the biotransformation of salicylate, in the analgesic dose range usually used in man, is rate limited (2), a significant number of other agents were shown also to be metabolized in man and animals by various enzyme systems which are capacity limited (3). Since clear evidence for the capacity-limited nature of acetylation has been obtained only for *p*-aminobenzoic acid (4), we carried out additional studies to determine whether the biotransformation of low doses of sulfanilamide was, indeed, a rate-limited phenomenon.

These studies were carried out using nonfasted male rats of the Sprague-Dawley strain, weighing between 250 and 300 g. Sulfanilamide was injected into the femoral vein in doses of 2.5, 5.0, or 10.0 mg. Blood was sampled by cardiac puncture at 12, 18, 30, 42, and, in two instances, 5 min. after administration. Since lymph was also collected in some of the experiments, the animals were kept under light ether anesthesia. How-

Figure 1—Comparison of blood levels of unchanged drug after intravenous administration of several doses of sulfanilamide. Straight lines are regression lines calculated from the individual values determined at each time level (same number of animals as indicated in Table I).

Table I—Effect of Dose on Percent of Total Sulfanilamide Present in Blood as Unmetabolized Drug

Minutes	Percent Unmetabolized ^a		
	Dose, mg.		
	2.5	5.0	10.0
5	72.7 (2)	—	—

18	65.8 ± 15.6 (4)	78.4 ± 2.8 (4)	87.1 ± 2.4 (3)
30	55.6 ± 16.9 (6)	72.6 ± 12.4 (4)	85.3 ± 4.5 (3)
42	56.5 ± 11.6 (7)	68.9 ± 11.1 (4)	79.0 ± 4.3 (5)

^a Mean ± *SD*. Numbers in parentheses indicate number of animals.

ever, several experiments carried out in unanesthetized animals verified the blood level data collected in the anesthetized rats. The volume of all but the final sample of blood was 0.2 ml. The final sample, taken at 42 min., was sufficiently large to permit the determination of the hematocrit as well as the drug content in whole blood, plasma, and red cells. These data were then used to calculate the plasma concentrations for the earlier blood samples from the same animal. The distribution of sulfanilamide between red blood cells and plasma was also determined in another group of animals at 12, 18, and 30 min. after intravenous administration. For all samples the amounts of free (unmetabolized) and total (unmetabolized plus metabolized) sulfanilamide were determined by the method of Bratton and Marshall (5).

The results of the studies of distribution between plasma and red blood cells indicated that the interpretation of the data would be the same whether plasma concentrations or whole blood levels were used. The

analyses of the data, therefore, were carried out using the actual values obtained for blood rather than the calculated plasma values. These analyses clearly indicate that the biotransformation of sulfanilamide has the characteristics of a capacity-limited process (3).

First of all, the percentage of the unchanged drug in the blood increases with dose (Table I). When the regression functions of the individual values of percent free sulfanilamide on time were estimated and tested for the three doses, it was found that the regressions were linear only for the 5.0 and 10.0-mg. doses and that the negative slopes of only these two regression lines were significantly different from zero. This indicates that above a dose of 2.5 mg., the rate of metabolism increases relatively with time. Thus, the fractional composition of sulfanilamide in blood is dependent on dose—a characteristic that is a good index of deviation from apparent first-order kinetics.

Second, deviation from first-order kinetics also can be demonstrated when the data are treated as in Fig. 1. For first-order kinetics the principle of superimposition should apply when blood concentration/dose is plotted against time (3). However, it can be readily seen that the regression line for the 2.5-mg. dose is not superimposable on the other two lines, and statistical analysis verified this conclusion. The slope of the line for the 2.5-mg. dose was found to be significantly different from those of 5.0 and 10.0 mg., and the slopes of the latter two lines were found to be insignificantly different from each other.

Finally, deviation from apparent first-order kinetics can be shown by the lack of linearity of semilogarithmic plots of blood concentration as a function of time (Fig. 2). Although each of the regression lines is insignificantly different from a straight line and the corresponding slopes are significantly different from zero, the slope of the line for the 2.5-mg. dose is again significantly different from those for the other two doses. Therefore, the drug half-life becomes dose dependent at a dose between 2.5 and 5.0 mg. Alinearity of the plots for the 5.0 and 10.0-mg. doses would be demonstrable only if the time of sampling was extended beyond 42 min.

The demonstration that a capacity-limited system for acetylation of sulfanilamide exists in the rat is important for drug metabolism studies in this species but may not be necessarily relevant to man. However, the saturation phenomenon occurred at doses in the rat that, when extrapolated to man, lie well within the therapeutic dose range. Moreover, Levy (3) pointed out that several capacity-limited drug-metabolizing systems observed in man have been demonstrated also in rats. These include a limited capacity for the conjugation of salicylate (6) and benzoate (3) with glycine and for sulfate and glucuronide conjugation with *N*-acetyl-*p*-aminophenol (7). Whether capacity-limited acetylation of sulfanilamide can be added to the list of similarities between man and the rat has to await additional evidence. Certainly it becomes increasingly apparent that drug metabolism studies must be carried out at multiple-dose levels and that linearity of the semilogarithmic plots of drug elimination as a function of time is frequently insufficient to discriminate between dose-independent or dose-dependent biotransformations.

Figure 2—Semilogarithmic plots of blood levels of unchanged drug after intravenous administration of several doses of sulfanilamide. Straight lines are regression lines calculated from the individual values; ×, ●, and □ are means at each time for doses of 2.5, 5.0, and 10.0 mg., respectively. Bars surrounding points represent standard deviations (same number of animals at each point as indicated in Table I).

Apparent Dose-Dependent Elimination Kinetics as an Experimental Artifact

Keyphrases □ Dose-dependent elimination kinetics, apparent—experimental artifact consideration □ Plasma concentration—experimental blank errors

Sir:

It is now known that the kinetics of elimination of several drugs are dose dependent. The decline in the plasma concentrations of some drugs is exponential throughout, but the apparent first-order rate constant for this process decreases with increasing dose (1). The elimination of other drugs involves one or more saturable processes, and semilogarithmic plots of plasma concentrations as a function of time curve downward until they attain an exponential phase which is reached at the same concentration irrespective of the dose (2). In view of the great interest and investigative activity in the area of dose-dependent pharmacokinetics, it is appropriate to point out that errors in blank corrections can artifactually lead to the conclusion that an entirely linear, dose-independent system is in fact dose dependent and nonlinear.

Figure 1 shows hypothetical plasma concentrations obtained after intravenous injection of 1, 3, and 10 weight units of a drug which is actually eliminated by apparent first-order kinetics ($t_{1/2} = 2.0$ hr.), with the plasma concentration data describable by means of a one-compartment open model. However, the data points in the figure are, in each case, 2 mg./l. lower than the "real" concentrations. This would be so if, for a number of possible reasons, a 2 mg./l. error in the

Figure 1—Hypothetical plasma concentration data obtained after intravenous injection of 1, 3, and 10 weight units of a drug which is eliminated by apparent first-order kinetics ($t_{1/2} = 2$ hr.), if the blank correction is 2 mg./l. too large. Arrows indicate apparent half-life. Inset: Relationship between initial plasma concentration (C_0) and apparent half-life (" $t_{1/2}$ ").

blank value determination would have occurred. The data points thus obtained can be fitted readily to straight lines which yield a decreasing half-life with increasing dose. In the example shown, there is an almost 50% change in the apparent half-life.

If plasma concentrations are determined over a wide concentration range, an error in the blank correction can lead to the erroneous conclusion that elimination involves a combination of parallel linear and saturable (*i.e.*, capacity-limited) processes. Such systems may show an initial exponential concentration decline phase at high concentrations, a subsequent downward curvature, and finally another exponential phase which is steeper than the initial exponential phase (2). This pattern is evident in Fig. 2; the figure shows hypothetical plasma concentration data at two doses (differing 10-fold) of a drug, which is actually eliminated by apparent first-order kinetics but where an error of 3 mg./l. in the blank correction causes appreciable deviations from linearity. In this example, parallel straight lines may be fitted erroneously to the two sets of terminal data points, suggesting that the elimination kinetics above a plasma concentration of about 10 mg./l. are capacity limited.

The potential artifacts outlined in this article necessitate that considerable attention be directed to the correct determination of blank values. The magnitude

and 1.02 δ (t, CH₃); and (b) a mixed melting-point determination of the product prepared by the method of Demers and Jenkins (1) with a sample of ethyl diphenamate prepared by reacting ethyl diphenoyl chloride with ammonia showed no depression, and single melting-point determinations and NMR spectra were identical within experimental error.

Ethyl Diphenamate (IV)—(a) This was prepared following the procedure of Demers and Jenkins (1), m.p. 93° (lit 93°).

Anal.—Calcd. for N¹: 5.20. Found: 5.19.

(b) Items prepared by reacting ethyldiphenoylchloride with ammonia as follows. Approximately 74 mmoles of ethyl diphenoyl chloride was prepared in a manner reported by Demers and Jenkins (1), except that the final product was not isolated following the 8-hr. reflux period because of its hygroscopic nature. Instead the solvent was first removed *in vacuo*, and three successive 10-ml. portions of benzene were then added to the residue and each stripped off in a like manner to remove unreacted thionyl chloride, solvent, and HCl. The residue was dissolved in 200 ml. of anhydrous ether and cooled in a dry ice bath. Ammonia was then bubbled slowly into the mixture for several minutes (Scheme II). A white precipitate (NH₄Cl and ethyl diphenamate) formed immediately and was collected. The solid was triturated with water to remove the NH₄Cl. The remaining solid (ethyl diphenamate) was collected and recrystallized from alcohol and water. Yield 95%, m.p. 89–90°, NMR spectrum identical to that obtained in (a).

Evidence for Capacity-Limited Biotransformation of Sulfanilamide

Keyphrases ☐ Sulfanilamide—capacity-limited biotransformation ☐ Biotransformation, sulfanilamide—rate limited ☐ Dose dependence—sulfanilamide half-life

Sir:

Blood as well as lymph concentrations of various agents were determined following intravenous administration in recent studies concerned with the influence of plasma protein binding on rate of drug distribution to the body (1). Among these agents were several sulfonamides. The data obtained with sulfanilamide appeared to indicate that the fraction of unmetabolized drug increased with increasing dose. Subsequent to the recently presented evidence that the biotransformation of salicylate, in the analgesic dose range usually used in man, is rate limited (2), a significant number of other agents were shown also to be metabolized in man and animals by various enzyme systems which are capacity limited (3). Since clear evidence for the capacity-limited nature of acetylation has been obtained only for *p*-aminobenzoic acid (4), we carried out additional studies to determine whether the biotransformation of low doses of sulfanilamide was, indeed, a rate-limited phenomenon.

These studies were carried out using nonfasted male rats of the Sprague-Dawley strain, weighing between 250 and 300 g. Sulfanilamide was injected into the femoral vein in doses of 2.5, 5.0, or 10.0 mg. Blood was sampled by cardiac puncture at 12, 18, 30, 42, and, in two instances, 5 min. after administration. Since lymph was also collected in some of the experiments, the animals were kept under light ether anesthesia. How-

Figure 1—Comparison of blood levels of unchanged drug after intravenous administration of several doses of sulfanilamide. Straight lines are regression lines calculated from the individual values determined at each time level (same number of animals as indicated in Table I).

Table I—Effect of Dose on Percent of Total Sulfanilamide Present in Blood as Unmetabolized Drug

Minutes	Percent Unmetabolized ^a		
	Dose, mg.

5	72.7 (2)	—	—
12	61.5 ± 12.3 (4)	81.3 ± 4.3 (4)	85.6 ± 3.8 (3)
18	65.8 ± 15.6 (4)	78.4 ± 2.8 (4)	87.1 ± 2.4 (3)
30	55.6 ± 16.9 (6)	72.6 ± 12.4 (4)	85.3 ± 4.5 (3)
42	56.5 ± 11.6 (7)	68.9 ± 11.1 (4)	79.0 ± 4.3 (5)

^a Mean ± *SD*. Numbers in parentheses indicate number of animals.

ever, several experiments carried out in unanesthetized animals verified the blood level data collected in the anesthetized rats. The volume of all but the final sample of blood was 0.2 ml. The final sample, taken at 42 min., was sufficiently large to permit the determination of the hematocrit as well as the drug content in whole blood, plasma, and red cells. These data were then used to calculate the plasma concentrations for the earlier blood samples from the same animal. The distribution of sulfanilamide between red blood cells and plasma was also determined in another group of animals at 12, 18, and 30 min. after intravenous administration. For all samples the amounts of free (unmetabolized) and total (unmetabolized plus metabolized) sulfanilamide were determined by the method of Bratton and Marshall (5).

The results of the studies of distribution between plasma and red blood cells indicated that the interpretation of the data would be the same whether plasma concentrations or whole blood levels were used. The

analyses of the data, therefore, were carried out using the actual values obtained for blood rather than the calculated plasma values. These analyses clearly indicate that the biotransformation of sulfanilamide has the characteristics of a capacity-limited process (3).

First of all, the percentage of the unchanged drug in the blood increases with dose (Table I). When the regression functions of the individual values of percent free sulfanilamide on time were estimated and tested for the three doses, it was found that the regressions were linear only for the 5.0 and 10.0-mg. doses and that the negative slopes of only these two regression lines were significantly different from zero. This indicates that above a dose of 2.5 mg., the rate of metabolism increases relatively with time. Thus, the fractional composition of sulfanilamide in blood is dependent on dose—a characteristic that is a good index of deviation from apparent first-order kinetics.

Second, deviation from first-order kinetics also can be demonstrated when the data are treated as in Fig. 1. For first-order kinetics the principle of superimposition should apply when blood concentration/dose is plotted against time (3). However, it can be readily seen that the regression line for the 2.5-mg. dose is not superimposable on the other two lines, and statistical analysis verified this conclusion. The slope of the line for the 2.5-mg. dose was found to be significantly different from those of 5.0 and 10.0 mg., and the slopes of the latter two lines were found to be insignificantly different from each other.

Finally, deviation from apparent first-order kinetics can be shown by the lack of linearity of semilogarithmic plots of blood concentration as a function of time (Fig. 2). Although each of the regression lines is insignificantly different from a straight line and the corresponding slopes are significantly different from zero, the slope of the line for the 2.5-mg. dose is again significantly different from those for the other two doses. Therefore, the drug half-life becomes dose dependent at a dose between 2.5 and 5.0 mg. Alinearity of the plots for the 5.0 and 10.0-mg. doses would be demonstrable only if the time of sampling was extended beyond 42 min.

The demonstration that a capacity-limited system for acetylation of sulfanilamide exists in the rat is important for drug metabolism studies in this species but may not be necessarily relevant to man. However, the saturation phenomenon occurred at doses in the rat that, when extrapolated to man, lie well within the therapeutic dose range. Moreover, Levy (3) pointed out that several capacity-limited drug-metabolizing systems observed in man have been demonstrated also in rats. These include a limited capacity for the conjugation of salicylate (6) and benzoate (3) with glycine and for sulfate and glucuronide conjugation with *N*-acetyl-*p*-aminophenol (7). Whether capacity-limited acetylation of sulfanilamide can be added to the list of similarities between man and the rat has to await additional evidence. Certainly it becomes increasingly apparent that drug metabolism studies must be carried out at multiple-dose levels and that linearity of the semilogarithmic plots of drug elimination as a function of time is frequently insufficient to discriminate between dose-independent or dose-dependent biotransformations.

blank value determination would have occurred. The data points thus obtained can be fitted readily to straight lines which yield a decreasing half-life with increasing dose. In the example shown, there is an almost 50% change in the apparent half-life.

If plasma concentrations are determined over a wide concentration range, an error in the blank correction can lead to the erroneous conclusion that elimination involves a combination of parallel linear and saturable (*i.e.*, capacity-limited) processes. Such systems may show an initial exponential concentration decline phase at high concentrations, a subsequent downward curvature, and finally another exponential phase which is steeper than the initial exponential phase (2). This pattern is evident in Fig. 2; the figure shows hypothetical plasma concentration data at two doses (differing 10-fold) of a drug, which is actually eliminated by apparent first-order kinetics but where an error of 3 mg./l. in the blank correction causes appreciable deviations from linearity. In this example, parallel straight lines may be fitted erroneously to the two sets of terminal data points, suggesting that the elimination kinetics above a plasma concentration of about 10 mg./l. are capacity limited.

The potential artifacts outlined in this article necessitate that considerable attention be directed to the correct determination of blank values. The magnitude

Figure 2—Hypothetical plasma concentration data (●) obtained after intravenous injection of two different doses of a drug which is eliminated by apparent first-order kinetics, if the blank correction is 3 mg./l. too large. The dashed lines represent the correct curve. Note the apparent parallelism of the straight lines fitted to the last three points of each set of data.

and variability of the blank, relative to the lower range of drug concentrations encountered in the investigation, must be carefully considered in the pharmacokinetic analysis of the data. It is recommended that apparent dose-dependent changes in elimination-rate constants, as shown in Fig. 1, be tested statistically for lack of parallelism of the respective log concentration *versus* time curves in the same concentration range. Where plasma concentration data show the pattern presented in Fig. 2, it is best to focus attention on the plasma concentration and/or urinary excretion pattern of the metabolite that is presumed to be subject to capacity-limited formation.

An underestimation of blank values, resulting in higher than correct drug concentration data, has exactly the opposite effects as those described here. Apparent first-order elimination-rate constants may be mistakenly assumed to increase with increasing dose [a type of kinetics that can actually occur due to dose-dependent distributional effects (3)], and a decrease in the slope of log drug concentration *versus* time curves with decreasing concentration might be treated as a linear multicompartiment model or be interpreted as suggesting saturation of a renal tubular reabsorption process [a type of kinetics that can, in fact, occur (4)]. Thus, one must be concerned not only with the speci-

ficity and sensitivity of an analytical method but also with the possibility of systematic errors in the blank correction.

Flocculation Theory and Polysorbate 80-Sulfaguanidine Suspensions

Keyphrases □ Flocculation theory—sulfaguanidine-polysorbate 80 suspension □ Sedimentation height—sulfaguanidine-polysorbate 80 suspension

Sir:

Flocculation has been defined as an open network structure formed by aggregated suspension particles (1). Three possible mechanisms by which such a structure can occur are: (a) aggregation in the secondary minimum which can theoretically result when the forces of attraction exceed the forces of repulsion (2, 3); (b) adsorption bridging—the aggregation of particles whose surface sites are occupied by segments of extended macromolecules; the extended molecules act as bridges between particles (4); and (c) chemical bridging—the aggregation by chemical reaction between adsorbed ions extending from the particle surface and media precipitation ions (5, 6).

In a study of the aggregation of a sulfaguanidine suspension with particles wetted by polysorbate 80, it was reported that the addition of increasing amounts of aluminum chloride produced a "flocculated system" which showed a steady increase in sedimentation height (7). A maximum volume was reached, and further additions of salt produced no change in sedimentation height.

Aluminum chloride at the concentrations used in the report could not react with the nonionic surfactant in a manner similar to those interactions that cause flocculation by chemical bridging.

Polysorbate 80 has never, in our experience, shown the characteristics exhibited by macromolecules that produce floccules in suspensions; therefore, it seemed

Aluminum chloride at the concentrations used in the report could not react with the nonionic surfactant in a manner similar to those interactions that cause flocculation by chemical bridging.

Polysorbate 80 has never, in our experience, shown the characteristics exhibited by macromolecules that produce floccules in suspensions; therefore, it seemed

Figure 1—Aggregation of sulfaguanidine in a suspension containing polysorbate 80 and aluminum chloride. Key: ●—●, from Jones et al. (7); and ○--○, this report.

doubtful that in this experiment aggregation by adsorption bridging would occur.

We do not believe that the theory of long-range forces of attraction, classically believed to be responsible for aggregation in the secondary minimum, applies to the aggregation of hydrophilic particles (5). Since the sulfaguanidine covered with surfactant is a hydrophilic system, no flocculation will occur by mechanism a.

What we believed likely to happen is that the dispersed sulfa particles settle as individual entities and/or aggregate by surfactant-water film to surfactant-water film interactions to settle as close packed coagula (1). In either or both cases, the final height could not vary in the manner described in the report.

Since the properties of the system used did not appear to us to be capable of producing a flocculated structure on the basis of any of the three mechanisms enumerated, we studied these same systems for clarification.

Sulfaguanidine NF suspensions in water with polysorbate 80 and aluminum chloride were prepared in the exact manner described in the report (7), with the exception that mixing was done by a magnetic stirrer. The results of our experiments were always a sedimentation to a small volume (Fig. 1). The height did not change over the range of aluminum chloride concentrations shown. The suspensions sedimented in about 3 hr. and the final (H_u/H_o) was measured after 24 hr. The experimental results reported here indicate that the particles are either in the dispersed state and/or the coagulated state (1).

The system reported to be flocculated, i.e., to increase to approximately twice its minimum (H_u/H_o) height was found in this laboratory to give only a constant height under all conditions stated in the report. These results support our *a priori* assumption that flocculation cannot take place in this system.

Carboxyl Protection Using Salt Formation for the Synthesis of Linear Sequential Polypeptides: Synthesis of Poly-(L-tyrosyl-L-glutamyl-L-alanylglycyl)glycine-1-¹⁴C Ethyl Ester

Keyphrases □ Polypeptides, linear sequential—synthesis □ Poly-(L-tyrosyl-L-glutamyl-L-alanylglycyl)glycine-1-¹⁴C ethyl ester—synthesis □ Carboxyl protection—peptide synthesis □ Immunochemical properties—linear sequential polypeptide

Sir:

The least elaborate approach to carboxyl protection in peptide synthesis is the use of salt formation with such bases as triethylamine, tributylamine, or dicyclohexylamine. This method of protection seems to work best when an activated ester of an *N*-protected amino acid is used for the coupling reaction to amino acids and peptides which were carboxyl protected by salt formation (1, 2).

We have extended this method of protection to the synthesis of high molecular weight linear polypeptides. This is illustrated by a new synthesis of the antigenic polymer poly-(L-tyrosyl-L-glutamyl-L-alanylglycyl)glycine-1-¹⁴C ethyl ester (Scheme I).

The previously reported tetrapeptide (3), *N*-carbobenzoxycarboxy-*O*-*tert*-butyl-L-tyrosyl- γ -*tert*-butyl-L-glutamyl-L-alanylglycine methyl ester (I), was saponified with 1 equivalent of *N* NaOH to yield the tetrapeptide free acid, *N*-carbobenzoxycarboxy-*O*-*tert*-butyl-L-tyrosyl- γ -*tert*-butyl-L-glutamyl-L-alanylglycine (II), m.p. 159–160°, $[\alpha]_D^{25} - 10.3^\circ$ (c 4.23 in dimethylformamide).

Anal.—Calcd. for $C_{35}H_{48}N_4O_{10}$: C, 61.4; H, 7.1; N, 8.2. Found: C, 61.5; H, 7.15; N, 8.1.

Coupling II with pentachlorophenol, using dicyclohexylcarbodiimide, yielded the tetrapeptide activated ester, *N*-carbobenzoxycarboxy-*O*-*tert*-butyl-L-tyrosyl- γ -*tert*-butyl-L-glutamyl-L-alanylglycine pentachlorophenyl ester (III), m.p. 185°, $[\alpha]_D^{25} - 17.0^\circ$ (c 1.06 in dimethylformamide).

Anal.—Calcd. for $C_{41}H_{47}Cl_5N_4O_{10}$: C, 52.8; H, 5.1; N, 6.0. Found: C, 52.6; H, 4.9; N, 6.0.

Carboxyl Protection Using Salt Formation for the Synthesis of Linear Sequential Polypeptides: Synthesis of Poly-(L-tyrosyl-L-glutamyl-L-alanylglycyl)glycine-1-¹⁴C Ethyl Ester

Keyphrases □ Polypeptides, linear sequential—synthesis □ Poly-(L-tyrosyl-L-glutamyl-L-alanylglycyl)glycine-1-¹⁴C ethyl ester—synthesis □ Carboxyl protection—peptide synthesis □ Immunochemical properties—linear sequential polypeptide

Sir:

The least elaborate approach to carboxyl protection in peptide synthesis is the use of salt formation with such bases as triethylamine, tributylamine, or dicyclohexylamine. This method of protection seems to work best when an activated ester of an *N*-protected amino acid is used for the coupling reaction to amino acids and peptides which were carboxyl protected by salt formation (1, 2).

We have extended this method of protection to the synthesis of high molecular weight linear polypeptides. This is illustrated by a new synthesis of the antigenic polymer poly-(L-tyrosyl-L-glutamyl-L-alanylglycyl)glycine-1-¹⁴C ethyl ester (Scheme I).

The previously reported tetrapeptide (3), *N*-carbobenzoxycarboxy-*O*-*tert*-butyl-L-tyrosyl- γ -*tert*-butyl-L-glutamyl-L-alanylglycine methyl ester (I), was saponified with 1 equivalent of *N* NaOH to yield the tetrapeptide free acid, *N*-carbobenzoxycarboxy-*O*-*tert*-butyl-L-tyrosyl- γ -*tert*-butyl-L-glutamyl-L-alanylglycine (II), m.p. 159–160°, $[\alpha]_D^{25} - 10.3^\circ$ (c 4.23 in dimethylformamide).

Anal.—Calcd. for $C_{35}H_{48}N_4O_{10}$: C, 61.4; H, 7.1; N, 8.2. Found: C, 61.5; H, 7.15; N, 8.1.

Coupling II with pentachlorophenol, using dicyclohexylcarbodiimide, yielded the tetrapeptide activated ester, *N*-carbobenzoxycarboxy-*O*-*tert*-butyl-L-tyrosyl- γ -*tert*-butyl-L-glutamyl-L-alanylglycine pentachlorophenyl ester (III), m.p. 185°, $[\alpha]_D^{25} - 17.0^\circ$ (c 1.06 in dimethylformamide).

Anal.—Calcd. for $C_{41}H_{47}Cl_5N_4O_{10}$: C, 52.8; H, 5.1; N, 6.0. Found: C, 52.6; H, 4.9; N, 6.0.

where DCC = dicyclohexylcarbodiimide, PCP = pentachlorophenyl, and TEA = triethylamine

Scheme 1

Treatment of III with anhydrous hydrogen bromide in glacial acetic acid removed the *N*-carbobenzoxy and the *tert*-butyl protecting groups to yield the polymerizing unit, L-tyrosyl-L-glutamyl-L-alanylglycine pentachlorophenyl ester hydrobromide (IV), m.p. 180°, $[\alpha]_D^{25} - 3.3^\circ$ (c 1.83 in dimethylformamide).

Anal.—Calcd. for $\text{C}_{25}\text{H}_{26}\text{BrCl}_5\text{N}_4\text{O}_8$: C, 39.1; H, 3.4; N, 7.3 Found: C, 39.1; H, 3.6; N, 7.6.

The polymerization of IV was conducted under dilute conditions in the presence of a preformed monomer glycine-1- ^{14}C ethyl ester hydrochloride. This established polymerizing procedure has been shown to yield linear high molecular weight polypeptides (3–6) when the side groups are protected. In this case, the polymerizing unit (IV), dissolved in dimethyl sulfoxide, was added dropwise to a solution of glycine-1- ^{14}C ethyl ester hydrochloride containing the total amount (3.5 equivalents) of triethylamine such that the final concentration of reactants was never more than 70 mmole/l. The polymerization was allowed to proceed for a week, after which the mixture was acidified and dialyzed extensively for 3 days. The precipitated polypeptide, poly-(L-tyrosyl-L-glutamyl-L-alanylglycyl)glycine-1- ^{14}C ethyl ester (V), was collected by centrifugation, converted to its sodium salt, and dialyzed extensively for a week to remove all low molecular weight materials. This dialyzed polymer was lyophilized, converted to the free acid form by acidification, and again dialyzed to remove all traces of salt. Radioactive assay indicated 85% incorporation of the starting preformed monomer.

Anal.—Calcd. for $\text{C}_{19}\text{H}_{24}\text{N}_4\text{O}_7 \cdot \frac{1}{2} \text{H}_2\text{O}$: C, 53.15; H, 5.85; N, 13.05. Found: C, 52.8; H, 5.9; N, 13.0.

Filtration of the polymer through a calibrated column (7) of synthetic polysaccharide¹ (2.5 × 45 cm.), using a solution of 0.1 M NaCl–0.05 M NaHCO₃ buffer as eluent, indicated a molecular weight of at least 1×10^5 .

To evaluate this method of preparing polypeptides with one that uses conventional protecting groups (3–6), a comparison was made of this polypeptide with that prepared using the *tert*-butyl ester for carboxyl protection (3). It was found that both polymers eluted

from a column of the polysaccharide (2.5 × 45 cm.) in the same fractionation pattern, using a 0.1 M NaCl–0.05 M NaHCO₃ buffer as eluent. The two polymers were considered to be structurally identical since both materials were similarly antigenic in rabbits; each polypeptide crossreacted with the antibodies produced by the other, giving the same precipitin curve which was similar to that previously reported (8). From this evidence it was concluded that this method of carboxyl protection is compatible with the synthesis of linear high molecular weight polypeptides.

Aporphines V: Total Synthesis of (±)-Apomorphine

Keyphrases □ (±)-Apomorphine—total synthesis □ IR spectrophotometry—structure □ UV spectrophotometry—structure

Sir:

(–)-Apomorphine [(–)-I], the semisynthetic alkaloid obtained by vigorous treatment of morphine with strong mineral acids, has found medicinal application

¹ Sephadex G-100.

Scheme I

as a powerful, centrally acting emetic and has been included in the official drug compendia of the United States (1) and is regulated by Federal Narcotic Laws (2). Apomorphine exerts a direct stimulating action on the vomiting center in the brain and thus initiates emesis (3). The biochemical mechanism of its action is not yet clearly understood.

The finding that subcutaneous administration of apomorphine to patients with selected neurologic disorders temporarily changed the neurologic manifestations in the same direction as with the administration of oral L-dopa has stimulated renewed interest in these catecholaminelike compounds (4).

We wish to report the first total synthesis of (±)-apomorphine [(±)-I] and to describe a versatile pathway with potential for the elaboration of structurally similar alkaloids. Although (±)-apomorphine has not been synthesized previously, the preparation of (±)-apomorphine dimethyl ether [(±)-II] has been the subject of considerable interest and was first successfully carried out by Späth and Hromatka (5) and subsequently by Hey and Palluel (6) and Sugawara and Tachikawa (7). Their general methods were based on a Bischler-Napieralski cyclization of an *o*-nitrophenyl-*N*-phenylethylacetamide to a 3,4-dihydroisoquinoline derivative, which was subsequently transformed *via* the Pschorr procedure to apomorphine dimethyl ether. Several workers have found this sequence impracticable, since the Bischler-Napieralski cyclization is generally unsatisfactory (8) when the amide used lacks an activating substituent on the aromatic ring of the *N*-phenylethyl moiety. Our scheme (Scheme I) was based on the alkylation of the Reissert anion (III) with 2-nitro-3,4-dimethoxybenzyl chloride (IV) (9). A variety of 1-alkylisoquinolines has been prepared by this method (10). The standard procedure (11), in which phenyllithium

is used to generate the anion in ether at -20° , gave a 35% yield of V, m.p. $208-209^{\circ}$, IR (KBr): ν_{\max} , 2245 cm^{-1} (w), 1675 (s), 1640 (s), 1530 (s), 1375 (m); $\lambda_{\max}^{\text{MeOH}}$: 282 $\text{m}\mu$ (ϵ , 6100), 297 (ϵ , 6300), 316 (ϵ , 6100).

Anal.—Calcd. for $\text{C}_{26}\text{H}_{21}\text{N}_3\text{O}_5$: C, 68.56; H, 4.65; N, 9.23. Found: C, 68.57; H, 4.73; N, 9.22.

A procedure for the generation of the anion III employing sodium hydride in *N,N*-dimethylformamide at room temperature has recently been reported (12). Applying this modification to the synthesis of aporphines (13, 14), we obtained excellent yields of the desired isoquinoline (VI) without the isolation of V. The crude product (V) was hydrolyzed to furnish a 90% yield of VI (from III), m.p. $129-130^{\circ}$; $\lambda_{\max}^{\text{MeOH}}$: 261 $\text{m}\mu$ (ϵ , 6800), 272 (ϵ , 7200), 281 (ϵ , 5900), 308 (ϵ , 4400), 322 (ϵ , 5200).

Anal.—Calcd. for $\text{C}_{18}\text{H}_{16}\text{N}_2\text{O}_4$: C, 66.66; H, 4.97; N, 8.64. Found: C, 66.48; H, 4.88; N, 8.56.

Treatment of the base VI with methyl iodide gave the ammonium salt, m.p. $190-193^{\circ}$, in a quantitative yield (15). The methiodide VII was reduced with potassium borohydride to the tetrahydroisoquinoline VIII, m.p. $97-98.5^{\circ}$, in 80% yield (15). Reduction of the nitro compound VIII with palladium-on-charcoal and hydrogen gave 1-(2-amino-3,4-dimethoxybenzyl)-2-methyl-1,2,3,4-tetrahydroisoquinoline (IX), m.p. $85-87.5^{\circ}$, in 80% yield; $\lambda_{\max}^{\text{MeOH}}$: 212 $\text{m}\mu$ (ϵ , 39,000), 265 (ϵ , 11,000), 272 (ϵ , 1400), 285 (ϵ , 1600). This compound was previously reported as a brown oil (5-7). It furnished a dipicrolonate, m.p. $191-192^{\circ}$, which did not depress the melting point of an authentic sample of the dipicrolonate, m.p. $189-190^{\circ}$ (6). The amine IX was converted to (±)-apomorphine dimethyl ether [(±)-II] by modifications of procedures of Späth and Hromatka (5), copper powder being used as the coupling agent for the diazonium salt. (±)-II was isolated as an oil in 41%

yield after column chromatography. TLC (silica gel, chloroform) of this product showed only one component, and the R_f was identical with that of a sample of (–)-II prepared in 74% yield from (–)-I hydrochloride and diazomethane. The oily (±)-II was converted into a crystalline picrate, m.p. 187–189° dec., and a crystalline perchlorate, m.p. 263° dec.

The two preparations of apomorphine dimethyl ether [(–)-II and (±)-II] showed identical IR (film), UV, and NMR spectra; $\lambda_{\text{max}}^{\text{MeOH}}$: 216 m μ (ϵ , 47,000), 269 (ϵ , 19,000), 306 s (ϵ , 2300); NMR (CDCl_3): 2.57 (3H, singlet), 2.66–3.37 (7H, multiplet), 3.73 (3H, singlet), 3.91 (3H, singlet), 6.91–7.18 (4H, multiplet), 8.28 (1H, doublet, $J = 2$ c.p.s.). (±)-Apomorphine dimethyl ether was converted to its hydroiodide salt with 57% hydriodic acid. Recrystallization from acetone–water yielded white needles, m.p. 279° dec.¹

Anal.—Calcd. for $\text{C}_{19}\text{H}_{22}\text{INO}_2$: C, 53.91; H, 5.24; I, 29.98; N, 3.31. Found: C, 54.08; H, 5.40; I, 30.17; N, 3.13.

The demethylation of this hydroiodide proved an exceptionally facile reaction, considering the sensitivity of apomorphine to oxidizing agents as well as to acylating agents. The hydroiodide was heated with an equimolar mixture of 57% hydriodic acid and acetic anhydride at reflux for 1 hr. When the reaction mixture was diluted with ether, pure (±)-apomorphine hydroiodide was precipitated and isolated as a white crystalline powder, m.p. 282° dec.,¹ in 93% yield. This compound oxidized only slowly when stored in the cold under nitrogen. $\lambda_{\text{max}}^{\text{MeOH}}$: 217 m μ (ϵ , 41,000), 273 (ϵ , 17,000), 309 (ϵ , 3300).

Anal.—Calcd. for $\text{C}_{17}\text{H}_{18}\text{INO}_2$: C, 51.66, H, 4.59, I, 32.11; N, 3.54. Found: C, 51.48; H, 4.69; I, 32.00; N, 3.40.

BOOKS

REVIEWS

International Encyclopedia of Pharmacology and Therapeutics. Section 13, Volume 1-Anticholinesterase Agents. Edited by C. RADOUCO-THOMAS, Pergamon Press Ltd., Oxford, England, 1970. ix + 508 pp. 15.5 × 23.5 cm. Price \$24.00.

The number of compounds that inhibit the class of enzymes known as cholinesterases has increased markedly in recent years. These compounds, which have had only limited applications in medical therapy and have few equals as investigational tools in pharmacology, are now important industrially as insecticides and militarily as the highly toxic "nerve gases," e.g., sarin, soman, and tabun. Concurrently, large numbers of papers have been published dealing with chemical and biological aspects of these inhibitors and of the enzymes with which they react. Many reviews have subsequently appeared, of which the one edited by Koelle in 1963, *Cholinesterases and Anticholinesterase Agents*, may be the most extensive and most widely used.

The present volume of anticholinesterase agents for the most part covers the same literature as that of the review of Koelle and attempts to include most papers published through late 1968. The material is presented in two major subsections, with an introduction, titled "History of the Research With Anticholinesterase Agents," by Professor A. G. Karczmar, the Section Editor. This part considers in brief, historic detail the pharmacology of physostigmine, the concept of neurohumoral transmission, some novel aspects of the cholinergic system, organophosphorous inhibitors, early work on cholinesterases, the therapeutic uses of inhibitors of these enzymes, and some interesting points of disagreement among investigators of these areas.

Subsection I, titled "Reactions of Cholinesterases With Substrates, Inhibitors and Reactivators," compiled by Dr. Earl Usdin, comprises the major portion of the volume. The author states that a somewhat different point of view has guided this review: an intention not only to describe the reactions of cholinesterases with substrates, inhibitors, and reactivators, but to make known the differences and similarities among the reactions of these three classes of compounds. In this effort, reference has been made to the active

yield after column chromatography. TLC (silica gel, chloroform) of this product showed only one component, and the R_f was identical with that of a sample of (–)-II prepared in 74% yield from (–)-I hydrochloride and diazomethane. The oily (±)-II was converted into a crystalline picrate, m.p. 187–189° dec., and a crystalline perchlorate, m.p. 263° dec.

The two preparations of apomorphine dimethyl ether [(–)-II and (±)-II] showed identical IR (film), UV, and NMR spectra; $\lambda_{\text{max}}^{\text{MeOH}}$: 216 m μ (ϵ , 47,000), 269 (ϵ , 19,000), 306 s (ϵ , 2300); NMR (CDCl_3): 2.57 (3H, singlet), 2.66–3.37 (7H, multiplet), 3.73 (3H, singlet), 3.91 (3H, singlet), 6.91–7.18 (4H, multiplet), 8.28 (1H, doublet, $J = 2$ c.p.s.). (±)-Apomorphine dimethyl ether was converted to its hydroiodide salt with 57% hydriodic acid. Recrystallization from acetone–water yielded white needles, m.p. 279° dec.¹

Anal.—Calcd. for $\text{C}_{19}\text{H}_{22}\text{INO}_2$: C, 53.91; H, 5.24; I, 29.98; N, 3.31. Found: C, 54.08; H, 5.40; I, 30.17; N, 3.13.

The demethylation of this hydroiodide proved an exceptionally facile reaction, considering the sensitivity of apomorphine to oxidizing agents as well as to acylating agents. The hydroiodide was heated with an equimolar mixture of 57% hydriodic acid and acetic anhydride at reflux for 1 hr. When the reaction mixture was diluted with ether, pure (±)-apomorphine hydroiodide was precipitated and isolated as a white crystalline powder, m.p. 282° dec.,¹ in 93% yield. This compound oxidized only slowly when stored in the cold under nitrogen. $\lambda_{\text{max}}^{\text{MeOH}}$: 217 m μ (ϵ , 41,000), 273 (ϵ , 17,000), 309 (ϵ , 3300).

Anal.—Calcd. for $\text{C}_{17}\text{H}_{18}\text{INO}_2$: C, 51.66, H, 4.59, I, 32.11; N, 3.54. Found: C, 51.48; H, 4.69; I, 32.00; N, 3.40.

¹ Determined on a duPont differential thermal analyzer under nitrogen.

BOOKS

REVIEWS

International Encyclopedia of Pharmacology and Therapeutics. Section 13, Volume 1-Anticholinesterase Agents. Edited by C. RADOUCO-THOMAS, Pergamon Press Ltd., Oxford, England, 1970. ix + 508 pp. 15.5 × 23.5 cm. Price \$24.00.

The number of compounds that inhibit the class of enzymes known as cholinesterases has increased markedly in recent years. These compounds, which have had only limited applications in medical therapy and have few equals as investigational tools in pharmacology, are now important industrially as insecticides and militarily as the highly toxic "nerve gases," e.g., sarin, soman, and tabun. Concurrently, large numbers of papers have been published dealing with chemical and biological aspects of these inhibitors and of the enzymes with which they react. Many reviews have subsequently appeared, of which the one edited by Koelle in 1963, *Cholinesterases and Anticholinesterase Agents*, may be the most extensive and most widely used.

The present volume of anticholinesterase agents for the most part covers the same literature as that of the review of Koelle and attempts to include most papers published through late 1968. The material is presented in two major subsections, with an introduction, titled "History of the Research With Anticholinesterase Agents," by Professor A. G. Karczmar, the Section Editor. This part considers in brief, historic detail the pharmacology of physostigmine, the concept of neurohumoral transmission, some novel aspects of the cholinergic system, organophosphorous inhibitors, early work on cholinesterases, the therapeutic uses of inhibitors of these enzymes, and some interesting points of disagreement among investigators of these areas.

Subsection I, titled "Reactions of Cholinesterases With Substrates, Inhibitors and Reactivators," compiled by Dr. Earl Usdin, comprises the major portion of the volume. The author states that a somewhat different point of view has guided this review: an intention not only to describe the reactions of cholinesterases with substrates, inhibitors, and reactivators, but to make known the differences and similarities among the reactions of these three classes of compounds. In this effort, reference has been made to the active

sites of the enzymes, to the mechanisms and kinetics of the reactions, and to structure-activity relationships; stereoisomeric effects have been emphasized. Separate sections are included that are concerned with studies of the active sites of cholinesterases and on the "aging" of the organophosphate-enzyme product, since the latter phenomenon has particular significance in the therapy of poisoning by organophosphate inhibitors.

Subsection II, titled "Toxicity of Anticholinesterases and Treatment of Poisoning," by Dr. J. H. Wills, has two goals: (a) to complement and update reviews concerned with the pharmacology and toxicology of anti-ChE compounds, and (b) to describe and place on as firm a foundation as possible the treatment of poisoning by ChE inhibitors. Dr. Wills has assembled a large amount of basic data and information about the toxicology of a variety of inhibitors of ChE; and, more importantly, he has laid a foundation for therapy by a highly competent and thorough pharmacological analysis of the relevant material. The medical literature should still be consulted for clinical applications, to which the discussion of Dr. Wills is a prerequisite.

This review will be helpful to the student, investigator, and teacher interested in the various phases of ChE enzymes and their inhibitors, especially those for whom the historiographic approach is important. The subsection by Dr. Usdin, in addition to almost 300 pages of data and discussion, includes over 50 pages of references, a testimony to literature searches aided by computers. The computer, however, cannot be faulted for the fact that in an important table listing inhibitor constants the references are identified by number, whereas they are listed alphabetically. More rigorous editing here and throughout the text would have added to the readability and importance of this very useful review.

The Chemistry and Biochemistry of Steroids. Edited by N. KHARASCH, Intra-Science Research Foundation, Santa Monica, Calif., 1969. iv + 166 pp. 21.5 × 28.5 cm. Price \$12.00.

This book represents a compilation of a series of lectures presented by Drs. Leland J. Chinn, John S. Baran, Paul D. Klimstra, and Raphael Pappo at the University of Southern California during the fall of 1968. The authors are all research chemists with G. D. Searle and Company and considerable discussion is given to research conducted in the Searle laboratories over the past two decades. Taken in this light, the book represents informative reading for students in medicinal chemistry interested in an industrial career.

The book is not, however, a complete text describing "The Chemistry and Biochemistry of Steroids" as represented by the publishers. Only selected areas of steroid chemistry are emphasized, and often times repeated (e.g., synthesis of 19-norsteroids), and the biochemical aspects are even more limited in scope. For example, the initial chapter by Dr. Chinn represents an excellent discussion of mineralocorticoids, but little mention is made of the equally important glucocorticoids. Moreover, the chapter on conformational analysis is lucidly presented, but the section on structure-receptor interaction fails to evaluate critically the various hypotheses associated with this nebulous subject.

The chapters on biosyntheses of cholesterol and hypocholesterolemic agents by Dr. Baran are an up-to-date summary of the research in these fields. To confuse the matter, however, these chapters are followed by another given the same title as the text itself, but which deals largely with the metabolism of cholesterol. Similarly, a chapter entitled "Biological and Clinical Aspects of Estrogenic Hormones" is four pages in length and describes mainly Dr. Baran's own research with 11 β -methyl-19-norsteroids.

The chapters by Dr. Klimstra on oral contraceptives and androgenic and anabolic steroids are well-documented reviews. As pointed out by the author, however, similar reviews recently have been published in other texts.

The final two chapters are written by Dr. Raphael Pappo and pertain to a discussion of the chemistry and biology of 2-oxasteroids and total and partial synthesis of steroids. The author has contributed significantly to the former and describes in detail the chemical development of the 2-oxa isostere of methyltestosterone which is marketed as an anabolic agent under the name of Anavar. A considerable portion of the chemistry presented in this chapter describes the author's own work and has not been published elsewhere.

Thus, this book represents an interesting and easy-to-read series of lectures representing selected areas of steroid chemistry and biology. It is not, however, a text on "The Chemistry and Biochemistry of Steroids" as the title implies.

International Encyclopedia of Pharmacology and Therapeutics. Pharmacology of the Endocrine System and Related Drugs: The Neurohypophysis. Executive Editor, G. PETERS; Section Editors, H. HELLER and B. T. PICKERING. Pergamon Press Ltd., Oxford, England, 1970. x + 486 pp. 15 × 23.5 cm. Price \$16.00.

This volume I of section 41 of the *International Encyclopedia of Pharmacology and Therapeutics* is composed of 12 chapters by 19 distinguished contributors. The subject matter includes the history of neurohypophyseal research, the chemistry of the natural and synthetic neurohypophyseal hormones, their distribution and evolution in vertebrates, structural-activity relationships of the natural and synthetic hormones, and the latest theories on their storage, release, biosynthesis, and analysis in body fluids. There is also an expanded chapter on the physiological and pharmacological effects of posterior pituitary peptides and their derivatives on the kidney, uterus, and mammary gland. In addition, there are chapters on the effects of posterior pituitary hormones and their derivatives in lower vertebrates, their cellular mode of action and fate, as well as a concluding discourse on the clinical pharmacology of oxytocin and vasopressin.

Through this text which deservedly carries the term encyclopedia are extensive references to books, reviews, monographs, and original papers which easily bring the researcher up to date on the most recent data available concerning every conceivable aspect of the neurohypophysis. Appended is a complete author and subject index.

The reader is urged to spend some time studying a series of electron-micrographs which very clearly demonstrate the ultrastructural changes and the effects on hormone release of ether anesthesia, and ether-and-hemorrhage on rat and rabbit neural lobes.

One major and obvious oversight is the unintentional absence of pages 264-265, 268-269, 272-273, 276, and 277. It is hoped that the publisher can, at this time, still rectify this before the book begins to circulate widely. It is too fine a reference source to be known for its missing pages and accompanying facts. This work should be included in all medical research libraries and is recommended to all investigators interested in the most up-to-date information concerning the pharmacology and endocrinology of the posterior pituitary.

Cytotoxic Drugs in the Treatment of Cancer. Edited by EVELYN BOESEN and WALTER DAVIS. Williams & Wilkins Co., Baltimore, MD 21202, 1969. ix + 208 pp. 15 × 23 cm. Price \$12.75.

This book is aimed primarily at the physician using cytotoxic agents to control cancer; it is intended to provide a basic understanding of the biochemistry of these agents. Alkylating agents, antimetabolites, plant products such as vincristine and vinblastine, and antibiotics are first discussed historically, and nucleic acid synthesis is reviewed. A chapter about structure-activity relations in the nitrogen mustard and antimetabolite classes of compounds describes briefly the rationale behind these drugs. This chapter is followed by a review of methods of testing for anticancer activity, and an excellent discussion of the advantages and disadvantages of the methods in use today.

The remainder of the book is devoted to consideration of the clinical application of the various classes of cytotoxic agents and of individual compounds in each class. The alkylating agents (nitrogen mustards, dimethane-sulfonates, polyethyleneimines, and diepoxides) are extensively discussed, especially from a clinical standpoint. Throughout this discussion and others, rational drug therapy and the uses and limitations of cytotoxic agents are stressed. A brief chapter at the end of the book covers the use of drugs in conjunction with other methods of treatment and special techniques of administration.

This reviewer feels that the book has accomplished its stated objective of discussing the use and limitations of cytotoxic drug therapy, and that the book will be of value to the physician concerned with the clinical use of such agents. Although some areas of current research interest are omitted, notably the work being done on camptothecin, the book would be a valuable addition to a medically oriented library.

Neuropsychopharmacology and the Affective Disorders. By JOSEPH J. SCHILDKRAUT. Little, Brown and Co., Boston, MA 02106, 1970. xiv + 111 pp. 14.5 × 21.5 cm. Price \$10.50.

This book, the contents of which were originally published in the *New England Journal of Medicine*, briefly reviews the biochemical pharmacology of psychoactive drugs. The emphasis is on the findings of the past decade concerning the changes in biogenic amine metabolism produced by various psychoactive drugs.

Nursing Home Standards: A Tragic Dilemma in American Health.

By JORDAN BRAVERMAN. American Pharmaceutical Association, Washington, DC 20037, 1970. i + 75 pp. 21.5 × 27.5 cm. Price \$2.50.

This study of nursing home standards examines both state and Federal regulations relative to the construction and operation of nursing homes. Also covered are the standards which American nursing homes must meet to qualify for certification and operation under Federal Medicare and state licensure programs as well as the apparent absence of even minimum standards in some areas. Summary tables of Federal and state standards are given.

In the article titled "Essential Oil of *Anemopsis californica* Part II: Minor Constituents" (1), the following correction should be made:

On page 1215, Table II, the value under Polyester Vinyl Plasticizer, 160°, RRT, for Peak No. 2, Methyleugenol, should read 18.4 instead of 26.3.

(1) D. R. Sanvordeker and M. G. Chaubal, *J. Pharm. Sci.*, **58**, 1213(1969).

In the article titled "Two-Phase Method for the Investigation of Interphase Transport II: Experimental Aspects" (1), the following correction should be made:

On page 1332, column 2, the last line should read 10^{-5} cm.²/sec. for dinitrotoluene instead of 10^{-6} cm.²/sec.

(1) S. A. Howard, A. Suzuki, M. A. Farvar, and W. I. Higuchi, *J. Pharm. Sci.*, **58**, 1330(1969).

In the article titled "Study of Density Gradients in Certain Oil-in-Water Emulsions Using Multichannel Gamma Ray Analysis" (1), the following correction should be made:

On page 1452, under "Summary," the third line should read o/w emulsions instead of w/o emulsions.

(1) W. H. Parsons and D. L. Dondero, *J. Pharm. Sci.*, **58**, 1449 (1969).

In the article titled "Phytochemical Evaluation of Some Cantharellid Fungi" (1), the following correction should be made:

On page 1497, Structure I should be

(1) E. D. Henry and G. Sullivan, *J. Pharm. Sci.*, **58**, 1497(1969).

In the article titled "Aminosteroids" (1), the following correction should be made:

The nomenclature for Compound V of Scheme I should be: 3-aza-17 β -acetamido-6 α ,16 α -dimethyl-A-homoandrost-4 α -en-4-one.

(1) A. P. Shroff, *J. Pharm. Sci.*, **59**, 110(1970).

In the article titled "Estimation of Mean Potency and Content Uniformity of Tablets: A New Approach" (1), the following correction should be made:

On page 214, References 9 and 11, *J. Acoust. Soc. Am.* should read *J. Am. Statist. Assoc.*

(1) J. P. Comer, H. L. Breunig, D. E. Broadlick, and C. B. Sampson, *J. Pharm. Sci.*, **59**, 210(1970).

In the article titled "Constituents from *Gymnema sylvestre* Leaves V: Isolation and Preliminary Characterization of the Gymnemic Acids" (1), the following correction should be made:

On page 627, column 2, under "Comparison of Gymnemic Acids Isolated by Various Investigators," line 23, "their acids A₂ and A₃ being" should read "their acids A₂, A₃, and A₄ being."

(1) J. E. Sinsheimer, G. S. Rao, and H. M. McIlhenny, *J. Pharm. Sci.*, **59**, 622(1970).

In the article titled "Constituents from *Gymnema sylvestre* Leaves VI: Acylated Genins of the Gymnemic Acids—Isolation and Preliminary Characterization" (1), the following correction should be made:

On page 630, column 1, under *Genin G*, line 12, Calcd. for C₄₃H₆₆O₁₁ should read Calcd. for C₄₃H₆₆O₁₀.

(1) J. E. Sinsheimer and G. S. Rao, *J. Pharm. Sci.*, **59**, 629(1970).

In the article titled "Theoretical Model Studies of Drug Absorption and Transport in the Gastrointestinal Tract I" (1), the following corrections should be made:

On page 645, Eq. 16 should read:

$$\begin{aligned} (\text{H}^+)_{-h}^2 + \{K_{a,R} + K_{a,HB} + (\text{TR})_{-h} + (\text{Na}^+)_{-h}\} (\text{H}^+)_{-h}^2 + \\ \{[(\text{TR})_{-h} + K_{a,R} - (\text{TB})_{-h}] K_{a,HB} + \\ (K_{a,R} + K_{a,HB}) (\text{Na}^+)_{-h} - K_w\} (\text{H}^+)_{-h}^2 - \\ \{K_{a,R} K_{a,HB} (\text{TB})_{-h} + (K_{a,R} + K_{a,HB}) K_w - \\ K_{a,R} K_{a,HB} (\text{Na}^+)_{-h}\} (\text{H}^+)_{-h} - \\ K_{a,R} K_{a,HB} K_w = 0 \end{aligned}$$

On page 646, Eq. 17 should read:

$$\begin{aligned} \gamma (\text{H}^+)_{-0}^2 + [\beta + \gamma \eta + \alpha + \gamma (\text{Na}^+)_{-0}] (\text{H}^+)_{-0}^2 + \\ \{[\alpha + \beta] \eta - \gamma K_w - \gamma \delta + (\gamma \eta + \beta) (\text{Na}^+)_{-0}\} (\text{H}^+)_{-0}^2 - \\ \{[\beta + \gamma \eta] K_w + \beta \delta - \beta \eta (\text{Na}^+)_{-0}\} (\text{H}^+)_{-0} - \\ \beta \eta K_w = 0 \end{aligned}$$

and

$$\delta = \frac{K_{a,HB}}{D_{HB}} [D_B (\text{B}^-)_{-h} + D_{HB} (\text{HB})_{-h}]$$

On page 647, in Fig. 5, the ordinate should read *F* and *f*.

On page 650, in the caption of Fig. 10, the diffusion efficiency coefficient *T* should be replaced by *T*².

Although the equations were incorrectly stated in the article, the calculations are correct and, therefore, the conclusions drawn are unaltered.

(1) A. Suzuki, W. I. Higuchi, and N. F. H. Ho, *J. Pharm. Sci.*, **59**, 644(1970).

In the article titled "Theoretical Model Studies of Drug Absorption and Transport in the Gastrointestinal Tract II" (1), the following corrections should be made:

On page 653, Eq. 19 should read:

$$K_u = \frac{AD_{eff(1)}}{VL_1}$$

On page 655, in Fig. 4 the ordinate should read in the following ascending order: 0.85, 0.90, 0.95, 1.00.

(1) A. Suzuki, W. I. Higuchi, and N. F. H. Ho, *J. Pharm. Sci.*, **59**, 651(1970).

In the article titled "Dissolution of Slightly Soluble Powders under Sink Conditions I: Development of an Apparatus and Dissolution Studies of Salicylic Acid Powders" (1), the following corrections should be made:

On page 980, column 1, paragraphs 5 and 6 under "Apparatus," the propeller dimensions of 1.9 cm., 2.6 cm., and 3.0 cm. should read 3.8 cm., 5.2 cm., and 6.0 cm., respectively.

(1) I. Ullah and D. E. Cadwallader, *J. Pharm. Sci.*, **59**, 979(1970).
