REVIEW ARTICLE

Recent Trends in the Synthesis of Linear Peptides

A. KAPOOR

Keyphrases ☐ Peptides, linear—synthesis trends ☐ Amino protecting groups—peptide synthesis ☐ Carboxyl protection—peptide synthesis ☐ Group protection, amino acids—peptide synthesis ☐ Bond formation—peptides

Synthetic peptides with an ordered sequence of amino acids are of great interest as biologically active substances, as test materials for probing the details of biochemical processes, and as models with which to study the chemical and physical properties of proteins. The synthesis of peptides is also of great importance to confirm structures deduced for naturally occurring peptides and fragments obtained from protein hydrolysates.

Insulin, which produces hypoglycemia, is perhaps one of the most frequently used peptide hormones in medicine. Other peptide hormones of therapeutic interest are adrenocorticotrophic hormone (ACTH), oxytocin, vasopressin, melanocyte-stimulating hormones (α - and β -MSH), angiotensin, bradykinin, glucagon, *etc.* Another important class of biologically active peptides includes the antibiotics such as tyrocidins, gramicidin, bacitracin, valinomycin, polymyxin, and actinomycin-D which are produced by lower organisms such as bacteria and fungi.

Since the turn of this century, synthetic peptide chemistry has undergone periods of varying activity. After the excellent contributions of Fischer (1), who may well be considered as the father of the present day concept of step-by-step synthesis of peptides, a rather slow

period of development followed. The next breakthrough came with the introduction of the carbobenzyloxy protecting group in 1932 by Bergmann (2) who, with his collaborators, used this protecting group in combination with acid chloride and azide methods to synthesize a wide range of relatively small peptides which were used for the studies of the substrate specificity of enzymes. The next major triumph of synthetic peptide chemistry was the synthesis of the posterior pituitary hormone in 1953 by du Vigneaud *et al.* (3). This opened a new era. The rapid advances and continuous refinement in techniques of isolation, purification, sequence determination of the peptides and proteins, and availability of a rich choice of protecting and coupling methods led to the synthesis of a large number of pure peptides with intricate structures. The synthesis of peptide hormones such as angiotensin (4), bradykinin (5), eledoisin (6), α -MSH (7), β -MSH (8), gastrin (9), ACTH (10), insulin (11), secretin (12), glucagon (13), thyrocalcitonin (14), and many others is a remarkable achievement on the part of peptide chemists. In addition to commercial synthesis of corticotropin, angiotensin, and many other hormones, a number of hormone analogs with more potency than the natural hormones have been synthesized (15, 16).

The tremendous growth of interest in the synthesis of peptides is well reflected in ever increasing publications in this field. So rich is the literature concerning the synthesis of peptides that it is barely possible to include every development in a review article of this size. Fortunately, there have been a number of timely reviews and books in this field which have provided peptide researchers with necessary information. An excellent review article by Fruton (17) marked the begin-

ning of monographs in the field of peptides. This was followed by a number of reviews by Wieland (18–22) and many others (23–29). “Chemistry of Amino Acids” in three volumes by Greenstein and Winitz (30), published in 1961, “Peptides” in two volumes by Schroder and Lubke (31), in 1965, and “Peptide Synthesis” by Bodanszky and Ondetti (32), in 1966, provide a comprehensive literature survey of the progress in the synthesis of peptides. The scope of this review therefore will be limited to a brief survey of the existing methods frequently used in peptide synthesis. The contributions of modified and new methods will be discussed in some detail along with some of the problems associated with their use in the synthesis of peptides.

In essence, peptide and protein molecules consist of amino acids which are linked to each other by amide bonds to form what may be called “peptide chains.” The amide bond formation involves the elimination of water; this can be brought about either by elevated temperatures, or by suitable activation of carboxyl or amino groups (Scheme I).

Elevated temperature peptide synthesis has not been the choice approach because of extensive racemization. However, the recent work of Fox, who has successfully used thermal condensation, will be briefly discussed at a later stage.

The synthesis of pure peptides requires the protection of all functional groups not expected to participate in the desired reaction. The carboxyl activation which is most frequently used in the formation of the peptide bond involves the introduction of a negative group, X, which will augment the electrophilic character of the carboxyl carbon atom. This facilitates the attack of a nucleophilic amino group to form the peptide bond (Scheme II).

The peptide bond formation through the activation of the amino group has met with relatively less success; however, suitable selection of esters to block the carboxyl of amino acids may make them better reactive partners. For example, the positive inductive effect of tertiary butyl esters would make the free electron pair of amino nitrogen more reactive, when compared

to methyl, ethyl, or benzyl esters. In general, a peptide synthesis can be accomplished with the proper selection of (a) amino or *N*-protecting groups; (b) carboxyl or *C*-protecting groups; and (c) carboxyl-activating groups. When the incorporation of polyfunctional amino acids is required in the peptide chain, the ω -groups, which may give rise to side reactions, must also be protected by suitable blocking groups. The protecting groups must be readily and selectively removed during or at the end of the synthesis.

AMINO-PROTECTING GROUPS

A detailed review on the most important amino protecting groups was recently published by Boissonnas (33).

Benzyloxycarbonyl and Related Groups—The carbobenzyloxy or more appropriately the benzyloxycarbonyl (Z) group which was introduced in 1932 by Bergmann and Zervas (2), has been and still is responsible for the major work done in the peptide synthesis field. This versatile group can be conveniently introduced by the treatment of benzyloxycarbonyl chloride with the corresponding amino acid in aqueous alkaline solution. These derivatives are stable compounds and the protecting group can be easily removed by a variety of methods. The most frequently used conditions for the cleavage of benzyloxycarbonyl group are the hydrogenolysis (2) and the treatment of hydrobromic acid and acetic acid (34). The other deprotecting conditions which may be employed are reduction with sodium in liquid ammonia (35) and hydrogen chloride in ethanol (36). Bartrop and Schofield (37) have reported another approach for the removal of this protecting group by means of UV irradiation. Photochemical solvolysis is considerably enhanced by *m*-methoxyl substitution in the benzene ring. The use of 3,5-dimethoxybenzyloxycarbonyl as an amino-protecting group and the deprotection by irradiation of this group from several amino acids and a dipeptide derivative was reported by Chamberlin (38) (Scheme III).

The removal of the benzyloxycarbonyl group by hydrobromic acid probably follows the protonation of the carbonyl oxygen as the first step followed by fission of the benzyl-oxygen bond. The carbamic acid intermediates so formed undergo decarboxylation with the liberation of the amino group (39). The benzyloxycarbonyl group is fairly stable to alkaline conditions required for the removal of methyl, ethyl, or the benzyl

Scheme IV

esters which are frequently used for carboxyl protection. However, the formation of urea or hydantoin derivatives may be encountered when the *N*-benzyloxycarbonyl peptides, particularly in the peptides where glycine is next to the amino acid which is protected by the benzyloxycarbonyl group, are treated with alkali (40). The formation of *N*-carboxy anhydrides (Leuch's anhydride) is another serious limitation with the use of benzyloxycarbonyl groups particularly when they are used in combination with acid chlorides (41). The formation of Leuch's anhydride *via* the carbamic acid derivatives was recently confirmed when the C-activated *N*-benzyloxycarbonyl amino acids were subjected to catalytic hydrogenation under anhydrous conditions (42) (Scheme IV).

Scheme V

A number of substituted benzyloxycarbonyl and other urethan-type protecting groups have been used frequently for amino protection. The electron-releasing substituents in the benzyl group normally increase the rate of cleavage while the electron-attracting groups increase their stability towards acids. The substituted benzyloxycarbonyl groups which have been successfully used in the synthesis of peptides include *p*-bromo (43), *p*-chloro (44), *p*-nitro (45), and *p*-methoxy (46) derivatives. In a comparative study of different *p*-substituted benzyloxycarbonyl glycine ethyl esters, it was observed that the *p*-methoxy derivatives were cleaved five to ten times faster than the other derivatives on treatment with hydrogen bromide in acetic acid (47). β -Phenylazo and *p*-(*p*'-methoxyphenylazo)benzyloxycarbonyl derivatives (48) which afford the colored

compounds have been used relatively less frequently. Sieber and Iselin (49) suggested the use of 2-(*p*-diphenyl)-isopropoxyxycarbonyl (Dpoc) group for amino protection. This group has an interesting feature; it can be removed under mild acid condition. The Dpoc group can be easily introduced into amino acids by reacting either the mixed carbonate or the azide of Dpoc with esters or salts of amino acids (Scheme V).

Among the modified urethan derivatives, *tert*-butyloxycarbonyl (*t*-BOC) has come to be a considerably important amino-protecting group (46, 50). The removal of this protecting group is accomplished with considerable ease with 90% trifluoroacetic acid. While this group is reasonably sensitive to acidic conditions, it can still be used in combination with even more acid-sensitive groups such as trityl group. The advantage of this fact has been applied in planning the synthesis of longer peptide chains. *tert*-BOC amino acids can be prepared by using *tert*-butylazidoformate (51), *tert*-butyl-*p*-nitrophenyl carbonate (52), *tert*-butyl-penta-chlorophenyl carbonate (53), or *tert*-butyl fluoroformate (54) as condensing agents.

The use of *tert*-amtyloxycarbonyl (*t*-AOC) group for amino protection has been suggested by Sakakibara (55). This protecting group has no particular advantage over the *t*-BOC group with the exception that *t*-AOC-protected derivatives are relatively less soluble in water and can be easily extracted with organic solvents from the aqueous reaction media. Deprotection of the *t*-AOC group can be achieved under the same conditions used for the removal of the *t*-BOC group.

p-Toluenesulfonyl (Tosyl) Group $\left(\text{CH}_3-\text{C}_6\text{H}_4-\text{SO}_2 \right)-$

For a period of time this group enjoyed considerable popularity and even today affords a good protection for ω -amino functions, particularly in the case of lysine (56). The main limitations for the tosyl-protecting group is that α -tosyl amino acids generally cannot be coupled through the mixed anhydride method or through their active esters (57). Usually the acid chloride (58), azide (59), and tetra-ethyl pyrophosphite (60) methods have been used for the synthesis of peptides with α -tosyl protection. The ready decomposition of tosyl amino acid chlorides in alkaline solutions to toluenesulfonamide, probably because of the high reactivity of amide nitrogen, has been reported by Beecham (61) (Scheme VI).

The tosyl group is remarkably stable to the commonly

used methods for the cleavage of other protecting groups. The method of choice for the removal of the tosyl group is reduction with sodium in liquid ammonia, which was suggested by du Vigneaud (62). The mechanism of deprotection which was reinvestigated by Kovacs (63) appears to proceed by the formation of sulfite and toluene instead of thiocresol as previously reported. There are recent conflicting reports which indicate that during reduction, in addition to the removal of tosyl group, cleavage of the peptide chain between certain amino acids is also possible (64, 65). In the case of carboxyl-activated δ -tosyl ornithine derivatives, the easy six-membered lactam formation poses an additional problem in the use of tosyl group (66).

Trifluoroacetyl (TFA) Group (CF_3CO)—This group which was introduced by Weygand (67) has a remarkable advantage in that it can be cleaved by very mild alkali hydrolysis; however, a number of problems are associated with the use of this group. Some of the serious factors which have contributed to the relative lack of interest in this protecting group are (a) possibilities of racemization both at the amino protection and at the peptide bond formation stage; (b) problems in the removal of this group from larger peptides; and (c) difficulties encountered in the introduction of TFA group, particularly in serine and threonine (Scheme VII).

Scheme VII

Because of high vapor pressures, TFA-protected amino acid and peptide esters can be easily sublimed in high vacuum (68). This offers new applications for the quantitative determination of amino acids in protein hydrolysates. The gas chromatographic separation of diastereomeric TFA dipeptide esters provides a useful tool in determining the degree of racemization during peptide synthesis (69).

Triphenylmethyl (Trityl) and Related Groups—

The trityl group is peculiar, in that while it is very easily removed from a peptide, it is quite difficult to introduce this group to the amino acids. Tritylation which is normally carried out with trityl chloride proceeds in rather low yields; however, the yields may be improved to a certain extent by using diethylamine instead of triethylamine as an acid acceptor in the reaction (70). The easiest tritylation is that of amino acid esters. However, the saponification of the ester which necessarily follows offers serious problems. The lack of hydrolysis may well be attributed to the bulky trityl group. The tritylglycine ethyl ester and the

tritylalanine methyl ester are perhaps the only esters which can be saponified at room temperature under normal conditions (70). This may be explained by the lack of an elaborate side chain in these amino acids which would permit the nucleophilic attack by the hydroxyl group. The trityl group can be removed with acetic acid even in the presence of *tert*-butoxycarbonyl group and this selective detritylation was used by Schwyzler for the synthesis of an ACTH sequence (71). The trityl group can also be removed by catalytic hydrogenation. Under controlled conditions of hydrogenation, benzyl esters may be removed in preference to trityl groups as in the case of trityl amino acid benzyl esters (72). This procedure may find use in the preparation of trityl amino acids.

Benzyl and dibenzyl protections for the amino group have met with little success because of their stability in acids and considerable resistance to catalytic hydrogenation. The benzhydryl group, which has been so far used only for the protection of sulfhydryl and carboxyl groups, holds good promise for amino protection as the properties of this group are between those of benzyl and trityl groups.

Phthalyl Group—This group which was introduced into peptide synthesis in the late forties (73, 74) until recently did not enjoy popularity because of difficulties encountered during phthalylation. However with the elegant conditions introduced by Nefkens (75), this protecting group is gaining considerable attention. Phthalylation, according to Nefkens's procedure, is carried out using *N*-ethoxycarbonylphthalimide in dilute sodium carbonate solution. The mechanism suggested for the reaction assumes the opening of the five-membered ring and subsequent formation of the phthalyl-amino acid with the elimination of urethan (Scheme VIII).

Scheme VIII

The phthalyl group has recently been used for the selective protection of the ω -amino group of lysine (72) and of ornithine (76). The deprotection of this group is achieved only by hydrazinolysis. Since the phthalyl group is not stable to alkali, the ester group used for

carboxyl protection in the synthesis of peptides with phthalyl protection must be hydrolyzed under acidic conditions. A combination of phthalyl and *tert*-butyl groups is quite suitable. A useful method for the introduction of phthalyl protection with ethoxyacetylene and phthalic acid was reported recently (77). *N*-protected derivatives were prepared from amino acids or their esters, both in anhydrous and in aqueous solution.

Arylsulfonyl and Related Groups—These groups were introduced by Zervas *et al.* (78) and provide an excellent method for amino protection. Tritylsulfonyl and arylsulfonyl amino acids, with electron-withdrawing substituents in the ring are rapidly cleaved by mild acid treatment. The *o*-nitrophenylsulfonyl (NPS) group, which has been the group of choice, is selectively removed when the *tert*-butyl ester is present. This group can be also removed by Raney nickel (79) and this provides a useful approach to avoid the partial cleavage of the other acid-labile groups present. However, the benzyloxycarbonyl group is removed under the same conditions. Raney-nickel cleavage of NPS group fails when applied to sulfur-containing peptides. Other useful deprotecting agents for the NPS group which were suggested by the Scoffone laboratories are thioglycolic acid and thiophenol (80). A disulfide is formed in addition to the free amino acid or peptide (Scheme IX).

Scheme IX

Various other reagents have been reported for the cleavage of the NPS group (81). The NPS derivatives of amino acids generally are not easily obtainable in a crystalline form, and their purification and characterization is often carried out by preparing the corresponding dicyclohexylammonium salts. Fontana *et al.* (82) suggested the use of the 2,4-dinitrophenylsulfonyl (DNPS) group which gave easily crystallizable compounds with a higher melting point when compared with the corresponding NPS derivatives. The DNPS group can be cleaved with the same conditions as those used for the NPS group. When the NPS or DNPS are cleaved with acid from tryptophan peptides, the sulfonyl halide formed during the removal step reacts quantitatively at the 2-position of the indole ring (80). This reaction mechanism has been discussed by Wunsch (83) (Scheme X).

The use of sulfonyl halides has been successfully extended as modifying reagents for polypeptides and proteins. Tryptophan was converted to 2-hydroxytryptophan through an intermediate 2-thio-aryl-tryptophan derivative (84). When the *N*-*o*-nitrophenylsulfonyl

Scheme X

group is removed from cysteine peptides bearing free thiol groups by means of hydrogen chloride in methanol or in nonpolar solvents, an *N* → *S* transfer of the NPS group takes place to give the corresponding *S*-NPS derivative (85) (Scheme XI).

Scheme XI

Therefore, during the preparation of cysteine peptides using *N*-NPS derivatives of amino acids and *S*-protected cysteines, the removal of NPS-group must be done either in *S*-protected cysteine peptides or in the oxidized *-S-S-*peptides, *i.e.*, in the cystine peptides.

Tritylsulfonyl amino acids have a remarkable advantage over trityl amino acids in that they can be coupled conveniently by the mixed anhydride or *p*-nitrophenyl ester methods. Trityl amino acids do not

Scheme XII

undergo coupling with these methods because of steric hindrance.

Schiff Bases—Schiff bases are normally quite unstable and cannot be used as protecting groups. However, Schiff bases which can be stabilized by hydrogen bonds by the use of 1,3-dicarbonyl compounds (86) or by hydroxy derivatives (87) provide suitable protecting groups in the synthesis of peptides (Scheme XII).

CARBOXYL PROTECTION

The primary consideration for the substitution of the carboxyl group is the release of the amino acid from its zwitterion state rather than actual protection. The protecting groups most commonly used have been limited to methyl, ethyl, benzyl, *tert*-butyl, and *p*-methoxybenzyl esters. Several new carboxyl groups have come to the limelight in recent years.

Methyl and Ethyl Esters—These esters are normally prepared by introducing dry hydrogen chloride into a suspension of the amino acid in absolute methanol or ethanol. The corresponding amino acid esters are obtained as hydrochlorides. Another convenient approach is the use of thionyl chloride (88) or acetyl chloride (89). Methyl or ethyl esters are removed during or after the synthesis of peptides by alkaline hydrolysis which generally produces a number of problems such as racemization, transpeptidation, and formation of urea or hydantoin derivatives. Alkali-labile *N*-protecting groups, such as phthaloyl, have to be excluded when *C*-protection is carried out by methyl or ethyl esters. Cleavage of sensitive amide bonds is another possibility when alkali is used for the removal of these esters. Removal of methyl or ethyl *C*-protection becomes more difficult as the number of amino acids increase in the peptide chains. Dilute hydrochloric acid in aqueous acetone (73) and lithium halides in pyridine (90) have been recommended as alternative methods for the removal of the methyl or ethyl *C*-protection.

Benzyl Esters—The main advantage of benzyl esters over methyl or ethyl esters is their easy removal by hydrogenolysis. These esters can be prepared in satisfactory yields by using other catalysts rather than hydrochloric acid. Polyphosphoric acid (91), *p*-toluenesulfonic acid (92), and benzene sulfonic acid (93) have been successfully used for benzylation. Water formed during the reaction is removed by azeotropic distillation. The catalytic hydrogenation of benzyl esters in ethanol may be accompanied by transesterification and formation of the ethyl ester. This can be prevented by the use of *tert*-butanol as solvent (94). Benzyl esters cannot be cleaved selectively by hydrogenation in the presence of a benzyloxycarbonyl group; however, they may be hydrogenated selectively in the presence of trityl groups. Benzyl esters are removable by hydrogen bromide and by sodium in liquid ammonia. Benzyloxycarbonyl groups in the presence of these esters may be selectively removed by controlled treatment with hydrogen bromide in glacial acetic acid (95) or in nitromethane (96). Catalytic hydrogenation of benzyl esters in large peptides is generally quite difficult.

***p*-Nitrobenzyl Esters**—These esters which can be prepared by the modification of esterification methods

(97) used for the preparation of benzyl esters have a definite advantage in that they are stable to hydrogen bromide-acetic acid reagent; therefore, these esters allow the selective removal of the benzyloxycarbonyl group. They are removed easily by hydrogenolysis. The derivatives of *p*-nitrobenzyl esters are generally higher melting compounds and can be easily crystallized. Another significant advantage is the α -esterification when the benzyloxycarbonyl-aspartic anhydride is treated with *p*-nitro benzyl alcohol under anhydrous conditions (98).

***p*-Methoxybenzyl Esters**—*p*-Methoxybenzyl esters which were first reported by Weygand and Hunger (99) have not gained great popularity mainly because of the difficulties encountered during their preparation. However, Stewart (100) has suggested a convenient method for the preparation of *p*-methoxybenzyl esters by imidazole-promoted condensation of the corresponding *p*-nitrophenyl esters with *p*-methoxybenzyl alcohol. Since these esters are more sensitive to acid reagents, their future use as carboxyl protecting agents seems to be imminent.

Recently, Weygand *et al.* (101) reported an extensive study on the kinetics of different methoxy-substituted benzyl esters and found 2,4-dimethoxy and 2,4,6-trimethoxy benzyl esters as suitable protecting groups for amides such as asparagine and glutamine. These esters are stable to catalytic hydrogenation and methanolic hydrochloric acid, but can be conveniently removed by trifluoroacetic acid.

Methyl-Substituted Benzyl Esters—The use of 2,4,6-trimethylbenzyl and pentamethylbenzyl groups for carboxy protection was recently reported by Stewart (102). The advantage of these esters over benzyl esters is their rapid cleavage by hydrogen bromide in acetic acid under conditions which result in complete removal of the benzyloxycarbonyl group.

The introduction of these esters has been a significant contribution in the synthesis of peptides (103). They are cleaved with extreme ease by acid reagents probably by the formation of the carbonium ion. The free *tert*-butyl esters of most amino acids are stable and distillable liquids, and normally do not undergo self-condensation to form diketopiperazine derivatives. They are very stable to hydrogenation and less sensitive to alkali treatment. These esters have been particularly useful when the incorporation of monoamino dicarboxylic acids is desired in the peptide chains. Among the methods for their removal, the treatment with trifluoroacetic acid is perhaps most suitable (104).

β -Methylthioethyl Esters—The use of β -methylthioethyl esters for the protection of carboxyl group is a novel approach which was suggested by Rydon (105). Their utility in the synthesis of peptides is based on the observations that the meththiodides and sulfones derived from β -methylthioethyl esters of amino acids and peptides are split to the parent carboxylic acids under extremely mild alkaline conditions. In the initial reports, their removal was suggested by first converting

these esters into the meththiodides by the action of methyl iodide, and subsequent treatment of the meththiodides with aqueous alkali solution at room temperature. The free carboxylic acid is regenerated along with the formation of dimethylvinylsulfoniumiodide. The above method for deprotection failed with a series of *N*-*tert*-butoxycarbonylglutamic acid peptides in which the side chain carboxyl group was protected as benzyl ester because of contamination with considerable amounts of side products, which led to difficulties during purification. In a recent communication, Rydon (106) has proposed a new method for the removal of these esters. The new approach involves the oxidation of methylthioethyl esters with ammonium molybdate to the corresponding sulfones which, in turn, can be readily split at room temperature in mild alkaline solutions (Scheme XIII).

Amides and Substituted Hydrazides—The hydrazide group itself is not suitable for carboxyl protection because an amino group cannot be acylated selectively in its presence. The hydrazides used are therefore blocked with suitable amino protecting groups in order to prevent the side reactions (107, 108). These include benzyloxycarbonyl, *tert*-butoxycarbonyl, and trityl hydrazides. The cleavage of hydrazide bond to form the free acid is not possible; therefore, this type of carboxyl protection is suitable only for the synthesis of intermediates which can be converted into reactive derivatives such as azides.

Phthalimidomethyl Esters—This carboxyl-protecting group introduced by Neffkens (109) has an attractive feature in that it is stable to catalytic hydrogenation, but can be removed under a number of conditions such as the following: hydrogen chloride in organic solvents, diethylamine in ethanol, dilute aqueous sodium hydroxide, and hydrazine.

Diphenylmethyl Esters (Benzhydryl)—Significant progress was made in the laboratories of Zervas (110),

Fruton (111), and Hiskey (112) by the introduction of benzhydryl esters. This group can be conveniently removed by hydrogen chloride (or hydrogen bromide) in nonpolar solvents or by hydrogenolysis. With the introduction of NPS amino-protecting groups, the use of these esters is guaranteed a secure place for carboxyl protection in the synthesis of peptides. The NPS group can be selectively removed in the presence of the benzhydryl group (113) (Scheme XIV).

4-(Methylthio)phenyl Esters (MTP)—This ester for carboxyl protection (115) may be considered as an extension of Rydon's approach (105). The interesting feature of this ester is that it can be directly converted by oxidation to the sulfoxide, 4-(methylsulfinyl)phenyl ester, and further oxidation of the sulfoxide leads to the formation of the sulfone, 4-(methylsulfonyl)phenyl active ester, which can be used for coupling in the synthesis of peptides (Scheme XV).

method of blocking the carboxyl group with 4-picolyl esters was recently suggested from the laboratories of Young (116). These esters, in addition to being good protecting groups, also provide a basic "handle" when incorporated into the C-terminal residue and facilitate the isolation of the growing peptide after each coupling step. The 4-picolyl esters at the termination of the synthesis can be removed by catalytic hydrogenation or by electrolytic reduction. The usefulness of this procedure for the lengthening of the peptide chain from C-

terminal residues of amino acid was demonstrated by the synthesis of Val⁵-Angiotensin II.

A related method using *p*-dimethylazobenzyl esters has also been reported (117).

Salt Formation—The protection of the carboxyl group by salt formation represents the least elaborate approach. In order to avoid protonation of the amino group in amino acids, a suitably strong base such as sodium hydroxide or organic bases such as triethylamine, tributylamine, or dicyclohexylamine may be used. The relative lack of success of this approach is due to low yields and the difficulties encountered during the purification of the reaction products. However, recently a number of active esters of *N*-protected amino acids have been used successfully for coupling with amino acids and peptides that were *C*-protected by suitable salt formation (118, 119).

PROTECTION OF ω -GROUPS IN THE AMINO ACIDS

Excellent surveys enumerating the masking of ω -groups during the synthesis of peptides have been reported (31, 32).

The selective formation of α -esters by the ring opening of the *N*-benzyloxycarbonyl glutamic anhydride by the corresponding alcohols was indeed a big contribution by Gibian and Klieger (120). The selective ring opening to form α -esters in the case of *N*-protected aspartic anhydride is relatively more difficult; however, the reaction of *p*-nitrobenzyl alcohol with *N*-benzyloxycarbonyl aspartic anhydride usually results in the formation of α -*p*-nitrobenzyl ester (121). β -Carboxyl can then be protected by a tertiary butyl ester. Another very useful approach for selective protection of carboxyl groups of glutamic acid by diphenylmethyl and phenacyl esters has been suggested by Zervas (114).

Serine and threonine can be incorporated in the peptide chain with their free hydroxy groups; however, in order to limit any possibility of side reactions it is advantageous to suitably mask the hydroxyl group.

A number of derivatives with suitable protection for the hydroxyl groups of serine and threonine have been reported (32). Among the most promising of the masking groups for the hydroxy function of serine and threonine is the 2,2,2-trifluoro-1-benzyloxycarbonylaminoethyl (Z-TF) group suggested by Weygand. This group can be cleaved by catalytic hydrogenation or with

hydrogen bromide in acetic acid. A very useful combination of this hydroxyl-protecting group with *p*-methoxybenzyloxycarbonyl and tertiary butyloxycarbonyl as amino protection has been suggested (122).

The weakly basic imidazole ring in the side chain of histidine poses a number of problems and it is desirable to provide suitable protection for the imidazole ring in the synthesis of peptides incorporating histidine. Benzyl (123), benzyloxycarbonyl (124), and trityl (125) groups for imidazole protection have been successfully used in combination with a variety of amino-protecting groups for the synthesis of histidine peptides. Two very attractive protecting groups, 2,2,2-trifluoro-1-benzyloxycarbonylaminoethyl (Z-TF) and 2,2,2-trifluoro-1-*tert*-butyloxycarbonylaminoethyl (BOC-TF) for the imino group of histidine, appear to be of particular interest (126). The first-mentioned protecting group (Z-TF) can be removed by catalytic hydrogenation while the latter (BOC-TF), which is stable to hydrogenation, can be conveniently cleaved with trifluoroacetic acid. A combination of these groups with pentachlorophenyl active esters for lengthening the peptide chains and for the synthesis of sequential polypeptides incorporating histidine has shown promising results in the author's laboratories. The use of adamantyloxycarbonyl (AdOC) group was suggested for amino protection (127) and this group has been successfully employed by Wunsch (13) for histidine protection during the synthesis of glucagon.

Arginine, which contains a guanidine group of an unusually basic nature, can be incorporated if suitable protonation is available. In order to reduce the basic character of the guanidine group, the classical approach is to convert this group into the nitroguanidine derivatives. Zervas has used the tribenzyloxycarbonyl and tritrityl derivatives of arginine (128) in the synthesis of peptides. It is interesting to observe that one acyl group, the ω -benzyloxycarbonyl group, is removable by hydrogen bromide in acetic acid. However, all three benzyloxycarbonyl groups are labile to hydrogenolysis. The α -trityl group forms tritrityl arginine which can also be selectively removed, thereby offering a useful ditrityl arginine derivative for lengthening the peptide chain from *C*-terminal residue. The trityl group in the guanido moiety is exceptionally stable to hydrogenolysis and can be cleaved only by hydrogen bromide in acetic acid. The idea of using derivatives of ornithine throughout the synthesis and to convert ornithine to arginine by guanylation at a suitable stage was proposed by Fruton (129) and was successfully applied by Bodanszky (130) for the synthesis of biologically active peptides. The tosyl group has also been used for the protection of

Scheme XVI

the guanido group in arginine. While the α -amino tosyl group can be conveniently removed by electrolytic reduction, the removal of tosyl protection from ω -tosyl arginine under the same conditions is relatively difficult, particularly in longer peptides. In addition to nitration, protonation, tosylation, and other methods, the use of the tetrachloroisopropoxyphthaloyl (TIP) group and the *p*-nitrobenzyloxycarbonyl (NZ) group for the protection of the guanido group in arginine has been suggested (131, 132). An interesting method for the removal of the nitro or *p*-nitrobenzyloxycarbonyl guanido-protecting groups by acidic zinc reduction has been suggested by Pless and Guttmann (133) even in larger peptides. This method leaves the α -amino benzyloxycarbonyl group intact (Scheme XVI).

The sulfhydryl group in cysteine is highly reactive and must be afforded suitable protection. The *S*-benzyl group which is cleaved by sodium in liquid ammonia was suggested by du Vigneaud (134) and has remained the group of choice. However, in order to provide the sulfhydryl-protecting groups which can be removed under relatively milder conditions, an extensive search was undertaken in various laboratories. A number of *SH*-protecting groups such as acyl, trityl, benzhydryl, benzyloxycarbonyl, and *p*-methoxybenzyloxycarbonyl have been suggested. All these groups can be selectively removed under mild conditions without affecting sensitive parts of the molecule and especially the already existing *-S-S-*bridge. Another approach is the incorporation of *o*-tosyl serine (135) or β -chloroalanine (136) residues into a peptide chain and their subsequent conversion into *S*-protected cysteine residues by nucleophilic displacement reactions. The use of the acetamidomethyl group for the protection of the *SH* group of cysteine has been suggested recently (137). This protecting group is stable under conditions which cause the removal of commonly employed acid-labile substituents, but can be easily cleaved with two equivalents of Hg at pH 4.

A series of *tert*-arylalkyl groups such as 1-phenylcyclohexyl (PCH), for *SH* protection of cysteine were reported by König (138). Because of the stability of these groups toward HCl/acetic acid, HBr/acetic acid and hydrazide, they allow the selective removal of *N*-benzyloxycarbonyl, *N*-*tert*-butyloxycarbonyl, and *N*-phthalyl groups. Trifluoroacetic acid is the reagent of choice for the cleavage of PCH and related protecting groups (Scheme XVII).

FORMATION OF THE PEPTIDE BOND

Since the turn of this century, a number of classical methods joining the amino acids through amide bonds have been developed for the formation of well defined peptides. In a broad sense, a peptide bond may be formed either by the activation of an amino group or by the activation of a carboxyl group. The amino group is capable of amide formation by way of its free electron pair. The nucleophilic character of the amino group would be expected to increase with the substitution of electron-releasing groups, thereby allowing easy formation of the amide bond. This approach has not been fully explored. However, a number of reactive

Scheme XVII

derivatives of the amines have been reported for the formation of peptide bonds. The actual coupling may be visualized to proceed through the activated carboxyl component. For example, isocyanates, which are prepared from amino ester hydrochlorides and phosgene as reactive amino derivatives (139), form a peptide bond with *N*-protected amino acids or peptides through a mixed anhydride of a carbamic acid (Scheme XVIII).

Scheme XVIII

Other methods based on reactive amine derivatives which have been used in the synthesis of peptides include phosphazo (140), phosphorus acid esters (141), arsenious acid esters (142), and phosphorus pentoxide (143). While these methods have a definite place in peptide chemistry, the bulk of peptide synthesis involves the peptide bond formation through the activation of the carboxyl group.

Scheme XIX

Peptide Synthesis by Activation of the Carboxyl Group—Mixed Anhydride Methods—The actual application of the mixed anhydride method in the synthesis of peptides was made in the laboratories of Wieland (144). One of the main considerations in the selection of anhydride-forming acid, or the “partner” acid as more appropriately termed by Bodanszky and Ondetti (32), is the presence of an electron-releasing structure.

The acids with low dissociation constants and long, branched aliphatic chains are more useful and lead to selective formation of peptide bonds. Introduction of carbonic acid-half ester-half chlorides, where the alkoxy group provides the electrons, is a tremendous improvement in mixed anhydride method. Ethylchloroformate (145) and isobutylchloroformate (146) are the reagents of choice for the formation of mixed anhydrides of *N*-protected amino acids and peptides (Scheme XX).

N-Acyl amino acids, after activation with isobutylchloroformate, are used for the coupling reaction without the isolation of the active intermediate; however Anderson (148) has reported the isolation of *N*-phthalyl alanine mixed anhydride with isobutyl carbonic acid. This is perhaps the first time that a reactive derivative of a mixed anhydride has been isolated. In the author's experience, a combination of modified mixed anhydride and pentachlorophenyl active ester methods provides a useful approach for lengthening the peptide chains of *N*-protected, *C*-activated peptide units from *C*-terminal residues of amino acids (149). The synthesis of these peptide units without any significant racemization is of considerable importance for the preparation of sequential polypeptides. Another approach for the preparation of mixed anhydrides is by the use of diphenylphosphoric acid (150) which is particularly useful for the activation of hindered trityl

Azide Method—Despite a number of disadvantages, this method, which was introduced by Curtius (151), is very highly regarded in the synthesis of peptides, mainly because racemization during the coupling reaction is not observed. The azides are unstable compounds which are used without isolation and are prepared *via* the crystalline hydrazides of *N*-protected amino acid or peptide esters.

Scheme XXI

Carbodiimides—Among the most frequently used carbodiimides is the *N,N'*-dicyclohexylcarbodiimide which was introduced by Sheehan and Hess (155). This method is perhaps the most popular method of peptide synthesis and the mechanism of possible routes of acylation with the aid of carbodiimides has been discussed in detail by Khorana (156). When a dialkylcarbodiimide is allowed to react with a carboxyl group, an *o*-acylurea is first formed which in turn reacts readily with nucleophiles. One of the disadvantages of this method is the rearrangement of the reactive intermediate *o*-acylurea to a more stable *N*-acylurea which is only slightly susceptible to reactions with nucleophiles. Another disadvantage is the difficulty of the removal of *N,N'*-dicyclohexylurea which is formed as a by-product. To meet this difficulty, dialkylcarbodiimides such as *N*-ethyl, *N'*-(γ -dimethylaminopropyl) carbodiimide which yield water soluble ureas have been devised (157). The use of insoluble polycarbodiimides such as polyhexamethylene carbodiimide, which allows easy purification of reaction products, has been suggested by Frankel (158) (Scheme XXII).

The use of an interesting coupling reagent, ethoxyacetylene, was reported by Arens (159). The coupling

coupling reagent. The actual activation proceeds *via* the formation of the mixed anhydride which is preceded by the displacement of the 2-ethoxy substituent by carboxylic acids. Slow formation but rapid consumption of the active derivative should minimize the side reactions (Scheme XXX).

Reactive *N*-acyl Derivatives—The transfer of acyl residues from derivatives of *N*^{im}-acylhistidine to amino groups, and thus the possibility of carboxyl activation by imidazolid formation, has been described by several authors (168). Sheehan found that the intramolecular amide (active lactam) of *N*- α -*p*-nitrobenzyloxycarbonyl histidine reacts with benzylamine to form *N*- α -*p*-nitrobenzyloxycarbonyl histidine benzylamide (169). This, along with the contributions from Staab (170), Anderson (171), and Beyerman (172), have led to a number of useful coupling reagents such as *N,N'*-carbonyldiimidazole, thionyl diimidazole, and carbonyl dipyrazole. The reaction proceeds through the formation of acyl derivatives which couple with the amino group to form the peptide bond. The liberated imidazole has a beneficial catalytic effect on the rate of the reaction (Scheme XXXI).

Active Esters—The synthesis of peptides *via* the aminolysis of activated esters was pioneered with the

Scheme XXIX

Scheme XXX

use of phenylthiol esters by Wieland (173). One of the main advantages with the use of active esters is the possibility of isolation and purification of the reactive intermediates. These esters have relatively less energy when compared to other activating methods such as mixed anhydride or DCC, and therefore normally do not acylate weaker nucleophiles such as the OH group in hydroxy or phenolic amino acids. A large number of methyl esters with different negative substituents were examined by Schwyzer, and as a result, cyanomethyl esters were introduced in the synthesis of peptides (174). Bodanszky embarked on an elaborate study of phenyl esters, in which the already pronounced electron attraction of the phenyl group was further enhanced by appropriate substituents, and recommended the use of *p*-nitrophenyl esters (175), which indeed was a valuable service to the peptide chemists. Schwyzer's group, shortly afterwards, described the preparation of a series of negatively substituted aryl esters, among them the very interesting *p*-methanesulfonylphenyl ester (176). The use of halogen-substituted phenyl esters such as 2,4,5-trichlorophenyl and pentachlorophenyl ester was suggested by Kupryszewski (177). A detailed kinetic study of various active esters was reported by Stick and Leemann (178). The use of pentachlorophenyl esters has been reinvestigated by Kovacs and this author as a versatile tool for the synthesis of peptides and sequential polypeptides (179). The pentachlorophenyl active esters have the following advantages: (a) they are one of the most active esters; (b) they are generally higher melting compounds than other active esters, which leads to their easy crystallization and purification; (c) they are conveniently prepared without any significant racemization by *N,N'*-dicyclo-

Scheme XXXI

Scheme XXXII

hexylcarbodiimide (DCC) method; (d) they are stable to controlled hydrogenation conditions and make an excellent combination with *N*-benzyloxycarbonyl and *tert*-butyl protecting groups when the incorporation of trifunctional amino acids in the peptides is desired. Pentachlorophenyl esters of *N*-protected amino acids also couple in satisfactory yields with amino acids and peptides *C*-protected by suitable salt formation (118).

Further search for active esters led Nefkens (180) to the use of *N*-hydroxyphthalimide esters which were shortly followed by the introduction of analogous esters namely the *N*-hydroxysuccinimide esters from the laboratories of Anderson (181) (Scheme XXXII). During the past few years, the latter esters have received considerable attention mainly due to the easy removal of the by-product of acylation, *N*-hydroxysuccinimide, by water.

Another type of active esters which have already proven their worth in the synthesis of peptides, and which hold a bright future, are the reactive derivatives of *o*-acylhydroxylamine such as the esters of *N*-hydroxypiperidine introduced by Young (182). The coupling through these esters proceeds without any significant racemization. This may be attributed to less chances for oxazolone formation because of the ability of the heterocyclic nitrogen atom to share and then accept the proton from the incoming amine. The condensation is accelerated on account of the stability through hydrogen bonding of the transition complex of the adduct; and further, the leaving group will be a tautomer of 1-hydroxypiperidine rather than the unstable anion (183) (Scheme XXXIII).

Scheme XXXIII

Closely related to *N*-hydroxypiperidine esters are the oxine esters which also undergo coupling without racemization, and their reaction mechanism seems to be analogous to 1-piperidyl esters (184). The idea of stabilization of the transition complex through hydro-

gen bonding and therefore limiting the possibility of oxazolone formation during coupling has been extended in the use of *o*-hydroxyphenyl esters. Their initial success in the synthesis of peptides without any racemization (183) will certainly lead to the development of more versatile active esters (Scheme XXXIV).

Scheme XXXIV

Young (185) prepared the acyl amino acid esters of 2-hydroxypyridine and of 2-mercaptopyridine (SPyr). Esters of the latter (2-pyridylthioesters) react very rapidly and exothermically with amino esters, giving high yields of protected peptides. A notable feature of these esters (SPyr) is the easy coupling with strongly hindered amino acids such as valine, isoleucine, and α -aminoisobutyric acid (186).

Active esters can be prepared by the condensation of the phenols or corresponding components with *N*-protected amino acids and peptides by a number of coupling methods. Most frequently used are the dicyclohexyl carbodiimide and mixed anhydride methods. A number of active esters of hydroxyamino acids with *N*- α -NPS and *o*-*tert*-butyl protection have been recently reported (187). These intermediates should be quite useful in lengthening the peptide chains. By using isopropyl alcohol, Walter *et al.* (188) were able to prepare previously unreported NPS-protected glutamine and asparagine *N*-hydroxysuccinimide esters. In certain cases, the rate of aminolysis by active esters may be accelerated by the use of suitable catalysts such as imidazoles and 2-hydroxypyridine.

During the preparation of active esters, the *C*-terminal amino acid residue of the peptide chain may undergo racemization; however, with the use of controlled experimental conditions, this problem can be overcome. Formation of the peptide bond is normally associated with the partial loss of optical purity of the amino acid whose carboxyl is activated. This problem may be avoided by lengthening the peptide chains from *C*-terminal residues of amino acids, in which case the

Glucagon—The synthesis of the pancreatic hormone, glucagon, was achieved by the condensation of five fragments (13). A combination of NPS, and *tert*-butyl and benzyloxycarbonyl groups were used throughout the synthesis. *N*-Terminal histidine was used as *N* α ,*N*-(im)-di-adamantyloxycarbonyl histidine and the peptide bond formation and condensation of the fragments was carried out mainly with DCC/HOSu method. The following fragments were synthesized and then condensed stepwise (Scheme XXXV).

Secretin—The structure of secretin resembles glucagon a great deal. The presence of four arginine residues in secretin imparts a strong basic character to the molecule. The C-terminal amino acid valine is present in the amide form. Synthesis of secretin was accomplished in a stepwise manner, starting from C-terminal amino acid

protection. BOC protection was predominantly used for amino groups and the coupling reactions were mainly carried out by azide methods. Di-Z-histidine was used for the preparation of the tripeptide III and was converted to the ditrityl derivative before coupling for the formation of the tridecapeptide amide (Scheme XXXVII).

Peptide Synthesis with the Help of Polymeric Support—The isolation and purification of each intermediate during the building of a peptide chain is of utmost importance to limit the extent of racemization in the final product. However, the development of newer techniques and the modification of conventional methods has inspired the synthesis of the peptides without the isolation of intermediates. An apparent advantage of the approach is the tremendous saving of time which is normally required for the stepwise purification. Knorre and Shubina (190) have elongated the peptide chain at the carboxyl end by coupling an aqueous solution of formyl amino acid with an amino acid ester by means of water-soluble carbodiimides. The reaction mixture upon passing through resin columns is freed from reactant and reagents. The purified product, thus obtained, is saponified and is used directly for the next step in the synthesis. A protected hexapeptide was synthesized with less than 5% racemization. Sheehan (191) used a somewhat similar approach but extended the peptide chain from the amino end. The technique proved quite successful for the synthesis of a protected heptapeptide.

The above two approaches were only the beginning of the new ventures into less conventional approaches in the synthesis of peptides. In 1963, Merrifield (192) proposed an ingenious idea for lengthening the peptide chains by providing an insoluble polymeric support to the C-terminal residue of amino acids and extending the peptide chains by stepwise addition of succeeding amino acids. In this approach, which is called solid phase method for peptide synthesis, the growing peptide chain is at all times during the synthesis firmly bound by a covalent linkage to a solid particle and is, therefore, completely insoluble in all the reaction solvents. This allows separation of the peptide chain from soluble starting materials and by-products by filtration and thorough washings. Thus the intermediate peptides are purified, not by the usual recrystallization procedures, but by dissolving away the impurities. This greatly simplifies the manipulations and shortens the time required for the synthesis of peptides. After the desired sequence is assembled, the peptide is removed from the solid support. For a supporting solid, a copolymer of 98% styrene and 2% divinyl benzene in the form of small (20–80 μ) beads is chloromethylated and the product is attached to the *N*-protected amino acid to give a substituted benzyl ester derivative. The amino group was originally protected by the benzyloxy-carbonyl group but it was replaced by the *tert*-butoxy-carbonyl group and recently by *o*-nitrophenylsulfonyl group (193). The advantage of the last two groups is the easy removal by relatively mild acid conditions which minimizes the danger of cleavage of the peptide chain from the resin during the synthesis. After deprotection of the amino group, the next protected amino acid is coupled by DCC or active ester methods

Scheme XXXVIII

in solvents having high dielectric constants, such as methylene chloride or dimethylformamide (Scheme XXXVIII).

The selection of benzyl ester linkage can be justified on the basis of its stability to various synthetic reactions and easy cleavage by anhydrous hydrogen bromide at the end of the synthesis. The reactions outlined in Eq. 38 constitute one cycle in which a dipeptide is formed. However, additional cycles may be carried out in the same way, one at a time, until the desired sequence of amino acids in the peptide is completed. One of the most critical requirements for a successful synthesis, using a polymeric support is the quantitative coupling reaction. Unless this can be achieved at each step of the synthesis, a chain which does not react at one step will have a chance to react at each of the later stages and will lead therefore to undesired peptides with different amino acid composition. An excess of activated component, a longer period of reaction time, and the use of low cross-linked, high swelling resin generally leads to complete coupling. Of course the potential difficulty in the final purification after the peptide is removed from the resin must be accepted in return for convenience and speed in building up the peptide chain. In case DCC is used for activation, the possibilities for the loss of excess reagent due to the formation of *N*-acylurea must be considered. A suitable selection of active esters (194) for coupling to resin attached amino acids or peptides would eliminate this side reaction, and would also permit the incorporation of hydroxy amino acids without any protection on hydroxyl group. Active ester coupling has been of particular use in the case of glutamine or asparagine incorporation on account of the dehydration of carboxamide groups in the side chains of these amino acids when DCC is used. In the case of peptides incorporating aspartyl

Scheme XXXIX

or glutamyl residues with side chain carboxyl esterified, transpeptidation normally does not occur under the conditions used during synthesis by solid phase method. However, the treatment of HBr-trifluoroacetic acid, which is used to liberate the peptide from the resin support, may lead to the formation of amino succinyl derivatives in the case of peptides containing β -benzyl aspartyl-seryl residues. The opening of the imide derivatives may produce undesirable peptides with β -aspartyl linkages. Bumpus has reported the difficulties encountered during the formation of arginylproline bond under the conditions of the solid phase method using DCC (195). For the synthesis of peptides where the C-terminal amino acid occurs as an amide such as in oxytocin, the desired peptides, after the synthesis, are cleaved from the resin by ammonolysis in methanol. Although this approach has been quite successful with smaller peptides, particularly those with glycine as C-terminal amino acid, a considerable degree of difficulty was encountered during the ammonolytic cleavage of secretin where the C-terminal valine could not be removed from the resin as an amide (196).

Letsinger and Kornet (197) suggested as a modification to Merrifield's approach the use of "popcorn polymer" of polystyrene with a very low degree of cross-linking by divinylbenzene. In addition, the N-terminal amino acid was the anchoring group with the resin and the chain was extended by stepwise incorporation of subsequent amino acids. This approach has not gained much popularity mainly because of the possibility of racemization which is normally associated with the lengthening of the peptide chains from the N-terminal residues of amino acids (Scheme XXXIX).

A very interesting idea was proposed by Shemyakin (198) in which the insoluble cross-linked polystyrene was substituted by a soluble polymeric support. This offers the apparent advantage of having all reactions carried out in solution, thereby eliminating the problem of permeability or diffusion. The polymeric support was an emulsion polystyrene of average molecular weight of 200,000. The coupling of amino acid and peptide derivatives of oxymethyl-polystyrene was carried out with hydroxysuccinimide esters of BOC-protected amino acids. This approach may prove to be a very effective synthetic tool if certain problems can be overcome, such as formation of viscous gum when the linear polystyrene is thrown out of solution by pouring it into water (Scheme XL).

One of the main concerns in the solid phase peptide synthesis is that the purification of intermediates cannot be effected. At about the same time, a new approach was suggested from the laboratories of Katchalski (199) and Wieland (200). Where in Merrifield's method, it is the peptide which is bound to the insoluble carrier and the N-blocked amino acid-activated derivative is added while in solution, in the new approach a solution of free peptide ester is added to an insoluble polymer-supported, N-blocked amino acid-active ester. The reaction between peptide ester and active amino acid ester can be carried out in the presence of a large excess of insoluble active ester, and the unreacted reagent (active ester) can be readily removed by filtration or centrifugation and washing. The new peptide remains in solution and can be suitably purified before it is reacted with the next insoluble active ester

Scheme XL

component. Katchalski proposed a number of insoluble polymer-active esters. However, best use was made of DCC coupling of *N*-protected amino acids or peptides with a polymer made from 4-hydroxy-3-nitrostyrene cross-linked with 4% divinylbenzene (Scheme XLI). Another very interesting feature of this approach is the application of these insoluble polymer-active esters in the synthesis of cyclic peptides. The use of insoluble polymer-active esters attached to peptides limits the intermolecular condensation and facilitates intramolecular aminolysis, thereby avoiding the formation of linear polymers; cyclic peptides of high purity are isolated in good yields (201) (Scheme XLII).

Wieland utilized formaldehyde cross-linked *p,p'*-dihydroxydiphenylsulfone as a starting material for the synthesis of the corresponding insoluble *N*-blocked amino acid active esters (200) (Scheme XLIII).

The synthesis of peptides with polymeric active esters was also investigated by Blout (202). BOC-amino acid *N*-hydroxysuccinimide active ester derivatives of copoly(ethylene-*N*-hydroxymaleimide) were used as insoluble active ester reagents. For the preparation of these esters, copoly(ethylenemaleic anhydride) was condensed with hydroxylamine hydrochloride, and the resulting *N*-hydroxy polymer derivative was coupled either by mixed anhydride or DCC methods with BOC-amino acids (Scheme XLIV).

The substitution of activated amino acids in the polymers previously mentioned can be varied by appropriate adjustment of the *N*-protected amino acid: polymer molar ratio. Satisfactory results are obtained when 1–2 mmole of activated amino acid is bound to each gram of the resin.

Weygand (203, 204) investigated the possibilities for the coupling of the *N*-protected peptides with amino acids or peptides anchored to polymers. The advantage of this approach is the availability of a relatively larger number of peptide intermediates, which can be properly characterized before incorporation in the peptide chain. Dipeptides, *N*-protected by BOC, were reacted with the bromoacetyl derivative of polystyrene; and, after the removal of *N*-protection from the resulting dipeptide polymer derivatives, coupling was carried

Scheme XLV

out with *N*-protected di- or tetrapeptide *N*-hydroxy-succinimide esters. Selective removal of the peptides from the polymer was achieved by sodium thiophenolate, and the *N*-protected peptides so obtained were free from racemization (Scheme XLV).

While the above approach which has also been used by Anfinsen (205) is indeed a very useful modification in solid phase synthesis of peptides, the proper evaluation of this will depend on the successful synthesis of larger peptides.

The success of the solid phase method and new approaches using various forms of solid supports is apparent from the synthesis of a large number of biologically active peptides such as bradykinin, oxytocin, angiotensin, insulin, *etc.*, and their analogs. However, the most frequently used approach is still the one which was originally suggested by Merrifield, and in order to accelerate the synthesis of peptides, a simple automated apparatus has been designed (206). It consists of a reaction vessel where the actual synthesis takes place and devices which transfer reagents and solvents into and out of the vessel. The entire series of events is controlled by a programmer which can be arranged in advance to direct the various operations of the instrument. The automated process produces a protected peptide chain attached to the solid polymer support, and after cleavage from the resin and deprotection, the peptide is suitably purified.

It was apparent, from the onset of the introduction of the solid-phase method, that the synthesis of larger peptides and proteins would become feasible, and this was indeed demonstrated by the synthesis of a protein. A linear polypeptide of 124 amino acid residues, with the sequence of bovine pancreatic ribonuclease A (RNase A), was synthesized by Merrifield using 369 chemical reactions and 11,931 steps of the automated peptide synthesis machine without any intermediate isolation steps (207). Anhydrous hydrogen fluoride was used for the single step cleavage of the peptide from resin and simultaneous removal of all protecting groups.

The properties of anhydrous hydrogen fluoride (HF) as a reagent for the acidolysis of various protecting

groups have been studied by Sakakibara (208). Amino acids with various protecting groups, particularly the nitro group in nitroarginine, *tert*-butyl group in *S*-*tert*-butyl cysteine and many other protecting groups can be conveniently removed by HF at low temperatures in the presence of anisole. When carefully handled, HF should prove to be an effective tool for planning the strategy in the synthesis of peptides.

Iselin suggested the use of hydrazine for the cleavage of peptides from polymer support (209). Hydrazinolysis leaves the *N*-protection intact, and the cleaved peptide is isolated as hydrazide which can be directly coupled to another peptide after conversion into the azide. The same approach has been used by Anfinsen for the synthesis of water-insoluble *N*-protected peptide hydrazides which do not contain ω -protected aspartic or glutamic acid residues or other hydrazine-labile groups (210).

The possibility of a side reaction during esterification of the C-terminal amino acid with chloromethylated resin has been reported by Beyerman (211). This side reaction probably occurs between the free triethylamine and chloromethyl groups producing a quaternary ammonium compound (Scheme XLVI).

The *N*-protected C-terminal amino acid may be attached to the polymeric support by DCC method, if the chloromethylated polymer is first reacted with thioglycol and the resulting thioether is oxidized with perbenzoic acid. The *N*-protected peptides attached to the modified solid support can be selectively cleaved from the resin without affecting the *N*-protected group (212) (Scheme XLVII).

Solid phase method of peptide synthesis has been extended in the synthesis of polymers with different sequence and size. Different applications in the synthesis of oligo-nucleotides have been reported (213). Oligomers of nylon (214) and polypeptides with an ordered sequence of amino acids, such as H(prolyl-glycyl-glycyl)-OH (215), and H(prolyl-prolyl-glycyl)-OH (216) have been successfully synthesized with solid support. Recently, Rothe (217) reported the synthesis of different-sized oligomers of epsilon amino caproic acid by using dimeric and tetrameric units for the chain growth. Coupling of these units with the polymer-supported chain was carried out with the aid of diester chlorides of phosphorus acid instead of DCC.

The reverse of the peptide synthesis by solid phase, *i.e.*, the degradation of the peptide on a polymeric support using the Edmann method, has been suggested by two different groups. Stark's (218) procedure involves attaching the peptide by its *N*-terminal residue to a support of polystyryl isothiocyanate, cyclizing, isolating and analyzing the residual peptide, and reattaching the peptide to the resin. Repetition of these

Scheme XLVI

Scheme XLVII

steps leads to the establishment of the sequence of amino acid residues in the peptide chain. In the method proposed by Laursen (219), the peptide is attached by its C-terminal amino acid and the degradation is performed in the usual manner. The liberated thiazolinone is removed in each cycle simply by filtration (Scheme XLVIII).

A closely related approach, using a combination of Edmann degradation on polymeric support and mass-spectrometric methods, has been suggested by Weygand (220) for the determination of the extent of amino acid residues incorporated in the growing peptide chains attached to the resin supports.

Leuch's Anhydrides—*N*-Carboxy- α -amino acid anhydrides (Leuch's anhydrides, NCA's) have been widely used in polymerization reactions (221) in anhydrous media for the synthesis of homopeptides and the random synthesis of heteropeptides. While the controlled synthesis of heteropeptides *via* Leuch's anhydrides has been attempted by many laboratories, relatively little success has been achieved in the use of this method. Bartlett (222), on the basis of his studies with NCA's of various amino acids, reported that the reaction cannot be

controlled adequately to provide a useful general method for peptide synthesis in water. Grant (223) proposed the limited use of Leuch's anhydrides for the formation of dipeptides in water at pH 5, particularly when the reacting amine is a much weaker base than the amine resulting from the synthesis. The real breakthrough in the utilization of NCA's in peptide synthesis came with the development of suitable reaction conditions by Denkwalter *et al.* (224). They proposed the addition of solid NCA directly to an amino acid at 0–2°, generally at pH 10.2, with rapid mixing of the reactants, thus minimizing side reactions. Rapid mixing, in the case of relatively insoluble NCA's, may enhance the rate of dissolution of the NCA thereby reducing the possibility for carbamate exchange which leads to the formation by overactivation of tripeptides, and also to inactivation of the starting amino acids. Overactivation of more soluble NCA's *via* their anions is also limited by rapid mixing, thus preventing the formation of oligomers. Carbamate stability increases with pH, but at a pH above 10.5, hydrolysis of NCA becomes an important side reaction leading to the formation of hydantoic acid, most likely through NCA anion. The peptide carbamate is decarboxylated at pH 3–5 to produce the free peptide which can be immediately extended in length by repetition of the process with a new *N*-carboxyanhydride, or can be first isolated and purified before continuing with the synthesis. Racemization was not detected during the synthesis of peptides *via* NCA's; this method, used under careful

Scheme XLVIII

Scheme XLIX

conditions and in combination with other more conventional methods, should prove to be of great value in the synthesis of larger peptides (Scheme XLIX).

The extraordinary rapidity of the NCA method, which is particularly useful in the sequential preparation of higher peptides without isolation of intermediates, is indeed a very interesting feature of this method. Another significant advantage of the NCA method is that the reactions are carried out in aqueous medium and with the exception of the ϵ -amino group of lysine and sulfhydryl group of cysteine, polyfunctional amino acids used as a nucleophile can be used without any protection of the third functionality. NCA's with the exception of those of proline and glycine are quite stable when stored at low temperatures with protection from moisture.

Since the thiocarbamate salts proved to be more stable than the corresponding carbamate salts, the use of sulfur analogs of NCA's, the 2,5-thiazolidinediones (*N*-thiocarboxyanhydrides, NTA's), in the peptide bond formation has been suggested (225). NTA's usually give higher yields in the peptide synthesis. The optimal pH for their reaction is lower, *i.e.*, 9–9.5. Low pH usually favors the desired aminolysis of an anhydride over hydrolysis. NTA of glycine does not form the isocyanate which is characteristic of glycine NCA; therefore, the chances of hydantoic acid formation as an undesirable side reaction are eliminated with the use of the NTA of glycine. There is another interesting difference between the NCA and the NTA of unprotected histidine. While the NCA of histidine undergoes intramolecular imidazole catalyzed isocyanate formation, this reaction is relatively less favored in the case of the NTA of histidine; therefore NTA of histidine is more suitable for the incorporation of histidine in histidyl peptides.

The tremendous scope of the NCA and NTA methods in the synthesis of larger peptides was demonstrated by a group of workers at Merck (226) when they applied these approaches, in combination with the *N*-hydroxy-succinimide and azide methods, toward the successful synthesis of a protein (*S*-protein) composed of 104 amino acids. The fragment condensation approach was used to attach 19 fragments. About 40% of the bonds

in the peptide fragments were formed through the use of NCA's and NTA's; the remainder with *N*-hydroxy-succinimide active esters. The azide method was used throughout for the condensation of fragments which contained 6–17 amino acids. The acetamido methyl group which is resistant to HF at 0° was used for the protection of sulfhydryls of eight cysteines, and acid labile BOC-protecting group was employed as a temporary blocking group of the growing peptide chain. All the protecting groups at the end of the synthesis were removed by HF still leaving the cysteines protected by the acetamido methyl group. After removal of sulfhydryl protections by mercuric acetate, the deprotected tetraheptapeptide was oxidized at pH 6.5 in the presence of mercaptoethanol to form four disulfide bridges. The resulting *S*-protein combined with the *S*-peptide to produce the enzyme activity.

Synthesis of Peptides with the Aid of Synthetic Polysaccharide¹—Wieland (227, 228) has suggested the use of cationic benzyl ester derivatives for stepwise lengthening of the peptide chains from C-terminal residues of amino acids. These derivatives are strongly adsorbed on columns of sulfoethyl-(SE)-polysaccharide, and can be purified by rinsing of the colored zones with methanol. The azoesters of the peptide derivatives can be easily removed at the end of the synthesis by catalytic hydrogenation (Scheme L).

Synthesis of Polypeptides—Practically all the methods which are used for the stepwise synthesis of oligopeptides have been tried for the synthesis of polypeptides with an ordered sequence of amino acids. High molecular-weight polypeptides with known repeating sequences of amino acids, especially those which are water-soluble and contain polyfunctional amino acids, are of special interest. These polypeptides would be expected to resemble proteins more closely than those consisting of only difunctional amino acids. Polymerization of the selected sequences of amino acids in proteins can be of considerable help in the conformational studies and also to explore possible biological activities. The polymerization with the help of active esters such as pentachlorophenyl esters (179) has been quite useful and recently, in the author's laboratories, a number of sequential polypeptides incorporating histidine and serine at suitable distances have been synthesized *via* pentachlorophenyl esters. These polymers possess a definite pattern of activity comparable to the proteolytic hydrolysis of chymotrypsin. Further studies with polypeptides incorporating amino acids around the active site of enzymes are under progress and may provide interesting data for the catalytic activity of certain enzymes.

Fox (229) has introduced a rather unconventional but extremely interesting approach for the synthesis of polymers by thermal condensation. In this type of polymerization instead of "prespecified" sequences, the polymers obtained are of "predetermined" sequences. The thermal method of polymerization would lead to the polymers in which reacted α -amino acids are largely racemized. For the synthesis of thermal poly-

Cyclic Peptides—Most peptide antibiotics are cyclic in character and in contrast to proteins, contain both D and L amino acid residues. Certain amino acids common to proteins, *e.g.*, arginine, methionine, and histidine, occur rarely in peptide antibiotics. The cyclic peptide antibiotics include both homodetic and heterodetic structures. The synthesis of homodetic cyclic peptides is, in principle, the same as that of linear peptides. However, it is essential to work at the right dilution to suppress polycondensation as much as possible in favor of the formation of the intramolecular peptide bond. An interesting phenomenon, “doubling reaction,” was reported by Schwyzer (231). If a linear cyclizable peptide with an odd number of amino acid residues, *e.g.*, a pentapeptide, is subjected to cyclization, the corresponding cyclic pentapeptide is not obtained, but rather, through dimerization, a cyclic decapeptide is obtained. A detailed classification of different types of cyclic peptides and specific synthetic methods for their preparation have been reviewed in detail during recent years (29, 31, 32).

aspartyl and glutamyl residues under basic conditions. The formation of glutarimide derivatives from *N*-protected γ -glutamyl dipeptides and subsequent ring opening to yield α -peptides has been reviewed (179). In the case of the transpeptidation reactions with esterified glutamyl and aspartyl peptides, the imide ring formation is a well established base catalyzed reaction; and, to prevent this type of transpeptidation reaction, *tert*-butyl esters, which can be removed by acid treatment, provide a special advantage.

Racemization—Synthesis of biologically active peptides must proceed without affecting the configuration about any of the asymmetric centers of the components. A continuously increasing amount of attention is being devoted to the problem of racemization, and many laboratories are actively engaged in developing new approaches which would limit the degree of racemization during the synthesis of peptides. While there are many instances where racemization has been observed during the introduction or removal of protecting groups from amino acids or peptides, the most critical aspect, which has received the maximum attention, is the possibility of racemization during the peptide bond formation. Racemization may occur

Vol. 59, No. 1, January 1970 □ 21

Scheme LIV

either because of the formation of oxazolone (azalactone) intermediates or by the direct proton abstraction from the asymmetric alpha carbon. A recent discussion by Bodanszky and Ondetti (32) summarizes generally accepted beliefs about the loss of optical purity during the synthesis of peptides.

Mechanistic investigations of racemization began when it was shown by Young (233) that the reaction between benzoyl-L-leucine *p*-nitrophenyl ester and glycine ethyl ester, in the presence of a tertiary base, proceeds through the reversible formation, racemization, and coupling of the oxazolone (Scheme LII).

Independent of the above work, Goodman (234) reported the preparation of the optically active crystalline oxazolone from benzoyl-L-phenylalanine. On the basis of equilibrium studies of this oxazolone with various nucleophiles, it was concluded that during the coupling process a small steady state concentration of oxazolone can form which racemizes much faster than its ring opens. The reason for the racemization-free coupling of azide method may be attributed to the inhibition of bond movements (essential for proper conformation for oxazolone formation) due to the attraction between the negative charge developing on the amide oxygen and the positive charge on the central nitrogen atom of the azide group (235) (Scheme LVIII).

There is a clear dependence of oxazolone formation in the presence of base; Kemp (236) recently reported kinetic evidence which supports the presence of equilibrated amide anions as reactive intermediates leading to azalactone formation in the case of peptide activated esters.

Goodman's group (237) synthesized optically active 2-(1-benzoyloxycarbonyl-amino-1'-methyl)ethyl-4-benzoyloxazolone from benzoyloxycarbonylaminoisobutyl-L-phenylalanine, and reported a number of interesting observations about racemization and ring opening reactions of this oxazolone with several amino acid esters (Scheme LIV).

Racemization of oxazolones may follow pseudo-first-order or second-order kinetics, depending on the attacking amino ester and the nature of the solvent. One of the most important factors which controls the

Scheme LV

Scheme LVI

racemization process is the nucleophilicity-basicity ratio of the attacking nucleophile. Racemization rate can be accelerated by the presence of chlorides or phosphates which increase the ionic strength of the solution and facilitate the charge separation necessary for racemization. The coupling or ring-opening reaction is always a second-order reaction which is governed by the nucleophilicity of amino components in different solvents. The rate at which a reagent opens an oxazolone ring is a measure of the reagent's nucleophilicity, and the rate at which a reagent racemizes an oxazolone is a measure of reagent's basicity. Certain 1,2-dinucleophiles such as hydrazine which have high nucleophilicity-basicity ratio open the oxazolone ring without racemization (Scheme LV).

Elegant studies carried out by Young (238) on base-catalyzed racemization of various acyldipeptide *p*-nitrophenyl esters have, in fact, established that racemization of many peptide activated species proceeds through oxazolone during the coupling reaction (Scheme LVI).

The degree of racemization of peptide product will no doubt depend on the relative rates of each reaction. For example, coupling of acylpeptides by means of DCC can lead to racemization since this is an excellent reagent for the preparation of oxazolones. In the coupling reactions which proceed through oxazolone formation, the chances of racemization can be limited by the use of nonpolar solvents and by proper selection of the tertiary base. When an oxazolone is formed from the C-terminal residue of a peptide chain, the possi-

Scheme LVII

bility of proton abstraction from the alpha carbon of penultimate amino acid residue may lead to its partial racemization, due to rearrangement of the oxazolone (239) (Scheme LVII).

In the case of acetyl and benzoyl amino acids, oxazolones are formed very readily. This, perhaps, is the reason for the racemization in the case of benzoyl and formyl-L-leucine *p*-nitrophenyl esters. The tendency toward oxazolone formation decreases from benzoyl to acetyl to formyl, and this is indeed paralleled by a decrease in racemization during the coupling reactions. The oxazolone formation, in the case of urethan-protecting groups such as benzyloxycarbonyl-protected amino acids, is not favored, and this may be due to resonance stabilization due to the polarization of the carbonyl bond of benzyloxycarbonyl amino acids. The phthalyl-protected amino acids which do not undergo oxazolone formation also should be safe from racemization. However, racemization in the case of activated acyl amino acids such as benzyloxycarbonyl esters of β -cyanoalanine, derivatives of cysteine, and phthalyl-D-valine, which cannot form oxazolones, has been recorded. The mechanism of this type of racemization may be postulated mainly as a result of excellent studies by Liberek (240). Racemization in these cases most likely occurs by direct exchange of hydrogen at the asymmetric center, particularly when the activation is strong and when the acyl groups and the side chains are powerfully electrophilic.

It has been observed that *N*-benzyloxycarbonyl-S-benzyl cysteine esters racemize easily in the presence of base. This racemization may proceed either by resonance stabilization of the anion formed by α -hydrogen abstraction or by reversible β -elimination of the benzyl thiol moiety. The racemization of *N*-benzyloxycarbonyl-S-benzyl-L-cysteine-*p*-nitrophenyl ester was attributed to base-catalyzed reversible β -elimination of good leaving benzyl thiol group (241, 242). However, in a recent study using benzyl (35S) thiol, Kovacs *et al.* were able to demonstrate that racemization in the case of *p*-nitrophenyl, as well as of the pentachlorophenyl esters of *N*-benzyloxycarbonyl-S-benzylcysteine, does not follow the β -elimination readdition mechanism (243).

On the basis of conformational studies of the amide bond, it has been suggested that oxazolone formation is possible only in the case of *trans*-conformation of the amide, since in the case of *cis* amides, the distance of oxygen atom of amide bond and carbon atom in carboxyl group is too far to facilitate the formation of oxazolones (244).

Detection of Racemization—There are several methods available for determining the optical purity of a peptide once it has been synthesized. However, these methods must be distinguished from different approaches in which synthetic model peptides are used to detect the degree of racemization during peptide bond formation. These approaches are based on the isolation of enantiomers by employing such techniques as countercurrent distribution, fractional crystallization and gas-liquid chromatography (GLC), paper and thin-layer chromatography. Most frequently used model peptides, in the fractional crystallization method, are

Young's benzoyl-L-leucylglycine ethyl ester (245) and Anderson's benzyloxycarbonyl-L-phenylalanylglycine ethyl ester (246). The formation of D-alloisoleucine from L-isoleucine has been observed by many authors, and the amounts of alloisoleucine and leucine can be quantitatively determined. This affords a good method to determine the extent of racemization during coupling reaction (247). The GLC separation of diastereoisomeric *N*-trifluoroacetyl dipeptide esters provides a good method for the detection of racemization (248); however, it entails a two-step chemical modification of the sample before analysis (replacement of *N*-protecting groups such as benzyloxycarbonyl or *tert*-butyloxycarbonyl by trifluoroacetyl residues). Halpern's findings that *tert*-butyloxycarbonyl amino acid amides can also be separated by GLC (249), and the separation of trifluoroacetyl tripeptide esters by Weygand by GLC (250) will provide further versatility to this method. Recent work on the preparation of diketopiperazines and their steric analysis by different analytical methods (251) may be useful for the determination of degree of racemization, particularly of dipeptides which do not yield volatile trifluoroacetyl derivatives suitable for gas chromatographic analysis.

A relatively new, though extremely promising approach, is the application of nuclear magnetic resonance (NMR) spectroscopy for the detection of racemization in peptides (252). A series of diastereoisomeric *N*-acylalanylphenylalanine methyl esters and *N*-acylphenylalanylalanine methyl esters have been shown to possess different NMR spectra. The methyl doublet signal in an L-L (or D-D) is at lower field than the equivalent signal for the D-L (or L-D) analog. This is most probably due to deshielding. The application of this property has been extended in determining the degree of racemization during the synthesis of a number of peptides with different *N*-acyl-protecting groups. The sensitivity of the NMR method was improved by the use of ^{13}C -H satellite peak of predominant L-L isomer as an internal standard (225).

In many cases, the biological activity of a natural peptide depends, to a large extent, on its optical purity, and the comparison of the biological activities of the natural and synthetic compounds can be used as a reasonable criteria for the optical purity of the synthetic compound. However, the exactitude of biological testing methods poses a serious limitation to this approach. The comparison of optical rotations of synthetic and natural peptides is useful to some extent for determining the optical purity; however, in the compounds with several asymmetric centers, identical values of optical rotation do not necessarily imply optical homogeneity. The most satisfactory method for the determination of steric homogeneity is the enzymatic hydrolysis (253). Renal amino peptidase can be used for total hydrolysis, and the analysis of the hydrolysate can be performed with L or D amino acid oxidase. The hydrolysis with stereo specific enzymes such as leucine amino peptidase, carboxyl peptidase A and B, trypsin, and chymotrypsin has been successfully used for the determination of optical purity. The complete disappearance of the original peptide established by electrophoresis or paper chromatography is evidence for the optical

purity of the peptide bond for which the enzyme is selective. Another method for the determination of the optical purity of the synthetic peptides is the total hydrolysis by acid; the comparison of the hydrolysate with a control containing the expected amino acid residues treated under the identical conditions, provides a guideline for optical purity. A serious drawback of the acid hydrolysis is that some free amino acids, when exposed to acid, may behave differently from the same moieties built in a peptide sequence.

CONCLUSION

A proper selection of protecting groups and coupling methods is one of the most important tasks during the synthesis of larger peptides. Both the classical and relatively less conventional methods have their advantages and disadvantages. It is hard to rationalize the scope and usefulness of one particular method without considering the utilities and refinements of many other techniques which are so important to the successful completion of the synthesis of peptides and polypeptides. The considerations must be given to the control of racemization, the maximum yields during coupling, and the product purification.

Wherever possible, the amino component should be first liberated and then added to the activated component. In addition to the proper selection of the solvents, the choice of hindered amines, such as tribenzylamine or the amines with suitable basicity such as *N*-methylmorpholine, further limit the degree of racemization in the reactions which require the use of a tertiary amine. The use of bifunctional catalysts which were developed by Beyerman is often helpful in accelerating the aminolysis of active esters without accelerating oxazolone formation.

The remarkable progress during the past few years in the techniques used in peptide synthesis strongly confirms that the aims which were once visualized for peptide synthesis, are indeed attainable. This has been demonstrated by the total synthesis of ribonuclease A. Although the synthetic peptide was relatively less active when compared with pure natural bovine pancreatic ribonuclease A, the complete synthesis of a protein molecule with true enzyme activity towards its natural substrate must be considered as one of the landmarks in the progress toward the continuous efforts for better understanding of biochemical processes. These present indications of the progress and refinement of the techniques used in the synthesis of peptides hold excellent promise for the future. The synthesis of larger quantities of biologically active peptides for medicine and the synthesis of intricate enzymes and complex proteins appear to be only a few steps away.

Intermolecular and Intramolecular Catalysis in Deamination of Cytosine Nucleosides

ROBERT E. NOTARI, MARILYN LUE CHIN, and ALEX CARDONI

Abstract □ The rates of deamination of arabinosylcytosine (Ara-C), cytidine (Cyd) and cytosine (C) are compared in the presence and in the absence of catalytic buffers. Ratios of the rate constants in the absence of intermolecular catalysis by buffers indicate intramolecular catalysis by the 2'-hydroxyl in Ara-C. For example, the ratio of the deamination rate constants at pH 4.7, 70° is 53/1.4/1 for Ara-C/Cyd/C. In contrast to Cyd and C which show catalysis by both the acidic and basic components of the buffers, Ara-C exhibits only general-acid catalysis. These data suggest that intramolecular participation by the 2'-hydroxyl in Ara-C replaces the general-base catalytic role which the buffers perform in the deamination of C and Cyd. Mechanisms for inter- and intramolecular catalysis in the deamination of Ara-C, Cyd, and C are discussed.

Keyphrases □ Cytosine nucleosides—deamination □ Catalysis, inter- and intramolecular—cytosine nucleosides □ Kinetics—cytosine nucleosides deamination □ UV spectrophotometry—analysis

Cytosine (C), cytidine (Cyd) and 1-β-D-arabinosylcytosine (Ara-C)¹ are known to undergo hydrolytic deamination in aqueous buffered solutions to yield the corresponding uracil derivatives as shown in Scheme I.

The authors have previously reported on the kinetics of Ara-C deamination in phosphate buffers at several temperatures in the presence and absence of sodium bisulfite (1). The major catalytic species in aqueous phosphate buffers at 70°, pH 6–8, was shown to be H₂PO₄⁻. Other workers have demonstrated that the deamination of C and Cyd is subject to buffer catalysis by carboxylate and pyridine buffers at pH < 6, 95° (2, 3). The catalytic constants for the individual buffer species could not be calculated from previous data for C and Cyd (2, 3) and the catalytic constant for H₂PO₄⁻ was not reported (1).

In the authors' initial publication the fact was emphasized that insufficient data was available to quantitatively compare the catalytic effects of buffers on the deamination of Ara-C, Cyd, and C. The authors have now demonstrated that the kinetics of deamination of the arabinosyl nucleoside is dramatically different from either the ribosyl nucleoside or cytosine itself and that C and Cyd behave relatively similarly by comparison. This report provides the first data allowing: (a) comparison of the catalytic constants for several buffer components in the deamination kinetics of C, Cyd, and Ara-C and (b) a direct comparison of their deamination rates in the

absence of buffer catalysis under a variety of experimental conditions. The results clearly indicate a significant contribution due to intramolecular participation by the 2'-hydroxyl in the hydrolytic deamination of Ara-C. There is evidence that C and Cyd are subject to both general-acid and general-base catalysis while general-acid catalysis predominates in the case of Ara-C at 70 and 80°. Under certain conditions the apparent first-order rate constants for Ara-C deamination are shown to increase rapidly as a function of acetic acid concentration and then become relatively constant and independent of the buffer concentration. This apparent change in the rate determining step is not evident in the buffer data for the deamination of C or Cyd under the conditions of this report.

EXPERIMENTAL

Materials—Arabinosylcytosine and arabinosyluridine (Upjohn Co., Kalamazoo, Mich.), and cytosine, uracil, cytidine, and uridine (Mann Research Laboratories, New York, N. Y. and Nutritional Biochemicals Co., Cleveland, Ohio) were used.

Analytical Methods—The wavelengths of maximum absorption as a function of pH were determined using a Cary model 15 spectrophotometer. Beer's law plots for cytosine and uracil in 0.1 N HCl were constructed using a Beckman DU spectrophotometer and the absorptivities, *a*, were calculated to be 1.0 × 10⁴ (275 mμ), 5.9 × 10³ (259 mμ) for C, and 3.8 × 10³ (275 mμ), 8.2 × 10³ (259 mμ) for U. Solution of the simultaneous equations for total absorption, *A*, from a mixture of C and U yields:

$$C = (1.37 A_{275} - 0.625 A_{259}) \times 10^{-4} \quad (\text{Eq. 1})$$

$$U = (1.67 A_{259} - 0.990 A_{275}) \times 10^{-4} \quad (\text{Eq. 2})$$

The concentration of each component in mixtures containing C and U were calculated from the *A*₂₇₅ and *A*₂₅₉ in 0.1 N HCl using Eqs. 1 and 2.

A similar treatment for arabinosylcytosine and arabinosyluracil results in Eqs. 3 and 4.

$$\text{Ara-C} = (0.927 A_{280} - 0.389 A_{260}) \times 10^{-4} \quad (\text{Eq. 3})$$

$$\text{Ara-U} = (1.21 A_{260} - 0.546 A_{280}) \times 10^{-4} \quad (\text{Eq. 4})$$

The concentration of Ara-C or Ara-U in a mixture was calculated from Eq. 3 or 4 using the *A*₂₈₀ and *A*₂₆₀ in 0.1 N HCl where the absorptivities were determined as 1.3 × 10⁴ (280 mμ), 6.0 × 10³ (260 mμ) for Ara-C, and 4.3 × 10³ (280 mμ), 1.0 × 10⁴ (260 mμ) for Ara-U.

The method of Loring and Ploeser (4) was employed in the analysis of cytidine and uridine mixtures.

Kinetics of Deamination—The kinetics of hydrolytic deamination of C, Cyd, and Ara-C, were determined under pseudo first-order conditions by maintaining constant pH and a sufficient excess of buffer. The temperature and ionic strength were held constant within each study. The pH was measured at the temperature of the

¹ USAN approved name is cytarabine; common name is cytosine arabinoside.

Scheme I

kinetic run using a digital readout pH meter (Sargent model DR) and combination electrode pH 7–14, 0–80° before and after the reactions were carried out. All reactions were followed for one to seven half-lives in the case of Cyd, for more than 40% of the reaction in the case of C, and until complete loss of substrate in the case of Ara-C. The concentrations of the reactants and products were determined as described in the previous section. Details of the experimental conditions are given in Tables I, II, and III.

RESULTS

Kinetics of Deamination—Good first-order plots were obtained under all experimental conditions when graphed according to the equation

$$\ln X = \ln X_0 - k_1 t \quad (\text{Eq. 5})$$

where X is the molar concentration of unreacted C, Cyd, or Ara-C and X_0 is the corresponding initial concentration. The apparent first-order rate constants, k_1 , calculated from the slopes of these plots are listed in Tables I, II, and III. The effect of buffer concentra-

tion on the apparent first-order rate constants is discussed in the following sections.

General Acid-General Base Catalysis in Deamination of C and Cyd—Plots of the apparent first-order rate constants, k_1 , versus total buffer concentration were linear for both C and Cyd under the conditions given in Tables II and III. The apparent first-order rate constants were shown to be defined by the equation:

$$k_1 = k_{HA}[HA] + k_A[A^-] + k_i \quad (\text{Eq. 6})$$

where HA is the acidic component and k_i is the rate constant in the absence of HA or A^- . At any given pH a plot of k_1 versus $[HA]$ will be linear with intercept, k_i , and slope defined as $S = (k_{HA} + k_A R)$ where R is the ratio $[A^-]/[HA]$. Thus a knowledge of S and R at two or more pH values will allow calculation of both catalytic constants. The calculation can also be done by a plot of k_1 versus $[A^-]$ where $S = (k_{HA} R + k_A)$ and $R = [HA]/[A^-]$. Both of these methods were applied to the data in Tables II and III with consistent results. The catalytic constants calculated in this way are listed in Table IV. It is apparent that both the acidic and basic components of the buffers are catalytic. The effects of a number of buffer systems on the deamination of C have been established as part of another study which will examine the possibility of a Brønsted correlation of the catalytic constants for various buffers. In all cases general-acid and general-base catalysis is indicated. As evidenced in Table IV neither species appears to predominate as the catalyst.

The reaction mixtures were examined for material balance by calculating the sum of the concentrations of C and U or Cyd and Urd as a function of time. Under all conditions reported in Tables II and III there was no indication of the presence of any reaction product other than the U or Urd.

General-Acid Catalysis in Deamination of Ara-C—The method described in the previous section was applied to data for the deamination of Ara-C in phosphate buffers at pH 6.15 and 6.90 (1) by

^a Ionic strength adjusted with NaCl to 0.020. ^b Ionic strength adjusted with NaCl to 0.26.

determining the slopes of the plots k_1 versus $[HPO_4^{2-}]$. Solving the simultaneous equations for the catalytic constants yields a value of 2.0×10^{-2} (l./mole/hr.) for $k_{H_2PO_4^-}$ and a negligible value for $k_{HPO_4^{2-}}$ (estimated to be 3×10^{-4} l./mole/hr.).

Catalysis in the presence of the acetic acid-acetate buffer system did not exhibit the usual linear dependency of rate constant on buffer concentration. Plots of k_1 versus total buffer concentration (or the concentration of either component) showed negative deviation from linearity. Typical examples are presented in Figs. 1 and 2. Figure 2 also shows a plot for the deamination of Cyt to allow a direct comparison.

The plot k_1 versus CH_3COONa at pH 3.7 shows the greatest degree of deviation of all cases reported in this paper. This plot shows essentially two regions. In the region of low buffer concentration there exists a sharp increase in k_1 with increasing concentration of buffer. Examination of Fig. 1 will reveal that this increase can be attributed to CH_3COOH rather than $[CH_3COO^-]$ since the most significant buffer catalysis is seen to occur at pH 3.7 where there is primarily CH_3COOH (see Table I). As the pH is increased to 4.7 and 5.7 the slopes of the plots can be seen to decrease. Indeed the nearly linear plot of k_1 versus CH_3COONa at pH 5.7 represents the case where the buffer is composed primarily of the acetate with relatively little acetic acid present. This plot shows an increase in k_1 of only 1.4×10^{-3} (hr.⁻¹) when total buffer concentration is increased from 0.055 to 0.39 *M*. The plot at pH 3.7 shows an increase of more than 10×10^{-3} (hr.⁻¹) over the same range. If one assumes that all of the increase in k_1 at pH 5.7 is due to the acetate the maximum catalytic constant for CH_3COO^- would be $1.4 \times 10^{-3}/0.3$ or 4.7×10^{-3} (l./mole/hr.). (See Table I for sodium acetate and acetic acid concentrations.) This would allow calculation of the acetic acid catalytic constant at pH 3.7 from the initial slope of k_1 versus CH_3COOH which is 94×10^{-3} (Fig. 2) yielding a value of $k_{CH_3COOH} = 93 \times 10^{-3}$ (l./mole/hr.). Thus the maximum possible contribution

due to the acetate component of the buffer at 70° is negligible in comparison to that of acetic acid.

Since the plots in Figs. 1 and 2 show decreasing buffer dependency with increasing buffer concentration, a more accurate assessment of the catalytic constants can be performed using the initial slopes. The initial slopes of k_1 versus CH_3COOH were obtained at pH 3.7 and 4.7 by regraphing the data in Fig. 2 on an expanded scale. Applying the technique discussed in the previous section results in the following:

$$0.094 = k_{HA} + 0.1 k_{A^-} \quad (\text{Eq. 7})$$

$$0.103 = k_{HA} + k_{A^-} \quad (\text{Eq. 8})$$

Solving for the constants yields $k_{HA} = 9.3 \times 10^{-2}$ and $k_{A^-} = 1 \times 10^{-2}$ (l./mole/hr.). However, the initial slope of k_1 versus CH_3COONa at pH 5.7 is 0.0090 which would indicate a negative value for acetate since $S = k_{A^-} + 0.1 k_{HA}$ at this pH. If it is assumed that k_{A^-} is actually zero and that the small positive value calculated from Eqs. 7 and 8 is due to the approximation in determining the initial slopes, the catalytic constant $k_{HA} = 0.093$ can be used to calculate the initial k_1 values at pH 5.7 according to Eq. 6 where k_i is 1.39×10^{-3} (hr.⁻¹). The calculated values for $10^3 k_1$ (hr.⁻¹) are 2.32 at 0.01 *M* CH_3COOH and 1.84 at 0.005 *M* CH_3COOH which agree with the experimental values 2.29 and 1.84. Since the most pronounced acetate effect would be exhibited at pH 5.7 it is evident that its catalytic constant is negligible as compared to that for acetic acid.

The same generalities can be made for the acetic acid-acetate buffer at 80° . The slope of k_1 versus $[CH_3COO^-]$ at pH 5.7 was again minimal in comparison to that of pH 4.7 and 3.7. Attempts to calculate the catalytic constants from the initial slopes using Eq. 6 resulted only in approximate values for k_{HA} (15×10^{-2} l./mole/hr.) and k_{A^-} (0.1×10^{-2} l./mole/hr.). However, the data are unambiguous in exhibiting the predominance of acetic acid as the catalytic species.

It is apparent that acetic acid is also responsible for the negative deviation in the k_1 versus buffer concentration plot since this is most pronounced at pH 3.7. When the acetic acid is increased from 0.05 to 0.10 there is a corresponding increase in k_1 of 4.6×10^{-3} for a slope value, $S_1 = 92 \times 10^{-3}$. However, when the concentration is increased from 0.5 to 3.6 *M* there is an increase of only 2.6×10^{-3} in k_1 for a value of $S_2 = 0.8 \times 10^{-3}$. Thus the ratio S_1/S_2 is 115/1. The rate constant, k_1 , has become relatively independent of buffer concentration in the region of 0.5 to 3.6 *M* acetic acid, pH 3.7, 70° . This type of plot is evidence for a change in the rate determining step of the reaction (5). In the buffer region up to 0.5 *M* acetic acid the reaction was significantly catalyzed by acetic acid. At concentrations greater than 0.5 *M*, acetic acid has supplied sufficient catalysis

to result in a new rate determining step which is apparently independent of buffer.

The deamination of Ara-C differs from that of C and Cyd in one other aspect. Under certain experimental conditions, particularly in dilute carboxylate buffers at pH 2–4, 60–80°, material balance data provide evidence for the formation of an intermediate in the deamination of Ara-C to Ara-U. By proper control of conditions we can demonstrate formation of as much as 40% of the intermediate which subsequently reacts to form Ara-U. The isolation and identification of this intermediate is currently in progress and will be the subject of a future report.

The presence of the intermediate does not affect the validity of the rate constants reported in the present paper. It has been shown that rate constants determined from Ara-C concentration are the same as those calculated directly from the UV absorption data. In addition, the intermediate shows no effect on the spectra of the reaction mixtures from 250–300 m μ and would not therefore be expected to interfere with the spectrophotometric assays.

DISCUSSION

Intramolecular Participation in the Hydrolytic Deamination of Ara-C—The rate constants for deamination of Ara-C, Cyd, and C in the absence of buffer at a variety of pH values, 70 and 80°, are given in Table V. The data at 70° show a slight rate enhancement when the ribosyl nucleoside, Cyd, is compared to cytosine alone, C. The ratio of the rate constants is 2.2/1 at pH 4.0 and 1.4/1 at pH 4.7. This increase in deamination rate may be due to participation by the 5'-hydroxyl to form the 6,5'-anhydro cyclonucleoside intermediate, I. The formation of similar 6,5'-cyclic intermediates has

been proposed in the 5-H exchange of ribofuranosyl nucleosides in MeONa-MeOD (6). In the present case, however, this increase in deamination rate, which may be attributed to the ribosyl 5'-hydroxyl, is insignificant in comparison to the rate increase of the arabinosyl nucleoside which is 142 times faster than C at pH 3.7. At pH 4.7 the ratio of Ara-C/Cyd/C is 53/1.4/1. (Other ratios are listed in Table V.) It is obvious from these data that the configuration of the 2'-hydroxyl in Ara-C (Scheme I) is responsible for a 30- to 40- fold rate increase as compared to the deamination of Cyd where the 2'-hydroxyl is *trans* to the pyrimidine base. It should also be mentioned here that Fig. 2 illustrates why the uncatalyzed rate constants rather than those in buffer solutions must be compared for a true indication of the degree of intramolecular catalysis. As the buffer concentration is increased the ratio of reactivity of Ara-C to Cyd or C would be found to first increase and then decrease. Figure 1 shows the most dramatic example of this fact in that Ara-C deamination becomes practically

^a Determined from intercepts of plots of k_1 versus buffer concentration. See Tables I, II, and III for experimental details. ^b Estimated from plot of k_2 versus pH where k_1 is intercept of k_2 versus buffer concentration for data in Table I. ^c Taken from Reference 9.

Figure 2—Apparent first-order rate constants at 70° for deamination of Ara-C in acetate buffers at pH 3.7, ● and 4.7, ○ ($10^3 k_1$ in hr.^{-1}) and Cyd at pH 4.7, ▲ ($10^3 k_1$ in hr.^{-1}) versus acetic acid concentration.

independent of buffer at concentrations above 0.5 M acetic acid. Since the rate constants in Table V do not reflect the differences in intermolecular catalysis by buffer, it is apparent that the 2'-hydroxyl in the arabinosyl nucleoside is capable of intramolecular catalysis while the 2'-hydroxyl in cytidine does not exhibit effective intramolecular participation.

Buffer Catalysis of Ara-C, Cyd, and C Deamination—Table IV summarizes the values of the catalytic constants in the acetic acid-acetate and phosphate buffer systems. It is readily apparent that catalysis of the deamination of Cyd and C differs from that of Ara-C in both magnitude and type. Cyd and C are catalyzed by both the acidic and basic components of the buffers. Thus general-acid and general-base catalysis are evident.

The catalytic constants for deamination of Ara-C were calculated only in dilute buffer solutions in the case of the acetic acid-acetate system because of the decreasing effect of buffer at higher concentrations (Fig. 1). It is obvious that Ara-C is subject primarily to general-acid catalysis under the conditions of this study. Furthermore, the catalytic constants for acetic acid and H_2PO_4^- are significantly larger than those for the corresponding constants in C or Cyd deamination (Table IV).

In a preliminary communication we have discussed two possibilities for participation by the 2'-hydroxyl (7). One case is that of intramolecular general-acid catalysis and the other that of general-base (Scheme II).

Scheme II

Consideration of the buffer data suggests that the general base mechanism is the more likely of the two. This is evident from the fact that Ara-C deamination exhibits buffer catalysis primarily by general acids whereas C and Cyd are susceptible to catalysis by both acidic and basic buffer components. Thus the Ara-C appears to be supplying its own basic catalyst and to require only the general-acid catalyst to undergo relatively rapid deamination.

Intramolecular catalysis by nucleophilic attack of the 2'-oxygen on C-6 would lead to the formation of the 2',6-cyclic intermediate, II, shown in Scheme III. This mechanism is basically similar to that previously proposed for Cyt (2) and Ara-C (1) except that the arabinosyl 2'-hydroxyl now serves as the general base.

The formation of 2',6-cyclonucleosides has also been implicated in the 5-H exchange reactions of Ara-U and 5'-deoxy Ara-U in MeONa-MeOD (6) and Ara-U and Ara-C in aqueous acid-base (8). This mechanism accounts for the increased deamination rates of Ara-C over Cyt and C in the absence of buffer since only H_3O^+ is required for the reaction to proceed.

Scheme III is also consistent with the observed behavior of the first-order rate constants for Ara-C deamination, k_1 , as a function of acetic acid concentration at pH 3.7, 70° (Figs. 1 and 2). The dependency of k_1 on acetic acid at low buffer concentrations can be explained on the basis of reversible proton addition to the C-5 of II as shown in the scheme. The maximum concentration of II would thus be a function of the rate of ring formation and the relative rate of proton addition to the cyclic intermediate. Thus at low buffer concentrations and sufficient H^+ -ion to catalyze the 2'-hydroxyl attack, one would expect to accumulate II. This is in agreement with the authors' observation that Ara-C deamination involves formation of an intermediate under such conditions (see *Experimental*). Increasing the concentration of acetic acid would result in a more rapid loss of II which would approach a steady state in high buffer concentrations. The observed deamination rate constant in more concentrated buffer (0.5 to 3.6 M acetic acid) appears to approach a constant value which would represent the rate constant for the formation of II under steady state conditions at pH 3.7. This would be

expected to be a constant at a given pH since it represents a process which is first-order in Ara-C protonated at N-3.

Scheme III is therefore consistent with the current data for inter- and intramolecular catalysis in Ara-C deamination. The deamination of C and Cyt presumably proceeds through a similar mechanism with the intermolecular general-acid and general-base catalysis being supplied by buffers. It is possible that the 5'-hydroxyl in Cyt participates to some extent as discussed earlier under the formation of I. This effect is minimal as compared to the 2'-hydroxyl in Ara-C under the present experimental conditions.

SUMMARY

1. At pH 3.7-4.7 70-80°, in the absence of buffers arabinosylcytosine undergoes hydrolytic deamination 30 to 40 times faster than cytidine which deaminates slightly faster than cytosine. This rate enhancement is attributed to intramolecular participation by the 2'-hydroxyl in the arabinosyl nucleoside.

2. First-order deamination rate constants, k_1 , for cytidine and cytosine showed a linear dependency on buffer concentration. Catalytic constants could be calculated from slopes of appropriate plots in the usual fashion. Both compounds were susceptible to general-acid and general-base catalysis by the buffer components.

3. Deamination rate constants for arabinosylcytosine did not show the usual linear dependency on acetic acid-acetate buffer concentration. Curves were obtained with negative deviation from linearity. In the most extreme case studied, a region where k_1 is nearly independent of buffer concentration is reported.

4. Catalytic constants were estimated from the initial slopes of k_1 versus acetic acid concentration in the arabinosyl case. Although the values for the catalytic constants are estimates it is unequivocal that general-acid catalysis predominates in Ara-C deamination. General-acid catalysis was also shown in phosphate buffer which showed no curvature.

5. It is hypothesized that Ara-C is subject to general-base type of intramolecular catalysis by the 2'-hydroxyl group. Thus only intermolecular general-acid catalysis is observed whereas both general-acid and general-base catalysis are required in the deamination of cytosine and cytidine.

Dynamic Dialysis as a Method for Studying Protein Binding I: Factors Affecting the Kinetics of Dialysis Through a Cellophane Membrane

MARVIN C. MEYER* and DAVID E. GUTTMAN†

Abstract □ A potentially useful method for determining the extent to which binding occurs in a protein-small molecule system consists of studying the kinetics of dialysis of the small molecule in the absence and presence of protein. The kinetics of dialysis of a number of compounds, in the absence of protein, was studied in some detail in order to characterize the nature of the dialytic process and its dependency on experimental variables. It was shown that the rate of escape of the small molecule from a dialysis cell was a first-order process provided that sink conditions were maintained. The influence of such variables as cell size, solution volume, stirring rates, temperature, pH, ionic strength, and viscosity on the rate process was considered and investigated. It was found that stirring rate (above a minimum), ionic strength, and viscosity did not markedly affect the kinetic picture. Temperature, pH (for one compound), the size of the cell, and the volume of solution contained by the cell did affect the rate of escape. Binding by the cellophane membrane was not encountered as a problem with the compounds studied. Experimental variables could be readily controlled to yield reproducible and dependable results.

Keyphrases □ Dialysis, dynamic—protein binding □ Protein binding determination—cellophane membrane, dialysis □ Permeation half-lives, apparent—small molecules □ Temperature, stirring, pH—buffer concentration effect—dialysis rate □ Viscosity effect—dialytic rate □ Ultrafiltration—phenol red-methylcellulose interaction determination □ UV spectrophotometry—analysis

A previous report (1) described a potentially useful method for studying protein-small molecule interactions. The technique consisted of determining, as a function of time, the escape of the small molecule from a dialysis cell, in the presence and absence of protein. The report indicated the promise of this approach for the rapid and convenient determination of fundamental binding parameters.

The present communication describes studies which were conducted to evaluate the influences of experimental variables which might be encountered in utilizing this technique. The effect of temperature, pH, viscosity, stirring rate, membrane area, liquid volume of the system, and binding of the small molecule by the dialysis membrane were considered.

EXPERIMENTAL

Materials—Bovine serum albumin (BSA), Fraction V (Calbiochem Laboratories) was used in this study. The 8-nitrotheophylline was synthesized according to the procedure reported by Morozowich (2). Other xanthine derivatives, phenol red, and methyl orange were obtained from commercial sources. Regenerated cellulose dialysis tubing [Union Carbide No. 20, 2.50 cm. (0.984 in.) flat width, with an average pore size of 24 Å] was conditioned prior to use by rapidly running distilled water through the tubing for several hours, with the tubing immersed in distilled water. The tubing was stored in distilled water at 2°.

Dynamic Dialysis Studies—The experimental system, the general protocol, and the treatment of data were described previously(1). Generally the systems were prepared to contain 7 ml. of a solution of small molecule in 0.04 M, pH 7.3, phosphate buffer, inside a 7-cm. long sac prepared from the dialysis tubing. The sac was im-

mersed in 200 ml. of 0.04 M, pH 7.3, phosphate buffer contained in a water-jacketed beaker, in the manner previously described (1). The systems were maintained at $25 \pm 0.2^\circ$. The contents of the sac were stirred with a twisted glass rod rotated at 125 r.p.m. Stirring of the external solution was achieved with a magnetic stirring bar. At time intervals, 100 ml. of the external solution was removed and immediately replaced with 100 ml. of fresh buffer. The concentration of small molecule in the removed sample was determined spectrophotometrically and the concentration of small molecule in the protein compartment was calculated from a knowledge of the initial concentration and the total amount of small molecule which had appeared in the external solution. During the investigation of a particular experimental variable, the remaining variables were held constant, as described in the conditions for the general system. Whenever possible, the order of experiments concerned with a particular variable, was selected to evaluate any progressive or irreversible effect.

The influence of temperature on the rate of dialysis of phenol red was studied at 25, 10, and $40 \pm 0.2^\circ$, in that order. Excellent temperature stability was attained through the use of the water-jacketed beakers in combination with a constant-temperature water bath and circulator.

In order to test the effect of stirring the system, the dialysis of phenol red was followed under four different conditions of stirring. The same dialysis sac was used for the four experiments. At the termination of each run the dialysis sac was thoroughly rinsed with distilled water. In the initial study, a dialysis sac containing the dye was suspended in the external buffer solution. The twisted glass rod used to agitate the sac contents, and the magnetic stir bar used to stir the external buffer bathing solution, were in place, but motionless. In a second study, only the magnetic stir bar was rotated. The third and fourth studies had external stirring *via* the magnetic stir bar, and internal stirring at either 125 or 500 r.p.m. The internal rate of stirring was controlled with a Servodyne rotator.

The influence of viscosity on the rate of dialysis was studied using methylcellulose (Fisher-100 cps.) as the viscosity inducing agent. Phenol red solutions were prepared at pH 7.3, to contain 0, 0.032 or 0.064% methylcellulose. The relative viscosities of the various phenol red-methylcellulose solutions or phenol red-BSA solutions, at pH 7.3 and 25° , were determined using a Gilmont falling-ball viscometer.

The effect of pH on dialytic rate was evaluated over a pH range of 3–11 for 8-nitrotheophylline, caffeine, 8-chlorotheophylline, and phenol red, in 0.06 M phosphate buffer. In addition, the dialysis of 8-chlorotheophylline was studied at pH 3 in 0.006 M phosphate buffer. The same dialysis sac was used for each experimental series involving a given small molecule. The pH of each system was maintained by preparing the internal and external solutions at the same pH and buffer concentration. The pH values were measured before and after each dialysis run and no variation in pH was noted during the course of an experiment.

The influence of the size of the dialysis sac, *i.e.*, the membrane area exposed to the external buffer solution, and the influence of the volume of the solution both inside the sac and external to the sac, were studied in a series of experiments conducted with phenol red in 0.04 M, pH 7.3, phosphate buffer, at 25° . First, three control runs were made in which 7 ml. of phenol red solution was placed into each of three, 7-cm. long, dialysis sacs. The sacs were placed into 200 ml. of pH 7.3 phosphate buffer in the usual manner. The loss of phenol red from each of these sacs was followed through about three half-lives. For the second portion of this study the sacs were rinsed and 6, 5, or 4 ml. of dye solution, of the same concentration as the initial control run, was placed into the three sacs and dialyzed. The third experimental series involved rinsing the sacs from the previous study, placing 7 ml. of phenol red solution into two of the sacs, and placing the two sacs into 350 or 500 ml. of pH 7.3 buffer

Table I—Summary of Apparent Permeation Half-Lives for Various Small Molecules

Compound	Mol. Wt.	Apparent Permeation Half-Life, min. ^a	No. of Trials
Trypan blue	960.83	No diffusion after 2 hr.	(2)
Phenol red	354.37	77.1 ± 5.6	(9)
Methyl orange	327.34	51.0 ± 4.0	(5)
Warfarin	308.32	67.5 ± 6.9	(5)
8-Nitrotheophylline	225.17	33.2 ± 2.7	(15)
8-Chlorotheophylline	214.62	38.2 ± 2.1	(6)

^a Values reported are average values ± 1 SD.

solution. The loss of phenol red was again followed. The fourth experimental series was conducted to ensure that the sacs had not suffered any damage or alteration in dialytic characteristics during the course of the first three studies. This study involved repeating the control runs in which 7 ml. of phenol red solution was placed into the dialysis sacs and the sacs were immersed in 200 ml. of buffer. Finally, a portion of each sac was cut off so that instead of each being 7 cm. long they were reduced to 6, 5, or 4 cm. The sacs were then placed into the three jacketed beakers containing 200 ml. of pH 7.3 buffer. A sufficient volume of the phenol red solution was added to the sacs to equalize the internal and external liquid levels. The final volumes inside the sacs were 5.7, 3.6, and 2.1 ml., respectively, for the 6-, 5-, and 4-cm. sacs. In addition to these studies, a system was also run in which the level of the liquid inside the sac exceeded the external liquid level. For this system 10 ml. of the phenol red solution was placed into a 10-cm. long dialysis sac and the sac was immersed in 425 ml. of buffer. The height of the internal liquid extended about 1.5 cm. above the height of the external liquid level. Data from this system were compared with data obtained with the same sac containing only 7 ml. of phenol red solution. In the latter system the internal and external liquid levels were the same. A final study determined the effect of variation in internal liquid volume under conditions of a progressively decreasing internal volume during the course of the dialysis. Initially 10 ml. of 0.44 mg./ml. phenol red-buffer solution, at pH 7.3, was placed into a 9-cm. long dialysis sac, and the sac was placed into 500 ml. of

0.064	5.18	1.290	1.23

^a BSA and/or methylcellulose solutions in pH 7.3 phosphate buffer at 25°. ^b BSA in pH 6.9 phosphate buffer at 25°.

pH 7.3 buffer. The dialysis was allowed to proceed with sampling of the external solution as usual. After approximately 2 hr., 2 ml. of the internal solution was withdrawn without replacement. Sampling of the external solution proceeded for an additional 2 hr., at which time 2 ml. was again withdrawn from the internal solution. After an additional 2 hr. the sac was removed and washed with distilled water. Ten milliliters of a 0.28 mg./ml. phenol red solution was then placed into the sac, the sac was immersed in 500 ml. of fresh buffer, and the rate of phenol red dialysis was again determined for the 10-ml. internal volume system. Thus in these studies the internal volume was decreased from 10 to 8 to 6 ml. and then restored to 10 ml.

The influence of the volume of solution in the sac on the rate of dialysis of 8-chlorotheophylline was also studied. The investigation was conducted by initially placing 10 ml. of 8-chlorotheophylline in pH 11.0 buffer solution into a 9-cm. sac, and suspending the sac in 500 ml. of pH 11.0 buffer. After the dialysis had been followed for a period of 1–1.5 hr., 4 ml. of the 8-chlorotheophylline solution inside the sac was withdrawn without replacement. The dialysis was allowed to proceed for an additional period of time. Thus the positioning of the membrane remained undisturbed throughout the course of the dialysis. This procedure was repeated at pH 3.0 using the same membrane.

The potential effect of membrane binding of the small molecule on the dialytic rate was illustrated by simulating strong membrane binding using activated charcoal (Merck, NF Powder). In these studies the dialysis of methyl orange in pH 7.3, 0.04 M, phosphate buffer, at 25°, was followed in the presence of 7.45 mg. of charcoal and in the absence of charcoal. The same dialysis sac was used for both experiments.

Ultrafiltration Studies—Ultrafiltration was employed to measure the interaction between phenol red and methylcellulose. Phenol red solutions were prepared, in pH 7.3, 0.04 M, phosphate buffer, to contain from 0.0–0.09% methylcellulose. Ten milliliters of each

Figure 2—The influence of stirring on the apparent first-order escape of phenol red from the dialysis cell, at 25°. Δ , no stirring; \square , external stirring only; \circ , internal stirring at 125 r.p.m.; \bullet , internal stirring at 500 r.p.m.

solution was placed into 12.5-cm. long, double-walled dialysis sacs. The sacs were prepared by partially everting a 25-cm. segment of hydrated cellulose dialysis tubing. The sacs were secured in glass stoppered centrifuge tubes by means of the excess tubing extending out of the mouth of the centrifuge tube. The tubes were centrifuged at 2000 r.p.m. for about 5 min. The filtrate, approximately 0.2 ml., was discarded to minimize error due to moisture initially associated with the membrane. The centrifugation was then continued for approximately 25 min. to collect an additional 0.5 ml. The filtrate and solution inside the sac were analyzed spectrophotometrically to obtain the free and total dye concentration, respectively. There was no evidence of leakage of the methylcellulose from the sac, as determined by the colorimetric test of Kanzaki and Berger (3), or of significant membrane binding of the phenol red.

Analytical Methods—The compounds studied were assayed spectrophotometrically with a spectrophotometer (Beckman DU) equipped with a power source and digital, absorbance read-out (Gilford). Concentrations were determined from Beer's law plots prepared at appropriate wavelengths and pH's.

RESULTS AND DISCUSSION

There are at least three mechanisms which have been suggested to explain the selective permeability of dialysis membranes (4).

Figure 4—The effect of pH on the apparent first-order escape of 8-nitrotheophylline at 25°. Key: \square , pH 3.0; \circ , pH 7.0; Δ , pH 11.0.

Figure 5—The effect of pH and buffer strength on the apparent first-order escape of 8-chlorotheophylline at 25°. Key: \circ , pH 3.0, 0.06 M buffer; Δ , pH 3.0, 0.006 M buffer; \square , pH 11.0, 0.06 M buffer.

Cellophane membranes are generally thought to function on the basis of diffusion through pores (5), rather than by dissolution in the membranes, or some other mechanism.

Table I indicates the relationships observed between molecular weight and the apparent permeation half-lives for the dialysis of a variety of small molecules, as determined in the system employed at 25°. The permeation half-life is defined as the time required for the total small molecule concentration within the dialysis sac to decrease by 50%. The half-lives were determined from studies conducted at pH 7.0–7.3, with the exception of studies involving the xanthenes. The dialytic rates of the xanthenes studied were determined, in separate experiments, to be independent of pH. As a result, average half-lives for these compounds include data for studies conducted over a pH range of 3–11.

The data in Table I show that the bulky, high molecular weight compounds diffuse through the membrane with the most difficulty, and the smaller, lower molecular weight xanthenes diffuse more rapidly, and at similar rates. Some of the data in Table I conformed quite well to the direct relationship between the permeability of small molecules through membrane pores and the square root of the molecular weight, as suggested by Danielli (6). Trypan blue, phenol red, and warfarin, however, permeated the membrane at rates which were considerably slower than would be predicted on this basis. These relatively bulky compounds illustrate the in-

Figure 6—The effect of pH on the apparent first-order escape of phenol red at 25°.

Figure 7—Effect of liquid volume and membrane area on the apparent permeability constant for the dialysis of phenol red at pH 7.3 and 25°.

fluence of molecular volume on membrane permeability, which has also been discussed by Danielli (6).

Osmotic Effect of the Protein—It was not anticipated that there would be any dilution of the contents of the dialysis sac due to the presence of protein because the protein concentrations were at least 100 times less than the buffer concentration of 0.04 *M* which was present both inside the dialysis sac and external to it. The lack of dilution was verified by determining that solutions of 1.7% BSA prepared in pH 7.3, 0.04 *M*, phosphate buffer, and placed into dialysis sacs, showed no change in BSA concentration after several hours, when the sacs were placed into the external buffer bathing solution.

The Effect of Temperature on Rate of Dialysis—Figure 1 illustrates the effect of temperature on the rate of dialysis of phenol red, at pH 7.3. The apparent half-life for escape of phenol red from the dialysis cell was calculated to be 122.4, 67.8, and 48.6 min. for the 10, 25, and 40° systems, respectively. The data were further treated utilizing the Arrhenius expression, and the energy of activation for the dialysis of phenol red through the cellophane membrane was graphically determined to be 5.5 kcal./mole/deg. The results of these studies clearly indicate the importance of adequate temperature control, in order to preclude any temperature effect on the intrinsic dialytic rate of the small molecule through the membrane.

Influence of Stirring on Rate of Dialysis—The effect of agitation on the rate of dialysis through a membrane has been discussed by Carr (7). At the initiation of dialysis a concentration gradient for the diffusing species exists across the membrane, from a region of uniform high diffusate concentration on one side, to a region of zero concentration on the other. As the dialysis proceeds there is an accumulation of diffusate on one side and a depletion on the other, with a resulting marked diminution of the concentration gradient across the membrane. Therefore agitation of the solution on each side of the membrane tends to homogenize the concentrations of the solutions and results in an increase in the rate of dialysis, which is proportional to the concentration gradient.

The dynamic dialysis system allows stirring, both internally *via* a twisted glass rod attached to a variable speed motor, and externally by means of a magnetic stir bar. Figure 2 illustrates the effect of stirring on the rate of dialysis of phenol red. There was no apparent difference between an internal stirring rate of 125 and 500 r.p.m., indicating that no advantage is to be gained by stirring the internal solution at other than a moderate stirring rate. It was interesting to observe that for the unstirred systems, there was an initial rapid rate of dialysis, followed by a significantly slower rate which was apparent after approximately 1 hr. This was undoubtedly a result of the accumulation and depletion phenomena discussed with respect to the diffusion gradient existing across the membrane. In the totally unstirred system it was observed that a visible diffusion layer developed on the outside of the membrane.

In view of these results, subsequent dynamic dialysis studies were conducted under stirred conditions. The external solution was agitated at a relatively constant rate with a magnetic stir bar. The contents of the dialysis sac were stirred with a twisted glass rod rotated at approximately 125 r.p.m.

Influence of Viscosity on Rates of Dialysis—The dynamic dialysis method for measuring protein-small molecule interactions is dependent on the assumption that the free, unbound diffusing species will dialyze with an identical rate in the presence or absence of protein. It was therefore necessary to establish that increased viscosity of the internal solution, due to the presence of protein, did not affect the rate of dialysis. In other words, it was necessary to show that in the presence of protein, diffusion through the membrane rather than diffusion to the membrane was still the rate-limiting step. To study the potential effect of viscosity, an agent was required which would simulate the viscosity of a protein solution, would not bind the diffusing species, and would not diffuse through the dialysis membrane. Phenol red was utilized as the small molecule and methylcellulose was employed in these studies to simulate the viscosity of solutions containing protein.

The relative viscosities of a series of protein-phenol red solutions of various BSA concentrations were measured with a Gilmont falling-ball viscometer. Other experiments showed that phenol red solutions, at 25°, containing 0.01–0.07% methylcellulose, in pH 7.3 buffer, had relative viscosities comparable to those of 1–5% BSA-phenol red solutions, also at pH 7.3 and 25°. The relative viscosities were calculated as the observed viscosity divided by the viscosity of water at the experimental temperature. Table II illustrates the relative viscosities obtained for solutions of BSA and methylcellulose at various concentrations. In addition, data obtained by Shikama (8), using an Ostwald-type coil viscometer, are given for comparison.

It was also necessary to show that methylcellulose did not interact, to a significant degree, with phenol red. The lack of interaction was established through ultrafiltration experiments. The results of these studies indicated that a maximum of approximately 4 % of the phenol red was bound to the methylcellulose, over the concentration range studied. This amount was too small to significantly affect the rate of phenol red dialysis in the dynamic dialysis system.

The results of the dialysis studies of phenol red at pH 7.3 and 25°, in the presence and absence of methylcellulose, is given in Fig. 3. It is apparent that the increased viscosity did not affect the rate of dialysis. Thus it may be concluded that increases in viscosity due to the presence of at least 5.2 % BSA, will not influence the rate of dialysis.

Influence of pH and Buffer Concentration on Rates of Dialysis—

The effect of pH on dialytic rate was studied to observe whether or not the degree of ionization of a diffusing species affected the observed rate of dialysis. In addition, it was of interest to investigate the possibility that ionizable groups in the cellophane membrane could influence the rate of dialysis of a charged species. It should be noted, however, that there is some disagreement in the literature (5, 9) as to whether charged groups, primarily carboxyl groups, are actually present in cellophane.

The dialysis of 8-nitrotheophylline, which has a *pK_a* of 2.11, was studied at pH 7.0, 3.0, and 11.0, in that order, with the same dialysis sac utilized for all three experiments. The results are illustrated

Figure 8—The effect of a pressure head on the apparent first-order escape of phenol red, at pH 7.3 and 25°. Key: □, 10 ml. of solution inside sac; ○, 7 ml. of solution inside sac.

in Fig. 4. It is apparent that the rate of dialysis was constant over the wide pH range. In addition to the lack of effect of pH, Fig. 4 indicates the excellent reproducibility for various experiments conducted with the same dialysis sac.

As a further test of the effect of pH on the rate of dialysis, the behavior of 8-chlorotheophylline, which has a pK_a of 5.28, was studied. The investigations were conducted at pH 3.0 and 11.0 in 0.06 *M* phosphate buffer, and at pH 3.0 in 0.006 *M* phosphate buffer, using the same dialysis sac. The results of these studies are shown in Fig. 5 and indicated that the state of ionization of the 8-chlorotheophylline and the buffer concentration, within the concentration range utilized, did not influence the rate of dialysis.

The dialysis of caffeine, which is nonionized over the pH range of interest, was studied at pH 3.0 and 11.0. The results were identical to those obtained for 8-nitrotheophylline and 8-chlorotheophylline and showed that the rate of caffeine dialysis was independent of pH and highly reproducible for a given membrane.

Finally, the dialysis of phenol red, at several pH's, was studied using the same sac for each pH. This dye was selected because it is a dibasic acid with a $pK_1 < 1$ and a $pK_2 = 7.9$. The dialysis studies were conducted at pH 11.0, 3.0, and 7.9. The order of the experiments was again chosen to enable the determination of reversibility of any observed effect of pH. The results of these studies are shown in Fig. 6, and illustrate a definite pH effect. The observed results may be rationalized on the basis of an increased effective molecular size due to an increased state of hydration of the phenol red as it changed from a singly charged to a doubly charged anion. This increase in effective size may retard passage of the ion either through the tortuous pores of the membrane or through a diffusion layer. The possibility also exists that the pH affected the ionization of groups of the membrane and that these groups are only important in retarding the dialysis of a relatively large anionic species such as phenol red.

The primary conclusion to be obtained from these experiments is that if protein binding studies are to be conducted at several pH's, using the dynamic dialysis technique, it may be necessary to run control experiments in the absence of protein at each pH, to es-

Figure 9—The influence of changing solution volume, within the dialysis sac, during the course of phenol red dialysis at pH 7.3 and 25°. (I), initial 10-ml. volume of the dialysis cell decreased by 2 ml. at approximately 2-hr. intervals; (II), volume of the dialysis cell restored to 10 ml.

tablish the value for the apparent permeability constant for the small molecule.

Influence of Dialysis Sac Size and Solution Volume on Rates of Dialysis—The rate of dialysis would be expected to depend on the area of the membrane exposed to the solution of diffusing species. It was, therefore, considered important to evaluate the extent to which sac size influenced rate of dialysis. In addition, experiments were conducted to determine if the volume of external bathing solution could affect the observed rate of dialysis.

The first experimental series followed phenol red dialysis from systems in which the internal volume was 6, 5, or 4 ml. The next series utilized an external volume of 350 or 500 ml. of buffer bathing solution. Finally, the length of the sacs was decreased and the phenol red dialysis was followed from sacs which were 6, 5, or 4 cm. long. In order to evaluate the effects of volume and sac size variation, the apparent permeability rate constants obtained from the various experiments were divided by the appropriate apparent rate constant obtained with the same sac under control conditions. This was done to normalize the data so as to correct for variation in the intrinsic permeability of each of the three dialysis sacs employed in these studies. Control runs were conducted with 7-cm. long sacs containing 7 ml. of phenol red solution. The control sacs were suspended in 200 ml. of external buffer bathing solution.

The results of these investigations are illustrated in Fig. 7, where the K_e ratio is the apparent permeability constant obtained for a given experimental condition, divided by the constant obtained for the given membrane in the control study. It is apparent from this figure that a decrease in the volume of the liquid inside the sac, or decreasing the length of the sac, with a concomitant decrease in volume of the internal solution, caused a progressive increase in the apparent permeability rate constant, and therefore a progressive decrease in the apparent half-life for dialysis. An analysis of these results showed that as the ratio of membrane surface area to the volume of solution in the sac increased, the apparent permeability constant also increased.

In addition to these studies, a system was also run in which the level of the liquid inside the sac exceeded the external liquid level, i.e., a pressure head was present inside the sac. The results of this study are shown in Fig. 8 and indicate an increase in the apparent half-life of dialysis of approximately 50% for the system with the smaller surface area-to-liquid volume ratio.

As a final illustration of the effect of varying the internal liquid volume, a system was investigated which involved progressively decreasing the internal volume of phenol red solution throughout the course of the run. After sampling of the internal solution, without replacement, the internal and external liquid levels immediately equalized. Thus the area of the membrane exposed to both solutions remained relatively constant. The results of this study are illus-

trated in Fig. 9 and clearly demonstrate the previously observed increase in rate of dialysis with decrease in internal liquid volume. It should be noted that the influence of volume of internal liquid was entirely reversible as evidenced by the close agreement between the two runs, with 10 ml. of liquid inside the sac, conducted before and after the systems involving 8 and 6 ml. of internal liquid. Results, analogous to these, were obtained when 8-chlorotheophylline was employed as the diffusing species at both pH 3 and 11.

Several explanations may be offered to account for the observed behavior. It was noted that as the volume of the liquid inside the sac was decreased the sac assumed a semicollapsed state. It is possible, therefore, that as the size of the sac was increased for a given internal volume, or the volume was decreased for a given size sac, the mean distance from the center of the sac to the membrane decreased, and this decrease resulted in an increased rate. However, this would suggest that diffusion to the membrane was the rate limiting step, and since the solutions were stirred inside and outside, this explanation seemed unlikely in view of the stirring rate experiments. It is possible, however that as the distance between the stirring rod and the membrane decreased, more efficient stirring resulted and the thickness of the diffusion layer, which may still be present under moderate stirring conditions, was reduced and led to an enhancement of the diffusion rate. Alternatively, it is possible that as the surface-to-volume ratio increased, *i.e.*, as the bag was able to assume a somewhat collapsed state, the decrease in tension on the sac caused an alteration in the pore structure to one more favorable for the passage of the phenol red molecule. This may be visualized as either a decrease in the tortuosity of the pore, or perhaps a realignment of charged groups, which may be present in the membrane, in the vicinity of the pores. Other workers (5) have observed that changes in the tension on a membrane can have an effect on the permeability characteristics of a membrane. While the changes in the tension of the membrane, due to the changes in volume of the internal solution, are admittedly relatively small, it is conceivable that they are sufficiently great to cause an alteration in the tortuosity or size of the pore. This is more convincing when one examines the schematic concept which Mosse (10) has presented of the complex and tortuous nature of the pore structure of a cellulose derivative membrane. As further evidence for this hypothesis of variable pore structure, the work of Craig (5) may be cited. He studied the rate of diffusion of ribonuclease through cellophane casing under various conditions of membrane stretching. A three-fold increase, in the apparent half-life observed for ribonuclease diffusion with linear stretching of the membrane, was attributed to deformation of the pores. The degree of stretching was much greater in these studies than in the present investigation. However, the results do give some insight into the potential effect of alteration of pore structure.

As a result of these experiments it was concluded that the volume of the solution external to the dialysis sac does not affect the rate of dialysis of a small molecule from within the sac. However the size of the sac and the volume of the diffusate solution within the sac can have a significant influence on the rate of dialysis. Fortunately, when sac size and volume are maintained constant, excellent run to run reproducibility can be achieved.

Binding of Small Molecules by the Dialysis Membrane—Some degree of membrane binding of a compound is a frequently observed occurrence in dialysis studies. If it is extensive, then a correction must be applied to account for the amount of small molecule which has been bound in this manner.

If this type of interaction is essentially an adsorption phenomenon, then it should be reversible. Ideally the membrane may be considered as another binding species and for systems containing protein, the

membrane may be treated mathematically as though a second protein species were present. If the preceding concepts of membrane binding are correct, then in the absence of protein, a small molecule which strongly interacts with the membrane should yield curvature in the semilog plot of total drug remaining in a dialysis sac *versus* time. Thus the possibility of sac binding must be recognized in using the dynamic dialysis technique or erroneous characterization of protein binding behavior may result.

If membrane binding is acknowledged to be essentially an adsorption phenomenon, then very strong sac binding should be simulated by the presence of an adsorbent such as charcoal. Experiments were, therefore, conducted to measure the diffusion of methyl orange from a dialysis sac, in the presence and absence of 7.45 mg. of charcoal. The results of these studies are shown in Fig. 10 and illustrate the expected result that the presence of the adsorptive agent resulted in a nonexponential escape of the methyl orange from the dialysis sac.

Most studies in the literature, involving diffusion of small molecules through cellulose dialysis tubing, have reported less than 10%, and usually negligible membrane binding. Since a reasonably strong association between the small molecule and membrane would be necessary for any significant effect on the kinetics of dialysis, it is likely that only in the event of very strong sac binding would the dynamic dialysis method be affected. One means of detecting any effect of sac binding would be to observe for curvature in the semilog plot of total drug concentration remaining in the sac *versus* time, in the absence of protein. Such curvature was never observed for any of the small molecules employed during the course of these investigations.

Dynamic Dialysis as a Method for Studying Protein Binding II: Evaluation of the Method with a Number of Binding Systems

MARVIN C. MEYER* and DAVID E. GUTTMAN†

Abstract □ A method for determining the concentrations of unbound and bound small molecule in a protein solution is described, based on the fact that the rate of disappearance of small molecule from a dialysis cell is proportional to the concentration of the unbound species. Curves describing the kinetics of dialysis for 8-nitrotheophylline, 8-chlorotheophylline, caffeine, warfarin, methyl orange, and phenol red in the presence and absence of albumin were obtained and analyzed to yield estimates of unbound and bound forms of the compounds. The data were treated by means of Scatchard plots to provide values for the binding parameters, n and K . The values were found to be in agreement with those reported in the literature and/or determined by independent methods. The ease of application and merits of the method were demonstrated by a comprehensive study of the influence of pH on the binding of 8-nitrotheophylline by bovine serum albumin. Utilization of the method for the study of competitive inhibition of protein binding was also illustrated.

Keyphrases □ Dialysis, dynamic—protein binding determination □ Small molecule binding—protein □ Protein binding—competitive inhibition, drugs □ Kinetic equations—dialysis, small molecules □ pH binding profile, small molecule—kinetics □ UV spectrophotometry—analysis

Previous reports in this series (1, 2) have described in detail a new method for the determination of the degree of interaction between proteins and small molecules. The method is based on the fact that the rate of disappearance of small molecule from a dialysis cell is proportional to the concentration of the unbound species. The influence of experimental variables such as pH, temperature, stirring rate, viscosity, size of the membrane, volumes of liquid within the system, and membrane binding of the small molecule have been previously considered (2).

The present communication describes a series of studies designed to further evaluate the dynamic dialysis method as a technique to quantitate protein binding systems, and to obtain values for the fundamental binding parameters of n (the number of binding sites involved in the interaction) and K (the intrinsic association constant characterizing the interaction). The method was also applied to the comprehensive determination of the effect of pH on the interaction between 8-nitrotheophylline and bovine serum albumin over a wide range of pH. Studies were also conducted to demonstrate the potential of the dynamic dialysis method for the study of competitive inhibition of protein binding.

EXPERIMENTAL

Materials—Human serum albumin, (HSA) Fraction V, (Calbiochem), was used in this study. Warfarin sodium (Endo Laboratories) was used, and the remainder of the materials utilized in the study have been previously described (2).

Dynamic Dialysis Studies of Protein Binding—The protocol for the dynamic dialysis system and the treatment and interpretation of

data have been discussed previously (1, 2). The method was employed to assess the binding of phenol red, warfarin, caffeine, 8-chlorotheophylline, 8-nitrotheophylline, salicylate, and methyl orange by bovine serum albumin (BSA). Initially, 7 ml. of a control solution, prepared to contain the given small molecule in 0.04 *M* phosphate buffer at an appropriate pH, was placed into a 7-cm. long dialysis sac. The sac was then immersed in the buffer bathing solution of 0.04 *M*, phosphate buffer. The system was maintained at $25 \pm 0.2^\circ$. Each control dialysis was followed for about 2 hr., and the results were used to calculate the apparent permeability rate constant characterizing the escape of small molecule from each sac. The sac was then rinsed thoroughly with distilled water and blotted with tissue to remove excess moisture. Seven milliliters of a small molecule-protein solution, prepared in 0.04 *M* buffer at the same pH as the control, was then introduced into the sac. The sac was placed into fresh buffer bathing solution and the dialysis of the small molecule from the protein compartment was followed for 5 to 9 hr. The frequency at which 100-ml. samples were removed from the external solution and replaced with fresh buffer solution was dictated by the need to maintain sink conditions, and by the sensitivity of the assay method for the particular small molecule. It was observed from preliminary experiments that sink conditions were approximated if the concentration of small molecule in the external solution was not allowed to exceed one-tenth of that unbound in the internal solution. At the termination of a run, the internal solution was sampled and analyzed for small molecule content. The binding parameters obtained from the dynamic dialysis studies were then compared with values obtained by alternate approaches such as equilibrium dialysis or ultrafiltration, and/or with literature values.

For the study of the influence of pH on the interaction between BSA and 8-nitrotheophylline, three separate experimental systems could be conveniently run at one time, each maintained at a different pH. For these determinations, a series of solutions were prepared containing 8-nitrotheophylline in the presence and absence of BSA. The solutions covered a pH range of 3.0–10.9, in 0.04 *M* phosphate buffer. The protein systems contained approximately 0.75% BSA. The external buffer bathing solution was also prepared at the same pH and buffer concentration as the internal solution. The dialysis was followed for a sufficient period of time to fully characterize the kinetics of each system. The pH's of the internal and external solutions were redetermined at the termination of each experimental run and were found not to have changed.

Data Treatment—Kinetic curves for each system investigated were analyzed by the previously reported method (1). The data treatment yielded values for the concentrations of unbound (D_f) and bound (D_b) species, for a number of different total small molecule concentrations (D_t). Results were displayed in the form of Scatchard plots where $\bar{v}/(D_f)$ (\bar{v} = moles of small molecule bound per mole of protein) was plotted as a function of \bar{v} . Values of the binding parameters (n 's and K 's) were estimated by fitting the data, with the aid of a nonlinear regression computer program,¹ to the generalized binding expression given in Eq. 1.

$$\bar{v}_d = \sum_{i=1}^i \frac{n_i K_i (D_f)}{1 + K_i (D_f)} \quad (\text{Eq. 1})$$

Two classes of binding sites were assumed if the experimentally determined Scatchard plot exhibited curvature (3). In this report experimental data are indicated in the Scatchard plots by points while solid lines represent behavior predicted on the basis of computed n and K values.

Salicylic acid	Experimental: dynamic dialysis	1	5	2.00×10^5	1.75×10^3

^a n_i = the number of binding sites in the i 'th class. ^b K_i = the intrinsic association constant for the i 'th class of sites (l_i/M).

Ultrafiltration—Ultrafiltration was utilized to study the binding of warfarin by BSA and HSA and the procedure used was that previously described (2). These studies were performed with solutions containing warfarin in a concentration range of 0.032–0.380 mg./ml. in 0.04 *M*, pH 7.3, phosphate buffer. The initial protein concentration was 0.37% for the BSA studies, and 0.39 or 0.78% for the HSA studies. After centrifugation the concentration of small molecule in the filtrate and the total small molecule concentration of the solution remaining in the sacs was determined. From a knowledge of these concentrations and the total protein concentration in the system, the values for $\bar{v}_i(D_f)$ and \bar{v} were calculated. Preliminary experiments indicated that approximately 4% of the warfarin introduced into the system was bound to the membrane.

Equilibrium Dialysis Studies—The binding of warfarin by BSA was also studied by the technique of equilibrium dialysis. These experiments were conducted using 10-ml. capacity, Plexiglas dialysis cells. The warfarin concentrations employed in these studies

ranged from 0.002–0.6 mg./ml., in 0.04 *M*, pH 7.3, phosphate buffer. The BSA concentration was 0.4%. Preliminary experiments indicated that about 3% of the warfarin was bound to the membrane separating the two compartments of the dialysis cell, and that equilibrium was attained in the cells within 12 hr. The systems were prepared by placing 5 ml. of warfarin solution on one side of the membrane, and 5 ml. of warfarin and protein solution on the other. The cells were agitated, on a platform shaker, for at least 14 hr. at room temperature, $25 \pm 2^\circ$. After equilibration, both sides of the cell were sampled, and from a knowledge of the total warfarin in the system, the free warfarin concentration, the degree of membrane binding, and the total protein concentration, the values for $\bar{v}_i(D_f)$ and \bar{v} were calculated.

Dynamic Dialysis Studies of Competitive Inhibition of Binding—The preliminary step in these studies was to determine if the presence of the competitor in the system exerted an effect on the intrinsic rate of dialysis of the small molecule under consideration. 8-Nitrotheophylline was utilized as the test species, and 8-chlorotheophylline or salicylic acid were employed as the competitors. A control run with 8-nitrotheophylline was first conducted, and then using the same membrane sac, the dialysis of 8-nitrotheophylline was followed in the presence of the competitor. Then an 8-nitrotheophylline and BSA system was dialyzed to obtain the kinetic and equilibria parameters operant in the absence of competitor. Finally, still using the same membrane, 8-nitrotheophylline, BSA, and competitor were dialyzed. Two approaches were used in the competitive studies. In the first, a known competitor concentration was incorporated inside the dialysis sac. The decline of both 8-nitrotheophylline and competitor concentration inside the sac was followed by determining the amounts of 8-nitrotheophylline and competitor appearing in the external solution. The second approach was such that the concentration of competitor remained essentially constant throughout the dialysis. Here a known competitor concentration was placed into the dialysis sac containing the 8-nitrotheophylline. In addition, the external buffer bathing solution was prepared to contain an equivalent concentration of competitor. Further, the samples which were withdrawn from the external solution were replaced with a solution which contained the same concentration of the competitor as originally present. In this manner the concentration of the competitor was held constant during the course of the dialysis. All studies involving 8-nitrotheophylline and/or competitor species were conducted at 25° in pH 7.0, 0.04 *M*, phosphate buffer.

Analytical Methods—The compounds studied were assayed spectrophotometrically with a Beckman DU spectrophotometer equipped with a Gilford power source and digital, absorbance read-out. Concentrations were determined from Beer's law plots constructed at appropriate wavelengths and pH values.

The concentration of 8-nitrotheophylline in the presence of BSA was determined spectrophotometrically at pH 11 versus an appropriate BSA blank. The absorbance due to protein was negligible in the visible region of the spectrum, and at pH 11 there were no spectral manifestations of interactions between the BSA and 8-nitrotheophylline.

Figure 1—The loss of 8-chlorotheophylline from inside a dialysis sac, in the presence and absence of BSA. The studies were run at pH 7.0 and 25°.

Figure 2—The binding of 8-chlorotheophylline by BSA at pH 7.0 and 25°. Key: O, 0.812 and 1.218% BSA, dynamic dialysis; Δ , literature values; (6), equilibrium dialysis at pH 6.85 and 9°.

Because BSA interfered with the direct spectrophotometric determination of caffeine, warfarin, and 8-chlorotheophylline, extraction procedures were utilized. Two milliliters of sample containing caffeine and BSA were quantitatively extracted with 25 ml. of chloroform, and the organic layer was examined spectrophotometrically at 272 $m\mu$ versus an appropriate chloroform blank. Samples containing 8-chlorotheophylline and BSA were assayed for 8-chlorotheophylline by diluting 2 ml. of sample to 3 ml. with diluted phosphoric acid (1:5) and extracting with 25 ml. of a chloroform-isopropyl alcohol (19:1) solution. The organic phase was assayed spectrophotometrically at 276.5 $m\mu$ versus an appropriate solvent blank. Solutions containing both warfarin and BSA were assayed by the method of O'Reilly *et al.* (4). Centrifugation was utilized to break any emulsions formed during the extraction procedures.

Samples containing 8-nitrotheophylline in combination with 8-chlorotheophylline, caffeine, or salicylic acid were assayed for both components by a differential spectrophotometric assay conducted at 386 $m\mu$, and 276.5, 272, or 302 $m\mu$, respectively. Samples containing 8-nitrotheophylline, 8-chlorotheophylline, and BSA were adjusted to pH 11 and assayed for 8-nitrotheophylline at 386 $m\mu$. The 8-chlorotheophylline concentration was determined by extracting an acidified sample and measuring the absorbance of

Figure 3—The loss of caffeine from inside a dialysis sac, in the presence and absence of BSA. The studies were run at pH 7.0 and 25°.

Figure 4—The binding of caffeine by BSA at pH 7.0 and 25°, as depicted by a Scatchard plot. Key: O, 1.83% BSA, \square , 3.65% BSA.

the organic phase at 276.5 $m\mu$. The latter absorbance was corrected for the small contribution of the 8-nitrotheophylline to the reading at this wavelength.

RESULTS AND DISCUSSION

Determination of the Binding Constants for the Interaction of Various Small Molecules with BSA—A previous report (1) described studies employing this technique with phenol red and methyl orange. For comparative purposes, binding parameters for these two compounds are presented in Table I, along with values for a number of other compounds which were investigated. It should be noted that parameters characterizing the binding of methyl orange (1, 5) were reported incorrectly and have been corrected in Table I.

Figure 5—The binding of salicylic acid by BSA at pH 7.0 and 25°.

Figure 6—The loss of warfarin from inside a dialysis sac, in the presence and absence of BSA. The studies were run at pH 7.3 and 25°. Key: ○, 0.63% control; □, 1.465% control; ●, 0.63% BSA, experimental; ■, 1.465% BSA, experimental; ○, 0.63% BSA, theoretical; □, 1.465% BSA, theoretical.

Binding of 8-Chlorotheophylline—Figure 1 illustrates the results of dynamic dialysis experiments with 8-chlorotheophylline in the presence and absence of BSA at 25° and pH 7.0. Transformation of the data, in the manner described, yielded the Scatchard plot of Fig. 2. Data obtained by Eichman *et al.* (6) for this system at pH 6.85 and 9°, using equilibrium dialysis, is also shown. The small differences between Eichman's data and those of the present study can be attributed to a difference in the temperatures employed.

Binding of Caffeine—Caffeine has been shown to interact rather weakly with BSA (6, 7). It was, therefore, of interest to attempt to quantitate its binding behavior by the dynamic dialysis approach.

Figure 7—The binding of warfarin by BSA and HSA at pH 7.3 and 25°. Key: △, BSA, ultrafiltration and equilibrium dialysis; ●, HSA, ultrafiltration; ○, 0.63% BSA, dynamic dialysis; □, 1.465% BSA, dynamic dialysis.

Results obtained at 25° in 0.04 M pH 7 buffer are shown in Fig. 3. It can be seen that in spite of relatively high protein concentrations, the difference in kinetic behavior in the absence and presence of protein was small and reflects the weak nature of the interaction. Figure 4 shows the corresponding Scatchard plot. From a least-squares fit of the Scatchard plot, it was determined that the interaction between BSA and caffeine could be appropriately characterized by the parameters $n = 1$, and $K = 1.02 \times 10^3$ l./mole. These values are in reasonable agreement with the parameters reported by Eichman *et al.* (6) from equilibrium dialysis studies at pH 6.85 and 9°. The somewhat lower association constant obtained in the present study, which was conducted at a higher temperature than the work of Eichman *et al.*, is consistent with a previous observation (8) of decreased xanthine binding with increased temperature.

It should be noted that the binding of a weakly interacting compound is difficult to quantitate accurately by any experimental technique due to magnification of experimental error by subsequent data treatment. The caffeine studies demonstrate that the dynamic dialysis method can be useful in characterizing even weak interactions.

Binding of Salicylic Acid—Figure 5 illustrates a Scatchard plot derived from the kinetics of dialysis of salicylic acid at pH 7.0 and 25° in the presence of 1.616% BSA and in the absence of BSA. The data were found to be consistent with the binding parameters given in Table I.

The binding observed in this study was somewhat stronger than that observed by Davison and Smith (9) in their studies conducted at 4° and pH 5.4, in acetate buffer. They reported binding constants of $n_1 = 0.37$, $n_2 = 3.5$, $K_1 = 3 \times 10^4$ l./mole, and $K_2 = 1 \times 10^2$ l./mole, and observed little difference in binding behavior between pH 5.4 and 7.0. They also reported that acetate can competitively inhibit salicylate binding and this might be the reason for the difference in strengths of binding between the two studies.

Binding of Warfarin—The binding of warfarin by albumin has been well studied and characterized (10) and thus, it was felt that warfarin would serve admirably as an additional compound with which to assess this new approach for quantitating binding behaviors. The results of the dynamic dialysis examination of warfarin binding are summarized in Fig. 6 which depicts the kinetics of dis-

Figure 8—The loss of free warfarin from inside a dialysis sac, in the presence of BSA, at pH 7.3 and 25°. Key: ●, ■, dynamic dialysis data; ○, □, theoretical data.

Figure 9—The loss of 8-nitrotheophylline from inside a dialysis sac in the presence and absence of 0.75% BSA. The studies were conducted at a variety of pH's and 25°. Key: ---, average control run.

appearance of warfarin from a 0.630% solution of BSA and from a 1.465% solution of BSA, as well as for corresponding control systems. The difference between control runs is significant and reflects the fact that a different membrane was used for the two systems. The control runs were repeated and found to be entirely reproducible.

The Scatchard plot is shown in Fig. 7. It was disturbing to compare this plot with that presented by O'Reilly (10) who studied, by equilibrium dialysis, the interaction of warfarin with human serum albumin (HSA). O'Reilly's data indicated a much weaker degree of interaction and the marked lack of agreement prompted further studies on the binding of warfarin. To assess whether or not HSA possessed a significantly different affinity for warfarin than did BSA, the binding of warfarin by the two proteins was investigated using ultrafiltration. The results are also shown in Fig. 7 and demonstrate that the nature and extent of binding were the same for both proteins. The interaction was also investigated by equilibrium dialysis and the results are presented in Fig. 7. It is obvious that the three different experimental methods provided data which were in excellent agreement and, therefore, indicated that neither the source of the albumin nor the experimental approach could explain the lack of agreement with the results of O'Reilly. In view of this, O'Reilly's data were examined more critically to reveal two computational errors. First, a correction for sac binding was made which was based on the total concentration of warfarin rather than on the concentration of free warfarin in the system. This, however, resulted in only a minor error since the sac binding was only of the order of 3.6%. A more serious computational error was involved in the calculation of \bar{v} . When a correction was made the \bar{v} values increased and were quite consistent with those of the present study. The combined data of Fig. 7 were used to generate the n and K values presented in Table I.

Theoretical Treatment Describing the Escape of a Small Molecule from a Protein-Containing Compartment—It has been demonstrated that kinetic data obtained in the dialysis of a small molecule in the absence and presence of protein can be treated to gain estimates of (D_f) and (D_b) and subsequently n 's and K 's. The validity of the approach has been confirmed by the close agreement of binding parameters, estimated by using this method, with those determined by classical methods. It did seem desirable, however, as a further

Figure 10—The binding of 8-nitrotheophylline by BSA at various pH's and 25°.

check, to compare experimentally observed kinetic behavior with that theoretically expected on the basis of initial concentration conditions and binding parameters. Theoretical expressions for such a system have been considered, in a pharmacokinetic context, by Kruger-Thiemer (11) who derived equations which describe the rates of loss of unbound and total small molecule capable of being bound from a protein compartment. His derivations were restricted to situations where binding occurred to one class of sites on the protein but can be readily modified to account for the existence of two classes of sites. Such a modification results in Eq. 2 which describes dynamic dialysis behavior, *i.e.*, the rate of disappearance of total concentration of small molecule (D_t) from a protein compartment as a function of an apparent first-order elimination constant, K_e , the concentration of unbound small molecule (D_f) , the total concentration of protein (P_t) , the number of binding sites

Figure 11—The influence of pH on the binding of 8-nitrotheophylline at 25°. Key: Δ , delta absorbance values determined from spectrophotometric studies; \circ , fraction bound values calculated from dynamic dialysis studies.

Figure 12—The loss of 8-nitrotheophylline in the presence and absence of caffeine, and the loss of caffeine in the presence and absence of 8-nitrotheophylline, from inside a dialysis sac. The studies were conducted at pH 7.0 and 25°.

in each of two classes, n_1 and n_2 , and the corresponding dissociation constants, k_1 and k_2 .

$$\frac{-d(D_t)}{dt} = \frac{K_d(D_t)}{1 + [n_1(P_t)]/[(D_f) + k_1] + [n_2(P_t)]/[(D_f) + k_2]} \quad (\text{Eq. 2})$$

Equation 3 gives the rate of loss of free drug (D_f) from the protein compartment.

$$\frac{-d(D_f)}{dt} = \frac{K_d(D_f)}{1 + [n_1 k_1 (P_t)]/[(D_f) + k_1]^2 + [n_2 k_2 (P_t)]/[(D_f) + k_2]^2} \quad (\text{Eq. 3})$$

Figure 13—The loss of 8-nitrotheophylline from inside a dialysis sac, in the presence and absence of 8-chlorotheophylline. The studies were conducted at pH 7.0 and 25°. Key: □, control; ○, with 0.75 mg./ml. 8-chlorotheophylline; ●, with 1.74 mg./ml. 8-chlorotheophylline.

Finally, Eq. 4 gives the relationship between the total and unbound drug concentration.

$$(D_t) = (D_f) \left[1 + \frac{n_1(P_t)}{(D_f) + k_1} + \frac{n_2(P_t)}{(D_f) + k_2} \right] \quad (\text{Eq. 4})$$

An expression for (D_t) as a function of time cannot be obtained directly by integration of Eq. 2 and, therefore, a more circuitous approach must be utilized to generate theoretical kinetic data. First, the value for the initial free drug concentration (D_f^0) in the protein compartment is calculated as follows: Eq. 4 may be written in terms of initial total (D_t^0) and initial unbound (D_f^0) drug concentrations. The resulting equation may then be rearranged to yield a cubic expression in (D_f^0):

$$(D_f^0)^3 + (D_f^0)^2 [k_1 + k_2 + (P_t)(n_1 + n_2) - (D_t^0)] + (D_f^0) [k_1 k_2 + (P_t)(n_1 k_2 + n_2 k_1) - (D_t^0)(k_1 + k_2)] - (D_t^0)(k_1 k_2) = 0 \quad (\text{Eq. 5})$$

It may be noted that when one class of binding sites is involved, a quadratic expression in (D_f^0) results. By integration of Eq. 3 between the limits of $t = 0$ to t , and (D_f) = (D_f^0) to (D_f), an expression for time may be obtained:

$$t = \frac{1}{K_e} \left\{ \ln \frac{(D_f^0)}{(D_f)} + \frac{n_1(P_t)}{k_1} \left[\ln \frac{(D_f^0)(k_1 + D_f)}{(D_f)(k_1 + D_f^0)} \right] + \frac{n_2(P_t)}{k_2} \ln \frac{[(D_f^0)(k_2 + D_f)]}{[(D_f)(k_2 + D_f^0)]} - (P_t)(D_f^0 - D_f) \times \left[\frac{n_1}{(k_1 + D_f^0)(k_1 + D_f)} + \frac{n_2}{(k_2 + D_f^0)(k_2 + D_f)} \right] \right\} \quad (\text{Eq. 6})$$

Thus, for values of n_1 , n_2 , k_1 , k_2 , (D_t^0), and (P_t), a value of (D_f^0) may be calculated from Eq. 5. Then assuming various values for (D_f), the time, t , at which the assumed (D_f) concentrations will be present in the protein compartment can be calculated from Eq. 6. Finally, using Eq. 4, the values for (D_t), corresponding to the times which were determined from Eq. 6, are calculated. These computations were carried out with the aid of a Fortran IV computer program and a CDC 6400 computer.

Comparisons between dialytic behaviors which were theoretically expected and experimentally determined for warfarin are shown in Figs. 6 and 8. Theoretical points were obtained using the outlined treatment with (D_f^0) and (P_t) values selected to correspond to the experimental system. The values of n and K used were those tabu-

lated in Table I. The K_s values employed corresponded to the experimentally determined apparent permeability constants for the membranes. The close agreements between experimental results and theoretical predictions illustrate the applicability of the equations and supports the validity of this experimental approach for studying binding behavior.

Kinetic Determination of the pH-Binding Profile for the Interaction of 8-Nitrotheophylline with BSA—The influence of pH on the binding of 8-nitrotheophylline by BSA, as determined by spectrophotometric investigations, has been previously reported (12). It seemed appropriate, in view of the interesting pH effects observed, to study more quantitatively the effect of pH on the interaction. In addition, it was thought that such a study would serve to evaluate further the dynamic dialysis method and demonstrate its applicability and convenience. From kinetic data obtained with the dynamic dialysis procedure, it was possible to generate Scatchard plots characterizing the interaction at each pH. Thus, binding behavior over a wide range of pH could be conveniently obtained in a relatively short period of time. Accumulation of such data by conventional techniques of equilibrium dialysis or ultrafiltration would require considerably more effort and a much greater expenditure of time.

The results of these studies are summarized in Fig. 9 where the kinetic behavior of 8-nitrotheophylline in the presence of BSA under different conditions of pH is shown. An average control run is also depicted. Data for pH 6, 8, and 10 were also obtained, but were omitted to reduce the complexity of the figure. From examination of the data of Fig. 9, it would appear that as the pH was increased from pH 3 to 10.9, the degree of interaction between the 8-nitrotheophylline and the BSA steadily decreased. The data were further treated by computer analysis, in the usual manner, to obtain the values for \bar{v} and $\bar{v}/(D_f)$. In addition, the fraction of 8-nitrotheophylline bound to the BSA at each total 8-nitrotheophylline concentration was determined. The resulting Scatchard plots are shown in Fig. 10. Data for studies conducted at pH 6 and 8, which were similar to that obtained for pH 7, have been omitted to permit the figure to be more readily interpreted. This figure dramatically

Figure 16—The loss of 8-chlorotheophylline from inside a dialysis sac, in the presence and absence of BSA and 8-nitrotheophylline. These data were obtained in the same experimental run as was illustrated in Fig. 15. Key: \square , control; \circ , with 0.818% BSA and 0.82 mg./ml. 8-nitrotheophylline.

demonstrates differences in binding behavior as the pH was varied. At pH 3 the interaction was somewhat unique. The apparent linearity of the plot indicates the participation of one class of binding sites, containing a relatively large number of sites. The Scatchard plots representing other pH values are curved, indicating that at these pH's more than one class of sites were involved. The unusual behavior apparent at pH 3.0 is likely related to a pH dependent alteration of the protein configuration. Here the interaction is relatively weak as apparent from the shallow slope of the Scatchard plot. Thus the high degree of binding, suggested by the kinetic data

Figure 17—The binding of 8-nitrotheophylline by BSA in the presence and absence of a variable 8-chlorotheophylline concentration. The studies were conducted at pH 7.0 and 25°. obtained at pH 3, was a reflection of the involvement of a relatively large number of binding sites rather than a high intrinsic affinity. The pH 4 Scatchard plot also suggests the participation of a large number of binding sites with the added involvement of a second class of sites with a significantly higher affinity. Two or more classes of sites were apparently involved throughout the remainder of the pH range studied. An increase in pH from 4 to 6 resulted in a decrease in the total number of sites available for binding and an increase in the strength of association. As the pH was increased from 7 to 10.9 the extent of interaction diminished, probably as a

result of changes in the degree of ionization of participating groups on the protein and/or pH-induced conformation changes (13). In order to compare more readily the results of this study to those obtained from the spectrophotometric studies previously reported (12), a plot of fraction bound *versus* pH was constructed and is shown in Fig. 11. The fraction bound, which is plotted, was that obtained at a total 8-nitrotheophylline concentration of 1.4×10^{-4} mole/l. in the presence of 0.75% BSA. The pH profile previously reported, for the interaction between 1.42×10^{-4} M 8-nitrotheophylline and 0.4% BSA, is illustrated for comparative purposes. There is good qualitative agreement between the two methods. However, at the extremes of pH, *i.e.*, at pH 3 and 10.9, the two techniques yielded significantly different results. The spectrophotometric studies indicated a relatively small degree of interaction at these pH extremes, whereas the dynamic dialysis method detected appreciable binding, with about 68% bound at pH 3 and 23% bound at pH 10.9. Some of this difference can, of course, be attributed to the higher BSA concentration used in the dynamic dialysis systems. However, the data may also reflect a shortcoming of the spectrophotometric method in that if interaction does not alter spectral properties of the small molecule, then the interaction cannot be detected from spectral studies. It is important to note that both studies yielded pH profiles having the same general shape and both studies, therefore, indicated that three or more classes of sites on BSA are involved in the binding of 8-nitrotheophylline, as previously discussed (12).

The binding of 8-nitrotheophylline by BSA, at pH 7.0, was further evaluated to determine the binding parameters characterizing this interaction. The data appeared to be adequately described by an interaction involving two classes of binding sites, where $n_1 = 1$, $n_2 = 4$, $K_1 = 2.34 \times 10^5$ l./mole, and $K_2 = 2.53 \times 10^3$ l./mole.

Competitive Inhibition of Protein Binding—Inhibition of protein-small molecule interactions due to the presence of a species capable of competing for binding sites is a well recognized phenomenon and has recently been reviewed (14). Equation 7 describing competitive binding may be easily derived from mass law considerations and defines the dependency of binding of a species "D," in the presence of a competitor "C," on the unbound "D" concentration (D_f), and unbound competitor concentration (C_f), the number of binding sites on the protein (n) which interact with the drug and the competitor, and the corresponding intrinsic association constants for "D" and "C" (K_d and K_c).

$$\bar{v}_d = \frac{n_1 K_{d1} (D_f)}{1 + K_{d1} (D_f) + K_{c1} (C_f)} + \frac{n_2 K_{d2} (D_f)}{1 + K_{d2} (D_f) + K_{c2} (C_f)} \quad (\text{Eq. 7})$$

Here, $\bar{\nu}_d$ = moles of Species "D" bound per total mole of protein. This equation may be rearranged in the form of a Scatchard equation, as given in Eq. 8.

$$\frac{\bar{\nu}_d}{(D_f)} = \frac{\sum n K_d + (D_f) K_{d1} K_{d2} \sum n + (C_f)(n_1 K_{c2} K_{d1} + n_2 K_{c1} K_{d2})}{1 + (C_f)[\sum K_c + K_{c1} K_{c2} (C_f)]} - \frac{\bar{\nu}_d \left[\frac{\sum K_d + K_{d1} K_{d2} (D_f) + (C_f)(K_{c2} K_{d1} + K_{c1} K_{d2})}{1 + (C_f)[\sum K_c + K_{c1} K_{c2} (C_f)]} \right]}{(Eq. 8)}$$

It may be shown that while Eq. 8 is derived in terms of $\bar{\nu}_d$, a completely analogous equation can similarly be derived in terms of $\bar{\nu}_c$ (moles of Species "C" bound per mole of protein).

An expression describing the rate of loss of small molecule "D" from a protein compartment containing a competitor "C," can be derived from the consideration that the rate of loss of "D" is proportional to the concentration of unbound species (D_f):

$$-\frac{d(D_i)}{dt} = K_e(D_f) \quad (Eq. 9)$$

From mass balance:

$$(D_i) = (D_b) + (D_f), \quad (Eq. 10)$$

where (D_b) is the concentration of "D" which is bound. Further, in the presence of competitor, it can be shown that,

$$(D_b) = \frac{n_1 K_{d1} (D_f) (P_i)}{1 + K_{d1} (D_f) + K_{c1} (C_f)} + \frac{n_2 K_{d2} (D_f) (P_i)}{1 + K_{d2} (D_f) + K_{c2} (C_f)} \quad (Eq. 11)$$

Combining Eqs. 10 and 11 and solving for (D_f) an expression for (D_f) is obtained which may then be substituted into Eq. 9 to yield:

$$-\frac{d(D_i)}{dt} = \frac{K_e(D_i)}{1 + \frac{[n_1 K_{d1} (P_i)]/[1 + K_{d1} (D_f) + K_{c1} (C_f)] + [n_2 K_{d2} (P_i)]/[1 + K_{d2} (D_f) + K_{c2} (C_f)]}{(Eq. 12)}}$$

The intuitive expectation that the presence of a competitor will result in a faster decline of (D_i) is verified by inspection of Eq. 12, which predicts that the rate of loss of (D_i) will increase with increasing (C_f) . Further, the equation indicates that as (D_f) and (C_f) approach zero, the slope of a semilog plot of (D_i) versus time will approach a constant value which is a function of K_e , n , (P_i) , and the association constants (K_d , K_c) for the given system. Finally, Eq. 12 shows that if the values of K_{d1} (D_f), and K_{d2} (D_f) are significantly smaller than the values of K_{c1} (C_f), and K_{c2} (C_f), then the slope of a semilog plot of (D_i) versus time will be constant, if (C_f) is constant.

A series of studies were conducted to evaluate dynamic dialysis as a tool for studying the phenomenon of competitive inhibition of protein binding. The studies were carried out by using 8-chlorotheophylline and salicylic acid as the small molecules "C" competing with 8-nitrotheophylline "D" for binding sites on the BSA molecule.

As a prerequisite to these studies it was necessary to determine if the presence of "C" exerted an effect on the rate of dialysis of "D," in the absence of BSA. Thus, a control run with 8-nitrotheophylline was first conducted, and then using the same membrane sac, the dialysis of 8-nitrotheophylline was followed in the presence of competitor, with the competitive concentration either maintained constant or allowed to decline. The loss of both "D" and "C," from inside the sac, was followed in the latter case.

The results of such studies where caffeine was employed as the inhibitor are shown in Fig. 12. Here the initial caffeine concentration was approximately eight times that of 8-nitrotheophylline. Only a slight reduction in the permeation rate of the caffeine caused by the presence of 8-nitrotheophylline was noted. However, the dialytic rate of 8-nitrotheophylline was significantly reduced by the presence of caffeine. In addition, the semilog plot for such a system was not linear. A reasonable explanation for the observed effect is that complex formation occurred between 8-nitrotheophylline and caffeine and that the complex diffused through the membrane at a slower rate than did 8-nitrotheophylline alone.

The effect of a constant 8-chlorotheophylline concentration on the dialysis of 8-nitrotheophylline was also measured and the results are shown in Fig. 13. It is apparent that the presence of 8-chlorotheophylline resulted in a decrease in the rate of loss of 8-nitrotheophylline.

Figure 21—The loss of 8-nitrotheophylline from inside a dialysis sac, in the presence and absence of BSA, and BSA and 9.8 mg./ml. salicylic acid. The studies were conducted at pH 7.0 and 25°. Key: ○, 8-nitrotheophylline control; □, 8-nitrotheophylline control in the presence of 9.8 mg./ml. salicylic acid; ●, 8-nitrotheophylline and 0.802% BSA; ■, 8-nitrotheophylline, 0.802% BSA, and 9.8 mg./ml. salicylic acid.

Finally, the influence of the presence of salicylate on the dialytic behavior of 8-nitrotheophylline was studied using a constant salicylate concentration. The results are illustrated in Fig. 14 and demonstrate the previously observed effect; the permeation rate of the 8-nitrotheophylline was decreased in the presence of salicylate ion.

This unexpected effect is currently being rigorously investigated. Preliminary results indicate that complex formation is indeed

Figure 22—The binding of 8-nitrotheophylline by BSA in the presence and absence of a constant salicylic acid concentration of 9.8 mg./ml. The studies were conducted at pH 7.0 and 25°. Key: □, 8-nitrotheophylline and BSA; ○, 8-nitrotheophylline, BSA and 9.8 mg./ml. salicylic acid; ●, theoretical data for the binding of 8-nitrotheophylline by BSA in the presence of 9.8 mg./ml. salicylic acid.

responsible for the observed behavior. Studies are in progress to evaluate the possibility that dynamic dialysis might be of utility in investigating and quantitating small molecule-small molecule interactions as well as small molecule-macromolecule binding.

Relative to protein binding studies, these results emphasize the importance of considering small molecule-small molecule interactions before attempting to study the phenomenon of competitive inhibition. Thus, if the degree of interaction between "D" and "C" is moderately large, results of competitive binding studies might well be uninterpretable since one does not know *a priori* whether inhibition is due to competition for binding sites or the inability of "D:C" complexes to be bound by the protein. In the present studies, for example, the interaction between 8-nitrotheophylline and caffeine was sufficiently large to preclude a meaningful study of the inhibition of 8-nitrotheophylline binding by caffeine. The ability of 8-chlorotheophylline and salicylate to inhibit the binding of 8-nitrotheophylline could, however, be studied since in the former case relatively low concentrations could be employed and in the latter, the apparent degree of complexation was relatively low.

The binding of 8-nitrotheophylline by BSA in the presence of a variable concentration of 8-chlorotheophylline was studied at pH 7.0 and 25° and the results are depicted by Fig. 15. Figure 16 summarizes results which characterize the dialysis of 8-chlorotheophylline from the competitive system. It should be noted that preliminary experiments demonstrated that 8-chlorotheophylline, in the concentration used in this study, did not significantly affect the intrinsic rate of 8-nitrotheophylline dialysis. Figure 15 clearly illustrates the displacing effect caused by competition and which resulted in an increase in the rate of loss of 8-nitrotheophylline from the protein compartment. The data of Figs. 15 and 16 were analyzed in the manner previously described to obtain the concentrations of unbound 8-nitrotheophylline and 8-chlorotheophylline at various times during the course of the dialysis. Then, knowing unbound and total concentrations, the bound concentrations could be calculated. This permitted subsequent computations of $\bar{v}_e/(C_f)$, $\bar{v}_d/(D_f)$, \bar{v}_e , and \bar{v}_d . The results of these computations are illustrated in Figs. 17 and 18 in the form of Scatchard plots. The competitive effect is clearly evident. In addition the plots suggest that both of the theophylline derivatives were bound to the same sites on the protein since the ordinate intercept, which is equal to Σn , appears to be the same for all systems.

Also depicted in Figs. 17 and 18 are points obtained by independent considerations of competitive binding. Here, Eq. 8 was utilized to solve for the concentration of bound species by using n and K values determined from independent studies and experimental values of (D_f) and (C_f) . The concentration of protein used corresponded to that in the experimental systems. Thus, theoretical points for a Scatchard plot were generated and are represented by the closed circles in the figures. The agreement of theory and experiment is reasonable, particularly in view of the fact that small variations in the values of the four association constants can have rather marked influences on the shape and position of a theoretically generated plot.

Figure 19 compares results obtained in the dialysis of various 8-nitrotheophylline systems with and without a constant concentration of 8-chlorotheophylline. The constancy of the latter was ensured by formulating internal solution, external solution, and replacement solution to contain the same concentration of 8-chlorotheophylline. It is apparent from the figure that the rate of dialysis of 8-nitrotheophylline was markedly increased by incorporation of 8-chlorotheophylline in the system. In addition, it can be observed that for the competitive study, the semilog plot appeared essentially constant after about 1 hr. which is indicative of the binding of a constant fraction of the 8-nitrotheophylline. Figure 20 illustrates the Scatchard plot corresponding to this system. The permeability constant utilized in analyzing the kinetic data to obtain the Scatchard plot was obtained from the study of 8-nitrotheophylline dialysis in the presence of 0.763 mg./ml. of 8-chloro-

theophylline. The competitive effect is dramatically reflected by this figure. Theoretical points are also shown in Fig. 20. These were calculated in the manner previously described using the assumption that here (C_f) could be approximated by the analytical concentration of competitor in the system. The agreement between theoretical and experimental data is excellent and serves to confirm the utility of the dynamic dialysis method in studying competitive binding.

The results of similar studies, employing salicylate as a competing species, are depicted in Figs. 21 and 22. These similarly demonstrate the kinetic manifestations of competitive inhibition and the ability to quantitate competitive binding behavior by the dynamic dialysis approach.

In summary, this investigation has demonstrated the utility of the dynamic dialysis approach by application to a variety of protein-binding systems. The method was shown to be applicable to the quantitation of binding covering a spectrum of binding strengths. In addition it was demonstrated that competitive inhibition of binding can be readily detected and quantitatively evaluated by the technique. Some idea of the relative rapidity and convenience of the method was evidenced by the ability to comprehensively study the influence of pH, over a wide range, on the interaction of 8-nitrotheophylline with BSA. Although the present study was limited to protein-containing systems, there is no reason why the method could not be used in studies of binding by other natural macromolecules, synthetic polymers, adsorbents, and micelle-forming materials.

Effect of Tablet Processing and Formulation Factors on Dissolution Rate of the Active Ingredient in Human Gastric Juice

SISSEL SOLVANG and PER FINHOLT

Abstract □ The effect of the granulation and tableting processes on the dissolution rate of phenobarbital, sodium phenobarbital, phenacetin, and prednisone in human gastric juice has been investigated. A study has also been made on the influence of the particle size of the active ingredient and the effect of different binders on the dissolution rate of phenobarbital.

Keyphrases □ Tablet dissolution rates—human gastric juice □ Gastric juice, human—phenobarbital, phenacetin, prednisone tablets, dissolution □ Formulation, processing effects—dissolution rates □ Particle size effect—phenobarbital dissolution □ Binders effect—tablet dissolution

The effect of formulation and processing factors on the dissolution rate of the active ingredients of compressed tablets has been the subject of a number of reports (1–14). Various dissolution media such as water, hydrochloric acid, buffer solutions, simulated gastric juice, and simulated intestinal fluid, have been used, but, surprisingly enough, not that solvent, in which the dissolution process takes place *in vivo*—that is, human gastric juice.

The scope of the present investigation was to study the effect of the granulation and tableting processes and the influence of certain formulation factors on the dissolution rate of the active ingredient in human gastric juice.

EXPERIMENTAL

Materials—All drugs were of Pharmacopoea Nordica grade. The phenobarbital and phenacetin powders were separated into the desired size fractions by sieving. The prednisone used was a micronized product, having a particle size between 1 and 8 μ determined with a Celscope, an apparatus that works on the Coulter counter principle.

The gastric juice was obtained as described in an earlier paper (15). A mixture of equal parts of gastric juice and water was used as dissolution medium. This mixture is named "diluted gastric juice" in the present paper.

Preparation of Granules and Tablets—The desired size fraction of the drug powder was mixed with potato starch (or potato starch + lactose) and gently moistened with the granulating solution. The moistened mass was sieved and dried. The dry granules were separated into different size fractions by sieving. The 0.71–1.00 mm. size fraction of the granules¹ was mixed with a lubricant and compressed into tablets on a single punch tablet machine. Specifications for the experimental granules and tablets are given in Table I.

Determination of Hardness—The hardness of the tablets was determined with a Pfizer tablet hardness tester.

Determination of Disintegration Time—The disintegration time of the tablets was determined according to *The Nordic Pharmacopoeia*: three tablets were placed in a conical flask, mixed with 30 ml. of water at a temperature between 36 and 40° and kept at this temperature with frequent swinging of the flask.

Determination of Dissolution Rate—The dissolution rate was determined by the beaker method of Levy (16) with minor changes

Table I—Specifications for Experimental Granules and Tablets

	—Phenobarbital Granules and Tablets ^a —		
	I	II	III
Phenobarbital ^b	100 g.	100 g.	100 g.

Tablet hardness: 6.6 kg.cm. ⁻²			
Disintegration time: 1.5 min.			

^a 1000 tablets, diameter 8 mm. ^b Particle size: 0.21–0.30 mm., if not otherwise stated. ^c 4% solution of gelatin in water as granulating agent. ^d 2% solution of sodium carboxymethylcellulose in water as granulating agent. ^e 50% solution of Carbowax 6000 in alcohol (95%) as granulating agent. ^f 1000 tablets, diameter 8 mm. ^g A crystalline powder with most particles within the 0.11–0.30 mm. range was used. ^h 10% solution of gelatin in alcohol as granulating agent. ⁱ 1000 tablets, diameter 13.5 mm. ^j 1000 tablets, diameter 8 mm.

(15). For each test the drugs, granules, and tablets were—if not otherwise stated—used in amounts that were more than sufficient for saturation of the dissolution medium with the drug. The drug powders and the granules were gently spread over the surface of the fluid, and settled down through the fluid during the test. The tablets were dropped into the dissolution medium. At appropriate intervals samples of the dissolution medium were withdrawn, filtered and analyzed.

Analytical Methods—*Determination of Prednisone*—The samples withdrawn were diluted with 0.1 N HCl and absorbances were

¹ Granules passing through standard sieve U. S. No. 18 (sieve opening 1.00 mm.), but not through sieve No. 25 (sieve opening 0.71 mm.).

measured at 243 $\text{m}\mu$ with a Beckman DK 2A spectrophotometer.

Phenobarbital and phenacetin were determined as described earlier (15).

RESULTS AND DISCUSSION

Effect of the Granulation and Tableting Processes—The rate of dissolution of phenobarbital, phenacetin, and prednisone was determined before and after granulation and compression into tablets.

It will be seen from Figs. 1–3 that the rate of release of all three drugs from the granules is higher than the rate of dissolution of the pure drugs. The granulation process has increased the dissolution rate, probably by making the originally hydrophobic drug particles hydrophilic.

Figs. 1 and 3 show that phenobarbital and prednisone are released at a higher speed from the tablets than from the granules. The reason for this is probably that the drugs—during the dissolution test—are more rapidly wetted when contained in tablets, because the tablets are dropped into the dissolution medium and disintegrate completely within 1–2 min., whereas the granules are spread over the surface of the fluid and settle more slowly down through the fluid. It is also possible that the compression process leads to

Figure 3—Rate of dissolution of prednisone from powder, granules, and tablets in diluted gastric juice (surface tension 41.1 dynes cm^{-1} , pH 1.50). Key: ○, prednisone powder; ▲, prednisone granules; ●, prednisone tablets.

deformation or crushing of the granule particles, thus increasing the specific surface area of the granules and their rate of dissolution. In this connection it may be noted that Higuchi *et al.* (17) have shown that the specific surface area of tablet granules becomes greater with increasing compression pressure. These authors assumed that this was due to the crushing of the granule particles. In a later paper Higuchi *et al.* (18) have shown that with normal tableting pressures, deformation of the granules takes place but without the particles breaking up. The particles are changed from being almost spherical to being nearly disk-shaped and hence their surface area is increased.

The experiments, the results of which are given in Figs. 1–3, were so scaled that there would always be undissolved drug remaining at the end of each test. Figure 4 shows the results of an experiment where such amounts of phenobarbital powder, granules and tablets were used for each test that a complete dissolution might occur (one 100-mg. tablet or an equivalent amount of granules or drug powder). It will be seen that this procedure leads in principle to the same result as the other procedure, *i.e.*, the tablets showing a faster dissolution rate than the granules and the drug powder.

Effect of Particle Size of the Active Ingredient—Phenobarbital tablets were prepared according to Formula I. Different size fractions of the drug powder were used. Figure 5 shows that the rate of dissolution of phenobarbital from the tablets increases with decreasing particle size of the drug. This result was expected since the granulation process has made the surface of the drug particles hy-

drophilic. In addition the dissolution medium has a low surface tension.

Effect of Different Binders—Phenobarbital tablets were prepared according to Formulas I, II, and III. The same pressure was, as far as possible, used for the compression of the three batches of tablets.

Figure 6 shows that there are great differences in dissolution rates. These differences could not be attributed to differences in disintegration times during the dissolution test. Tablets I disintegrated within 45 sec., tablets II within 6 min., and tablets III within 20 sec. This means—as an example—that even though tablets III had a slightly shorter disintegration time in diluted gastric juice than tablets I, the rate of dissolution was much lower.

It will be seen from Fig. 6 that the tablets prepared with gelatin as granulating agent have a much higher dissolution rate than the tablets prepared with CMC or polyethylene glycol 6000 as binders. This result is in accordance with earlier findings (8) from this laboratory that the use of gelatin as binder leads to granules and tablets with a very high dissolution rate in 0.1 N HCl. The high dissolution rate of these granules and tablets is believed to be due to the ability of gelatin to make originally hydrophobic surfaces of drug particles hydrophilic. This theory is supported by earlier experiments with phenacetin as model substance, showing that this hydrophobic drug after mixing with potato starch and granulation with gelatin dissolved at the same high rate in 0.1 N HCl as the ungranulated drug did in 0.1 N HCl containing 0.2% polysorbate 80 as wetting agent (8).

The reason why phenobarbital dissolves so slowly from tablets II is probably that the binder, sodium carboxymethylcellulose, at

Figure 6—Rate of dissolution of phenobarbital from tablets I, II, and III in diluted gastric juice (surface tension 39.4 dynes cm^{-1} , pH 1.50).

Figure 7—Rate of dissolution of phenobarbital and sodium phenobarbital from powder, granules I, and tablets I in 0.1 N HCl. The dotted line parallel with the x-axis indicates the concentration of a saturated solution of phenobarbital in 0.1 N HCl at 37°. Key: —, phenobarbital; ---, phenobarbital sodium; ○, powder; ▲, granules I; ●, tablets I.

the pH of the dissolution medium (pH 1.5) is converted into the less hydrophilic free acid.

As far as tablets III is concerned the slow dissolution is assumed to be due to a complex formation between the drug and the granulating agent. Each tablet III contained 100 mg. of phenobarbital and about 35 mg. of polyethylene glycol 6000. Higuchi and Lach (19) and later Singh *et al.* (20) have shown that phenobarbital forms stable compounds of reduced solubility with polyethylene glycols. Singh *et al.* found the ratio to be 45.5 mg. of polyethylene glycol 4000 per 100 mg. of phenobarbital at 37° and pH 5.3. The following experiment seems to indicate that a complex of reduced solubility is formed between the drug and the granulating agent of tablets III.

Two tablets were placed in 40 ml. of hydrochloric acid solution pH 1.5 (the pH of the diluted gastric juice) and the mixture was equilibrated at 37° for 30 hr. A phenobarbital concentration of only 65 mg. % was found, whereas tablets I and II gave a phenobarbital concentration of 180 mg. % under the same experimental conditions. The complex between the drug and the granulating agent of tablets III is probably formed during the dissolution test and not

Figure 8—Rate of dissolution of phenobarbital and sodium phenobarbital from powder, granules I, and tablets I in diluted gastric juice (surface tension 40.5 dynes cm^{-1} , pH 1.70). The dotted line parallel with the x-axis indicates the concentration of a saturated solution of phenobarbital in diluted gastric juice at 37°. Key: —, phenobarbital; ---, phenobarbital sodium; ○, powder; ▲, granules I; ●, tablets I.

during the preparation of the tablets, since the amount of alcohol used for granulation (about 35 g. per 100 g. of phenobarbital) can not dissolve more than 4% of the total amount of drug present.

It may be mentioned that complexation in some cases may increase dissolution rates. Wurster and Kildsig (21) found that addition of creatinine, tartaric acid, malic acid, or succinic acid to the dissolution medium increased the solubility and the dissolution rate of *m*-aminobenzoic acid.

Comparative Studies of Release Rate of a Drug and Its Sodium Salt from Granules and Tablets—In a previous study (15) the rate of dissolution of sodium phenobarbital in diluted gastric juice was determined and compared with the rate of dissolution of the salt in a hydrochloric acid solution having the same pH as the diluted gastric juice. It was found that initially nearly the same high drug concentration was obtained in both dissolution media. However, the precipitation of the free acid in excess of solubility took place at a much slower rate in gastric juice than in hydrochloric acid.

In the present study the rate of dissolution of phenobarbital and sodium phenobarbital from granules and tablets has been determined using 0.1 *N* HCl and diluted gastric juice as dissolution media. Comparisons with the rate of dissolution of the pure drug have been made.

Figures 7 and 8 show that the rate of dissolution of the sodium salt in both dissolution media is lowered by granulating a mixture of the drug and potato starch with gelatin. Compression of the granules into tablets results in a further reduction of the dissolution rate. If the free acid is used instead of the sodium salt, the granulation procedure and the tableting have—as mentioned earlier—the opposite effect: the dissolution rate is increased by granulation of the drug and further increased by compression of the granules.

By comparing the curves for sodium phenobarbital powder in Figs. 7 and 8 it will be seen that the precipitation of the free acid is much faster in 0.1 *N* HCl than in diluted gastric juice. It is also evident from these figures that granulated sodium phenobarbital forms a supersaturated solution of the free acid in diluted gastric juice but not in 0.1 *N* HCl. The rate of precipitation of the free acid in diluted gastric juice is obviously so low compared with the rate of dissolution of the granules that a supersaturated solution may be formed, whereas in 0.1 *N* HCl this is not the case.

Figures 7 and 8 also show that granulation of the free acid leads to a greater increase of the dissolution rate in 0.1 *N* HCl than in diluted gastric juice. This was expected since 0.1 *N* HCl has a much higher surface tension than diluted gastric juice.

Tablets prepared from the free acid had a much higher dissolution rate in both media than tablets prepared from the sodium salt. This was due to the fact that tablets containing the free acid disintegrated rapidly in 0.1 *N* HCl and diluted gastric juice, whereas tablets containing the sodium salt, although disintegrating fast in water, did not disintegrate in the acidic media, but swelled and dissolved slowly from the surface.

Some experiments were done to prepare sodium phenobarbital tablets with better dissolving properties in acidic media. Dry granulation of a mixture of the drug and potato starch instead of wet granulation of the same mixture with gelatin did not cause any improvement. Better results were obtained by direct compression of a mixture of the drug with microcrystalline cellulose. But even these tablets exhibited much slower dissolution rate than phenobarbital tablets prepared according to Formula I.

SUMMARY AND CONCLUSIONS

1. The rate of release of phenobarbital, phenacetin, and prednisone from granules and tablets prepared with gelatin as granulating agent was faster than the rate of dissolution of the pure drugs. Phenobarbital and prednisone were released at a higher speed from the tablets than from the granules. It is thus evident that both the granulation process and the compression of the granules may increase the rate of dissolution of drugs in human gastric juice.

2. The rate of dissolution of phenobarbital from tablets prepared with gelatin as granulating agent increased with decreasing particle size of the drug.

3. Phenobarbital tablets prepared with gelatin as granulating agent were found to dissolve much faster in human gastric juice

than tablets prepared with sodium carboxymethylcellulose or polyethylene glycol 6000 as binders, probably because gelatin makes the originally hydrophobic surface of the drug particles hydrophilic, whereas sodium carboxymethylcellulose at the pH of the dissolution medium is converted into the less hydrophilic free acid and polyethylene glycol 6000 forms a complex of reduced solubility with phenobarbital.

4. The rate of dissolution of sodium phenobarbital in human gastric juice and in 0.1 *N* HCl was lowered by granulating a mixture of the drug and potato starch with gelatin. Compression of the granules into tablets resulted in a further reduction of the dissolution rate. These tablets dissolved much slower in both media than tablets prepared in a similar way from phenobarbital. The reason for this was that the sodium phenobarbital tablets, although disintegrating rapidly in water, did not disintegrate in the acidic media, but swelled and dissolved slowly from the surface. In contrast to this the phenobarbital tablets disintegrated very rapidly in acidic media as well as in water. Attempts to use dry granulation or direct compression in order to obtain sodium phenobarbital tablets dissolving as fast as the phenobarbital tablets in acidic media were not successful. It appears thus to be more difficult to prepare fast dissolving tablets from the highly soluble sodium salt of phenobarbital than from the corresponding poorly soluble free acid. It has often been claimed that rapid dissolution of the active ingredient of tablets in the stomach represents a problem only as far as poorly soluble drugs are concerned, but it may certainly be a problem also when the drug in question is very soluble.

Assessment of Pharmacokinetic Constants from Postinfusion Blood Curves Obtained after I.V. Infusion

J. C. K. LOO and S. RIEGELMAN

Abstract □ Pharmacokinetic constants have usually been derived from the parameters of the exponential equation which describe the blood curve after a single bolus i.v. injection. Occasionally, due to potential toxicity, irritation, or limited solubility, it is not possible to inject a drug by a single bolus; it may be feasible to circumvent these difficulties by administering the drug intravenously at a slower rate of infusion. A mathematical equation is presented which enables one to determine the parameters identical to an i.v. bolus injection curve by utilizing the postinfusion blood curve. The equation is applicable to all compartmental models that may be described by linear first-order differential equations with constant coefficients. Experimental data are presented whereby drugs were administered by very rapid and prolonged i.v. infusion with blood sampling at appropriate intervals. The experimentally estimated parameters calculated from the postinfusion blood curves were in agreement with those obtained from the rapid infusion blood curves.

Keyphrases □ Pharmacokinetic constants determination—post-infusion curves □ Kinetic equations—slow i.v. infusion □ Griseofulvin—slow, rapid i.v. infusion □ Sulfisoxazole—slow, rapid i.v. infusion

Pharmacokinetic parameters are usually derived from the exponential equations which describe the blood curve after a single bolus i.v. injection. Occasionally, due to potential toxicity, irritation, or limited solubility, it is not possible to inject a drug by a single bolus. It may be feasible to circumvent these difficulties by administering the drug intravenously at a slower rate of infusion. An equation is derived below which enables one to determine the parameters identical to those obtained from an i.v. bolus injection curve by utilizing the post-infusion blood level *versus* time curve. The equation is applicable to all compartment models describable by linear first-order differential equations with constant coefficients. Experimental data will be presented from studies in which drugs were administered by very rapid and prolonged i.v. infusion into man and rabbit.

THEORETICAL

If drug elimination and distribution processes obey first-order kinetics then the blood curve, after a single bolus i.v. injection, is describable by a summation of exponential terms.

$$(Cp)_{i.v.} = \sum_{i=1}^n A_i e^{-k_i t} \quad (\text{Eq. 1})$$

where $(Cp)_{i.v.}$ represents the plasma concentration¹ at time t , after administration of the i.v. dose, A_i is the intercept at zero time, and k_i is the corresponding first-order rate constant as defined in Eq. 1. The Laplace transform of Eq. 1 is

$$\bar{Cp}(s) = \sum_{i=1}^n \frac{A_i}{(s + k_i)} = f_1(s) \quad (\text{Eq. 2})$$

¹ The plasma concentration could be expressed as the concentration of the free drug and/or its metabolite.

where \bar{Cp} represents the Laplace transform of Cp . If the same dose of the drug is infused continuously at a constant rate (k_0) (see Footnote 2) until time τ , then ceased abruptly, the Laplace transform for this input function is:

$$f_2(s) = \frac{k_0}{s} (1 - e^{-\tau s}) \quad (\text{Eq. 3})$$

where $f_2(s)$ is the step function of height k_0 starting at zero-time and stopping at $t = \tau$. The Laplace transform (1) of the postinfusion curve is the product of the input function $f_2(s)$ and the unit impulse function $f_1(s)$.

$$(\bar{Cp})_{\text{post}}(s) = f_1(s) \cdot f_2(s) \quad (\text{Eq. 4})$$

$(\bar{Cp})_{\text{post}}$ denotes the Laplace transform of the plasma concentration when $t > \tau$. Substituting Eqs. 2 and 3 for $f_1(s)$ and $f_2(s)$, respectively, one obtains:

$$(\bar{Cp})_{\text{post}}(s) = \frac{k_0}{s} (1 - e^{-\tau s}) \left[\sum_{i=1}^n \frac{A_i}{s + k_i} \right] \quad (\text{Eq. 5})$$

Separating terms we arrive at:

$$(\bar{Cp})_{\text{post}}(s) = \frac{k_0}{s} \left[\sum_{i=1}^n \frac{A_i}{s + k_i} \right] - \frac{k_0}{s} e^{-\tau s} \left[\sum_{i=1}^n \frac{A_i}{s + k_i} \right] \quad (\text{Eq. 6})$$

The antitransform of Eq. 6 at times greater than τ is

$$(Cp)_{\text{post}} = k_0 \left[\sum_{i=1}^n \frac{A_i}{k_i} - \sum_{i=1}^n \frac{A_i}{k_i} e^{-k_i t} - \sum_{i=1}^n \frac{A_i}{k_i} + \sum_{i=1}^n \frac{A_i}{k_i} e^{-k_i(t-\tau)} \right] \quad (\text{Eq. 7})$$

Upon simplification of Eq. 7, we have:

$$(Cp)_{\text{post}} = k_0 \left[\sum_{i=1}^n \frac{A_i}{k_i} e^{-k_i(t-\tau)} - \sum_{i=1}^n \frac{A_i}{k_i} e^{-k_i t} \right] \quad (\text{Eq. 8})$$

Substituting τ for k_0 and setting $t' = (t - \tau)$ upon simplifying Eq. 8, one gets³

$$(Cp)_{\text{post}} = \sum_{i=1}^n \frac{A_i(1 - e^{-k_i \tau})}{k_i \tau} e^{-k_i t'} \quad (\text{Eq. 9})$$

When the infusion time is sufficiently short such that $\sum_{i=1}^n (1 - e^{-k_i \tau})$ approaches $\sum_{i=1}^n k_i \tau$, Eq. 9 reduces to:

$$(Cp)_{\text{post}} = \sum_{i=1}^n A_i e^{-k_i t'} \quad (\text{Eq. 10})$$

This equation is equivalent to the equation defining an i.v. bolus injection blood curve. However, when the infusion time is sufficiently

² k_0 is expressed as the fractional infusion rate and is equal to amount infused per unit time/amount of dose administered = (infusion time)⁻¹.

³ This is a general solution for the postinfusion curves pertaining to all multicompartment model systems. However, an equation for the special two-compartment model case has been derived previously by Rescigno and Segre (7).

Table I—The Biexponential Equations^a Describing the Postinfusion Curves Obtained after Rapid and Prolonged Administration of Sulfisoxazole Intravenously into a Male Rabbit

Calculated values	19.8	0.1244 ± 0.0099	80.2	0.01115 ± 0.00091	

^a The equation is: $P\% = A_1 e^{-k_1 t} + A_2 e^{-k_2 t}$. A_1 , A_2 , and $P\%$, are expressed in percentage of $(A_1 + A_2)$. k_1 , k_2 are expressed in reciprocal minutes. t is the time after infusion in minutes. ^b These values were determined from the experimental data by using an IBM 360/50 digital computer programmed according to a nonlinear regression subroutine of the B.M.D. X85 series. ^c Standard deviation units. ^d These values were generated from Eq. 9 by using the parameters of the postinfusion curves after the fastest infusion experiment.

long such that $\sum_{i=1}^n (1 - e^{-k_i \tau'})$ approaches n , Eq. 9 becomes:

$$(Cp)_{\text{post}} = \sum_{i=1}^n \frac{A_i}{k_i \tau} e^{-k_i t'} \quad (\text{Eq. 11})$$

It is evident from these considerations that k_i is the same whether it is obtained from a postinfusion curve or a single i.v. bolus curve. However, the intercepts of the exponential terms (i.e., A_i and $A_i[(1 - e^{-k_i t})/(k_i \tau)]$) are different and the differences increase as the infusion time lengthens. Since these intercepts are used to calculate kinetic constants intrinsic to multicompartmental models, an appropriate

correction must therefore be made. The intercepts can be calculated from the following equation:

$$A_i = \frac{k_i \tau}{1 - e^{-k_i \tau}} A_i' \quad (\text{Eq. 12})$$

where A_i' is the intercept, extrapolated to $t' = 0$, obtained from the postinfusion curve. Incorporating Eq. 12 into Eq. 1, we arrive at the following equation:

$$(Cp)_{i.v.} = \sum_{i=1}^n \frac{k_i \tau}{1 - e^{-k_i \tau}} A_i' e^{-k_i t} \quad (\text{Eq. 13})$$

Thus, an equation has been derived which will lead to the same parameters as obtained after a single i.v. bolus injection. If the parameters were obtained from free drug plasma concentration versus time curve, then the kinetic and volume constants intrinsic to the compartmental model can be calculated by procedures previously described⁴ (2, 3). However if the parameters were de-

Figure 1—Sulfisoxazole plasma level after intravenous infusion into rabbit. Key: A, after an infusion time period, τ , of 60 min.; B, after 30-min. infusion; C, after 10-sec. infusion; C_p , plasma concentration after infusion has stopped; $C_{p\tau}$, plasma concentration at the end of the infusion. The use of $C_p/C_{p\tau}$ normalizes the data allowing more convenient comparison of data among the experiments.

Figure 2—Griseofulvin plasma level after intravenous infusion into man. Key: A, plasma level after 3-min. infusion; B, plasma level after 2-hr. infusion.

⁴ In Reference 3 the equation for the Vd^0 is in error. The correct equation should be $Vd^0 = Vd_{ss} = V_p (k_{21} + k_{12}/(k_{21})) = V_d$ infusion. This error has been pointed out to the authors by Gibaldi (4).

Table II—The Biexponential Equations^a Describing the Postinfusion Curves Obtained after Rapid and Prolonged Intravenous Administration of Griseofulvin into a Male Human Subject

rived from the metabolite or total drug concentration *versus* time curve then different procedures must be developed to calculate these constants.

EXPERIMENTAL PROCEDURE

Griseofulvin—Griseofulvin was injected into a healthy male adult in a specially prepared solution of griseofulvin dissolved in polyethylene glycol 300. The solution was not injected directly. It was diluted into a rapidly flowing normal saline solution, which was administered by intravenous drip over a 3-min. period. Several weeks later the drug was administered over a 2-hr. interval at a constant rate of infusion into the same test subject. The plasma samples were assayed for the intact drug by a modification of the method of Bedford *et al.* (5).

Sulfisoxazole—The left and right marginal ear veins of a male rabbit (4.5 kg.) were cannulated by small catheters (Bardic Intracath Cat. No. 1619 small catheters 20.32 cm. (8 in.), i.d. 0.015 mm.). Sulfisoxazole injection (Roche) was diluted to an appropriate volume with sterile normal saline solution and then infused into the left vein by means of a constant infusion pump. Blood samples were then withdrawn from the right cannula. The catheters were removed from the ear veins after the experiments. The rabbits were utilized for additional experiments after their ear veins had properly healed. The plasma samples were assayed for sulfonamide (unconjugated at the N₁ position) using the Bratton and Marshall procedure (6).

RESULTS AND DISCUSSION

The rapid infusion or the single bolus i.v. blood curves are describable by the following biexponential equation:

$$Cp_{i.v.} = A_1 e^{-k_1 t} + A_2 e^{-k_2 t} \quad (\text{Eq. 14})$$

By applying Eq. 9 to Eq. 14, one gets

$$(Cp)_{\text{post}} = \frac{A_1(1 - e^{-k_1 \tau})}{k_1 \tau} e^{-k_1 t'} + \frac{A_2(1 - e^{-k_2 \tau})}{k_2 \tau} e^{-k_2 t'} \quad (\text{Eq. 15})$$

or

$$(Cp)_{\text{post}} = A_1' e^{-k_1 t'} + A_2' e^{-k_2 t'} \quad (\text{Eq. 16})$$

where A_1' and A_2' are definable from Eq. 15; Figs. 1 and 2 represent the experimental data obtained on griseofulvin and sulfisoxazole. The experimentally determined A_1' , A_2' , k_1' , k_2' , and the corresponding values as calculated from Eq. 9 are summarized in Tables I and II.

The experimental data points were initially fitted to biexponential equations by the use of an E.A.I. T.R. 48 analog computer. The experimental data together with the initial estimated parameters were then refitted or reassessed with an IBM 360/50 computer programmed in accordance with a modified nonlinear least-squares regression subroutine of the B.M.D. X85 series.

The theoretical A_1' and A_2' were calculated using A_1 , A_2 , k_1 , and k_2 values obtained from the single i.v. bolus or rapid infusion curves.

The satisfactory correlation between the experimental values and the calculated values are evident. Most of the experimental values are within one standard deviation of the calculated values. All of the

experimental values are within two standard deviations of the calculated values. From Tables I and II it is seen that the ratio A_1'/A_2' decreases as the infusion time increases. This observation is in accordance with Eq. 9. Since $k_1 > k_2$, the value $A_1(1 - e^{-k_1 \tau})/(k_1 \tau)$ will decrease more rapidly with increasing τ than the value for $A_2(-e^{-k_2 \tau})/(k_2 \tau)$ thus accounting for the above observation.

From Fig. 1 it is seen that the changes in the intercept ratio are also reflected by the decreasing degree of the initial curvature of the blood curve with increasing infusion time. Since this curved region is critical to the definition of the multicompartmental pharmacokinetic parameters, sampling must be sufficiently frequent to characterize adequately this region of the blood curve, especially if the infusion is prolonged. It is, therefore, advisable to minimize the infusion time not only for the convenience of the subject, but also to reduce the necessity for frequent sampling.

In Fig. 2 the data points lie close to the theoretical line as calculated from the single i.v. bolus parameters. The change in the initial curvature is not so apparent visually from the Cp versus t curve. However, the computer-analyzed data given in Table II show a drastic change in the intercept A_1 and very little change in the intercept A_2 . This is quite in accord with Eq. 15. The graphical representations given in Figs. 1 and 2 are for illustrative purposes only and should not be used for final estimation of the parameters of the equation in lieu of a computer solution.

The findings reported in this study suggest that in multicompartmental pharmacokinetic studies the post infusion curve can be utilized to obtain pharmacokinetic parameters in lieu of the more conventional single i.v. bolus injection. This infusion procedure is especially useful when one encounters potential difficulties, such as solubility and toxicity.

Inhibited Dissolution of Drug Crystals by a Certified Water-Soluble Dye

J. PICCOLO and R. TAWASHI

Abstract Quantitative experiments to investigate the effect of FD&C Blue No. 1 on the dissolution of single crystals of sulfathiazole, phenobarbital, thymol, and sulfaguanidine under controlled conditions, are described. At a very low concentration FD&C Blue No. 1 exerted a remarkable inhibition on dissolution. Dissolution experiments on compressed disks and crystalline powder, gave a significantly lower dissolution rate than the pure drug alone. The dependence of the dissolution rate on the inhibitor concentration was studied in sulfaguanidine crystals, and a concentration of 100 mcg./ml. reduced the dissolution rate by 55%. The data presented is in agreement with the current theories concerning dissolution inhibition by small concentrations of impurities and suggests the dye molecules are preferentially adsorbed at the primary dissolution sources in the crystals investigated.

Keyphrases Drug crystal dissolution—inhibition Crystal dissolution inhibition—water-soluble dye Dissolution rates, behavior—single crystals, compressed disks FD&C Blue No. 1—crystal dissolution inhibition

The effect of small quantities of dissolved impurities on the dissolution, growth, and habit modification of crystalline materials has been a subject of different papers (1-3). The development of the dislocation theory, supported by the fact that many organic and inorganic crystals grow by dislocation (4), offered a new basis for examining the influence of impurities on dissolution and growth of crystals.

Albon and Dunning (5) found that a low concentration of raffinose (1 part in 10,000 parts) lowered the rate of step movement of sucrose crystals. The inhibitory action of raffinose and the retardation of step advancement was explained as being governed by the adsorption of raffinose on the steps of sucrose crystals. Ives *et al.* (6, 7) studied the dissolution kinetics in single crystals of lithium fluoride. The dissolution rate of lithium fluoride was inhibited by small concentrations of ferric ion (1 p.p.m.). The concept of impurity adsorption on the kinks—the primary dissolution sources—was discussed.

Crystal poisoning and habit modification by dyes were reported by Buckley (2), Whetstone (8), and Engelhardt (9). At the present, certified water-soluble dyes are used extensively as colorants in drug formulations, e.g., in tablets, tablet-coating, suspensions, *etc.* The possible effect of these colorants on drug dissolution and eventually drug availability needs a careful study. The purpose of this report is to investigate quantitatively the effect of FD&C Blue No. 1 (as an example of certified dyes) on the dissolution behavior of some drug crystals.

EXPERIMENTAL

Materials—Conditions have been selected to grow nearly perfect drug crystals, suitable for single-crystal work. Crystals of sulfaguanidine, thymol, and phenobarbital monohydrate were grown by slow evaporation at room temperature from a saturated solution

Figure 1—Single-crystal dissolution of phenobarbital monohydrate as a function of time. Key: ▲, in 0.1 N HCl; ■, in 0.1 N HCl containing 10 mcg./ml. FD & C Blue No. 1.

of the appropriate solvent. The solvents used were acetone for sulfaguanidine, carbon tetrachloride for thymol (10), and a mixture of 50% acetone in water for phenobarbital monohydrate (11). Sulfathiazole Form I crystals were prepared from a saturated solution of sulfathiazole in 95% ethanol using the method described by Grove and Keenan (12). The materials used in this study are USP grade and solvents were purified before use.

Dissolution Rate Studies—The linear dissolution rate was measured by a direct optical method which has been previously described (13, 14). A single crystal was fixed in a rubber slit and placed in a jacketed dissolution cell. The cell was then filled with 200 ml. of 0.1 N HCl at 30°, stirring was maintained at 150 r.p.m. by synchronized motor (Hurst Corp., Princeton, Ind.). The distance between the two parallel faces and boundary movement were measured as function of time. Measurements were done with a microscope fitted with a special filar micrometer (Zeiss). Each point represents the average of ten determinations. The rate of dissolution was determined in absence and in presence of low concentrations of FD&C Blue No. 1 (5-100 mcg./ml.).

To study the dissolution behavior from compressed disks, the same apparatus was used after a slight modification. Tablets from the drug crystals were prepared, having the same diameter (1.88 cm.) and compressed under the same pressure. The tablets were

Figure 2—Single-crystal dissolution of sulfathiazole as a function of time. Key: ●, in 0.1 N HCl; ▲, in 0.1 N HCl containing 5 mcg./ml. FD&C Blue No. 1.

Table I—Single-Crystal Dissolution Rate in cm./sec.

Material	Dissolution Rate in 0.1 N HCl	Dissolution Rate in 0.1 N HCl Containing 10 mcg./ml. Dye
Phenobarbital monohydrate	4.2×10^{-6}	2.9×10^{-6}
Sulfathiazole	8.8×10^{-6}	5.1×10^{-6}
Sulfaguandine	6.8×10^{-6}	4.6×10^{-6}

prepared without the use of any fillers, antiadhesives, or lubricants. The tablet was placed in one end of a short glass tube having the same diameter as the tablet, the other end of the tube was filled with molten white bees wax and left to set. At time zero, the tube was introduced into the dissolution cell containing 200 ml. of 0.1 N HCl at 30°, stirring at 150 r.p.m. Samples were pipeted out at specified time and assayed spectrophotometrically for drug content at the appropriate wavelength in the UV region of the spectrum. The dissolution behavior was studied in absence and in presence of FD&C Blue No. 1. A blank having the same concentration of FD&C Blue No. 1 as the dissolution media was used as a reference in determining the drug release in presence of the dye.

Dissolution behavior of the crystalline powder was determined in absence and in presence of FD&C Blue No. 1 using the same dissolution cell. The crystalline powder was introduced into the dissolution cell at time zero; samples were pipeted out at specified time and assayed for drug content. To exclude the effect of particle size on the dissolution rate, the crystals used in the dissolution study came from the same batch.

RESULTS AND DISCUSSION

The results in Figs. 1–3 show that small concentrations of FD&C Blue No. 1 exerted a remarkable effect on the dissolution behavior of phenobarbital monohydrate, sulfathiazole, and sulfaguandine. The linear dissolution rates in 0.1 N HCl and in 0.1 N HCl containing 10 mcg./ml. Blue No. 1 are given in Table I.

The dissolution behavior of sulfaguandine single crystals was studied in presence of variable concentrations of FD&C Blue No. 1 ranging from 0–100 mcg./ml. The data presented in Fig. 3 shows inhibiting effect of the dye on dissolution and Fig. 4 demonstrates

Figure 3—Single-crystal dissolution of sulfaguandine as a function of time. Key: ●, in 0.1 N HCl; ▲, in 0.1 N HCl containing 10 mcg./ml. FD&C Blue No. 1; ○, in 0.1 N HCl containing 50 mcg./ml. FD&C Blue No. 1; ■, in 0.1 N HCl containing 100 mcg./ml. FD&C Blue No. 1.

Figure 4—Effect of dye concentration on the dissolution rate of sulfaguandine single crystals.

the dissolution rate dependence on the inhibitor concentration. It is obvious that this curve tends to stabilize after 50 mcg./ml.

Dissolution from the planar surface of a compressed disk was carried out to substantiate the results obtained from single crystals. Figure 5 shows the dissolution behavior of sulfathiazole compressed disks in 0.1 N HCl and in 0.1 N HCl containing 5 mcg./ml. Blue No. 1. The inhibition obtained is in close agreement with that obtained from a sulfathiazole single crystal.

Figure 6 represents the same phenomenon in compressed disks of thymol. The thymol crystals used in preparing the tablet were grown from CCl₄. These crystals exhibited spiral steps as shown in Fig. 7. Because of the fragile nature and shape irregularities of these crystals, it was difficult, in practice, to measure the dissolution rate of single crystals.

The effect of 50 mcg./ml. of dye on 1.5 g. of sulfathiazole crystalline powder is shown in Fig. 8. Although the dye concentration is high, the dissolution rate was reduced by a value smaller than those obtained from studies on single crystals and tablets. This can be explained by the relatively large surface area provided by 1.5 g. of the crystalline powder.

Figure 5—Dissolution behavior of sulfathiazole compressed disks. Key: ○, in 0.1 N HCl; ■, in 0.1 N HCl containing 5 mcg./ml. FD&C Blue No. 1.

Figure 6—Dissolution behavior of thymol compressed disks. Key: O, in 0.1 N HCl; ■, in 0.1 N HCl containing 5 mcg./ml. FD&C Blue No. 1.

The inhibitory effect of Blue No. 1 on the dissolution of the investigated drug crystals, is in agreement with the work of Saad and Higuchi (1), representing a situation where a relatively large amount of sodium cholate retarded the growth and dissolution rates of cholesterol crystals. The inhibition of the surface dissolution rate by the dye is in agreement with the studies of Ives *et al.* dealing with the effect of traces of ferric ion on the dissolution kinetics of a single crystal of lithium fluoride.

The data obtained are consistent with the kink mechanism proposed by Gilman *et al.* (15) and Ives (16). The mechanism involves preferred adsorption of the dye molecules at the primary dissolution sources of the crystal surface. The kinks in crystal ledges are the primary dissolution sources, where individual drug molecules can deposit or escape readily.

In absence of dye, the drug molecules will be lost preferentially from the kinks where binding is weakest and effect a motion of the kinks along the ledges. The mean time for stripping will always be a simple factor of the ledge length. Continuous dissolution will require successive nucleation of the kinks. In presence of dye inhibition, the dye molecules tend to deposit on the kinks and reduce the kink nucleation rate.

The fact that the curve in Fig. 4 tends to stabilize after a certain concentration of dye is in agreement with previous observations reported by Ives and Plewes (7). It is in accord with the postulate that the observed optimum concentration in the plot of rate of dissolution *versus* inhibitor concentration represents a situation where mono-kink adsorption is attained.

A further evidence was found in investigating the morphological changes produced by the dye on the dissolving faces of sulfaguandine and sulfathiazole crystals. Figures 9 and 10 show the dissolution features produced by 0.1 N HCl and 0.1 N HCl containing 50

Figure 7—Thymol crystal exhibiting spiral steps. Magnification: 125 \times .

Figure 8—Dissolution behavior of sulfathiazole crystalline powder. Key: ●, in 0.1 N HCl; ▲, in 0.1 N HCl containing 50 mcg./ml. FD&C Blue No. 1.

μ /ml. of the dye for a limited period of time. FD&C Blue No. 1 seems to act as an etchant producing etch pits on these dissolving faces. The observations are similar to those obtained by Gilman *et al.* (15) in their study of dislocation etch pit formation in lithium fluoride in presence of ferric ion as dissolution inhibitor.

The major emphasis in this study is on surface dissolution of single crystals and of compressed disks of the drug crystals. For the present, the inhibited dissolution in presence of Blue No. 1, is

Figure 9—Effect of FD&C Blue No. 1 on the dissolving face of sulfaguandine single crystal after 15 min. Key: a, in 0.1 N HCl, b in 0.1 N HCl containing 50 mcg./ml. FD&C Blue No. 1. Magnification: 125 \times .

Figure 10—Effect of FD&C Blue No. 1 on the dissolving face of sulfathiazole single crystal after 15 min. Key: a, in 0.1 N HCl, b, in 0.1 N HCl containing 50 mcg./ml. FD&C Blue No. 1. Magnification: 500X.

limited to the systems that have been studied, and to the experimental conditions described. The significance of dissolution inhibition in powder systems in presence of a low concentration of the dye is not clear yet. The extension of this study to other powder systems and other water-soluble dyes will contribute to better

understanding of the role of water-soluble colorants in drug formulations.

Phenylisoquinolines and Hydroisoquinolines

J. SAM, R. M. SHAFIK*, and K. APARAJITHAN

Abstract □ The synthesis of some derivatives of 5-, 6-, and 7-phenylisoquinoline, 3,4-dihydroisoquinoline, and 1,2,3,4-tetrahydroisoquinoline are described. Results of preliminary pharmacological tests are reported.

Keyphrases □ Phenylisoquinolines—synthesis □ Hydroisoquinolines—synthesis □ Pharmacological screening—phenylisoquinolines, hydroisoquinolines □ IR spectrophotometry—identity

Several alkaloids which incorporate the 1-benzylisoquinoline (I) or tetrahydroisoquinoline (II) moiety in their structures possess interesting biological properties (1, 2). The latter structural feature has been proposed (3) as a precursor in the biosynthesis of the aporphine alkaloids (III). Whereas, extensive investigations (4, 5) have been directed toward the synthesis of 1-benzylisoquinolines, little effort has been expended in studies of arylisoquinolines (VII) and the corresponding hydrogenated derivatives (VIII, X, and XI) (6). Consequently,

it was of interest to determine whether compounds such as VII and hydrogenated VII possess CNS properties similar to known aporphines (7) (bulbocapnine) and/or cardiovascular properties.

The synthetic approach followed is shown in Scheme I. The nitration of isoquinoline yielded 5-nitroisoquinoline (V) (8). The reduction of the latter compound to 5-aminoisoquinoline (VI) (9, 10) followed by diazotization and coupling with benzene, according to a procedure similar to that described by Cadogan (11) for the preparation of biphenyls, provided 5-phenylisoquinoline. Hydrogenation of VIIa hydrochloride using plati-

Several alkaloids which incorporate the 1-benzylisoquinoline (I) or tetrahydroisoquinoline (II) moiety in their structures possess interesting biological properties (1, 2). The latter structural feature has been proposed (3) as a precursor in the biosynthesis of the aporphine alkaloids (III). Whereas, extensive investigations (4, 5) have been directed toward the synthesis of 1-benzylisoquinolines, little effort has been expended in studies of arylisoquinolines (VII) and the corresponding hydrogenated derivatives (VIII, X, and XI) (6). Consequently,

it was of interest to determine whether compounds such as VII and hydrogenated VII possess CNS properties similar to known aporphines (7) (bulbocapnine) and/or cardiovascular properties.

The synthetic approach followed is shown in Scheme I. The nitration of isoquinoline yielded 5-nitroisoquinoline (V) (8). The reduction of the latter compound to 5-aminoisoquinoline (VI) (9, 10) followed by diazotization and coupling with benzene, according to a procedure similar to that described by Cadogan (11) for the preparation of biphenyls, provided 5-phenylisoquinoline. Hydrogenation of VIIa hydrochloride using plati-

num oxide catalyst yielded 5-phenyl-1,2,3,4-tetrahydroisoquinoline (VIIIa) whereas VIIb gave the 2-methyl derivative (XIb).

The 6-, and 7-phenyl-2,3-dihydroisoquinolines (X) were prepared *via* the Bischler-Napieralski reaction by heating *N*-acylbiphenylethylamines (IX) with polyphosphoric acid (12). Reduction of X with sodium borohydride provided the 1,2,3,4-tetrahydroisoquinolines (VIII). Dehydrogenation of VIII_e in *p*-cymene with 10% palladium on carbon (13) provided the corresponding unsaturated isoquinoline (VIIc).

Heating VIIIa with cyanamide (14) gave the guanidine derivative (XIa). Methylation of VIII_e yielded the corresponding *N*-methyl derivative (XIc). Treating

VIII_e with 5-chloro-8-hydroxyquinoline and formaldehyde provided the Mannich product (XIe). The compounds that were prepared are listed in Table I.

PHARMACOLOGICAL RESULTS¹

Acute effects (Table II) after intraperitoneal injection were observed in male albino mice (20–30 per compound) weighing 25–35 g. Estimated 48-hr. LD₅₀ and 95% confidence limits were determined by the method of Horn (15). The method of Irwin (16) was utilized in noting the effects produced.

¹ The authors are grateful to Dr. W. Marvin Davis, Department of Pharmacology, for the pharmacological data.

Scheme 1

EXPERIMENTAL²

5-Phenylisoquinoline (VIIa)—Method A—A solution of 14.4 g. (0.1 mole) of 5-aminoisoquinoline (VI) in 300 ml. of dry benzene was treated with 25 ml. of freshly prepared isoamyl nitrite. The reaction mixture, which turned brown, was heated under reflux on a steam bath for 1 hr. and then allowed to remain at room temperature for 18 hr. The solvent and unreacted isoamyl nitrite were removed by distillation. The dark-colored residue was extracted with hot petroleum ether (30–60°). The pale yellow liquid obtained after the removal of the solvent was distilled under reduced pressure. The picrate (VIIa) and the methiodide (VIIb) were prepared in the usual manner and recrystallized.

5-Phenyl-1,2,3,4-tetrahydroisoquinoline (VIIIa)—Method B—A solution of 7 g. (0.029 mole) of 5-phenylisoquinoline (VIIa) in 50 ml. of 1 *N* hydrochloric acid was hydrogenated at 47 p.s.i. with 0.1 g. of PtO₂ catalyst for 12 hr. The mixture was heated to dissolve the solid that had separated and then filtered to remove the catalyst. The hydrogenated product was separated from the cooled filtrate and recrystallized.

***N*-Acylbiphenylethylamines (IX)**—*N*-[2-(3-biphenyl)ethyl]formamide (IXa) and *N*-[2-(4-biphenyl)ethyl]formamide (IXc) were prepared using a procedure similar to that described by Cannon and Webster (12) for the preparation of *N*-acylphenylethylamines. To 0.014 mole of the appropriate 2-biphenylethylamine was added 22.5 ml. of formic acid and 18 ml. of acetic anhydride. The solution was refluxed for 7 hr. and thereafter diluted with water and extracted with ether. The ether layer was washed subsequently with 10% sodium hydroxide, 10% hydrochloric acid, and water, respectively, and then dried over anhydrous sodium carbonate. The ether was removed under reduced pressure; the crude products (65% of IXa and 55% of IXc) were used without further purification in Method C.

N-[2-(3-biphenyl)ethyl]acetamide (IXb), and *N*-[2-(4-biphenyl)ethyl]acetamide (IXd) were prepared according to the procedure described by Sam *et al.* (17, 18).

6-, and 7-Phenyl-3,4-dihydroisoquinolines (X)—*Method C*—To 61 g. of commercial polyphosphoric acid, heated to 150°, was added with stirring 0.015 mole of the appropriate, dried, *N*-acylbiphenylethylamine (IX). The mixture was kept at 180–190° for 3 hr. and then set aside for 9 hr. at room temperature. Thereafter, the mixture was diluted with 500 ml. of water and allowed to remain at room temperature for an additional 12 hr. The solution was

filtered, rendered alkaline with a solution of 70 g. of sodium hydroxide in 140 ml. of water and then extracted with ether. The ether extract was washed with water and dried over anhydrous sodium sulfate. The amine was distilled under reduced pressure and/or converted to a salt in the usual manner and recrystallized.

6-, and 7-Phenyl-1,2,3,4-tetrahydroisoquinolines (VIII)—*Method D*—A solution of the proper phenyl-3,4-dihydroisoquinoline (X) in 80 ml. of ethanol was treated dropwise, while stirring, with a solution of 8 g. of sodium borohydride in 80 ml. of ethanol. The reaction mixture was allowed to remain at room temperature for 18 hr. and then heated under reflux for 1 hr. The ethanol was distilled under reduced pressure and the residue diluted with water and extracted with ether. The ether extract was washed with water and dried over anhydrous sodium sulfate. The ether was evaporated; the residue was distilled under reduced pressure and/or isolated as a salt and recrystallized.

1-Methyl-7-phenylisoquinoline (VIIc)—Method E—A mixture of 5.2 g. (0.023 mole) of 1-methyl-7-phenyl-1,2,3,4-tetrahydroisoquinoline (VIIIe), 5 g. of 10% Pd-C and 350 ml. of dry *p*-cymene was heated under reflux with stirring for 1 hr. The catalyst was removed by filtration and washed with two 50-ml. portions of hot benzene. The combined filtrate was extracted with dilute hydrochloric acid. The acid extract was rendered alkaline with dilute sodium hydroxide, and then extracted with ether. The ether extract was washed with water and dried over anhydrous magnesium sulfate. The residue obtained on evaporation of the ether was distilled. A picrate was prepared in the usual manner and recrystallized.

5-Phenyl-3,4-dihydro-2(1H)-isoquinolinocarboxamidine hydrochloride (IXa)—*Method F*—A mixture of 1.23 g. (0.005 mole) of 5-phenyl-1,2,3,4-tetrahydroisoquinoline (VIIIa), 0.25 g. (0.006 mole) of cyanamide and 3 ml. of water was heated in an oil bath at 180° for 1.5 hr. The product was isolated from the resulting mixture by recrystallization.

2-Methyl-5-phenyl-1,2,3,4-tetrahydroisoquinoline (XIb)—Method G—A suspension of 5.05 g. (0.014 mole) of 5-phenyl-2-methylisoquinolinium iodide (VIIb) in 50 ml. of water was hydrogenated at 47.5 p.s.i. with 0.1 g. of PtO₂ for 48 hr. The mixture was heated and filtered to remove the catalyst and then cooled. The product was removed by filtration and recrystallized.

1,2-Dimethyl-7-phenyl-1,2,3,4-tetrahydroisoquinoline (XIc)—Method H—Methylation of 1.5 g. (0.0067 mole) of 1-methyl-7-phenyl-1,2,3,4-tetrahydroisoquinoline (VIIIe) by the Eschwiler-Clarke method (17) gave a liquid which was distilled under reduced pressure. A hydriodide and a methiodide (XIId) were prepared in the usual manner and recrystallized.

2-[5-Chloro-8-hydroxy-7-quinolylmethyl]-1-methyl-7-phenyl-1,2,3,4-tetrahydroisoquinoline (XIe)—Method I—To a solution of 0.49 g. (0.0022 mole) of 1-methyl-7-phenyl-1,2,3,4-tetrahydroisoquinoline (VIIIe) in 10 ml. of ethanol was added 0.4 g. (0.0022 mole)

² All melting points were taken in open glass capillaries using a Thomas-Hoover melting point apparatus and are uncorrected. IR spectra of all compounds were determined on a Perkin-Elmer model 137 infracord spectrophotometer using KBr pellets. The spectra were consistent with the assigned structures.

Table II—Acute Interperitoneal Toxicity and Symptomatic Observations

No. ^a	LD ₅₀ ,mg./kg.	Observations
VIIa ^{b,c}	242(208–282)	Sedation, ataxia, tremors
VIIb ^d	141(117–170)	Sedation, ataxia, tremors
VIIc ^{b,c}	521(447–607)	Sedation, ataxia, loss of righting reflex
VIIc ^{e,c}	187(165–210)	Sedation, tremor, vasodilation
VIIIa ^{b,c}	96(76–123)	Sedation, convulsion at toxic doses
VIIIb ^{b,c}	104(86–125)	Slight motor excitation; convulsions at lethal doses
VIIIc ^{b,c}	141(117–170)	Slight analgesia early followed by long-continuing clonic convulsions
VIIIb ^{b,c}	153(126–184)	Slight analgesia early, clonic convulsions, tremors, and ataxia
VIIIe ^{b,c}	77(66–89)	Sedation, convulsion at toxic doses
Xb ^{b,c}	52(45–61)	Long-continuing clonic convulsions

Aqueous Stability of Clindamycin

T. O. OESTERLING

Abstract □ The kinetics and mechanism of degradation of the antibiotic clindamycin were studied in buffered aqueous solution in the pH range 0.4–12. Clindamycin showed maximum stability at pH 3–5; however, high temperature studies indicated that not more than 10% degradation will occur in the pH range 1–6.5 after two years at 25°. In the pH range 0.4–4 the major degradative pathway was hydrolysis of the thioglycoside linkage to form 1-dethiomethyl-1-hydroxy clindamycin and methyl mercaptan. The major degradative pathway in the pH range 5–10 was scission of the 7-(S)-Cl of clindamycin to form the 7-(R)-OH analog, lincomycin. Evidence was obtained that supports the hypothesis that this conversion to lincomycin proceeds through an oxazolonium intermediate and that the extent of conversion depends on the degree of protonation of the amine function of clindamycin. The activation energy for clindamycin degradation in 0.1 M HCl, where thioglycoside hydrolysis is predominant, is 38.0 ± 1.2 kcal./mole, and the activation energy in 0.2 M citrate buffer adjusted to pH 5, where conversion to lincomycin is predominant, is 29.1 ± 0.6 kcal./mole.

Keyphrases □ Clindamycin—stability, aqueous solution □ Stability—clindamycin aqueous solutions □ Degradation, clindamycin—kinetics, mechanism, product identity □ pH effect—clindamycin stability □ Temperature effect—clindamycin stability □ GLC—analysis □ Mass spectroscopy—identity

The synthesis and biological properties of the antibiotic clindamycin (I) were first reported by Magerlein *et al.* (1, 2). Clindamycin possesses marked antiparasitodal activity (3) and is highly effective in the treatment of infections caused by Gram-positive organisms (2).

The purpose of this study was to investigate the degradation of clindamycin in aqueous solution in order to supply basic information necessary for the successful formulation of the drug in liquid dosage forms. The effects of pH and temperature on the rate of clindamycin degradation were studied and the major products of degradation in the pH range 0.4–12 were identified. From these data, the conditions of maximum stability of clindamycin in aqueous solution were established and the stability of clindamycin in pharmaceutical formulations could be predicted.

EXPERIMENTAL

Materials—Clindamycin, lincomycin, lincomycin tetraacetate, 7-epilincosamin, and 7-epiclindamycin (The Upjohn Co.) were used and all other chemicals were reagent grade.

Figure 1—Typical gas-liquid chromatogram of acetylated sample from low pH (<4) reaction mixtures. Key: Peak 1, 1-dethiomethyl-1-hydroxy clindamycin tetraacetate; Peak 2, suspected anomer of Peak 1; Peak 3, clindamycin triacetate; Peak 4, cholesteryl acetate.

Kinetic Studies—pH-Rate Studies—Reaction mixtures containing clindamycin hydrochloride and buffers were prepared to cover the pH range 0.40–12 using the buffers shown in Table I. Individual buffer systems were prepared from citric acid, tartaric acid, acetic acid, succinic acid, disodium phosphate, boric acid, and sodium carbonate, and adjusted to the desired pH at 70° by the addition of hydrochloric acid or sodium hydroxide.

The concentration of clindamycin hydrochloride was 1% (0.02 M) in the pH range 1–6, 0.2% at pH 7, and 0.1% at pH values greater than 7. Reaction mixtures at higher pH contained less clindamycin due to the relatively low solubility of the undissociated species (about 2 mg./ml.). After preparation, volumes of each reaction mixture equivalent to 12 mg. of clindamycin hydrochloride were filled into ampuls, sealed, and placed into a 70° constant-temperature bath. At appropriate times two samples were withdrawn, the pH of one was measured, and an aliquot of the second equivalent to 10 mg. of clindamycin hydrochloride was freeze-dried. The amount of intact clindamycin present in the freeze-dried samples was determined by the gas-liquid chromatographic assay described below.

Temperature-Rate Studies—The effect of temperature on the rate of clindamycin degradation was studied in 0.1 M hydrochloric acid and in 0.2 M citrate buffer adjusted to pH 5.

Ampuls containing 10 mg./ml. of clindamycin hydrochloride in 0.1 M hydrochloric acid were placed into constant-temperature baths set at 47, 53, 70, 79, and 93°. At appropriate times 1.0-ml. samples were withdrawn, freeze-dried, and the amount of intact clindamycin present in the freeze-dried samples was determined by the gas-liquid chromatographic assay described below.

Ampuls containing 10 mg./ml. of clindamycin hydrochloride in the citrate buffer were placed into 47, 53, 60, 70, 80, and 90° constant-temperature baths. At appropriate times two ampuls were withdrawn, the pH of one was measured, and 1.0 ml. of the other was freeze-dried. The pH did not vary by more than 0.2 pH units from the initial pH during the reaction in all of the buffered reaction mixtures including the pH-rate studies described above. The amount of intact clindamycin present in the freeze-dried samples was determined by the gas-liquid chromatographic assay described below.

Gas-Liquid Chromatographic Assay—One milliliter of deionized water was added to the freeze-dried sample, the pH was adjusted to 11 with concentrated ammonium hydroxide, and the solution was extracted with two 1-ml. portions of ethyl acetate. The ethyl acetate extracts were combined and the solvent was removed with a stream

Figure 2—Typical gas-liquid chromatogram of acetylated sample from high pH (5–8) reaction mixture. Key: Peak 1, clindamycin triacetate; Peak 2, suspected 7-epilinclomycin tetraacetate or 7-epiclindamycin triacetate; Peak 3, lincomycin tetraacetate; Peak 4, unknown; Peak 5, cholesteryl acetate.

of nitrogen. To the residue 1.0 ml. of a mixture of pyridine (dried over KOH)–acetic anhydride (2:1) containing 10 mg./ml. cholesteryl acetate as internal standard was added. After acetylating for 1 hr. at 100°, the solution was cooled to room temperature and 1 μ l. was injected into an F & M model 402 gas chromatograph adjusted to the following conditions. Samples were partitioned between helium carrier gas flowing at 40 ml./min. and 3% OV-1 on diatomaceous earth (Gas Chrom Q) 60–80 mesh in a U-shaped glass column 120 cm. long \times 3 mm. i.d. Columns were preconditioned by heating at 300° for at least 6 hr. with low helium flow and then for 1 hr. under no flow conditions. The column temperature was 220°, flash heater temperature 230°, and flame ionization detector 240°. Air and hydrogen flow rates were adjusted to give maximum response.

The concentration of clindamycin per sample was obtained by comparing clindamycin–internal standard peak height ratios to the peak height ratios of a standard curve prepared from known amounts of clindamycin. Standard curves were obtained daily.

Determination of pKa of Clindamycin at 70°—Ten milliliters of a 2.0 mg./ml. solution of clindamycin hydrochloride were titrated with 0.05 N NaOH in a jacketed vessel at 70° with a Radiometer

Figure 3—Arrhenius plot for degradation of clindamycin in 0.1 M HCl.

TTTIC titrator and SBR2C titrator. The average pKa of six replicate titrations was 6.90 ± 0.10 .

Identification of Degradation Products—Degradation products were identified by mass spectral studies and by comparison of gas-liquid chromatographic retention times and thin layer chromatographic R_f values with authentic samples when available. Mass spectra of acetylated clindamycin and degradation products were obtained by processing acetylated reaction mixture samples through an LKB 9000 gas chromatograph-mass spectrometer and recording mass spectra of peaks of interest as they exited from the gas chromatograph column. Thin layer chromatographic studies were carried out by spotting about 50 μ l. of clindamycin reaction mixtures on Silica Gel G and developing with chloroform-methanol 90:10. Spots were visualized with iodine vapor.

RESULTS AND DISCUSSION

Identification of Products—Gas-liquid chromatographic data indicated that the mechanism of clindamycin degradation is pH-dependent with a change in mechanism occurring in the vicinity of pH 4–5. For example, chromatograms similar to Fig. 1 were obtained from reaction mixtures whose pH was less than 4, whereas samples from reaction mixtures in the pH range 5–8 yielded chromatograms similar to the one shown in Fig. 2. The major product of degradation in the pH range 0.4–4, represented by Peak 1 in Fig. 1, had a shorter retention time than clindamycin while the major degradation product at higher pH, represented by Peak 3 of Fig. 2, had a longer retention time than clindamycin. Chromatograms from reaction mixtures at pH greater than 8 which were buffered with borate, carbonate, or NaOH showed only disappearance of clindamycin and no other peaks were observed.

The identity of the major degradation product of clindamycin at pH less than 4 was established by mass spectral studies and with a knowledge of the reactivity of lincomycin (V), the 7(R)-OH analog of clindamycin, in acid. Prescott (5) and Herr and Slomp (6) have

Scheme I

Table I—Apparent First-Order Rate Constants of Degradation of Clindamycin

pH	Buffer	Temperature, °C.	k , sec. ⁻¹ × 10 ⁻⁶
0.44 ^a	0.5 M HCl	70	19.0
0.54 ^a	0.4 M HCl	70	19.3
0.66 ^a	0.3 M HCl	70	14.3
0.83 ^a	0.2 M HCl	70	8.25
1.10 ^a	0.1 M HCl	70	4.50
1.10 ^a	0.1 M HCl	70	4.66
1.10 ^a	0.1 M HCl	47	0.0199
1.10 ^a	0.1 M HCl	53	0.252
1.10 ^a	0.1 M HCl	59	1.43
1.11 ^a	0.1 M HCl	79	13.0
1.11 ^a	0.1 M HCl	93	66.5
1.94	0.2 M Citrate	70	0.831

11.00	0.2 M Carbonate	70	149
11.66 ^b	0.1 M NaOH	70	204

^a Calculated from $\text{pH} = -\log f(\text{HCl})$; where (HCl) is the experimental molarity and f is the mean activity coefficient for HCl at 70° extrapolated from the literature (4). ^b Calculated from $\text{pH} = \text{pKw} - \text{pOH}$; where $\text{pKw} = 12.77$ at 70° (4), $\text{pOH} = -\log f(\text{NaOH})$, (NaOH) is the experimental molarity, and f is the mean activity coefficient for NaOH extrapolated from the literature (4).

reported that lincomycin (V) degrades in acid *via* thioglycoside hydrolysis to form *l*-dethiomethyl-*l*-hydroxylincomycin and methyl mercaptan. Clindamycin might be expected to react in acid in a manner similar to lincomycin and mass spectral data indicate that the molecular weight of the compound represented by Peak 1 of Fig. 1 is 562. This molecular weight corresponds to acetylated *l*-dethiomethyl-*l*-hydroxycyclindamycin which indicates that II in Scheme I is the major product of clindamycin degradation at pH less than 4.

II can be detected gas chromatographically as the predominant reaction product for about three clindamycin half-lives after which it begins to disappear. The decrease in magnitude of the gas-liquid chromatographic peaks of II and clindamycin at extended reaction times is accompanied by the appearance of several small peaks of shorter retention time. This further degradation may result from breakdown of the sugar moiety or amide hydrolysis (6).

Peak 2 of Fig. 1 represents another product of clindamycin degradation at pH less than 4 which is present in the early stages of the reaction. As the reaction proceeds, Peak 2 behaves similarly to Peak 1 and decreases in magnitude after about three clindamycin half-lives. Since thioglycoside hydrolysis proceeds through a carbonium ion intermediate (7), the products of clindamycin would be methyl mercaptan and an anomeric mixture of II. Mass spectral studies indicated that Peak 1 represents one of the anomers and

Figure 4—Arrhenius plot of clindamycin degradation at pH 4 in 0.2 M citrate buffer.

Peak 2 may represent the other. The identification of Peak 2 was not attempted.

Lincomycin (V) was identified as the major degradation product of clindamycin at pH greater than 5. Mass spectral studies of Peak 3 of Fig. 2 showed that the molecular weight of this compound was 574, the molecular weight of acetylated lincomycin. Further, the gas-liquid chromatographic retention time of Peak 3 of Fig. 2 is identical to authentic lincomycin tetraacetate. Lincomycin, as well as clindamycin, is unstable in the pH range 5–8 as both Peaks 1 and 3 of Fig. 2 disappear at long reaction times. One possible route of degradation of lincomycin and clindamycin at extended reaction times is amide hydrolysis.

It is obvious from Fig. 2 that lincomycin is not the sole product of clindamycin degradation at pH 5–8. At least two other reaction products are represented by Peaks 2 and 4 of Fig. 2. Both Peaks 2 and 4 represent minor products and neither was ever present in

Figure 5—Apparent first-order disappearance of clindamycin in 0.1 M HCl at various temperatures. Key: ○ 47°, □ 53°, △ 59°, ● 69°.

Figure 6—pH-Rate profile of clindamycin degradation at 70°.

amounts greater than that shown in Fig. 2. Peak 2 may represent acetylated 7-epilincmoycin or acetylated 7-epicindamycin since its retention time was identical to authentic samples of each. Magerlein has reported the formation of a trace of 7-epilincmoycin after refluxing an aqueous solution of clindamycin at pH 7.8 (8). Peak 4 of Fig. 2 was not identified.

Although lincomycin (V) and Peaks 2 and 4 of Fig. 2 could not be detected above pH 8 by GLC, TLC of these reaction mixtures indicated that some of these degradation products were present but were not being extracted for gas chromatographic assay. Thin layer chromatograms of the reaction mixtures above pH 8 showed clindamycin and lincomycin by comparison with authentic samples and three other spots which were not identified. Gas chromatograms of reaction mixtures below pH 8 showed that the major degradation products were extracted by ethyl acetate. The sum of the moles of acetylated IV (Scheme I) and clindamycin between pH 5 and 8 and of acetylated II and clindamycin below pH 5 was greater than 90% of the initial clindamycin concentration in the early stages of the reaction.

Temperature-Rate Studies—Arrhenius plots of clindamycin degradation in 0.1 M HCl and at pH 4 are shown in Figs. 3 and 4. The activation energy for clindamycin degradation in 0.1 M HCl was calculated to be 38.0 ± 1.2 kcal./mole. The principal degradative pathway in 0.1 M HCl is hydrolysis of the 1-thio- α -D-galactopyranoside moiety of clindamycin at Position 1 to form 1-dethio-1-hydroxy-clindamycin (II) and methyl mercaptan (Scheme I). The activation energy for clindamycin degradation in 0.1 M HCl falls in the 30–38 kcal./mole range reported by other investigators for acid degradation of compounds of similar structure such as alkyl 1-thio- β -D-glucopyranosides (9), alkyl β -D-xylopyranosides (10), and alkyl α - and β -D-glucopyranosides (11).

The activation energy for clindamycin degradation at pH 5, the pH of maximum stability, was calculated to be 29.1 ± 0.6 kcal./mole. Using the rate constants in Table I and the appropriate activation energy, the prediction can be made that clindamycin in pharmaceutical formulations adjusted to pH 1–6.5 will not degrade by more than 10% after 2 years at 25°.

pH-Rate Studies—Clindamycin disappeared from reaction mixtures by an apparent first-order process under all of the conditions studied. Some typical log clindamycin concentration-time curves are shown in Fig. 5.

The effect of pH on the rate of clindamycin degradation in the pH range 0.40–12 at 70° is shown in Fig. 6.

Different buffer species did not appear to significantly influence the rate of degradation since a continuous curve was obtained for the pH profile and since the rate constant did not vary with different buffers at the same pH (Table I).

The pH profile of clindamycin (Fig. 6) shows that the rate of degradation increases with decreasing pH in the pH range 0.4–4. This is expected since both major degradative routes in this pH region, thioglycoside and amide hydrolysis, are susceptible to hydrogen ion catalysis. Being of similar structure, lincomycin (V) should also degrade by these two routes in acid media and the rate constant should agree with that of clindamycin when reacted under similar conditions. Forist, *et al.* (12) studied the degradation of V in 0.1 N HCl at 70° and the rate constant of 4.85×10^{-6} sec.⁻¹

calculated from their data agrees quite favorably with the clindamycin values in Table I.

In the pH range 5–12 the degradative rate increases with increasing pH with an inflection point in the pH 9–10 region. GLC and TLC of reaction mixtures in this pH region show that at least four products are formed by clindamycin degradation. The times of appearance of the various products and their relative concentrations indicate parallel reactions. Assuming there are parallel reactions occurring, the shape of the pH-rate profile in Fig. 6 in the pH 4–12 region might be interpreted as follows. In the pH 4–9 region all degradative rates are increasing with increasing pH with one of the reactions predominating. Above pH 9 the rate constant of the reaction which was predominating at pH 5–9 becomes constant but the rates of the other reactions continue to increase with increasing pH.

Gas-liquid and thin layer chromatographic data of this study show that the predominant degradative reaction at pH 5–9 is conversion to lincomycin (V). Results of studies by Magerlein (8, 13) show how the rate of lincomycin conversion could be predominant in this pH range and then become constant above pH 9. Magerlein has postulated that conversion to lincomycin occurs through the oxazolonium ion intermediate (VII) shown in Scheme II and that the extent of conversion is highly dependent on the participating ability of the substituent on the amide carbonyl (13). For example, solvolysis is anchimerically assisted by the neighboring amide carbonyl if the carbonyl substituent is methyl, whereas when R_1 is a strong electron withdrawing group such as trifluoromethyl, participation does not occur. Magerlein also reports that the 7(S)-Cl position of clindamycin is resistant to direct S_N2 nucleophilic displacement (8).

Scheme II

In the present study no conversion to lincomycin was observed at pH values less than 5, whereas lincomycin was detected by GLC or TLC in all reaction mixtures buffered to pH values greater than 5. Assuming that the protonated form of the *N*-methyl-4-propylpyrrolidine portion of clindamycin (R_1) is analogous to trifluoromethyl as a nonparticipating substituent and $k_1 \ll k_2$, no conversion to lincomycin would be expected in the pH range where R_1 is fully protonated, *i.e.*, at pH values less than 5. On the other hand, it is possible that lincomycin can be detected in the pH 5 reaction mixtures because the small amount of nonprotonated R_1 has facilitated conversion to lincomycin and the increase in rate of clindamycin degradation is partly due to this reaction. As the pH increases the rate of conversion to lincomycin increases due to the presence of more nonprotonated R_1 . The leveling trend in the pH profile at pH 9, two pH units above the pKa of 6.90, might be due to a constant rate of lincomycin conversion since at pH 9 and above all of R_1 exists in the nonprotonated form. The further increase in overall rate above pH 10 might then be due to an increase in the rate of other reactions such as amide hydrolysis.

The relationship between pH and the mechanism of clindamycin degradation could be summed as follows. Below pH 4 clindamycin degrades *via* thioglycoside and amide hydrolysis with thioglycoside hydrolysis predominant in the pH range 0.4–4. Above pH 5 clindamycin degrades by conversion to lincomycin and by other reactions such as amide hydrolysis. The extent of lincomycin conversion is dependent on the degree of protonation of the *N*-methyl-4-propylpyrrolidine moiety. At pH less than 5 where the amine is fully protonated no conversion to lincomycin occurs. Then this process can be detected in the vicinity of pH 5 and its rate increases as pH increases to pH 9 and then becomes constant since the amine function is completely nonprotonated. The overall rate of clindamycin degradation continues to increase with increasing pH above pH 9, however, due to the hydroxide ion dependency of the other degradative routes.

Coumarins XI: A Total Synthesis of (±)-Columbianetin

M. SHIPCHANDLER*, T. O. SOINE†, and P. K. GUPTA‡

Abstract □ (±)-Columbianetin [(±)-I] has been synthesized by a ten-step sequence starting with 2,6-dihydroxybenzoic acid which was converted to the methyl ester, benzylated, and reduced to the benzyl alcohol which was oxidized to the aldehyde and monodebenzylated to provide 2-hydroxy-6-benzyloxybenzaldehyde (VI). Treatment of VI with methyl bromoacetate converted it to methyl 3-benzyloxy-2-formylphenoxyacetate which was cyclized to methyl 4-benzyloxybenzofuran-2-carboxylate, the latter being converted to 2-(α-hydroxyisopropyl)-4-benzyloxybenzofuran (XIV) by the action of CH_3MgI . Reduction and debenzoylation of XIV to the corresponding dihydrobenzofuran followed by acid-catalyzed condensation with ethyl propiolate provided (±)-I.

Keyphrases □ (±)-Columbianetin—total synthesis □ TLC—separation identity □ Mass spectroscopy—identity □ UV spectro-photometry—identity □ IR spectrophotometry—identity □ NMR spectroscopy—identity

The isolation of two new coumarins from the umbellifer, *Lomatium columbianum* Math. and Const., was reported in 1964 (1). One of these coumarins, a glycoside assigned the name columbianin, has since been shown to occur in *L. dissectum* var. *multifidum* (Nutt.) Math. and Const. (2) and *L. nuttallii* (A. Gray) Macbr. (3). Acid hydrolysis of columbianin yielded D-glucose and a tertiary coumarinic aglycone, columbianetin (I) and led to the postulation of II as the structure for the glycoside. More recent studies (4) have revised the structure to III, *i.e.*, the β-D-gentiobioside of I (III). The other coumarin, columbianadin, was assigned Structure IV,

i.e., the angelate ester of I, and has been found in *Peucedanum palustre* (5) as well as in *Zosimia absinthifolia* (Vent.) Link (6, 7). The absolute configuration of I has been shown to be 8(S) (8).

The recent total synthesis of marmesin (V) and its optical antipode, nodakenetin, by Nakajima *et al.* (9) and confirmed by Harada *et al.* (10) in a study of the absolute configuration suggested that a similar synthesis could be applied to the preparation of I by utilizing 2-hydroxy-6-benzyloxybenzaldehyde (VI) as starting material in place of the isomeric 2-hydroxy-4-benzyloxybenzaldehyde employed by these workers. The preparation of VI from 2,6-dihydroxybenzaldehyde (*i.e.*, γ-resorcyaldehyde) was the obvious route but a survey of the literature pertaining to the preparation of the latter (11–15) indicated that all of the published methods were characterized by poor overall yields as well as lengthy synthetic sequences. Thus, a synthesis of

The relationship between pH and the mechanism of clindamycin degradation could be summed as follows. Below pH 4 clindamycin degrades *via* thioglycoside and amide hydrolysis with thioglycoside hydrolysis predominant in the pH range 0.4–4. Above pH 5 clindamycin degrades by conversion to lincomycin and by other reactions such as amide hydrolysis. The extent of lincomycin conversion is dependent on the degree of protonation of the *N*-methyl-4-propylpyrrolidine moiety. At pH less than 5 where the amine is fully protonated no conversion to lincomycin occurs. Then this process can be detected in the vicinity of pH 5 and its rate increases as pH increases to pH 9 and then becomes constant since the amine function is completely nonprotonated. The overall rate of clindamycin degradation continues to increase with increasing pH above pH 9, however, due to the hydroxide ion dependency of the other degradative routes.

Coumarins XI: A Total Synthesis of (±)-Columbianetin

M. SHIPCHANDLER*, T. O. SOINE†, and P. K. GUPTA‡

Abstract □ (±)-Columbianetin [(±)-I] has been synthesized by a ten-step sequence starting with 2,6-dihydroxybenzoic acid which was converted to the methyl ester, benzylated, and reduced to the benzyl alcohol which was oxidized to the aldehyde and monodebenzylated to provide 2-hydroxy-6-benzyloxybenzaldehyde (VI). Treatment of VI with methyl bromoacetate converted it to methyl 3-benzyloxy-2-formylphenoxyacetate which was cyclized to methyl 4-benzyloxybenzofuran-2-carboxylate, the latter being converted to 2-(α-hydroxyisopropyl)-4-benzyloxybenzofuran (XIV) by the action of CH_3MgI . Reduction and debenzoylation of XIV to the corresponding dihydrobenzofuran followed by acid-catalyzed condensation with ethyl propiolate provided (±)-I.

Keyphrases □ (±)-Columbianetin—total synthesis □ TLC—separation identity □ Mass spectroscopy—identity □ UV spectro-photometry—identity □ IR spectrophotometry—identity □ NMR spectroscopy—identity

The isolation of two new coumarins from the umbellifer, *Lomatium columbianum* Math. and Const., was reported in 1964 (1). One of these coumarins, a glycoside assigned the name columbianin, has since been shown to occur in *L. dissectum* var. *multifidum* (Nutt.) Math. and Const. (2) and *L. nuttallii* (A. Gray) Macbr. (3). Acid hydrolysis of columbianin yielded D-glucose and a tertiary coumarinic aglycone, columbianetin (I) and led to the postulation of II as the structure for the glycoside. More recent studies (4) have revised the structure to III, *i.e.*, the β-D-gentiobioside of I (III). The other coumarin, columbianadin, was assigned Structure IV,

i.e., the angelate ester of I, and has been found in *Peucedanum palustre* (5) as well as in *Zosimia absinthifolia* (Vent.) Link (6, 7). The absolute configuration of I has been shown to be 8(S) (8).

The recent total synthesis of marmesin (V) and its optical antipode, nodakenetin, by Nakajima *et al.* (9) and confirmed by Harada *et al.* (10) in a study of the absolute configuration suggested that a similar synthesis could be applied to the preparation of I by utilizing 2-hydroxy-6-benzyloxybenzaldehyde (VI) as starting material in place of the isomeric 2-hydroxy-4-benzyloxybenzaldehyde employed by these workers. The preparation of VI from 2,6-dihydroxybenzaldehyde (*i.e.*, γ-resorcyaldehyde) was the obvious route but a survey of the literature pertaining to the preparation of the latter (11–15) indicated that all of the published methods were characterized by poor overall yields as well as lengthy synthetic sequences. Thus, a synthesis of

VI starting from readily obtainable 2,6-dihydroxybenzoic acid (VII) appeared attractive (see Scheme I). The usual Fischer method of acid-catalyzed esterification of VII is reported (16) to give low yields and the authors found it also gave a poor yield of the methyl ester (VIII).

Scheme I

Employment of the method of Tomino (17), however, reacting the silver salt of VII with methyl iodide provided a 75% yield of VIII. Benzylation of VIII was carried out by the method of Doyle *et al.* (16) who prepared it without characterization and simply hydrolyzed it for further synthetic procedures. In the present study IX was obtained in 90% yield and, upon saponification, yielded the corresponding acid already described by Doyle *et al.* (16). Lithium aluminum hydride reduction of IX yielded the corresponding alcohol (X) in 90% yield. Oxidation of X with active manganese dioxide provided the aldehyde (XI) in 72% yield (18). Removal of a single benzyl group to obtain the desired monobenzyl ether (VI) in 66% yield was effected by catalytic hydrogenolysis with palladium-on-carbon.

The sequence of reactions to provide (\pm)-I from VI is shown in Scheme II and begins with alkylation of VI in 90% yield with methyl bromoacetate to provide XII followed by cyclization in the presence of magnesium methoxide by the method of Davies *et al.* (19) resulting in XIII in 63% yield.¹ Treatment of XIII with methyl magnesium iodide resulted in an oily tertiary alcohol (XIV) reminiscent of the similarly oily isomeric product obtained by Nakajima *et al.* (9) who proceeded directly to its hydrogenation without further characterization. Utilizing the alkaline palladium-on-carbon (20) of the above authors in the present study to minimize hydrogenolysis of the allylic tertiary alcohol function, the resulting product appeared to be only that (XV) resulting from simple debenzoylation of XIV. This was illustrated by its mass spectrum which showed a strong molecular ion peak at m/e 192 accompanied by the base peak at m/e 177 (doubly charged ion at m/e 88.5), undoubtedly due to a loss of methyl radical (see Scheme III).² The m/e 177 ion does not fragment further to any

appreciable extent. Compound XV, when hydrogenated further in the presence of commercially available palladium-on-carbon, provided the dihydrobenzofuran compound (XVI) which was subsequently obtained also by direct hydrogenation of XIV in the presence of the same catalyst. TLC examination in each case revealed a spot

with a higher R_f value than that of XVI, presumably the hydrogenolyzed desoxy compound. Compound XVI gave a molecular ion at m/e 194 in the mass spectrum and its fragmentation behavior had a marked resemblance to that of columbianetin (I) as evidenced by the loss of H_2O from the molecular ion followed by methyl expulsion to give the benzopyrylium ion at m/e 161 (21) (see Scheme IV). Further, a strong peak at m/e 59 is due to the protonated form of acetone arising from the side chain of the molecular ion. Loss of acetone from the molecular ion provides an ion of m/e 136 (base peak) which fragments further as illustrated.

The final conversion of XVI to (\pm)-I was accomplished through the method of Kaufman and Kelly (22) who employed ethyl propiolate in the presence of an acid to form the coumarinic lactone ring. This method has also been used successfully by Ganguly *et al.* (23). In the present study, condensation of XVI with ethyl propiolate in the presence of zinc chloride provided (\pm)-I in low yield. The identity of the racemic product was established by TLC, UV, IR, and mass spectral comparison with natural (+)-columbianetin.

EXPERIMENTAL

Melting points were determined in a Thomas-Hoover melting point apparatus and are uncorrected. IR spectra were determined with a Perkin-Elmer 237B grating infrared spectrophotometer and, unless otherwise specified, were determined in potassium bromide pellets. NMR spectra were determined with Varian Associates A-60 and A-60D instruments using tetramethylsilane (TMS) as the internal standard. Unless otherwise specified, all spectra were obtained in $CDCl_3$ in approximately 15% concentration and s. refers to singlet, d. to doublet, t. to triplet, and m. to multiplet. Mass spectra were determined with a Hitachi Perkin-Elmer RMU-6D mass spectrometer (courtesy of Mr. A. R. Swanson and Mr. D. L. Hobbs, School of Chemistry, University of Minnesota). The instrument was operated with a source temperature of 250° and an ionizing voltage of 50 ev. The samples were introduced by the direct inlet technique. UV spectra were determined on a Cary-14 recording spectrophotometer in 95% ethanol. Silica gel for column chromatography (Baker Analyst No. 3405) was activated at 110° and impregnated with 5% of water. Alumina for column chromatography (Woelm neutral alumina purchased from Brinkmann Instruments, Inc., Great Neck, N. J.), silica gel and alumina for TLC (Chroma-

¹ Attempts to reduce XIII catalytically under varying conditions prior to treatment with the Grignard reagent were uniformly unsuccessful and accompanied only by debenzoylation and/or reduction of the aromatic ring.

² Fragmentation supported by the appearance of corresponding metastable ions has been indicated by heavily-lined arrows here and in Scheme IV. Numbers in parentheses correspond to abundance ratios.

gram sheets with fluorescent indicator supplied by Distillation Products Industries, Rochester, N. Y.), and preparative silica gel-coated thin-layer plates (Brinkmann Instruments, Inc.) were also used. Microanalyses were performed by the Microanalytical Laboratory, School of Chemistry, University of Minnesota or by the Schwarzkopf Microanalytical Laboratory, Woodside, N. Y.

Methyl 2,6-Dihydroxybenzoate (VIII)—*Method A*—Using the method of Doyle *et al.* (16) which employs methanolic hydrogen chloride provided a 32% yield of white crystals, m.p. 68–70°. Lit (16) reported m.p. 69–71°.

Method B—The method of Tomino *et al.* (17) employing the silver salt of 2,6-dihydroxybenzoic acid³ with methyl iodide provided a 75% yield of white crystals, m.p. 68–70° which on repeated crystallization gave m.p. 69–70°.

Methyl 2,6-Dibenzoyloxybenzoate (IX)—Methyl 2,6-dihydroxybenzoate (VIII) (16.8 g., 0.1 mole), benzyl bromide (34.2 g., 0.2 mole) and anhydrous potassium carbonate (36.0 g., 0.26 mole) were refluxed together in 100 ml. of dry acetone for 4 hr. with magnetic stirring (16). At the end of the reflux period the solvent was removed under vacuum and the residual mass was extracted with ether several times. The extract was washed with aqueous sodium hydroxide solution (10%), followed by water, and was finally dried over anhydrous sodium sulfate. Removal of the solvent under vacuum gave an oily mass which solidified upon standing. The product was crystallized from ethanol to yield 31.2 g. (90% of theory) of white crystals, m.p. 71–73°. Repeated crystallization from aliphatic naphtha⁴ gave an analytical sample, m.p. 73–74°.

Anal.—Calcd. for $C_{22}H_{20}O_4$: C, 75.84; H, 5.79. Found: C, 76.12; H, 6.08.

The above ester was hydrolyzed by the method of Doyle *et al.* (16) and 2,6-dibenzoyloxybenzoic acid was crystallized twice from ethyl acetate-naphtha, m.p. 123–124°. Lit. (16) gives m.p. 124–126°.

2,6-Dibenzoyloxybenzyl Alcohol (X)—Methyl 2,6-dibenzoyloxybenzoate (IX) (17.4 g., 0.05 mole) was dissolved in 150 ml. of anhydrous ether and the solution was added dropwise to a magnetically stirred slurry of 3.8 g. (0.1 mole) of lithium aluminum hydride in 100 ml. of dry ether kept in an ice bath. The reaction mixture was stirred for 30 min. after the addition was complete and the excess of lithium aluminum hydride was then decomposed by the cautious addition of the required amount of water. After stirring for 15 min. following the decomposition, the reaction mixture was filtered through a sintered-glass funnel and the residual mass was thoroughly washed with ether. The filtrate and washings were combined, dried over anhydrous sodium sulfate, and the

solvent removed under vacuum. The product was crystallized from cyclohexane, to provide 14.4 g. (90% of theory) of white needles, m.p. 78–79°. Several recrystallizations gave an analytical sample, m.p. 79–80°.

Anal.—Calcd. for $C_{21}H_{20}O_4$: C, 78.72; H, 6.29. Found: C, 79.01; H, 6.31.

2,6-Dibenzoyloxybenzaldehyde (XI)—Active manganese dioxide⁵ (16 g.) was added to 200 ml. of toluene and stirred magnetically for a few minutes before addition of 8 g. (0.024 mole) of 2,6-dibenzoyloxybenzyl alcohol (X). The mixture was then refluxed for 4 hr. with continued stirring. The reaction mixture was filtered through a diatomaceous earth⁶ bed while hot and the residue was washed well with hot and cold benzene. The combined filtrate and washings were stripped of solvent under reduced pressure and the resulting oil which had an odor reminiscent of benzaldehyde solidified on standing. The product was crystallized from cyclohexane to yield 5.7 g. (72% of theory) of white needles, m.p. 80–81.5°. Repeated crystallization provided an analytical sample, m.p. 81.5–82.5°. The compound gave a positive test with 2,4-dinitrophenylhydrazine reagent.

Anal.—Calcd. for $C_{21}H_{20}O_5$: C, 79.22; H, 5.70. Found: C, 79.51; H, 5.66.

2-Hydroxy-6-benzoyloxybenzaldehyde (VI)—Palladium-on carbon (5%, 2 g.)⁷ was shaken in an atmosphere of hydrogen for 30 min. in 50 ml. of ethanol. 2,6-Dibenzoyloxybenzaldehyde (XI) (3.18 g., 0.01 mole) was dissolved in 100 ml. of ethanol with the aid of heat. After cooling, this was added to the prerduced catalyst and hydrogenated at atmospheric pressure until the uptake of hydrogen amounted to 270 ml. (1.1 mole equivalent). The catalyst was removed by filtration and washed well with hot and cold ethanol. The

Scheme IV

filtrate, on alumina TLC examination, showed very little of the starting material (a blue spot under UV light having the greatest mobility when developed with $\text{C}_6\text{H}_6:\text{CHCl}_3$, 1:1) while the monobenzyl compound appeared as a yellowish-green fluorescent spot. A third spot, having the least polarity and showing a dark spot under UV light, was assumed to be 2,6-dihydroxybenzaldehyde. The filtrate and washings were combined and concentrated under reduced pressure to 70 ml. On standing and cooling, the product crystallized out as yellow needles weighing 1.35 g., m.p. $72-73^\circ$. The mother liquor was evaporated to dryness and chromatographed through a silica gel column 25 g., 1.92×25.40 cm. (0.75×10 in.). The product was eluted with cyclohexane:benzene (3:1) and on evaporation of the eluant solvent under reduced pressure followed by crystallization provided 0.16 g. more of the product for a total yield of 1.51 g. (66% of theory). Repeated crystallization from naphtha gave an analytical sample as lemon-yellow needles, m.p. $73-74^\circ$.

Anal.—Calcd. for $\text{C}_{13}\text{H}_{12}\text{O}_3$: C, 73.67; H, 5.30. Found: C, 73.46; H, 5.16.

The compound gave a violet coloration with ferric chloride solution but did not show a hydroxyl peak in the IR. It showed, however, a split $\text{C}=\text{O}$ band at 1625 and 1650 cm^{-1} (probably due to hydrogen bonding).

Methyl 3-Benzoyloxy-2-formylphenoxyacetate (XII)—2-Hydroxy-6-benzoyloxybenzaldehyde (VI) (2 g., 0.009 mole), anhydrous potassium carbonate (10 g., 0.073 mole) and methyl bromoacetate (10 g., 0.073 mole) were refluxed together in 60 ml. of dry acetone for 72 hr. The precipitated potassium bromide and the unreacted potassium carbonate were filtered off and washed well with solvent. The filtrate and washings were combined and most of the unreacted methyl bromoacetate was removed under vacuum with the final traces being removed by passing a stream of air over the residue for a few hours. The product was crystallized from ethanol to give 2.38 g. (90% of theory), m.p. $99-101^\circ$. Several recrystallizations gave an analytical sample as white needles, m.p. $100-101^\circ$.

Anal.—Calcd. for $\text{C}_{17}\text{H}_{16}\text{O}_5$: C, 67.99; H, 5.37. Found: C, 67.91; H, 5.59.

Methyl 4-Benzoyloxybenzofuran-2-carboxylate (XIII)—Magnesium methoxide was prepared from magnesium metal powder (20 g., 0.825 mole, 70–80 mesh) and 600 ml. of dry methanol. Methyl 3-benzoyloxy-2-formylphenoxyacetate (XII) (4 g., 0.013 mole) was added and the mixture refluxed for 12 hr. (19). After removal of most of the methanol, crushed ice and water were added and the excess of methoxide was decomposed by portionwise addition of 130 ml. of concentrated hydrochloric acid while cooling the mixture continually in an ice bath combined with simultaneous addition of crushed ice to the reaction flask. After decomposition of all of the methoxide, the aqueous layer was extracted several times with ether and the extract dried over anhydrous sodium sulfate. Removal of the solvent under reduced pressure and crystallization from

ethanol gave 2.27 g. of the product, m.p. $128-129^\circ$. The mother liquor was chromatographed through a silica gel column (25 g., 1.92×25.40 cm.) (0.75×10 in.). The product was eluted with benzene and the column monitored with a hand UV lamp, the desired compound showing a blue fluorescence. Evaporation of the eluant and crystallization provided an additional 0.1 g. of the product for a total yield of 2.37 g. (63% of theory). Repeated crystallizations provided an analytical sample as shiny white plates, m.p. $129-130^\circ$.

Anal.—Calcd. for $\text{C}_{17}\text{H}_{14}\text{O}_4$: C, 72.33; H, 5.00. Found: C, 71.99; H, 5.22.

2-(α -Hydroxyisopropyl)-4-benzoyloxybenzofuran (XIV)—Grignard reagent was prepared from 0.4 g. (0.017 mole) of magnesium metal powder (70–80 mesh) and 1.4 ml. (0.022 mole) of methyl iodide in 20 ml. of dry ether under nitrogen. Methyl 4-benzoyloxybenzofuran-2-carboxylate (XIII) (0.4 g., 0.0014 mole) in 8 ml. of dry tetrahydrofuran was added dropwise with magnetic stirring at 0° . The reaction mixture was then stirred at room temperature for 15 min. and allowed to stand for 18 hr. The Grignard complex was then decomposed with saturated aqueous solution of ammonium chloride (10 ml.) and the ethereal layer separated. The aqueous layer was extracted with ether (4×20 ml.) and the combined ethereal solutions were dried over anhydrous sodium sulfate. Silica gel TLC examination ($\text{CHCl}_3:\text{EtOAc}$, 1:1 as developing solvent) showed a blue spot under UV light with slightly less mobility than the starting material which was present only in traces. Removal of the ether under reduced pressure provided a yellow oil which could not be induced to crystallize. The IR spectrum (neat) showed the complete disappearance of the $\text{C}=\text{O}$ band and the appearance of a hydroxyl absorption at 3370 cm^{-1} . In the NMR spectrum the gem-dimethyl protons appeared at 1.62 (s., 6H), the *t*-hydroxyl proton at 2.30 (broad s., 1H), the benzylic protons at 5.15 (s., 2H), and the aromatic protons including the protons of the benzofuran ring appeared between 6.50 and 7.50 δ (m., 9H). The peak at 2.30 δ disappeared completely upon addition of D_2O . This oily compound (XIV) was subjected to hydrogenation without further characterization.

2-(α -Hydroxyisopropyl)-4-hydroxybenzofuran (XV)—The oily compound (XIV) prepared as above was stirred with 0.2 g. of alkali treated 5% palladium-on-carbon (20) in 20 ml. of ethanol in an atmosphere of hydrogen at atmospheric pressure for 24 hr. As the reaction proceeded a spot having less polarity than the starting material appeared on silica gel TLC examination ($\text{CHCl}_3:\text{EtOAc}$, 1:1 as the developing solvent using UV light for spot detections). At the end of 24 hr. the TLC examination showed very little of the starting material. The catalyst was removed by filtration and washed well with hot and cold ethanol. The filtrate and washings were combined and the solvent removed under reduced pressure. The product was crystallized from ethyl acetate-cyclohexane to yield 0.18 g. (66% of theory in two steps), m.p. $158-161^\circ$. The product

was further purified by passing it through a silica gel column 10 g., 1.60×20.32 cm. (0.63×8 in.) using chloroform as the eluant. An analytical sample was prepared by repeated crystallization, m.p. $163-164^\circ$. Compound XV gave a violet coloration with alcoholic ferric chloride solution.

Anal.—Calcd. for $C_{11}H_{12}O_3$: C, 68.73; H, 6.29. Found: C, 68.58; H, 6.51.

2-(α -Hydroxyisopropyl)-4-hydroxy-2,3-dihydrobenzofuran (XVI)
—The oily compound (XIV) prepared as above was hydrogenated in a Parr apparatus at 10 p.s.i. pressure in the presence of 0.4 g. of palladium-on-carbon (5%) in 20 ml. of ethanol for 24 hr. At the end of this period the catalyst was removed by filtration and washed well with hot and cold ethanol. The filtrate and washings were combined and the solvent removed under reduced pressure. Silica gel TLC examination ($CHCl_3$:EtOAc, 1:1 as developing solvent) showed two spots when treated with iodine vapors. The spot with the higher R_f value was presumably the corresponding desoxy compound which was eluted out along with other impurities using benzene on a silica gel 10 g., 1.60×20.32 cm. (0.63×8 in.) column. Elution with a large volume of chloroform, evaporation under reduced pressure and crystallization from ethyl acetate-cyclohexane gave 0.18 g. (65% of theory in two steps) of the product, m.p. $150-152^\circ$. An analytical sample was obtained by several recrystallizations, m.p. $153-154^\circ$.

Anal.—Calcd. for $C_{11}H_{14}O_3$: C, 68.02; H, 7.27. Found: C, 68.12; H, 7.26.

The same product was obtained from the corresponding benzofuran compound (XV) when 0.1 g. was hydrogenated for 24 hr. in a Parr apparatus at 10 p.s.i. pressure in the presence of the same catalyst (0.1 g.) in 10 ml. of ethanol. The isolation was effected in the same manner to yield 0.055 g. of the product.

(\pm)-Columbianetin [(\pm)-I]—2-(α -Hydroxyisopropyl)-4-hydroxy-2,3-dihydrobenzofuran (XVI) (0.2 g., 0.001 mole), zinc chloride (0.2 g., 0.0015 mole, fused before use) and ethyl propiolate (1.0 g., 0.0058 mole) were heated at 90° for 1 hr. under nitrogen (22). After cooling, the yellow mass was treated with dilute hydrochloric acid (4 ml.) and the acid layer extracted exhaustively with chloroform. The chloroformic extract was dried over anhydrous sodium sulfate and the solvent removed under reduced pressure. Silica gel TLC examination ($CHCl_3$:EtOAc, 1:1 as developing agent) showed a fluorescent spot under UV light with the same R_f value as authentic (+)-columbianetin⁸ along with several other spots. The oily residue was chromatographed through neutral alumina 20 g., 1.92×25.40 cm. (0.75×3.5 in.) and eluted with chloroform. The fractions were examined by TLC and those containing (\pm)-I were mixed together and the solvent removed under reduced pressure. The product, weighing 0.028 g., m.p. $167-168.5^\circ$ was obtained after three crystallizations from chloroform-*n*-hexane. All the mother liquors were combined, concentrated, and streaked on a preparative silica gel plate and developed with the same solvent system. The zone corresponding to (\pm)-I was scraped off and eluted with methanol. The solvent was then removed and the product was passed through a short neutral alumina 5 g., 1.27×5.08 cm. (0.5×2 in.) column using chloroform as the eluant. Removal of the solvent and two crystallizations from chloroform-*n*-hexane provided 0.013 g. of white crystals, m.p. $165.5-168.5^\circ$, providing a total yield of 0.041 g. (16% of theory). Several crystallizations gave an analytical sample, m.p. $170-171^\circ$.

Anal.—Calcd. for $C_{14}H_{14}O_4$: C, 68.28; H, 5.73. Found: C, 68.24; H, 5.84.

The product had an identical R_f value to that of (+)-columbianetin on a silica TLC sheet using the $CHCl_3$:EtOAc, 1:1 solvent system. It also had an identical UV spectrum with the natural product.

The IR spectra in KBr pellets of the two samples showed minor differences which were removed when solution spectra (2.5% in $CHCl_3$) were compared. In the mass spectrum the molecular ion appeared at m/e 244. When the mass spectra of the natural I and the synthetic (\pm)-I were run under identical conditions it was found that the base peaks appeared at m/e 59 and all of the major peaks above m/e 75 were in excellent agreement insofar as abundance ratios were concerned.

Drug Absorption III: Effect of Membrane Storage on the Kinetics of Drug Absorption

J. T. DOLUISIO, W. G. CROUTHAMEL, G. H. TAN, J. V. SWINTOSKY, and L. W. DITTERT

Abstract □ Monoexponential and biexponential disappearance of drug was observed both from the simulated gut phase of a three-phase *in vitro* model for drug absorption and from the lumen of an *in situ* rat gut. Monoexponential disappearance occurred when accumulation of drug in the membrane phase was low or absent, whereas biexponential disappearance occurred when membrane accumulation was appreciable. In all cases, overall transfer of drug to blood was essentially irreversible. Kinetic analysis of biexponential lumen phase data, in terms of a two-compartment open model, was accomplished by applying the technique of "feathering." An analog computer was programmed with the calculated rate constants and the computer generated curves were compared with experimental absorption data from the three phases of the *in vitro* model. Good agreement between the computer curves and the experimental data confirmed the validity of the computational technique and the accuracy of the individual rate constants. An analog computer was also used to simulate the fraction of the dose of drug in the membrane for the *in situ* experiments since the membrane was not available for analysis.

Keyphrases □ Drug absorption—membrane storage effect □ Membrane storage effect—drug absorption kinetics □ Intestinal drug transfer—*in vitro*, *in situ* preparations □ Model, three-phase—drug absorption kinetics □ Analog computer generated curves, experimental data curves—comparison

This paper reports on two kinetic cases of drug transfer commonly observed in an *in vitro* three-phase model for drug absorption (1), and in an *in situ* rat intestinal preparation (2). The objectives of this investigation were (a) to correlate kinetic models observed in the *in vitro* system with the kinetics of drug disappearance from the lumen in the *in situ* system; (b) to evaluate the role of drug accumulation in a "membrane compartment" on the observed kinetics; and (c) to compare various computational methods for estimating the rate constants involved.

Many investigators have attempted to correlate o/w partitioning of drugs in various solvent systems with their gastrointestinal absorption rates. Although rank ordering of a homologous series of drugs in terms of their pH-partition behavior and apparent gastrointestinal absorption rates may be possible, a direct correlation between these two factors is often difficult to demonstrate (3). Possible reasons for the lack of correlation are: (a) there is no solvent system that mimics all the physicochemical properties of the absorbing membrane; (b) o/w partition coefficients are equilibrium parameters whereas gastrointestinal drug absorption is a dynamic process; and (c) no experimental procedure was available which would allow determination of reproducible realistic drug absorption rates in a living system under closely controlled conditions.

Previous reports from these laboratories (1) have dealt with the use of an *in vitro* model for the drug absorption process which employs an artificial lipid-like barrier (organic solvent) separating two aqueous buffered phases representing gut lumen fluid and blood.

This technique allows a study of the o/w partition behavior of drugs in a dynamic system which mimics the *in vivo* absorption process and in which all phases can be analyzed so that each rate constant can be evaluated individually. In this model several kinetic mechanisms involving reversible and irreversible transfer among the phases were observed (4). A frequently observed mechanism was one involving reversible transfer of drug from "gut lumen" (Phase A) to "absorbing membrane" (Phase B) followed by irreversible transfer from "absorbing membrane" to "blood" (Phase C); that is, $A \rightleftharpoons B \rightarrow C$. This mechanism fits the expectations of the pH-partition hypothesis because it suggests partitioning of drugs into the membrane. The *in vivo* gut to blood transfer of many drugs may be described by the $A \rightleftharpoons B \rightarrow C$ mechanism because factors such as the volume, pH, and protein-binding capacity of the blood as well as the large tissue distribution and rapid metabolism and excretion of these drugs often tend to make the rate constant for the $C \rightarrow B$ process very small. Consequently, the transport from gut to blood may take on some characteristics of a unidirectional process.

The development of a method for determining drug absorption rates from segments of the gastrointestinal tracts of rats, *in situ*, which yields rates which are closely reproducible from animal to animal and are comparable to those calculated from blood concentration data following oral drug administration to humans and intact animals has also been reported (2). By following the concentration of drug in the lumen of the intestine at closely spaced intervals and analyzing the data using methods for estimating appropriate rate constants in multicompartmental systems when only one phase is available for analysis (5, 6), it is possible to quantitate the kinetic model which describes the absorption of drugs showing biexponential disappearance from the gut lumen.

EXPERIMENTAL

In Vitro Three-Phase Model—Apparatus and Reagents—All chemicals were reagent grade unless otherwise specified. A Leeds & Northrup 7401 pH meter, a Beckman model DB spectrophotometer, a Hitachi-Perkin-Elmer spectrophotometer, and an Electronic Associates, Inc. TR-48 analog computer were utilized.

The glass tubes, rocking apparatus, and aqueous buffers used in these studies were described in previous communications (1, 4).

Procedure—The procedure for studying drug transfer kinetics in the *in vitro* three-phase model has been described in previous communications (1, 4).

In Situ Rat Gut—Apparatus and Reagents—All chemicals were reagent grade unless otherwise specified. Chlorpromazine hydrochloride,¹ prochlorperazine edisylate,¹ trimeprazine tartrate,¹ trifluoperazine hydrochloride,¹ and haloperidol were used.² All solutions were prepared with distilled, deionized, boiled water. A Beckman

¹ Smith Kline & French Laboratories, Philadelphia, Pa.

² McNeil Laboratories, Fort Washington, Pa.

Figure 1—Semilogarithmic plot of fraction of dose of salicylic acid remaining in rat intestinal lumen, in situ, versus time. Dose = 22 mg., half-life = 8 min., lumen solution pH = 6.0.

Zeromatic II pH meter, a Haake type FBE constant-temperature water bath, and a Cary model 15 spectrophotometer were utilized.

The perfusion and drug solutions used in these studies were described in a previous communication (2).

Test Animals—Male Sprague Dawley albino rats weighing 220–260 g. were fasted 15–20 hr. prior to use.

Procedure—The procedure for studying drug disappearance from the *in situ* rat gut lumen and the analytical methods employed for these drugs have been described in previous communications (2, 7).

RESULTS AND DISCUSSION

Figure 1 illustrates the disappearance of salicylic acid (SA) from the *in situ* rat gut lumen when the pH of the lumen solution is 6.0 (2). The figure shows that the disappearance follows first-order kinetics (monoexponential) for the entire experiment (three half-lives). In another experiment, only trace amounts of salicylic acid could be demonstrated in the lumen solution when 75 mg. of drug was administered intravenously and drug-free buffer was placed in the gut lumen. These results suggest that the kinetics of oral salicylic acid absorption under these conditions may be described in terms of the following model:

that is, overall drug absorption follows apparent irreversible first-order kinetics.

The disappearance of prochlorperazine (PCZ) from the *in situ* rat gut lumen (pH 6.0) is shown in Fig. 2. In this case, the disappearance follows a biexponential profile in contrast to the monoexponential profile observed with salicylic acid. These results sug-

Figure 2—Semilogarithmic plot of fraction of dose of prochlorperazine hydrochloride in rat intestinal lumen, in situ, versus time. Dose = 10 mg., half-life (of straight line) = 23 min., lumen solution pH = 6.0.

Figure 3—Plot of fraction of salicylic acid in Phases A and C of a three-phase *in vitro* model for drug absorption. pH: Phase A, 2.0; Phase C, 7.4. Phase B consisted of cyclohexane.

gest that the kinetics of prochlorperazine absorption may be described in terms of the following model:

that is, rapid distribution of prochlorperazine occurs between the gut lumen and a compartment representing the membrane followed by slower, essentially irreversible, transfer of the drug from the membrane compartment into the blood. As with salicylic acid, when prochlorperazine was administered intravenously, only a negligible amount of drug could be detected in the gut lumen, confirming that at least one step in the transfer process is essentially irreversible. It can be assumed that the initial transfer is reversible since the disappearance of drug from the gut lumen was not simple first-order (monoexponential).

Current concepts of passive drug absorption suggest that drugs pass through the absorbing membrane after first dissolving or partitioning into it. In the *in vitro* model, drug partitioning into the "Membrane" phase is the only way drug can transfer from Phase A (gut lumen) to Phase C (blood); and the membrane could be considered a discrete compartment in any absorption model. Based on this premise, Eq. 2 is the explicit equation describing the absorption of many passively absorbed drugs. However, if accumulation of drug in the membrane compartment is negligible, Eq. 1 may adequately fit the data. Since both salicylic acid and prochlorperazine are essentially irreversibly transferred from lumen to blood, it would appear that these drugs differ greatly in the degree to which they accumulate in the membrane. This phenomenon can be easily illustrated by means of data obtained in the three-phase *in vitro* model for drug absorption which have previously been described (1, 4). Figure 3 shows plots of the fractions of salicylic acid in Phases A and C of the model system when the simulated gut Phase A is buffered at pH 2.0 and the simulated membrane Phase B is cyclohexane. Figure 4 shows a semilogarithmic plot of the Phase A data, and the plot suggests that the disappearance of salicylic

Figure 4—Semilogarithmic plot of Phase A data from Fig. 3 showing first-order nature of drug transfer.

Figure 5—Semilogarithmic plot of fraction of salicylic acid in Phase A of a three-phase in vitro model for drug absorption. The pH of Phase A = 2.0. The pH of Phase C = 7.4. Phase B consisted of 0.1% n-octanol in cyclohexane. Values of the intercepts and slopes were determined graphically: $X_1 = 0.27$; $X_2 = 0.73$; $a = 1.08$; and $b = 0.12$. The following values for the rate constants in the model (Eq. 5) were calculated using Eqs. 6–8: $k_{12} = 0.37$; $k_{21} = 0.48$; and $k_{23} = 0.35 \text{ hr.}^{-1}$.

acid from Phase A may be described in terms of an irreversible first-order transfer of drug between Phases A and C:

$$F_A \xrightarrow{b} F_C \quad (\text{Eq. 3})$$

where F_A and F_C are the fractions of total drug in the respective phases, and b is the apparent first-order rate constant describing the overall transfer process. A semilogarithmic plot of $(F_C^\infty - F_C)$ versus time has the same slope as the plot in Fig. 4. Consequently, Eq. 3 can be used to describe this system even though the equation ignores the existence of Phase B. This simplification is justifiable because F_B is extremely low, therefore essentially constant, throughout the experiment. (The concentrations of salicylic acid in cyclo-

Table I—Kinetic Data for the Disappearance of Drug from Rat Intestinal Lumen, *In Situ* (Lumen pH = 6.0)

	X_1^a	X_2^a	a^a	b^a	k_{12}^b	k_{21}^b	k_{23}^b
Prochlorperazine	0.47	0.53	0.20	0.030	0.11	0.065	0.055
Chlorpromazine	0.40	0.60	0.70	0.036	0.30	0.35	0.084
Trifluoperazine	0.41	0.59	0.28	0.026	0.13	0.12	0.056
Trimeperazine	0.18	0.82	0.36	0.031	0.091	0.18	0.12
Haloperidol	0.16	0.84	0.35	0.030	0.082	0.17	0.13

^a Intercepts (X_1 and X_2 as fraction of dose) and Slopes (a and b in hr.^{-1}) were determined as illustrated in Fig. 5 from semilogarithmic plots of fraction of dose in the lumen versus time. ^b Rate constants (in hr.^{-1}) were calculated by means of Eqs. 6–8.

Figure 6—Plots of the fractions of salicylic acid in Phases A (●), B (×), and C (○) for the experiment shown in Fig. 5. The points were obtained experimentally, and the lines were drawn by an analog computer programmed with Eq. 5 and the following values of the rate constants: $k_{12} = 0.37$; $k_{21} = 0.50$; and $k_{23} = 0.40 \text{ hr.}^{-1}$.

hexane were so low that they could not be measured experimentally.) Thus, F_B may be considered to be at steady state; and, under these circumstances, b is a complex function of the rate constants controlling transfer of drug to and from Phase B (4). Because F_B cannot be measured experimentally, and because the overall transfer is monoexponential, the individual rate constants

Figure 7—Plots of the fractions of prochlorperazine hydrochloride in the lumen, the membrane compartment, and the blood compartment of the *in situ* rat intestinal preparation versus time. The points were obtained experimentally from the lumen solution (pH = 6.0). Initially, these data were plotted on semilogarithmic paper and values of the intercepts and slopes for the biexponential equation were determined as shown in Fig. 2. Values for the rate constants (Eq. 4) were then calculated using Eqs. 6–8; and these values ($k_{12} = 0.11$, $k_{21} = 0.065$, $k_{23} = 0.055 \text{ hr.}^{-1}$) were used to program an analog computer which generated the membrane compartment and blood compartment curves.

Figure 8—Plots for chlorpromazine similar to those shown in Fig. 7; ($k_{12} = 0.30$, $k_{21} = 0.35$, $k_{23} = 0.084 \text{ hr.}^{-1}$).

cannot be determined easily. It might be concluded that when simple first-order disappearance of drug from the lumen is observed in the *in situ* preparation it can be presumed that membrane accumulation of drug is not great. Inherent in this conclusion is the assumption that transfer of drug from gut lumen to membrane is reversible. If drug transfer from gut to membrane were irreversible, disappearance from the gut lumen would always be monoexponential.

Figure 5 shows a semilogarithmic plot of fraction of salicylic acid in Phase A of the three-phase model when Phase A is buffered at pH 2.0 and Phase B is 0.1% *n*-octanol in cyclohexane. In this case, disappearance of salicylic acid from Phase A follows a bi-exponential profile, suggesting that there is appreciable accumulation of salicylic acid in Phase B. The presence of significant amounts of drug in Phase B was confirmed experimentally (see Fig. 6). The kinetic model may be depicted as follows:

Mathematically, F_A is given by the following biexponential equation:

$$F_A = X_1 e^{-a t} + X_2 e^{-b t} \quad (\text{Eq. 5})$$

Figure 9—Plots for trifluoperazine similar to those shown in Fig. 7; ($k_{12} = 0.13$, $k_{21} = 0.12$, $k_{23} = 0.056 \text{ hr.}^{-1}$).

Table II—Data Illustrating the Accuracy of the Feathering Technique for Determining Rate Constants from Curves Generated by an Analog Computer

Value	k_{12}	k_{21}	k_{23}
Analog ^a	0.25	1.00	0.20
Feathering ^b	0.25	0.98	0.19
Analog	0.25	1.00	0.080
Feathering	0.23	0.87	0.065
Analog	0.25	0.35	0.050
Feathering	0.25	0.35	0.048

^a Values used to program an analog computer which generated curves.
^b Values obtained by feathering the computer generated curves.

The values of X_1 , X_2 , a , and b can be determined graphically from the semilogarithmic plot as shown in Fig. 5; and k_{12} , k_{21} , and k_{23} can be calculated from these values using the following equations (5, 6):

$$k_{12} = \frac{X_1 a + X_2 b}{X_1 + X_2} \quad (\text{Eq. 6})$$

$$k_{23} = \frac{ab}{k_{12}} \quad (\text{Eq. 7})$$

$$k_{21} = a + b - k_{12} - k_{23} \quad (\text{Eq. 8})$$

The results of these calculations are summarized in the legend of Fig. 5.

A distinct advantage of the three-phase model over the *in situ* gut preparation is that all phases are easily accessible for analysis. In cases such as the one under discussion, it is possible to confirm values estimated for the individual rate constants by using them to predict data for Phases B and C and then comparing the predicted data with experimental data for these phases. Such a comparison is shown in Fig. 6 for the salicylic acid data. In this figure, the lines were drawn by an analog computer programmed with Eq. 4, and the points are actual experimental data for the three phases. The values of the computer constants used to generate the lines are shown in the legend of Fig. 6. These values are slightly different from those calculated using Eqs. 6–8 (see Fig. 5) but the agreement is close and the discrepancies can be attributed to experimental error and to error in feathering the semilogarithmic plot (see Fig. 5).

Figure 10—Plots for trimeperazine similar to those shown in Fig. 7; ($k_{12} = 0.091$, $k_{21} = 0.18$, $k_{23} = 0.12 \text{ hr.}^{-1}$).

Figure 11—Plots for haloperidol similar to those shown in Fig. 7; ($k_{12} = 0.082$, $k_{21} = 0.17$, $k_{23} = 0.13 \text{ hr.}^{-1}$).

When the absorption of highly lipid soluble drugs such as the phenothiazine or butyrophenone tranquilizers was studied in the *in situ* rat gut preparation, biexponential loss of drug from the lumen solution was always observed. Such experiments were carried out with prochlorperazine, chlorpromazine, trifluoperazine, trimeperazine, and haloperidol. In each case the data were plotted on semilogarithmic paper, and values for X_1 , X_2 , a , and b (Eq. 5) were determined by feathering as illustrated in Fig. 5. These values along with values for the three rate constants k_{12} , k_{21} , and k_{23} (calculated by means of Eqs. 6–8) are shown in Table I. The three rate constants were used as input to an analog computer programmed with Eq. 4, and curves for each of the three compartments were generated by the computer. The results for the four phenothiazines and haloperidol are shown in Figs. 7–11. The lines are computer generated curves and the points are experimental data from the gut lumen. These figures show that, as might be expected, there is good agreement between the theoretical curve and the experimental data for the gut lumen compartment. Also with these highly lipid soluble drugs, the three-compartment model predicts that the amount of drug in the membrane compartment reaches a maximum of between 20 and 40% of the dose. Thus, there is appreciable membrane storage of these drugs during gastrointestinal absorption.

One might question whether analog computer simulations such as those described truly reflect drug behavior in the inaccessible phases of the model. The accuracy of these simulations depends in turn upon the accuracy of the rate constants calculated by means of Eqs. 6–8. The results of an experiment based on ideal data generated by an analog computer suggest that the accuracy of the rate constants depends directly upon the accuracy of the data obtained in the gut lumen. An analog computer programmed with the three-compartment model and with known values of k_{12} , k_{21} , and k_{23} (see Table II) was used to generate an ideal plot of the fraction of the dose in the “gut lumen” compartment *versus* time. Points were picked off the curve and plotted on semilogarithmic paper. The curve was

feathered to obtain X_1 , X_2 , a , and b and values for k_{12} , k_{21} , and k_{23} were calculated using Eqs. 6–8. The results in Table II show excellent agreement between the calculated and known values of the rate constants suggesting that rate constants calculated from experimental data in this manner and analog simulations based on these rate constants are as accurate, but no more accurate, than the experimental data itself. The *in situ* rat gut preparation yields such precise and reproducible data that the analog simulations in Figs. 7–11 might be expected to truly represent distribution of these drugs among the gut lumen, absorbing membrane, and blood compartments of the experimental animals.

SUMMARY

The disappearance of salicylic acid and certain other drugs (2) from the *in situ* rat gut lumen was found to be monoexponential, whereas certain highly lipid soluble drugs exhibited biexponential disappearance in the same preparation. In each case, the overall transfer of drug from gut lumen to blood was essentially irreversible. Experiments with an *in vitro* three-phase model for drug absorption showed that monoexponential disappearance from the lumen can be expected when accumulation of the drugs in the membrane is negligible. Conversely, biexponential disappearance from the lumen can be expected when accumulation of the drugs in the membrane is appreciable.

By feathering the lumen data which exhibited biexponential drug loss and applying standard mathematical techniques, specific rate constants were determined for drug transfer into and out of the membrane. The validity of these derived rate constants was confirmed by means of an analog computer for data obtained with the three-phase *in vitro* model in which the amounts of drug in all three phases were determined experimentally. The validity of the computational method was confirmed using ideal data generated by an analog computer programmed with known rate constants.

Resolution of the absorption process into its individual components should allow closer and more meaningful study of the factors influencing it. For example, fasting of animals has been reported to slow drug disappearance from the gut lumen (7); and studies are presently being conducted to determine which rate constants are affected by this fasting. Experiments are also being carried out to determine the effect of pH on the individual rate constants, and simultaneous sampling of serum and lumen contents are also being conducted to further elucidate the overall gut to blood transfer process.

Effect of Molecular Interaction on Permeation of Organic Molecules Through Dimethyl Polysiloxane Membrane

MASAHIRO NAKANO* and NAGIN K. PATEL†

Abstract □ In order to investigate the nature of permeation of organic molecules through a nonpolar membrane in the presence of other molecular species, some model studies have been made with *p*-nitrophenol as an ionizable diffusate and *N,N*-dialkylamides and alkylxanthines as complexing agents. Effect of diethylpropionamide on permeation of salicylic acid was also examined. 8-Methoxycaffeine and caffeine were used as model compounds for nonionizable molecules and permeability constants were determined with and without complexing agents. The permeability of a diffusate increased in the presence of complexing agents which interact strongly with the diffusate in nonpolar environments, while it decreased in the case of the agents which complex with the diffusate mainly in aqueous solution.

Keyphrases □ Molecules, organic—dimethyl polysiloxane membrane permeation □ Membrane permeation, organic molecules—molecular interaction effect □ Ionizable diffusates—complexing agents—membrane permeation □ Colorimetric analysis—spectrophotometer □ UV spectrophotometry—analysis □ GLC—analysis

Extensive studies by Garrett and Chemburkar on diffusion of drug molecules through a silicone rubber membrane (1–3) have contributed much to knowledge on drug diffusion through a polymeric membrane. Because of the nonpolar nature of silicone rubber materials (4), a dimethyl polysiloxane membrane would be useful for investigation of effects of molecular interaction on drug permeation through a membrane. The first objective of the present investigation was to examine the nature of permeation of molecules through a nonpolar membrane in the presence of some other molecular species. This would provide additional information concerning the effect of complex formation on drug absorption which has been studied by Levy and his associates (5, 6).

The second objective was to explore some possibilities of controlling rate of permeation of organic molecules through a membrane by physicochemical means. In view of possible application of silicone rubber materials to some dosage forms (7, 8), it would be worthwhile to examine how the rate of permeation of molecules through a membrane can be modified.

EXPERIMENTAL

Materials—Dimethyl polysiloxane¹ sheeting in a labeled thickness of 5 mil was used throughout this study. *p*-Nitrophenol², salicylic acid³, 8-methoxycaffeine⁴ (recrystallized from methanol-carbon tetrachloride), and caffeine⁵ (recrystallized from water) were used

as model diffusates. Other compounds employed as complexing agents are also commercially available chemicals and were purified whenever necessary (9).

Diffusion Studies—The quasi steady-state diffusion cell described by Garrett and Chemburkar (1) was used with the following modifications. One polytetrafluoroethylene⁶ O-ring was used instead of two silicone rubber gaskets and the diameter of the area available for diffusion was 32 mm. The cell was initially equilibrated overnight in a shaker bath maintained at 30° with 100 ml. of distilled water in both arms. Subsequently water was removed by suction and 50 ml. of 0.005 *N* sodium hydroxide (for *p*-nitrophenol and salicylic acid) or water (for 8-methoxycaffeine and caffeine) was added to one arm and an equal volume of test solution was placed in the other arm.⁷ All the solutions were prewarmed to 30°. In order to suppress the dissociation of *p*-nitrophenol and salicylic acid, their solutions were prepared in 0.001 *N* and 0.004 *N* hydrochloric acid, respectively. The cell was mechanically shaken horizontally at a rate of 148 ± 2 strokes/min.

Analytical Methods—*p*-Nitrophenol—A 0.5-ml. aliquot of a desorbing solution was pipetted into a 10-ml. volumetric flask, then 5 ml. of 0.01 *N* sodium hydroxide was added to it, and the mixture was made up to volume with water. The absorbance of this solution was recorded on a spectrophotometer⁸ at the wavelength of maximum absorbance, 400 $m\mu$. No complexing agent was found to interfere with the assay at this wavelength.

Salicylic Acid—A 0.5-ml. aliquot from the desorbing solution was acidified with 2 ml. of 0.1 *N* hydrochloric acid to suppress the dissociation and made up to volume (10 ml.) with water. The concentration of the resultant solution was spectrophotometrically determined at 302 $m\mu$. Diethylpropionamide did not interfere with the assay.

8-Methoxycaffeine—A 1-ml. aliquot was pipetted out of both desorbing and diffusing solutions. When methyl nicotinate was used as a complexing agent, absorbance at both 262 and 281 $m\mu$ was recorded and the content of each component was calculated by the standard method of simultaneous spectrophotometric analysis (10). When tryptophan was used as a complexing agent, 8-methoxycaffeine was extracted into carbon tetrachloride. A 1-ml. portion of carbon tetrachloride solution was then appropriately diluted with methanol and the xanthine was spectrophotometrically determined at 281 $m\mu$. In the presence of phenols and *p*-hydroxybenzoic acid, the sample solutions were made alkaline with sodium hydroxide (0.005 *N* with respect to the final concentration) and 8-methoxycaffeine was then extracted into carbon tetrachloride.

Caffeine—A 1-ml. aliquot was pipetted out of both desorbing and diffusing solutions. The concentration of caffeine in the presence of salicylamide was determined in the following way. The sample solution was made alkaline with sodium hydroxide (0.005 *N* with respect to the final concentration) and the concentrations of salicylamide were determined at 328 $m\mu$. The concentration of caffeine was then calculated from absorbance at 272 $m\mu$ and correction was made for absorbance due to salicylamide at the same wavelength. The concentration of caffeine in the presence of *p*-bromophenol was determined in the following way. To a 1-ml. aliquot was added 9 ml. of 0.1 *N* sodium hydroxide and the resultant solution was shaken with 2 ml. of chloroform. One milliliter of the organic layer was pipetted out and absorbance at 272 $m\mu$ was measured after appropriate dilution with methanol.

Determination of Partition Coefficient—Five-milliliter portions of sample solutions were shaken with a 5-ml. portion of carbon

tetrachloride by means of an aliquot shaker⁹ in a low temperature incubator¹⁰ (25°) for about 2 hr. The concentrations of aromatic compounds remaining in the water layer were determined as described in the *Analytical Methods*. The concentrations in carbon tetrachloride were assumed to be equal to the difference between the initial concentration in water and the concentration in water after extraction. The concentrations of aliphatic molecules remaining in the water layer were determined by GLC. A gas chromatograph¹¹ equipped with a dual flame ionization detector and a 0–10 mv. recorder¹² was employed. The chromatographic column was a 0.31-cm. (0.125-in.) o.d. stainless steel column, 1.83 m. (6 ft.) in length and packed with 10% silicone elastomer¹³ on a diatomite¹⁴ (80–100 mesh). The column was silanized *in situ* with hexamethyldisilazane and equilibrated overnight at the operating conditions; oven temperature 140°; injection port temperature, 301°; detector temperature, 283°; hydrogen pressure 15 lb./sq. in.; air pressure, 25 lb./sq. in.; helium pressure, 40 lb./sq. in. (80 ml./min.). Either dimethylacetamide or diethylpropionamide was used as an internal standard.

RESULTS AND DISCUSSION

Ionizable Diffusates—*p*-Nitrophenol and salicylic acid, with *pK_a* values (11) of 7.1 and 3.0 were selected as model ionizable compounds. The concentration of diffusible species in the desorbing solution can be kept to a zero value by maintaining diffused molecules in a dissociated form. During the first 4 to 5-hr. period of the permeation experiment, the drug concentration of the diffusing solution is not altered significantly; and it may be assumed that the concentration of a diffusate during this period is equal to its initial concentration, *C*₀, in the diffusing solution. For such a system the following equation modified from that derived by Garrett and Chemburkar (2) for a steady-state diffusion can be employed

$$C_2 = k_p \frac{AC_0 t}{V_2} \quad (\text{Eq. 1})$$

where *C*₂ = concentration of diffusate in desorbing solution, *A* = area of the membrane, *V*₂ = volume of the desorbing solution, and *k_p* = permeability constant, which is the product of diffusivity of the drug in the membrane and its membrane/water partition coefficient divided by thickness of the membrane. Plots of *C*₂ versus *t* will give a straight line with slope = *k_p* × *AC*₀/*V*₂ from which *k_p* can be computed.

Effect of Complexing Agents on Permeation of *p*-Nitrophenol—A typical set of data for the permeation of *p*-nitrophenol in the presence and absence of complexing agents are plotted in Fig. 1 in accordance with Eq. 1. Depending on the nature of the complexing agent, two opposing effects on the rate of permeation were observed. Accordingly, the rate of permeation increased in the presence of diethylpropionamide while it decreased in the presence of caffeine. In order to explore the observed effects, the rate of permeation of *p*-nitrophenol was determined in the presence of a number of complexing agents. The data for this study were plotted in the same way as illustrated in Fig. 1. All the results gave linear relationships of *C*₂ versus *t*. The apparent permeability constants, *k_p*, were computed from the slopes of the lines and they are summarized in Table I. If one compares the effect of amides on the *k_p* values, it can be observed from the table that effect on the permeation varies among the *N,N*-dialkylamides and that it is concentration dependent, *k_p* value increasing with increase in concentration of diethylpropionamide.

In order to explain the difference in the drug permeability in the presence of the amides, apparent partition coefficients (CCl₄/H₂O) of the amides as well as of *p*-nitrophenol in the presence of the amides were determined and these results are summarized in the third and fifth columns of Table I. In view of approximately the same hydrogen bonding ability of the amides with *p*-nitrophenol in a nonpolar solvent (12), the observed difference in the apparent partition coefficients of *p*-nitrophenol can be related to the difference

in the partition coefficients of the amides themselves. This point is elaborated by the following scheme and equation:

$$R_{app.p} = \frac{P_m + PQ_m}{P} = \frac{P_m(1 + K_m Q_m)}{P} = R_p(1 + K_m Q_m) \quad (\text{Eq. 2})$$

where *P* and *Q* represent equilibrium concentrations of *p*-nitrophenol and an amide, respectively. *R_x* is a partition coefficient of species *X*, *K* is a stability constant, and the subscript *m* stands for "in the membrane." According to Eq. 2, the apparent partition

Figure 1—Permeation of *p*-nitrophenol in the presence of 10 mM caffeine (□) or 10 mM diethylpropionamide (Δ) and in the absence of complexing agent (○) at 30°. The diffusing solution was 50 ml. of 4 mM *p*-nitrophenol in 0.001 *N* hydrochloric acid with or without complexing agent and the desorbing solution was 50 ml. of 0.005 *N* sodium hydroxide solution.

coefficient of the phenol depends on the values of R_P , K_m , and Q_m . Since the partition coefficient of uncomplexed phenol, R_P , is constant, and the stability constants of hydrogen bonded complex, K_m , are about the same for the *N,N*-dialkylamides (12), the apparent partition coefficient is primarily a function of the amide concentration in the membrane. Thus amides with greater partition coefficients gave greater apparent partition coefficients of *p*-nitrophenol as seen in Table I.

In order to evaluate the role of diethylpropionamide in the transfer of the phenol across the membrane, diethylpropionamide was placed unilaterally in the diffusing solution, in the desorbing solution, and in the membrane; and bilaterally in both the diffusing and desorbing solutions. These data, as given in Table II, showed that the amide substantially increased the permeability constant of the phenol only when it was placed in the diffusing solution. From these results it is highly improbable that the amide merely changes the permeation characteristic of the membrane (diffusivity of a diffusate in the membrane). The increased permeation of *p*-nitrophenol may be attributed to the increase in concentration of *p*-nitrophenol in the membrane at its interface with diffusing solution or in other words, to the increase in apparent partition coefficient. The greater apparent partition coefficient of *p*-nitrophenol in the presence of diethylpropionamide may be rationalized by the greater partition coefficient of the amide itself and the presence of hydrogen bonding interaction in the nonpolar medium between the phenol and the amide (13). Dimethylacetamide, on the other hand, though it is as good a proton acceptor as diethylpropionamide, does not partition into a nonpolar solvent, and consequently has insignificant effect on the partition coefficient of the *p*-nitrophenol, thus supporting the importance of partitioning prior to diffusion through the membrane.

A possible alternative mechanism includes faster diffusion of the *p*-nitrophenol-amide complex through the membrane than uncomplexed *p*-nitrophenol. This is highly unlikely since the stability constant of such a complex in a bulk aqueous solution was found to be very small (12).

The results showing the influence of dioxane, *n*-amyl alcohol, dimethyl sulfoxide, and xanthines on rate of permeation of *p*-nitrophenol are also included in Table I. Although dioxane and *n*-amyl alcohol partition into the nonpolar solvent to an appreciable

^a 16 mM. ^b 32 mM. ^c CCl₄/H₂O at 25°.

extent, they failed to modify the permeability constant of *p*-nitrophenol in any substantial way. This is in accord with the small increase in partition coefficients of *p*-nitrophenol in the presence of these molecules. The weak proton acceptor property of ethers and alcohols (14) may explain the present observation; namely, K_m in Eq. 2 is so small that $R_{app,P}$ does not differ significantly from R_P . Dimethyl sulfoxide, on the other hand, is reported to be a strong proton acceptor (15). The failure of the sulfoxide to modify the permeability can be attributed to its small partition coefficient. Thus a large partition coefficient, together with the strong hydrogen acceptor property of the complexing agent appear to be the factors responsible for accelerated permeation of *p*-nitrophenol.

Alkylxanthines in general reduced the apparent permeability coefficients of *p*-nitrophenol. *p*-Nitrophenol interacts with alkylxanthines both in aqueous and nonpolar solutions (12). In the case of theophylline with a very minor partitioning into the nonpolar solvent, its complexation with *p*-nitrophenol in aqueous solution might be the sole cause of the reduction in the permeability. The retarding effect of 8-methoxycaffeine was not found to be as pronounced as expected from its great complexing tendency (16) since the xanthine partitions into a nonpolar solvent to an appreciable extent.

In spite of an increase in the apparent partition constant of *p*-nitrophenol in the presence of alkylxanthines, its permeability decreased. For example, the permeability constants of caffeine and 8-methoxycaffeine are 0.216×10^{-2} cm./hr. and 3.73×10^{-2} cm./hr., while their partition coefficients are relatively large, namely, 0.21 and 5.4 (see Tables III and IV). This discrepancy may have resulted from the fairly small diffusivity of alkylxanthines. It should be noted here that permeation is a kinetic phenomenon whereas partition coefficients are equilibrium constants.

Effect of Diethylpropionamide on Permeation of Salicylic Acid—The permeation behavior of salicylic acid in the presence and absence of diethylpropionamide is depicted in Fig. 2. The partition coefficients of salicylic acid at a 4 mM concentration in the absence and presence of the amide (40 mM) are 0.59 and 5.7, respectively. Thus, the increased permeation of salicylic acid in the presence of diethylpropionamide may be attributed to its increase in the partitioning property.

Nonionizable Diffusates—8-Methoxycaffeine and caffeine were chosen as model nonionizable molecules. For these drugs the following equation developed by Garrett and Chemburkar for quasi steady-state diffusion is applicable.

$$\log \frac{C_0}{C_1 - C_2} = \frac{0.869k_p A}{V_2} t \quad (\text{Eq. 3})$$

wherein C_1 is the concentration of diffusate in a diffusing solution and all other terms are as previously defined in Eq. 1. A plot of $\log C_0/(C_1 - C_2)$ versus t will yield a straight line and the permeability constant can be calculated from the slope of the line.

Effect of Complexing Agents on Permeation of 8-Methoxycaffeine—The permeation data for 8-methoxycaffeine in the presence and absence of tryptophan or *p*-chlorophenol are plotted in Fig. 3. The apparent permeability constants obtained from these plots and from similar plots with other complexing agents are compiled in Table III together with pertinent partitioning data. In the case of phenols, *p*-nitrophenol reduced the permeability constant of 8-methoxycaffeine, while *p*-chlorophenol increased it. Since both of these phenols interact with the xanthine in aqueous as well as in non-

Table III—Apparent Permeability Constants, k_p , and Apparent Partition Coefficients, R , of 8-Methoxycaffeine in the Presence of Complexing Agents

Figure 2—Permeation of salicylic acid in the presence (Δ) and absence (○) of diethylpropionamide at 30°. The diffusing solution was 50 ml. of 4 mM salicylic acid in 0.004 N hydrochloric acid solution with or without 40 mM diethylpropionamide and the desorbing solution was 50 ml. of 0.005 N sodium hydroxide solution.

polar environment (12), two counteracting effects may take place for the present systems. Complexation in aqueous solution would reduce the permeability constant of 8-methoxycaffeine while interaction at the membrane interface with the diffusing solution would increase it. With *p*-nitrophenol, whose partition coefficient is small, complexation with 8-methoxycaffeine in aqueous solution is a dominant factor, while for *p*-chlorophenol, with a large partition coefficient, hydrogen bonding interaction at the interface outweighs the complexation effect in an aqueous solution, resulting in a net increase in the permeability constant.

Methyl nicotinate (Table III) was observed to lower the permeation of 8-methoxycaffeine. Although methyl nicotinate has a large partition coefficient, it has no hydrogen bonding affinity for the xanthine in a nonpolar environment (12). Therefore complexation in the aqueous solution may account for the reduction in the

Figure 3—Permeation of 8-methoxycaffeine (4 mM) in the presence of 24 mM tryptophan (◻) or 60 mM *p*-chlorophenol (Δ) and in the absence of complexing agent (○) at 30°.

Figure 4—Permeation of caffeine (16 mM) in the presence of 16 mM salicylamide (◻) or 32 mM *p*-bromophenol (Δ) and in the absence of complexing agent (○) at 30°.

permeation of the xanthine. The apparent partition coefficients of 8-methoxycaffeine are reduced due to the presence of tryptophan and *p*-hydroxybenzoic acid. These complexing agents are not partitioned into the nonpolar solvent as shown in Table III. Thus the decrease of the permeability constants of 8-methoxycaffeine by tryptophan and *p*-hydroxybenzoic acid can be inferred as being due to the complexation in the aqueous solution.

Effect of Salicylamide and *p*-Bromophenol on Permeation of Caffeine—Data for the permeation of caffeine with and without complexing agents are presented in Fig. 4. The permeation and partitioning results for caffeine and salicylamide are given in Table IV. It should be noted in Fig. 4 that the permeation rate plots yielded an intercept on the abscissa, indicating an apparent time lag. Comparing the k_p value of caffeine with those of other drugs this would be expected, since caffeine gave the lowest value. This figure also illustrates that the rate of permeation of caffeine was accelerated by *p*-bromophenol and it was decelerated by salicylamide. The results may be rationalized in the same way as for 8-methoxycaffeine. For example, with salicylamide whose partition coefficient is small ($R = 0.14$), complexation in an aqueous solution may be considered to have a dominant effect, while with *p*-bromophenol whose partition coefficient is large ($R = 3.14$), interaction at the interface would outweigh the complexation in an aqueous solution. The permeability constant of salicylamide was also found to decrease in the presence of caffeine. These observations can be substantiated by the measured values of partition coefficient of the diffusate in the presence of the complexing agents. Experimentally obtained values are summarized in Table IV.

CONCLUSIONS

This study illustrates that the rate of permeation of a drug can be increased or decreased in the presence of a complexing agent, and the magnitude of this effect is dependent upon the physicochemical nature of the agent. From the results it may be concluded that the agents which complex with a diffusate (a) only in aqueous solution would reduce the permeability constant; (b) both in aqueous and nonpolar environments would either decrease or increase it depending upon the partitioning behavior of the complexing agents and the relative stability constants of the complex in both environments; and (c) only in nonpolar environment would increase it.

If a drug in question is an acidic molecule, a complexing agent of an aliphatic proton acceptor type, with a fairly large partition coefficient and favorable toxicological characteristics, would be a candidate for an agent which may be used to enhance the permeation of the drug across biological membranes.

Factors Affecting the Synthesis of Penicillinase by *Staphylococcus Aureus*

R. F. BOYD and JOSEPH JUDIS

Abstract □ The effects of aeration, ferric ions, porphyrins, and disodium versenate were studied on the production of penicillinase (ps) by *Staphylococcus aureus* 55-C-1 in synthetic medium. The production of ps was twice as high in shaken compared to static cultures although growth ultimately was the same. Ferric ions in a concentration of $2.5 \times 10^{-4} M$ had some stimulatory effect on ps production in static cultures but caused much greater ps stimulation in shaken cultures. This stimulatory effect could be demonstrated only if ferric ions were added prior to 3 hr. of incubation. Hemin in a concentration of $2.5 \times 10^{-5} M$ depressed ps production in the presence of ferric ions but one-tenth the concentration of hemin did not. Hematin in the same concentration was without effect. Protoporphyrin in a concentration of $2.5 \times 10^{-5} M$ inhibited growth in the absence of ferric ions and depressed ps production in the presence of ferric ions. One-tenth the concentration of protoporphyrin had no effect on growth but depressed ps production and only slightly depressed ps production in the presence of ferric ions. A concentration of $2.5 \times 10^{-6} M$ hematoporphyrin inhibited ps production in the presence of ferric ions when the former was added early in the growth curve. Disodium versenate in a concentration of $1.32 \times 10^{-5} M$ in the presence of ferric ions permitted good growth but no ps production.

Keyphrases □ Penicillinase production—*Staphylococcus aureus* □ Aeration, shaking effect—penicillinase production □ Porphyrins, ferric ions, disodium versenate, effect—penicillinase production □ Optical density—*S. aureus* growth determination □ Manometric determination—penicillinase

Abraham and Chain (1) were the first to show that certain bacteria produce an enzyme capable of hydrolyzing penicillin. Since the latter paper was published

in 1940, a number of workers have demonstrated that the resistance of strains of *Staphylococcus aureus* to penicillin was related to the production of penicillinase, the enzyme which was shown to hydrolyze penicillin. Although in some studies penicillin resistance was demonstrable in the absence of penicillinase production (2, 3), there seems to be good correlation between the ability of staphylococci to produce penicillinase and to be resistant to the action of penicillin both *in vitro* and *in vivo* (4-6). Penicillinase production has been similarly implicated in penicillin resistance of *Bacteroides* sp. (7).

In some microorganisms, penicillinase has been found to be an inducible enzyme and many studies (8-12) have concentrated on the nature of the induction of penicillinase elaboration. Some strains of *S. aureus* produced penicillinase constitutively (13, 14) and a number of workers have been concerned with the conditions and factors affecting constitutive production of penicillinase. It was felt that if the factors which control or affect penicillinase production in a strain of *S. aureus* producing penicillinase constitutively could be identified, it was possible that this knowledge could be applied ultimately in the treatment of an infection caused by a penicillinase-producing strain of *S. aureus*. That is, a strain which otherwise would be resistant to penicillin could be made susceptible to the action of penicillin if penicillinase production could be inhibited by the concurrent administration of a nontoxic

Factors Affecting the Synthesis of Penicillinase by *Staphylococcus Aureus*

R. F. BOYD and JOSEPH JUDIS

Abstract □ The effects of aeration, ferric ions, porphyrins, and disodium versenate were studied on the production of penicillinase (ps) by *Staphylococcus aureus* 55-C-1 in synthetic medium. The production of ps was twice as high in shaken compared to static cultures although growth ultimately was the same. Ferric ions in a concentration of $2.5 \times 10^{-4} M$ had some stimulatory effect on ps production in static cultures but caused much greater ps stimulation in shaken cultures. This stimulatory effect could be demonstrated only if ferric ions were added prior to 3 hr. of incubation. Hemin in a concentration of $2.5 \times 10^{-5} M$ depressed ps production in the presence of ferric ions but one-tenth the concentration of hemin did not. Hematin in the same concentration was without effect. Protoporphyrin in a concentration of $2.5 \times 10^{-5} M$ inhibited growth in the absence of ferric ions and depressed ps production in the presence of ferric ions. One-tenth the concentration of protoporphyrin had no effect on growth but depressed ps production and only slightly depressed ps production in the presence of ferric ions. A concentration of $2.5 \times 10^{-6} M$ hematoporphyrin inhibited ps production in the presence of ferric ions when the former was added early in the growth curve. Disodium versenate in a concentration of $1.32 \times 10^{-5} M$ in the presence of ferric ions permitted good growth but no ps production.

Keyphrases □ Penicillinase production—*Staphylococcus aureus* □ Aeration, shaking effect—penicillinase production □ Porphyrins, ferric ions, disodium versenate, effect—penicillinase production □ Optical density—*S. aureus* growth determination □ Manometric determination—penicillinase

Abraham and Chain (1) were the first to show that certain bacteria produce an enzyme capable of hydrolyzing penicillin. Since the latter paper was published

in 1940, a number of workers have demonstrated that the resistance of strains of *Staphylococcus aureus* to penicillin was related to the production of penicillinase, the enzyme which was shown to hydrolyze penicillin. Although in some studies penicillin resistance was demonstrable in the absence of penicillinase production (2, 3), there seems to be good correlation between the ability of staphylococci to produce penicillinase and to be resistant to the action of penicillin both *in vitro* and *in vivo* (4-6). Penicillinase production has been similarly implicated in penicillin resistance of *Bacteroides* sp. (7).

In some microorganisms, penicillinase has been found to be an inducible enzyme and many studies (8-12) have concentrated on the nature of the induction of penicillinase elaboration. Some strains of *S. aureus* produced penicillinase constitutively (13, 14) and a number of workers have been concerned with the conditions and factors affecting constitutive production of penicillinase. It was felt that if the factors which control or affect penicillinase production in a strain of *S. aureus* producing penicillinase constitutively could be identified, it was possible that this knowledge could be applied ultimately in the treatment of an infection caused by a penicillinase-producing strain of *S. aureus*. That is, a strain which otherwise would be resistant to penicillin could be made susceptible to the action of penicillin if penicillinase production could be inhibited by the concurrent administration of a nontoxic

substance inhibiting the production of penicillinase by these microorganisms. A study was, therefore, undertaken to examine the effects of several conditions and substances on the production of penicillinase by a strain of *S. aureus* producing this enzyme constitutively.

MATERIALS AND METHODS¹

Materials—The culture media used in all experiments was that used by Wright and Mundy (15) with certain modifications made by Leitner and Cohen (14). The medium was made up in two separate portions. Solution 1 contained the following: L-leucine, 0.8 g.; L-tryptophan, 0.025 g.; L-proline, 0.05 g.; DL-phenylalanine, 0.26 g.; DL-threonine, 0.5 g.; L-histidine monohydrochloride, 0.15 g.; L-tyrosine, 0.21 g.; DL-valine, 1.00 g.; L-arginine monohydrochloride, 0.4 g.; L-glutamic acid, 0.65 g.; DL-serine, 0.61 g.; glycine, 0.06 g.; DL-methionine, 0.05 g.; DL-alanine, 0.43 g.; DL-lysine monohydrochloride, 1.70 g.; L-aspartic acid, 0.45 g.; DL-isoleucine, 0.44 g.; L-cystine, 0.05 g. The above amino acids were dissolved in a solution consisting of 482 ml. of distilled water and 18 ml. of 4% NaOH. Solution 2 contained the following minerals and vitamins: KCl, 0.2 g.; $MgSO_4 \cdot 7H_2O$, 0.1 g.; thiamine hydrochloride, 0.01 g.; and nicotinamide, 0.01 g. These chemicals were dissolved in 500 ml. of distilled water and then mixed with Solution 1, cleared by filtration, and the pH adjusted to 7.2 using 1 N HCl.

¹ The culture used in all experiments was *Staphylococcus aureus* strain 55-C-1 obtained from Drs. Felix Leitner and Sidney Cohen, Department of Microbiology, Michael Reese Hospital and Medical Center, Chicago, Ill. (14).

The medium was autoclaved for 15 min. at 15 pounds of pressure. The culture was maintained on nutrient agar and transferred monthly.

The experimental cultures were grown in side-arm, 300-ml. flasks (Bellco No. 10-514, 14 × 130 mm.) containing a total volume of 40 ml. of medium including all other additions. The flasks were inoculated with 0.3 ml. of a 24-hr. statically grown culture which had reached an optical density of 0.30 (measured in 16 × 150-mm. screw-cap test tubes at 625 mμ in a Bausch & Lomb Spectronic 20 spectrophotometer). Also added was 0.2 ml. of 50% dextrose. Any pH adjustments were made with 1 N HCl. During typical growth experiments, samples were removed at various time intervals and frozen until assayed for penicillinase activity. The period of storage at -10° never exceeded 24 hr. and in preliminary experiments, it was found that the penicillinase activity of samples stored for various periods of time up to 24 hr. under these frozen conditions did not vary by more than 10% from the values of the samples prior to freezing. Thawing of the samples up to three times within a 24-hr. period of storage in the frozen state yielded similar results, that is, penicillinase activities varying by no more than 10% from that of the fresh sample prior to freezing. Optical density measurements of cell suspensions were made at 625 mμ in a Bausch & Lomb Spectronic 20 spectrophotometer in all cases and optical density measurements were related to viable cell counts as had been determined by Steinman (16) and confirmed by the present authors. An optical density of 0.102 in a 14 × 130-mm. side-arm flask was equivalent to 1.7×10^8 cells/ml.

Methods—Penicillinase was measured manometrically at 37° and pH 7.46 by the method of Henry and Housewright (17) because this has been the most commonly used method by other investigators especially with whole cells. The main compartment of the Warburg flasks contained 2.0 ml. of chloramphenicol succinate

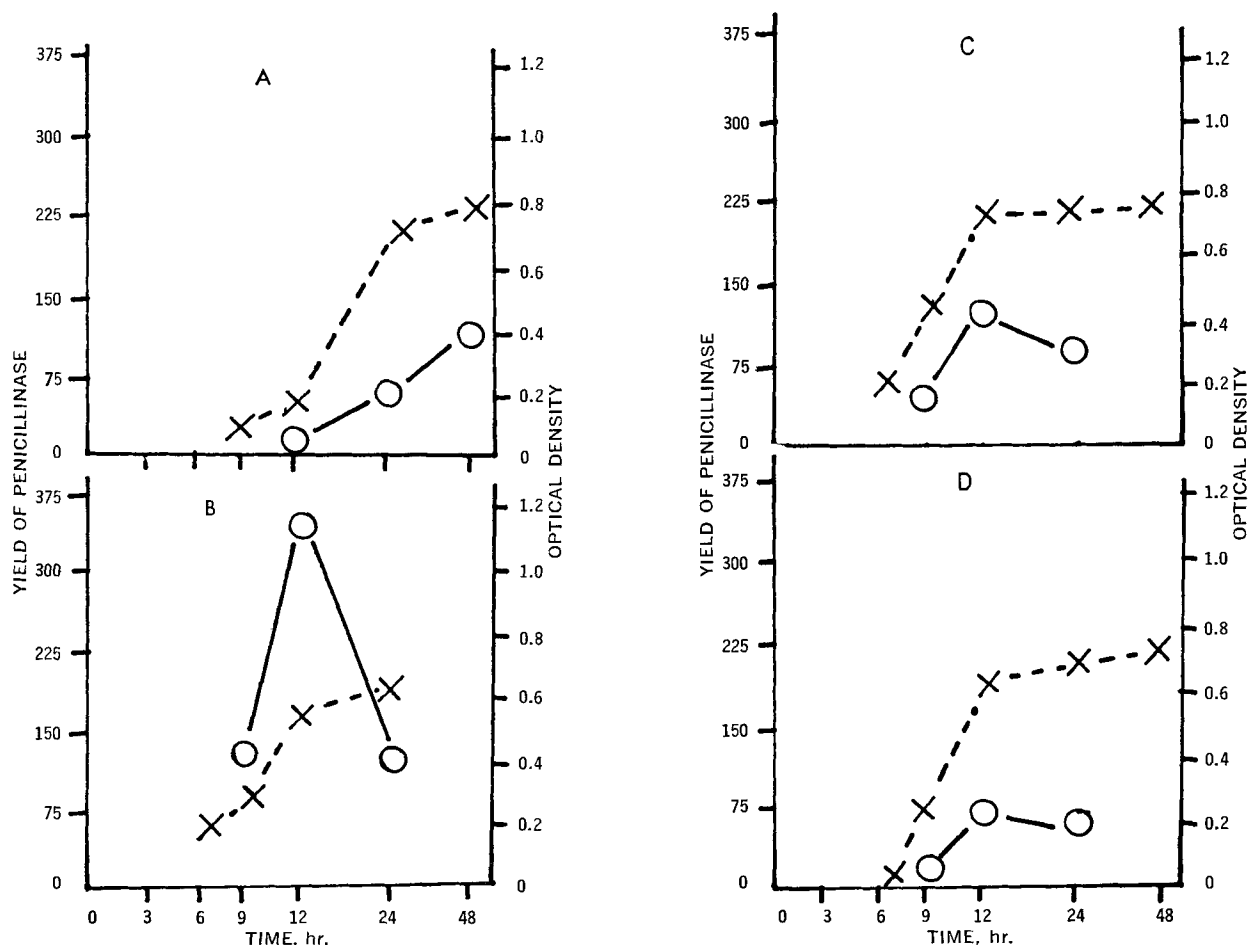

Figure 2—The effect of ferric ions on the production of penicillinase in cultures of *S. aureus* shaken at an amplitude of 0.8 cm. (a) no added ferric ions. (b) 2.5×10^{-4} M final concentration of ferric ions. (c) 2.5×10^{-5} M final concentration of ferric ions. (d) 2.5×10^{-6} M final concentration of ferric ions. Key: O, penicillinase; X, growth.

solution (200 mcg./2 ml. of 0.017 M NaHCO_3) and 0.5 ml. of distilled water. One side-arm contained 0.5 ml. of bacterial suspension. Bacterial cultures were centrifuged and the cells resuspended in the same volume of distilled water. The other side-arm of the two side-arm Warburg flasks contains 0.2 ml. sodium penicillin G (12 mg./0.2 ml. of 0.017 M NaHCO_3). The flasks were flushed with 5% carbon dioxide and 95% nitrogen for 15 min. Following equilibration, the contents of the side-arms were tipped into the main compartments and measurements taken every 5 min. Occasional assays of the supernatant were made, and it was found that 95% of the

enzyme was associated with the bacterial cells. Activity was expressed as microliters of carbon dioxide per hour per 1.7×10^8 cells/ml.

Culture flasks were shaken on a Burrel Wrist Action shaker to effect aeration. Ferric chloride ($6\text{H}_2\text{O}$) was dissolved in distilled water and autoclaved. The porphyrins were dissolved in distilled water, the pH adjusted to 7.6, and the solution sterilized by Seitz filtration. Adjustment of pH was necessary because the porphyrins tend to precipitate out of solution at lower pH's.

Biochemicals (Nutritional Biochemicals Corp. or the California Corporation for Biochemical Research) and chloramphenicol succinate (Parke, Davis & Co.) were used and all other chemicals were of reagent grade.

Table I—Penicillinase Production in Shaken and Static Cultures

Cultural Conditions	Time of Incubation, hr.	Optical Density	Yield of Penicillinase ^a

	72	0.745	50
	96	0.824	65

^a The units of penicillinase activity are microliters of CO_2 /hr./ 1.7×10^8 cells/ml.

RESULTS AND DISCUSSION

The effect of the degree of aeration of the cultures on penicillinase production can be seen from the data presented in Table I. Although more vigorous aeration as shown by a 1.5-cm. stroke did not give greater yield than more moderate aeration, penicillinase production in aerated cultures was clearly greater than in static cultures. This effect was observed even though the final cell density reached in static cultures was equivalent to that reached in shaken cultures.

The addition of ferric ions was studied on penicillinase production in both static and shaken cultures (Figs. 1–3). Penicillinase production in static cultures was only slightly affected by the addition of ferric ions. However, these ions were clearly stimulatory to penicillinase production in shaken cultures at either of the two stroke amplitudes used. In order to gain some clue as to the mechanism by which ferric ions may be stimulatory to penicillinase production, the time of addition of the ferric ion and the age of the cultures were studied. From Fig. 4, it can be seen that if ferric ions

Figure 3—The effect of ferric ions on the production of penicillinase in cultures of *S. aureus* shaken at an amplitude of 1.5 cm. (a) no added ferric ions. (b) 2.5×10^{-4} M final concentration of ferric ions. (c) 2.5×10^{-5} M final concentration of ferric ions. (d) 2.5×10^{-6} M final concentration of ferric ions. Key: O, penicillinase; X, growth.

are added at 0 or 3 hr. of incubation, the stimulatory effects are seen but if added after that time, there is a decreasing effect on penicillinase production.

Sack (18) and Sack and Judis (19) showed that certain porphyrin compounds affected the production of coagulase by *S. aureus* and

it was of interest to determine whether such compounds would affect penicillinase production by this organism. Hemin (Fig. 5) in a concentration of 2.5×10^{-6} M depressed penicillinase production in the presence of ferric ions, but in a concentration of 2.5×10^{-6} M this depression did not appear. Hematin, in the presence of ferric ions, had no effect on penicillinase production as stimulated by ferric ions (Fig. 6). Protoporphyrin, in a concentration of $2.5 \times$

Figure 4—Influence of time of addition of ferric ions on the stimulation of penicillinase production in shaken cultures of *S. aureus*. Ferric ions, in a final concentration of 2.5×10^{-4} M were added at the following times of incubation: (a) 0 hr.; (b) 3 hr.; (c) 6 hr.; (d) 9 hr.; (e) 12 hr.; (f) no added ferric ions. Figure 6—Effect of hematin on the production of penicillinase by *S. aureus* in shaken cultures. The concentration of ferric ions, where added, was 2.5×10^{-4} M. (a) Hematin added at a concentration of 2.5×10^{-6} M. (b) Ferric ions added only. (c) Hematin (at same concentration as in a) and ferric ions added. (d) Neither hematin nor ferric ions added. Key: ○, hematin added; △, ferric ions added only; ●, hematin and ferric ions added; □, neither hematin nor ferric ions added; X, growth.

10^{-6} M inhibited the production of penicillinase but had no effect on growth (Fig. 7). In the presence of ferric ions, there was observed a slight decrease in penicillinase production when added at 0, 3, or 6 hr. of incubation but had no effect after 6 hr. of incubation. At a concentration of 2.5×10^{-5} M, protoporphyrin inhibited both growth and penicillinase production but not in the presence of ferric ions (Fig. 8).

Hematoporphyrin, at a concentration of 2.5×10^{-5} M, inhibited both growth and penicillinase production in the absence of ferric ions and was capable of inhibiting growth in the presence of ferric ions to a considerable extent. When the concentration of hematoporphyrin was reduced to 2.5×10^{-6} M, growth was not affected although penicillinase production was reduced (Fig. 9). The addition of ferric ions overcame the inhibition of growth and penicillinase production if the hematoporphyrin was added as

Figure 8—Effect of protoporphyrin on the production of penicillinase by *S. aureus* in shaken cultures. The concentration of ferric ions, where added, was 2.5×10^{-4} M. (a) Protoporphyrin added at a concentration of 2.5×10^{-5} M. (b) Protoporphyrin (same concentration as in a) and ferric ions added. (c) Ferric ions only added. late as after 9 hr. of incubation but penicillinase production was inhibited if the porphyrin was added at 0, 3, or 6 hr. of incubation. The data obtained in the studies on the effects of disodium versenate are represented in Fig. 10. A concentration of disodium versenate of 1.32×10^{-5} M permitted good growth but no penicillinase production. Reduction in concentration of the disodium versenate to 6.7×10^{-6} M also permitted good growth and only moderate production of penicillinase and a further reduction of the concentration of disodium versenate to 3.35×10^{-6} M permitted both good growth and good penicillinase production. In all of these studies, ferric ions were present and whether the disodium versenate was added at 0 hr. of incubation or 12 hr., the results obtained were the same.

It is interesting to speculate on the mechanism by which ferric ions stimulate the production of penicillinase. In experiments in

which the time of addition of ferric ions to the culture was varied, it was seen that maximal stimulation of penicillinase production by ferric ions occurred if the latter were added early in the growth period. It is during this time that RNA synthesis and protein synthesis are most active and possibly some inhibitor either in the medium or produced by the microorganism is present and it is the latter which ferric ions are inactivating. Also, perhaps ferric ions may be inhibiting the synthesis of a repressor substance as suggested by Cohen *et al.* (20). For example, Rogers (21) who studied the relationship between growth of *S. aureus* and hyaluronidase production found that early in the growth curve, cellular growth was more rapid than enzyme production and at a certain time, the reverse was true. The initial lag in the formation of the enzyme was found to be primarily due to accumulation of α -amino butyric acid, which was subsequently (22) found to inhibit the formation of the enzyme. In the authors' studies with penicillinase, it was found that in the presence of ferric ions, penicillinase is produced rapidly and subsequently drops. This might lead one to believe that the penicillinase formed in the presence of ferric ions is an unstable one but further studies comparing the stability of the staphylococcal penicillinase and commercially purchased penicillinase indicated no difference in stability. It is possible that the role of ferric ions is to inhibit the production of something analogous to the α -amino butyric acid found by Rogers to affect the production of hyaluronidase.

Perhaps the inhibitory effects shown by porphyrins can be related to their ability to coordinate with inorganic ions (23). Disodium versenate is known to form a strong metal complex with ferric ions and perhaps inhibit the production of penicillinase by making the stimulatory effect of ferric ions impossible. It should be of interest to explore the effect of disodium versenate on the course of staphylococcal infections in experimental animals, especially the ability of penicillin to eradicate infections caused by penicillin resistant staphylococci. If, indeed, disodium versenate is able to inhibit the production of penicillinase by a penicillin resistant staphylococcus, the latter should become amenable to penicillin therapy.

Assay of Hyoscyamine, Atropine, Scopolamine, and Phenobarbital in Unit Doses of Tablets and Elixirs

RUPERT O. ZIMMERER, Jr. and LEE T. GRADY

Abstract □ A gas chromatographic assay for unit dose quantities of scopolamine and atropine-hyoscyamine was developed for tablets and elixirs containing phenobarbital. The method allows the complete assay of unit dose forms. Standards assayed with precisions of 4.8% for scopolamine, 6 mcg./unit dose, 2.5% for atropine-hyoscyamine at 100 mcg./dose, and 1.0% for phenobarbital (spectrophotometric) at 16 mg./dose. Homatropine served as extracted internal standard. Derivatives of the alkaloids were unnecessary using properly cured columns.

Keyphrases □ Hyoscyamine, atropine, scopolamine, phenobarbital tablets, elixirs—analysis □ Internal standard, “extracted”—homatropine □ GLC—analysis □ UV spectrophotometry—analysis

Quantitative methods for small amounts of belladonna alkaloids are few. No method has been reported which is suitable for the complete assay of hyoscyamine sulfate, atropine sulfate, scopolamine hydrobromide, and phenobarbital tablets and elixir.¹ This paper reports the development of a procedure which allows the complete assay of these formulations on unit dose forms.

Das Gupta and Ferguson (1) noted recently the need for determination of small amounts of atropine in elixirs and tablets and applied a dye-complex method. A separation of phenobarbital by partition column and subsequent colorimetric determination of total belladonna alkaloids was reported by Koch *et al.* (2). This sequence was adapted to kaolin-pectin suspensions by Bracey and Selzer (3). None of these methods determined scopolamine.

Sterescü and Popovici (4) determined atropine and scopolamine individually by paper chromatography in the presence of papaverine and sparteine. Schill and Agren separated scopolamine from hyoscyamine by partition chromatography on kieselguhr columns (5). Countercurrent distribution (6) also separates these alkaloids. Paper chromatographic separation of scopolamine from atropine-hyoscyamine was effective, and Reichelt (7) was able to separate as much as 50-fold ratios. Thin-layer chromatographic separation of scopolamine from the other belladonna alkaloids has been particularly successful, for example Wartman-Hafner's system (8).

Some workers have explored the gas chromatography of belladonna alkaloids. Kazyak and Knoblock (9)

used silicone gums on silanized supports to separate atropine and scopolamine, but reported no satisfactory system. Brochmann-Hanssen and Fontan (10) reported separation of these from morphine and homatropine, most useably with a cyanosilicone liquid phase. The identification of alkaloids, including atropine, in blood was studied by Jain and Kirk (11) who recommended a polyester for general use. Most recently, Solomon *et al.* (12) used methylsilicone gum on silanized diatomite in assaying atropine and scopolamine in plant extracts; however, their system decomposed the alkaloids.

MATERIALS AND METHODS

Chromatographic grade methylene chloride (Matheson, Coleman & Bell). Borate buffer, 0.05 *M*, was prepared from boric acid and sodium hydroxide. Dibasic potassium phosphate and sodium hydroxide were used to prepare 0.2 *M* phosphate pH 10.5 buffer. Both buffers were standardized against the glass electrode. Homatropine hydrobromide, atropine sulfate, and scopolamine hydrobromide (Merck & Co., Inc.) and hyoscyamine sulfate and the tablet and elixir (A. H. Robins & Co., Inc., Richmond, Va.) were also used.

Internal Standard Solution—Dissolve 20 mg. homatropine hydrobromide in 250 ml. 0.005 *N* sulfuric acid and mix well.

Alkaloids Standard Solution—Dissolve 16.2 mg. scopolamine hydrobromide in 100 ml. 0.005 *N* sulfuric acid. Dissolve 30.8 mg. atropine sulfate in 200 ml. 0.005 *N* sulfuric acid, add 10.0 ml. of the scopolamine solution, and make to 250 ml. with acid. Dilute 20.0 ml. of this solution to 100 ml. with the acid. All solutions were prepared fresh daily.

Gas Chromatography²—Analyses were performed using an 0.6-m. × 3-mm. i.d. glass column packed with 3% methylphenyl-silicone gum on 80/100 mesh silanized, acid-washed, flux-calcined diatomite.³ Column temperature was 210°, with the injection port at 235°. Helium flow was about 60 ml./min. Samples, 1–2 µl., were injected on-column. Flame ionization detectors were used.

Column Preparation—Maintain the column at 250° for 1 hr. with helium flowing to remove oxygen and solvents, stop the flow of helium and heat at about 340° 4 hr., lower temperature to 250°, and condition with helium flowing until stable. A suitable initial test for support inertness, necessary with these low polarity liquid phases, is the delivery of a single, symmetric peak for injected cholesterol with no evidence of decomposition.

PROCEDURE

Standards—Weigh 16.2 mg. phenobarbital USP reference standard into a separator and add 5.0 ml. of the alkaloids standard Solution. Add 1.00 ml. of the internal standard solution and

^a 103.7 mcg. Hyoscyamine sulfate and 19.4 mcg. atropine sulfate, 6.5 mcg. scopolamine hydrobromide, 16.2 and mg. phenobarbital in each tablet or 5 ml. of elixir.

extract with two 25-ml. portions of methylene chloride, filtering through anhydrous sodium sulfate into a 100-ml. volumetric flask. Wash the sodium sulfate with 25 ml. methylene chloride, dilute to volume, and mix well. Pipet 10 ml. of the solution into a 150-ml. beaker and evaporate to dryness on a steam bath. Add 1 ml. alcohol and, using pH 9.5, 0.05 *M* borate buffer, quantitatively transfer the residue to a 100-ml. volumetric flask. Dilute to volume with buffer and determine the absorbance at 240 m μ using 1-cm. silica cells.

To the aqueous phase in the separator remaining after extraction of phenobarbital add 4.0 ml. of pH 10.5, 0.2 *M* phosphate buffer and extract twice with 10 ml. of methylene chloride, filtering through anhydrous sodium sulfate. Wash the sodium sulfate with 5 ml. of the methylene chloride. Evaporate⁴ the combined extracts to about 0.1 ml. at reduced pressure and inject an appropriate volume into the chromatograph. Record the chromatogram, decreasing the amplifier attenuation by a factor of about 16 about halfway between the hyoscyamine-atropine peak and the scopolamine peak to increase the measured peak height of scopolamine. Obtain the peak heights, *H*, of scopolamine, hyoscyamine-atropine, and homatropine and determine *R*s for each drug, where *R*s is = *H* alkaloid/*H* homatropine. *R*_u values are determined similarly for the assay preparations. The amount of each alkaloid in each dosage form may be calculated⁵ from the formula $W_u = W_s (R_u/R_s)$, where *W*_u = weight of unknown, *W*_s = exact weight of standard.

When using a column for the first time prepare additional standards by adding 4.0 and 6.0 ml. of alkaloid solution and carrying out the assay. A plot of *R*_u versus amount yields a straight line. Assay values should be read directly from this calibration curve if the line does not pass through zero.

The amount of phenobarbital in each dosage form may be calculated from the formula $W_u = W_s (A_u/A_s)$, where *W*_u = weight of unknown, *W*_s = exact weight of standard, *A*_u = absorbance of unknown, and *A*_s = absorbance of standard.

Tablet Composite—Weigh and finely powder not less than 20 tablets. Transfer the equivalent of one tablet to a 60-ml. separator, add 1.0 ml. of the internal standard solution, 5 ml. water, mix, and adjust the pH to a value not greater than 3 with 1 *N* H₂SO₄ (about 0.5 ml. for those used in this report). Proceed as directed in the standard assay beginning with "Extract with two 25-ml. portions..."

If necessary, the aqueous phase in the separator, after adding 4 ml. pH 10.5 buffer, should have the pH adjusted to greater than 9 using 1 *N* NaOH (about 0.5 ml. for those used in this report).

Tablet Content Uniformity—Finely powder one tablet and transfer to a 60-ml. separator and proceed as in tablet assay above. Discard the phenobarbital extracts. Determine hyoscyamine-atropine only after evaporation of the extract to about 1 ml.

Elixir—Pipet 5.0 ml. of the elixir into a 60-ml. separator and add 1.0 ml. of the internal standard solution. Proceed as in the tablet assay, beginning with "Add 1.00 ml. internal standard solution..."

RESULTS AND DISCUSSION

The small amounts and similar structures of the alkaloids in these formulations recommended gas chromatographic analysis. More-

over, a method was desired that would allow the entire assay to be performed on individual dose units.

Ten complete standards were taken through the procedure. The coefficients of variation in the hyoscyamine-atropine and scopolamine assay ratios were 2.5 and 4.8%, respectively. Phenobarbital precision was 1.0%. Applicability of the procedures to commercial formulations was checked (See Table I). The elixir was assayed in triplicate. Tablet composites of three lots were assayed. Placebos were not available.

In summary, this procedure allows assay of individual dose units of hyoscyamine sulfate, atropine sulfate, scopolamine hydrobromide, and phenobarbital tablets and elixir. The method is specific, rapid, and highly sensitive. Precisions are typical for gas chromatography, and using duplicates where possible, particularly for scopolamine, is recommended for accuracy.

This procedure also applies to other, simpler official tablets and solutions of belladonna alkaloids after appropriate change in the amount of internal standard and, usually, elimination of the acid extraction step. This has been done with hyoscyamine sulfate tablets NF and morphine sulfate and atropine sulfate tablets NF.

Applicability to content uniformity determination is inherent in single dose procedures, so only an estimate was prepared in a single lot. Content uniformity is based on hyoscyamine-atropine rather than scopolamine (the least abundant active ingredient) because of the better precision for that peak and to eliminate some of the time for concentration. This decision assumes that the ratio of scopolamine to the other alkaloids is fixed prior to manufacture of the dosage forms.

Comments on Procedure—Homatropine was chosen as the "extracted" internal standard prior to selection and acceptance of the column. It differs from these alkaloids only in a methylene group and the nature of substitution of the carbinol so chromatographic characteristics are nearly identical. Because of functional group similarities, minor alkaline ester cleavage, or amine degradation are controlled. Mechanical losses of various layers and volumetric considerations along the way are rendered insignificant as the partition behaviors are the same. Finally, purified material is readily available.

Phenobarbital must be eliminated in any event prior to the gas chromatographic work-up, so the acid extraction conveniently was adopted to determine phenobarbital. Methylene chloride was chosen because it is easily evaporated and distribution data indicated that the double extraction removes all but 0.2% of the phenobarbital. Spectrophotometric assay was chosen for speed and precision and to avoid introduction of a second column. The spectra of extracted standard and those from elixir and tablets showed no differences and all were identical to directly prepared standards. pH limits for the two extractions are specified in the procedure so that different product formulations will not interfere with alkaloid, particularly scopolamine, recovery. Phosphate buffer was added so that the final pH of the aqueous phase was 9.1 and was used instead of alkali to minimize ester cleavage. At this pH distribution data indicate that the two extractions remove 99.6% of the atropine and all scopolamine. Heat and air during the subsequent concentration should be avoided to prevent cleavage or oxidation of the small amounts of the alkaloids. The additional problem of racemization is not considered in this report.

The final volume, 0.1 ml., was chosen so that almost any flame ionization-equipped gas chromatograph would have the necessary sensitivity. The chromatograph in this laboratory was used at one-

⁴ Rotary Evapo-mix, Büchler Instruments, Fort Lee, N. J.

⁵ For the case of a linear curve "passing through zero."

Figure 1—Typical chromatogram (tablet). Key: 1, homatropine; 2, hyoscyamine-atropine; 3, attenuation change; 4, scopolamine.

tenth of its maximum usable sensitivity range for scopolamine. The reagents must be pure as high boiling impurities are concentrated 200 times. Gas chromatographic grade methylene chloride is essential.

Reagent blanks were run to locate the origin of the additional peaks appearing in the chromatogram and see if there were interferences. Ten small peaks corresponding to those seen on the extracted chromatogram appeared. There were no peaks with retentions the same as or close enough to any of the drugs to interfere with the analysis (see Fig. 1). All these additional peaks were attributable to the reagent blank, mostly from methylene chloride. Of these, six emerged prior to homatropine. The others had relative (atropine = 1.0) retentions of 0.88, 1.18, 2.05, and 2.75. However, a less efficient column could allow minor species to bias the homatropine measurement. Additional standards, in triplicate, showed the analysis to be linear in the region of interest for both hyoscyamine-atropine and scopolamine. For this particular column the two lines obtained graphically terminated along the abscissa, so the assay data reported herein were taken from the calibration curves. The formula presented in the procedure would be accurate only where calibration curves have been demonstrated to "pass through zero." The column was rechecked (cholesterol, alkaloids, standard curves) at the end of the study and found intact.

Chromatography—The difficulties associated with the GLC of polar amines are well known. Improperly or partially-cured and conditioned columns often cause extensive tailing of such compounds and nonlinear recoveries of sample sizes. An additional problem is partial on-column dehydration of atropine and scopolamine as was reported by Solomon *et al.* (12). Although the preparation of less polar derivatives often allows successful chromatography, the additional steps and problems are appreciable. Current phases, supports, and column treatments have extended the range of molecules which can be chromatographed directly, without prior formation of less polar derivatives.

The peaks were symmetric and tailing was negligible (see Table II). Examination of the chromatograms of pure compounds gave peaks

Table II—Gas Chromatographic Data

Parameter	Homa- tropine	Hyoscyamine- Atropine	Scopol- amine
Retention ^a	0.65	(1.00)	1.76
Theor. plates (15)	1000	1100	1200
Asymmetry, <i>As</i> (15)	1.10	1.02	1.08
Tailing ^b	1.06	1.06	1.04
Response ^c	0.97	(1.00)	0.99

^a Actual retentions = $\times 2.95$ min., see Fig. 1. ^b T. F. = $a + b/2a$ at 5 % of peak height. ^c Equimolar amounts, ratio of peak areas.

of equal area ($\pm 1\%$ by planimeter). A mixture was prepared containing atropine and scopolamine in the same proportion (20:1) as that found in the commercial preparation: the scopolamine peak area was 97.4% of the value calculated based on equimolar amounts, showing that nonlinear adsorption losses are minor. Repetitive injections, $n = 12$, of this mixture in assay quantities gave coefficients of variation in the assay ratios of 1.0 and 4.0% for atropine and scopolamine, respectively. As seen from these results, most of the overall assay precision is attributable to the GLC step. Accuracy for scopolamine relative to atropine thus would be improved by duplicate injection of the same sample. Peaks in the procedural blank also were separated completely, so additional length of column was superfluous. Efficiencies of the order of a thousand plates appear sufficient for this assay.

The column preparation detailed in this procedure was essential to successful chromatography. Tailing values prior to curing were 1.4–1.7 with asymmetry factors of greater than 1.2. Resolution and recoveries were increased. Similar effects have been found with columns prepared from various samples of low (*W*) and medium (*G*) density silanized supports, both self-coated and supplier-coated. Street (13) reported recently his procedures for support treatment prior to coating and noted the importance of this for GLC of amines and alkaloids. Vessman (14) found that 315° conditioning of SE 30 on a silanized support did not eliminate tailing of high boiling amines, including scopolamine, and that alkali treatment of the support decreased tailing but decomposed the silicone.

Differential Nonaqueous Titration of Isoniazid and Sodium *p*-Aminosalicylate Mixtures

M. B. DEVANI and C. J. SHISHOO

Abstract □ Isoniazid and sodium *p*-aminosalicylate are estimated potentiometrically in nonaqueous media. Their mixtures are amenable to differential nonaqueous titrimetry. The titration solvent consists of a mixture of equal volumes of acetonitrile and acetic anhydride, the titrant is acetous perchloric acid, and electrode system is the glass-calomel electrode pair. Satisfactory resolution of end points is obtained with the ratio of sodium *p*-aminosalicylate-to-isoniazid as high as 4:1. Both of these components in mixtures can be determined in a single titration by the proposed method without resorting to preliminary separation.

Keyphrases □ Isoniazid, Na *p*-aminosalicylate mixture—analysis □ Perchloric acid, acetous—titrant □ Differential nonaqueous titration—analysis

A variety of chromatographic, volumetric, colorimetric, spectrophotometric, and nonaqueous titrimetric procedures have been described for the analysis of isoniazid as well as sodium *p*-aminosalicylate (1–3).

The individual components in mixtures are generally determined after initial separation by one of these

methods (4–6). Although satisfactory results can be obtained by these methods, they suffer from several drawbacks, particularly that of time-consuming preliminary separation processes. While isoniazid and sodium *p*-aminosalicylate can be readily determined in nonaqueous media individually, their differential titration in a mixture has not been reported.

The present study has been directed to find a simple differential nonaqueous titration procedure for the analysis of isoniazid–sodium *p*-aminosalicylate combinations. The mixtures having sodium *p*-aminosalicylate-to-isoniazid ratio up to 4:1 are resolved in a solvent system of acetonitrile–acetic anhydride (1:1). When the disproportion ratio of the components is higher, only one end point corresponding to total base is realized.

PROCEDURE

Apparatus—All titrations were performed potentiometrically. A pH meter (Polymetron) employing a glass electrode and a calomel electrode with a salt bridge was used for the purpose. A saturated solution of lithium chloride in glacial acetic acid served as the salt bridge (7). Electrodes were dipped in acetic anhydride for at least 24 hr. before use.

Reagents and Solutions—Isoniazid BP was recrystallized from alcohol and dried at 105°. Sodium *p*-aminosalicylate USP was taken for analysis. Acetonitrile was purified by shaking it with two batches of silica gel (50 g./l.), two batches of alumina (20 g./l.), and phosphorus pentoxide (20 g./l.). Finally it was distilled over phosphorus pentoxide (5 g./l.) (8). Acetic anhydride reagent grade was distilled before use.

A 0.1 *N* solution of perchloric acid in glacial acetic acid was prepared and standardized potentiometrically against primary standard potassium acid phthalate dissolved in acetic acid. All other chemicals and solvents used in the study were reagent grade and were employed without further purification.

Analysis of Isoniazid—In a 100-ml. beaker about 60 mg. isoniazid, accurately weighed, was dissolved in 25 ml. of acetonitrile and stirred magnetically. An equal volume of acetic anhydride was added to it. The solution was further stirred for 5 min. and titrated potentiometrically against 0.1 *N* acetous perchloric acid. Near the

^a Standard deviation based on at least five determinations. ^b Corresponds to isoniazid plus sodium *p*-aminosalicylate.

Figure 2—Titration curves using acetonitrile-acetic anhydride (1:1) mixture as solvent system. Key: a, sodium *p*-aminosalicylate 0.25 meq.; b, isoniazid 0.4 meq.; c, isoniazid-sodium *p*-aminosalicylate mixture containing 0.2 meq. of each component.

end point, titration was continued adding 0.05 ml. of titrant at intervals of 1 min. and the solution kept stirred vigorously. A blank titration was performed.

Titration curves were traced, plotting potential reading (mv.) versus volume of titrant (ml.).

Analysis of Sodium *p*-Aminosalicylate—About 60 mg. of sodium *p*-aminosalicylate, accurately weighed, was mixed with 25 ml. of acetonitrile in a 100-ml. beaker and stirred for about 15 min. An equal volume of acetic anhydride was then added and stirring continued further for 5 min. before the solution was titrated potentiometrically with 0.1 *N* acetous perchloric acid. The end point was determined from the titration curve as described earlier.

Differential Titration of Isoniazid-Sodium *p*-Aminosalicylate Mixture—About 0.1 meq. of isoniazid and 0.1 meq. of sodium *p*-aminosalicylate, accurately weighed, were mixed with 25 ml. acetonitrile and stirred for about 15 min. An equal volume of acetic anhydride (25 ml.) was added to it and the stirring was continued for about 5 min. The solution was titrated rapidly, stirring all the time, until the first end point was obtained. The titration was carried out slowly near the second end point. The exact end points were determined from the titration curve as before.

Effect of Isoniazid Concentration on Differential Titration—Isoniazid and sodium *p*-aminosalicylate, in varying proportions corresponding to desired ratios (Table I), were accurately weighed and titrated as above.

RESULTS AND DISCUSSION

Isoniazid and sodium *p*-aminosalicylate, individually, have been titrated with perchloric acid as monoacidic and diacidic bases, using different solvents (9–12). Acetonitrile and acetic anhydride have been found suitable solvents for the titration of bases (13, 14). In the preliminary experiments, both these solvents were tried. The titration curves using acetonitrile as well as acetic anhydride as solvents (Curves *a* and *b* of Fig. 1) indicate two inflections: the first corresponds to sodium *p*-aminosalicylate content and the second indicates the isoniazid end point. It is seen that with acetonitrile, the first inflection is sharply defined while the second inflection point is indistinct (Fig. 1, Curve *a*). On the other hand, the first inflection is somewhat vague but the second inflection stands out quite distinctly in acetic anhydride medium (Fig. 1, Curve *b*).

Figure 3—Effect of sodium *p*-aminosalicylate-to-isoniazid ratio on differential titration. The ratios above the curves indicate milliequivalents of sodium *p*-aminosalicylate-isoniazid.

On the basis of these results, mixtures of the two solvents, in varying proportions, were tried as solvent systems. It was seen that while isoniazid-sodium *p*-aminosalicylate (1:1) mixture could be successfully resolved in the solvent mixtures having acetonitrile-acetic anhydride in ratios of 4:1, 2:1, 1:1, 1:2, and 1:3, the solvent mixture in 1:1 was most ideally suited.

Typical titration curves of isoniazid, sodium *p*-aminosalicylate, and isoniazid-sodium *p*-aminosalicylate mixture are shown in Fig. 2. Both the compounds, individually as well as in a mixture, are determined with fair degree of accuracy. Both isoniazid and sodium *p*-aminosalicylate are titrated as monoacidic bases in acetonitrile-acetic anhydride (1:1) mixture.

Since in the usual dosage forms, the amount of sodium *p*-aminosalicylate considerably predominates over the content of isoniazid, the effect of varying the ratio of concentrations of the components on the sensitivity of the differentiating titration was studied. Typical titration curves are shown in Fig. 3 and the recovery of components is recorded in Table I.

Two distinct inflections in the titration curves are obtained when sodium *p*-aminosalicylate-to-isoniazid ratio does not exceed 4 (Fig. 3, Curves *a* to *e*). In the titration of mixtures with ratio of disproportion exceeding 4, only one end point corresponding to the total base is obtained (Fig. 3, Curve *f*). The differential titration of mixtures having sodium *p*-aminosalicylate-to-isoniazid ratio higher than 4:1 was tried employing solvent mixture acetonitrile-acetic anhydride in proportion other than 1:1. The resolution of the end points was not satisfactory.

The proposed procedure makes possible a simple and accurate determination of isoniazid-sodium *p*-aminosalicylate combinations, without preliminary separation of the components. The technique is applicable to those mixtures in which sodium *p*-aminosalicylate-to-isoniazid ratio does not exceed 4.

Nonaqueous Titrimetric Determination of Isoniazid in Presence of Excess of Sodium *p*-Aminosalicylate in Dosage Forms

C. J. SHISHOO and M. B. DEVANI

Abstract □ Isoniazid in the presence of excess of sodium *p*-aminosalicylate is estimated by differential titration of the acetonitrile extract of the mixture against perchloric acid. Sodium *p*-aminosalicylate content is then calculated from the total basicity obtained by direct titration of the mixture with the same titrant. The procedure is applied to determine the isoniazid and sodium *p*-aminosalicylate content of tablets, granules, and cachets. The results obtained are comparable to those obtained by the official method.

Keyphrases □ Isoniazid, Na *p*-aminosalicylate mixture—analysis □ Differential titration, nonaqueous—analysis □ Perchloric acid—titrant

Commercial dosage forms of isoniazid-sodium *p*-aminosalicylate combinations usually contain the components in molar proportions of 1:33. The conventional methods for the analysis of these dosage forms give erroneous and inconsistent results (1, 2).

Differential titration of isoniazid-sodium *p*-aminosalicylate mixture has been described earlier (3). The method is restricted only to the analysis of the mixtures having sodium *p*-aminosalicylate-to-isoniazid ratio up to 4:1.

In the present study, mixtures having large disproportion of the components were extracted with acetonitrile to remove the bulk of sodium *p*-aminosalicylate. The molar proportion of sodium *p*-aminosalicylate-to-isoniazid in the acetonitrile extract was favorable for the differential nonaqueous titration of these compounds. The nonaqueous titrimetric procedure described earlier (3) was applied to estimate isoniazid in the presence of sodium *p*-aminosalicylate in the acetonitrile extract and found to give satisfactory recovery of isoniazid. Sodium *p*-aminosalicylate content of the mixture was determined from total basicity obtained by direct titration of the mixture.

The procedure was applied to the analysis of tablets, granules, and cachets and the results were found comparable to those obtained by the official method (4).

Table I—Recovery of Isoniazid in the Presence of Excess Sodium *p*-Aminosalicylate

^a Isoniazid content was determined from the titration of acetonitrile extract of the mixture. ^b Amount of sodium *p*-aminosalicylate was estimated from the total basicity of the mixture determined by direct titration, as described, after subtraction of the volume of titrant corresponding to isoniazid content of the mixture. ^c Standard deviation based on at least five determinations.

EXPERIMENTAL

Apparatus and Reagents—The reagents and apparatus were employed as described previously (3). The electrodes were dipped in acetic anhydride for 24 hr. before use.

Analysis of Mixtures Containing Isoniazid and Excess of Sodium *p*-Aminosalicylate—*Isoniazid*—Milliequivalent quantities of finely powdered isoniazid and sodium *p*-aminosalicylate as given in Table I were accurately weighed and transferred to a 100-ml. beaker. After adding 25 ml. of acetonitrile, the mixture was stirred vigorously for 20 min. and filtered. The residue in the beaker was treated with 10 ml. acetonitrile and stirred for 5 min. and filtered. It was further washed twice with 5 ml. of acetonitrile. An equal volume of acetic anhydride was added to the combined filtrates and washings. The mixture was stirred for 5 min. It was then titrated against 0.1 *N* acetic perchloric acid. Near the second end point, 0.05 ml. of titrant was added at an interval of 1 min. A blank titration was performed. Titration curves were obtained by plotting potential reading (mv.) versus volume (ml.) of the titrant.

Total Basicity—An aliquot of the mixture equivalent to 0.25 meq. of sodium *p*-aminosalicylate was accurately weighed and transferred to a 100-ml. beaker. Acetonitrile (25 ml.) was added to it and stirred. After addition of an equal volume of acetic anhydride, it was titrated as described previously.

Analysis of Dosage Forms—The procedure was applied to analyze the powder mass obtained from tablets, granules and cachets.

EXPERIMENTAL

Apparatus and Reagents—The reagents and apparatus were employed as described previously (3). The electrodes were dipped in acetic anhydride for 24 hr. before use.

Analysis of Mixtures Containing Isoniazid and Excess of Sodium *p*-Aminosalicylate—*Isoniazid*—Milliequivalent quantities of finely powdered isoniazid and sodium *p*-aminosalicylate as given in Table I were accurately weighed and transferred to a 100-ml. beaker. After adding 25 ml. of acetonitrile, the mixture was stirred vigorously for 20 min. and filtered. The residue in the beaker was treated with 10 ml. acetonitrile and stirred for 5 min. and filtered. It was further washed twice with 5 ml. of acetonitrile. An equal volume of acetic anhydride was added to the combined filtrates and washings. The mixture was stirred for 5 min. It was then titrated against 0.1 *N* acetic perchloric acid. Near the second end point, 0.05 ml. of titrant was added at an interval of 1 min. A blank titration was performed. Titration curves were obtained by plotting potential reading (mv.) versus volume (ml.) of the titrant.

Total Basicity—An aliquot of the mixture equivalent to 0.25 meq. of sodium *p*-aminosalicylate was accurately weighed and transferred to a 100-ml. beaker. Acetonitrile (25 ml.) was added to it and stirred. After addition of an equal volume of acetic anhydride, it was titrated as described previously.

Analysis of Dosage Forms—The procedure was applied to analyze the powder mass obtained from tablets, granules and cachets.

Figure 1—Typical titration curve of acetonitrile extract of isoniazid-sodium *p*-aminosalicylate (1:50) mixture after diluting it with equal volume of acetic anhydride.

Where magnesium stearate was used as a lubricant in the preparation of tablets, the aliquot of tablet mass equivalent to 0.25 meq. of sodium *p*-aminosalicylate was mixed with salicylaldehyde (3.0 ml.) and treated three times with 10-ml. quantities of acetonitrile and filtered. The combined filtrates were then diluted with equal volume of acetic anhydride and titrated as described to obtain reading for total basicity.

RESULTS AND DISCUSSION

[At the very outset, it was evident that because of the large excess of sodium *p*-aminosalicylate associated with isoniazid in commercial dosage forms, a direct differential nonaqueous titrimetry would be of no avail (3).

The quantitative extraction of isoniazid-sodium *p*-aminosalicylate mixture has been attempted by several workers (5-7). However, either the separation of the components was not efficient or the procedure adopted was time consuming.

In the present work, advantage was taken of the difference in solubilities of these compounds in acetonitrile to obtain molar ratio of the components in the extract favorable for differential titration. Thus, the removal of the bulk of sodium *p*-aminosalicylate was effected by extracting the mixture with acetonitrile. The acetonitrile extract contained only a part of sodium *p*-aminosalicylate but the whole of isoniazid. The end points for both the components could be resolved in the titration of acetonitrile extract (after diluting it with equal volume of acetic anhydride) against acetous perchloric acid.

A typical titration curve thus obtained is reproduced in Fig. 1. The first inflection in the curve (see Fig. 1) corresponds to the sodium *p*-aminosalicylate while the second inflection denotes the end point corresponding to isoniazid present in the extract.

Acetonitrile extracts of a number of mixtures were analyzed by the proposed procedure for their isoniazid content (see Table I).

^a Per unit dosage. ^b Per gram of the granules.

The recovery of isoniazid from synthetic mixtures having sodium *p*-aminosalicylate-to-isoniazid ratio as high as 50:1 was found to be satisfactory.

For the estimation of sodium *p*-aminosalicylate, an aliquot of the mixture dissolved in acetonitrile-acetic anhydride (1:1) mixture is titrated against acetous perchloric acid. Only one inflection point in the titration curve is obtained which corresponds to total basicity of the mixture. The amount of sodium *p*-aminosalicylate present in the mixture can be calculated from the reading for the total basicity of the mixture after subtracting the volume of the titrant required for isoniazid.

The procedure was applied to analyze commercial dosage forms. The results agreed closely with those obtained by the official method (4) (see Table II). The usual diluents, lubricants, and colors used in the preparation of dosage forms did not appear to interfere with the titration. However, the presence of magnesium stearate in tablets as lubricant induces high recoveries of sodium *p*-aminosalicylate. In such a case, the sample of the powdered tablet was treated with salicylaldehyde and extracted with acetonitrile. The solubility of sodium *p*-aminosalicylate increases in the presence of salicylaldehyde, so that its complete extraction is effected with a relatively small volume of solvent. The extract after diluting with equal volume of acetic anhydride is titrated as usual. The method gave satisfactory recovery of sodium *p*-aminosalicylate.

Sampling and Analysis of Oxygen in the Void Volume of Ampuls and Vials

L. F. CULLEN and G. J. PAPARIELLO

Abstract □ A technique recognized as a considerable aid in stabilizing parenteral formulations sensitive to oxidative decomposition consists of replacing air in the container's headspace with an inert atmosphere. To monitor and investigate inert gas flushing techniques and to assist in evaluating antioxidant suitability, a procedure is described for the sampling and analysis of gaseous oxygen content in the void volume headspace of ampuls and vials. The procedure utilizes a paramagnetic oxygen analyzer in conjunction with a unique sampling cell and flow system which permit the collection of the headspace gas without atmospheric contamination. The sampling device and flow system were designed and evaluated to provide the necessary sensitivity, accuracy, and precision for the quantitative analysis of low air contaminant levels in the sample gas. With this method it is possible to analyze nine samples per hour with a relative standard deviation of 3.9% at a 19- μ l. air level (*i.e.*, 5 mcg. of oxygen), which corresponds to approximately 2% of the theoretical gaseous void volume of a typical 1-ml. ampul product. Accuracy of the technique is demonstrated by experimentally confirming the relationship of headspace oxygen consumption to intact bisulfite and metabisulfite antioxidant content, following accelerated storage, in sealed ampuls.

Keyphrases □ Oxygen sampling, analysis—void volumes, ampuls, vials □ Sampling device, void volume oxygen—diagram □ Ampuls—oxygen determination □ Vials—oxygen determination

The adverse influence of atmospheric oxygen on both the physical and chemical stability of parenteral formulations and the numerous problems arising from the oxidative decomposition of drugs in the development of new products has been emphasized repeatedly in the past (1-6). The inclusion of a suitable antioxidant system to inhibit the oxidative process and the replacement of air in the headspace of a product's container with an inert atmosphere are generally recognized as considerable aids in stabilizing an injectable formulation. However, prior to the recent development of a method for measuring the oxygen level in the headspace of vial products (7), a survey of the literature failed to disclose any other analytical procedures specifically designed to monitor the efficiency of the inert gas flushing technique on the various parenteral containers. Thus, the pharmaceutical manufacturer has been in the dark with regard to the effectiveness of his oxygen exclusion process employed during the filling operation.

Clearly, a need existed for a sensitive, accurate, and rapid procedure for sampling and analysis of low air contamination levels in the void volume of inert gas flushed parenteral products, including ampuls. Such a technique could be employed to monitor and investigate

the inert gas flushing processes and to assist in evaluating antioxidant suitability.

The accurate sampling of the void volume from a sealed, glass ampul within a controlled oxygen-free atmosphere and subsequent analysis, under similarly controlled conditions, for low oxygen levels is indeed difficult. Existing methods of oxygen analysis could not be readily modified to handle this problem. Several of the wide variety of methods which have been employed to determine gaseous oxygen vary from a highly sensitive luminescent-bacterial method (8), to colorimetric methods (9-12), microvolumetric (13, 14) and manometric (15) techniques, galvanic cell-type systems (16, 17), and coulometric procedures (18, 19). Many of these methods have the necessary accuracy and sensitivity at the oxygen level considered; however, they are either time-consuming and/or require meticulous care for satisfactory results. Furthermore, none of the procedures offered a convenient system for the sampling of the headspace gas within a sealed, glass ampul. Rapid and precise polarographic (7, 20) and gas chromatographic procedures (21, 22) which have found extensive use in oxygen analysis are also restricted by not affording systems readily adaptable to the collection and analysis of the headspace gas under anaerobic conditions.

Several commercial instruments are available which utilize the paramagnetic property of oxygen for its determination. This instrumentation is primarily employed for the continuous monitoring of the oxygen levels of expired air in respiratory physiology (23-25). The reported accuracy and sensitivity of the Beckman E2 Oxygen Analyzer (26), which has available a small volume internal analysis system equipped to measure nonflowing samples and an adaptable sample inlet port, suggested a promising approach. A consideration of the capabilities and limitations of this instrument led to the design of a unique sampling cell and flow system, of definite and critical specifications, which were evaluated to provide an accurate and rapid sampling technique for the analysis of the headspace gas of ampul products. The design of the sampling device permitted an extension of the procedure to the analysis of low air contamination levels in the void volume of inert gas-flushed injectable vial products. With this method it is possible to analyze nine ampuls and/or vials per hour.

Figure 1—Headspace gas sampling device.

EXPERIMENTAL

Sampler Construction—The sampling device, designed to collect the headspace gas in an ampul without atmospheric contamination, is illustrated in Fig. 1. Dimensional details of this cell are given in Fig. 2. The O-ring-sealed components of the sampler, the sleeve adapter and chamber plug were machined from brass rods. For fine control of the flushing gas during deaeration of the sampling cell and to prevent damage to the detector of the analyzer from pressure surges, minimum void volume metering valves¹ were fitted to the sample chamber. Following the removal of a port connector on each of the metering valves, the valves were soldered directly onto openings in the cell, as shown in Fig. 1. This reduced the increase in total void space of the sampler introduced by the micrometer valves and eliminated the need for additional fittings. The septum inlet assembly is used for calibration purposes in the ampul

procedure and as the injection port for a gas-tight syringe containing headspace gas sampled from vial products.

Apparatus—A Beckman E2 Oxygen Analyzer² equipped with 0-1 and 0-10% oxygen percentage ranges was employed in all experiments. The sensitive detection system of the analyzer utilizes the magnetic susceptibility of oxygen to provide the basis for a quantitative evaluation of the oxygen content in the sample gas. Detailed discussions of this characteristically strong property of oxygen and how it is applied to the paramagnetic oxygen analyzers were described by Catton (27) and Johnson (28).

Accurate flow control of nitrogen during deaeration of the sampling device was provided by a flowmeter unit.³

A vacuum pump⁴ in conjunction with a fine metering valve⁵ permitted a complete and graduated evacuation of the flow system and analysis cell of the oxygen analyzer. A McLeod-type vacuum gauge⁶ was inserted into the manifold to monitor the efficiency of the evacuation process.

Rubber vacuum tubing (0.32 cm. [0.125 in.] i.d. \times 0.32 cm. [0.125 in.] wall thickness)⁷ was connected to each of the threaded fittings of the metering valves and sample ports of the oxygen analyzer with 0.95 cm. (0.375 in.) o.d. tubing clamps. To minimize the total void volume of the actual analysis system, only 3.81-cm. (1.5-in.) lengths of this vacuum tubing were employed.

Pressure-Lok gas-tight syringes of 0.5-ml. and 1.0-ml.⁸ capacity were used to calibrate the system in the analysis of both ampul and vial products and to sample the headspace gas in the analysis of vial products.

Analytical Procedures—Ampul Products—A diagram of the flow system indicating the equipment arrangement for the analytical method is shown in Fig. 3. The collection of an uncontaminated sample of headspace gas followed by conveyance of the gaseous sample from the sampling device to the sensitive detector of the oxygen analyzer consists of the following steps: (a) deaeration, with nitrogen,⁹ of the sampling device containing the sealed ampul; (b) complete evacuation of the analysis cell to purge it of air; and (c) the introduction of the sample or calibration gas into the cell. Exact flow rate conditions are described to avoid sudden pressure changes which can damage the magnetic unit.

In operation, the sealed ampul is placed into the sleeve component of the sampler and pressed into firm contact with the 0.95 cm. (0.375 in.) O-ring seal with the ampul retainer. This assembly is inserted into the sample chamber and tightened. In preparation for deaeration of the sampling device and flow system, as illustrated in Fig. 3, the flowmeter needle valve (V-1) is closed, and the second stage of a two-stage regulator on the nitrogen cylinder is set to deliver 10 psig. Needle valves V-2 and V-3 are opened to provide a nitrogen gas flow rate of approximately 125 ml./min. Valves V-4 and V-5 are set to permit a flow rate of 250 ml./min., with the T-bore stopcock (T-6) vented to the atmosphere. To nitrogen-flush the sampling device, slowly open flowmeter needle valve (V-1) until a flow rate of 220 ml./min. is established as indicated by a 105 mm. metering-tube reading with the Pyrex float. After a 2-min. flush close valve V-1, followed by valves V-2, V-3, and V-4 in successive order. Break ampul, then evacuate flow system and detector by closing valve V-5 to produce a flow rate of 70 ml./min., setting stopcock (T-6) for system evacuation, and drawing a vacuum for 1.5 min. To ensure a relatively complete deaeration process, a vacuum reading after approximately 1.25 min. of this evacuation period should indicate a system pressure of less than 0.4 mm. Hg. To convey sample gas mixture to the evacuated detector of the analyzer for compositional analysis, close valve V-5 and slowly open valve V-4 to a flow rate of 100 ml./min. Following sample readout, the magnetic unit is gradually adjusted to atmospheric pressure by venting stopcock (T-6) to the atmosphere and slowly opening valve V-5 to deliver a flow rate of 70 ml./min. The sampling cell pressure

Figure 3—Flow system for oxygen analysis.

is brought to atmospheric by opening valve V-4 to provide a flow rate of 250 ml./min.

The exact flow system conditions described above for the analysis of the headspace gas are used in calibration of the system. Calibration is effected by injecting, in duplicate, known volumes of air at the appropriate level into the nitrogen-purged sampling device, which contains an ampul. Standardization is repeated at the end of a series of 20 samples in order to minimize the effects of instrumental variations. Calculations are made using corresponding instrument responses of standards and headspace gas of ampul products.

Vial Products—The flow system, as illustrated in Fig. 3, and exact analytical conditions described under *Ampul Products* for conveyance of the sample gas from the sampling device to the detector were employed in the analysis of vial products. The chamber plug, dimensionally detailed in Fig. 2, is inserted to seal the sampling chamber. In sampling, an accurately measured portion of the headspace gas is drawn into a gas-tight syringe and locked in the syringe prior to withdrawal from the vial. This is followed by injection into the nitrogen-flushed sampling cell after penetration of the septum and opening the actuation valve of the syringe. The volume of the headspace gas mixture sampled should, preferably, contain the equivalent of 0.02–2.5 ml. of air. It should be noted that during the vial sampling process a partial vacuum is created. Consequently, a correction must be made for this sampling effect in order to determine the actual sample volume.

The system is calibrated by injecting appropriate levels of air, sampled directly from the atmosphere, into the nitrogen-purged sampling device. Using this standardization technique and the Eq. 1 which corrects for the previously described sampling effect, the percent air in the sample can be calculated.

$$\% \text{ air (v/v)} = \frac{(R_V)(A_S)(V_T)100}{(R_S)(V_V)} \quad (\text{Eq. 1})$$

where R_V = response of sample; R_S = response of standard; A_S = volume of air injected for calibration; V_V = measured void volume of vial; V_T = measured void volume of vial (V_V) plus the indicated sample volume of the gas-tight syringe.

As an alternate technique in standardization of the system, known volumes of either air or air-inert gas calibration mixtures are sampled from vial packages filled with water to yield a headspace volume equivalent to the vial products. Employing the gas-tight syringe to collect, store, and transport the headspace gas as described previously, the withdrawal of identical volumes of sample and reference gas from equal voids eliminates a consideration of the dilution factor introduced in the sampling process, as required in Eq. 1. Calculations are made using the corresponding instrument responses of standards and samples of the headspace gas of vial products.

RESULTS AND DISCUSSION

Design of Sampling Device—The major consideration in the development of the sampling system was to design a sampling cell of a sufficiently low void volume to provide the necessary sensitivity for accurately monitoring inert gas flushing efficiency at levels greater than 98%, i.e., less than 2% air contamination. Two percent

air contamination corresponded to a 20- μ l. air level (i.e., 5 mcg. of oxygen) in the typical 1-ml. ampul product investigated. At such levels of oxygen, the analyzer has a reported accuracy of $\pm 1.7 \mu$ l. air ($\pm 0.4 \mu$ l. oxygen) and a limit of detection of 0.2 μ l. air in the sample gas with its 3.5-ml. internal analysis system at 760 mm. pressure (28). However, with a gaseous void volume of approximately 1 ml. for most ampul products, insufficient sample gas is available to satisfy the detector at atmospheric pressure. Thus, it was realized that a special flow system, as described under *Analytical Procedure*, would be required which results in the analysis of the sample gas at a reduced pressure. Under these operating conditions, the accuracy and sensitivity characteristics of the detector are reduced, necessitating an evaluation of pressure effects in establishing the optimum sample chamber volume for the sampling device.

In designing the cell for optimum accuracy and sensitivity conditions, a balance had to be considered between: (a) satisfying the pressure requirements of the detector by increasing the void space of the sample chamber in order to approach atmospheric conditions in the analysis cell; (b) reducing the volume of the sample chamber to prevent a loss in sensitivity from an unnecessary high dilution with the inert gas. Employing the ideal gas laws to calculate the effect of sample concentration and pressure on instrument readout (28), the dimensional parameters of the sampling system were derived. A graphic representation of the effect of sample cell volume on the obtainable theoretical accuracy is shown in Fig. 4.

It was calculated that a sample chamber and associated metering valves with a 5.2-ml. void volume provided the optimum analysis conditions. A sampling device of these dimensions has an ultimate, theoretical accuracy of $\pm 7 \mu$ l. air and a limit of detection of 0.7 μ l. air. The sampling device and flow system have been fabricated to these specifications (see Figs. 2 and 3). Thus, the indicated accuracy and sensitivity to monitor inert gas flushing efficiency at levels greater than 98% has been built into the system.

Linearity and Sensitivity—A typical calibration curve obtained by injecting known volumes of air into the sampling device in the

Figure 4—Effect of void volume of sample device on the theoretical accuracy of system.

Figure 5—Relationship of instrument response to air level.

50–250 μ l. range, equivalent to 14–68 mcg. of oxygen, demonstrates the linearity of the instrument response-air level relationship (Fig. 5). These data had been collected with the oxygen analyzer set at its most sensitive operating range, i.e., the 0–1% oxygen percentage range. The 0–10% range on the instrument extends the applicability of the sampling and flow system (Fig. 3) to include the analysis of most ampul and vial parenteral products at any level of inert gas flush efficiency by permitting an evaluation of headspace gas which contains 0.25 to 2.5 ml. of air. A linear relationship exists between instrument response and air level at these higher concentrations.

The actual measured lower limit of sensitivity of both the ampul and vial procedures is 2 μ l. of air in the sample gas mixture. This air level represents 0.2% of the total void volume of the typical 1-ml. and 2-ml. ampul products. The determined sensitivity of 2 μ l. of air approaches the theoretical sensitivity of 0.7 μ l. of air.

Ampul Procedure—Precision—Repeatability of the procedure was determined by assaying the headspace gas of 20 individual ampuls flushed with a 0.4% (v/v) oxygen-nitrogen calibration gas mixture.¹⁰ Experimentally, 1.0-ml. aliquots of water were introduced into 1-ml. ampuls under an atmosphere of the oxygen-nitrogen gas mixture within an inflatable polyethylene glove chamber. Using the gas mixture the ampuls were flushed for exactly 20 min., then immediately sealed under the oxygen-nitrogen atmosphere with approximately 1 ml. of headspace above the water. Following the analysis of the headspace gas, the void volumes of the individual ampuls were measured and calculated into the results. This eliminated any differences in the void volumes of the ampuls produced by the sealing process. Reported in terms of air at 25° and 760 mm. Hg, a relative standard deviation of 3.9% was determined at the 19- μ l. air level. The 19- μ l. air level, which corresponds to 98.1% nitrogen flushing efficiency, demonstrates the precision of the procedure at a high level of inert gas layering.

Accuracy—Accuracy of the ampul procedure was established by experimentally determining the relationship of oxygen consumption to intact bisulfite and metabisulfite content after interaction in sealed ampuls. In this study, 1.0 ml. of an 0.1% solution of the antioxidant (sodium bisulfite or sodium metabisulfite) was introduced into 1-ml. ampuls and flushed with air-nitrogen gas mixtures in order to obtain either 60 or 500 μ l. air per 1 ml. of ampul void volume. A gas proportioning unit¹¹ provided accurate metering of air and nitrogen to the desired ratio during this flushing process. The ampuls were sealed to contain a void volume of about 1 ml. under the air-nitrogen atmosphere, then immediately assayed for the initial antioxidant content (29) and headspace air. The ampuls were stored at temperatures from 35 to 60° to accelerate oxygen consumption and assayed for antioxidant and headspace air content at periodic time intervals. Typical data collected in this study are summarized in Table I.

The theoretical consumptions of sodium bisulfite and sodium metabisulfite by the oxygen content of 1.00 ml. of air at 25° and

Table I—Relationship of Consumed Air to Intact Antioxidant Level

Reaction Condition	Air Remaining per Ampul, μ l. ^a	Anti-oxidant Remaining per Ampul, mg. ^a	Anti-oxidant Reacted per Ampul, mg.	Air Consumed per Ampul, μ l. Exptl.	Theoret.
Sodium Metabisulfite					
30 hr., 35°	22	0.89	0.07	41	43 ^b
48 hr., 45°	9	0.87	0.09	58	56 ^b
48 hr., 60°	4	0.86	0.10	61	62 ^b
24 hr., 35°	161	0.43	0.53	332	329 ^b

Sodium Bisulfite					
30 hr., 35°	22	0.85	0.07	39	37 ^c
48 hr., 45°	6	0.83	0.09	53	51 ^c
24 hr., 35°	192	0.39	0.53	297	300 ^c
48 hr., 60°	48	0.14	0.78	443	442 ^c

^a Average assay value on five individual ampuls (air analyses $\sigma_{av.} = \pm 3.2\%$; antioxidant analyses $\sigma_{av.} = \pm 1.9\%$). ^b Calculated from the relationship that 1.62 mg. of $\text{Na}_2\text{S}_2\text{O}_5$ is equivalent to 1.00 ml. air at 25°, 760 mm. ^c Calculated from the relationship that 1.77 mg. of NaHSO_3 is equivalent to 1.00 ml. air at 25°, 760 mm.

760 mm. are 1.77 and 1.62 mg., respectively (6). The results indicate the experimental values are in excellent agreement with theory. Data obtained on ampuls containing less than 10 μ l. of air in the headspace gas, i.e., less than 1% air in the typical 1-ml. and 2-ml. ampul products, demonstrate that the technique quite adequately meets the accuracy requirements for monitoring inert gas flushing efficiency at levels greater than 98%.

Vial Procedure—Precision and Accuracy—Both the precision and accuracy of this technique were obtained by performing replicate assays on known volumes of air injected into nitrogen-flushed vials with a butyl rubber stopper-aluminum cap closure and measuring the percentage recovery. This was accomplished by flushing and crimping empty vials, with accurately measured void volumes of approximately 15 ml., under an absolute nitrogen atmosphere. Following the removal and analysis of a portion of the headspace gas from the individual vials to correct for residual air in the flushing process, 0.15 and 1.50-ml. levels of air were injected into the vials, producing synthetic air contamination levels at 1.0 and 10%, respectively. Data collected on replicate assays of 15 individual vials at the 1.0% contamination level indicated recoveries of 97 to 103% of the theoretical amount present with a relative standard deviation of 4.2%. Recoveries of 99 to 101% of theory were obtained on 15 individual vials at the 10% air contamination level with a relative standard deviation of 2.1%. In this phase of the study, the data were calculated as described by Eq. 1.

NOTES

Muscarinic Agents: The Isomeric 6-Acetoxy-2-methylisoquinuclidine Methiodides

WENDEL L. NELSON and RAYMOND S. WILSON*

Abstract □ Preparation of 6-*endo* and 6-*exo*-acetoxy-2-methylisoquinuclidine methiodides are described. Muscarinic assay data are reported. Neither of the compounds showed activity when compared to acetylcholine and 3-acetoxyquinuclidine methiodide.

Keyphrases □ 6-Acetoxy-2-methylisoquinuclidine methiodides—synthesis □ Pharmacological screening—6-acetoxy-2-methylisoquinuclidine methiodides □ IR spectrophotometry—identity, structure □ NMR spectroscopy—structure

Hypotheses delineating the architectural features of cholinergic receptors have been based on observations of pharmacological activity of various substituted derivatives of the neurohormone, acetylcholine. Differences in the activity of these analogs of acetylcholine have long been explained on the basis of molecular steric and electronic effects in the drug-receptor interaction (1, 2). Spectral data concerned with conformational aspects of acetylcholine have also been studied and developed in recent attempts to describe receptor site architecture (3-7).

In further studies to determine the conformational requirements of the drug-receptor complex, in which the authors' assume a large degree of complementarity of the drug and receptor in this interaction, a number of conformationally rigid or semirigid analogs of acetylcholine have been prepared (8-13). Each, although incorporating the essential features for cholinergic activity, also inherently must be constructed of an additional number

of carbons to maintain the desired conformational rigidity. Comparison of activities of agents structurally similar to each other seems valid.

PREPARATION OF ANALOGS

In a program of preparation of agents to further determine the geometric requirements of the muscarinic agents, it was decided to prepare cholinergic analogs in the isoquinuclidine system in which

of carbons to maintain the desired conformational rigidity. Comparison of activities of agents structurally similar to each other seems valid.

PREPARATION OF ANALOGS

In a program of preparation of agents to further determine the geometric requirements of the muscarinic agents, it was decided to prepare cholinergic analogs in the isoquinuclidine system in which

the quaternary ammonium head is held in a fixed position by the carbocyclic skeleton. The compounds, 6-*endo*- and 6-*exo*-acetoxy-2-methylisoquinuclidine methiodides,¹ I and II, represent *anti* and *gauche* conformations of acetylcholine, IA and IIA, respectively, in a fused system.

Preparation of I was accomplished beginning with methyl 3-cyclohexencarboxylate (III) (Scheme I). Epoxidation of III with *m*-chloroperbenzoic acid produced epoxide IV. The authors could not detect the presence of more than a single epoxide, which has been assigned the *trans* stereochemistry by Henbest (14). It would not be unusual to expect both epoxides, which may be both dependent on solvent and oxidizing agent (15).

The epoxide (IV) was allowed to react with methylamine, with the expected *trans*-diaxial opening by this nucleophile. The reaction mixture was heated at reflux to effect ring closure to the isoquinuclidone, V, as well as dimeric and polymeric products. Similar opening of this epoxide has been reported by Huffman (15), who readily sublimed a quinuclidone from the mixture when benzylamine was used. In this case, only a sticky glass was obtained, and the sublimation failed. Crude V was acetylated to produce VI, 6-*endo*-acetoxy-2-methyl-3-isoquinuclidone.

Lithium aluminum hydride reduction of VI provided VII. Considerable losses were encountered in this reduction, probably due to the water solubility of the product. The crude amino alcohol was acetylated and then was allowed to react with methyl iodide to afford I.

Scheme I

During the early part of the work on I, a method appeared for the preparation of II from the Diels-Alder adduct of 1,3-cyclohexadiene and *N*-methylidene-urethan (16). This method obviated the intended conversion of VII to an intermediate ketone useful to reach II.

Of interest is the difference in NMR spectra of I and II. Whereas the spectrum of I shows magnetic equivalence of the *N*-methyl groups at 3.28 δ , two different signals are observed for the methyl groups in II at 3.26 and 3.35 δ , respectively. This difference reflects the long range effect of the acetoxy group (*vide infra*), although it is not possible to assign it a shielding or deshielding effect in this case, although the latter is most probable.

The best models available are 2 β -substituted steroids (effects on the C-19 methyl group) and 17 β -substituted compounds (effects on the C-18 methyl groups) (17, 18). Deshielding effects of the acetoxy group are noted in each case. However, the geometry of the isoquinuclidine ring is not completely analogous.

PHARMACOLOGICAL TESTING

The isoquinuclidines, I and II, as racemates, were tested for muscarinic activity in rabbit ileum. Neither of the compounds showed activity at concentrations up to 10^{-2} *M*. Acetylcholine showed half maximal activity at 1×10^{-7} *M* ($pD_2 = 7$, $\alpha = 1.0$).

¹ An *exo* substituent is defined as one which is *cis* to the nitrogen containing bridge to the isoquinuclidine ring, and an *endo* substituent is *trans* to the bridge.

For comparison, a structurally related compound, 3-acetoxy-quinuclidine methiodide VIII was also tested in this system. This compound showed a dose-response curve parallel to that of acetylcholine, and a pD_2 of 4.2, $\alpha = 1.0$. Similar results have been reported (19).

Two rational explanations may be advanced for the lack of activity in the isoquinuclidines. The conformations of acetylcholine, which these compounds represent, may not be those in the drug-receptor complex at the muscarinic site. A more valid possibility is that the carbocyclic skeleton present in these compounds may prevent either of the compounds from forming a drug-receptor complex leading to pharmacological action. The observed lack of activity may be due to this hydrocarbon portion of the molecules, which may interact with hydrophobic regions outside the site, or prevent interaction of the quaternary ammonium head and acetoxy moieties.

Examination of Dreiding models of II shows a great deal of steric hindrance about the acetoxy group, to one of the *N*-methyl groups. The NMR spectrum supports some type of interaction between these groups, at least an electronic effect. Additionally, each of these compounds can be analyzed as an α,β -di-alkyl-substituted acetylcholine, with both an isopropyl and neopentyl group attached to nitrogen. One of these factors, or both, may be responsible for the lack of pharmacological activity.

EXPERIMENTAL

Melting points were determined on a calibrated Thomas-Hoover Unimelt and are corrected. IR spectra were recorded on Beckman IR-8 and IR-20 spectrophotometers. NMR spectra were determined with Varian Associates A-60 and T-60 spectrometers using tetramethylsilane as an internal standard in organic solvents and dimethylsilapentanoic acid sodium salt in aqueous solution. Elemental analyses were conducted by Drs. G. Weiler and F. B. Strauss, Oxford, England.

3-Carbomethoxy-7-oxabicyclo[4.1.0]heptane (IV)—To a cooled solution (0°) of 137 g. (0.98 mole) of methyl 3-cyclohexencarboxylate in 200 ml. of $CHCl_3$ was slowly added a $CHCl_3$ solution of 180 g. (1.02 moles) of *m*-chloroperbenzoic acid. After the addition, the mixture was stirred at room temperature for 2 hr. then worked with 5% aqueous sodium sulfite solution, 5% aqueous sodium hydroxide solution, water, and dried ($MgSO_4$). Evaporation of the $CHCl_3$ afforded a colorless oil, identical in IR spectral qualities with those reported by Henbest (14).

6-*endo*-Acetoxy-2-methyl-3-isoquinuclidine (VI)—To a cooled (0°) solution of 93.0 g. (0.60 mole) of crude epoxide, IV, in 200 ml. of CH_3OH was slowly added 77.5 g. (1.00 mole) of 40% aqueous methylamine. The mixture was allowed to stand at room temperature for 3 days, heated to reflux for 1 hr., then evaporated *in vacuo* to remove solvents and excess methylamine. The crude amino alcohol was refluxed for 3 hr. to effect ring closure to lactam VI. The residue, 87.0 g. of a viscous glass, resisted all attempts at sublimation, a technique that had been successful in similar compounds (15). The IR spectrum showed both ester (5.80 μ) and amide (6.10 μ) carbonyl bands.

The crude mixture (87.0 g., 0.40 mole) was dissolved in 86.4 g. (1.10 moles) of pyridine and 110.7 g. (1.10 moles) of acetic anhydride was added. The solution was refluxed for 2 hr.; excess pyridine, acetic anhydride, and acetic acid were removed utilizing a water aspirator. Aqueous 2% HCl was added and after 1 hr. the mixture was extracted with EtOAc. The EtOAc layer was dried ($MgSO_4$) and solvent evaporated. The residue oil, was distilled, b.p. 110° (1.0 mm.) affording 31.5 g. (17% of theory) of VI; IR (neat), 3.02, 3.41, 5.82, 6.05, 6.96, 7.19, 7.33, 8.12, 8.55, 8.79, 9.53, 9.80, 11.0, 12.15 μ ; NMR δ ($CDCl_3$), 5.10 (sextet, H_6 , $J_{6,1} \sim J_{6,5} \sim 4$ c.p.s., $J_{6,5'} = 10$ c.p.s.), 3.75 (multiplet, H_1 proton, $W_{1/2} = 8$ c.p.s.), 3.05 (singlet,

O
N— CH_3 proton), 2.18 (singlet, CH_3 —C—), 1.6–2.7 (multiplet, seven protons, methylene-methine envelope).

6-*endo*-Acetoxy-2-methylisoquinuclidine Methiodide (I)—A solution of isoquinuclidone VI, 29.9 g. (0.165 mole) in 100 ml. of anhydrous ether was added dropwise to a slurry of 12.0 g. (0.316 mole) of lithium aluminum hydride in 150 ml. of ether. After the addition, the mixture was refluxed for 4 hr. Excess lithium aluminum hydride was destroyed with a 40% aqueous solution of Rochelle salt. The mixture was filtered (Celite), dried, and the solvent removed. The crude product was partitioned between ethyl acetate

and 5% aqueous hydrochloric acid. The acidic solution was made alkaline with 20% aqueous NaOH and extracted with EtOAc, which was dried, and solvent removed affording crude VII, 6.5 g. (22%) as a dark orange oil; IR (neat), 3.05 (broad), 3.47, 6.12, 6.58, 6.98, 8.65, 8.83, 9.38, 9.88, 10.55, 11.05, and 12.21 μ .

A mixture of crude VII, 1.5 g. (11 mmoles), and 1.0 g. (10 mmoles) of acetic anhydride was refluxed for 1 hr. and then allowed to stand overnight at room temperature. Sufficient 10% aqueous NaOH was added to make the mixture alkaline, and the ester extracted with ether. The crude ester was partitioned between ether and aqueous acid again, the acidic solution neutralized, and the basic ester isolated, 500 mg (30%); IR (neat), 2.91, 3.42, 5.78, 6.13, 6.96, 7.10, 7.32, 8.09, 8.60, 8.79, 9.29, and 9.65 μ .

To a solution of 500 mg. (3.0 mmoles) of the crude acetate ester of amino alcohol VII in 10 ml. of methanol was added 10 ml. of methyl iodide and the mixture allowed to stand overnight. The solvent and excess methyl iodide were removed, the solution was decolorized (Norite) in methanol, and crystallized twice from methanol-ethyl acetate affording 300 mg. (53%) of colorless crystals, m.p. 165–165.5°; IR (KBr) 3.29, 3.36, 5.73, 6.79, 6.88, 7.69, 8.02, 8.64, 9.30, 9.55, 9.63, 10.49, 10.77, and 11.03 μ ; NMR (D_2O) δ , 5.48 (sextet, H_6 proton, $J_{6,1} \sim J_{6,5} = 4$ c.p.s., $J_{6,5'} = 10$ c.p.s.); 3.60 (broadened quartet, $H_1, J_{1,7} \sim 3$ c.p.s.), 4.45 (broadened singlet, CH_3 protons),

3.28 [singlet, $N(CH_3)_2$], 2.12 (singlet, $CH_3-C(=O)-$), 1.26–3.0 (multiplet, seven protons, methylene-methine envelope).

Anal.—Calcd. for $C_{11}H_{20}INO$: C, 40.60; H, 6.15; N, 4.31. Found: C, 40.67; H, 6.02; N, 4.21.

6-*exo*-Acetoxy-2-methylisoquinclidine Methiodide (II)—This compound was prepared by the method of DeGraw and Kennedy (16).

3-Acetoxyquinclidine Methiodide (VIII)—This compound was prepared by the method of Grob (20, 21) from 3-hydroxyquinclidine.

ACKNOWLEDGMENTS AND ADDRESSES

Received August 15, 1969 from the College of Pharmacy, University of Washington, Seattle, WA 98105

Accepted for publication September 22, 1969.

This investigation was supported in part by grant MH-13,514 from the National Institutes of Health, U. S. Public Health Service, Bethesda, Md.

* Recipient of the Lunsford Richardson Pharmacy Award, Regional Honorable Mention, 1969, for a manuscript based in part on this work.

The authors wish to thank Dr. Frank F. Vincenzi and Mr. Peter H. Blake for the muscarinic assays.

Potential Antitumor Agents: Derivatives of 2-Hydrazino-5-nitropyridine

BENJAMIN PRESCOTT and GEORGE CALDES

Abstract □ Fifty-one hydrazones of 2-hydrazino-5-nitropyridine have been synthesized for tolerance in DBA mice and for study as potential antitumor agents against the three mouse tumor systems (sarcoma 180, adenocarcinoma 755, and leukemia 1210). Of four compounds with activity against the sarcoma 180 tumor, two derivatives—*p*-acetaminobenzaldehyde and *p*-nitrobenzaldehyde—showed good inhibition and confirmed activity. The salicylaldehyde derivative showed slight activity against the adenocarcinoma 755 tumor. None of the compounds were active in the leukemia 1210 mouse tumor system. The highest tolerated dose of the active compounds in mice by intraperitoneal injection was 2 g./kg. The compounds were thus of low toxicity.

Keyphrases □ 2-Hydrazino-5-nitropyridines—synthesis □ Acute toxicity, mice—2-hydrazino-5-nitropyridines □ Biological activity—2-hydrazino-5-nitropyridines

The synthesis of thiosemicarbazones and hydrazones has received considerable attention since Domagk's (1) report on the antituberculous activity of tibione (*p*-acetylaminobenzaldehyde thiosemicarbazone). Numerous reports followed which indicated that a number of different hydrazones possessed potential antimicrobial, antifungal, and antitumor activity. Freedlander and Furst (2) studied the effects of substituted hydrazines and related compounds on myeloid mouse leukemia C-1498. Petersen and Domagk (3) synthesized the guanylhydrazone of *p*-benzoquinone-monothiosemicarbazone and found the product to possess strong bacteriostatic action on *Mycobacterium tuberculosis* and various other organisms. In addition Chang (4) reported that the isonicotinylhydrazones of 2-carboxymethoxy-3-methoxybenzaldehyde and 2-carboxymethoxybenzaldehyde were effective against mouse leprosy. Following these reports Jucker (5) published a review of hydrazone derivatives used as medicinals.

A few hydrazone derivatives of 2-hydrazino-5-nitropyridine were prepared by Mangini and Frenguelli (6). However, no biological properties were reported concerning these compounds. In extensive investigations

from this laboratory into the bacteriostatic, fungistatic, and carcinostatic effects of hydrazones (7, 8) particularly with a view to their possible application as potential chemotherapeutic agents, results indicated that certain hydrazones may possess significant biological activity.

The present report also describes the synthesis of 51 5-nitro-2-pyridylhydrazones with analyses, tests for acute toxicity in mice, and for their effectiveness as potential antimicrobial and antitumor agents. Studies with this series of hydrazones reported herein have shown that certain derivatives have some effect as potential anticancer agents.

MATERIALS AND METHODS

The desired 2-hydrazino-5-nitropyridine was synthesized from 2-chloro-5-nitropyridine by a modification of the method of Mangini and Frenguelli (6). Seventy-nine grams (0.5 mole) of 2-chloro-5-nitropyridine was warmed to solution in 2 l. of 95% EtOH, in a 3-l. three-necked flask equipped with a stirrer, thermometer, and dropping funnel. Twenty-five grams (0.5 mole) of 95% hydrazine hydrate were added dropwise to the stirred solution and the mixture cooled in an ice bath. The alcoholic solution turned orange colored immediately after the hydrazine was added and a voluminous yellowish-green precipitate began to separate with the evolution of a gas. The mixture was stirred for an additional 2 hr. at room temperature after all the hydrazine had been added and held at room temperature overnight. The heavy precipitate that formed was filtered, washed with petroleum ether, and air-dried. The crude greenish insoluble condensation product was crystallized from a large volume of 70% EtOH. The yellow fine crystals melted at 203–205° with decomposition.

Anal.—Calcd for $C_5H_4N_4O_2$: C, 38.96%; H, 3.92%; N, 36.25%. Found: C, 38.87%; H, 3.87%; N, 36.5%. The 2-hydrazino-5-nitropyridine readily reacted with aldehydes to form crystalline hydrazones which exhibited intense colors ranging from bright yellow, orange, through shades of red. All the aldehydes employed were commercial preparations. The chemical structures of the hydrazones are shown in Scheme I.

The general procedure for the synthesis of the hydrazones was as follows: a solution of the aldehyde (0.1 mole) in 95% ethanol (50 ml.) was added to a warm solution of the 2-hydrazino-5-nitropyridine (0.1 mole) in 95% ethanol (200 ml.) and refluxed gently for 30 min. on a hot plate. In numerous instances immediate reaction took place as seen by the formation of a solid. The solutions were cooled to room temperature and the insoluble products filtered, washed with cold water and petroleum ether, and air-dried. The products were purified by recrystallization from 70% ethanol in presence of decolorizing carbon. The compounds appeared as colorful, shiny crystals with yields from 90–95%. Table I gives a summary of the aldehydes used and the analysis of the compounds.

Biological Studies—Acute toxicity studies were performed in the DBA strain of mice as maintained at the National Institutes of Health, Bethesda, Md. The chemicals were suspended in 0.25% methocel (Dow methylcellulose) so that the dose per 20-g. mouse was contained in 0.25-ml. volume for intraperitoneal injection and the results judged by 72-hr. survival. The tolerated dose of each of the fifty-one compounds is 2 g./kg. The compounds are of low toxicity and may be administered in larger doses than are commonly used in the administration of various anticancer drugs.

Antitumor Studies—The compounds were tested for antitumor activity in the three tumor (sarcoma 180, adenocarcinoma 755, and leukemia 1210) mouse screening program by screeners under contract to the Cancer Chemotherapy National Service Center. The

Scheme I—5-Nitro-2-pyridylhydrazones; I, preparation of 2-hydrazino-5-nitropyridine; II, aldehyde where R = aliphatic, aromatic, or heterocyclic group; III, hydrazone derivative.

^a All melting points are uncorrected and were determined on a Fisher-Johns melting point apparatus. ^b Degussa reported m.p. 226–228° (Beilstein, 4th ed., 2nd Suppl. vol. 22, p. 488).

testing procedures employed have been described previously (9). Among the fifty-one compounds, four derivatives, salicylaldehyde, 4-chlorobenzaldehyde, 4-nitrobenzaldehyde, and 4-acetaminobenzaldehyde were found to exhibit significant inhibition against the S-180 mouse tumor system with the latter two compounds showing confirmed activity. The salicylaldehyde derivative showed slight activity against the adenocarcinoma 755 tumor in a dose of 450 mg./kg. None of the compounds in the series showed any significant or reproducible antitumor effects in the L-1210 mouse tumor system. The results of the biological tests supplied by the

Cancer Chemotherapy National Service Center are summarized in Table II.

Antibacterial Activity—*In vitro* bacteriostatic studies were performed on the fifty-one compounds with *Staphylococcus aureus* FD 209 and with *Mycobacterium tuberculosis* B 103. None of the compounds exhibited any appreciable antibacterial activity. The highly active *p*-acetaminobenzaldehyde derivative was also studied by Y. T. Chang of the Laboratory of Pharmacology and Toxicology, National Institutes of Health, for its effect on rat leprosy in mice and found to be inactive. In the light of the results with the *p*-acetaminobenzaldehyde and *p*-nitrobenzaldehyde derivatives as antitumor agents a test of their effectiveness in clinical tests is indicated.

Synthesis of New Hydrazidines with Vasoconstrictor Activity

GEORGE C. WRIGHT*, ROBERT P. HALLIDAY, and CHARLES S. DAVIS†

Abstract □ A series of hydrazidines with a structural similarity to the guanidines of the guanethidine series was synthesized. The observation that the hydrazidines raised blood pressure led to their screening as nasal decongestants. The most active compound, 3-(hexahydro-1*H*-azepino)propionimidic acid hydrazide dihydrochloride, was less potent than phenylephrine hydrochloride.

Keyphrases □ Hydrazidines—synthesis □ Vasoconstrictive activity—hydrazidines □ Hypertensive activity—hydrazidines

A series of hydrazidines with a structural similarity to the guanidines of the guanethidine series (1) was prepared for screening as antihypertensive compounds. The observation that the amino-substituted imidic acid hydrazides (III) raised blood pressure led to the screening of these compounds as nasal decongestants. In this paper the name hydrazidine refers to the general class of

compounds, —C(=N)N—N= ; specific types are named according to the system of *Chemical Abstracts*.

Several disubstituted aminoacetimidic acid hydrazides (III*a*–*c*, Table I) were prepared by a modification (Method *A*) of Kauffmann's procedure (2) for the synthesis of aliphatic hydrazidines.

Certain limitations to Method *A* have been observed. The reaction did not occur with acetonitriles possessing a labile α -hydrogen atom which could yield a resonance stabilized anion, as in the case of 2-phenyl-2-(2-pyridyl)-acetonitrile. In the case of 3-aminopropionitriles (IV), the competitive retrograde Michael reaction (a) was dependent upon the nature of the amino substituent (R_2N^-). When R_2N^- was incapable of resonance stabilization, competition was nil, and the desired hydrazidine V was formed. With R_2N^- capable of resonance stabilization, *e.g.* $\text{C}_6\text{H}_5\text{N}^-\text{Et}$, however, the amine VI was a primary product of the reaction.

A variety of substituted imidic acid hydrazides (III*d*–*i*, Table I) has been prepared *via* a modified procedure (Method *B*) of Westermann *et al.* (3), through the intermediate *N*-formamidoalkylamidines (IX*a*–*f*, Table II). Method *B* affords a safer preparation of the hydrazides (III) than Method *A*, where metastable sodium hydrazides are formed as intermediates.

PHARMACOLOGIC RESULTS

All of the hydrazidines that were tested (Table II) for their effect on nasal volume were less active than phenylephrine hydrochloride. The most active compound was III*g* which caused marked changes in nasal volume with relatively little effect on systemic blood pressure. Although these studies are preliminary in nature and involve few animals, a tentative order of decreasing potency of the compounds may be listed as III*g* > III*f* > III*h* > III*c* > III*i* > III*b* > III*d*. Thus, the 3-disubstituted aminopropionimidic acid hydrazides appear to be the most potent compounds prepared.

EXPERIMENTAL

Chemistry

2-(Hexahydro-1*H*-azepino)acetimidic Acid Hydrazide Dihydrochloride, III*c*—(Method *A*)—The reaction was conducted with special equipment and precautions as described by Kauffmann *et al.* (2). The main modification was the substitution of sodium hydride for sodamide in the generation of sodium hydrazide (I), affording a more rapid and reliable reaction with acetonitrile (*n* = 1).

Thus, to a mixture of 50% NaH (14.4 g., 0.30 mole) dispersed in mineral oil and dry ether (300 ml.) was added dropwise a solution of anhydrous hydrazine (9.6 g., 0.30 mole) in dry ether at 0–5°; this then was warmed to 10–15° over a 2-hr. period. The gray suspension was cooled to 0–5°, and treated dropwise with a solution of azepinoacetonitrile (41.4 g., 0.30 mole) in dry ether. The resultant creamy white suspension was warmed to 15° for 1.5 hr., cooled to 0–5° and treated with H_2O (14 ml.). The reaction mixture was stirred for 1 hr., and then filtered. The ethereal filtrate was dried (Na_2SO_4), concentrated, and distilled to give 17.4 g. (29%) of the free base; b.p. 114–126° (0.3–0.5 mm.).

The dihydrochloride (III*c*) was prepared by treating the free base in acetonitrile at 60° with a saturated solution of hydrogen chloride in acetonitrile. The salt suspension was heated to boiling, cooled, and filtered. Recrystallization from ethanol gave white crystals.

Method *B*—The method of Westermann *et al.* (3) was employed with several modifications. The methyl imidates VII rather than ethyl imidates were used since the intermediate nitrile hydrochlorides encountered in the preparation of the imidates were readily soluble in methanol. To ensure anhydrous conditions the semi-stable imidates were stored in a vacuum desiccator overnight. The commercially available formic acid hydrazide (VIII), which contained water, was unacceptable for the preparation of Compounds IX. Anhydrous VIII was prepared as follows.

Formic Acid Hydrazide (VIII)—To a solution of anhydrous hydrazine (960 g., 30 moles) in anhydrous ethanol (3.7 l.) was added ethyl formate (2220 g., 30 moles) at 20–25° during 2 hr. with mechanical stirring. The stirring was continued an additional

0.5 hr. The product was filtered on cloth (S/26 Jaybeeco Chain Weave); and the cake was kept wet with cold, anhydrous ethanol until all of the slurry was on the filter, after which it was protected from air with a rubber dam. The product was dried in a vacuum desiccator over CaCl₂ and finally over P₂O₅; m.p. 55–56°, yield: 1150–1330 g. (64–74%). A second crop was obtained by concentrating the mother liquor under N₂ to about 500 ml.; m.p. 54–56° [lit. (4) m.p. 54°], yield: 305–470 g. (17–26%).

Methyl 3-Dimethylaminopropionimidate Dihydrochloride—A solution of 3-dimethylaminopropionitrile (88.0 g., 1.05 moles) in absolute methanol (700 ml.) was treated with dry hydrogen chloride at 10–20° over 3 hr. until saturated. The reaction was diluted with dry ether, and the resultant white crystalline product was collected by filtration and washed with dry ether (1 l.); m.p. 99–100° [lit. (5) m.p. 100° dec.], yield: 118 g. (55%). Both dilution and filtration operations were conducted in a dry box.

N-Formamido-3-dimethylaminopropionamidine Hydrochloride (IXa)—To a mixture of methyl 3-dimethylaminopropionimidate dihydrochloride (105.0 g., 0.52 mole) and absolute ethanol was added dropwise triethylamine (78 ml., 0.57 mole) at 2–4° with

rapid stirring, under an atmosphere of dry N₂. Then formic acid hydrazide (35.0 g., 0.58 mole) was added at 4–7° during 1 min. The temperature was held at 5–7° for 15 min., and allowed to rise gradually to 13° over 25 min., and finally to 23° over 2.5 hr. The mixture was cooled to 10°, and the solid product was collected and washed with ethanol and ether. Recrystallization from 95% ethanol (300 ml.) gave white crystals.

3-Dimethylaminopropionimidic Acid Hydrazide Dihydrochloride, IIIe—To *N*-formamido-3-dimethylaminopropionamidine hydrochloride (90.0 g., 0.46 mole) was added 270 ml. of a cold solution of dry hydrogen chloride in methanol. The reaction mixture was allowed to warm to room temperature over 40 min. The solid product was collected, and washed with ethanol and ether. Recrystallization from methanol (300 ml.) gave white crystals.

Pharmacology

Volume changes in the nasal cavity were measured utilizing a modification of the method of Jackson (6). Mongrel dogs were anesthetized with sodium pentobarbital, 35 mg./kg., i.v., and a

tracheotomy performed. A femoral artery was cannulated for blood pressure recording. A 22.9-cm. (9-in.) metal rod fitted with a small rubber ball was passed into the dog's mouth to the soft palate so that the ball pressed against the wall of the nasopharynx. A glass nose cannula was then inserted into a nostril, and a clamp was applied to hold the cannula in place and to seal the other nostril. The cannula was connected to a Grass PT-5A volumetric low pressure transducer, and the volume (pressure) changes of this cavity were measured. In some experiments only blood pressure was monitored. All compounds were administered intravenously

Gas Chromatographic Determination of Chlorphenesin in Plasma

J. F. DOUGLAS, J. A. STOCKAGE*, and N. B. SMITH

Abstract □ A procedure is described for the determination of chlorphenesin in plasma. Chlorphenesin is extracted from plasma with chloroform, reacted with bis-(trimethylsilyl)-acetamide, and the silylated derivative is measured quantitatively by gas chromatography. The technique is reproducible and accurate in the range of 1-10 mcg./ml. Dibutyl phthalate is used as internal standard for quantitation by the relative peak height method.

Keyphrases □ Chlorphenesin in plasma—determination □ Plasma, analysis—chlorphenesin □ GLC—analysis □ Dibutyl phthalate—internal standard

Chlorphenesin (3-*p*-chlorophenoxy-1,2-propanediol) has been shown to suppress immunological response in a number of animal systems (1-3) and to inhibit the

release of histamine from sensitized human leucocytes by ragweed antigen (4). Although chlorphenesin has been known since 1949 and a number of procedures have been described in the literature for the analysis of chlorphenesin (5, 6) or chlorphenesin carbamate (7), none are sufficiently sensitive to measure the presence of chlorphenesin in biological fluids after therapeutic doses. Procedures for the quantitative analysis in plasma of a closely related compound, mephensin [3-(*o*-tolylloxy)-1,2-propanediol], have been reported by Titus *et al.* (8) and by Wyngaarden *et al.* (9). However, these analyses depend upon diazotization or nitration of mephensin at the *para* position of the phenol ring and are not applicable to chlorphenesin which contains a chlorine atom at this location.

tracheotomy performed. A femoral artery was cannulated for blood pressure recording. A 22.9-cm. (9-in.) metal rod fitted with a small rubber ball was passed into the dog's mouth to the soft palate so that the ball pressed against the wall of the nasopharynx. A glass nose cannula was then inserted into a nostril, and a clamp was applied to hold the cannula in place and to seal the other nostril. The cannula was connected to a Grass PT-5A volumetric low pressure transducer, and the volume (pressure) changes of this cavity were measured. In some experiments only blood pressure was monitored. All compounds were administered intravenously

Gas Chromatographic Determination of Chlorphenesin in Plasma

J. F. DOUGLAS, J. A. STOCKAGE*, and N. B. SMITH

Abstract □ A procedure is described for the determination of chlorphenesin in plasma. Chlorphenesin is extracted from plasma with chloroform, reacted with bis-(trimethylsilyl)-acetamide, and the silylated derivative is measured quantitatively by gas chromatography. The technique is reproducible and accurate in the range of 1-10 mcg./ml. Dibutyl phthalate is used as internal standard for quantitation by the relative peak height method.

Keyphrases □ Chlorphenesin in plasma—determination □ Plasma, analysis—chlorphenesin □ GLC—analysis □ Dibutyl phthalate—internal standard

Chlorphenesin (3-*p*-chlorophenoxy-1,2-propanediol) has been shown to suppress immunological response in a number of animal systems (1-3) and to inhibit the

release of histamine from sensitized human leucocytes by ragweed antigen (4). Although chlorphenesin has been known since 1949 and a number of procedures have been described in the literature for the analysis of chlorphenesin (5, 6) or chlorphenesin carbamate (7), none are sufficiently sensitive to measure the presence of chlorphenesin in biological fluids after therapeutic doses. Procedures for the quantitative analysis in plasma of a closely related compound, mephensin [3-(*o*-tolylloxy)-1,2-propanediol], have been reported by Titus *et al.* (8) and by Wyngaarden *et al.* (9). However, these analyses depend upon diazotization or nitration of mephensin at the *para* position of the phenol ring and are not applicable to chlorphenesin which contains a chlorine atom at this location.

Figure 1—The relationship between relative peak height and concentration of chlorphenesin in plasma.

This manuscript describes a procedure for the quantitative determination of chlorphenesin in plasma.

EXPERIMENTAL

Equipment and Reagents—A F and M model 402 dual column gas chromatograph equipped with a hydrogen flame ionization detector and a 1-mv. Minneapolis-Honeywell recorder were employed. The chromatographic columns used were 91.4-cm. \times 0.635-cm. (3-ft. \times 0.25-in.) glass tubes packed with 5.0% DC200 on 80–100 mesh diatomaceous earth¹. The instrument settings were as follows: temperature-column, 170°; injection port, 275°; detector block, 230°. Gas flow rates—hydrogen, 60 ml./min; helium (carrier gas), 38 ml./min; oxygen, 70 ml./min. Sensitivity settings were range 10 with an attenuation factor of 8 \times . The reagents were redistilled

chloroform, dibutyl phthalate (Eastman), and bis-(trimethylsilyl)-acetamide (Applied Science).

Procedure—Plasma, 0.5 ml., was diluted with 0.5 ml. of saline and the fluid was thoroughly shaken with 0.5 ml. of redistilled chloroform. Following centrifugation, 0.2 ml. of the chloroform layer was transferred to a small centrifuge tube and treated with 20 μ l. of bis-(trimethylsilyl)acetamide for 1 hr. at room temperature. The reaction mixture was evaporated to dryness in a stream of nitrogen, and the residue was taken up in 20 μ l. of redistilled chloroform containing 100 mcg./ml. of dibutyl phthalate. This chloroform solution (2.6 μ l.) was injected into the gas chromatograph, and the concentration of chlorphenesin was determined by the relative peak height method using dibutyl phthalate as internal standard.

RESULTS AND DISCUSSION

It was necessary to convert chlorphenesin to a suitable derivative for gas chromatographic analysis since its chromatogram showed two peaks. Chlorphenesin can be quantitated gas chromatographically when relative peak height is used as an index of concentration since a linear relationship exists between relative peak height and drug concentration (trimethylsilyl ether derivative of chlorphenesin) in the range of 1–10 mcg./ml. of plasma (Fig. 1). The reproducibility of the procedure is indicated by the standard error of the triplicate determinations shown in Fig. 1.

The extraction procedure effectively separates chlorphenesin from normal interfering plasma constituents since determinations in normal human plasma give little or no blank (<0.5 mcg./ml.). It was also established that the known major metabolites of chlorphenesin, *p*-chlorophenoxyacetic acid and *p*-chlorophenoxyacetic acid (10), do not interfere in the assay procedure.

Determination of Trace Amounts of Water in Glycerides by Near-Infrared Spectroscopy

R. J. WARREN, J. E. ZAREMBO, C. W. CHONG, and M. J. ROBINSON

Abstract □ A rapid accurate method for determining trace amounts of water in glycerides is presented. The method is based on the measurement of the combination band for water which occurs at $1.896\ \mu$ in chloroform solution. In addition to the advantage of making it possible to work at low levels, the method is specific for water and free of interferences due to other OH groups. Several commercial samples of glyceryl mono- and distearates were analyzed by this method, and showed water contents of 0.4 to 1.2%.

Keyphrases □ Glycerides—water determination □ Water determination—trace amounts □ Near IR spectrophotometry—analysis

During the authors' investigation of methods for the analysis of mono-, di-, and triglycerides, it became necessary to develop a rapid and accurate method for the analysis of trace amounts of water. Chemical methods, such as the Karl Fischer technique, were tedious, time-consuming, and/or unsatisfactory for these particular needs. Solution spectra on conventional IR instruments were rejected because of the many overlapping absorption bands from the various —OH groups in the glyceride molecule itself. Near-IR spectroscopy was investigated to determine the feasibility of using this technique to determine the OH absorption of water in the presence of OH groups on the glyceride molecule. It was found that OH groups in different molecular environment, such as water or glyceride —OH's, do behave differently, and are amenable to investigation by near-IR spectrophotometry. This has also been shown by others (1). The absorption of water OH, attributable to a combination band of the OH group (2, 3), occurs at $1.896\ \mu$ in chloroform solution. The various OH groups of the glyceride molecule are found in the vicinity of 1.430 and $2.100\ \mu$ (4). This leaves the area of water absorption free from OH absorptions related to the materials under investigation, and presents us with a method specific for water and free from interfering substances.

EXPERIMENTAL

Glycerides were obtained from the Kessler Chemical Company. The glycerides are commercial samples consisting of a mixture of mono-, di- and tripalmitate, stearate and glyceryl esters. There are also traces of free glycerol, stearic, palmitic, myristic, and other unknown acids in trace amounts. Duplicate analyses of these samples, made using the proposed method, showed 1.2, 1.4, 0.4, 0.5, and 0.8% water.

The near-IR spectra were obtained on a Cary model 14 recording spectrophotometer, using matched fused silica cells of infrared quality having a light path of 5 cm. Chloroform was used as a solvent and as solvent compensator in the reference beam.

RESULTS AND DISCUSSION

The method for the determination of water in glycerides is as follows: transfer about 2.5 g. of sample, accurately weighed, to a

Figure 1—Spectra obtained from calibration curve (see text for calculation).

50-ml. volumetric flask; dissolve in, and dilute to volume with chloroform. Record the absorption spectrum of this solution *versus* chloroform in 5-cm. cells from 1.930 to $1.850\ \mu$. Measure the difference (ΔA) between the absorbances at 1.896 and $1.920\ \mu$. From a calibration chart of standards, determine the percent of water present.

$$\text{calculation: } \frac{\text{wt. of water present (from chart)} \times 100}{\text{wt. of glyceride sample}} = \% \text{ water}$$

The calibration or standard curve is prepared as follows: dissolve known amounts of water in 50 ml. of chloroform, and run the absorption spectrum on the Cary Model 14 in 5-cm. cells from 1.930 to $1.850\ \mu$. Measure the difference (ΔA) between the absorbances at 1.896 and $1.920\ \mu$. Plot the absorbance *versus* concentration values to prepare a calibration curve.

The spectra obtained from the calibration curve are shown in Fig. 1. Plotting these values against the concentration or percent water produces the calibration or working plot shown in Fig. 2.

This method has the advantages of being rapid, accurate for small

Figure 2—Calibration or working plot obtained from the values in Fig. 1 plotted against concentration.

amounts of water, and free from interferences. In addition, it makes it possible to determine water down to the level of 0.05% based on an initial sample weight of 2.5 g.

Torizuka *et al.* (1) while investigating the dynamics of protein metabolism in man, found that anabolic steroids such as 19-nor-testosterone phenylpropionate and 4-chlorotestosterone acetate, did not inhibit degradation of protein but exclusively stimulated its synthesis. The primary site of action is possibly at the nuclear level for the production of RNA's essential for protein biosynthesis (2). There are a large number of theoretical possibilities by which an androgen molecule can stimulate this RNA production. One of them suggested by Hübener (3) would be to inhibit a repressor aimed at an operator gene and controlled by a regulator gene. The interaction between androgen molecule and protein has been reported by Westphal (4) and that this interaction is on the β -face of the steroid molecule was suggested by Wolff *et al.* (5).

This work was initiated to investigate this hypothesis and to see if creation of high electron densities in Ring A and D would impart or enhance biological

response. 6 α , 16 α -Dimethylprogesterone was chosen for these molecular modifications. Treatment of I with pyrrolidine gave the enamine II which could be converted into 20-oximino Compound III with hydroxylamine hydrochloride. Beckman rearrangement of III using thionyl chloride, followed by acid hydrolysis gave the desired 17 β -acetamido-6 α , 16 α -dimethylandro-4-en-3-one (IV). Compound I when subjected to Schmidt rearrangement gave 3-aza-17 β -acetamido-6 α , 16 α -dimethylandro-4-en-4-one (V). The spectral data confirmed all the structural assignments. Compounds IV and V were subjected to Herschberger androgen-anabolic assay (6) and judged inactive (see Scheme I).

EXPERIMENTAL

All melting points were taken on a Fisher-Johns melting point apparatus and are uncorrected. The UV and IR data were obtained on Cary Model 11 and Beckman IR-5 spectrophotometers, respectively. Elemental analyses were performed by Midwest Micro-lab, Inc., Indianapolis, Ind.

3-[1-Pyrrolidinyl]-6-16 α -dimethylpregn-3,5-dien-20-one (II)—Two grams of I was dissolved in 10 ml. of MeOH with heat and treated with 10 drops of pyrrolidine. Heating was continued for an additional 5 min. when copious precipitates of enamine separated. The precipitates were collected by filtration, washed several times with MeOH and dried to give 1.8 g. (77%) of II, m.p. 137–139°; $\lambda_{\text{max}}^{\text{EtOH}}$ 278 m μ ; $\lambda_{\text{max}}^{\text{KBr}}$ 5.88, 6.1, and 6.23 μ .

Molecular Orbital Conformation of Oxotremorine and a Comparison With the Muscarinic Pattern

LEMONT B. KIER

Abstract □ The conformational preference of oxotremorine has been calculated using extended Hückel molecular orbital theory. The molecule was found to be comparatively free in regard to the relationship of the two rings and the rotation of the lactone ring. The energy-permitted stereochemistry allows the quaternary nitrogen, the triple bond, and the carbonyl oxygen to assume the same relationship as previously calculated for the muscarinic pharmacophore, if the triple bond in oxotremorine is assumed to mimic the electronic character of the ether oxygen in the muscarinics.

Keyphrases □ Oxotremorine—molecular orbital conformation □ Molecular orbital conformation, oxotremorine—muscarinic activity □ Conformational molecular preference—oxotremorine

A current hypothesis on the peripheral and central actions of tremorine (I) and its metabolite oxotremorine (II) (Scheme I) is that the latter molecule is a muscarinic

Scheme I

agonist. The peripheral action of oxotremorine, studied by Cho *et al.* (1) leaves little doubt that this compound is a peripheral muscarinic agent equal in potency to acetylcholine. The effects can be blocked by pretreatment with anticholinergic drugs like methanthelinium or atropine bromides. In animals so pretreated, a tremor, ataxia, and spasticity still persist. Atropine sulfate blocks these effects and so it is presumed that the tremor effect is due to activation of muscarinic receptors in the central nervous system (2).

Studies by Lundgren and Malmberg (3) suggest that oxotremorine-induced tremors are not due to direct action in the CNS, but are due to the ability of the drug to induce an increased biosynthesis of acetylcholine in the CNS. Oxotremorine, however, fails to stimulate *in vitro* systems containing choline acetylase. It has been observed that there is a rise in acetylcholine level which roughly parallels the oxotremorine-induced

Figure 1—Proposed steric relationship of essential features in oxotremorine and muscarine (6).

Figure 2—Calculated relationship of pyrrolidine ring and triple bond in oxotremorine.

tremor duration. Recent detailed studies by Cox and Potkanjak (4) on this comparative time course show a lack of parallel behavior between tremor manifestation and acetylcholine increase.

Since oxotremorine may be a CNS muscarinic agonist, it is of interest to contemplate how the structure of this molecule compares with known muscarinic agents. Cho *et al.* (1) have commented on the structural dissimilarity of oxotremorine to known muscarinic agents and suggested that oxotremorine was highly active owing to a process at the receptor related to Koshland's (5) induced-fit theory. However, Bebbington *et al.* (6) have compared molecular models of oxotremorine with muscarine and noted that the two could conceivably assume a common geometry, in which the same pattern of charged atoms would prevail. This required the invoking of the acetylenic bond as a negative site of binding in the oxotremorine molecule, mimicking the ether oxygen in muscarine. A plausible explanation for the possible direct receptor action of oxotremorine then centers on the ability of the molecule to assume a favorable conformation, mimicking the muscarinic pharmacophore, Fig. 1.

In a previous study, the author calculated the conformations of three potent muscarinic agents using a molecular orbital theory in which overlap integrals and nonbonded interactions are treated for all valence

Figure 3—Calculated relationship of the two rings in oxotremorine.

electrons (7). The method, known as extended Hückel theory, generates a total energy as a function of geometry; hence, conformation preference can be assessed by energy minimization (8). A common pattern of charged atoms or groups was calculated for acetyl-

Figure 4—Calculated relationship of the lactone ring and the triple bond in oxotremorine.

Figure 5—Calculated energy-permitted relationship of essential features in oxotremorine. Shaded area shows region which oxygen atom may occupy relative to the other molecular features.

choline, muscarine, and muscarone. The author has predicted that this pattern is a reasonable working model of the muscarinic pharmacophore.

In the present study, the author undertook molecular orbital calculations on the oxotremorine molecule, to determine its preferred conformation and to see whether a pattern of charged atoms or groups corresponded to the previously calculated muscarinic pharmacophore.

EXPERIMENTAL

The molecule was calculated as the protonated salt. Standard bond lengths and angles were used according to Pople and Gordon (9). The Coulomb integrals and Slater exponents were those previously employed by Hoffmann (8) and the author (7). In comparing the energy *versus* geometry profiles, the preferred conformation was taken to be the geometry of lowest energy. All geometries within 1 kcal. or less of this energy minimum were considered to be equally preferred.

RESULTS AND DISCUSSION

The results of the calculations show that the molecule can exist in a variety of preferred structures. The two rings exhibit considerable independence with respect to their conformational preferences. When the distance between any two first-row atoms on opposite rings exceeds 4 Å., the two rings are not influential in respect to their preferred conformations. We have justified the assumption that distant atoms do not influence conformation in a recent quantum mechanical discussion (10). This assumption has been used by others (11).

The pyrrolidine ring is symmetrically disposed relative to the triple bond, Fig. 2. The two rings can assume any conformation except that which eclipses their methylene connecting groups, Fig. 3. The lactone ring can assume two zones of conformational preference to within 60° of coplanarity with the acetylenic bond, Fig. 4. The distance separating the pyrrolidine protonated nitrogen from the center of the triple bond is 3.0 Å. The distance between the carbonyl oxygen and the protonated nitrogen ranges from 4.3–7.2

Figure 6—Calculated muscarinic pharmacophore based on conformations calculated for acetylcholine, muscarine, and muscarone (7).

Å., owing to the variation possible in conformational preference. The carbonyl oxygen distance from the center of the triple bond ranges from 3.1–4.2 Å.

An allowed pattern of atoms can thus be drawn for oxotremorine, Fig. 5. This calculated energy-allowed pattern clearly mirrors the muscarinic pattern, previously proposed, Fig. 6.

It can be concluded that oxotremorine can assume a muscarinic pharmacophore, within its structure, on the basis of theoretical calculations of its preferred conformations. Although conclusive pharmacological evidence that would brand oxotremorine as a central muscarinic agonist is still lacking, these studies implicate the feasibility of this mechanism.

Antiradiation Compounds XIII: 1-(Dithioacetic Acid)-Pyridinium Betaines

WILLIAM O. FOYE, YOUNG JA CHO, and KYUNG HEE OH

Abstract □ Active mono-*S*-alkyl esters prepared from 1-(dithioacetic acid)-pyridinium betaine (III) were found to be sufficiently stable for screening as radiation-protective agents, and *e*-withdrawing substituents in the pyridine ring gave stable betaines. Reaction of the methyl ester of III with phenacyl bromide and alkali resulted in *S*-alkylation to give a ketene mercaptal betaine (VIII). Both the allyl and *p*-nitrobenzyl esters of 1-(dithioacetic acid)-pyridinium halides were radiation-protective in mice, and betaines with substituents in the pyridine ring were radiation-protective in a bacterial test.

Keyphrases □ Antiradiation compounds—synthesis □ 1-(Dithioacetic acid)-pyridinium betaines—synthesis □ Pharmacological screening—antiradiation compounds □ IR spectrophotometry—structure

Amino and guanidino zwitterions containing the thiosulfate (1), phosphorothioate (2), and trithiocarbonate (3) groups, as well as other zwitterionic structures (4) which contain the β -mercaptoethylamine moiety have shown appreciable radiation-protective abilities in mice. α -Acetamidinium thiosulfate zwitterions (5) have also shown good radiation-protective properties. It appeared likely, therefore, that other zwitterions containing, or giving rise to, a thiolate anion should be radiation-protective. Dithioacetic acid pyridinium betaines, obtained from the reaction of carbon disulfide and pyridinium ylids, appeared to have the necessary structural requirements for protective activity in a charged nitrogen and a thiolate anion, and were therefore investigated for possible radiation-protective properties.

Pyridinium betaines are compounds, termed by Kröhnke (6), which contain a negatively charged carbon, oxygen, or sulfur adjacent to, or at greater distance from, the positively charged nitrogen; the term ylid is now generally used where the charges are on adjacent atoms. When phenacylpyridinium bromide is treated with alkali, a red solution of the ylid (I) results. Reaction with carbon disulfide gives the α -dithiocarboxylate zwitterion (II) which decomposes to the dithioacetic acid betaine (III) in methanolic alkali (6). This compound, although unstable, can be isolated, and remains stable long enough for derivatives to be prepared. Conversion to the active allyl and *p*-nitrobenzyl esters (IV) was carried out, and compounds of sufficient stability for antiradiation screening were obtained.

Reaction of the dithioacetic acid betaine (III) with bromoethylamine hydrobromide did not give the desired ester; also, no reaction with phenyl halides or

Å., owing to the variation possible in conformational preference. The carbonyl oxygen distance from the center of the triple bond ranges from 3.1–4.2 Å.

An allowed pattern of atoms can thus be drawn for oxotremorine, Fig. 5. This calculated energy-allowed pattern clearly mirrors the muscarinic pattern, previously proposed, Fig. 6.

It can be concluded that oxotremorine can assume a muscarinic pharmacophore, within its structure, on the basis of theoretical calculations of its preferred conformations. Although conclusive pharmacological evidence that would brand oxotremorine as a central muscarinic agonist is still lacking, these studies implicate the feasibility of this mechanism.

Antiradiation Compounds XIII: 1-(Dithioacetic Acid)-Pyridinium Betaines

WILLIAM O. FOYE, YOUNG JA CHO, and KYUNG HEE OH

Abstract □ Active mono-*S*-alkyl esters prepared from 1-(dithioacetic acid)-pyridinium betaine (III) were found to be sufficiently stable for screening as radiation-protective agents, and *e*-withdrawing substituents in the pyridine ring gave stable betaines. Reaction of the methyl ester of III with phenacyl bromide and alkali resulted in *S*-alkylation to give a ketene mercaptal betaine (VIII). Both the allyl and *p*-nitrobenzyl esters of 1-(dithioacetic acid)-pyridinium halides were radiation-protective in mice, and betaines with substituents in the pyridine ring were radiation-protective in a bacterial test.

Keyphrases □ Antiradiation compounds—synthesis □ 1-(Dithioacetic acid)-pyridinium betaines—synthesis □ Pharmacological screening—antiradiation compounds □ IR spectrophotometry—structure

Amino and guanidino zwitterions containing the thiosulfate (1), phosphorothioate (2), and trithiocarbonate (3) groups, as well as other zwitterionic structures (4) which contain the β -mercaptoethylamine moiety have shown appreciable radiation-protective abilities in mice. α -Acetamidinium thiosulfate zwitterions (5) have also shown good radiation-protective properties. It appeared likely, therefore, that other zwitterions containing, or giving rise to, a thiolate anion should be radiation-protective. Dithioacetic acid pyridinium betaines, obtained from the reaction of carbon disulfide and pyridinium ylids, appeared to have the necessary structural requirements for protective activity in a charged nitrogen and a thiolate anion, and were therefore investigated for possible radiation-protective properties.

Pyridinium betaines are compounds, termed by Kröhnke (6), which contain a negatively charged carbon, oxygen, or sulfur adjacent to, or at greater distance from, the positively charged nitrogen; the term ylid is now generally used where the charges are on adjacent atoms. When phenacylpyridinium bromide is treated with alkali, a red solution of the ylid (I) results. Reaction with carbon disulfide gives the α -dithiocarboxylate zwitterion (II) which decomposes to the dithioacetic acid betaine (III) in methanolic alkali (6). This compound, although unstable, can be isolated, and remains stable long enough for derivatives to be prepared. Conversion to the active allyl and *p*-nitrobenzyl esters (IV) was carried out, and compounds of sufficient stability for antiradiation screening were obtained.

Reaction of the dithioacetic acid betaine (III) with bromoethylamine hydrobromide did not give the desired ester; also, no reaction with phenyl halides or

2,4-dinitrochlorobenzene took place. Kröhnke *et al.* (7) have found that the methyl ester of dithioacetic acid pyridinium betaine exists in methanolic alkali as both the carbon ylid (V) and the sulfur ylid (VI), and that alkyl halides react preferentially with the thiolate anion. To determine whether a di-S-alkyl derivative would form preferentially to an S-alkyl-C-alkyl derivative, reaction of the methyl ester (IV) with phenacyl bromide was carried out. The product, according to the IR spectrum, was the ketene mercaptal, 2-methylthio-2-phenacylthio-1-vinylpyridinium bromide (VII). In the IR, both C=O and C=C absorption were found; no absorption due to C=C would be expected in the C-alkylation product of IV.

Treatment of VII with methanolic alkali gave yellow crystals of a low-melting, unstable compound from which HBr had been lost. This compound still revealed IR absorption due to both C=O and C=C, as well as enol, and was therefore concluded to be the betaine (VIII). Similar treatment of the phenacyl ester of 1-(dithioacetic acid)-pyridinium bromide (IX) by Kröhnke (6) led to ring-closure to give a stable, high-melting dihydrothiophene betaine (X), which was ultimately converted to a thiophene. Compound X was prepared, and its IR spectrum showed no evidence of either C=O or C=C. Similar attempts to convert VIII to a dihydrothiophene resulted in decomposition.

Besides making modifications in the dithioacetic acid portion of the molecule, the authors also desired to learn the effects that *e*-withdrawing substituents in the pyridine ring might have both on stability of the betaines and their radiation-protective ability. Accordingly, 1-phenacyl and 1-*p*-nitrobenzyl derivatives of nicotinamide, ethyl nicotinate, and ethyl isonicotinate were prepared. Reaction of 1-phenacyl-3-carbamylpyridinium bromide with carbon disulfide and alkali gave at once a red solution from which the dithioacetic acid betaine (XI) was isolated. The compound could not be recrystallized without decomposition, but it was stable after being dried.

Treatment of 1-*p*-nitrobenzyl-3-carbamylpyridinium chloride with carbon disulfide in alkali gave a red solution only slowly. Isolation of the product and elemental

analysis showed that the *p*-nitrophenyl group had not been removed; the α -dithiocarboxylic acid betaine XII was obtained.

Similarly, reaction of both 1-phenacyl- and 1-*p*-nitrobenzyl-3-carbethoxypyridinium halides with carbon disulfide and alkali gave the α -dithiocarboxylic acid betaines without loss of the benzoyl or *p*-nitrophenyl groups. The same result was obtained with the 1-phenacyl- and 1-*p*-nitrobenzyl-4-carbethoxypyridinium halides; in these cases, very poor analyses were obtained for the products. None of these compounds could be recrystallized without decomposition, but they were relatively stable after drying.

RADIATION-PROTECTIVE PROPERTIES¹

Tests were carried out in mice *versus* 825r (X-rays) with an observation period of 30 days. The *p*-nitrobenzyl ester (IV) of dithioacetic acid pyridinium chloride gave fair protection (33%), and the allyl ester (IV) provided slight protection (17%) to mice. In anti-radiation testing on bacteria, 1-(dithioacetic acid)-3-carbamylpyridinium betaine (XI) gave good protection (>45%), and the α -*p*-nitrophenyl-3-carbamyl (XII), α -benzoyl-3-carbethoxy (XIII), and α -*p*-nitrophenyl-4-carbethoxy pyridinium dithioacetic acid betaines gave poor protection (1–24%).

EXPERIMENTAL

Analyses for carbon, hydrogen, and nitrogen were done by Weiler and Strauss, Oxford, England. Sulfur analyses were done by Parr bomb peroxide fusion. Melting points were taken on a Mel-Temp apparatus and are corrected. IR absorption spectra were obtained with a Perkin-Elmer model 137B spectrometer.

1-(Dithioacetic acid)-pyridinium Betaine (III)—Phenacylpyridinium bromide (6) (28 g., 0.10 mole) was dissolved in 120 ml. of methanol, and 8 ml. of carbon disulfide (0.12 mole) was added at room temperature, followed by 60 ml. of 2 *N* methanolic sodium hydroxide. After 2 hr., the orange crystals were filtered and washed with water. Recrystallization was accomplished from water not over 60°, giving 15.3 g. (90%), m.p. 110–112° (lit. m.p. 110°) (6). The product decomposed after standing in a desiccator for a day.

Anal.—Calcd. for $\text{C}_7\text{H}_7\text{NS}_2$: S, 37.87. Found: S, 38.05.

1-(Dithioacetic acid *p*-nitrobenzyl ester)-pyridinium Chloride (IV)—*p*-Nitrobenzyl chloride (1.71 g., 0.01 mole) was dissolved in dimethylformamide (20 ml.), and 1-(dithioacetic acid)-pyridinium betaine (1.57 g., 0.009 mole) was added gradually with stirring. A red solution resulted from which yellow crystals were separated and washed with ether. The yield was 1.03 g. (37%); m.p. 167–168°.

Anal.—Calcd. for $\text{C}_{14}\text{H}_{13}\text{ClN}_2\text{O}_2\text{S}_2$: C, 49.34; H, 3.80; N, 8.25; S, 18.82. Found: C, 48.66; H, 3.89; N, 7.99; S, 19.25.

1-(Dithioacetic acid allyl ester)-pyridinium Bromide (IV)—1-(Dithioacetic acid)-pyridinium betaine (0.85 g., 0.005 mole) was added to a solution of chloroform (5 ml.) and allyl bromide (2 ml., 0.01 mole). Warming on a water bath gave a red solution, and addition of ether

¹ Antiradiation screening of some of the compounds described has been carried out at the Walter Reed Army Institute of Research, and results have been reported through the courtesy of Drs. D. P. Jacobus and T. R. Sweeney.

produced yellow crystals, which were filtered and washed with ether. The yield was 1.0 g. (71%); m.p. 107–111°.

Anal.—Calcd. for $C_{10}H_{12}BrN_2S_2$: C, 41.38; H, 4.40; N, 4.82; S, 22.10. Found: C, 40.92; H, 4.46; N, 4.67; S, 22.68.

1-(2-Methylthio-2-phenacylthio-1-vinyl)-pyridinium Bromide (VII)—1-(Dithioacetic acid methyl ester)-pyridinium betaine (6) (1.83 g., 0.01 mole) was dissolved in 5 ml. of chloroform, and phenacyl bromide (2.0 g., 0.01 mole) was added. A yellow solution resulted, and addition of ether and refrigeration for a few days produced yellow crystals; 3.08 g. (81%), m.p. 90–95°; IR (KBr) 1675 ($C=O$), 1630 ($C=C$), 1600 (doublet, ring stretch) cm^{-1} .

1-(2-Methylthio-2-phenacylthio-1-vinyl)-pyridinium Betaine (VIII)—To a solution of the previous product (3.82 g., 0.01 mole) in 5 ml. of methanol cooled by an ice bath was added 2 *N* methanolic sodium hydroxide. After the solution was refrigerated for 1 hr., yellow crystals appeared and were filtered and washed with water. Recrystallization from methanol gave 2.35 g. (75%), m.p. 80–83°; IR (mineral oil) 1675 ($C=O$), 1615 ($C=C$), 1575 (enol) cm^{-1} .

Anal.—Calcd. for $C_{16}H_{18}NOS_2$: C, 63.78; H, 4.19; N, 4.64; S, 21.28. Found: C, 63.32; H, 4.67; N, 4.24; S, 21.03.

1-Phenacyl-3-carbethoxypyridinium Bromide—A solution of ethyl nicotinate (8) (6.53 g., 0.044 mole), phenacyl bromide (7.86 g., 0.044 mole), and methanol (60 ml.) was refluxed for 16 hr. The solvent was removed by a stream of air, and the residue was washed with ether. Recrystallization from ether–methanol gave 14 g. (93%); m.p. 181–182°.

Anal.—Calcd. for $C_{16}H_{18}BrNO_3$: C, 54.87; H, 4.61; N, 4.00. Found: C, 54.61; H, 4.65; N, 3.62.

1-(p-Nitrobenzyl)-3-carbethoxypyridinium Chloride—A solution of ethyl nicotinate (8) (3.02 g., 0.02 mole), *p*-nitrobenzyl chloride (3.24 g., 0.02 mole), and methanol (30 ml.) was refluxed for 35 hr. Addition of ether produced yellow crystals which were collected and recrystallized from ether–methanol, giving 2.15 g. (41%); m.p. 96–97°.

Anal.—Calcd. for $C_{15}H_{15}ClN_2O_4$: C, 55.82; H, 4.68; N, 8.68. Found: C, 55.66; H, 4.95; N, 8.85.

1-Phenacyl-4-carbethoxypyridinium Bromide—A solution of ethyl isonicotinate (8) (7.55 g., 0.05 mole), phenacyl bromide (9.95 g., 0.05 mole), and methanol (95 ml.) was refluxed for 5 hr. The solvent was evaporated, and the residue was washed with ether. The product was recrystallized from methanol, giving 15.1 g. (85%) of yellow crystals, m.p. 183.5–185°.

Anal.—Calcd. for $C_{16}H_{18}BrNO_3$: C, 54.87; H, 4.61; N, 4.00. Found: C, 54.60; H, 4.51; N, 4.12.

1-(p-Nitrobenzyl)-4-carbethoxypyridinium Chloride—A solution of ethyl isonicotinate (8) (7.55 g., 0.05 mole), *p*-nitrobenzyl chloride (8.56 g., 0.05 mole), and methanol (25 ml.) was refluxed for 24 hr. The solvent was removed by a stream of air, and the residue was washed with ether. Recrystallization from ether–methanol gave 8.0 g. (49%); m.p. 173.5–174°.

Anal.—Calcd. for $C_{15}H_{15}ClN_2O_4$: C, 55.82; H, 4.68; N, 8.68. Found: C, 55.32; H, 4.75; N, 8.82.

1-(Dithioacetic acid)-3-carbamylpyridinium Betaine (XI)—1-Phenacyl-3-carbamylpyridinium bromide (9) (11 g., 0.034 mole) dissolved in 1 l. of methanol was treated with carbon disulfide (2.6 g., 0.34 mole) dissolved in 4 ml. of methanol, and the solution was stirred at room temperature for 25 min. It was then treated with 20 ml. of 2 *N* NaOH in methanol, stirred at 5–10° for 25 min., and

stored over dry ice overnight. The orange precipitate was filtered, washed with cold ether, and dried *in vacuo*. The yield was 2.53 g. (35%); m.p. 104.5–107°.

Anal.—Calcd. for $C_8H_8N_2OS_2$: C, 45.26; H, 3.79; N, 13.19. Found: C, 45.36; H, 3.92; N, 12.95.

1-[α -(p-Nitrophenyl)dithioacetic acid]-3-carbamylpyridinium Betaine (XII)—1-(*p*-Nitrobenzyl)-3-carbamylpyridinium chloride (9) (2.93 g., 0.01 mole) dissolved in 250 ml. of methanol was treated with carbon disulfide (1 g., 0.013 mole) dissolved in 5 ml. of methanol. Addition of 6 ml. of 2 *N* NaOH in methanol gave a red solution which deposited greenish crystals when stored over dry ice. A yield of 2.19 g. (67%) was obtained; m.p. 115–117°.

Anal.—Calcd. for $C_{14}H_{11}N_3O_5S_2$: C, 50.43; H, 3.32; N, 12.63. Found: C, 49.97; H, 3.44; N, 12.39.

1-(α -Benzoyldithioacetic acid)-3-carbethoxypyridinium Betaine (XIII)—To 1-phenacyl-3-carbethoxypyridinium bromide (3.5 g., 0.01 mole) in 32 ml. of methanol was added carbon disulfide (1 g., 0.013 mole) in 5 ml. of methanol, and the solution was stirred for 15 min. Addition of 6 ml. of 2 *N* NaOH in methanol gave a red solution from which a black precipitate appeared after several hours at room temperature. The product was collected and washed with cold ether, giving 0.77 g. (29%) of red-black solid; m.p. 120–124°.

Anal.—Calcd. for $C_{17}H_{15}NO_3S_2$: C, 59.11; H, 4.37; N, 4.06. Found: C, 59.84; H, 3.99; N, 4.23.

1-[α -(p-Nitrophenyl)dithioacetic acid]-3-carbethoxypyridinium Betaine—1-*p*-Nitrobenzyl-3-carbethoxypyridinium chloride (2 g., 0.006 mole) in 10 ml. of methanol was treated with carbon disulfide (0.5 g., 0.006 mole) in 2 ml. of methanol, and the solution was refluxed 3 hr. After addition of 2 *N* NaOH in methanol (3.6 ml.), a red precipitate appeared, which was filtered and dried. The yield was 1.7 g. (75%); m.p. 125–126°.

Anal.—Calcd. for $C_{16}H_{14}N_2O_4S_2$: C, 53.02; H, 3.95; N, 7.74. Found: C, 53.17; H, 4.53; N, 8.37.

Trace Solvent Contamination as Determined by Surface Pressure Measurement

JOEL L. ZATZ

Abstract ☐ Amphipathic contaminants, present in organic solvents, were detected by spreading the solvent on water and measuring its surface pressure. The method is quite sensitive and, in many cases, is superior to conventional techniques.

Keyphrases ☐ Solvent contamination, trace—determination ☐ Contaminants in solvents—surface pressure effect ☐ Surface pressure measurements—solvent contamination determination

A number of instances have been reported in which the presence of small quantities of impurities caused a significant change in the properties of the system. For example, the stability of suspensions of channel black in toluene was increased considerably by the presence of traces of moisture in the solvent (1). Contact angle hysteresis in experiments on wetting of solids by liquids has been ascribed to the presence of impurities (2). In studies of adsorption by solids from the liquid phase a high order of solvent purity is necessary. Traces of contaminants may be preferentially adsorbed, leading to spurious results (3). Similar considerations apply to work on monolayers. Surface-active impurities will be concentrated at the interface resulting in a considerable error. Grease from the fingers may represent an important source of contamination (4).

Spectroscopy and chromatography are often used to check the purity of solvents. Both of these methods are capable of detecting small concentrations of foreign substances, under favorable conditions. However, spectroscopy is useful only at wavelengths at which the pure solvent does not itself strongly absorb. Of the various chromatographic techniques, gas chromatography is probably the most sensitive. Contaminants of very low volatility (polymers for example) may be sorbed so strongly by the column that they are not eluted for many hours.

In this communication, another method for detecting solvent contamination is described. A small quantity of the liquid to be tested is spread on an aqueous substrate. Water-insoluble molecules and a number of water-soluble amphipathic molecules and polymers will be concentrated at the air-water interface, causing changes in surface tension which are easily detectable.

EXPERIMENTAL

Water employed as the substrate was deionized and then distilled in an all-glass still. All organic liquids were reagent or spectro grade. Glassware was cleaned in chromic acid cleaning solution prior to use. Near IR spectra were obtained using the Beckman DK-2 spectrophotometer. All gas chromatography was performed using a Perkin-Elmer vapor fractometer, model 154. A column of propylene glycol was employed; helium was the carrier gas.

The Teflon surface balance has been previously described (5). Surface tension was determined by the Wilhelmy plate method (6), using a roughened platinum plate. The apparatus employed had a

Table I—Surface Pressure of Pure Organic Liquids Spread on Water

Liquid	Surface Pressure, dynes/cm.
Hexane	0.2
Benzene	0.2
Isopropanol	1.2
Acetone	0.7

sensitivity of 0.1 dynes/cm. The water surface was swept with the Teflon barrier. Then 1 ml. of the organic liquid to be tested was placed dropwise on the water surface and allowed to spread. After a waiting time of 10 to 15 min. the barrier of the surface balance was moved so as to reduce the available surface area to 80 cm.² and the surface tension was determined.

RESULTS AND DISCUSSION

The spreading experiments are summarized in Table I. Results are expressed in terms of surface pressure, which is the decrease in surface tension using a clean water surface as reference. All of the liquids tested had positive spreading coefficients (7), and spreading was observed visually in all cases. Volatile, poorly soluble liquids, such as benzene and hexane, would be expected to disappear very rapidly from the surface, producing a negligible surface pressure. However, even liquids as water-insoluble as these may diffuse through the surface layers of water and require some time for back diffusion to the surface and subsequent evaporation (8). For this reason, it is necessary to wait for about 10 min. after spreading before measuring surface pressure. Pure, insoluble liquids will then indeed yield no significant surface pressure (Table I).

Molecules of water-soluble substances, such as isopropanol and acetone, are distributed between the surface and bulk regions, resulting in a low surface pressure (Table I). The surface pressure values obtained for these solvents were independent of surface area and persisted after the surface was swept clean. The observed surface pressures were therefore due to the presence of solvent molecules in the interface and not to impurities. Regardless of the solubility of the solvent, impurities concentrated at the surface cause large changes in surface pressure, which indicate their presence.

The sensitivity of the spreading test was recently demonstrated in this laboratory. A sample of benzene spectrograde, taken from an old bottle which had been opened many times, gave a surface pressure of 11.3 dynes/cm. when spread on water. Near IR spectra of the contaminated benzene and of benzene known to be pure were identical. Gas chromatography at low attenuation of the impure sample yielded a large peak and a much smaller one (whose area was about $1/2000$ that of the large peak). The pure sample of benzene produced the same two peaks of the same relative size.

The impure sample of benzene was passed through a silica gel-alumina column. The purified material, spread on water, gave a surface pressure of 0.2 dynes, showing that the contaminant had been removed by the column.

Assume, for purposes of calculation, that contamination occurred as a result of careless handling and that the contaminant was a skin lipid. Skin phospholipids spread on water occupy an area of about 80 to 100 Å.² per molecule at moderate surface pressures (9). Under the conditions of the author's spreading test one could therefore be capable of detecting less than 10^{16} molecules, or about 10^{-8} moles of contaminant.

The spreading test may be extended to nonspreading liquids which are volatile or water-soluble. Such liquids may be deposited on the surface by first dissolving them in a solvent (e.g., hexane)

which is capable of spreading. The spreading test may also be applied in certain cases to the detection of solid contaminants, such as detergents which are leached by solvents. The recent report of silicones present in disposable syringes (10) suggests another possible application. Silicones are surface active; if spread on water, as little as 0.01 mg. can easily be determined (11).

Although the spreading method is very sensitive, it is limited to those impurities which are not very volatile and which have some affinity for the surface. Included in this category are surfactants, lipids, most polymers, and some other materials such as steroids and antibiotics. The method is incapable of detecting, for example, the presence of low boiling homologs or isomers in hexane. Therefore it should not be considered a substitute for other methods of checking purity. Nevertheless, if it is necessary to determine trace quantities of surface-active impurities, the spreading method represents a convenient and efficient tool.

Anticholinesterase Activity of Some Degradation Products of Physostigmine

B. A. HEMSWORTH and G. B. WEST

Abstract □ The anticholinesterase activities of four degradation products of physostigmine have been determined *in vitro* using biochemical and biological assay techniques and *in vivo* by means of the rat chromodacryorrhea response. The degradation products are at least 100 times less active than the parent compound as anticholinesterase agents. Eseroline, rubreserine, and eserine blue are effective in high concentrations against the cholinesterase of horse and rabbit plasma but are much less active against the red blood cell cholinesterase; they exert no inhibitory action on the two human cholinesterase enzymes. *In vivo*, the degradation products are at least 1000 times less active than physostigmine. Lack of coloration of solutions of physostigmine does not necessarily indicate full anticholinesterase activity because a colorless product of hydrolysis, eseroline, possesses little or no anticholinesterase activity.

Keyphrases □ Physostigmine—degradation products □ Anticholinesterase activity—physostigmine degradation products □ Biological assay—physostigmine degradation products □ *In vitro* assay—physostigmine degradation products activity

When physostigmine in solution undergoes decomposition, a red-colored compound is formed which turns blue on further decomposition (1). Hydrolysis which initially removes the urethane grouping and produces eseroline, a colorless compound (Scheme 1), is followed by oxidation to yield rubreserine, a red material, which is converted into eserine blue or eserine brown. The molecular weight of eserine blue exceeds that of rubreserine and it has been suggested that condensation of rubreserine with other physostigmine degradation products occurs at this stage in the reaction.

The end product of the degradation by heat or by exposure to oxygen and alkali is eserine brown.

The anticholinesterase activity of these degradation products has been investigated. Their biological activity has particular relevance as solutions of physostigmine are used in ophthalmology. Furthermore, in the preparation of eye drops sterilization is effected by filtration or by autoclaving the solution at 98 to 100° for 30 min. (BPC, Supplement, 1966) or by steam sterilization at 121°. (USP XVII, 1965). This heating process may result in decomposition of the physostigmine, with possible loss of activity. A preliminary note concerning this work has been published (2).

METHODS

Warburg Manometric Technique—The anticholinesterase activity of the different compounds was compared by this technique using horse serum (0.5 ml.) as the source of cholinesterase and acetylcholine (0.5 ml.) at a final concentration of 0.0138 *M* (3) as the substrate. The pH value of the incubation mixture was controlled by adding 1.5 ml. of 0.04 *M* sodium bicarbonate (adjusted to pH 7.6 by the addition of hydrochloric acid) and each compound under test was added to 0.5 ml. of this bicarbonate solution before addition to the incubation flask. The total volume of fluid in each flask was 3 ml. After gassing with a mixture of 95% nitrogen and 5% carbon dioxide for 10 min., the flasks were incubated at 37° and the manometers read at 10-min. intervals for 30 min. Values in the text are the mean of three experiments. Differences in percentage inhibition greater than 15% are significant (*p* = 0.05).

Biological Assay Technique—Horse serum (0.1 ml.) was used as the source of cholinesterase, with acetylcholine as the substrate (2 ml. of 5 mcg./ml.). Each compound under test was dissolved in 2

which is capable of spreading. The spreading test may also be applied in certain cases to the detection of solid contaminants, such as detergents which are leached by solvents. The recent report of silicones present in disposable syringes (10) suggests another possible application. Silicones are surface active; if spread on water, as little as 0.01 mg. can easily be determined (11).

Although the spreading method is very sensitive, it is limited to those impurities which are not very volatile and which have some affinity for the surface. Included in this category are surfactants, lipids, most polymers, and some other materials such as steroids and antibiotics. The method is incapable of detecting, for example, the presence of low boiling homologs or isomers in hexane. Therefore it should not be considered a substitute for other methods of checking purity. Nevertheless, if it is necessary to determine trace quantities of surface-active impurities, the spreading method represents a convenient and efficient tool.

Anticholinesterase Activity of Some Degradation Products of Physostigmine

B. A. HEMSWORTH and G. B. WEST

Abstract □ The anticholinesterase activities of four degradation products of physostigmine have been determined *in vitro* using biochemical and biological assay techniques and *in vivo* by means of the rat chromodacryorrhea response. The degradation products are at least 100 times less active than the parent compound as anticholinesterase agents. Eseroline, rubreserine, and eserine blue are effective in high concentrations against the cholinesterase of horse and rabbit plasma but are much less active against the red blood cell cholinesterase; they exert no inhibitory action on the two human cholinesterase enzymes. *In vivo*, the degradation products are at least 1000 times less active than physostigmine. Lack of coloration of solutions of physostigmine does not necessarily indicate full anticholinesterase activity because a colorless product of hydrolysis, eseroline, possesses little or no anticholinesterase activity.

Keyphrases □ Physostigmine—degradation products □ Anticholinesterase activity—physostigmine degradation products □ Biological assay—physostigmine degradation products □ *In vitro* assay—physostigmine degradation products activity

When physostigmine in solution undergoes decomposition, a red-colored compound is formed which turns blue on further decomposition (1). Hydrolysis which initially removes the urethane grouping and produces eseroline, a colorless compound (Scheme 1), is followed by oxidation to yield rubreserine, a red material, which is converted into eserine blue or eserine brown. The molecular weight of eserine blue exceeds that of rubreserine and it has been suggested that condensation of rubreserine with other physostigmine degradation products occurs at this stage in the reaction.

The end product of the degradation by heat or by exposure to oxygen and alkali is eserine brown.

The anticholinesterase activity of these degradation products has been investigated. Their biological activity has particular relevance as solutions of physostigmine are used in ophthalmology. Furthermore, in the preparation of eye drops sterilization is effected by filtration or by autoclaving the solution at 98 to 100° for 30 min. (BPC, Supplement, 1966) or by steam sterilization at 121°. (USP XVII, 1965). This heating process may result in decomposition of the physostigmine, with possible loss of activity. A preliminary note concerning this work has been published (2).

METHODS

Warburg Manometric Technique—The anticholinesterase activity of the different compounds was compared by this technique using horse serum (0.5 ml.) as the source of cholinesterase and acetylcholine (0.5 ml.) at a final concentration of 0.0138 M (3) as the substrate. The pH value of the incubation mixture was controlled by adding 1.5 ml. of 0.04 M sodium bicarbonate (adjusted to pH 7.6 by the addition of hydrochloric acid) and each compound under test was added to 0.5 ml. of this bicarbonate solution before addition to the incubation flask. The total volume of fluid in each flask was 3 ml. After gassing with a mixture of 95% nitrogen and 5% carbon dioxide for 10 min., the flasks were incubated at 37° and the manometers read at 10-min. intervals for 30 min. Values in the text are the mean of three experiments. Differences in percentage inhibition greater than 15% are significant ($p = 0.05$).

Biological Assay Technique—Horse serum (0.1 ml.) was used as the source of cholinesterase, with acetylcholine as the substrate (2 ml. of 5 mcg./ml.). Each compound under test was dissolved in 2

Scheme I—The relationship between physostigmine and some of its degradation products.

ml. of 0.04 M sodium bicarbonate and added to the incubation mixture. Incubation was carried out at 37° for 30 min., during which time all of the acetylcholine was hydrolyzed when no anticholinesterase was present. In the presence of an inhibitor, the residual acetylcholine was assayed biologically on three different preparations. The isolated colon and uterus of a rat were set up in de Jalon's solution at 32° while the ileum of a guinea pig was suspended in Tyrode's solution also at 32°. Contractions were recorded isotonically on a Grass polygraph. Assays were carried out using the 2 × 2 dose schedule. The amounts of anticholinesterase and horse serum used had no effect on any of these assay preparations. Values in the text are the mean results from the three preparations. Differences in percentage inhibition greater than 15% are significant ($p = 0.05$).

Anticholinesterase Activity Using Plasma and Red Blood Cells—Blood was collected from rabbits, man, and horses into heparinized syringes. After centrifugation to obtain the plasma, the red cells were washed three times with 0.9% (w/v) saline and then haemolyzed in a volume of distilled water corresponding to the initial volume of plasma. The anticholinesterase activities of the compounds under test were then compared using the biological assay techniques, as described previously.

Chromodacryorrhea Test in Rats—Male rats (100–200 g.) were first injected subcutaneously with acetylcholine (200 mcg./100 g. rat) and those producing red tears within 2 min. were used (4). The anticholinesterase activities of the test compounds were then evaluated by injecting them intraperitoneally 30 min. before the subcutaneous injection of a smaller dose of acetylcholine (20 mcg./100 g. rat), and examining for the presence of red tears at 2-min. intervals for 14 min.

Degradation Products of Physostigmine—Samples of eseroline, rubreserine, eserine blue, and eserine brown were supplied by Dr. G. A. Smith, Department of Pharmacy, Heriot-Watt University, Edinburgh, Scotland. They were dissolved in freshly distilled water and the solutions were stored at 4° until required.

RESULTS

Anticholinesterase Activity Determined Manometrically—Concentrations of physostigmine as low as 10^{-8} M were effective in inhibiting the cholinesterase of horse serum and higher concentrations had correspondingly greater activities (Fig. 2). All the degradation products tested were less active than the parent compound and activities of these products at concentrations of 5×10^{-5} M only

Figure 1—The anticholinesterase activities of physostigmine (ES), eseroline (EL), rubreserine (R), eserine blue (E Blue), and eserine brown (E Brown), determined manometrically using horse serum as the source of cholinesterase. The ordinate shows percentage inhibition of cholinesterase with reference to 5×10^{-5} M physostigmine as 100%. The effects of graded concentrations of physostigmine are also shown for comparison.

are recorded. Eserine blue was the most active of these products and at this concentration produced 52% inhibition of the cholinesterase, comparable with that produced by physostigmine at 10^{-7} M (Fig. 1). Thus, eserine blue is at least 500 times less active as an anticholinesterase agent, and eseroline is about 5000 times less active in this test.

Anticholinesterase Activity Determined Biologically—Concentrations of physostigmine as low as 10^{-7} M were effective in reducing the cholinesterase activity of horse serum and higher concentrations exerted greater activity (Fig. 2). All the degradation products were less active than the parent compound which reduced cholinesterase activity to 54% of control at 10^{-7} M. The most active of these products, eserine blue, is about 100 times less active than physostigmine in this test.

Inhibition of Cholinesterase of Plasma and Red Blood Cells—Concentrations of physostigmine greater than 10^{-5} M completely inhibited both plasma and red cell cholinesterase of rabbit, horse, and man. Comparisons of the activities of the degradation products of physostigmine are shown in Fig. 3 where only concentrations of 5×10^{-5} M are recorded. Eserine blue, the most active of the degradation products, inhibited the pseudo-cholinesterase of rabbit plasma by about 50%, but it was almost inactive against the true cholinesterase of the red cells; against the cholinesterase of horse plasma, it exerted about 60% inhibition (as it did against horse serum, Figs. 1 and 2) whereas it was only slightly less active against the cholinesterase of horse red cells; however, it was inactive against the cholinesterase enzyme of both human plasma and red cells. This difference

Figure 2—The anticholinesterase activities of physostigmine (ES), eseroline (EL), rubreserine (R), eserine blue (E Blue), and eserine brown (E Brown), determined biologically using horse serum as the source of cholinesterase. The ordinate shows percentage inhibition of cholinesterase with reference to 5×10^{-5} M physostigmine as 100%. The effects of graded concentrations of physostigmine are also shown for comparison.

Figure 3—The anticholinesterase activities of physostigmine (ES), eseroline (EL), rubreserine (R), eserine blue (E Blue), and eserine brown (E Brown) determined biologically using plasma (open columns) and red blood cells (closed columns) as sources of cholinesterase. Activities recorded on the ordinate are percentages of those obtained with 5×10^{-5} M physostigmine. All compounds were tested at concentrations of 5×10^{-5} M. A = rabbit, B = horse, C = man.

in activity of eserine blue against the cholinesterases of all three species contrasts markedly with that of physostigmine, which was equally active against the true and pseudocholinesterases, even at concentrations of 10^{-8} M. The other degradation products of physostigmine were less active than eserine blue; with the rabbit and horse enzymes, they had greater effects on the plasma cholinesterase, but with the human enzymes, all were without significant effect at concentrations of 5×10^{-5} M.

Rat Chromodacryorrhea Response—Physostigmine was active at doses of 0.1 mg./kg., red tears being produced within 2 min. of the injection of acetylcholine. However, eserine blue, rubreserine, and eseroline were about 1000 times less active than physostigmine in this test. Eserine brown was inactive at all dose levels tested.

DISCUSSION

The results show that the degradation products of physostigmine used in the present work are all much less active as anticholinesterase agents than the parent compound. These products lack the urethane grouping, but it is of interest that when oxidation occurs the anticholinesterase activity first increases and then decreases. Thus, eserine blue is more active than rubreserine or eseroline and under certain circumstances may exert an activity equivalent to about 1% of the parent compound. This result agrees with that of Ellis *et al.* (5) who showed that eserine blue was more active than rubreserine as an anticholinesterase agent. However, these workers were unable to find any anticholinesterase activity in eseroline or eserine brown.

The results using the standard Warburg technique agree well with those involving biological assay of the residual acetylcholine, when a standard enzyme preparation such as horse serum is used. When the two cholinesterases of horse blood are used as the source of the enzyme and comparisons are made of the anticholinesterase activities of the degradation products, rubreserine and eserine blue have a greater inhibiting effect on the plasma cholinesterase. With rabbit blood, almost no activity has been found at the high concentrations tested on the red cell enzyme although results with the plasma enzyme have corresponded well with those obtained using the horse enzyme. Both human plasma enzyme and red cell cholinesterase are not inhibited to any great extent by these degradation products when used at concentrations of 5×10^{-5} M; however, physostigmine is equally active against both enzymes in much lower concentrations (6, 7). It is most likely that species differences of plasma cholinesterase (8–10) play a role in the different degrees of inhibition of cholinesterase produced by the degradation compounds.

From the clinical point of view, only physostigmine therefore exerts an anticholinesterase activity, and this is supported by the results of the *in vivo* test where the red tear response involving protection of the injected acetylcholine from both true and pseudocholinesterases shows that all the degradation compounds (including eserine blue) are 1000 times less active than physostigmine. The similar activities of the degradation compounds *in vivo* may be due to the fact that male rats were used in this test and male rat serum has been shown to contain much lower levels of pseudo-cholinesterase than does the serum of female rats (11, 12).

Since all ophthalmic solutions (BPC and USP) are now required to be sterile and physostigmine eye drops may be sterilized by heat, the formation of relatively inactive decomposition products (one of which is colorless) must be taken into account. These intermediate products have no therapeutic value and so the appearance of a pink color is not the only guide to loss of activity of the solution because a colorless solution may also be inactive.

Sterically Hindered Esters of Vitamin A II: Vitamin A α,α -Dimethylpalmitate

A. J. FORLANO*, C. I. JAROWSKI, H. F. HAMMER, and E. G. MERRITT

Abstract □ A previous study showed that short-chain sterically hindered esters of vitamin A demonstrated better stability in solution than the commercial palmitate. The oxidative stability of the short-chain sterically hindered esters, however, was poor. This work indicated that a long aliphatic chain with steric hindrance in the α -position was necessary for maximal stability. A compound of this type, vitamin A α,α -dimethylpalmitate, was prepared and evaluated.

Keyphrases □ Sterically hindered vitamin A esters □ Vitamin A α,α -dimethylpalmitate—synthesis □ Stability—vitamin A α,α -dimethylpalmitate □ UV spectrophotometry—analysis □ IR spectrophotometry—analysis

The possibility of developing a vitamin A ester of optimum stability was suggested by the observation that steric hindrance in the α -position of the acid portion was required for good solution stability and that

Scheme I

Preparation of Vitamin A α,α -Dimethylpalmitate

a long aliphatic chain was required for maximal oxidative stability (1, 3). Previously, Forlano and Harris (2) prepared a series of vitamin A esters containing an electronegative group such as chlorine in the α -position of the acid portion. These esters demonstrated increased stability in anhydrous ethanolic HCl compared to commercial vitamin A palmitate. Biologically inactive anhydrovitamin A, formed by the elimination of a molecule of water, was the main degradative pathway in acidic solutions. Since it also was observed that the resultant polarization of the ester linkage by the electronegative groups rendered these esters more sensitive to solvent-catalyzed elimination, the increased stability in anhydrous acidic media was somewhat academic.

A careful re-examination of the Forlano and Harris data (2) indicated that the replacement of the electronegative groups with electropositive groups should yield esters having greater stability towards solvent- and base-catalyzed attack. A series of compounds incorporating electropositive groups in the α -position of the esters (1, 3) were demonstrated to resist such attack. The excellent stability pattern of these esters in alcoholic acid was quite unexpected, since it was assumed that the introduction of an electropositive group would increase the basicity of the carbonyl group and consequently favor proton-catalyzed attack. It became evident that steric factors as well as electronic effects were important parameters in the stability of vitamin A esters. These data indicated that reactions which involved either hydrolysis of the ester or lysis of the alkyl oxygen bond as the initiating step of the degradation were considerably decreased by the introduction of steric hindrance in the α -position of the acid. The increase in steric hindrance from a methyl to an ethyl group produced a slight but significant increase in solution stability. These short-chain (C_3 – C_6) esters, however, lacked good oxidative stability, suggesting the need for a long aliphatic chain.

From previous studies, therefore, it was determined that the features needed for optimum stability in a vitamin A ester are:

Table II—Stability of Vitamin A Esters at 20° in the Presence of Diacetyl Tartaric Acid Mono- and Diglycerides With and Without Corn Oil

90	158,000 ^d	49	255,000 ^d	79	No UV ^c	0	No UV ^c	0

^a Vitamin A α,α -dimethylpalmitate, ^b Vitamin A palmitate, ^c No detectable vitamin A by UV method; samples had solidified indicating that considerable oxidation and polymerization had occurred, ^d Samples still fluid at this time.

1. Steric hindrance in the α -position of the acid portion, provided by electropositive alkyl groups, which protect the carbonyl and alkyl oxygen groups from reactive species through physical blockage and electronic effects.

2. A long aliphatic chain to protect the conjugated double bond system from oxygen.

Vitamin A α,α -dimethylpalmitate, Scheme I, which was not prepared previously theoretically appeared to satisfy all these requirements, and this report, describing its preparation and properties, shows that it does. The biological availability of vitamin A from the α,α -dimethylpalmitate and α,α -methylthylcaproate will be discussed in a future report.

EXPERIMENTAL

The α,α -dimethylpalmitic acid was prepared by the method of Bui-Hoi *et al.* (4). The acid chloride, prepared by reacting the acid with thionyl chloride, was subsequently condensed with vitamin A alcohol to form the ester.

Materials—Sodamide 90%,¹ isobutyrophenone,² 1-bromotetradecane,³ and diethylene glycol.¹

Procedure—Eighty-eight grams sodamide (2.03 moles) was added to 600 ml. boiling dry toluene in a three-neck flask equipped with a reflux condenser, dropping funnel, and thermometer; 300 g. isobutyrophenone (2.03 moles) was added dropwise to the stirring mixture and the system was refluxed for 1 hr. after the addition was completed. The reaction mixture was cooled to room temperature and 400 g. 1-bromotetradecane (1.45 moles) was added and stirring was initiated. After the initial evolution of heat subsided, the mixture was refluxed for 4 hr. with stirring. The cooled mixture was slowly poured into 5 l. 5% acetic acid solution cautiously, since some unreacted sodamide may be present.

The separated organic solution was washed with water until free of base, dried with anhydrous Na_2SO_4 , and the toluene was removed by atmospheric distillation. The isobutyrophenone and 1-bromotetradecane were subsequently removed by vacuum distillation at 85–95° 15 mm., and 151–168° 8 mm., respectively. There were 486 g. α,α -dimethylpalmitophenone (1.41 moles) collected at 213–217° 6 mm. (87% yield) and this was added slowly to a suspension of 72 g. sodamide in 600 ml. boiling anhydrous toluene with stirring. The suspension was refluxed for 8 hr. and the cooled mixture was carefully washed with water to destroy any excess sodamide. Emulsification at this point can be reversed by distilling the mixture, since water forms an azeotrope with toluene which distills below the boiling point of both solvents. The residue was vacuum distilled using an air condenser, and 344 g. α,α -dimethylpalmitamide was collected by distilling between 229–235° 10 mm.. Then 344 g. (1.21 moles) of the amide was hydrolyzed in 1250 ml. diethylene glycol containing 265 g. KOH by heating the mixture at 210–220° for 16 hr. with constant agitation. The cooled solution was diluted with three times its volume of water and made strongly acidic with concentrated

HCl. The free fatty acid, which rose to the top of the solution, was removed with chloroform. The chloroform layer was washed with water until neutral and the solvent was removed. The residue was distilled under vacuum and 200 g. of a material corresponding to α,α -dimethylpalmitic acid was collected at 225–236° 20 mm.. The boiling point was the same as that reported by Bui-Hoi *et al.* (4).

The acid was converted to 142 g. of the acid chloride, b.p. 148–150° 1 mm., by refluxing 197 g. of the former compound with 166 g. thionyl chloride in CHCl_3 . Subsequently, 81 g. of the acid chloride was reacted with 80 g. vitamin A alcohol to yield 53 g. of vitamin A ester, purified by the alumina-column chromatographic procedure of Forlano and Harris (2). This material had an absorption maximum at 327 m μ , which is typical of vitamin A esters, and an $a = 84.71$ in isopropyl alcohol corresponding to 1.52×10^6 units of vitamin A/g. The IR spectrum was typical of a vitamin A ester showing no alcohol peaks. The heavy metal content was insignificant.

Vitamin A esters are not crystalline and because of their high molecular weight and lack of thermal stability they do not lend themselves to melting point or boiling point determinations. Consequently, the major determination of purity for vitamin A esters is the a determination (a measure of the concentration of vitamin A chromophore) at the vitamin A ester's UV maximum. The absence of shoulders on either side of the maximum indicated the absence of oxidative, isomerization and eliminative degradation products in the sample. The IR spectrum showed an absence of starting materials such as alcohols, carboxylic acids, or acid chlorides. The combination of column chromatography, proper UV maximum, and a value with an absence of shoulders and a good IR spectrum indicated that the product was chemically pure.

Testing Under Use Conditions—The new ester and commercial vitamin A palmitate were studied in a series of practical use tests. The first was a thin-film oxidation test at 64° by the previous method (1). The time required for the complete oxidation of the ester (Table I) indicated that the new ester was more resistant to oxidation than commercial vitamin A palmitate. All vitamin A assays were performed by the USP method (5).

Since vitamin A palmitate is the most stable commercial ester of vitamin A in resisting acid degradation, the relative stability of the α,α -dimethylpalmitate was determined in an acidic medium known to cause rapid degradation of the palmitate. The agent used was an acidic emulsifying agent, diacetyl tartaric acid mono- and diglycerides.⁴ The tests were conducted by dissolving enough vitamin A ester in the emulsifying agent to produce an initial concentration of 325,000 units/g. In the second part of this experiment the esters were dissolved in a mixture of equal parts of the emulsifying agent and corn oil (Wesson Oil). The samples were stored at 20° and were periodically assayed by the USP method (5). Table II shows that commercial vitamin A palmitate was completely inactivated in 42 days while the α,α -dimethylpalmitate ester retained half its original potency for twice as long. Corn oil prolonged the stability of the samples possibly due to a reduction in concentration of the acidic emulsifying agent.

The stability of the esters in the emulsifying agent was also determined at 28°. Table III shows that vitamin A palmitate was completely inactivated in half the time at 28° than at 20°. The slower rate of decomposition of the α,α -dimethylpalmitate was approximately the same at both temperatures.

Table III—Stability of Vitamin A Palmitate and Vitamin A α,α -Dimethylpalmitate in Diacetyl Tartaric Acid Mono- and Diglycerides at 28°

Time, days	Vitamin A Palmitate, units/g.	Vitamin A α,α -Dimethylpalmitate, units/g.
1	301,000	283,000
10	202,000	—
15	—	243,000
21	No UV curve ^a	216,000
31	No UV curve ^a	177,000
41	No UV curve ^a	179,000
53	No UV curve ^a	158,000
73	No UV curve ^a	115,000

^a At the time of assay, there was no UV absorption peak corresponding to vitamin A indicating complete loss of vitamin A potency.

The tests in Tables II and III were quite rigorous because the dispersing agent contained noticeable quantities of free acetic acid. The results clearly indicate the new ester's superior ability to withstand strong acidic conditions and acid-catalyzed degradation.

Further evidence of resistance to acid degradation may be found in the incidence of isomerization occurring in the diacetyl tartaric acid mono- and diglyceride mixtures. Isomerization, no doubt a pathway in acid-catalyzed degradation, is not readily detected because the molecule remains intact although there is a loss of biopotency. The degree of isomerization in terms of maleic values, as determined by reaction with maleic anhydride and colorimetric measurement (6), is given in Table IV. A value of approximately 33% represents the percentage of 13-*cis* isomers present and approaches isomeric equilibrium. The degree of isomerization of the α,α -dimethylpalmitate ester is smaller than that for the palmitate ester in the presence of the acidic emulsifier. Corn oil retarded isomerization and prolonged potency of the vitamin A esters probably by a reduction in concentration of the acidic emulsifying agent.

SUMMARY AND CONCLUSIONS

When the stability of a new ester of vitamin A was compared with commercial vitamin A palmitate, the following observations were made:

1. Vitamin A α,α -dimethylpalmitate was considerably more resistant to auto-oxidation than commercial vitamin A palmitate.

Table IV—Degree of Isomerization of Vitamin A/Esters (in Terms of Maleic Values^a) in the Presence of the Acidic Emulsifier, Diacetyl Tartaric Acid Mono- and Diglycerides at 25°

Time, days	DMP ^b	DMP + Corn Oil	VAP ^c	VAP + Corn Oil
0	<5	<5	<5	<5
11	8.2	8.6	9.3	6.3
21	10.8	9.6	19.0	9.7
42	12.6	9.7	22.4	11.8
90	16.4	12.7	36.3	21.6

^a Expressed as % of 13-*cis* isomers present; value of 33% indicates approximate isomeric equilibrium. ^b Vitamin A α,α -dimethylpalmitate. ^c Commercial vitamin A palmitate.

2. The new ester was more stable than vitamin A palmitate in the presence of the acidic emulsifier, diacetyl tartaric acid mono- and diglycerides.

3. Corn oil appears to retard the loss in vitamin A ester potency due to both acid-catalyzed degradation and isomerization probably by a reduction of the concentration of the acidic emulsifying agent.

4. Isomerization of the new ester is somewhat slower in the presence of the acidic emulsifier than the commercial palmitate.

Thin-Layer Chromatographic Method for the Determination of Flurandrenolone Acetonide and Some Closely Related Foreign Steroids

RAFIK H. BISHARA* and IVAN M. JAKOVLJEVIC

Abstract □ A method is presented for the separation and determination of flurandrenolone acetonide (6 α -fluoro-11 β ,16 α ,17 α ,21-tetrahydroxy-pregn-4-ene-3,20-dione-16,17-acetonide) and some closely related steroids. This is achieved by TLC on silica gel using a one-dimensional multiple development technique. The related foreign steroids are determined semiquantitatively while flurandrenolone acetonide is determined quantitatively by extracting its spot from the plate, and comparing it to a standard treated similarly.

Keyphrases □ Flurandrenolone acetonide, related steroids—separation, determination □ TLC—separation, identification □ Colorimetric analysis—spectrophotometer

Interest in this laboratory for the determination of steroid purity using TLC has made necessary the development of TLC solvent systems for the separation and quantitation of closely related steroids. A system for the separation of some estrogens (1) and another for the separation of a mixture of closely related 6-fluoro-16 α -hydroxycorticosteroids (2) have been reported recently. These solvent systems proved to be very useful for the separation of related foreign steroids, intermediates, or decomposition products from the therapeutically active steroid.

This paper describes a TLC method for the semiquantitation of the related foreign steroids that may possibly exist, or the steroids which may be formed under artificial decomposition of flurandrenolone acetonide. These related foreign steroids were arbitrarily chosen after examining the different methods of flurandrenolone acetonide syntheses (3, 4) and it was concluded that their presence was a possibility. Also included are some of the products resulting from severe hydrolytic deacetonation (5) and chromic acid oxidation (6) of flurandrenolone acetonide. The closely related foreign steroids were determined semiquantitatively by visualizing the developed plate under short wavelength UV light and comparing their intensities to known amounts, while flurandrenolone acetonide was determined quantitatively by extracting the silica gel, color development with tetrazolium blue reagent, and measuring the absorbance at 520 m μ .

EXPERIMENTAL

Reagents—All chemicals, if not otherwise mentioned, were of the highest grade commercially available.

Solvent System—Benzene-ethylacetate (1:1) (2).

Flurandrenolone Acetonide Reference Standard Solution—A solution containing exactly 10 mg. of flurandrenolone acetonide per milliliter of chloroform-methanol (1:1).

Related Foreign Steroids Solution—A mixture containing 1 mg. of each of the following steroids¹/5 ml. of chloroform-methanol

(1:1): (a) 6 α -fluoro-16 α ,17 α ,21-trihydroxy-pregn-4-ene,3,11,20-trione-16,17-acetonide; (b) 6 α -fluoro-11 β ,16 α ,17 α ,21-tetrahydroxy-pregn-4-ene-3,20-dione-16,17-acetonide-21-acetate; (c) 6 α -fluoro-11 β ,16 α ,17 α ,21-tetrahydroxy-pregn-4-ene-3,20-dione-16,17-acetonide-11-acetate; (d) 6 α -fluoro-11 β ,16 α ,17 α ,21-tetrahydroxy-pregn-4-ene-3,20-dione (flurandrenolone).

Specially treated ethanol, tetrazolium blue reagent, and tetramethylammonium hydroxide solution were prepared according to the method of Jakovljevic (7).

METHOD

The TLC plate² (20 \times 20 cm.) was activated before use by heating at 110° for 10–15 min. The developing chamber was lined with blotting paper and allowed to stand with the solvent for 30 min. before use.

Ten milligrams of the sample was weighed accurately and dissolved in 1 ml. of chloroform-methanol (1:1). The plate was divided into seven equal sections and the following amounts were applied 2.5 cm. from the bottom edge of the plate using micropipets.³

Section 1, 5 μ l. of the related foreign steroids solution; Section 2, 10 μ l. of the sample solution; Section 3, 10 μ l. of flurandrenolone acetonide standard solution; Section 4, was used as the plate blank; Section 5, 15 μ l. of the related foreign steroids solution; Section 6, 10 μ l. of the sample solution; Section 7, 10 μ l. of flurandrenolone acetonide standard solution.

The plate was developed in the chamber allowing the solvent front to travel 15 cm. after passing through the point of application. It was then removed from the chamber and the solvent allowed to evaporate for about 3 min. Developing and evaporation of the solvent were done at room temperature (25°). The plate was redeveloped twice more in the same direction as the first time. After the third removal of the solvent the spots were detected using a short wavelength UV light,⁴ and marked.

Evaluation of the Plate—In order to determine the percentage of related foreign steroids in flurandrenolone acetonide, each extra spot, other than the main compound, appearing in the sample sections was compared with the spot having the same mobility (R_f value) in the sections containing the related foreign steroids. Sections 1 and 5, equivalent to 1 and 3% of related foreign steroids, respectively, were used for the semiquantitation of possible impurities.

For the quantitative determination of flurandrenolone acetonide, the marked areas of the main spot in Sections 2 and 6 representing the sample, and Sections 3 and 7 representing the standard, as well as an equivalent area from the blank, Section 4, were removed and quantitatively transferred to separate glass-stoppered centrifuge tubes. Ten milliliters of absolute ethanol were added to each tube followed by vigorous shaking for 3 min. using a Vortex mixer.⁵ The tubes were centrifuged for about 10 min. at 2000 r.p.m. until the supernatant was clear. A 4-ml. aliquot from each tube (equivalent to 40 mcg. of flurandrenolone acetonide) was pipetted into separate 10-ml. volumetric flasks. The contents of all flasks were evaporated to dryness using mild heat and an air stream, then the color was developed with the tetrazolium blue reagent (7). The plate blank absorbance was subtracted from both the sample and the standard absorbances, and the corrected values were used for the calculation.

Figure 1—1. Flurandrenolone; 2. flurandrenolone acetonide; 3. 6 α -fluoro-11 β ,16 α ,17 α ,21-tetrahydroxy-pregn-4-ene-3,20-dione-16,17-acetonide-11-acetate; 4. 6 α -fluoro-16 α ,17 α ,21-trihydroxy-pregn-4-ene-3,11,20-trione-16,17-acetonide; 5. 6 α -fluoro-11 β ,16 α ,17 α ,21-tetrahydroxy-pregn-4-ene-3,20-dione-16,17-acetonide-21-acetate; 6. mixture. Each spot represents 2 mcg.

DISCUSSION

In recent years, TLC has become recognized as a valuable method for the separation and identification of closely related compounds. Many solvent systems for the TLC of steroids (1, 2, 8, 9) have been reported for the separation of closely related steroids and the resolution (2, 10) of α - and β -steroid pairs.

The related foreign steroids test (11–13) is now becoming one of the most important tests of steroidal drugs. This test uses TLC as a tool to detect any structurally related compounds that may exist in the therapeutically active steroid.

The method described here has been used satisfactorily in this laboratory for the semiquantitative determination of the related foreign steroids that may be present in flurandrenolone acetonide. It was also useful in stability studies where flurandrenolone was detected after severe hydrolytic deacetonation (5) of flurandrenolone acetonide. This reaction was found (7, 14) to occur in some formulations containing flurandrenolone acetonide that were aged by accelerated conditions.

The oxidation product formed upon exposing flurandrenolone acetonide to chromic acid (6) was isolated and identified by IR, TLC, and melting point, and found to be 6 α -fluoro-6 α ,17 α ,21-trihydroxy-pregn-4-ene-3,11,20-trione-16,17-acetonide. This compound separated by the TLC solvent system used in this method, was incorporated in the related foreign steroids mixture.

Although several solvent systems have been reported for the TLC of corticosteroids, it was found that none of them could resolve the mixture used in this work. The development of a new TLC system (2) in this laboratory made it possible to have complete resolution of this particular mixture. This was achieved after developing the plate three times in the same direction. Figure 1 shows the thin-layer chromatogram of the separated steroids individually and as a mixture. Their R_f values were reported previously (2). To overcome any unevenly distributed plate layers, the sample and the standard were applied in duplicates. It was found that the results were reproducible.

Table I—Variability Data^a

Average Absorbance of the Duplicate Samples	Plate Blank Absorbance	Corrected Absorbance
0.290	0.010	0.280
0.299	0.005	0.294
0.290	0.010	0.280
0.315	0.010	0.305
0.310	0.008	0.302
0.307	0.012	0.295
0.294	0.014	0.280
0.320	0.012	0.308

^a Numbers represent spectrophotometric readings at 520 m μ . Average \bar{x} = 0.293; range R = 0.028; variance S^2 = 0.00013742; SD = 0.01172262; RSD = ± 4.000894 .

The order of the plate sections makes it possible to have the sample close to two levels of the related foreign steroids; namely 1 and 3%, thus facilitating the visual semiquantitation under short wavelength UV light.

For the quantitative elution of flurandrenolone acetonide from the scraped silica gel, absolute ethanol was used instead of 95% ethanol since a clearer separation was obtained¹.

In order to evaluate the precision of this method, 100 mcg. of a flurandrenolone acetonide standard material was spotted in duplicate on eight TLC plates, which were then developed, eluted, and assayed as mentioned. It was found that the plate blank absorbances vary from 1.67–4.76% of the sample absorbances. The quantitative determination of flurandrenolone acetonide by this method showed (Table I) a relative SD of $\pm 4.0\%$ for eight independent assays.

Effect of Acute and Chronic Stress on Amobarbital Metabolism in the Rat

JAMES EDWARD HUFF,* STANLEY M. SHAW, and JOHN E. CHRISTIAN

Abstract □ Labeled amobarbital was employed in an investigation of the utilization of urinary excretion of a labeled compound as an index for indicating altered amobarbital metabolism due to a stress. A study of the effect of an external acute unilateral hindleg ligation stress showed significant differences in amobarbital and/or metabolite urinary excretion patterns between stress and control groups. Adrenal ascorbic acid as an index of acute stress showed a significant difference between groups. Repeated injection of amobarbital as an internal chronic stress resulted in a significant difference between stress and control rat urinary excretion of amobarbital and/or metabolites.

Keyphrases □ Amobarbital-¹⁴C metabolism—acute, chronic stress effect □ Adrenal ascorbic acid—acute stress index □ Stress, hindleg ligation—amobarbital-¹⁴C metabolism □ Excretion, fecal, urinary—amobarbital-¹⁴C □ UV spectrophotometry—analysis □ Scintillometry—analysis

The effect of various stress conditions or stressors on living organisms has been an area of increasing concern and activity in the scientific community. A recent review (1) listing 326 references defined stress "as the response of an organism to a variety of challenging and threatening events which inevitably occur and recur throughout life." These conditions of stress may be initiated by a variety of physical and/or mental stimuli which may include infections, wounds, burns, accidental injuries, exposure to toxic chemicals, noise, vibrations, extremes of temperature, prolonged or extreme physical activity, ionizing radiations, sleeplessness, pain, fear, anxiety, and other emotional strains (2). It is generally accepted that most stressors, if sufficiently intense and prolonged, initiate the general adaptation syndrome (3), with the successive stages of alarm reaction, adaptation, and exhaustion.

Information relating to the interaction between stress and drug effect is only in the embryonic stage. There exists a void in scientific knowledge, specifically pertaining to "what does happen" when a stressed individual receives a drug, the dose of which was titrated on normal subjects at the time of the drug's inception. Barry and Buckley (1) stated that the effect of stress may potentiate, counteract, or have no effect on the action of a drug, but that the variation in drug action, if any, should be known. Levy (4) recently stated that most pharmacokinetic studies are conducted on healthy ambulatory subjects. Levy suggested that many of these investigations should be carried out also on debilitated patients in order to assess the effect of various pathological conditions on the kinetics of drug absorption, distribution, and elimination.

Since barbiturates are centrally acting nervous system depressants used in conditions of mental and physical stress, an investigation of the effects of experimental stress on the pharmacology of barbiturates would seem

to be of paramount concern. Therefore, the overall objective of this investigation was to follow the urinary and fecal excretion of amobarbital and metabolites as observed in stressed and nonstressed rats, using tracer techniques, in order to determine if an alteration in the process of drug metabolism occurs from stressor effects; and to observe if the alteration can be detected using urinary excretion as a quantitative index of stress. The selected methods of stress were short term unilateral hindleg ligation, designated as an external acute stress, and repeated intraperitoneal administration of the barbiturate, designated as an internal chronic stress.

EXPERIMENTAL

Animals—Male rats of the Sprague-Dawley strain¹ were used throughout this investigation. They were maintained on commercial laboratory chow² and water *ad libitum*. The animal quarters were air conditioned and kept at 21.1–22.1° (70–72°F.) at all times. As closely as possible, lighting was regulated to allow 12 hr. of uniform illumination and 12 hr. of darkness each day.

The animals were initially placed in large community cages in groups of five for a period of 7–14 days. Gentling and petting were performed twice daily to individual rats. After this adjustment period the animals were randomly transferred to individual metabolism cages. For 7–10 days, the animals were individually weighed and handled each morning. Moreover, a conditioning regimen (5) was followed for the rats used in the acute stress studies. In the conditioning program the animals received 0.5 ml. of physiologic saline intraperitoneally for 5 days prior to measurement of experimental parameters.

Liquid Scintillation Counting—A liquid scintillation spectrometer³ was used for radioactivity determinations. An XDC scintillator (6) was used for counting urine samples since the scintillator solution can contain almost 30% water and still allow good counting efficiency for ¹⁴C. The TC scintillator counting solution of Mahin and Lofberg (7) was modified⁴ and used for ¹⁴C fecal counting. Absolute disintegration rates were determined by internal standardization (8).

Amobarbital-¹⁴C Assay—The radiochemical purity of amobarbital-2-¹⁴C⁵ was determined by TLC and autoradiography. A series of spots ranging from 1–100 mcg. of labeled amobarbital were spotted on commercial adsorbent (Adsorbosil-P-1) plates prepared in the usual manner and each developed in one of four solvent systems.⁶ Autoradiograms of the developed plates were obtained with Kodak No-Screen X-ray film. In all cases only one spot was visible and *R_f* values for the series of spots from each of four solvent systems were identical. No radiochemical impurities were present. No differences in *R_f* value of radiochemical purity were observed between the acid form and a sodium salt of the amobarbital-2-¹⁴C when spotted using alcohol, water, or urine as the dissolution vehicle.

³ Packard Model 3003 Tri Carb with Packard Model 574 Automatic Control, Packard Instrument Co., Inc., Downers Grove, Illinois.

⁴ The TC scintillator consisted of 5 parts toluene, 4 parts 2-ethoxyethanol, and 0.03% 2,5-diphenyloxazole (6 g./l. toluene).

⁵ Supplied by Smith Kline & French Laboratories, Philadelphia, Pa., as 5-ethyl-5-isopentylbarbituric acid-2-¹⁴C.

⁶ Chloroform-acetone (9:1), benzene-acetic acid (9:1), dioxane-benzene-aqueous ammonia (20:75:5), acetone-*n*-butyl alcohol-ammonium hydroxide (9:9:2).

Chemical purity of the labeled compound was determined spectrophotometrically.⁷ A series of five scan curves were attained from 350 to 190 $m\mu$ using standard and labeled amobarbital in concentrations of 25 to 1.6 mcg./ml. in 0.5 *N* sodium hydroxide solution. The Lambert-Beer law was obeyed and the resulting straight lines were similar. The scan curves were in agreement and exhibited identical maximum and minimum inflections at 253 and 232 $m\mu$, respectively. Melting point values were attained using a Buchi melting point apparatus for standard amobarbital (157–159°) and amobarbital-2-¹⁴C (158–159°). The amobarbital melting points were in good agreement with the official compendia (9).

Statistics—The Student's *t* test of significance between two sample means was used throughout the investigation. An analysis of variance using a two-factor experimental design with repeated measures on one factor was used with an *F* test to determine overall differences in each study. The level of significance used for all determinations between stress groups and control groups was $p < 0.05$.

Determination of Ascorbic Acid—Eight animals were subjected to unilateral hindleg ligation for 1.5 hr. while eight animals served as controls. Animals were sacrificed by cervical dislocation. The adrenals were rapidly removed, trimmed of fat, and frozen until assay. Less than 5 min. elapsed between removal of the rat from the metabolism cage until the adrenals were frozen. The method of Maickel (10) was employed for the determination of adrenal ascorbic acid. The study was conducted during the winter season.

External Acute Stress Program—An excretion study was undertaken during the winter season using unilateral hindleg ligation as the stress. Rupe (11, 12) showed that rats subjected to such stress exhibited a shortened duration of pharmacologic response to various drugs. Driever (13, 14) further demonstrated that stressed rats clear various drugs from the blood at an increased rate compared to controls. The stress was accomplished by wrapping a small unbroken rubber band (2 cm. in diameter) three times around the upper portion of the hindleg of the rat. A rapid swelling and purple discoloration of the leg took place. Hindleg ligation was applied to the stress group of 5 rats 1.5 hr. prior to intraperitoneal injection of amobarbital-2-¹⁴C and removed upon injection. A group of five animals served as controls. A dose of 10.18 μ c. (17.0 to 17.9 mg./kg.) of amobarbital-2-¹⁴C was administered to each 380–400-g. stress and control rat in the form of a freshly prepared sodium salt. Urine was collected at numerous intervals for a period of 144 hr. Fecal samples were taken at intervals of 0–24, 24–48, 48–72, and 72–96 hr.

Internal Chronic Stress Program—During the winter season, 30 rats weighing between 205–234 g. were randomly divided into two groups; the stress group received an anesthetic dose of 35 to 40 mg./kg. of unlabeled sodium amobarbital intraperitoneally twice daily while the control group received normal saline twice a day. Following the 14 days of pretreatment with unlabeled amobarbital or normal saline, all stressed and control rats received 4.98 μ c. (11.3 to 13.6 mg./kg.) of amobarbital-2-¹⁴C. The intervals of urine collection were 0–2, 2–4, 4–6, 6–8, 8–10, and 10–12 hr. while feces were collected only for the 0–24 hr. interval. The rats were sacrificed 24 hr. after the injection of labeled drug by cervical dislocation. The entire liver from each rat was rapidly removed, rinsed in normal saline, blotted on a paper towel, and accurately weighed.

RESULTS AND DISCUSSION

Adrenal Ascorbic Acid Depletion—Mean values of 445 ± 46 and 605 ± 22 mg.⁸ adrenal ascorbic acid per 100 g. (mg. %) of adrenal tissue weight for the stress and control groups, respectively, were obtained from this phase of the investigation. A greater depletion of adrenal ascorbic acid was observed in the ligated group than in the control group ($p < 0.01$), which indicated that a stress condition existed. The adrenal tissue weight of the stress and control groups was 35.38 ± 3.56 and 38.04 ± 3.54 mg., respectively. Although not statistically significant the adrenal tissue weight of the stress group was consistently lower than the control group.

External Acute Stress Urinary Excretion—Comparison between stress and control groups of the level of amobarbital and/or metabolites excreted at each urine collection interval showed that no statistical difference could be assigned to any specific time period. The cumulative mean percent of the administered dose of labeled

Figure 1—The effect of an external acute stress on the cumulative urinary excretion of amobarbital and/or metabolites. Key: ●, stress group; ▲, control group.

amobarbital recovered from the urine as amobarbital and/or metabolites during the 0–144 hr. collection interval was 82.7% for the control group and 90.2% for the stressed group. The urinary excretion rate reached a plateau at the 0–8 hr. interval (Fig. 1) with 74.8% excreted for the nonstressed group and 81.8% for the stressed group. Since the two curves were relatively straight lines after the 10–12 hr. collection period, only the 0–12 hr. cumulative interval is shown in Fig. 1. The control and stress urinary excretion data for the 0–12 hr. interval were 78.8 and 86.5%, respectively. Statistically significant differences ($p < 0.05$) were observed between the two curves for the 0–12 hr. cumulative excretion period. During the 0–12 hr. collection interval the urine volume of the stress animals (7.9 ml./animal) did not differ significantly from the controls (7.2 ml./animal).

Internal Chronic Stress Excretion—Since most drugs are prescribed in multiple doses at regular intervals, an internal chronic dosage program was designed to test the more subtle type stress effect of repeated drug administration. Repeated administration of amobarbital was selected as the chronic stress even though the use of repeated amobarbital injections may confound the development of enzyme induction and tolerance to the particular drug in measuring effects on metabolism of the same drug.

The mean urine, fecal, and total excretion of amobarbital and/or metabolites for the stress group were 88.3, 10.2, and 98.5% of the

Figure 2—The effect of an internal chronic stress on the cumulative urinary excretion of amobarbital and/or metabolites. Key: ●, stress group; ▲, control group.

⁸ Results expressed as the mean \pm standard error.

administered dose, while the values for the control group were 79.1, 11.1, and 90.2%. The mean cumulative urinary excretion plots for the stress and control groups (Fig. 2) indicate a higher cumulative urinary excretion level of amobarbital and/or metabolites for the stress group. An analysis of the stress and control data show a definite statistical difference ($p < 0.01$) between groups for the cumulative urinary excretion of amobarbital and/or metabolites. A statistical comparison of the individual time period urinary excretion data showed a significant difference ($p < 0.05$) between groups for the 6-8, 8-10, and 10-12 hr. collection intervals. During the 0-12 hr. collection interval the urine volume of the stress animals (7.0 ml./animal) did not differ significantly from the controls (6.5 ml./animal).

During the 2-week pretreatment period it was noticed that the stress rats exhibited a shorter and shorter sleep time response to the same dosage of amobarbital sodium, while the control rats were not noticeably affected by the saline injections. The sleep time observations were recorded only visually. Therefore, the following observations were only qualitative; but the trend of decreased sleep time was definitely noticeable. The injections of amobarbital caused immediate induction of sleep (≤ 5 min.) during the first three days of treatment. Sleep induction time was initially (3 to 6 days) decreased, also noted by Aston and Hibbeln (15), in that the rats exhibited narcosis almost as soon as the needle was withdrawn. Subsequently, however, the induction time increased until the 9-11 day period in which more than one-half the rats only exhibited ataxia and not anesthesia. The final injection of the central nervous system depressant resulted in the majority of the rats remaining awake, while the ones which lost the righting reflex did so for only a brief period of time (≤ 10 min.). Decreased sleeping time has been demonstrated by others (12, 16) after barbiturate administration to rats subjected to unilateral hindleg ligation. It is interesting to note that mean liver weights were recorded as 4.571 ± 0.087 and 4.478 ± 0.085 g./100 g. body weight for the internal chronic stress and control rats, respectively. The results indicated no differences between groups.

SUMMARY AND CONCLUSIONS

Tracer techniques were utilized in an investigation of the urinary excretion of amobarbital in stressed and nonstressed rats. Adrenal ascorbic acid depletion was used as an index of external acute stress induction. The adrenal ascorbic acid level of the hindleg ligation stress group was 445 ± 46 mg. % while that of the control group was 605 ± 22 mg. %. The significant difference of adrenal ascorbic acid levels between groups showed that a stress condition existed and that hindleg ligation as a stress was therefore applicable to the study of the utilization of urinary excretion as an index for indicating a stress condition. A study of the effect of an external acute unilateral hindleg ligation stress on the urinary excretion of amobarbital and/or metabolites showed significant differences in urinary excretion patterns between stress and control groups. An internal chronic stress study consisting of twice daily repeated injections

of amobarbital for 14 days showed a significant difference in urinary excretion of amobarbital and/or metabolites between treated and nontreated rats. Changes in urinary excretion phenomena as a quantitative index of a stress-altered metabolic rate response in rats were shown to be applicable for the detection of the effects of external acute ligation stress and internal chronic repeated injection stress.

Studies of Enzyme Active Sites: Synthesis and Catalytic Properties of L-Histidyl-glycyl-L-aspartyl-L-seryl-L-phenylalanine

Keyphrases □ Enzyme active sites—catalytic peptide □ L-Histidyl-glycyl-L-aspartyl-L-seryl-L-phenylalanine—synthesis, catalytic properties □ Paper chromatography, electrophoresis—identity

Sir:

Considerable attention has been focused recently on the role played by L-histidine and L-serine in the active site of chymotrypsin and other proteolytic enzymes towards the hydrolysis of various esters such as *p*-nitrophenyl acetate (1–4). One of the approaches for studying the active site of enzymes is the synthesis and evaluation of the catalytic activity of relatively simple peptides embodying as many as possible of the known features of active sites of proteolytic enzymes (5, 6). Katchalski *et al.* reported the synthesis of poly-L-histidine and copolymers of L-histidine and L-serine as model compounds to investigate the catalytic effect on the hydrolysis of *p*-nitrophenyl acetate (7). Sheehan and Cruickshank reported an interesting pentapeptide, L-threonyl-L-alanyl-L-seryl-L-histidyl-L-aspartic acid, possessing considerable catalytic activity (8). In order to provide increased flexibility in the molecule, recently Sheehan *et al.* reported the synthesis of L-seryl- γ -aminobutyryl-L-histidyl- γ -aminobutyryl-L-aspartic acid. This pentapeptide exhibited about 50% more catalytic activity towards the hydrolysis of *p*-nitrophenyl acetate, than that of previously reported synthetic peptides (9). As the separation of serine and histidine in a peptide chain led to relatively more catalytic activity, it was considered worthwhile to investigate the catalytic activity in simple peptides incorporating serine and histidine at different distances in the peptide chains. We now wish to report the preparation of a relatively more potent esterase model, L-histidyl-glycyl-L-aspartyl-L-seryl-L-phenylalanine (XIII).

The catalytic activity of the pentapeptide XIII was determined by the liberation of *p*-nitrophenol from *p*-nitrophenylacetate following the procedure used by Sheehan *et al.* (8, 9). The catalytic coefficient (7) for XIII was 179 l. mole⁻¹ min.⁻¹ compared with 92 l. mole⁻¹ min.⁻¹ for L-threonyl-L-alanyl-L-seryl-L-histidyl-L-aspartic acid (8), 147 l. mole⁻¹ min.⁻¹ for L-seryl- γ -aminobutyryl-L-histidyl- γ -aminobutyryl-L-aspartic acid (9) and 10⁴ l. mole⁻¹ min.⁻¹ for α -chymotrypsin (4).

The pentapeptide was synthesized as outlined in Scheme I. In order to limit the degree of racemization, the peptide chain was extended from the C-terminal residue phenylalanine and all peptide bonds were formed using the pentachlorophenyl active ester method (10, 11). *N*-Benzyloxycarbonyl-L-serine pentachlorophenyl ester (I) was condensed with L-phenylalanine methyl

ester hydrochloride (II) and the resulting dipeptide, *N*-benzyloxycarbonyl-L-seryl-L-phenylalanine methyl ester (III) was hydrogenated in the presence of hydrogen chloride in anhydrous methanol to afford L-seryl-L-phenylalanine methyl ester hydrochloride (IV). Coupling of IV with *N*-benzyloxycarbonyl- β -*t*-butyl-L-aspartic acid pentachlorophenyl ester (V) afforded *N*-benzyloxycarbonyl- β -*t*-butyl-L-aspartyl-L-seryl-L-phenylalanine methyl ester (VI). Hydrogenation of VI by the usual method afforded β -*t*-butyl-L-aspartyl-L-seryl-L-phenylalanine methyl ester hydrochloride (VII). Coupling of VII with *N*-benzyloxycarbonyl glycine pentachlorophenyl ester (VIII) afforded *N*-benzyloxycarbonyl glycyl- β -*t*-butyl-L-aspartyl-L-seryl-L-phenylalanine methyl ester (IX). Glycyl- β -*t*-butyl-L-aspartyl-L-seryl-L-phenylalanine methyl ester hydrochloride (X) was isolated by the hydrogenation of IX. Coupling of *N*-benzyloxycarbonyl-L-histidine azide (XI) with X led to the formation of *N*-benzyloxycarbonyl-L-histidyl-glycyl- β -*t*-butyl-L-aspartyl-L-seryl-L-phenylalanine methyl ester (XII), m.p. 158–159°.

Anal.—Calcd. for C₃₇H₄₇N₇O₁₁: C, 58.04; H, 6.14; N, 12.81. Found: C, 58.31; H, 5.97; N, 12.62.

Complete deprotection of the pentapeptide XII was achieved by saponification, hydrogenation and treatment with trifluoroacetic acid affording L-histidyl-glycyl-L-aspartyl-L-seryl-L-phenylalanine (XIII), m.p. 215–218° dec.

Anal.—Calcd. for $C_{24}H_{31}N_7O_9$: C, 51.34; H, 5.53; N, 17.47. Found: C, 51.12; H, 5.68; N, 17.19.

The free pentapeptide XIII was homogeneous to paper chromatography and paper electrophoresis under a variety of conditions.

Further studies on the catalytic activity and the chemistry of the pentapeptide XIII and other peptides incorporating histidine and serine separated by different distances of amino acids are under investigation.

Interference of Polycarboxylic Acids in the Determination of Ester Degradation by the Hydroxamic Acid Procedure

Keyphases ☐ Ester degradation determination—polycarboxylic acid interference ☐ Hydroxamate assay procedure—polycarboxylic buffer interference ☐ Colorimetric analysis—spectrophotometer

Sir:

In recent studies dealing with the kinetics of degradation of polyethylene glycol-600-mono-oleate in hydro-

Figure 1—Absorbance of ferric hydroxamate after heating hydroalcoholic solution buffered to various pH values with succinic acid for 24 hr.

alcoholic solution at 80°, inconsistent results were observed. The degradation of the ester was determined by the ferric hydroxamate procedure (1), which indicated an apparent increase in ester concentration as a function of time. Investigation of the system leads us to believe that the succinate buffer system employed appears to react with the ethanol present in the system to form esters.

Blank solutions were prepared containing 0.1 M succinic acid in 50% ethanol and adjusted to pH 2, 4, 5, and 7 with 0.1 N sodium hydroxide and then subjected to refluxing at 80° for 24 hr. Samples were then taken and assayed by the hydroxamate procedure (1) with the results shown in Fig. 1. It is readily apparent that even in the absence of the test compound there is an increase in absorbance at 520 mμ which indicates the formation of an ester species. The reaction probably proceeds *via* an intermediate anhydride formation as reported earlier (2, 3), which would show an identical pH dependency. As expected, similar results were noted in our experiments using other polycarboxylic buffer systems such as citrate and tartrate. The interference was essentially eliminated by the use of phosphate systems.

These findings clearly indicate again the potential side reactions induced by buffers which may give rise to significant interference with analytical procedures. To test the validity of the assumption that the reaction involved esterification of the ethanol, identical solutions were prepared but substituting acetone for ethanol. Acetone was chosen since, if the proposed mechanism were correct, it would not react with the proposed anhydride intermediates. Solutions, after heating under the identical conditions as cited previously, showed no change in absorbance at 520 mμ. These findings would further support the hypothesis that esterification was taking place during the heating process.

The above-cited interference could cause significant errors in the interpretation of high-temperature kinetic

Complete deprotection of the pentapeptide XII was achieved by saponification, hydrogenation and treatment with trifluoroacetic acid affording L-histidyl-glycyl-L-aspartyl-L-seryl-L-phenylalanine (XIII), m.p. 215–218° dec.

Books

REVIEWS

Amphetamine Abuse. Edited by J. ROBERT RUSSO. Charles C Thomas, Springfield, IL 62703, 1968. xii + 159 pp. 16 × 23.5 cm. Price 7.50.

This 159-page book is made up of the edited papers of the first National Institute on Amphetamine Abuse which resulted from a Delinquency Study and Youth Development Project of Southern Illinois University. It was funded from a grant awarded by the Office of Juvenile Delinquency and Youth Development, United States Department of Health, Education, and Welfare and held during February, 1966. One finds contained within this volume the various viewpoints of law enforcement, the drug industry, the sociologist, the psychiatrist, and medical researcher, and finally the interesting experience of a young amphetamine abuser himself.

Although no attempt was made to correlate the contradictions of opinions expressed, the book stands as a good example of the complex spectrum of this social problem. It covers the topics of use, misuse and abuse; psychiatric implications; violations; law enforcement problems; and the important role of education.

The reviewer can only reiterate the cover leaf description of the book which states that an educator predictively recommends education as a preventative, a member of the Narcotics Bureau pleads for stronger laws and greater police freedom in enforcement and so on. Hence, this book represents a forum for viewpoints from the various establishments affected by the amphetamine abuse problem, but does not cogently and coherently express ways to solve the problem. However, the book does clarify much confusion in this area, it provides some lines of communication and it will help provide some basis for future legal, medical, and moral decisions about amphetamine abuse.

Non-Specific Factors in Drug Therapy. Edited by KARL RICKELS. Charles C. Thomas, 301-327 East Lawrence Ave., Springfield, IL 62703, 1968, xii + 149 pp. 16 × 23.5 cm. Price \$7.75.

This symposium volume is derived from a session of the 4th World Congress of Psychiatry held in 1966. Nonspecific (*i.e.*, nondrug) factors are considered particularly as they relate both to pharmacologic treatment of depressions, neuroses, and schizophrenia, and to the psychopharmacologic effects of various drugs in normal subjects. Major nonspecific variables affecting drug therapy are grouped

as characteristics of patient, physician, treatment milieu, and non-treatment milieu. Examples of many nonspecific factors considered are attitudes of patient and physician (optimistic or pessimistic) toward drug treatment, personality characteristics of patients (or normals), duration as well as intensity of emotional disturbance being treated, and prior drug experiences. The relationship of such factors to side effects and paradoxical responses as well as to therapeutic success of drug treatment is examined.

Various nonspecific influences of psychological and sociocultural characteristics are discussed at length by several contributors in relation to the phenomena associated with placebo treatment including the controversial concept of "placebo reactors." While one chapter emphasizes the significance or "power" of the placebo and our knowledge of its relative effectiveness according to the varied circumstances, another chapter emphasizes the lack of knowledge on the true incidence of the placebo reactions and on the longitudinal consistency of the supposed "placebo reactor" characteristic. Certainly all agree to the need for further clarification of placebo phenomena and for enlarged and enlightened use of placebos in clinical drug studies.

Designed "to provide the reader with some of the latest findings and thoughts" in an interesting and significant area of psychopharmacology, the volume accomplishes this objective reasonably well. It will be most useful to those with some previous awareness of the subject and to those who will make use of the good selection of bibliographic citations included to pursue their interest among important earlier works.

Autoxidation of Hydrocarbons and Polyolefins: Kinetics and Mechanisms. By LEO REICH and SALVATORE S. STIVALA, Marcel Dekker, Inc., 95 Madison Ave., New York, NY 10016, 1969. xi + 527 pp. 15.5 cm. × 23.5 cm. Price \$29.75.

This book deals primarily with the kinetics and mechanisms of hydrocarbon and polyolefin autoxidation. Following a brief account of some early historical developments, Chapter 1 gives a clear, concise treatment of the general kinetics of free radical reactions. Chapter 2 covers the autoxidation of hydrocarbons in the absence of inhibitors and accelerators while Chapters 3 and 4 deal with simple hydrocarbon autoxidation in the presence of antioxidants and metal catalysts, respectively. The topic of weak chemiluminescence during hydrocarbon autoxidation is presented in Chapter 5,

data involving hydroalcoholic solutions such as elixirs which have been buffered with polyfunctional acids.

REVIEWS

Amphetamine Abuse. Edited by J. ROBERT RUSSO. Charles C Thomas, Springfield, IL 62703, 1968. xii + 159 pp. 16 × 23.5 cm. Price 7.50.

This 159-page book is made up of the edited papers of the first National Institute on Amphetamine Abuse which resulted from a Delinquency Study and Youth Development Project of Southern Illinois University. It was funded from a grant awarded by the Office of Juvenile Delinquency and Youth Development, United States Department of Health, Education, and Welfare and held during February, 1966. One finds contained within this volume the various viewpoints of law enforcement, the drug industry, the sociologist, the psychiatrist, and medical researcher, and finally the interesting experience of a young amphetamine abuser himself.

Although no attempt was made to correlate the contradictions of opinions expressed, the book stands as a good example of the complex spectrum of this social problem. It covers the topics of use, misuse and abuse; psychiatric implications; violations; law enforcement problems; and the important role of education.

The reviewer can only reiterate the cover leaf description of the book which states that an educator predictively recommends education as a preventative, a member of the Narcotics Bureau pleads for stronger laws and greater police freedom in enforcement and so on. Hence, this book represents a forum for viewpoints from the various establishments affected by the amphetamine abuse problem, but does not cogently and coherently express ways to solve the problem. However, the book does clarify much confusion in this area, it provides some lines of communication and it will help provide some basis for future legal, medical, and moral decisions about amphetamine abuse.

Non-Specific Factors in Drug Therapy. Edited by KARL RICKELS. Charles C. Thomas, 301-327 East Lawrence Ave., Springfield, IL 62703, 1968, xii + 149 pp. 16 × 23.5 cm. Price \$7.75.

This symposium volume is derived from a session of the 4th World Congress of Psychiatry held in 1966. Nonspecific (*i.e.*, nondrug) factors are considered particularly as they relate both to pharmacologic treatment of depressions, neuroses, and schizophrenia, and to the psychopharmacologic effects of various drugs in normal subjects. Major nonspecific variables affecting drug therapy are grouped

as characteristics of patient, physician, treatment milieu, and non-treatment milieu. Examples of many nonspecific factors considered are attitudes of patient and physician (optimistic or pessimistic) toward drug treatment, personality characteristics of patients (or normals), duration as well as intensity of emotional disturbance being treated, and prior drug experiences. The relationship of such factors to side effects and paradoxical responses as well as to therapeutic success of drug treatment is examined.

Autoxidation of Hydrocarbons and Polyolefins: Kinetics and Mechanisms. By LEO REICH and SALVATORE S. STIVALA, Marcel Dekker, Inc., 95 Madison Ave., New York, NY 10016, 1969. xi + 527 pp. 15.5 cm. × 23.5 cm. Price \$29.75.

This book deals primarily with the kinetics and mechanisms of hydrocarbon and polyolefin autoxidation. Following a brief account of some early historical developments, Chapter 1 gives a clear, concise treatment of the general kinetics of free radical reactions. Chapter 2 covers the autoxidation of hydrocarbons in the absence of inhibitors and accelerators while Chapters 3 and 4 deal with simple hydrocarbon autoxidation in the presence of antioxidants and metal catalysts, respectively. The topic of weak chemiluminescence during hydrocarbon autoxidation is presented in Chapter 5,

and the qualitative and quantitative aspects of autoxidation of saturated polyolefins are dealt with in Chapters 6 and 7, respectively. The final chapter is devoted to the investigation of polyolefin autoxidation by various techniques.

The arrangement and sequence of the subject matter is well organized and allows even the nonexpert to follow the kinetics without too much difficulty. There is an abundance of reaction rate equations which although essential for kinetic studies would appear to be overexcessive. There are also numerous chemical equations for the various autoxidation schemes. The problems given at the end of some chapters are adequate, being fairly difficult and of good variety and these should prove stimulating and challenging to the graduate student or research worker specializing in this field. However, I feel that answers to the numerical problems should have been provided and these would be most helpful to the student. The rate constants compiled in the various tables will prove to be a most useful feature to research workers in this field. The bibliography is up-to-date, covering the literature up to 1967. However, the inclusion of reference to private communication and unpublished work in a textbook is undesirable and meaningless. Several of the figures are very poorly drawn and detract from the quality of the book. The authors should have been able to reproduce the figures from the original papers. To sum up, the book can be highly recommended to the advanced graduate student and the specialist in this field who will find a wealth of material gathered together in a single book.

Purification of Inorganic and Organic Materials: Techniques of Fractional Solidification. Edited by MORRIS ZIEF. Marcel Dekker, Inc., 95 Madison Ave., New York, NY 10016, 1969. xvii + 318 pp. 15 × 23 cm. Price \$17.75.

An earlier volume edited by Zief and Wilcox, entitled "Fractional Solidification," brought together for the first time the basic principles, apparatus, and applications of all types of solid-liquid processes associated with ultra-purification of chemical compounds. The volume here reviewed is a logical sequel inasmuch as it presents reliable methods for the preparation and analysis of such compounds. The choice of the methods presented admittedly reflects the interests of the author, however, they are described by experts in the respective areas and were chosen on the basis of originality, reproducibility, and adaptability to problems normally encountered in the laboratory. Contributing authors represent a broad distribution of research laboratories, both foreign and domestic.

Part I of the book concerns the description of analytical methods for ultra-pure compounds, including a variety of spectral techniques, thermal methods, electrochemical and gas-liquid chromatographic procedures. Part II describes in detail the most useful methods available for zone melting, progressive freezing and column crystallization. Particularly unique are the chapters describing rapid purification of organic compounds, purification in kilogram quantities, zone melting chromatography, and the concentration of flavors at low temperature.

As though in answer to the question of how one maintains the integrity of an ultrapure compound, Part III presents, in a single chapter, a discussion and tabulation of data concerning containers for pure substances. Quite interesting is the fact that polyfluorocarbons compare most favorably with quartz and borosilicate as acceptable container materials.

While they ought to be, at least for pharmacological evaluation and for reference standards, medicinal compounds are not subjected to ultrapurification. The book under review presents considerations which are applicable to some organic medicinal compounds, if and when it should be desirable to render them ultrapure.

Pharmacology for the Preoperative Visit. Vol. 6, No. 1. Edited by J. S. GRAVENSTEIN. Little, Brown and Company, 34 Beacon St., Boston, MA, 1969. xi + 396 pp. 15.5 × 23.5 cm. Price \$22.00/yr. subscription rate.

Precis de Microbiologie. Vol. I. By S. LAMIN and A. GERMAN. Masson & Cie, Editeurs, 120, Boulevard Saint-Germain, Paris VI^e, France, 1969. viii + 669 pp. 16.5 × 21.5 cm. Price 75 fr.

The Psychopharmacology of the Normal Human. Edited by WAYNE O. EVANS and NATHAN S. KLINE. Charles C Thomas, 301-327 East Lawrence Ave., Springfield, IL 62703, 1969. xi + 252 pp. 15.6 × 23.3 cm. Price \$11.50.

Psychotropic Drug Response: Advances in Prediction. Edited by PHILIP R. A. MAY and J. R. WITTENBORN. Charles C Thomas, 301-327 East Lawrence Ave., Springfield, IL 62703, 1969. xii + 292 pp. 16 × 23.4 cm. Price \$12.75.

The Role of Learning in Psychotherapy. Edited by RUTH PORTER. Little, Brown and Company, 34 Beacon St., Boston, MA 02106, 1968. xii + 340 pp. 15.5 × 23.2 cm. Price \$12.00.

Steroid Reaction Mechanisms. By D. N. KIRK and M. P. HARTSHORN. American Elsevier Publishing Co., Inc., 52 Vanderbilt Ave., New York, NY 10017, 1968. xi + 476 pp. 14 × 22 cm. Price \$30.00.

and the qualitative and quantitative aspects of autoxidation of saturated polyolefins are dealt with in Chapters 6 and 7, respectively. The final chapter is devoted to the investigation of polyolefin autoxidation by various techniques.

The arrangement and sequence of the subject matter is well organized and allows even the nonexpert to follow the kinetics without too much difficulty. There is an abundance of reaction rate equations which although essential for kinetic studies would appear to be overexcessive. There are also numerous chemical equations for the various autoxidation schemes. The problems given at the end of some chapters are adequate, being fairly difficult and of good variety and these should prove stimulating and challenging to the graduate student or research worker specializing in this field. However, I feel that answers to the numerical problems should have been provided and these would be most helpful to the student. The rate constants compiled in the various tables will prove to be a most useful feature to research workers in this field. The bibliography is up-to-date, covering the literature up to 1967. However, the inclusion of reference to private communication and unpublished work in a textbook is undesirable and meaningless. Several of the figures are very poorly drawn and detract from the quality of the book. The authors should have been able to reproduce the figures from the original papers. To sum up, the book can be highly recommended to the advanced graduate student and the specialist in this field who will find a wealth of material gathered together in a single book.

Purification of Inorganic and Organic Materials: Techniques of Fractional Solidification. Edited by MORRIS ZIEF. Marcel Dekker, Inc., 95 Madison Ave., New York, NY 10016, 1969. xvii + 318 pp. 15 × 23 cm. Price \$17.75.

An earlier volume edited by Zief and Wilcox, entitled "Fractional Solidification," brought together for the first time the basic principles, apparatus, and applications of all types of solid-liquid processes associated with ultra-purification of chemical compounds. The volume here reviewed is a logical sequel inasmuch as it presents reliable methods for the preparation and analysis of such compounds. The choice of the methods presented admittedly reflects the interests of the author, however, they are described by experts in the respective areas and were chosen on the basis of originality, reproducibility, and adaptability to problems normally encountered in the laboratory. Contributing authors represent a broad distribution of research laboratories, both foreign and domestic.

Part I of the book concerns the description of analytical methods for ultra-pure compounds, including a variety of spectral techniques, thermal methods, electrochemical and gas-liquid chromatographic procedures. Part II describes in detail the most useful methods available for zone melting, progressive freezing and column crystallization. Particularly unique are the chapters describing rapid purification of organic compounds, purification in kilogram quantities, zone melting chromatography, and the concentration of flavors at low temperature.

As though in answer to the question of how one maintains the integrity of an ultrapure compound, Part III presents, in a single chapter, a discussion and tabulation of data concerning containers for pure substances. Quite interesting is the fact that polyfluorocarbons compare most favorably with quartz and borosilicate as acceptable container materials.

While they ought to be, at least for pharmacological evaluation and for reference standards, medicinal compounds are not subjected to ultrapurification. The book under review presents considerations which are applicable to some organic medicinal compounds, if and when it should be desirable to render them ultrapure.

The goal of pharmacological testing of chemical agents is (a) to detect any biological activity that may be present. Following demonstration of activity the next steps are (b) to identify the type of activity and then (c) to compare the activity with the activity of a

reference compound. To progress through steps *a* and *b* requires much experience and selective judgment. For comparison of activity, data from the experiments must be quantified. There is now a large number of excellent statistical procedures and a biologist must design his experiments so that one of the standard statistical procedures can be followed—otherwise an experimenter will end up with an experience and not an experiment. No reference to structure-activity relationships or even whether biological activity is present can be made until dose-response curves have been constructed and evaluated.

The hazards of pharmacological evaluation are many. The biologist must be aware and attempt constantly to eliminate as many variables as possible. He will always have fundamental questions that may be difficult to answer. Some of the points that must be considered are:

1. Selection of type of preparation is important. Preparations that are used widely are usually prudent choices.

2. The problem of choice of species is always present. To evaluate a particular type of pharmacological activity, choose a species that is highly sensitive to the particular agent. For example, one would not use the blood pressure of the rat to evaluate histamine-like compounds, *etc.*

3. It is necessary to determine the time-effect curves before attempting to compare the activity of two chemical agents. Agents will vary in time required for onset and duration of action. The agent's activity must be compared at time of peak effect.

4. The absorption, distribution, and excretion of agents in a given series may vary greatly. These factors

may be extremely important in determining the intensity and duration of biological activity.

5. In structure-activity relationship comparisons, the above variables make it highly desirable to evaluate compounds both *in vivo* and *in vitro*. If the relative activity of compounds evaluated in the two types of preparations remains constant, this is suggestive evidence that the difference in biological activity is related to differences in chemical structure and not related to factors such as plasma protein binding, metabolism, excretion, etc.

6. Perhaps an area where erroneous assumptions are sometimes made is in assuming that two compounds have the same mechanism of action. Unless two compounds have the same mechanism of action, one cannot compare statistically their biological activity. For example, it has recently been shown that choline is apparently devoid of muscarinic activity.¹ The literature contains many citations of the relative muscarinic activity of choline and acetylcholine and these comparisons are probably invalid. As for references to "mechanisms of action," this term means different things to different investigators. To a physiologist this term may refer to interactions at the organ level. A pathologist may be interested in cell damage or structural changes. A biochemist may be concerned with enzyme inhibition or activation. A molecular biologist may be interested in drug-receptor interactions, etc. All of these investigators using the techniques of their respective disciplines feel that they are determining the "mechanism of action." Each is for his particular biological level of integration, but one should remember that the "mechanism of action" at the molecular level awaits explanation for probably all drugs.

7. In comparing drugs one should also remember that although the end responses may look similar, the sites of action may be different. For example there could be a sequence of events as follows:

where S = substrate, E = enzyme. Drug 1 may act on E_1 and drug 2 on E_2 . Alteration of R may appear to

Figure 1—A simplified diagram illustrating the sites of action of some standard drugs. The reference drugs that stimulate or inhibit at the various sites are listed in Table I.

¹ When assayed using superfused guinea pig ilea, the intestinal stimulating action of choline is antagonized markedly by: (1) cooling the segment for 24 hr. at 2°, (2) treatment with triethylcholine, or (3) hexamethonium. None of these treatments alters the responsiveness of acetylcholine.

be the same but the sites of action that altered the response are different.

ANATOMY OF THE PERIPHERAL NERVOUS SYSTEM

Detailed outlines of the nervous system may be found in any standard physiology or pharmacology textbook. A simplified diagram illustrating the sites of action of some of the standard drugs is shown in Fig. 1 and Table I. Other anatomical points that should be considered in evaluating drug action are listed as follows:

1. Only postganglionic fibers are nonmyelinated.
2. Postganglionic sympathetic nerve fibers are usually long fibers with the ganglia outside the organs innervated. The ganglia and postganglionic parasympathetic nerve fibers usually lie within the organ innervated (the exceptions being the organs of the head and neck where the parasympathetic ganglia are on the surface or slightly removed from the organ that is innervated).
3. Various sympathetic fibers tend to be activated in unison. The activity of the parasympathetic nervous system tends to be much more localized—often serving as the efferent component of a reflex. For example, in a bright light miosis will occur, but the heart rate will not be slowed.

4. Acetylcholinesterase is found in high concentration where acetylcholine is the neurotransmitter. Inhibition of this enzyme with neostigmine or analogs or the organic phosphates will prolong the integrity of the acetylcholine molecule and increase its concentration at the transmitter site. The adrenergic enzymes, catechol-*O*-methyltransferase and monoamine oxidase, probably play a minor role in terminating the action of norepinephrine that has been liberated from the nerve terminal. Diffusion of norepinephrine from the receptor site appears to be the major terminating mechanism.

5. During the past 20 years evolution of the alpha and beta receptor theory has been seen along with the development of the respective stimulating and inhibiting agents. The major organs with their predominant type of receptor innervation are shown below:

Alpha Receptor	Beta Receptor
Vasoconstriction (cutaneous, renal, etc.)	Vasodilation (sk. muscle, etc.)
Myocardial ectopic excitation	Cardioacceleration
Splenic-capsule contraction	Myocardial augmentation
Myometrial contraction (rabbit, dog, human, etc.)	Myometrial relaxation (rat, nonpregnant cat, human)
Iris dilator contraction (mydriasis)	Bronchial relaxation
Nictitating membrane contraction	Intestinal relaxation
Intestinal relaxation	
Pilomotor contraction	
Glycogenolysis (?)	

6. The influence of drugs on the cholinergic nerve terminal has not been widely explored, but the future will probably see a marked increase of research activity. Evidence is appearing that many "nicotinic" agents may be acting by releasing acetylcholine from preganglionic or motor nerve terminals. These would be agents such as nicotine or choline. A number of agents have been reported that will inhibit or block the cholinergic nerve

Table I—Stimulants and Inhibitors at Various Sites in the Peripheral Nervous System

Site	Name	Neurotransmitter	Stimulants	Inhibitors
1	Postganglionic parasympathetic	Acetylcholine	Acetylcholine Methacholine Carbachol Neostigmine DFP	Atropine Scopolamine
2	Ganglionic	Acetylcholine	Acetylcholine Nicotine Tetramethylammonium Neostigmine	Hexamethonium (Ca) Nicotine (large concn.)
3	Postganglionic sympathetic	Norepinephrine	Norepinephrine (α) Epinephrine (α or β) Isoproterenol (β)	Phentolamine (α) Propranolol (β)
4	Sympathetic nerve terminal		Tyramine Ephedrine Cocaine	Reserpine Guanethidine Brethylum
5	Neuromuscular junction	Acetylcholine	Acetylcholine Nicotine	Curare Succinylcholine

terminal. These agents would include high Mg^{++} concentrations, hemicholinium (HC-3), triethylcholine, hexamethonium, or tetrodotoxin (puffer fish poison).

Since a drug or experimental chemical can only alter (stimulate or inhibit) the basal activity of the peripheral nervous system, one must understand the physiology of transmission. With this information one should have no difficulty in classifying autonomic agents.

The major influence of the autonomic nervous system innervation on the major organ system is outlined in Table II.

TERMINOLOGY

Often the same site of drug action is referred to by different names. For a large surplus of descriptive names, the autonomic drugs probably have a longer list than other classes of agents. The long list of synonyms used to describe autonomic drugs make the literature difficult to read for a nonpharmacologist. Table III lists those terms used commonly in the literature to describe actions of agents on the peripheral nervous system.

METHODS

The following portion of the manuscript discusses some of the procedures used to study the activity of chemical agents on the peripheral nervous system. The authors have tried to select preparations that are used quite widely and those with which they have had personal experience. Page space makes it necessary for the user of these preparations to refer to the original manuscripts for detailed procedures. All individuals interested in drug development must be familiar with a wide variety of preparations. One must clearly understand the uses and limitations of each preparation. In order to evaluate and explore new mechanisms, a biologist may need to develop his own special experimental procedures. The science of methodology is probably the pharmacologist's major tool that will lead to the discovery of new types of biologically active agents.

Observational Studies of Animals

Available methods for detecting drug actions in the intact unanesthetized animal are convenient and valuable but are less reliable and nonspecific in the analysis of individual drug effects. They can be used only for preliminary confirmation of drugs affecting the peripheral nervous system. Therefore, no attempt will be made to describe or to discuss these methods in detail. For definitive studies on the sites of drug actions, the *in vivo* and *in vitro* methods described in this paper should be employed.

Pupil Size—Mice are widely used in this experiment but dogs, cats, and rabbits can also be utilized. The pupil size is controlled primarily by tonic activity of the cholinergic nervous system. An increase in cholinergic activity or a blockade of adrenergic activity produces

Table II—Usual Responses Seen with Autonomic Function Alteration (Stimulation or Inhibition)^a

Organ	Sympathetic		Parasympathetic	
	Stimulation	Inhibition	Stimulation	Inhibition
Heart				
Rate	↑	↓ or 0	↓ ^b	↑ or 0
Force	↑	↓ or 0	↓ ^b	↑ or 0
Arterioles	↑	↓	— ^c	—
Veins	↑	↓	— ^d	—
Blood pressure	↑	↓ or 0	↓ ^e	↑ or 0
Eye				
Miosis (constriction)	↓	↑	↑	↓
Mydriasis (dilatation)	↓	↑	↓	↑
Intraocular pressure	↓	0	↑	↓
Bronchi	↑	0 or 0	↑	0 or 0
Salivary glands	↑ ^f	0	↑ ^g	↓
Gastrointestinal tone	↑	0 or 0	↑	0 or 0
Sweat glands	↑	↓ or 0	↑	↓

^a ↑, increased, stimulated; ↓, decreased, inhibited; 0, no change; —, not relevant. ^b Acetylcholine in the presence of atropine will produce a positive inotropic and chronotropic action. ^c Though there are no parasympathetic nerve fibers to arterioles, acetylcholine may be a powerful dilator (for example the limbs or the vascular beds of skeletal muscle). In some vascular beds ACh will induce constriction—aortic strips, rabbit ear, renal artery. ^d The cephalic vein is constricted by large doses of ACh. ^e Large doses of ACh administered intravenously will produce a pressor response. This response will be enhanced by prior treatment with atropine. ^f Small volume, high viscosity. ^g Large volume, low viscosity.

Table III—Synonymous or Related Terms Used in Autonomics

Site	Stimulant	Blocking Agent
Ganglia (sympathetic & parasympathetic)	Ganglionic stimulant	Ganglionic blocking agent
	Nicotinic	Ganglionic depressant
Postganglionic	Preganglionic stimulant	Preganglionic depressant
parasympathetic	Postganglionic parasympathetic stimulant	Postganglionic parasympathetic blocking agent
neuroeffector	Cholinergic	Anticholinergic
junction	Muscarinic	Antimuscarinic
	Parasympathetic stimulant	Parasympathetic blocking agent
	Parasympathomimetic	Parasympatholytic
	Cholinomimetic	Cholinolytic
Postganglionic	Postganglionic sympathetic stimulant	Postganglionic sympathetic blocking agent
sympathetic neuro-	Adrenergic stimulant	Adrenergic blocking agent
effector junction	Sympathetic stimulant	Sympathetic blocking agent
	Sympathomimetic	Sympatholytic
	Releasing agents	Antirelease agents
		Depleting agents
		"False transmitters"
Myoneural junction	Myoneural stimulants	Myoneural blocking agents
neuromuscular	Nicotinics	Myoneural depressants
junction		Neuromuscular blocking agents
		Relaxants
		Muscle relaxants

miosis, whereas an increase in adrenergic activity or a blockade of cholinergic activity produces mydriasis. The pupil size of mice can be measured with a dissecting microscope *via* a calibrated eyepiece (1-3). The drugs are administered parenterally (3) or topically on the cornea (1, 2).

Tone of the Nictitating Membrane—The position of the nictitating membrane is controlled primarily by the tonic activity of the adrenergic nervous system. Adrenergic agents cause contraction of this membrane while adrenolytic agents produce relaxation. Although cats are most satisfactory in this test, dogs and rabbits may also be used (4).

Respiratory Arrest—Subsequent to drug administration, respiratory arrest prior to cardiac arrest indicates that either the respiratory center is inhibited or that the neuromuscular junction of the phrenic nerve diaphragm is blocked. Mice can be used satisfactorily for this test (5). Central and peripheral effects can be differentiated by using isolated preparations.

Blood Pressure and Heart Rate—The overall peripheral vascular resistance is regulated by the adrenergic nervous system which can be blocked by adrenolytic agents or physiologically antagonized by cholinergic agents to produce hypotension. The heart rate is controlled primarily by the cholinergic mechanism which can be blocked by cholinolytic agents or physiologically antagonized by adrenergic agents to induce tachycardia. The indirect methods for blood pressure determination in dogs are described by Prioli and Winbury (6) and those in rats are reviewed by Van Proosdij-Hartzema (7) and Boura and Green (8). The advantages and disadvantages of these methods are discussed by Fregly (9).

***In Vivo* Study**

Dog Blood Pressure Preparations—Mongrel dogs are anesthetized with 15 mg./kg. of thiopental sodium and 250 mg./kg. of barbital sodium administered intravenously. The trachea is cannulated and the vagi are sectioned to eliminate the vagal reflexes. The arterial pres-

sure is measured with a pressure transducer (10-13) or mercury manometer (11, 14). The blood pressure can be measured at the common carotid artery, the femoral artery, or any other large artery. All compounds are injected *via* a polyethylene catheter inserted into the femoral vein. The injection is followed immediately by a wash of isotonic saline. In all cases the total volume of the injected solutions is kept constant. However, drugs can be injected directly into the femoral vein without using the polyethylene catheter. In this case, the isotonic saline wash is not necessary. The species of animal, the routes of administration, the procedures of cannulation, and the methods of recording may all be varied to meet the needs of the investigator. This preparation can also be done with rats, cats, and rabbits. Depressor responses that are blocked by atropine sulfate are regarded as muscarinic and pressor responses after 1-2 mg./kg. of atropine sulfate are regarded as nicotinic. However, due to the multiple factors affecting the mean systemic pressure, interpretation of the pressure change is difficult. If the blood flow in the large vessels is recorded by use of an electromagnetic flowmeter (4) simultaneously with the pressure change, then the interpretation of the experimental results is facilitated.

The catecholamines released by ganglionic stimulants can be estimated by collecting blood samples at the time of peak pressor response. Blood cells and protein in the blood samples are removed (15) and the catecholamines in the final samples are assayed fluorometrically using the method described by Chang (16). The sites of catecholamine release, either from the adrenal medulla (mainly epinephrine release) or from sympathetic nerve terminals (mainly norepinephrine release), have thus been differentiated (14).

The blood pressure preparation is widely used to determine dose-response curves and activities of drugs (10-12, 14). The eviscerated cat blood pressure preparation is quite sensitive to acetylcholine and can readily detect 0.002 mcg. ACh/kg. (17). The rat preparation is also widely used for bioassay of minute amounts of acetylcholine and the analogs from tissue extracts (11, 18, 19).

Recently more attention has been given to the direct measurement of blood pressure using unanesthetized animals. This preparation enables investigators to study the drugs with a very long duration, to repeat measurements of blood pressure over a long period of time, and to avoid the untoward interaction between anesthetics and drugs to be studied. The advantages and disadvantages of both preparations have been discussed by Freyburger (20). For dogs, the polyethylene catheters are implanted chronically in various parts of the circulation (21), mostly into thoracic aorta (22, 23) and the femoral artery (20). The transcutaneous needle puncture of a femoral artery immediately before experimenting is also used and is the most simple method to be performed with satisfactory results. Hypodermic needles (19–21 gauge) are widely used to obtain full pulse pressure measurements. However, smaller needles are recommended to avoid vessel hardening and hematomas (20, 24). The polyethylene catheters or hypodermic needles are connected to the pressure transducer for recording the blood pressure described previously. The direct measurements of blood pressure on unanesthetized rats are described by Weeks and Jones (25) and Fujita and Tedeschi (26).

Cat Superior Cervical Ganglia Preparation—Cats are anesthetized with 30–35 mg./kg. of pentobarbital sodium administered intrathoracically. The trachea is cannulated as usual and the carotid artery is exposed. The lymphatic gland is removed and all the arterial branches, except those running to the tissue around the superior cervical ganglion, are tied and divided. The small internal carotid artery and veins are divided, leaving only the vein from which perfusion fluid is to be collected, usually the internal jugular vein. A length of cervical sympathetic nerve, sufficient for placement of the electrodes, is freed and the cat's head is then fixed in position so that the contraction of the nictitating membrane can be recorded. The common carotid artery is then ligated and perfused. A small cannula is then tied into the internal jugular vein to collect the perfusion fluid. The electrodes are placed on pre- and postganglionic fibers (27–29). In order to prevent blood coagulation during manipulation, 0.5 ml./kg. of 8% solution of chlorazal fast pink or 5 mg./kg. of heparin sodium is injected intravenously (30). The nerve is stimulated with monophasic pulses, 6 msec. in duration, with maximal voltage of 10–15 v. and frequencies of 10–25 c.p.s. (31). A viable preparation will respond to single shock stimulation. This is an extremely useful preparation for detecting the release of acetylcholine from ganglia, either by preganglionic nerve stimulation (32, 33) or by close arterial injection of the drugs (34, 35). The effects of drug and nerve stimulation can be detected from the responses of nictitating membrane. An ingenious experiment was devised by Collier *et al.* (36) in which the ACh in the ganglia was replaced with ^3H -ACh through perfusion of the ganglia with Locke solution containing ^3H -choline during continuous preganglionic stimulation. Both preganglionic stimulation and close arterial injection of carbachol released radioactive materials and contracted the nictitating membrane, indicating that endogenous ACh was released during these treatments. The close arterial injection of ACh, however, contracted

the nictitating membrane without releasing appreciable amounts of radioactive substance. This suggests that ACh might not be involved in the release of endogenous ACh from the preganglionic site.

Dog Chorda Tympani-Wharton's Duct Preparation—Dogs weighing 12 kg. or more are anesthetized with 15 mg./kg. of thiopental sodium and 250 mg./kg. of the barbitol sodium administered intravenously. The trachea is cannulated. Wharton's ducts are located directly beneath the mylohyoides and extend across the lingual nerve between the chorda tympani nerve and the submandibular ganglion. Both Wharton's ducts and the chorda tympani nerve are ligated. The chorda tympani nerve is cut free from the lingual nerve with a thread attached to the nerve end. One of the Wharton's ducts is then cannulated with polyethylene tubing (PE-60) which is attached to a reservoir filled with physiological saline. The outflow of the reservoir is connected to a dropping tube and a Becker signal magnet is connected to a relay which is activated by each drop. A shielded silver electrode is attached to the chorda tympani nerve for stimulation. The nerve is stimulated supramaximally with 15 v. for a duration of 2 msec. with a single biphasic impulse and with a frequency of 20 c.p.s. for 1 sec. every 10 sec. (37). After 10–20 min. the saliva flow will remain quite constant for at least 90 min.

Salivation from the Wharton's duct can be stimulated either by drugs such as pilocarpine, acetyl- β -methylcholine, and acetylcholine injected intravenously into the femoral vein or by nerve stimulation. The salivation is effectively blocked by atropine. This preparation is useful for studying drugs which act on or block the cholinergic system causing salivation. Hemicholinium has been shown to block gradually the salivation induced by chorda tympani nerve stimulation, suggesting that its blocking effect is due to the inhibition of ACh synthesis in the nerve tissues (37).

Rabbit Sciatic Nerve-Gastrocnemius Muscle Preparation—Dutch rabbits, weighing 1–2 kg., are anesthetized with 200 mg./kg. of phenobarbital sodium administered slowly (at least 2 min.) into the marginal ear vein. The sciatic nerve is ligated and cut, and a shielded electrode is placed on the peripheral portion of the nerve. The gastrocnemius muscle is freed as completely as possible from surrounding muscles and a thread is attached to the tendon of the muscle. The twitches of the muscle are elicited by supramaximal stimulation and are recorded through a force transducer. The parameters for interrupted tetanic stimulation are 250 c.p.s. with pulse duration of 1 msec. at 15 v. applied for 0.2 sec. every 10 sec. Single shock stimulation is performed with pulse duration of 5 msec. and a supramaximal voltage of 15 v. is applied every 10 sec. The drugs are administered intravenously into the marginal ear vein. This is a convenient and simple preparation for studying drugs acting at the neuromuscular junction *in vivo* (37–41). Although there are some *in vitro* neuromuscular preparations available, this preparation has the advantage of studying the drug effects under physiological conditions. For example, hemicholinium and its derivatives have been shown to block neuromuscular transmission in all preparations. In this preparation, blockade can be efficiently reversed by choline (39–41)

but this is difficult using *in vitro* preparations. Animals other than rabbits, such as cats and rats, can be used satisfactorily.

There are two other preparations, the cat soleus muscle preparation and the cat tibialis anticus muscle preparation which are very useful and similar to the gastrocnemius muscle preparation. These can be prepared in a method similar to that described for gastrocnemius muscle except that close arterial injection can be made using the tibialis anticus preparation. Also, soleus muscle consists primarily of slow muscle, whereas tibialis anticus is fast muscle (42). The experimental procedures for these two preparations are described by some investigators in detail (42–44). The characteristics of slow and fast muscles are analyzed anatomically, histochemically and biochemically by some investigators. The fast muscle is composed of three distinct fibers (45) whereas the slow fiber is relatively homogeneous, consisting primarily of Type B fibers (46). Also, the fast muscle contains higher activities of glycolytic enzymes and lower activities of oxidative enzymes, while the reverse is true for the slow muscle (47, 48). The effects of drugs on slow and fast muscles will be discussed further in the following sections.

***In Vitro* Study**

The organ bath method is the most widely used technique for studying isolated organs. The equipment is rather simple and is available commercially. Usually, the organ bath is made of glass and placed inside a water bath so that the temperature can be well controlled. The physiological salt solution is warmed before it is added to the organ bath, so that there will be no temperature change when the tissue is washed. The physiological salt solution can be warmed either by putting the reservoir bottle in a water bath or by passing the physiological solution through coils connected to the organ bath within the same water bath. The isolated tissue is mounted in such a way that one end of the tissue is fixed at the bottom of the organ bath while the other is fixed to the recording lever or a force transducer for isotonic or isometric recording. The organ bath varies both in size and volume depending on the specific purposes and the size of tissues. The volume of the drug solutions to be added to the organ bath should be less than 10% of the total volume of the bath fluid to avoid possible decrease of fluid temperature in the organ bath.

The superfusion method was first described by Finkleman (49) and modified by Gaddum (50). It is more rapid and more sensitive than the organ bath method for bioassay. This technique reduces the volume of solution to an absolute minimum by replacing the organ bath with a slow flow of bathing fluid over the external surface of the tissue. Consequently, the total amount of drug required to induce a response in the tissue is very small. Recently, this technique has been used successfully to study the fate and release of vasoactive hormones in the circulation (51–53). In this application the heparinized blood was continuously removed from the anesthetized animal, assayed for its hormone content by superfusion over a series of isolated muscle preparations, and then returned to the animal body intravenously.

For superfusion, the isolated tissue is mounted in air in the middle of a wide glass tube immersed in a warm water bath. The physiological salt solution is oxygenated and kept in a bottle immersed in a warm water bath. It is then pumped through a Holter motor pump to the top of the isolated tissue. The rate of flow of the superfusion fluid is adjusted to 1–5 ml./min. depending on the size of the tissues; the drug solutions are injected into the stream of the superfusion fluid in volumes of not more than 0.1 ml. Of course drugs may be added directly to the perfusing solution. Isometric recordings are preferred to isotonic recordings because the changes in the length of the tissue may dislocate the superfusion fluid in some cases and cause dryness of part of the tissue.

Skeletal Muscle Preparations—Frog Rectus Abdominis Muscle Preparation—The frog rectus abdominis muscle is usually obtained from *Rana pipiens* weighing approximately 20 g. The frog is stunned and decapitated. The spinal cord is destroyed with a long needle. The rectus abdominis muscles are dissected from the pelvic girdle to their insertion in the cartilage of the pectoral girdle. The threads are attached to both ends of the muscle before they are dissected from the body. An initial tension of 0.5–1.0 g. is placed on the rectus muscle. The preparation is kept at room temperature (25°) in frog Ringer solution (NaCl, 6.5; KCl, 0.14; NaH₂PO₄, 0.005; glucose, 2.0; NaHCO₃, 0.4; and CaCl₂, 0.12 g./l.) and oxygenated with 95% O₂ and 5% CO₂. At least 30 min. is allowed for the preparation to stabilize. This preparation was originally described by Burn (54). Both the organ bath method (5–10 ml.) (54–56) and the superfusion technique (10, 39) can be used to perform experiments. The frog Ringer solution can also be made by diluting 1 l. of Ringer solution to 1.4 l. with distilled water.

The rectus abdominis muscle preparation is extremely useful because it develops slow contracture in response to acetylcholine. This contracture is blocked by curare and its derivatives. Depolarizing agents, such as decamethonium or succinylcholine, will induce contracture that is similar to acetylcholine. Although the semispinalis muscle of the chick has the same useful properties, the simplicity and economy of the rectus preparation are widely appreciated by many investigators.

After contraction, the rectus muscle does not relax rapidly. It is, therefore, difficult to obtain the straight base line which is essential for bioassay. Thus, in order to obtain this straight base line, the muscle must be stretched gently by increasing the tension. This disadvantage can be eliminated by using isometric recording instead of isotonic recording. Also since the rectus muscle does not relax rapidly, it takes at least 6-min. intervals between doses in the organ bath method to assay acetylcholine. The superfusion technique is considerably faster, since it requires only 1–2-min. intervals between doses.

The rectus muscle preparation can also be used for assaying acetylcholine and its derivatives, although its sensitivity is less than that of the guinea pig ileum, chick semispinalis muscle, and leech dorsal muscle treated with physostigmine. The sensitivity of

the preparation can be increased markedly by using the superfusion technique instead of the organ bath method and by treating the rectus muscle with physostigmine or neostigmine. The frog rectus muscle preparation, treated with 1.5×10^{-6} mole of physostigmine, can detect 0.01 mcg./ml. of acetylcholine chloride (1×10^{-7} mole) in the organ bath method (55) or 0.01 mcg. of acetylcholine chloride per injection in the superfusion method (10, 39).

Leech Dorsal Muscle Preparation—The Leech, *Hirudo medicinalis*, is pinned on its back through the mouth and the tail sucker and a cut is made along the two pale lateral lines to get two parallel strips from the dorsal body wall. The threads are attached at both ends of each piece. The muscle is suspended at room temperature (25°) in frog Ringer solution, or in leech Locke solution. These solutions are made by diluting 1 l. of Ringer solution or Locke solution (NaCl, 9.0; KCl, 0.42; glucose, 1.0; NaHCO_3 , 0.5; and CaCl_2 , 0.12 g./l.) to 1.4 l. with distilled water. The solution is oxygenated with 95% O_2 and 5% CO_2 . An organ bath with a capacity of 5–10 ml. is used. The preparation must be stabilized for about 3 hr. before an experiment is begun. The contraction responses are very slow. However, unlike the frog rectus muscle, it should not be stretched by increasing the tension. Consequently, the responses are slow and it is necessary to allow at least 20 min. between doses (56). Physostigmine (3×10^{-5} mole) is preferred to neostigmine (3×10^{-4} mole) in order to sensitize this preparation (57). The muscle can be sensitized about 1000-fold to acetylcholine responses by physostigmine. This preparation is highly sensitive and is suitable for detection of acetylcholine (less than 10^{-8} mole or 0.001 mcg./ml.) released from nerve tissue (58–60). However it is not suitable for studying the pharmacology of drugs because of the length of response time involved. It is much better to choose the guinea pig ileum, chick semispinalis muscle, or frog rectus abdominis muscle for studying the pharmacology of the drugs since a larger quantity of results can be obtained in a shorter period of time.

Chick Semispinalis Cervicis Muscle Preparation—A chick, 2–3 weeks old, is sacrificed with chloroform. A longitudinal incision is made in the skin at the back of the neck from the base of the skull to the region of the thoracic vertebrae. The two biventer cervicis muscles can be seen on either side of the midline just underneath the surface skin. Those located beneath the biventer cervicis muscles are the two semispinalis cervicis muscles. The semispinalis cervicis muscle is dissected away from the surrounding muscles and the threads are tied around each end of the preparation. The muscle can be mounted either in an organ bath (5–10 ml.) (61–63) or on a superfusion apparatus (64). An initial tension of 1 g. is placed on the tissue. Tyrode solution (NaCl, 8.0; KCl, 0.2; $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$, 0.26; NaH_2PO_4 , 0.05; glucose, 1.0; NaHCO_3 , 1.0; and CaCl_2 , 0.2 g./l.) at 40° , oxygenated with 95% O_2 and 5% CO_2 , is used for the bathing fluid.

Like the frog rectus abdominis muscle, this preparation produces a slow contracture in response to acetylcholine and acetylcholine-like substances. Because it is more sensitive to drugs mimicking acetylcholine and because the muscle contracts and relaxes more rapidly this preparation is more advantageous than the frog rectus abdominis preparation (61, 62). Consequently, artificial

stretching of the muscle is not required. This preparation is capable of detecting 0.004 mcg./ml. of acetylcholine chloride (2.4×10^{-8} mole). Edrophonium chloride is preferred to physostigmine, neostigmine, diisopropylfluorophosphate, and tetraethylpyrophosphate for inhibition of the cholinesterases in the tissue because these anticholinesterases either produce too little increase in sensitivity or cause a partial contracture of the muscle. Edrophonium chloride (final concentration of 8 mcg./ml. or 4×10^{-5} mole) is injected into the organ bath before each addition of acetylcholine. It is not included in the Tyrode solution, since, if used in this way, it will cause long lasting contracture even at extremely low concentrations (62).

Rat Phrenic Nerve-Diaphragm Preparation—A rat is decapitated and the blood is drained. The skin is removed from the middle of the chest. The thorax is opened and the front part of the left thoracic wall is removed. The phrenic nerve can be seen quite distinctly. The nerve is cut just below the thymus and a thread is attached to the cut end. The nerve is then freed carefully from the attached tissue. However, no attempt is made to clean the nerve completely from the tissues attached to it. An incision is made in the left abdominal wall just below the diaphragm. Two converging cuts are made through the diaphragm and the ribs towards the tendinous part of the diaphragm with the phrenic nerve attached to the center of the diaphragm. The fan-like preparation is about 3 mm. wide at the tendinous end and is about 15 mm. wide at the costal margin. A thread is attached to the tendinous part of the diaphragm. The preparation is fixed by a stainless steel rod with a pair of pins hooked on the rib. It is lowered into the organ bath and the thread from the muscle is attached to the writing lever or the force transducer. The nerve is stimulated with a pair of electrodes with a hole about 1 mm. wide. The right phrenic nerve-diaphragm preparation is isolated in the same manner. The organ bath should be 30–40 mm. in diameter and 30–40 ml. in capacity. Tyrode solution at 37° containing double the amount of dextrose or Krebs solution (NaCl, 6.9; KCl, 0.35; $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$, 0.14; KH_2PO_4 , 0.16; glucose, 2.0; NaHCO_3 , 2.1; and CaCl_2 , 0.28 g./l.) is used as bathing fluid. The solution should be well oxygenated with 95% O_2 and 5% CO_2 . The nerve is usually stimulated about 12 times per minute by rectangular-wave pulses of about 0.5-msec. duration at 3–5 v.

This preparation was originally described by Bülbring (65) and was modified and widely used thereafter by many investigators for studying drugs affecting the neuromuscular transmission (55, 66–68). The drugs are left in the organ bath either for quite short periods of time (3–8 min.) or for as long as the maximum effect can be observed. This preparation is composed mainly of fast muscle and is excellent for determining the drug potency to block or facilitate neuromuscular transmission. However, it is not a good preparation for differentiating between depolarizing and nondepolarizing neuromuscular blocking agents because, in many cases, depolarizing blocking agents fail to demonstrate initial facilitation and fail to reverse the effect of nondepolarizing blocking agents. For differentiating between depolarizing and nondepolarizing blocking agents the

chick biventer cervicis nerve muscle preparation and the chick sciatic nerve-tibialis anticus muscle preparations are preferred.

Chick Biventer Cervicis Nerve Muscle Preparation—This preparation is isolated by the same method described in the section on the chick semispinalis cervicis muscle. A loop is tied around the caudal belly of the muscle and hooked on the bottom of the electrode assembly. The oral end of the tendon is passed through the electrode and attached to a lever or an isometric force transducer. The whole assembly is placed in the organ bath (63). Superfusion technique has been applied to this preparation by Chiou and Long (64). The electrode assembly is similar to the one used in the organ bath method described by Ginsborg and Warriner (63) except that a small cup with a hole for superfusion is attached above the electrode. The small cup over the electrode is essential for superfusion of the biventer cervicis nerve muscle preparation because it eliminates the mechanical stimuli of the drops of superfusion fluid on the motor nerve, which cause irregular twitching of the muscle (64).

Tyrode or Krebs solution, at 37°, is used as bathing fluid and oxygenated with 95% O₂ and 5% CO₂. The initial tension placed on the muscle is 1 g. The organ bath is similar to that used for the rat phrenic nerve-diaphragm preparation. The nerve is stimulated about 6–12 times per minute by rectangular-wave pulses of about 0.5-msec. duration at 100 v. Supramaximal interrupted tetanic stimulation can also be applied (64). This preparation is extremely useful for easily differentiating between depolarizing and nondepolarizing neuromuscular blocking agents because the former agents contract slow fiber while the responses of fast fiber to the nerve stimuli are blocked, whereas the latter agents block the responses of fast fiber to the nerve stimuli without disturbing the tonus of the slow fiber. In addition, this preparation has been used successfully to demonstrate the acetylcholine releasing effects of some nicotinic agents which were originally believed to act directly at the acetylcholine receptors on the muscle membrane (64). The sensitivity of this preparation to acetylcholine and nicotinic agents can be increased markedly with 7×10^{-7} mole of physostigmine. Neostigmine is not a good agent to be used since it causes long-lasting contracture with concentrations at 1.5×10^{-6} mole or higher.

Chick Sciatic Nerve-Tibialis Anticus Muscle Preparation—Chicks, 3–8 days old, are decapitated and the skin of the legs is rapidly removed. The leg is removed from the body by cutting through the hip joint, and is suspended in a Petri dish containing Krebs-Henseleit solution equilibrated with 95% O₂ and 5% CO₂ at 4°. The muscles of the thigh are dissected and the sciatic nerve with the superficial peroneal branch is freed from the upper leg tissue. The fascia is removed from the lower leg and the tibialis anticus tendon identified. A thread is attached to the tendon of the muscle and the tibialis anticus muscle is freed towards but not up to the knee joint attachment where the nerve enters into this region. The upper and lower leg bones are then cut off leaving the muscle with its nerve attached to the knee joint. The tendon is fastened by the hook to a ring in the bottom of the organ bath. A thin steel rod is attached to the knee

joint by means of a pointed clamp, partially driven into the bone. The contraction of the muscle is recorded isometrically. The nerve is passed through an electrode similar to the one used in the rat phrenic nerve-diaphragm or the chick biventer cervicis nerve muscle preparations. The nerve is stimulated six times per minute for 0.5-msec. duration at supramaximal voltage. The organ bath is filled with 20 ml. Krebs-Henseleit fluid, at 37°, and is oxygenated with 95% O₂ and 5% CO₂.

This preparation was originally described by Van Riezen (69, 70) and is similar to the chick biventer cervicis nerve muscle preparation. It is a simple and useful preparation for measuring drug potency and for classifying the neuromuscular blocking agents into depolarizing and nondepolarizing agents. The curare-like drugs produce a neuromuscular blockade whereas the decamethonium-like drugs induce a contracture of the slow fiber when the neuromuscular transmission is blocked.

Smooth Muscle Preparations—Guinea Pig Ileum Preparation—Guinea pigs, weighing 300–500 g., are stunned by a blow on the head. The abdomen is opened, the cecum is lifted forward and the ileum which joins to the back portion of the cecum is identified. The terminal portion of the ileum is excised and placed in a dish containing Tyrode solution. The mesentery is trimmed away and pieces are cut from the length of ileum as required. Threads are tied around both ends of the ileum. Both the organ bath method (5–10 ml. capacity) (55, 56, 71–73) and the superfusion technique can be used satisfactorily (10, 49, 74, 75). Tyrode solution at 37°, oxygenated with 95% O₂ and 5% CO₂, is used. This is a simple, sensitive, and accurate preparation for the detection of acetylcholine (0.0025 mcg./ml. or 1.5×10^{-8} mole with organ bath method and 0.0025 mcg./injection with superfusion technique). Occasionally the spontaneous contraction of the ileum makes it difficult to establish a straight base line which is essential for bioassay. Antihistamines (71) or morphine (72, 73) may be added to the Tyrode solution to eliminate these spontaneous contractions. The longitudinal smooth muscle of the guinea pig ileum is preferred to the whole ileum in this respect because it produces very little if any spontaneous contractions (55). Three minutes should be allowed between doses in the organ bath method and 1 min. between doses in the superfusion technique.

A superfused cooled guinea pig ileum preparation has been developed particularly for bioassay of endogenous acetylcholine released by acetylcholine releasers (74, 75).

Longitudinal Smooth Muscle of Guinea Pig Ileum—The guinea pig ileum, up to 15.24 cm. (6 in.) in length, is excised according to the method described in the section on the guinea pig ileum preparation. The ileum is gently freed of excess mesentery and pulled over a glass rod immersed in Tyrode solution in a large shallow container at room temperature (25°). Dissection of the longitudinal muscle layer is performed by making the initial incision along the site of attachment of the mesentery. The mesenteric remnant is held with forceps to minimize crush damage and the longitudinal muscle is separated from the underlying structure by gentle tension with forceps in a direction parallel to the underlying circular muscle fiber (55, 76–80). A piece of longitudinal smooth muscle, about 2 cm. in length, tied at both ends,

is placed in an organ bath with a capacity of 1–5 ml. or in a superfusion assembly. The Tyrode solution, at 32°, is oxygenated with 95% O₂ and 5% CO₂. The preparation shows minimum spontaneous contractions when the Tyrode solution is kept at 32° (55, 81).

This preparation is preferred to the whole ileum for the following reasons (55): (a) The preparation consists of fairly pure longitudinal smooth muscle (about 82%) and the amount of noncontractile tissues such as nervous elements, serosa, etc., is small compared to that of the whole ileum. (b) The preparation is very thin so that the drugs can easily contact the cell membrane and can easily be washed away. Therefore, the preparation lasts longer and gives more consistent responses to the drugs. (c) The preparation shows little, if any, spontaneous contraction, whereas spontaneous contraction of the whole ileum makes it difficult to establish a uniform base line. (d) The preparation is much smaller than the whole ileum so that a much smaller organ bath can be used to perform the experiment. The capacity of 1 ml. has been used in this preparation, whereas 5 ml. is the minimum capacity for whole ileum preparation. The sensitivity of this preparation to acetylcholine is about the same as that of whole ileum preparation.

Peristalsis Movement of Guinea Pig Ileum—A piece of guinea pig ileum, about 4–6 cm. in length, is suspended in an organ bath with a capacity of 50 ml. The oral end of the ileum is tied to the short end of a “J” tube while the caudal end is attached to an inverted “U” tube which is fitted with a valve made from flat drainage tubing. The inverted U tube is suspended from a lever or a force transducer which records the longitudinal contractions. The long limb of the J tube is used to transfer the pressure changes in the intestinal lumen by air transmission to a float recorder. Tyrode solution from a Mariotte bottle enters the intestinal lumen through a polyethylene tube connected to the short end of the J tube. The peristaltic reflex is initiated by raising the pressure in the lumen by 2–3 cm. of Tyrode solution, at 37°, which is oxygenated with 95% O₂ and 5% CO₂.

This preparation was described by Bülbring *et al.* in detail (82). It can be used to study the intestinal peristalsis, longitudinal contractions, intraluminal pressure, and volume of fluid expelled. The peristaltic movements can be inhibited effectively by catecholamines. The doses of catecholamines required for complete inhibition of peristalsis are: 0.1 mcg./ml. of epinephrine HCl, 0.5 mcg./ml. of norepinephrine HCl, and 30 mcg./ml. of *dl*-isoproterenol sulfate. The inhibitory effect of the catecholamines on the peristaltic movement can be reversed by the adrenergic blocking agents (83). The drugs can be applied to the inside of the intestine as well as to the outside. This preparation can also be used to test local anesthetics, ganglionic blocking agents, and atropine-like compounds (84–86). However, the sensitivity of the tissue fluctuates considerably. Thus, it is more suitable for qualitative than quantitative work. This method is modified from those described by Bülbring and Lin (87), and Trendelenburg (88).

Coaxial Stimulation of Guinea Pig Ileum—A loop of guinea pig ileum is suspended in Krebs solution, at 37°, and oxygenated with 95% O₂ and 5% CO₂. The lower end of the intestine is tied to glass tubing into which an

electrode protrudes so that the electrode can move freely with the movements of the intestine. The upper end of the ileum is tied to a fine polyethylene tubing which encloses the upper part of the platinum wire from its emergence from the intestine, up above the surface of the bath fluid. A second platinum electrode is dipped into the bath fluid and makes the whole bath a diffuse external electrode. The arrangement permits a uniform excitation over the whole ileum and ensures that all the stimulation current applied traverses the intestinal wall. The preparation is stimulated with shocks of 0.5-msec. duration. The threshold voltage is about 1 v. and the maximal voltage is about 5–25 v. (89).

This preparation is more suitable for qualitative than for quantitative study and was originally described by Paton (89). It has been suggested that the postganglionic cholinergic fibers are selectively stimulated through coaxial electrodes in this preparation, which has been used to differentiate between direct and indirect drug actions on the guinea pig ileum (86, 90–92).

Nerve-Jejunum Preparation of Rabbit—The rabbit is stunned by a blow on the head. The abdomen is opened and the jejunum which has the most mobile mesenteric attachment is taken. The nerve which lies in the mesentery along with the arterial blood supply is identified. Great care is taken not to stretch or otherwise damage the nerve in the mesentery. The intestine, about 2–3 cm. in length, is mounted in the organ bath of 30-ml. capacity or on a superfusion assembly. The mesentery is threaded and passed through an electrode similar to that used in the rat phrenic nerve-diaphragm preparation. The nerve is stimulated with rectangular-wave pulses of 0.5-msec. duration and about 10 v. The slow rate stimulation (2–4 pulses/min.) may produce parasympathetic effects, whereas a high rate of stimulation (30–50 pulses/min.) produces sympathetic effects. To avoid fatigue, the stimulus should not be applied for more than 30 sec. and at least 1.5–2 min. should be allowed for recovery. Tyrode solution at 37°, oxygenated with 95% O₂ and 5% CO₂, is used to perform the experiment.

This preparation was originally described by Finkleman (49) and is suitable for qualitative rather than quantitative studies of adrenergic blocking agents, cholinergic blocking agents, and local anesthetics. The preparation is especially useful for evaluating agents acting on the adrenergic nerve terminals. Physiological antagonism between catecholamines and parasympathetic effects can also be shown in this preparation (56).

Rat Fundus Strip Preparation—A rat is decapitated and is left to bleed. The abdomen is opened. The fundal part of the stomach is dissected, opened out longitudinally and placed in a dish containing Krebs solution. Suitable transverse cuts are made to obtain a strip about 4–5 cm. long. Threads are attached at both ends and the strip is mounted in an organ bath of 5–10-ml. capacity. An initial tension of 1 g. is placed on the preparation. Krebs solution, at 37°, is oxygenated with 95% O₂ and 5% CO₂. Since the muscle does not relax spontaneously after contraction by drugs, it must be stretched to assist its recovery to the original length. Isometric recording is better than isotonic recording since the muscle length

can be kept constant. The preparation should be left in the organ bath at least 30 min. before use and 6 min. or longer should be allowed between doses.

This method was originally described by Vane (93). It is extremely sensitive to 5-hydroxytryptamine which contracts the muscle at dose levels as low as 0.4–0.8 ng./ml. For bioassaying 5-hydroxytryptamine in the tissue extracts, atropine or hyoscyne must be added to the Krebs solution. The sensitivity of this preparation to acetylcholine is lower than that of the leech dorsal muscle treated with physostigmine and is about the same as that of the guinea pig ileum. This muscle is rather insensitive to nicotine and histamine.

Rat Uterus Preparation—Young female rats, weighing 150–200 g., are decapitated and the abdomen opened. The animal should be in oestrus which can be induced by injecting subcutaneously 0.1 mg./kg. of stilbestrol 24 hr. before the animal is sacrificed. The two horns of uteri are transferred to a dish containing warm DeJalon solution (NaCl, 9.0; KCl, 0.42; glucose, 0.5; NaHCO₃, 0.5; and CaCl₂, 0.03 g./l.) or Krebs bicarbonate solution. Each horn is cut open and divided longitudinally so that four pieces can be obtained from one animal. The threads are tied to each end of each piece (about 2 cm. in length *in situ*), which is then mounted in an organ bath of 10 ml. capacity. The DeJalon solution, at 30–32°, is oxygenated with 95% O₂ and 5% CO₂, which maintains the pH at about 7.4. An initial tension of 0.5 g. is applied to the muscle and the contraction is measured isometrically. The preparation should be left for 30 min. before use (94).

The responses obtained with this tissue are quicker than those obtained with the rat fundus strip preparation but are slower than those produced by the guinea pig ileum preparation. Spontaneous contractions are quite obvious in this preparation when usual physiological salt solutions are used as bathing fluid. The calcium concentration in DeJalon solution is therefore lower than in other physiological salt solutions. Three minutes or longer should be allowed between doses.

This preparation is extremely useful for studying the cholinergic effects of acetylcholine and its derivatives for the following reasons (56): (a) The slope of the log dose-response curve obtained with acetylcholine and its derivatives is very steep and thus is convenient for analysis of the results. (b) It is remarkably insensitive to histamine. However, it is not suitable for bioassay of acetylcholine and its derivatives obtained from tissues because the sensitivity of this preparation is lower than those of the guinea pig ileum and the leech dorsal muscle treated with physostigmine. Though the preparation is less sensitive than the rat fundus strip for 5-hydroxytryptamine assays, it has the definite advantage of readily returning to basal tension following exposure.

This preparation is historically very important because it has β -adrenergic receptors. Therefore, it is very sensitive to epinephrine (10^{-7} mole) and *dl*-isoproterenol (2×10^{-8} mole) but is relatively insensitive to norepinephrine (2×10^{-6} mole) and ephedrine (2×10^{-5} mole) (94–96). The bioassay of catecholamines has been largely replaced by the sensitive fluorometric method. However, this preparation is still very useful for pharmacologic studies on catecholamines. For pharma-

cologic study of α -adrenergic agents, the rabbit aortic strip preparation can be used.

Rabbit Aortic Strip Preparation—A rabbit is sacrificed by a blow on the head and cutting the throat for bleeding. The descending aorta is removed and is placed in a dish containing Krebs solution at room temperature. The excised aorta is cut spirally with a small sharp-pointed scissors to produce a strip about 3 mm. wide and 2–4 cm. long. The uncut portion of the aorta is held gently between thumb and fingers of the free hand and is moved gradually forward to the scissors to permit a continuous spiral incision. It is not recommended to pull the aorta over a glass rod or a wooden rod for faster cutting because the aorta strip does not respond well to drugs because of injury by stretching on the rod. Threads are attached to both ends of the preparation which is then mounted in an organ bath of 10-ml. capacity. The Krebs solution, at 37°, is oxygenated with 95% O₂ and 5% CO₂. An initial tension of 3–4 g. is placed on the muscle. The preparation should be allowed to equilibrate for 30 min. or more before use (97, 98).

Since drug response is slow and recovery is long, 30 min. or more is necessary between doses. However, if isometric recording is used, a much shorter period of time is required for recovery and more accurate results can be obtained, due to the small changes in length during muscle contraction. In contrast to the rat uterus preparation, this preparation contains α -adrenergic receptors. Therefore, the effects of catecholamines on this preparation are not blocked by β -adrenergic blockers such as propranolol (99).

This preparation is extremely sensitive to epinephrine (5×10^{-9} mole) and norepinephrine (5×10^{-9} mole) but is less sensitive to *dl*-isoproterenol (2×10^{-7} mole), histamine (5×10^{-8} mole), 5-hydroxytryptamine (5×10^{-8} mole), and acetylcholine (2×10^{-6} mole) (98, 100, 101). Because of the long duration of the experiments, it is important to check the solutions of catecholamines for deterioration. If necessary, a freshly made solution should replace the original.

Dog Mesenteric Artery Preparation—Mongrel dogs are anesthetized with 15 mg./kg. of thiopental sodium and 250 mg./kg. of barbital sodium. The bundles of nerves which follow the vessels through the mesentery are freed at the central end of the arteries. The superior mesenteric artery is freed of mesenteric attachment and cannulated with polyethylene tubing (PE 100). Distally, the branching fans of smaller arteries are cut at the sites of entrance into the small intestine. The isolated preparation is quickly mounted in an organ bath with 100 ml. of Krebs bicarbonate solution at pH 7.3. It is oxygenated with 95% O₂ and 5% CO₂ and is maintained at 37°. The mesenteric arteries are perfused with a constant flow of Krebs bicarbonate solution (30–50 ml./min.). An arterial pressure transducer is attached to the cannula which leads from the pump to the artery. Changes of perfusion pressure are then proportional to changes in arterial resistance. The drugs are injected into the rubber tubing close to the mesenteric artery with a volume of not more than 0.1 ml. The nerve is pulled through the electrodes and is held in place by a ligature. The nerve is stimulated with 1-msec. duration, 50 c.p.s. frequency and 10–15 v. supramaximal voltage (102, 103).

This preparation gives reproducible pressor responses to injected catecholamines and to nerve stimulation for periods of several hours (102). The responses to nerve stimulation are postganglionic α -adrenergic in nature (103). Various adrenergic and adrenolytic agents have been studied with this preparation (103). This is a good preparation for qualitative study of the pharmacology of α -adrenergic and adrenolytic agents on the blood vessels innervated with sympathetic nerves.

Guinea Pig Tracheal Chain Preparation—Adult guinea pigs are sacrificed by a blow on the head. The trachea is dissected and transferred to a dish containing Krebs solution. The trachea is then sectioned into rings by cutting transversely between the segments of cartilage. The rings are tied together to form a chain with the muscular parts of the rings arranged alternatively at two sides of the tracheal chain. The Krebs solution, at 37°, is oxygenated with 95% O₂ and 5% CO₂. The capacity of the organ bath is about 10–15 ml. An initial tension of 0.2–0.5 g. is placed on the tracheal chain.

This preparation was originally described by Castillo and DeBeer (104). The tracheal muscle of the calf can also be used (105, 106). It is a slow responding preparation. Thus at least 15 min. should be allowed between doses for responses induced by small doses and 30 min. or longer for responses induced by large doses of agonists such as acetylcholine and histamine. This preparation can be used to study the pharmacologic effects and dose-response curves of catecholamines. In this case the preparation is contracted with acetyl- β -methylcholine first and then relaxed with various doses of catecholamines. Ariens added cumulative doses of catecholamines to the organ bath to get satisfactory cumulative dose-response curves (105, 106). The threshold doses of epinephrine, norepinephrine, and *dl*-isoproterenol are about 10⁻⁷ mole, 10⁻⁷ mole, and 5 × 10⁻⁸ mole, respectively.

Guinea Pig Vas Deferens Preparation—Male guinea pigs, weighing 400–800 g., are sacrificed by a blow on the head. The abdomen is opened in the midline and the intestines displaced to the right. The vas deferens is freed from connective tissue and cut from the epididymis. The vas deferens is held with small forceps near the cut end and is freed from the adjacent tissue. The right and left hypogastric nerves can be seen in the middle of the mesentery of the colon. One nerve is tied, and cut about 5 cm. from the vas deferens; this is cleaned to within 0.5 cm. of the vas deferens. The remainder of the nerve which is fine and diffuse is preserved by isolating the piece of peritoneum which contained it. The vas deferens is then cut from the urethra and removed together with its nerve and small piece of peritoneum and is placed in a dish containing Krebs solution. An organ bath containing 20 ml. of Krebs solution at 32°, oxygenated with 95% O₂ and 5% CO₂, is used. The preparation is set up as described below and an initial tension of 0.75–1.0 g. is applied.

For stimulating the hypogastric nerve, the vas deferens is set up in a method similar to that of the rabbit nerve jejunum preparation (Finkleman preparation) (107, 108). The vas deferens is tied by its proximal end to the bottom of the organ bath and the distal end to a lever or a force transducer. The hypogastric nerve is

stimulated submaximally with rectangular pulses of 2–3 v. and of 2 msec. duration for 2–3 sec. every minute at a frequency of 80 c.p.s.

For transmural stimulation one end of the vas deferens is tied to a supporting hook and the other (upper end) to the recording lever. The electrodes are two parallel lengths of platinum wire, 0.05-cm. (0.02-in.) diameter, cemented to the edges of a Perspex gutter so that the vas deferens can be suspended between them. Stimulation is performed for periods of 15 sec. at 3-min. intervals at a frequency of 25 c.p.s. with a pulse duration of 0.1 msec. at supramaximal voltage, usually 90–120 v. (109, 110). The transmural stimulation can also be performed by Paton's method (89) described in the section of the coaxial stimulation of the guinea pig ileum.

The vas deferens can also be stimulated alternatively through the hypogastric nerve and transmurally. For both stimulations, a frequency of 25 c.p.s. and a pulse width of 0.1 msec. with supramaximal voltage (90–120 v. for transmural and 30–60 v. for hypogastric nerve stimulation) are used (110).

This preparation was originally described by Huković (111) and modified by other investigators (107–110, 112). It is extremely useful for stimulating separately, preganglionic and postganglionic fibers; the former through the hypogastric nerve and the latter through transmural stimulation. The electrodes must be placed within 2 mm. of the tissue to obtain primarily postganglionic hypogastric nerve activation. The usual 3–5-cm. distance on the hypogastric nerve from the tissue will activate primarily preganglionic fibers. The preparation can also be done successfully using rats, rabbits, and mice (112, 113).

For studying the pharmacologic mechanism of adrenergic systems, this is an extremely useful preparation because when the vas deferens is removed without the hypogastric nerve and stimulated transmurally, the contractions produced are primarily due to the excitation of postganglionic adrenergic nerves (109, 110). It is also useful for studying the pharmacology of cholinergic agents and local anesthetics. This preparation can be contracted both by cholinergic and adrenergic agents. The greatest advantage of this preparation for studying adrenergic agents, as compared with the guinea pig tracheal chain preparation and rabbit aortic strip preparation, is that it responds and relaxes to the drugs rapidly. Consequently, much data can be obtained within a short period of time. However, the sensitivity of this preparation to most of the drugs in comparison with the other preparations is rather low and thus is not suitable for quantitative bioassay.

Heart Muscle Preparations—Rabbit Heart Preparation—A rabbit is sacrificed by a blow on the head. The heart is removed as quickly as possible. It is placed in a bath containing Ringer-Locke solution (NaCl, 9.0; KCl, 0.42; glucose, 1.0; NaHCO₃, 0.5; and CaCl₂, 0.12 g./l.) at room temperature and is squeezed gently to remove the blood. The aorta is identified, freed, and cut just below the point where it divides. The aorta is then tied onto the glass cannula of the perfusion apparatus. The Ringer-Locke solution, oxygenated with 95% O₂ and 5% CO₂, at 37° is perfused through the heart with constant pressure (30 mm. Hg). The fluid passes only through the coronary vessels and escapes from the in-

ferior vena cava since the aortic valve is closed by the pressure of the perfusion fluid. The perfusate is collected by a funnel and the rate of flow can be measured with a graduated cylinder and a stopwatch. A thread is attached to the ventricle by a hook and connected to spring levers or a force transducer to record the amplitudes of the heart contractions. Readings of the heart rate and of the coronary flow are usually taken over a period of 30 sec. Drugs are injected through the rubber cap into the perfusion fluid. The heart rate and the flow rate of the fluid should be taken approximately every 3 min.

This preparation is well known as the Langendorff preparation (114, 115) and can be used to study coronary dilators, coronary constrictors, and drugs affecting the inotropic and chronotropic effects of the heart (116, 117). For example, coronary vessels are constricted by vasopressin (8×10^{-11} mole/injection) and dilated by amyl nitrite (2×10^{-5} mole/injection). The rate and force of the heart are consistently increased by epinephrine (2.5×10^{-9} mole/injection), norepinephrine (3×10^{-9} mole/injection) or *dl*-isoproterenol (7.5×10^{-10} mole/injection) which are blocked effectively by β -adrenergic blocking agents such as propranolol (7.5×10^{-9} mole/injection). Ventricular fibrillation may be observed when chloroform (1×10^{-5} mole/injection) is given and followed by catecholamines. This preparation is used mainly for qualitative pharmacologic studies.

Guinea Pig Auricle Preparation—Guinea pigs are killed by a blow on the head. The heart is removed as quickly as possible and placed in Feigan solution (NaCl, 9; KCl, 0.42; CaCl_2 , 0.62; glucose, 1.0; and NaHCO_3 , 0.6 g./l.) at room temperature. All other tissue is cut away, leaving only the auricles. Threads are tied to the tips of each auricle and the preparation is mounted on a superfusion assembly or in an organ bath with a capacity of 25 ml. The auricle is maintained with a resting

tension of 1 g. and is allowed to stabilize for at least 30 min. before use. Feigan's solution is oxygenated with 95% O_2 and 5% CO_2 at 30°.

For transmural stimulation in the organ bath, platinum electrodes are placed on each side of the auricle at a distance of 1 cm. from the auricle (118, 119). The duration of the pulse is held constant at 20 msec., the voltage at 150 v., and the period of the stimulus at 15 sec. A frequency of 2 c.p.s. is used to elicit a parasympathetic response and a frequency of 15 c.p.s. is used to induce both sympathetic and parasympathetic response (119). The preparation can have the vagus nerve attached, which can be stimulated with biphasic stimulation of 35 c.p.s., 6-msec. duration, at 3 v. (120).

For transmural stimulation of the auricle in the superfusion assembly, platinum wire electrodes are placed above and below the auricle, so that they are in continuous contact with the bathing fluid, but not with the tissue. The stimulus parameters are the same as in the organ bath method (121).

Both Feigan solution and Locke-Ringer solution (NaCl, 9.0; KCl, 0.42; $\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$, 0.24; NaHCO_3 , 0.3; and glucose, 2.0 g./l.) can be used as bathing fluid. However, the former solution is preferred due to the higher concentration of CaCl_2 (0.62 g./l.) which produces a heart beat that is stronger, more consistent, and longer lasting. The pH of the solution should be kept at 7.4. This preparation can be done using the frog, turtle, chicken, rat, and rabbit as well (119).

The normal preparation is used primarily for qualitative studies of drugs affecting heart function, such as acetylcholine and its derivatives, catecholamines, atropine-like compounds, and adrenergic blocking agents. However, it can also be used to determine the affinity constants of competitive antagonists of acetylcholine. The transmurally stimulated and the vagus nerve

stimulated preparations are used primarily for the qualitative studies of the mechanisms of heart functions and drugs affecting heart functions (119, 120).

Kitten Papillary Muscle Preparation—Kittens are killed by a blow on the head and the heart is dissected as quickly as possible. The papillary muscles which are usually 0.5–0.7 mm. wide and 5–8 mm. long are dissected. The preparation is mounted on the apparatus described by Blinks (122, 123). The tension of the muscle is adjusted initially to approximately half the level associated with maximally developed tension and the length kept constant thereafter. The papillary muscle can also be obtained from the guinea pig.

This preparation is used primarily for qualitative studies of the drugs affecting heart function. The field stimulus can affect the heart function *via* sympathetic effects and parasympathetic effects. The heart function is also affected by synchronization of the contractions of the various parts of the preparation when the conduction in the muscle is slow. Field pulses of 50-ma. strength and 2-msec. duration are found to be nearly maximally effective in eliciting both sympathetic and parasympathetic effects (123).

Subcellular Preparations—Synaptic Vesicles—Rats, weighing about 300 g., are decapitated and the cerebral cortex or any other portion of the brain tissue is isolated as quickly as possible. All procedures described here should be performed at 0–4°. The brain tissue is weighed and homogenized in 0.32 *M* sucrose solution at 1200 r.p.m. for four strokes in a glass homogenizer with a Teflon plunger. The homogenate is diluted to 10% with 0.32 *M* sucrose and centrifuged in the cold for 10 min. at 900 $\times g$. The supernate is saved and the sediment is washed once by rapid rehomogenization in sucrose solution and centrifuged as above. The two supernates are combined and centrifuged for 20 min. at 11,500 $\times g$. The pellet is treated with distilled water (10 ml. per 1 g. tissue) containing 1×10^{-6} mole of Ca^{++} and 1.5×10^{-5} mole of physostigmine. The material is rehomogenized and centrifuged at 11,500 $\times g$ for 20 min. The supernatant is recentrifuged at 100,000 $\times g$ for 30 min. The synaptic vesicle is localized mainly at the pellet portion. This procedure is described by DeRobertis *et al.* (124–126). The procedure described by Whittaker *et al.* is essentially the same as that described by DeRobertis *et al.*, except that the final supernatant is subjected to density gradient purification in order to obtain a purer preparation (127, 128).

This is a convenient preparation to be used to study the drugs which release acetylcholine from the nerve terminals (129). Recently, it has been found that most of the nicotinic agents act through release of acetylcholine from the nerve terminals (64, 75). These nicotinic agents can also release acetylcholine effectively from the synaptic vesicle preparation. The acetylcholine-releasing effects of these nicotinic agents are markedly blocked by triethylcholine on the isolated guinea pig ileum and baby chick biventer cervicis nerve muscle preparations (64, 75), but are not blocked on the synaptic vesicle preparation (129). This indicates that the nicotinic agents are taken up by the nerve terminals before they can release acetylcholine from the synaptic vesicles. The uptake of nicotinic agents by the nerve terminals is possibly blocked by triethylcholine at the membrane site of the nerve terminals. This hypothesis can be further illustrated using the synaptosome preparation described in the following section. The acetylcholine released from the synaptic vesicles or synaptosomes can be bioassayed with superfused, cooled guinea pig ileum described in the section on the guinea pig ileum preparation. This preparation can also be obtained from the brains of animals such as guinea pig, rabbit, cat, mouse, and others.

Synaptosome Preparation—Rats, weighing about 300 g., are sacrificed by decapitation and the brain tissue is removed as quickly as possible. All manipulations are performed at 0–4°. A 10% homogenate of brain tissue is prepared in 0.25 *M* sucrose using a glass and Perspex homogenizer rotating at 1200 r.p.m. with a difference in diameter of 0.025 mm. between pestle and mortar. The homogenate is centrifuged at 1000 $\times g$ for 15 min. The supernatant is recentrifuged at 12,500 $\times g$ for 15 min., and the sediment is resuspended in 0.25 *M* sucrose (2 ml./g. of original tissue). Five milliliters of this crude mitochondrial fraction is carefully layered on the top of the synthetic polymer (Ficoll) gradient and the contents are centrifuged at 90,000 $\times g$ for 60 min. The synaptosomes are obtained mainly from the second and third fractions of the six distinct layers. These fractions are diluted with 0.25 *M* sucrose and centrifuged at 120,000 $\times g$ for 20 min. to remove the polymer gradient. The pellets are suspended in 0.25 *M* sucrose and aliquots are used for assay or incubation. The polymer gradients are made by successive layering of 5 ml. each of 20, 16, 12, 8, and 2% polymer solutions made with 0.25 *M* sucrose into a 2.54 \times 7.62-cm. (1 \times 3-in.) cellulose tube. The

tubes are allowed to stand at room temperature for 60 min. and at 4° for 30 min. (130, 131).

The synaptosomes can also be obtained by methods described by Whittaker *et al.* (127, 132, 133) or De-Robertis *et al.* (124). However, since these methods are performed with the density gradient in hypertonic sucrose solution, the synaptosomes show characteristic morphological changes (134), decrease in oxidative phosphorylation (135), and spontaneous release of bound acetylcholine (131).

The synaptosome preparation can be used to study the drugs which release acetylcholine from the nerve terminals and the drugs which block the release of acetylcholine. It is a convenient method and gives direct evidence to demonstrate the turnover, kinetics, and pharmacology of cholinergic mechanisms at the nerve terminals. It is hoped that combined use of the synaptic vesicle and synaptosome preparations may facilitate the clarification of cholinergic mechanisms which are much less understood than are adrenergic mechanisms. Methods for determining the quantity of drugs taken-up into synaptosomes and the volume of synaptosomes are described by Marchbanks (136, 137).

CONCLUSION

Bioassay is a technique developed entirely by the pharmacologists (138). A good bioassay technique must be sensitive, accurate, and rapid in responding to the

drugs administered. For years the leech dorsal muscle and the frog rectus abdominis muscle preparations were the only skeletal muscle preparations widely used for bioassay of nicotinic agents (54, 57). The introduction of the chick semispinalis cervicis muscle preparation furnishes a more rapid technique for the bioassay of these agents (62).

The superfusion technique was first described by Finkleman (49) and later modified by Gaddum (50). This is an extremely useful technique for bioassay because it can be performed with more speed, greater accuracy, and higher sensitivity than the organ bath technique (Table IV). It is highly recommended for bioassay of drugs of trace quantity. It is also a good technique for obtaining ample amounts of data within a short period of time. The methods for bioassay of drugs acting at the peripheral systems are summarized in Tables IV–VII.

Besides being used for bioassay, the biological preparations described are also widely used to study the sites of drug effects on the peripheral nervous system. The methods for studying the specific sites of the peripheral nervous systems are classified in Tables VIII and IX. The rat phrenic nerve-diaphragm muscle preparation has long been used as the sole preparation for *in vitro* study of neuromuscular transmission (65). The chick biventer cervicis nerve muscle preparation (63, 64) and chick sciatic-tibialis anticus preparation (69, 70) were introduced later. They have the advantages of consisting of both fast and slow muscles. They are easy to prepare and can survive with interrupted tetanic stimulation (74). The dog mesenteric artery preparation is an interesting one with sympathetic nerve attached to the artery. It is extremely useful for studying the pharmacology of drugs and nerve regulations on the blood vessels (102, 103).

The synaptic vesicle and synaptosomes are newly developed preparations with high potential for solving

the mechanism of drug actions at the nerve terminals. For example, nicotinic agents such as nicotine, trimethylamino alcohols, decamethonium, and others have been reported to release acetylcholine from the nerve terminals, which can be blocked by triethylcholine (64, 75). The action mechanism of these findings are explored by using synaptosome and synaptic vesicle preparations. Nicotine and choline have been found to be taken into the intracellular site of superior cervical ganglia (139) and synaptosomes (137), which can be blocked by hexamethonium and hemicholinium, respectively. It has also been found that nicotinic agents are capable of releasing acetylcholine from the synaptic vesicles, which is not blocked by triethylcholine nor by hemicholinium (129). It is thus concluded that the nicotinic agents are probably taken into nerve terminals for releasing endogenous acetylcholines whereas the uptake of nicotinic agents is blocked by triethylcholine or hexamethonium at the membrane site of the nerve terminals (64, 75, 129).

Preliminary Model for Methotrexate Pharmacokinetics

K. B. BISCHOFF*, R. L. DEDRICK, and D. S. ZAHARKO

Abstract □ A pharmacokinetic model is presented to describe the distribution of methotrexate in mice, and the required physicochemical, anatomical, and physiological data are discussed. The model is used to simulate methotrexate concentrations in plasma, lean tissue, liver, kidneys, and gastrointestinal tract following a single intravenous injection. Methotrexate is excreted in the urine and bile; partial reabsorption occurs in the gastrointestinal tract. Tissue-to-plasma distribution ratios were: muscle (0.15:1); kidney (3:1); liver (10:1). Observed bile concentrations were 300 times those of plasma.

Keyphrases □ Methotrexate pharmacokinetics—model □ Distribution, methotrexate—mice □ Tissue/plasma ratios—methotrexate □ Plasma protein binding—methotrexate □ Pharmacokinetic equations—methotrexate absorption, distribution, excretion □ Model, methotrexate distribution—one, two compartments plus gut lumen

This paper presents the results of some first attempts to formulate mathematical models for the distribution of the cancer chemotherapeutic agent methotrexate (MTX) in mammals. It begins with a short discussion of why and how such pharmacokinetic models can be of practical use as well as enhancing insight and appreciation of relevant physiological phenomena.

One important application of the models can be to aid in the evaluation of screening tests. Most cancer chemotherapeutic agents (as well as many other drugs) are initially screened by a series of experimental evaluations using mice. Normally, only the gross success or failure of the drug to combat tumors is considered. The actual sequence of events, however, can be divided into two major aspects: first, the spatial and temporal physical distribution of the drug within the body and, second, the physiological (therapeutic and toxic) effects at discrete tissue loci. The latter, of course, is the crucial issue, but until local concentrations for known time intervals throughout the body are defined, reliable correlations between drug distribution and drug effect cannot be established. Thus the distribution information is required to more fully appreciate the problems of drug evaluation.

If initial screening tests are successful, trials in other animal species, eventually leading to man, are performed. Many relevant interspecies differences are associated with chemical phenomena—such as metabolism, binding, and membrane transport. Physical aspects, such as organ sizes and intracorporeal fluid flow rates, also vary among species. These facts suggest a scale-up approach based on maximum use of physiological, anatomical, and physicochemical information. A reliable quantitative model based on physiology can

serve as a useful framework for designing experiments and evaluating results.

Such a model with appropriate scale-up information may significantly enhance success in the ultimate application in the clinic. Concentration history may be predictable at any site as a function of dose schedule and route of administration. This information, coupled with knowledge of drug concentration and exposure time necessary for maximum tumor toxicity, should provide a rational basis for optimization of dosage regimens. This can be critical for cancer chemotherapeutic agents because of the rather narrow range between effective and toxic doses.

RATIONALE AND GENERAL FEATURES OF MODELS

Before discussing the details of the experiments and models for MTX, a few brief statements will be made concerning pharmacokinetic models. The approach used here has been extensively discussed and illustrated elsewhere: Bischoff and Brown (1), Bischoff (2), Dedrick and Bischoff (3), and Bischoff and Dedrick (4). Mass transfer models are based on "lumping" body regions, with similar physicochemical properties, into discrete compartments. Volumes, flows, and other properties will all have independently verifiable anatomical significance. The use of parameters obtained from experiments other than the one being modeled is important, since it can lead to generally applicable *a priori* predictions. Further, the model leads to insight concerning some of the physiological mechanisms.

One broad assumption used in developing the model, that of flow-limited conditions, deserves mention here. This assumption, commonly used in pharmacokinetics, implies that the blood leaving a tissue is in diffusion equilibrium with the tissue, *i.e.*, the free (not protein bound) concentrations of blood and tissue are the same. This assumption requires that membrane permeability is sufficiently larger than the perfusion rate so that the latter is rate controlling. A mathematical criterion for this was given by Dedrick and Bischoff (3) and it was shown that the assumption was valid for certain barbiturates. MTX is not particularly lipid soluble and has a molecular weight of 454; thus, its permeability is probably somewhat lower than the barbiturates. Since there seem to be no numerical values available, the work will be done with flow-limited models, bearing in mind, however, that modifications may be necessary to account for finite permeabilities.

EXPERIMENTAL INVESTIGATIONS

The data discussed here are preliminary in nature from the first of a series of experiments. Only one dose level, 3 mg./kg., is considered. This dose is in the range of clinical therapeutic values [Henderson, Adamson, Denham, and Oliverio (5, 6)]. Other levels will be used in future work. Figure 1 shows the data points from several experiments. The points at any one time represent the distribution of methotrexate (MTX), 3',5'-tritium labeled in one mouse (CDF-1 male) which is injected *i.v.* and then sacrificed for tritium analysis of the various tissues. Thus these data represent many mice, which would tend to add variability.

Several features of Fig. 1 will be briefly described as an aid in developing models. The implied curves contain certain typical

Figure 1—Distribution of MTX in mice following pulse injection in tail vein.

features, e.g., immediately following injection there is a short time period of rapid drop in plasma concentration followed by a period of slower rate of decrease. One difference from many drugs, however, is the magnitude of the initial drop. Since Henderson *et al.* (5, 6) have shown that MTX is not appreciably metabolized in mice, this concentration drop results from rapid localization in tissues and excretion. The data points for the small intestine rapidly increase at the outset, which indicates the significant role of the biliary route, as has also been indicated by Henderson *et al.* (5, 6). In fact, 1–2 hr. postinjection, the gut concentration is about 100 times the plasma concentration. From chemical analysis in addition to the radioactivity counting, it appears that the MTX is not conjugated or metabolized in the enterohepatic cycling (5) in contrast to most drugs. The liver here acts differently than with many drugs in that even with its high perfusion rate, several minutes are required to attain maximum concentration. This effect is probably also influenced by biliary clearance and bile formation in the liver.

After a sufficient length of time, all of the curves level asymptotically, suggesting (but not proving) a zero-order absorption from the gut. The tissue/plasma ratios also vary substantially: muscle/plasma $\sim 0.15:1$; liver/plasma $\sim 10:1$; kidney/plasma $\sim 3:1$. These are some of the major characteristics that a successful model must predict.

An essential step in the synthesis of meaningful models is the definition of reliable physical parameters. One obvious set includes the organ weights and flows. The former were obtained from the previously described experiments. The relevant flows are more difficult to obtain, but the model developed here does not require an extensive set. Renal clearance was obtained by comparing integrated plasma concentration data with cumulative urinary excretion. The value was found to be somewhat less than an estimate of inulin clearance based on the literature (7). Little is known about quantitative biliary clearances. These were estimated by separate experiments with anesthetized mice in which the bile duct was cannulated and the flow rate and concentrations directly measured. An estimate of the time delay between injection and appearance of MTX in the bile was also noted.

The data in Fig. 1, together with results published by Henderson *et al.* (5, 6), indicate that gut absorption of MTX may be a zero-order process, in some concentration ranges, presumably caused by saturation of a transport mechanism. The saturation point in humans seems to lie between doses of 0.1–1.0 mg./kg., which is less

than our experimental level. An experiment was performed where a known amount of MTX was injected directly into the duodenum and determinations made of the fraction remaining after specific time intervals. Much more experimental work will be required to describe the gut absorption adequately. For the present, zero-order kinetics will be used. Finally, the binding of MTX was evaluated. Plasma protein binding was about 25% and could be correlated with a linear isotherm. Tissue binding is much more difficult to obtain. Separate steady infusion experiments were performed, and the results for the muscle/plasma distribution ratio agreed with that obtained during the kinetic study.

Such separate experiments serve independently to determine or verify most of the model parameters so that generalized *a priori* predictions can be attempted.

MODEL EQUATIONS

Based on the above considerations, the general equations as presented in Dedrick and Bischoff (3) can be considerably simplified. The muscle compartment will be considered to illustrate details. Equations for other compartments are derived similarly. The mass balance accounting for both free and bound drug is:

$$(f_B V_{MB} + f_{MT} V_{MT}) \frac{dC_M}{dt} + (1 - f_B) V_{MB} \frac{dx_{MB}}{dt} + (1 - f_{MT}) V_{MT} \frac{dx_{MT}}{dt} = Q_M [f_B C_P + (1 - f_B) x_B] - Q_M [f_B C_M + (1 - f_B) x_{MB}] \quad (\text{Eq. 1})$$

where the terms are defined in the *Nomenclature* Section at the end of the paper. The right-hand side of Eq. 1 represents inflow and outflow of free and bound drug. The left-hand side gives a complete accounting for the accumulation of (a) free drug in actual tissue and equilibrium blood in the total tissue [as defined by Mapleson (8)]; (b) bound drug in the equilibrium blood; and (c) bound drug in the actual tissue.

Now with the assumption of linear binding and using effective protein fractions to account for the different levels of binding (see *References* 3, 4),

$$x_p = BC_p, x_{MB} = BC_M, x_{MT} = BC_M \quad (\text{Eq. 2})$$

Eq. (1) becomes

$$\{[f_B + B(1 - f_B)]V_{MB} + [f_{MT} + B(1 - f_{MT})]V_{MT}\} \frac{dC_M}{dt} = Q_M [f_B + B(1 - f_B)](C_p - C_M) \quad (\text{Eq. 3})$$

To simplify the equations, define

$$\phi_B \equiv [f_B + B(1 - f_B)], \phi_{MT} \equiv [f_{MT} + B(1 - f_{MT})]$$

With a similar treatment for the other compartments, the full set of equations becomes (refer to Fig. 2):

$$\phi_B V_p \frac{dC_p}{dt} = Mg(t) + Q_L \phi_B C_L + Q_K \phi_B C_K + Q_M \phi_B C_M - Q_p \phi_B C_p \quad (\text{Eq. 4})$$

$$(\phi_B V_{MB} + \phi_{MT} V_{MT}) \frac{dC_M}{dt} = Q_M \phi_B (C_p - C_M) \quad (\text{Eq. 5})$$

$$(\phi_B V_{KB} + \phi_{KT} V_{KT}) \frac{dC_K}{dt} = Q_K \phi_B (C_p - C_K) - k_K C_K \quad (\text{Eq. 6})$$

$$(\phi_B V_{LB} + \phi_{LT} V_{LT}) \frac{dC_L}{dt} = (Q_L - Q_G) \phi_B C_p + Q_G \phi_B C_G - Q_L \phi_B C_L - k_L C_L U(t - D_L) \quad (\text{Eq. 7})$$

$$(\phi_B V_{GB} + \phi_{GT} V_{GT}) \frac{dC_G}{dt} = Q_G \phi_B (C_p - C_G) + k_G U(t - D_L) \quad (\text{Eq. 8})$$

$$Q_p = Q_M + Q_K + (Q_L - Q_G) + Q_G \quad (\text{Eq. 9})$$

Also, a balance on the gut lumen, assuming again a lumped compartment gives,

$$\frac{dM_{GL}}{dt} = k_L C_L U(t - D_L) - k_G U(t - D_L) - k_F M_{GL} U(t - D_F) \quad (\text{Eq. 10})$$

The bile excretion term in Eq. 7 contains a time delay term, $U(t - D_L)$, to approximate the bile formation and holding time. A continuous s -shaped function would be more realistic but would introduce additional mathematical complexity not considered important to this preliminary work. The same time delay appears in the zero-order gut absorption term in Eq. 8 since absorption cannot occur before the bile appears from the liver. These time delays appear also in Eq. 10 for the gut lumen with an additional time delay in the feces removal term, $U(t - D_F)$, representing the travel time down the small intestine.

As discussed in detail in Bischoff and Dedrick (9), with linear binding the above equations can be written in terms of total (free and bound) concentration in a simple form, with each parameter maintaining a well-defined physiological meaning. The concentrations actually measured in the laboratory were total wet tissue values, indicated by:

$$C_p' = \phi_B C_p \quad (\text{Eq. 11})$$

$$C_M' = \frac{\phi_B V_{MB} + \phi_{MT} V_{MT}}{V_{MB} + V_{MT}} C_M \quad (\text{Eq. 12})$$

$$C_K' = \frac{\phi_B V_{KB} + \phi_{KT} V_{KT}}{V_{KB} + V_{KT}} C_K \quad (\text{Eq. 13})$$

$$C_L' = \frac{\phi_B V_{LB} + \phi_{LT} V_{LT}}{V_{LB} + V_{LT}} C_L \quad (\text{Eq. 14})$$

$$C_G' = \frac{\phi_B V_{GB} + \phi_{GT} V_{GT}}{V_{GB} + V_{GT}} C_G \quad (\text{Eq. 15})$$

The basis of these equations can be stated in words:

$$C_M' = \frac{\left\{ \begin{array}{l} \text{amount in} \\ \text{[equilibrium blood]} + \text{[actual tissue]} \end{array} \right\}}{\text{(total volume of equilibrium blood and tissue)}} \\ = \frac{\left\{ \begin{array}{l} \text{[free + bound concentration in equilibrium]} \\ \text{[blood](volume of equilibrium blood)} \end{array} \right\} + \left\{ \begin{array}{l} \text{[free + bound concentration in actual]} \\ \text{[tissue](volume of actual tissue)} \end{array} \right\}}{\text{(total volume)}} \\ = \frac{[f_B + B(1 - f_B)]C_M V_{MB} + [f_{MT} + B(1 - f_{MT})]C_M V_{MT}}{V_{MB} + V_{MT}}$$

This then leads to Eq. 12. Similar reasoning was used for the other tissues.

The equilibrium (tissue/plasma) ratios are indicated by:

$$R_M \equiv \left(\frac{C_M'}{C_p'} \right)_{eq.} = \frac{\phi_B V_{MB} + \phi_{MT} V_{MT}}{\phi_B (V_{MB} + V_{MT})} \quad (\text{Eq. 16})$$

$$R_K \equiv \left(\frac{C_K'}{C_p'} \right)_{eq.} = \frac{\phi_B V_{KB} + \phi_{KT} V_{KT}}{\phi_B (V_{KB} + V_{KT})} \quad (\text{Eq. 17})$$

and similarly for R_G and R_L . These distribution ratios permit the relation between total and free concentrations to be written in a simpler form:

$$C_M' = \phi_B R_M C_M \quad (\text{Eq. 18})$$

and similarly for the others. If these relations are substituted into the mass balances, Eqs. 4–10, the final form is:

$$V_p \frac{dC_p'}{dt} = Mg(t) + Q_L \frac{C_L'}{R_L} + Q_K \frac{C_K'}{R_K} + Q_M \frac{C_M'}{R_M} - Q_p C_p' \quad (\text{Eq. 19})$$

$$(V_{MB} + V_{MT}) \frac{dC_M'}{dt} = Q_M \left(C_p' - \frac{C_M'}{R_M} \right) \quad (\text{Eq. 20})$$

$$(V_{KB} + V_{KT}) \frac{dC_K'}{dt} = Q_K \left(C_p' - \frac{C_K'}{R_K} \right) - \frac{k_K}{\phi_B R_K} C_K' \quad (\text{Eq. 21})$$

$$(V_{GB} + V_{GT}) \frac{dC_G'}{dt} = Q_G \left(C_p' - \frac{C_G'}{R_G} \right) + k_0 U(t - D_L) \quad (\text{Eq. 22})$$

$$(V_{LB} + V_{LT}) \frac{dC_L'}{dt} = (Q_L - Q_G) \left(C_p' - \frac{C_L'}{R_L} \right) + Q_G \left(\frac{C_G'}{R_G} - \frac{C_L'}{R_L} \right) - \left(\frac{k_L}{\phi_B R_L} \right) C_L' U(t - D_L) \quad (\text{Eq. 23})$$

$$\left(\frac{dM_{GL}}{dt} \right) = -k_0 U(t - D_L) - k_F M_{GL} U(t - D_F) + \left(\frac{k_L}{\phi_B R_L} \right) C_L' U(t - D_L) \quad (\text{Eq. 24})$$

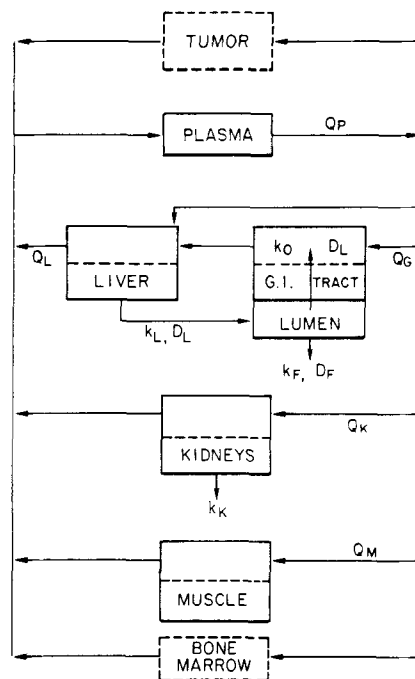

Figure 2—Compartmental model for MTX distribution. The bone marrow and a hypothetical tumor are indicated because these are regions of interest even though they would normally exert little influence on systemic drug distribution kinetics.

It should be again emphasized that all of the volume, flow, and other parameters in these equations have well defined physiological meanings and are not derived by “curve fitting” to an arbitrary set of functions.

This set of simultaneous linear differential equations could be solved analytically albeit with considerable algebraic complexity. Figure 1 shows that several of the regions are characterized by similarly shaped curves with different levels. These different levels can be accounted for by the distribution ratios, and thus it would appear that some of the equations could be combined by assuming that these tissues are essentially in physical distribution equilibrium. In particular, this is true of the highly perfused viscera, except for the liver which is complicated by the bile formation at short times. Similar behavior is found for other drugs—see Bischoff and Dedrick (9). The poorly perfused muscle tissue does not exactly follow the same pattern, particularly at short times, but since the muscle tissue is not of primary importance and also does not contain a large fraction of the drug, the simplifying equilibrium assumption will also be used. Using Eqs. 16–17, this means

$$C_M' = R_M C_p' \quad (\text{Eq. 25a})$$

$$C_K' = R_K C_p' \quad (\text{Eq. 25b})$$

$$C_G' = R_G C_p' \quad (\text{Eq. 25c})$$

and Eqs. 19–23 condense to:

$$V_p' \frac{dC_p'}{dt} = Q_L \left(\frac{C_L'}{R_L} - C_p' \right) - k_K' C_p' + Mg(t) \quad (\text{Eq. 26a})$$

where

$$V_p' \equiv V_p + R_M V_M + R_K V_K + R_G V_G \quad (\text{Eq. 26b})$$

and

$$V_L \left(\frac{dC_L'}{dt} \right) = Q_L \left(C_p' - \frac{C_L'}{R_L} \right) - k_L' \frac{C_L'}{R_L} \times U(t - D_L) + k_0 U(t - D_L) \quad (\text{Eq. 27})$$

Figure 3 is a diagram of the simplified model. A slight modification of the transport network, shifting the gut absorption term from the main body compartment to the liver compartment, is made to more closely correspond to actual anatomy.

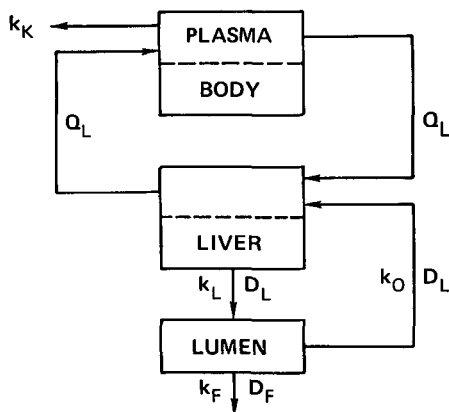

Figure 3—Two-compartment model plus gut lumen.

These equations can be readily solved for all times, but for these initial studies, further simplification is useful. Figure 1 shows that for all but short times, the liver behavior is similar to that of plasma and other tissues. Thus, for the longer-time regime:

$$C_L' = R_L C_p' \quad (\text{Eq. 28})$$

Eqs. 26, 27, and 24 condense to

$$V_p'' \left(\frac{dC_p'}{dt} \right) = Mg(t) - k_K' C_p' - k_L' C_p' U(t - D_L) + k_0 U(t - D_L) \quad (\text{Eq. 29a})$$

where

$$V_p'' \equiv V_p' + R_L V_L \quad (\text{Eq. 29b})$$

$$\left(\frac{dM_{GL}}{dt} \right) = -k_0 U(t - D_L) - k_F M_{GL} U(t - D_F) + k_L' C_p' U(t - D_L) \quad (\text{Eq. 30})$$

Figure 4 is a diagram of this model.

PARAMETER VALUES

The parameter values for the models are summarized in Table I. Those directly measured are averages from several mice, and those from correlations are adjusted to the mean-size standard mouse of 22 g.

EQUATION SOLUTIONS AND RESULTS

The various model equations are solved for sequential time steps. For $0 \leq t_1 \leq D_L$, the solutions to Eqs. 26 and 27 with an impulse i.v. injection, $g(t) = \delta(t)$, and with zero initial conditions, $C_{p1}'(0) = 0$, $C_{L1}'(0) = 0$, $M_{GL1}(0) = 0$, are:

$$\frac{C_{p1}' V_p'}{M} = \frac{\left(r_2 + \frac{Q_L}{R_L V_L} \right) e^{r_2 t} - \left(r_1 + \frac{Q_L}{R_L V_L} \right) e^{r_1 t}}{r_2 - r_1} \quad (\text{Eq. 31})$$

$$\frac{C_{L1}' V_p'}{M} = \frac{Q_L}{R_L V_L} \frac{e^{r_2 t} - e^{r_1 t}}{r_2 - r_1} \quad (\text{Eq. 32})$$

$$M_{GL1} \equiv 0 \quad (\text{Eq. 33})$$

Figure 4—Single-compartment model plus gut lumen.

Table I—Model Parameters for 22-g. Mouse

Parameter	Value
V_p	1 ml.
V_G , Gut wall and contents	1.5 g.
V_K	0.34 g.
V_M	~10 g.
V_L	1.3 g.
R_G , Intestine tissue	0.15, Estimate
R_K	3
R_M	0.15
R_L	10
R_{bile}	300
k_K'	0.26 ml./min. ^a
k_L'	0.75–1.1 ml./min. ^b
k_0 For 3 mg./kg.	0.39 mcg./min. = 0.64%/min.
k_F , Mean residence time ⁻¹	$\frac{1}{120} - \frac{1}{180}$ min. ⁻¹ = 7.5×10^{-3} min. ⁻¹
D_L	~2.5–5 min.
D_F	~120–180 min.

^a Inulin clearance reported by Selkurt (13) per gram of rat kidney: (0.75 ml./min. g. kidney) (0.34 g. kidney) = 0.26 ml./min. ^b Biliary clearance bounds estimate by: (a) maximum clearance = hepatic plasma, flow rate = (1.4 ml./min. ml. liver) * (1.3 g. liver) * (0.6 ml. plasma/ml. blood) = 1.1 ml./min.; (b) minimum clearance = (bile flow rate)(MTX concentration ratio) = (2.5 μ l./min.)(300) = 0.75 ml./min. * Bradley, Reference 13.

where

$$r_{(1/2)} = -1/2 \left[\frac{k_M'}{V_p'} + \frac{Q_L}{V_p'} \left(1 + \frac{V_p'}{R_L V_L} \right) \right] \pm R \quad (\text{Eq. 34a})$$

$$R \equiv \sqrt{1/4 \left[\frac{k_K'}{V_p'} + \frac{Q_L}{V_p'} \left(1 + \frac{V_p'}{R_L V_L} \right) \right]^2 - \frac{Q_L k_K'}{V_p' R_L V_L}} \quad (\text{Eq. 34b})$$

With the parameter values for a dose of 3 mg./kg.,

$$C_{p1}' = 4.57 e^{-0.014 t_1} + 26.6 e^{-0.496 t_1} \quad (\text{Eq. 35})$$

$$C_{L1}' = 54.9 (e^{-0.014 t_1} - e^{-0.496 t_1}) \quad (\text{Eq. 36})$$

For the next time period, $D_L \leq t_2 \leq D_F$ and with initial conditions

$$C_{p2}'(0) = C_{p1}'(D_L), C_{L2}'(0) = C_{L1}'(D_L), M_{GL}(0) \approx 0 \text{ and } g(t) \equiv 0$$

the solution to Eqs. 29 and 30 are:

$$C_{p2}' = \frac{k_0}{\sigma} + \left(C_{p1}'(D_L) - \frac{k_0}{\sigma} \right) e^{-(\sigma/V_p'') t_2} \quad (\text{Eq. 37})$$

where

$$\sigma = k_K' + k_L'$$

$$M_{GL2} = -\frac{k_0 k_K'}{\sigma} t_2 + \frac{K_L' V_p''}{\sigma} \left(C_{p1}'(D_L) - \frac{k_0}{\sigma} \right) (1 - e^{-(\sigma/V_p'') t_2}) \quad (\text{Eq. 38})$$

Again with the parameters for 3 mg./kg.

$$C_{p2}' = 0.508 + 6.0 e^{-0.0777 t_2} \quad (\text{Eq. 39})$$

and

$$\left(\frac{M_{GL}}{V_G} \right) = -0.088 t_2 + 51.3 (1 - e^{-0.0777 t_2}) \quad (\text{Eq. 40})$$

Finally, for long times, $t_3 > D_F$, the data indicate in Fig. 5 that the plasma and tissue concentrations are essentially constant. These data are not highly accurate, however, since, as can be seen in the plots, they represent less than 1% of the dose. Thus the radioactivity measured could result from substances other than MTX, from irreversible binding, or other small deviations. Nevertheless, in this regime

$$C_{p3}' \approx \frac{k_0}{\sigma} \quad (\text{Eq. 41})$$

Figure 5—Comparison between curves predicted by equations and observed data.

and

$$M_{GL3} = \left(M_{GL2}(D_F) + \frac{k_0 k_K'}{\sigma k_F} \right) e^{-k_L t_3} - \frac{k_0 k_K'}{\sigma k_F} \quad (\text{Eq. 42})$$

For 3 mg./kg.

$$C_{p3}' = 0.508 \quad (\text{Eq. 43})$$

$$\left(\frac{M_{GL3}}{V_G} \right) = 52e^{-0.0075t_3} - 12 \quad (\text{Eq. 44})$$

Comparison of the *a priori* predicted results with the data of Fig. 1 is shown in Fig. 5. Eqs. 35 and 36 are used up to $D_L \sim 5$ min., Eqs. 39 and 40 to $D_F \sim 120$ –180 min., and Eqs. 43 and 44 for the remaining time. On the whole, excellent agreement is obtained, but several comments are in order. For very short times, Eqs. 26 and 27 depend upon essentially instantaneous equilibration between all parts of the body except for the liver. This results in the nearly vertical line from 100% dose/l ml. plasma to 31% dose/3.2 ml. body, which is $C_{p1}'(0)$.

The major discrepancy is the gut lumen predictions for $t < 60$ min., where the predicted value is too high. Probably the main reason for this is the assumption of pure transport time delays which implies abrupt infusion of concentrated bile into the gut lumen at $t = D_L$. As more data are obtained, a better model for biliary clearance should be possible. Another modification would be to use a plug flow model of the small intestine rather than the simple lumped compartment. This approach is now under consideration, and the authors also have some data on drug passage through the intestines. The liver curve between 5 and 30 min. does not completely parallel the plasma curve, and so Eq. 28 is not exactly correct early in the second time region. The full two-compartment equations will be used eventually.

FUTURE WORK

Based on these encouraging initial results, work is in progress to extend and verify the model in several directions. One is to consider other dose levels. Because of the linear nature of the mathematical model, the relative concentrations should remain the same except for possible changes in absorption or excretion mechanisms. For smaller doses, the saturated zero-order gut absorption should become first order if a simple Michaelis-Menten form is followed. Some work by Burgen and Goldberg (10) using direct perfusion methods indicate that this happens for folic acid, which is close in chemical structure to MTX. Both their data and results of Henderson *et al.* (6) suggest that such behavior might occur at dose levels of ~ 0.1 mg./kg., which is much smaller than the 3 mg./kg. used here. This phenomenon merits careful investigation. Evidence by Guarino and Schanker (11) suggests that the bile excretion mechanism becomes saturated at high doses. Additional information in this regard is required. Data by Borsa *et al.* (12) indicate that this may be true with MTX in mice.

For some of these future studies, the simple form of the differential equations will not suffice and analytical solutions may no longer

be possible. The two-compartment model for short times will be utilized using numerical computation techniques to describe more accurately the very important action of the liver and biliary excretion. With more data concerning the latter process, the abrupt time-delay forms will probably also be modified to use a continuous sigmoid rather than a step function—this could also be readily handled with the computer solutions.

Finally, the fundamental issues of scale-up will be emphasized. Some data on rats are now available, and an attempt will also be made to directly apply the model to these data as well as to published human clinical data.

NOMENCLATURE

Intestinal Drug Absorption and Metabolism I: Comparison of Methods and Models to Study Physiological Factors of *In Vitro* and *In Vivo* Intestinal Absorption

WILLIAM H. BARR* and SIDNEY RIEGELMAN†

Abstract □ Two experimental methods for use in kinetic studies on a compartment model for intestinal metabolism and absorption were evaluated. The *in vitro* cannulated everted intestinal sac and the *in vivo* intestinal loop with complete mesenteric venous collection were compared in the same region of rabbit intestine. These experimental methods were used to study the effects of metabolism, tissue accumulation, and blood flow on the transport of salicylamide across the basal barrier and provide experimental evidence to support the cell compartment model. At lower initial mucosal concentration (10^{-3} M), over 60% of the drug appearing in mesenteric blood is conjugated with glucuronic acid. At higher initial mucosal fluid concentrations, glucuronide conjugation appears to be capacity limited and the disappearance from the lumen-curve shows a distinct distributive phase characteristic of a cell compartment model. The rate of transport of free drug across the basal barrier is blood flow rate-limited while the transport of glucuronide is essentially independent of blood flow. Appearance of free salicylamide into mesenteric blood, *in vivo*, shows a lag time of 4 min. compared to a lag time of about 10 min. for the appearance of free drug into serosal fluid *in vitro*. The steady state rate of appearance of free drug into the plasma (*in vivo*) is five to ten times greater than the rate of appearance of free drug into the serosal fluid (*in vitro*) at similar mucosal concentrations. The *in vivo* intestinal loop with complete venous collection was found to have many advantages in studying physiological factors of intestinal drug absorption.

Keyphrases □ Drug absorption—intestinal □ Everted intestine—drug absorption, *in vitro* □ Intestinal loop, cannulated—drug absorption, *in vivo* □ Salicylamide—absorption, accumulation, metabolism □ Glucuronic acid-salicylamide conjugation—concentration effect □ Fluorometry—analysis

From the standpoint of a drug administered orally to produce a systemic effect, intestinal absorption can be considered as the amount of unchanged drug absorbed from the intestinal lumen which appears in the portal circulation or intestinal lymph. Using this definition, the amount of drug disappearing from the lumen contents is sufficient to characterize the absorption process only if it reflects the rate of appearance of unaltered drug in the blood. If one accepts the above definition,

then it becomes quite important to evaluate critically the widely used (1) practice of assessing absorption by monitoring only the rate of disappearance of drug from the lumen. The condition that the rate of disappearance of free (unaltered) drug from the lumen contents is identical to the rate of appearance of free drug in the mesenteric blood is implicit in the classical lipid barrier model of intestinal absorption which assumes that the intestinal tissue is a single barrier which does not contribute to the material balance of the system.¹ When accumulation or metabolism of drug occurs in the intestinal tissue, these rates may not be identical and a tissue compartment model for absorption is considered here as a more appropriate model to describe the entire absorption sequence.

The studies described in this report were designed to compare *in vivo* and *in vitro* experimental methods and mathematical models that might be useful in studying the effect of physiological factors, such as accumulation and metabolism of drug in the intestinal tissue and intestinal blood flow, on the appearance of free drug into mesenteric blood.

The general multiple barrier tissue compartment model that will be used to describe these physiological variables in *in vivo* and *in vitro* preparations is shown in Fig. 1. This catenary three-compartment model assumes that the intestinal tissue can be described as a homogeneous compartment, which is separated from the lumen compartment by an apical barrier (α) and from the terminal blood or serosal fluid compartment by a

¹ In compartment theory, a barrier may be defined as that rate-limiting step between two compartments which distinguishes these compartments by the fact that the rate of distribution within each compartment is sufficiently rapid, compared to the rate of transport across the barrier, that each compartment may be described by a separate volume of distribution. The barrier is considered to be only a rate-limiting step of negligible volume which does not contribute to or alter the material balance of the system. See, for example, the discussion on the concept of a barrier by Riggs (Reference 32, p. 188) and the concept of a compartment being represented as a volume by Resigno and Segre (Reference 31, p. 16).

Intestinal Drug Absorption and Metabolism I: Comparison of Methods and Models to Study Physiological Factors of *In Vitro* and *In Vivo* Intestinal Absorption

WILLIAM H. BARR* and SIDNEY RIEGELMAN†

Abstract □ Two experimental methods for use in kinetic studies on a compartment model for intestinal metabolism and absorption were evaluated. The *in vitro* cannulated everted intestinal sac and the *in vivo* intestinal loop with complete mesenteric venous collection were compared in the same region of rabbit intestine. These experimental methods were used to study the effects of metabolism, tissue accumulation, and blood flow on the transport of salicylamide across the basal barrier and provide experimental evidence to support the cell compartment model. At lower initial mucosal concentration (10^{-3} M), over 60% of the drug appearing in mesenteric blood is conjugated with glucuronic acid. At higher initial mucosal fluid concentrations, glucuronide conjugation appears to be capacity limited and the disappearance from the lumen-curve shows a distinct distributive phase characteristic of a cell compartment model. The rate of transport of free drug across the basal barrier is blood flow rate-limited while the transport of glucuronide is essentially independent of blood flow. Appearance of free salicylamide into mesenteric blood, *in vivo*, shows a lag time of 4 min. compared to a lag time of about 10 min. for the appearance of free drug into serosal fluid *in vitro*. The steady state rate of appearance of free drug into the plasma (*in vivo*) is five to ten times greater than the rate of appearance of free drug into the serosal fluid (*in vitro*) at similar mucosal concentrations. The *in vivo* intestinal loop with complete venous collection was found to have many advantages in studying physiological factors of intestinal drug absorption.

Keyphrases □ Drug absorption—intestinal □ Everted intestine—drug absorption, *in vitro* □ Intestinal loop, cannulated—drug absorption, *in vivo* □ Salicylamide—absorption, accumulation, metabolism □ Glucuronic acid-salicylamide conjugation—concentration effect □ Fluorometry—analysis

From the standpoint of a drug administered orally to produce a systemic effect, intestinal absorption can be considered as the amount of unchanged drug absorbed from the intestinal lumen which appears in the portal circulation or intestinal lymph. Using this definition, the amount of drug disappearing from the lumen contents is sufficient to characterize the absorption process only if it reflects the rate of appearance of unaltered drug in the blood. If one accepts the above definition,

then it becomes quite important to evaluate critically the widely used (1) practice of assessing absorption by monitoring only the rate of disappearance of drug from the lumen. The condition that the rate of disappearance of free (unaltered) drug from the lumen contents is identical to the rate of appearance of free drug in the mesenteric blood is implicit in the classical lipid barrier model of intestinal absorption which assumes that the intestinal tissue is a single barrier which does not contribute to the material balance of the system.¹ When accumulation or metabolism of drug occurs in the intestinal tissue, these rates may not be identical and a tissue compartment model for absorption is considered here as a more appropriate model to describe the entire absorption sequence.

The studies described in this report were designed to compare *in vivo* and *in vitro* experimental methods and mathematical models that might be useful in studying the effect of physiological factors, such as accumulation and metabolism of drug in the intestinal tissue and intestinal blood flow, on the appearance of free drug into mesenteric blood.

The general multiple barrier tissue compartment model that will be used to describe these physiological variables in *in vivo* and *in vitro* preparations is shown in Fig. 1. This catenary three-compartment model assumes that the intestinal tissue can be described as a homogeneous compartment, which is separated from the lumen compartment by an apical barrier (α) and from the terminal blood or serosal fluid compartment by a

¹ In compartment theory, a barrier may be defined as that rate-limiting step between two compartments which distinguishes these compartments by the fact that the rate of distribution within each compartment is sufficiently rapid, compared to the rate of transport across the barrier, that each compartment may be described by a separate volume of distribution. The barrier is considered to be only a rate-limiting step of negligible volume which does not contribute to or alter the material balance of the system. See, for example, the discussion on the concept of a barrier by Riggs (Reference 32, p. 188) and the concept of a compartment being represented as a volume by Resigno and Segre (Reference 31, p. 16).

Figure 1—General compartment model for intestinal absorption including metabolism in the epithelial cell and transport across the apical (α) and basal (β) barrier into mesenteric blood (in vivo) or serosal fluid (in vitro). Key: F_1 is the amount of free (unmetabolized) drug in the lumen contents; F_2 is the amount of free drug in the tissue; F_3 is the amount of free drug in the blood in in vivo preparations and in the serosal fluid of isolated in vitro intestinal preparations; G_2 is the amount of metabolite formed in the intestinal cell (e.g., glucuronide). For some cases, more than one metabolite may be formed as illustrated by S_2 ; k_{m1} is the rate constant for the transfer of amount from Compartment m to Compartment n, e.g., k_{21} is the rate constant for the transfer of free drug from Compartment 2 to Compartment 1; k_{m1}^* is the rate constant for the transfer of amount of metabolite from Compartment m to Compartment n; k_{f2} is the rate constant for the formation of metabolite.

basal (β) barrier and that metabolism of the drug may occur in the tissue.

The anatomical entities corresponding to the α and β barriers cannot, at the present state of knowledge, be defined. There are many potential barriers that a drug may encounter during gastrointestinal absorption. It is probable that the barriers corresponding to the rate-limiting steps may be different for different preparations and drugs and possibly for different ionic species of the same drug. It is also clear that the present three-compartment model may be inadequate and additional compartments or a stochastic model may be required to describe the absorption mechanisms of some drugs.

It can be shown that the tissue compartment model will reduce to a simple apparent barrier model when metabolism is negligible and the rate constant for transfer of drug across the basal barrier is much greater than the rate constant for transfer of drug across the apical barrier. The important differences between the compartment and barrier models are summarized in Table I.

It is likely that no single experimental method will be ideal to study physiological factors of absorption and that the maximum information will often require corroborative evidence from more than one method. It was of interest, therefore, to compare different methods in the same intestinal region of the same animal. Two preparations were selected to compare *in vivo* and *in vitro* methods using the same intestinal region.

The *in vitro* preparation selected was a cannulated everted intestine which would eliminate possible variables due to blood flow and permit serial sampling from both the mucosal and serosal contents. The everted intestinal sac which was introduced by Wilson and Wiseman (2) has the advantage of simplicity and flexibility and is beginning to find use in studies on drug absorption (3–8). Everted intestinal sacs have also been used to show intestinal glucuronide formation (6) and

Table I—Comparison of Apparent Barrier and Tissue Compartment Models of Intestinal Absorption

Apparent Barrier Model	Tissue Compartment Model
The intestinal tissue does not contribute to or alter the material balance of free drug in the lumen, blood, or serosal compartments.	The intestinal tissue must be considered in the material balance of free drug in the system.
No appreciable accumulation of free drug in tissue.	Accumulation of free drug in tissue may occur.
Apical barrier is rate-limiting step for appearance of free drug in plasma ($k_{12} < k_{23}$).	Basal barrier is rate-limiting step for appearance of free drug in plasma ($k_{12} > k_{23}$).
No metabolism of drug in tissue.	Metabolism of drug in the tissue may occur.
Rate of appearance of free drug in plasma can be predicted by measurements on the disappearance of drug from the lumen fluid.	Measurements on lumen fluid alone may not be sufficient to characterize appearance of free drug in plasma. Tissue or blood may also have to be sampled.
Semilog plot of amount of drug in the lumen versus time will appear linear with intercept near to the initial amount in lumen.	Semilog plot of amount of drug in the lumen versus time is biexponential showing distributive phase.

to study the mechanisms involved in glucuronide transport (7, 8).

The *in vivo* method selected for this study was a cannulated intestinal preparation with complete mesenteric venous blood collection. By cannulating the mesenteric vein and leaving the arterial supply intact, the rate of appearance of drug in the blood is measured directly without the complicating factors of tissue distribution in the body, hepatic metabolism, and urinary excretion. This type of preparation has not been generally applied to studies of drug absorption, but has been used to study intestinal metabolic processes of sugars and amino acids in the cat (9), dog (10), guinea pig and rat (11), and steroid conjugation in humans (12).

These two preparations have the advantage that the terminal compartment is closed, permitting direct evaluation and comparison of transfer across the *in vivo* and *in vitro* basal barrier.

Through the use of experimental procedures such as the “*in vivo* intestinal loop with complete venous collection,” the assumptions of a closed system and irreversible transfer of drug from the tissue to the blood compartment are valid and permit considerable simplification of the general model (Model I) to the form,

which is described by the following differential equations:

$$-dF_1/dt = k_{12}F_1 - k_{21}F_2 \quad (\text{Eq. 1})$$

$$dF_2/dt = k_{12}F_1 - k_{21}F_2 - k_{23}F_2 - k_{f2}F_2^* \quad (\text{Eq. 2})$$

$$dF_3/dt = k_{23}F_2 \quad (\text{Eq. 3})$$

$$dG_2/dt = k_{f2}F_2^* - k_{23}^*G_2 - k_{21}^*G_2 \quad (\text{Eq. 4})$$

The quantity, F_2^* , will vary and be equal to F_2 in the case of first-order metabolism or be fixed at a certain value in the case of zero-order metabolism. The fixed amount may be considered that amount which saturates the enzyme system so that V_{max} is reached and is equal to $k_{f0}F_2^*$ which is an apparent zero-order rate constant.

Rabbits were selected as the experimental animal for several reasons. Cannulation of the mesenteric vein in smaller animals is difficult. A larger animal such as a dog would require the replacement of large amounts of blood to maintain blood flow. Furthermore, as the size of the animal increases, the thickness of the intestine precludes use for *in vitro* methods such as everted intestinal sacs or *in vitro* intestinal perfusions so that *in vivo* and *in vitro* methods cannot be easily compared in the same animal. It is stated that the general intestinal vasculature of the rabbit is very similar to that of man (13).

Salicylamide (SAM) was chosen as a suitable drug to use for the following studies on accumulation and metabolism in the cell compartment for two reasons. First, it has sufficient lipid solubility and is largely undissociated at physiological pH (pK_a 8.9) (14). Second, Schachter (6) has shown that salicylamide is appreciably conjugated with glucuronic acid in *in vitro* everted intestinal sacs. Salicylamide therefore provides a model substrate to study the effect of intestinal metabolism on the *in vivo* availability of a drug.

EXPERIMENTAL METHODS

Everted Sacs for Kinetic Studies—The apparatus used, a modification of that used by Crane and Wilson (15), is shown in Fig. 2. An intestinal segment (about 10 cm.) was quickly removed from a male New Zealand rabbit under pentobarbital anesthesia, washed gently with Krebs-Ringer bicarbonate solution (16) (pH 7.4),

Figure 2—Diagrammatic illustration of apparatus used in the *in vitro* cannulated everted intestine preparations. Key: (a) 1-ml. disposable plastic syringe used to collect serosal fluid; (b) large hypodermic needle (14 gauge); (c) rubber stopper; (d) 125-ml. conical flask; (e) disposable polyethylene centrifuge tube; (f) water bath (37°); (g) umbilical tape used to fasten intestine to centrifuge tube; (h) everted intestine; (i) inlet for gas mixture (O_2 - CO_2 , 95%-5%); (j) 1-ml. disposable plastic syringe used to collect mucosal fluid.

and everted by means of a glass rod inserted through the lumen. A disposable polyethylene centrifuge tube was inserted in one end of the intestine and tied securely with umbilical tape. The opposite end was tied and 7 to 10 ml. of Krebs-Ringer bicarbonate solution introduced through the hypodermic needle inserted in the polyethylene tube. The intestine was then placed in the mucosal fluid containing 75 ml. of 10^{-4} to 10^{-2} M drug in Krebs-Ringer bicarbonate solution maintained at 37° and saturated with 95% O_2 and 5% CO_2 by directly bubbling the O_2 and CO_2 into the mucosal fluid. Serial samples of known volume were taken from both mucosal and serosal fluids by means of 1-ml. disposable plastic syringes.

Fixed-time studies used everted sacs closed at both ends which were incubated either under the conditions used by Herz *et al.* (7) for rat intestine, which was oxygenated by an O_2 and CO_2 (95% and 5%) atmosphere flowing at 122–152.5 cm.³/hr. (4–5 ft.³/hr.), or by bubbling the O_2 - CO_2 mixture directly into the mucosal fluid.

In Situ Isolated Intestinal Preparation with Intact Arterial Supply and Complete Venous Collection—Male rabbits weighing between 2 and 3 kg. were anesthetized with pentobarbital or urethane-pentobarbital mixture. A small midline incision allows the gentle exposure of a 20–60-cm. midileal portion of the intestine. This portion was selected because of its accessibility and suitable vasculature to facilitate cannulation. The mesenteric arcades to adjacent portions were carefully tied off. The intestine was cut and cannulated with Tygon tubing for either perfusion (Fig. 3A) or a closed loop (Fig. 3B). The mesenteric vein was cannulated with an appropriate size of Silastic or polyethylene tubing and all venous blood collected in heparinized, calibrated centrifuge tubes. The mean-flow rate was determined directly by recording the quantity of blood collected in successive intervals, usually 10 min. The blood lost from the mesenteric vein was continuously replaced with an equal volume by an intravenous infusion, *via* the jugular vein, of heparinized blood-saline mixture or whole blood previously collected from donor animals. The carotid artery was also cannulated for systemic arterial samples.

The isolated intestine was kept warm and moist by frequent application of warm (37°) saline to a gauze pad covering the intestine

which in turn was covered by a dental rubber dam. A small lamp placed over the area was sufficient to maintain the preparation at 37°.

Spectrophotofluorometric Assay of Salicylamide (SAM) and Its Metabolites in Plasma and Biological Fluids—The usual colorimetric method of assaying salicylamide (SAM) by a ferric ion complex proved too insensitive to be applicable to these studies. Salicylamide (SAM) is fluorescent in basic solution. This property was used to develop a fluorescence assay in which free SAM (pKa 8.9) (14) was extracted from an acidified or buffered (pH 4.3) biological fluid into an ethylene dichloride-cyclohexane (65:35) mixture and reextracted into an aqueous 0.2 *N* sodium hydroxide solution. The fluorescence of SAM in the aqueous basic solution was determined directly by an Aminco-Bowman spectrophotofluorometer at the maximum activation and emission wavelengths of 350 and 430 mμ, respectively (both uncorrected). This procedure provided a sensitive and reproducible assay capable of estimating concentration of free SAM as low as 0.5 mcg./ml. Concentrations of 1 to 50 mcg./ml. were easily assayed with an average standard error of the mean usually less than ±3%. SAM glucuronide is expressed as the free SAM released after hydrolysis with bacterial β-glucuronidase. Total SAM (free, glucuronide, and sulfate) can be determined as free SAM after acid hydrolysis.

Analog Computer Simulation of Model—An analog computer² program corresponding to Eqs. 1–4 is shown in standard analog computer symbols in Fig. 4. The steps for subsequent metabolite transport, k_{21}^0 , k_{32}^0 , have been omitted in this program as they will not affect transport of free drug which is of interest here.

When the effect of metabolism in the cell is evaluated ($k_{fg} > 0$), metabolism in the cell proceeds by a first-order process at the variable rate, $k_{fg}F_2^*$, where F_2^* is equal to F_2 . When the variable input into the electronic comparator (F_2) equals the selected fixed reference voltage of the electronic comparator ($F_2^* \text{ ref.}$), the comparator operates through a digital output to an electronic switch which changes the rate of metabolism to a fixed (zero-order) rate³ equal to $k_{fg} (F_2^* \text{ ref.})$. When metabolism is negligible, the potentiometer representing k_{fg} is set to zero.

RESULTS AND OBSERVATIONS

Influence of Intestinal Region and Method of Oxygenating on *In Vitro* Glucuronidation—In order to compare intestinal metabolism in *in vitro* everted intestines and *in vivo* perfused intestines in the same region, preliminary studies were made to determine the region of intestine which produced maximal glucuronide formation and experimental factors influencing final glucuronide concentrations.

Closed rabbit everted sacs were incubated with 10^{-4} *M* salicylamide under a closed O₂ and CO₂ (95%–5%) atmosphere flowing at 122–152.5 cm.³/hr. (4–5 ft.³/hr.) similar to the conditions used by Herz *et al.* (7) to study conjugation of thyroxine analogs in rat everted intestines. All regions of the intestine had essentially the same final salicylamide glucuronide concentrations and glucuronide-to-free drug ratios in the serosal fluid as shown in Table II, Rows 1–8. The ileum appeared to have slightly greater amounts of glucuronide and was selected as the standard region for this and other reasons. It is the most convenient region for cannulation in the *in vivo* preparation and is the region usually used when minimal fluid flux is desired (17).

When the O₂ and CO₂ mixture was bubbled *directly* into the mucosal fluid, two effects were noted. First, peristaltic contractions of the intestine were increased, leading to variable amounts of fluid remaining in the sac. The final serosal concentrations in the bubbled preparation of both glucuronide and free drug showed greater variation due to the fluid loss. Second, both glucuronide and free drug serosal concentrations were generally higher than those found in the O₂ and CO₂ atmosphere conditions. The increase in serosal glucuronide was greater than the increase of serosal free drug, however, as is reflected by increased serosal glucuronide-to-free drug ratios. These data are shown in Table II where Rows 1–8 are under O₂–CO₂ atmosphere conditions and Rows 9–14 are with bubbled O₂–CO₂ conditions.

² The analog computer used was a TR-20 with a series 1133 Variplotter recorder, manufactured by Electronics Associated Inc., Long Branch, N. J.

³ Although this scheme has the disadvantage that the rate of metabolism shifts from first-order to zero-order instantaneously rather than following the more complex true enzyme kinetics, it is adequate to illustrate the points for which it is intended in this paper.

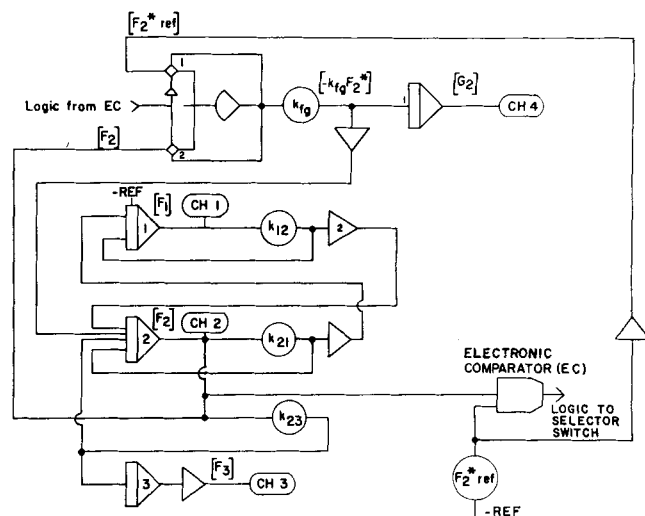

Figure 4—Analog computer program for the model $F_1 \rightleftharpoons F_2 \rightarrow F_3$ where metabolite formation may be first-order or zero-order when F_2 reaches the reference voltage of the comparator ($F_2^* \text{ ref.}$). (See text for discussion.)

It was subsequently found that the loss of fluid due to peristaltic squeezing can be satisfactorily prevented by leaving an open syringe in the cannulating needle to act as a reservoir for serosal fluid pushed up during contraction. This procedure improves the reproducibility and usefulness of this preparation and permits the use of directly bubbled oxygen in kinetic studies.

Figure 5 shows the typical linear plot obtained in the cannulated everted sac when appropriate volume corrections are made and the amount of drug reaching serosal fluid is plotted against time. The volume corrections are as follows.

Samples of equal volume are removed from the serosal fluid every 10 min., so that the volume decreases linearly with time. Since the mucosal concentration is essentially constant, a constant amount is delivered to the serosal fluid per unit time while the serosal concentration increases inordinately, due to the decrease of

Figure 5—The amount of free drug (O) and glucuronide in the serosal fluid (□) of the cannulated *in vitro* everted intestine as a function of time (initial concentration of 10^{-3} *M* SAM in mucosal fluid).

^a Comparison of concentrations of SAM (free) and SAM glucuronide in the serosal fluid after 1-hr. incubation at 37° with an initial mucosal concentration of 10⁻⁴ M SAM. Comparisons are made of different regions of the intestine (duodenum, jejunum, ileum) with the same oxygenating system or the same region (ileum) with different oxygenating systems [95% O₂-5% CO₂ bubbled in directly or in an atmosphere flowing through a Dubnoff shaker at 122–152.5 cm.³ (4–5 ft.³)/hr.]. ^b Each different letter indicates a particular experiment using a different rabbit. Intestinal segments come from the same animal if they have the same letter (e.g., D). ^c The ratio of the concentrations of glucuronide and free in serosal fluids after 1 hr. ^d Fluid loss due to one sample taken at 30 min. ^e Fluid loss due to peristalsis.

serosal volume, resulting in a convex concentration-time curve requiring the following correction.

When each sample aliquot of equal volume (v) is removed from the initial volume (V^0), the amount of drug in the serosal fluid (F_t), at a given time (t), corresponding to sample number (n), of concentration (C_{F_n}), is given by

$$F_t = C_{F_n} [V^0 - v(n - 1)]$$

and the cumulative amount of free drug, $\sum F_t$, which has reached the serosal fluid at time t , including the amount which has been removed during previous sampling is

$$\sum F_t = C_{F_n} [V^0 - v(n - 1)] + v \sum_{i=1}^{n-1} C_{F_i}$$

It is possible that even corrected-amount plots will be curved upwards if metabolism is significant and becomes capacity limited within the range of mucosal cell concentrations obtained during the course of the experiment.

Evaluation of *In Vivo* Intestinal Loop with Complete Venous Collection—The technique of collecting all venous blood draining from the region of absorption was developed to provide an *in vivo* preparation with intact circulation where the mesenteric venous blood could be treated as a closed compartment. The most important criterion for the usefulness of this preparation, therefore, is that all free drug and drug metabolites which are absorbed into the capillary blood must be collected in the venous effluent and not reach the general circulation. Since arteriovenous anastomoses in the gastrointestinal circulation are present (18, 19), the following study was performed to establish that the amount of drug which reaches the systemic circulation is negligible. A closed intestinal loop with complete venous collection was filled with 10 ml. of 10⁻³ M SAM (1.37 mg.). After 2 hr. the intestine was rinsed and 10 ml. of a 10⁻² M solution (13.7 mg.) was placed in the lumen. The venous blood was collected and assayed for free drug and glucuronide. The carotid artery was sampled periodically during the absorption process. The resulting concentrations of free drug and glucuronide in carotid arterial plasma and the mesenteric venous effluent as a function of time are shown in Fig. 6.

The concentrations in arterial blood were only very slightly above the arterial blood blank and were insignificant compared to venous effluent concentrations. Arterial blood concentrations were checked periodically throughout the experiments and never found to be significant. In some cases, total urine collection was also assayed at the end of the experiment and found to contain negligible amounts of free drug or glucuronide. These results show that the primary criterion for the usefulness of this preparation—*viz.*, complete collection of all absorbed drug and drug metabolites in the mesenteric venous effluent, is quite adequately satisfied.

Effect of Metabolism, Accumulation, and Blood Flow on the Disappearance of Free Drug from the Lumen and Appearance of Free

Drug in the Plasma—In the study previously described and illustrated by the plasma concentration curves in Fig. 6, the amounts of free drug in the lumen remaining to be absorbed were also determined and are shown in Fig. 7. These curves illustrate the difficulty of deducing mechanisms of absorption from measurements only on the disappearance of drug from the lumen. Curve *b*, obtained with the lower dose (1.37 mg.), appears linear throughout with an intercept equal to the initial amount in the intestinal lumen. This is exactly the type of curve predicted by a true irreversible barrier model, $F_1 \rightarrow F_3$. Curve *a*, which was obtained in the same intestinal preparation with a higher dose (13.7 mg.), shows a distinct distributive phase, however, and follows the shape predicted by a compartment model, $F_1 \rightleftharpoons F_2 \rightarrow F_3$. If the rate of appearance of free drug in the plasma (dF_3/dt) is examined for the lower concentration (1.37 mg.), it is apparent from Fig. 8 that the slope of the semilog-time-plot is not the same as the slope of the semilog-time-plot of amount remaining in the lumen. The barrier model would require that these slopes both be equal to $-k_{13}/2.303$, since $F_1 = F_1^0 e^{-k_{13}t}$, and $dF_3/dt = k_{13}F_1^0 e^{-k_{13}t}$. Thus, although the data on the disappearance of drug from the lumen suggests that the barrier model is applicable for the lower dose, the rate of appearance of drug in the plasma at this dose does not correspond to the barrier model. These apparently anomalous results can be readily reconciled by considering the effects of cellular metabolism on the amounts of free drug in the intestinal tissue.

Figure 6—Comparison of the concentrations of free drug, glucuronide, and total drug in the closed sac, in vivo preparation, containing (a) 10 ml. of 10⁻³ M (1.37 mg.) SAM, or (b) 10 ml. of 10⁻² M (13.7 mg.) SAM.

Figure 7—Comparison of the amount of free drug in the lumen remaining to be absorbed (log scale) in the closed loop *in vivo* preparation containing 10 ml. of 10^{-3} M SAM (●) and 10 ml. of 10^{-2} M SAM (○).

If it is assumed that at lower doses the free drug in the tissue is rapidly metabolized by a first-order process, the amount of free drug in the cell then remains very low and the cell compartment approximates a barrier containing negligible amounts of free drug.

At higher doses, metabolism in the cell is capacity-limited (*i.e.*, is approaching zero-order metabolism kinetics) and a smaller fraction is metabolized. This allows accumulation of the free drug in the tissue and requires distribution equilibrium to be established between the free drug in the lumen compartment and the cell compartment before monoexponential disappearance is observed. Indeed, when one examines the appearance of glucuronide in the plasma given in Fig. 6, this explanation appears quite reasonable. At 10^{-3} M, the fraction which appears as glucuronide in the plasma exceeds that of the free drug. At the higher (10^{-2} M) concentration, the fraction of drug which appears in the plasma as glucuronide is much less, particularly in the initial phase. The experimental results shown in Fig. 7 are in reasonable agreement with the types of lumen disappearance curves predicted by the analog computer program when the above assumptions on capacity-limited metabolism were made as shown in Fig. 9.

These *in vivo* studies provide experimental evidence for four important concepts: (a) an appreciable amount of drug absorbed from the lumen may appear in the plasma as metabolized drug; (b) the intestinal glucuronide conjugating system can apparently be saturated; (c) the intestine behaves like a compartment when the fraction of salicylamide metabolized is negligible. Approximate calculations⁴ show that the apparent volume of distribution in the cell compartment is almost equal to the volume of the mucosal fluid (about 10 ml.) and (d) measurements on the disappearance of drug from the lumen alone are not adequate to characterize the absorption process when metabolism in the cell is significant.

⁴ Present difficulties in assaying drug in the tissue allow only indirect evidence of tissue accumulation of free drug. The volume of distribution was estimated by the analog computer program. There are difficulties in curve fitting, however, as (a) the fraction of drug metabolized is changing and (b) some hydrolysis of glucuronide in the lumen fluid appears operative.

Figure 8—Comparison of the amount of free drug (F_1) in the lumen (●) and the rate of appearance of free drug (F_3) in the venous plasma (Δ) obtained in an *in vivo* closed loop preparation containing 10 ml. of a 10^{-3} M solution of SAM.

Effect of Blood Flow on the Rate of Appearance of Drug in Plasma—The effect of blood flow on the rate of appearance of drug in the plasma is shown by the fluctuations observed in the rates of appearance of free drug in the *in vivo* perfused intestine long after steady state should have been established. An example is given in Fig. 10 which shows the rate of appearance of free drug and glucuronide in plasma in an *in vivo* loop perfused with 10^{-3} M SAM. It is evident that there are considerable variations in the rate of appearance of free drug. When the rates of blood flow at the same time points are plotted, the peaks coincide. The rate of appearance of glucuronide, however, appears to be relatively constant, and independent of blood flow.

The rate of appearance of free salicylamide and glucuronide in the mesenteric plasma as a function of blood flow when the mucosal concentration is maintained constant by perfusion with 10^{-3} M SAM is shown in Fig. 11.

It is apparent that transport of free drug across the basal barrier is rate limited by blood flow while the more polar glucuronide is diffusion rate limited except at very low flow rates.

The role of intestinal blood flow in intestinal absorption has been controversial. Some reviewers have stated that although very little work has been done on the effect of blood flow, it may be a rate-limiting factor (20, 21). Others believe it to be unimportant because of the large rate of flow through the splanchnic region (13, 22), and that diffusion will always be rate limiting.

One must of course be cautious in extrapolating the results obtained in an anesthetized surgical preparation to absorption under normal physiological conditions. In general, the splanchnic circulation receives about 30% of the cardiac output of which about 15% goes to the intestines. For a rabbit with a cardiac output of 0.35 l./min. (0.26–0.48 by the direct Fick method), the flow through the entire intestine should be about 55 ml./min. (23). In the cannulated preparation about one-tenth of the intestine is used. Therefore, the flow rate through this segment should be about 4.0 to 7.0 ml./min. The actual flow rates achieved were somewhat less, ranging between 0.6 and 6 ml./min., but sufficiently close to indicate that similar effects might be observed in the intact animal.

Comparison of Lag Times in *In Vitro* and *In Vivo* Preparations—The existence of a lag time in the *in vitro* rabbit preparation is clearly evident from Fig. 5 and has also been demonstrated in the rat by other workers (4, 24, 25). Figure 5 shows a significant lag time of almost 10 min. for free drug and over 15 min. for the linear appearance of glucuronide into serosal fluid. The physiological significance of the lag time for transport of drug into the serosal fluid in the *in vitro* preparations has been questioned, however, because blood circulation is nonfunctional and the drug must additionally traverse the submucosa and muscularis layers which may account for a sizable drug reservoir or barrier.

Figure 9—Analog computer simulation of amounts of free drug remaining in the lumen when metabolism in the tissue compartment proceeds by first-order (bottom curve) at low initial dose, or zero-order at a higher initial dose (top curve). The rate constants for the analog program shown in Fig. 4 (corresponding to the symbolism in Fig. 1) were the same in both cases; k_{12} (0.5), k_{21} (0.5), k_{23} (0.2), and k_{13} (1.2) in units of reciprocal time. F_2^* ref. was set at 0.5 v. in the case of zero-order metabolism corresponding to a zero-order rate of 0.6 v., unit time⁻¹.

Several investigators have found it necessary to include a lag time in kinetic evaluations of drug absorption in man (26, 27). It is not possible to directly associate this lag time with the intestinal tissue, however, since in these cases other factors such as dosage form release, gastric emptying, intestinal transit times, and distribution in other tissues, e.g., hepatic (27), may also be involved. Conclusive evidence for an *in vivo* lag phase due to the intestinal tissue should be evident from the *in vivo* perfused intestinal loop with complete venous collection which would not be subject to the above criticisms.

To simulate the conditions of the *in vitro* everted intestinal preparations where the mucosal concentration is essentially constant, the loops were perfused with constant concentrations of 10^{-4} , 10^{-3} , or 10^{-2} M SAM in Krebs-Ringer bicarbonate solution. Periodic samples of the lumen perfusate showed that the perfusion rate used (1.9 ml./min.) was sufficient to maintain a constant mucosal concentration. Since all drug is collected in the venous effluent, the plasma can be treated as a closed compartment, and the cumulative amount absorbed is easily obtained. Examples of cumulative amounts of free drug absorbed at different perfusion concentrations are given in Fig. 12. The absolute slopes vary slightly for a given concentration since no attempt was made to keep blood flow conditions and length of the loop constant. The x-axis intercept of the extrapolated linear portion of the curve represents the lag time. This lag time is quite consistent for all perfusion concentra-

Figure 10—The rate of appearance of free drug (▽) and glucuronide (□) in the venous plasma correlated with the rate of blood flow (○) in an *in vivo* preparation with complete mesenteric venous collection perfused with a 10^{-3} M solution of SAM.

tions, ranging from 4 to 6 min. with an average of 4.5 (SE \pm 0.4) min.

These results show that intestinal lag time can be expected in a physiologically realistic preparation with intact mesenteric circulation even when dosage form delays and diffusion of drug in the lumen fluid are obviated by using a well-stirred solution of the drug. The *in vivo* lag time is, therefore, a real phenomenon attributable to the intestinal tissue.

DISCUSSION

Interpretation of Lag Time in Barrier and Compartment Models—

The lag time may be interpreted either as the approach to diffusion steady state in a barrier model or the approach to apparent distribution equilibrium in a tissue compartment. The usual (29) equation describing steady-state diffusion across the intestinal "barrier" is the application of Fick's law to a plane sheet

$$-dF_1/dt = dF_3/dt = P_m A_m (C_{F1} - C_{F3}) \quad (\text{Eq. 5})$$

where F_1 is the amount of free drug in the mucosal fluid, P_m is the permeability constant of the intestinal barrier equal to the diffusion constant D , divided by the thickness of the barrier, x ; A_m is the effective absorbing area, C_{F1} and C_{F3} are the concentrations of free drug in the mucosal fluid and serosal fluid, respectively. In the noncompartmental diffusion model for diffusion of drug through a simple⁶ cylindrical barrier of inner surface area, A_1 , and outer surface area, A_3 , the lag time, T , is given by

$$T = (A_1 - A_3)^2 / 6D \quad (\text{Eq. 6})$$

It is difficult to assign values to the parameters of Eqs. 5 and 6 for several reasons (29). The intestine is not a simple⁶ barrier but

⁶ That is, a single isotropic medium.

Figure 11—The rate of appearance of free drug (○ ●) and glucuronide (□ ■) in the venous plasma as a function of the mean rate of blood flow in two in vivo preparations perfused with 10^{-3} M SAM.

a composite barrier in which D may vary.⁶ The area of the mucosal surface is much greater than the area of the serosal surface due to villi and microvilli and is difficult to estimate. Metabolism in the tissue may alter the material balance of free drug in the barrier.

When the rate out of the cell across the basal barrier is the rate-limiting step ($k_{23} \ll k_{12}$), accumulation of drug in the tissue occurs. A steady-state approximation based on negligible quantities in the intestine, implicit in a barrier model, will not be valid. Following a single dose, disappearance of the drug from the lumen will be biexponential of the form⁷

$$F_1 = A_1 e^{-\alpha t} - A_2 e^{-\beta t} \quad (\text{Eq. 7})$$

and

$$F_2 = A_3 e^{-\alpha t} - A_4 e^{-\beta t} \quad (\text{Eq. 8})$$

The rapid initial rate of disappearance from the lumen which represents the distributive phase between the lumen compartment and tissue compartment is not paralleled by a rapid rate of appearance of drug in the plasma. In fact, the opposite is true. An initial slow rate of appearance will be observed, resulting in an apparent lag time. During the distributive phase, measurements on the lumen alone will not be sufficient to characterize the rate of appearance of the drug in the blood. Accordingly, the lag time can be considered as the time to reach distribution equilibrium in the tissue compartment corresponding to the distributive phase. Apparent distribution equilibrium can be defined as follows: Apparent distribution equilibrium between two connected compartments is established during the time that the rate of change of the amount of drug in one compartment is proportional to the rate of change of the amount of drug in the other compartment. Following this definition, which will be termed "the proportionality rates assumption," the following relationship exists

$$dF_2/dt = R(dF_1/dt) \quad (\text{Eq. 9})$$

where R is a proportionality constant.

⁶ The difficulties of describing the intestine by diffusion kinetics are apparent when one considers that the simplest compartment model consisting of two barriers (α and β) would be equivalent to a diffusion model for a composite cylinder of two coaxial cylinders having different permeability constants. Crank (30) states that the extra parameters involved make numerical analysis quite formidable.

⁷ A complete solution to these equations is given in Reference 31.

Figure 12—The cumulative amount of free drug appearing in the blood in in vivo intestinal loops with complete venous collection perfused with 10^{-2} M ($\nabla, \blacktriangledown$, two trials), 10^{-3} M (\odot, \bullet , two trials), and 10^{-4} M (\circ , one trial) salicylamide in Krebs-Ringer bicarbonate solution.

It might be noted that other definitions of distribution equilibrium have been proposed which are not applicable to the intestinal compartment model. Riggs (32) states that distribution equilibrium is achieved when the rate of transfer from Compartment 1 to Compartment 2 equals the rate of transfer from Compartment 2 to Compartment 1. The condition given by Riggs, $dF_{1 \rightarrow 2}/dt = dF_{2 \rightarrow 1}/dt$ for distribution equilibrium is applicable to the intestinal compartment model only when $k_{23} = 0$. Thus, if one accepts the definition of absorption used in this paper, the condition of distribution equilibrium given by Riggs would be valid only when there is no absorption. The basic relationship between the concentration in the reference region (C_1), total amount of drug in the two compartments which are in apparent equilibrium, and the volume of distribution (V_{12}) is the same for both the condition given by Riggs and the proportionality rates condition—viz., $V_{12} = (F_1 + F_2)/C_1$.

Implicit in Eq. 9, the slopes of the amount-time curves must be proportional at each point in time during apparent distribution equilibrium.

When k_{23} is less than k_{12} , the $e^{-\alpha t}$ term in Eqs. 7 and 8 will approach zero and the linear segments of the semilog plots of amount versus time in Compartments 1 and 2 will be parallel in the mono-exponential phase. Thus,

$$R = \frac{dF_2/dt}{dF_1/dt} = \frac{\beta F_2}{\beta F_1} = \frac{\beta F_2^\circ e^{-\beta t}}{\beta F_1^\circ e^{-\beta t}} = \frac{F_2}{F_1} \quad (\text{Eq. 10})$$

where β is the apparent hybrid rate constant obtained from the terminal linear segment of the semilog plot of amounts versus time in each compartment and F_1° and F_2° are the extrapolated intercepts of these segments.

This shows that the proportionality constant, R , is equal to the constant ratio of amounts of drug in Compartments 2 and 1, after apparent distribution equilibrium is achieved.

These relationships are illustrated and verified by the analog computer plot shown in Fig. 13. Using these relationships, the identity

can be written

$$F_1 + F_2 = C_1 V_1 + R F_1 \quad (\text{Eq. 11})$$

where C_1 is the concentration of free drug in Compartment 1 and V_1 is the true volume of Compartment 1. Rearranging Eq. 11, it is seen that the term $V_1(R + 1)$ is equal to V_{i2} , the apparent volume of distribution

$$V_{i2} = \frac{F_1 + F_2}{C_1} = V_1(R + 1) \quad (\text{Eq. 12})$$

When V_{i2} is constant, it is easily shown that only measurements on the concentration of drug in the first compartment (lumen contents) are necessary to describe the rate of appearance of drug in the third compartment since

$$dF_3/dt = V_{i2} dC_1/dt \quad (\text{Eq. 13})$$

After apparent distribution equilibrium is achieved, Compartments 1 and 2 may be considered one open functional compartment with a single volume of distribution (V_{i2}). Thus, the rate of appearance of drug in the blood can be followed after apparent distribution equilibrium by monitoring the lumen concentration only, providing metabolism does not occur. It is important to realize, however, that the apparent volume of distribution, V_{i2} , must be used rather than the actual lumen volume, V_1 , or the amount in the tissue will be ignored.

Interpretation of Blood Flow Effects on Drug Transference—When the intestine cannot be considered as a simple barrier, the terms P_m and A_m lose physical significance and can be replaced by an intestinal transference term (3). Transference can be defined for a given unit of tissue as the rate of transport of unaltered substance from the initial compartment to the terminal compartment per unit concentration difference between the initial and terminal compartment. For *in vitro* intestinal transfer, the terminal compartment will be the serosal fluid and transference will be identical to the tissue permeability coefficient as defined by Pappenheimer (33) in units of ml./min. per unit tissue. For *in vivo* intestinal absorption, intestinal transference will be dependent on both the tissue permeability and rate of mesenteric blood flow and is similar to the dialysis term used by Wolf to describe hemodialysis (34).

When the rate of transport of free drug is diffusion rate-limited by the basal barrier and accumulation in the tissue occurs, the transference term will include the apparent volume of distribution term V_{i2} as discussed in the previous section.

The relationship between intestinal transference (3), tissue permeability (P), and mesenteric blood flow (\dot{V}) is given by the following equation (35):

$$\mathfrak{J} = \dot{V}(1 - e^{-P/\dot{V}}) = kV_{i2} \quad (\text{Eq. 14})$$

where \mathfrak{J} is the transference constant in units of ml./min., k is the apparent first-order rate constant (time⁻¹) for the transfer of amount of drug (F)_{i2} from the combined mucosal fluid-tissue compartment to the serosal compartment. When the mucosal or tissue concentration is constant (\bar{C}_{F1}) and much greater than the plasma concentration and transfer is essentially unidirectional (transference is then a clearance term), the rate of appearance (dQ/dt) of the amount of free drug (Q) in plasma will be given by

$$\frac{dQ}{dt} = V_{i2} \frac{dC_{F1}}{dt} = \bar{C}_{F1} \mathfrak{J} = \bar{C}_{F1} \dot{V}(1 - e^{-P/\dot{V}}) \quad (\text{Eq. 15})$$

Thus, when P is very large relative to \dot{V} , the exponential term approaches zero and dQ/dt is proportional to blood flow as in the case of free drug. When \dot{V} becomes large relative to P , dQ/dt will become independent of blood flow as illustrated by the glucuronide.

In view of these results, it might be assumed that intestinal blood flow will most likely influence intestinal absorption when: (a) the absorbed substance has a high permeability coefficient such as very lipid-soluble drugs or pore-diffusible substances or (b) the blood flow through the absorbing area is low. The blood flow through the absorbing area could be altered by changes in cardiac output, redistribution, or local arterio-venous shunting. These

Figure 13—Illustration of apparent distribution equilibrium by analog computer model when tissue accumulation occurs. The top curves illustrate the parallel slopes for lumen and tissue compartments in the monoexponential phase in which distribution equilibrium, defined by $dF_2/dt = R(dF_1/dt)$, exists where R , the ratio between F_2 and F_1 becomes constant as shown in the bottom curves for these cases. Rate constants (unit time⁻¹) for Case (a) were k_{12} (0.5), k_{21} (0.5), k_{23} (0.1), and Case (b) k_{12} (0.5), k_{21} (0.5), k_{23} (0.05). Metabolism is considered negligible ($k_{1g} = 0$).

processes may be affected by pathological conditions, emotional state, food, or in fact, the drug itself. The intestinal vasculature is governed by sympathetic tone and many drugs such as sympathomimetics, ergot derivatives, and ganglionic blocking agents could conceivably reduce the effective flow through the absorbing region and reduce their own or the absorption of other drugs given concomitantly. It is clear that the role of intestinal blood flow on intestinal absorption may be quite important and requires much further study.

SUMMARY AND CONCLUSIONS

Most previous studies on mechanisms of drug absorption have used *in vivo* methods which sample only disappearance of drug from the lumen rather than appearance of drug across the basal barrier into the blood. When transport across the basal barrier has been followed, it has been with *in vitro* preparations with non-functional blood circulation such as the isolated perfused intestine or everted intestinal sacs.

In the present study, both the rate of appearance of free salicyl-amide and salicylamide glucuronide into the mesenteric blood were measured directly by cannulating the mesenteric vein of exposed rabbit intestine and collecting all venous blood draining from the absorbing region. Using this technique, it was shown that the usual *in vivo* measurements on the disappearance of drug from the lumen alone would be inadequate to characterize the appearance of free drug in the mesenteric blood due to accumulation and metabolism of drug in the tissues and the effect of mesenteric blood flow.

The effect of intestinal glucuronide conjugation was found in this study to be quite significant, *in vivo*. As much as 60% of the drug appeared in the blood as the biologically inactive glucuronide.

When significant metabolism of the drug in the tissue occurs, measurements on the lumen alone will not be sufficient to predict the rate of appearance of free drug in the blood. When metabolism is capacity limited (*i.e.*, shifts from first-order to zero-order) the apparent mechanism of absorption of free drug might erroneously appear to proceed by two different mechanisms if only disappearance from the lumen is followed. The disappearance from the lumen curves, at low doses, indicated that an apparent barrier model was applicable with no accumulation of free drug in the tissue. At larger initial doses, the glucuronide-forming system appeared to be saturated and kinetic evidence indicated accumulation of free drug, characteristic of the compartment model for absorption. Studies on tissue levels are now in progress to further evaluate this conclusion.

The mesenteric blood flow plays a significant role in the *in vivo* preparation. Comparison of the *in vitro* and *in vivo* lag times shows that the presence of an intact mesenteric blood circulation in the *in vivo* preparation reduces the lag time for appearance in the terminal compartment from about 10 min. to about 4 min. presumably by obviating the extra diffusional barriers or reservoirs beyond the lamina propria which are present in the *in vitro* preparation. In addition to circumventing the submucosa and muscularis barriers, the rate of blood flow is also shown to play a role in the rate of transport of free drug across the basal barrier. The rate of transport of free drug across the *in vivo* basal barrier was clearly blood flow rate-limited. The rate of transport of the more polar glucuronide across the basal barrier appeared to be diffusion rate-limited and independent of the rate of blood flow. The *in vivo* rates of transport of free drug was five to ten times as great as those observed at the same initial mucosal concentration in the *in vitro* preparation.

In vitro methods such as the everted intestinal sac may provide an indication of relative permeabilities. However, permeability constants obtained with *in vitro* methods will not necessarily reflect the permeabilities of the tissues *in vivo* because of the extra barriers involved. *In vitro* procedures may also give useful information on capacity of the intestinal mucosal enzymes to metabolize drugs providing attention is given to the effect of experimental variables associated with this type of preparation. For example, the method of oxygenation, serosal sampling, and fluid loss due to peristalsis were found to greatly affect serosal glucuronide concentration.

In conclusion, the barrier model, which assumes that the intestinal tissue barrier does not alter or contribute to the material balance of the system, should not be assumed in contemplating experimental design. Sampling from the lumen alone may be unsatisfactory to predict the rate of free drug in the mesenteric blood which is the most significant criterion for assessment of absorptive capacity. Methods which measure the rate of unaltered drug across the basal barrier, such as the intestinal loop with complete mesenteric blood collection, provide a useful experimental approach in studying the physiologic factors of absorption such as tissue accumulation, metabolism, and blood flow.

ACKNOWLEDGMENTS AND ADDRESSES

Received May 31, 1968, from the Schools of Pharmacy at the State University of New York at Buffalo* and the University of California Medical Center at San Francisco†.

Accepted for publication August 28, 1969.

Presented in part to the Basic Pharmaceutics Section, APhA Academy of Pharmaceutical Sciences, Las Vegas meeting, April 1967.

This investigation was supported in part by grant number T51-CM 728-C5 from the National Institutes of Health, U. S. Public Health Service, Bethesda, Md. and grant C-R-68-UB-7 from the United Health Foundation of Western New York.

The authors wish to thank Dr. Frederick Meyers for assistance in developing the *in vivo* cannulated intestinal loop preparation and Mrs. Darlene Tisdale for technical assistance.

Intestinal Drug Absorption and Metabolism II: Kinetic Aspects of Intestinal Glucuronide Conjugation

WILLIAM H. BARR* and S. RIEGELMAN†

Abstract □ Mechanisms of intestinal salicylamide glucuronide formation and transport were studied in the rabbit with *in vitro* cannulated everted intestines and *in vivo* perfused and closed loops with complete mesenteric venous blood collection. Both experimental techniques indicate that glucuronide formation is capacity limited when the lumen concentration exceeds 10^{-3} M. The glucuronide-to-free drug ratio appearing in mesenteric blood (*in vivo*) and serosal fluid (*in vitro*) decreases with increasing lumen concentrations. Appearance of glucuronide across the basal barrier is limited by the transport step rather than the rate of glucuronide synthesis leading to accumulation of glucuronide in the tissue compartment. Transport of glucuronide appears to be a simple first-order diffusion process into the lumen contents as well as the mesenteric blood. Some implications of these findings in pharmacokinetic studies and dosage form design are discussed.

Keyphrases □ Drug absorption, metabolism—intestinal □ Salicylamide glucuronide formation, transport—intestinal □ Everted intestinal sacs—experimental technique □ Intestinal loop—*in vivo* experimental technique □ Conjugation, intestinal—salicylamide, glucuronic acid

The absorbing columnar cell of the intestine appears to be equipped with a wide variety of enzyme systems capable of metabolizing drugs. It has been shown as early as 1952 that *in vitro* intestinal slices can conjugate phenolic drugs with glucuronic acid (1). Glucuronide formation in the intestine has been shown *in vitro* for a large number of compounds including salicylic acid, salicylamide, anthranilic acid, thyroxine analogs, *p*-nitrophenol, *o*-aminophenol, testosterone derivatives, and estrogens (1–6). Sulfate conjugation also occurs in intestinal slices (8, 9). Recently, Hartiala *et al.* have shown that intestinal acetylation of sulfonamides can occur *in vitro* (10) and the work of Tapley *et al.* (6, 7, 11) indicates that reduction, hydroxylation, and oxidation of steroids can also take place in the intestinal mucosa.

The extent to which these metabolic transformations can affect the physiologic availability of an orally administered drug *in vivo* is almost completely unknown. Some information on this point has been recently obtained by use of a technique which allows complete collection of all mesenteric blood draining the absorption site of an intestinal loop. It has been shown by this method that an appreciable amount of salicylamide is absorbed *in vivo* as the glucuronide (12). That work also indicated that the appearance of the salicylamide glucuronide in the plasma was diffusion limited rather than blood flow limited and that the system could be saturated, giving capacity-limited (pseudo-zero-order) kinetics for the appearance of glucuronide in the plasma.

It is the purpose of this report to present further information on the manner in which intestinal metabolism may affect the *in vivo* absorption process using glucuronic acid conjugation of salicylamide as a model.

The mechanism of glucuronide synthesis and trans-

port may be considered from the standpoint of the previously proposed cell compartment model (12):

where F_1, F_2, F_3 represent the amount of free drug in the lumen, tissue, and plasma (or serosal fluid *in vitro*), respectively; G_1, G_2, G_3 represent the amounts of glucuronide in the lumen, cell, and plasma (or serosal fluid *in vitro*), respectively; k_{mn} represents the rate constant for amount of free drug transferred from Compartment m to Compartment n . For example, k_{23} is the rate constant for transfer from Compartment 2 (the tissue) to the plasma or serosal fluid (Compartment 3); k_{mn}^G represents the rate constant for the transfer of amount of glucuronide from Compartment m to Compartment n ; k_{FG} represents the rate constant for the metabolism of amount of free drug to glucuronide; α and β refer to the apical and basal barriers, respectively.

EXPERIMENTAL

The methods used in this study are the same as used in the previous report in this series (12). Free salicylamide was determined by extraction into a 1,2-dichloroethane-cyclohexane mixture (65:35) from which it is reextracted into 0.2 N sodium hydroxide solution. The basic solution is read directly in an Aminco-Bowman spectrofluorometer at excitation and emission wavelengths of 350 and 430 mμ, respectively (uncorrected). Salicylamide glucuronide is determined as the total salicylamide after hydrolysis with bacterial β-glucuronidase less the free salicylamide.

All intestinal studies were done with the midileal portion of the intestine from male New Zealand rabbits weighing between 2.0 and 2.5 kg. Everted intestinal sacs for fixed time and kinetic studies were prepared as before (12) and oxygenated by an O_2 - CO_2 (95:5) gas mixture bubbled directly into Krebs-Ringer bicarbonate mucosal fluid.

The *in vivo* preparation with complete venous collection was prepared by cannulating the mesenteric vein serving the intestinal loop which was either open and perfused or closed containing solutions of salicylamide in Krebs-Ringer bicarbonate solution (12).

RESULTS

Capacity-Limited Glucuronide Appearance—If metabolism in the cell follows first-order kinetics, the ratio of free drug to metabolized drug appearing in the plasma (*in vivo*) or serosal fluid (*in vitro*) should be constant and independent of the initial dose or mucosal concentration. It can be shown by both *in vitro* and *in vivo* experimental techniques that the glucuronide-to-free drug ratio is not constant and that the appearance of glucuronide in plasma is capacity limited.

Figures 1a and 1b illustrate the cumulative amounts of glucuronide and free drug appearing in the serosal fluid in everted intes-

tines containing mucosal concentrations of 10^{-4} and 10^{-3} M of salicylamide, respectively. When the mucosal concentration is low (10^{-4} M), the amount and rate of glucuronide appearing in the serosal fluid exceed the free drug. When a higher mucosal concentration is used (10^{-3} M), the glucuronide exhibits the same prolonged lag time but the rate and amount of glucuronide appearing in the serosal fluid are always less than that of the free drug.

Figure 2 illustrates the cumulative amounts of glucuronide appearing in the plasma in the *in vivo* intestinal loops with complete venous collection perfused with 10^{-4} , 10^{-3} , and 10^{-2} M salicylamide. The rates of appearance of glucuronide in the plasma as measured by the slope of the cumulative amount-time curve (or the cumulative amounts of glucuronide after 60 min.) do not differ greatly¹ even though the mucosal concentration varies over a hundredfold

Figure 1a—The cumulative amount of free drug (○) and glucuronide (□) in the serosal fluid of the cannulated *in vitro* everted intestine with an initial mucosal concentration of 10^{-4} M SAM.

Figure 1b—The cumulative amount of free drug (○) and glucuronide (□) in the serosal fluid of the cannulated *in vitro* everted intestine with an initial mucosal concentration of 10^{-3} M SAM. Bars indicate the range of two experiments.

¹ It is difficult to exactly standardize the length of intestine and control the mean rate of blood flow in different experiments which causes some variation in the total amount of metabolite recovered in a set time. This is the probable explanation for the lower amounts of glucuronide obtained with 10^{-2} M perfusion shown in Fig. 2 rather than inhibition of glucuronide formation at higher concentrations of salicylamide.

Figure 2—Cumulative amounts of glucuronide appearing in the mesenteric blood in the *in vivo* preparation perfused with 10^{-4} M (□), 10^{-3} M (■), and 10^{-2} M (△) SAM. Broken lines show the range of amounts of free drug appearing in mesenteric blood perfused with 10^{-4} M (lower broken line) and 10^{-3} M (upper broken line) solutions of SAM.

range. The amounts of free drug appearing in the plasma, shown by the dotted lines for comparison, do show great variations in the slope as would be expected. These points are also illustrated by Fig. 3 which shows the mean rates of appearance in plasma for free drug and glucuronide as a function of the perfusion concentration. These data provide evidence that appearance of glucuronide in the plasma or serosal fluid is capacity limited in both *in vitro* and *in vivo* experimental situations. Figure 4 compares the glucuronide-to-free drug ratio after 1 hr. in the plasma for the *in vivo* procedure and the serosal fluid for the *in vitro* procedure. The parallel lines suggest that the *in vitro* everted intestines serve well to characterize the glucuronide-to-free drug ratio that might be observed *in vivo*.

Implications of a Capacity-Limited System—The data obtained from different experimental procedures, both *in vitro* and *in vivo*, clearly indicate that the appearance of glucuronide in serosal fluid

Figure 3—Comparison of mean rates of appearance in mesenteric blood of free drug (●) and glucuronide (■) obtained with *in vivo* preparations perfused with 10^{-4} , 10^{-3} , and 10^{-2} M solutions of SAM. Each point represents the mean rate of a separate experiment. Bars represent the range of rates for each separate experiment.

Figure 4—Illustrates the ratios of the cumulative amounts of glucuronide to the cumulative amounts of free drug (G_{60}/F_{60}) appearing in the plasma after 1 hr. in the *in vivo* preparation perfused with 10^{-2} , 10^{-3} , and 10^{-4} M SAM (■) and the glucuronide-to-free drug ratio in the serosal fluid of the *in vitro* everted intestine with initial mucosal fluid concentrations of 10^{-2} , 10^{-3} , and 10^{-4} M SAM (○). Bars indicate the range of two experiments.

or plasma is independent of the concentration of free drug in the lumen compartment at lumen concentrations greater than 10^{-3} M.

There are several possible physiologic mechanisms that might be postulated to account for this zero-order kinetic behavior. The two most likely possibilities are either capacity-limited glucuronide formation or capacity-limited transport of glucuronide out of the cell. The formation of glucuronide could be rate limiting if the amount of enzyme, glucuronyl transferase, responsible for coupling UDP-glucuronic acid and the phenol is limited. It is also possible that the amount of the cofactor, UDP-glucuronic acid, is limited due to small amounts present in the cell because of a slow rate of synthesis by the DPN-dependent oxidation of UDP-glucose or rapid breakdown by UDP-glucuronic acid pyrophosphatase (4).

The alternate possibility is that the transport of the polar glucuronide out of the cell is capacity limited. This would imply that some sort of carrier transport mechanism or active transport is swamped at high cellular concentrations of the glucuronide.

Appearance of Glucuronide in Lumen—Because of the extra diffusion barriers of the submucosal and muscularis layers on the basal side of the *in vitro* everted intestine, it might be expected that greater amounts of glucuronide would diffuse into the mucosal fluid than the serosal fluid if passive diffusion was the limiting factor of glucuronide transport. Representative data presented in Table I, which compares the amounts of glucuronide in mucosal fluid and serosal fluid after 1-hr. incubation, show that this is indeed the case. The amount of glucuronide in mucosal fluid is from 2 to 5 times greater than that in the serosal fluid. The relative permeabilities of the mucosal barrier and serosal barrier obtained from the *in vitro* everted intestine are probably not representative of the relative permeabilities of the mucosal and plasma barriers in the normal *in vivo* absorption process where the drug does not traverse the submucosal and muscularis layers. The fact that significant amounts of glucuronide formed in the cell actually appear in the lumen may be indicative of the *in vivo* process, which would be of considerable importance. If this phenomenon occurs in the normal absorption process, a reduction in the net amount of drug absorbed would occur since the drug present as the polar glucuronide is not

Table I—Comparison of Amounts of SAM Glucuronide Appearing in the Mucosal and Serosal Fluid of Everted Intestines after 1-hr. Incubation at 37°

No.	Initial Mucosal Concentration	Amount (mcg.) in Serosal Fluid	Amount (mcg.) in Mucosal Fluid	Ratio (S/M)
1	10^{-4} M	36.3	151.0	0.24
2	10^{-4} M	29.8	50.3	0.59
3	10^{-4} M	28.5	168.0	0.17
4	10^{-3} M	49.1	156.0	0.31
5	10^{-3} M	25.1	133.0	0.19

absorbed unless hydrolyzed (3, 13, 14). These considerations prompted the following studies to determine the relative amounts of glucuronide which appear in the lumen fluid *in vivo*.

***In Vivo* Lumen-Plasma Glucuronide Ratios**—To obtain an indication of the amount of lumen glucuronide and the relative permeabilities of the apical and basal barriers *in vivo*, the cannulated preparation with complete venous collection was employed. There are certain difficulties in obtaining true *in vivo* glucuronide ratios even with this preparation. First, hydrolysis of the glucuronide in mucosal fluid and possibly in the plasma complicates quantitation of the true total amount of glucuronide delivered to each fluid. Second, the concentration of glucuronide in the blood depends on the distribution ratio between plasma and red blood cells which is not known. Salicylamide (free) is equally distributed between the erythrocytes and plasma. It is assumed, on the basis of its low permeability to other cells, that the glucuronide does not enter the erythrocyte.

The concentration of the glucuronide in the lumen fluid cannot be accurately determined by the difference assay when the ratio of free drug to glucuronide is greater than 100. For this reason, it proved impractical to use a perfused intestine which maintains high concentrations of free drug. Closed loops were therefore used, and the cumulative amount of glucuronide in the mucosal fluid was obtained by multiplying the concentration by the fixed fluid volume. The cumulative amount of glucuronide in the blood was estimated by multiplying the volume of plasma collected by the concentration of glucuronide in the plasma, assuming that no glucuronide was present in the erythrocytes. The amount of free drug in the blood was obtained by multiplying the plasma concentration by the total blood volume as the free drug was found to be equally distributed between the plasma and erythrocytes. The cumulative amounts of glucuronide appearing in lumen fluid and plasma are shown in Fig. 5. It is seen that the amount of glucuronide in the

Figure 5—Cumulative amounts of free drug in blood (○), glucuronide in blood (□), and glucuronide in lumen fluid (■) of a closed loop in *in vivo* preparation containing 10 ml. of 10^{-3} M salicylamide in Krebs-Ringer bicarbonate solution.

mucosal fluid is significant but does not exceed the amount in the plasma. The ratio of plasma glucuronide to lumen glucuronide is from 3 to 5.

The occurrence of glucuronide in the lumen in the *in vivo* cannulated loop gives reasonable evidence that significant amounts of drug metabolites may be expected to be found in lumen during the normal absorption process in the intact animal. This may be an important consideration in explaining the presence of some drug metabolites in the lumen which has previously been assumed to be a consequence of enterohepatic cycling and biliary secretion.

It must be realized, however, that some mucosal glucuronide may be a result of mucosal cell disruption either as a result of experimental manipulation or the normal sloughing of intestinal mucosa. The latter process occurs to a high degree in normal intestinal function. The normal turnover time of intestinal epithelium is quite rapid (15).

Relative Rates of Glucuronide Synthesis and Transport—The cumulative amounts appearing in the plasma of free drug and glucuronide shown in Fig. 5 show that glucuronide is still appearing in the plasma while free drug is approaching an asymptote. This suggests that accumulation of glucuronide in the cell is occurring, which would indicate that the rate of synthesis of the glucuronide is greater than subsequent transport out of the cell ($k_{FG} \gg k_{21}^G, k_{23}^G$). Accumulation of glucuronide in the cell compartment is also suggested for *in vitro* intestinal preparations by the cumulative amounts appearing in the serosal fluid of the *in vitro* everted sacs shown in Fig. 1 and the data given by Herz *et al.* (5).

Further evidence for accumulation of metabolite in the cell, *in vivo*, can be obtained by comparing the rates of appearance in plasma of free drug and glucuronide as shown in Fig. 6. Several facts from this curve support the conclusion that the rate of glucuronide transport out of the cell rather than the rate of metabolism in the cell is the rate-limiting step for the appearance of glucuronide in the plasma. First, the linear terminal portions of the curve for both free drug and glucuronide indicate that exit from the cell is first-order and therefore proportional to the concentration in the cell. At time 60 min., the amount of free drug in the cell has dropped to 1/100th of its original concentration. The concentration of glucuronide in the cell at this time, however, is still quite high even though most of the free drug in the cell is gone. Second, if metabolism was the only rate-limiting step, the precursor-successor relationship (16) would predict that the precursor free drug curve should intersect the peak of the successor glucuronide curve and both curves would then decline with parallel slopes. The delay in the glucuronide peak requires an additional rate-limiting step in the model. The increase in the slope of the glucuronide curve compared to the slope of the free drug then reflects the slower diffusion step out of the cell for the glucuronide.

Active or Passive Transport of Glucuronide—The data presented in previous sections do not require an active transport process for the glucuronide. All data seem adequately explicable by rapid first-order or zero-order cellular glucuronide formation followed by a slow diffusion process proportional to the amount of glucuronide in the cell. This does not rule out an active transport system entirely. If such a process was present but saturated at low levels, the result would be a simultaneous mixed zero-order-first-order process, which at high concentrations of glucuronide in the cell would give the appearance of an apparent first-order process. Further work is necessary to determine the mechanisms involved in the transport of glucuronide out of the cell.

DISCUSSION

If the results of these studies on intestinal glucuronide formation and absorption of salicylamide in rabbits apply to man, there would be several important pharmaceutical and clinical implications to be considered. There are reasons to believe that these results may, in fact, be applicable to man. It has been shown that *in vitro* human intestinal slices produce comparable amounts of salicylic acid glucuronide to that formed by rabbit intestine (3). It has also been shown *in vivo* that human intestine forms steroid glucuronides (17). Analysis of the kinetics of glucuronide formation following oral doses of salicylamide in man suggests that intestinal metabolism may be a factor in the low plasma levels of free drug obtained after oral administration, even though absorption appears to be complete. Furthermore, as in rabbits, the process appears to be capacity limited at higher doses (18).

Figure 6—Comparison of the rates of appearance in plasma of free drug (O) and glucuronide (□) in a closed loop *in vivo* preparation. These data are from the same experiment shown in Fig. 5.

The extrapolation of this work to man offers many interesting implications.

(1) Intestinal metabolism may offer an alternate explanation for many drugs which are said to be poorly absorbed. Drug assays involving extraction into organic solvents measure only free drug and may not detect the amount of drug absorbed as the polar metabolite. Several phenolic compounds are said to be poorly absorbed orally while their *o*-methylated or dehydroxy congeners are well absorbed, *e.g.*, morphine, phenylephrine, and isoproterenol. Decreased or erratic therapeutic effects following oral doses may be a consequence of intestinal metabolic inactivation rather than decreased absorption.

(2) Drug assays which measure only total drug in the plasma may also be inadequate to characterize the absorption process of free drug when intestinal metabolism is significant. The apparent rate constant of absorption as measured by total drug in the plasma will be decreased and the peak time delayed due to the slower diffusion of the metabolite (*i.e.*, Fig. 5).

(3) The fact that appreciable amounts of metabolite are released from the cell back into the intestine may also affect the rate and extent of absorption. A cycling process may occur in which the drug is absorbed and partially metabolized in the cell. A fraction of the metabolite is released back into the lumen where it is non-absorbable unless it is hydrolyzed to the free drug by bacterial and endogenous enzymes. The free drug would be reabsorbed and the cycle repeated until all drug is absorbed or eliminated in the feces. If the hydrolyzing enzymes are localized in a particular portion of the intestine, hydrolysis of the metabolite may be delayed and a discontinuous absorption process observed.

(4) The total amount of drug absorbed may be decreased if the metabolite released back into the intestine is not completely hydrolyzed. Furthermore, if the metabolic process is capacity limited, one might expect that the fraction of the total dose which is absorbed into the systemic circulation, and subsequently recovered in the urine, would be less with small doses than larger doses.

(5) Several factors in formulation might be considered in light of the effect of lumen concentration on the glucuronide-to-free drug (G/F) ratio absorbed when intestinal metabolism is capacity limited. The best dosage form would be that which would give maximum availability in the shortest time such as a solution or a form with a rapid dissolution rate. A sustained-release form that delivered a low concentration over a long period of time could possibly be worthless because of the high glucuronide-to-free drug ratio seen at lower concentrations. Competitive inhibition of metabolism may occur and one drug of a combination formulation may modify the absorption of another (*e.g.*, aspirin, *N*-acetyl *para*-aminophenol and salicylamide).

(6) There are also important clinical consequences which deserve attention. The use of urinary excretion of drug glucuronides as an index of hepatic function is a common clinical procedure (19). It has recently been suggested that salicylamide would be an excellent choice for this purpose (20, 21). It is possibly unwise, however, to use salicylamide, or any other drug which is largely glucuronylated in the intestine, as a measure of the ability of the liver to form glucuronides. A further consideration is that intestinal glucuronide formation may be well developed in the intestine of the fetus and newborn before appreciable hepatic glucuronide formation is established (22). The role of the intestine in bilirubin glucuronide formation may be important but has not been clearly defined (22, 23). In cases of neonatal hyperbilirubinemia, caution should be exercised in determining hepatic conjugating ability by oral tolerance curves of compounds also metabolized in the intestine. Further information is necessary on the relative importance of intestinal and hepatic metabolism for both bilirubin and any proposed test drug.

(7) It is interesting that one of the first reports of intestinal glucuronide formation was by Hartiala (24) who found increased glucuronide in the portal blood after giving cinchophen. He used this finding to support his theory that cinchophen caused ulcers by forming glucuronides in the intestine and thus depleting glucuronic acid from the mucopolysaccharide protective layer. Actually the opposite may be true, and glucuronide formation may operate as a protective mechanism. Salicylamide forms large amounts of glucuronide in the intestine but produces no mucosal damage or ulceration (25). Aspirin forms relatively small amounts of glucuronide (3) and is well known to cause mucosal damage (26, 27).

SUMMARY

At concentrations below 10^{-3} M, a considerable fraction of salicylamide is rapidly conjugated with glucuronic acid in the intestinal mucosal cell and subsequently appears in the mesenteric blood in the *in vivo* preparation with complete mesenteric blood collection or the serosal fluid in the *in vitro* everted intestinal preparation. Appearance of salicylamide glucuronide in the plasma is rate limited by transport across the basal barrier rather than metabolism. Exit of glucuronide from the cell is bidirectional, appearing in the lumen contents as well as in the plasma by what appears to be first-order diffusion process.

The relative order of magnitude of the rate constants in the general compartment model of intestinal absorption for the *in vivo* preparation is $k_{FG} > k_{23} > k_{23}^G > k_{21}^G$. In the *in vitro* preparation greater amounts of glucuronide appear in the mucosal fluid than the serosal fluid due to the extra diffusional barriers of the sub-mucosal and muscularis layers and $k_{23}^G < k_{21}^G$.

When lumen or mucosal fluid concentrations are greater than 10^{-3} M, the conjugating system is capacity limited leading to zero-order appearance of glucuronide. Some implications of these findings in dosage form design, pharmacokinetic studies, and clinical studies are discussed.

In Vitro Dissolution from Several Experimental Capsule Formulations

JOSEPH C. SAMYN and WAN YIN JUNG*

Abstract □ The *in vitro* dissolution behavior of several experimental capsule formulations is presented. The first series of powder blends clearly demonstrated that the capsule lubricant, magnesium stearate, and the filler, lactose or dibasic calcium phosphate dihydrate, had the greatest influence on the disintegrations of the capsules. Additional blends of these ingredients with an added drug were studied. In those instances where a slow dissolution was observed, the capsule contents characteristically remained as a wet powder pack long after the gelatin wall had dissolved. The drug dissolution was thus limited by the rate of erosion, diffusion, and/or solution of the drug and/or filler from this wet powder mass. Auxiliary measurements of liquid penetration rates of the packed powders and water content and viscosities of the wet powder packs were performed. These data suggested that the high viscosities of several of these powder packs were due to their restricted water content arising from the added hydrophobic lubricant.

Keyphrases □ Capsules—*in vitro* dissolution □ Formulation components, effect—capsule dissolution □ Powder beds—liquid penetration rate □ Disintegration, capsules—lubricant, filler effects

Different dosage forms containing various drugs have been compared by several investigators (1–3). Reviews of the physical factors affecting drug availability have been published by Wagner (4) and Nelson (5). Wood (6) has considered the *in vitro* evaluation of the tablet in some detail. The influence of granulation, granule size, compressional load, particle size, and the presence of surfactants, lubricants, and other tablet additions on *in vitro* drug availability have been studied (7–13).

Capsule formulations have received considerably less attention than tablets, presumably because of their apparent simplicity and consideration as loose powders. Wood (14) pointed out that although the hard gelatin capsule is widely used in preliminary studies of a new drug, very little literature on drug availability, even *in vitro*, exists for this type of dosage form. He quoted the National Formulary XII (15) as follows: "Disintegration time limits are not specified for capsules, since the shell dissolves rapidly in the gastrointestinal tract."

He further reported the release of aspirin from hard gelatin capsules to be irregular and showed a mean delay time of about 15 min. The importance of particle dispersion from tablets and capsules has been reported (16, 17). The failure of the capsule contents to disperse during *in vitro* testing has also been reported. Calesnick *et al.* (2) stated that during their study, "the contents of the hard gelatin capsule remained as a pasty mass for some time after the gelatin capsule had dissolved." Aguiar *et al.* (18) reported a similar observation in the *in vitro* testing of several generic chloramphenicol preparations.

The method of assessing drug availability has also been the subject of much concern. The disintegration requirements of various official compendia have recently been reviewed and compared (19). Levy (20)

and Steinberg (21) reviewed the medical literature and suggested that low agitation conditions should prevail in the *in vitro* dissolution studies. In addition, higher pH values than that of the USP simulated gastric fluid, pH 1.2, have also been reported in the stomach. Kuna (22) stated that the pH of the gastric juice of the human resting stomach is near neutral, pH 7.3.

The present study is concerned with the influence of commonly used pharmaceutical adjuvants on disintegration and drug dissolution from experimental capsule formulations. Capsule fillers employed were lactose and dibasic calcium phosphate dihydrate. The latter is water insoluble and acid soluble. Preliminary mixtures were made with different concentrations of talc, starch, and magnesium stearate. These preparations clearly indicated that the filler, lactose or dibasic calcium phosphate dihydrate, and the capsule lubricant, magnesium stearate, had the greatest influence on the disintegration and dissolution characteristics. A low concentration of a water-soluble dye was incorporated in these preparations to permit dissolution measurements.

More typically, capsules are formulated to contain a relatively high proportion of the drug moiety. Therefore, a second series of preparations were prepared in which a drug of moderate solubility and no dominant hydrophobic or hydrophilic characteristics was used as a test drug. It was incorporated at approximately two-thirds of the total capsule weight. The two capsule fillers, lactose and $\text{CaHPO}_4 \cdot 2\text{H}_2\text{O}$, and the lubricant, magnesium stearate, which were the dominant factors in the first study were also added.

As with the first series of powder blends, dissolution rates of capsules were measured. They were found to vary over a wide range. In those cases where the dissolution rates were slow, the capsule contents characteristically remained as a "slug" of wet powder; *i.e.*, after dissolution of the gelatin capsule walls, the powder, although wet, remained intact as one or a few large masses. Additional measurements of liquid penetration rates, water contents of the wet powder beds, and the viscosities of the wet powder beds were performed to aid in explaining this behavior. The data suggested that the wet powder beds remained essentially intact because of their high viscosities. It will be shown that these high viscosities resulted from a reduced amount of water in the wet bed due to the presence of hydrophobic magnesium stearate.

MATERIALS AND PROCEDURES

The capsule fillers used in this study were lactose USP No. 80-mesh powder and dibasic calcium phosphate dihydrate. The magnesium stearate, corn starch, and talc were each USP grade powders.

The dye tracer used at 0.1% level in the first portion of the study was F. D. & C. Red No. 1. The drug employed in the second

Table I—Powder Blends Studied Showing Disintegration Times for No. 2 Capsules Packed with These Powders

	Disintegration Time in H ₂ O, min. (6 Capsules)			
	—% Magnesium Stearate—			
	0	1	2	5
Lactose	5–6	8–12 ^a	10–19 ^a	21–35 ^a

^a Capsule contents break up into small pieces which dissolve. ^b Capsule contents remain in capsule shape—powder does not wet. ^c Capsule contents remain in one or a few pieces which slowly dissolve or erode.

portion of the study was approximately 100-mesh chemical (90% through a No. 100-mesh screen and 50% through a 200-mesh). Dissolution test media easily wetted the drug. A powder blend of the drug with lactose yielded a 90% dissolution value in less than 5 min. under the test conditions employed. All of the powder mixtures were prepared by blending and screening the various ingredients. The low levels of magnesium stearate were added by serial dilutions. The No. 2 capsules were hand-filled to the desired weights.

Drug dissolution was measured in the USP disintegration apparatus without the use of disks. This is in keeping with the reduced agitation conditions suggested above and is essentially a return to the USP XV method (23). Test fluids employed were simulated gastric fluid (low pH) and water (neutral pH). All tests were run at 37 ± 1°. One capsule was added to 800 ml. of the selected media at zero time. Five-milliliter samples were withdrawn as a function of time and rapidly filtered through a type HA 0.45-μ Millipore¹ membrane held in a Swinney adapter.

All dilutions were made with distilled water and the amount of drug in solution was determined by visible or UV measurement on a Beckman DU spectrophotometer. The data were converted to percent drug dissolved.

The liquid penetration rate measurements and water contents of the various powder blends were determined by the method of Studebaker and Snow (24). A straight Plexiglas tube (1.25 cm. i.d., 12 cm. length) open at both ends was filled with 4.0 g. of the individual powder blends packed to a bulk density of 0.94 g./cm.³ with the aid of the Fisher Sub-Sieve Sizer² compaction apparatus. This represented the same bulk density as in a No. 2 capsule. The packed tube, free of the packing plugs, was mounted in a vertical position. Eight milliliters of distilled water was added to the upper surface of the bed at zero time. The rate of movement of the water interface through the packed bed was measured with the aid of a Gaerdner cathotometer³ except for the dibasic calcium phosphate powder blends at high magnesium stearate levels. These readings were made with a scale held up to the powder bed because insufficient visual contrast existed between the wet and unwet portions of the powder when viewed through the cathotometer. The additions of the 0.1% of a water-soluble dye to the first series of powder blends provided a clearer measure of the liquid interface since the dissolved dye migrated with the interface. Dye was not added to the second series of drug-filler-lubricant mixtures. These measurements were carried out at room temperature (no temperature controls). The data have been plotted as the square of the distance of penetration *versus* the elapsed time in agreement with the Washburn equation (25).

The water contents of the wet powder beds were determined on the samples after the completion of the liquid penetration rate measurements. The wet powder beds were removed from the Plexiglas tubes and segmented. Portions were immediately weighed and reweighed after overnight drying to constant weight. The water content was calculated based on the difference.

The comparative viscosities of the powder blends with varying amounts of water were measured with a Universal penetrometer.⁴

Samples were prepared as follows: 40 g. of powder blend was mixed with 20 ml. of distilled water in a 250-ml. beaker. The wet mass was transferred to a glass conical container and packed to give a smooth surface. The penetrometer consisted of an inverted cone (30° and 90° double cone) and a rod with a combined weight of 150 g. The apex of the cone was adjusted so as to just touch the surface of the wet powder bed prior to release. The combined cone and rod assembly was allowed to free fall for a 5-sec. period into the wet mass. The depth of penetration of the cone was read in 0.1-mm. units on the attached scale. Several readings were made on each bed, remixing the wet mass and reforming the smooth surface each time. A portion of the wet powder bed was weighed, dried to constant weight, and reweighed to determine the water content; the remainder of the wet mass was mixed with additional water and the measurements repeated. By this procedure, a series of penetration measurements were obtained at various water contents.

RESULTS AND DISCUSSION

The first series of powder blends using lactose or CaHPO₄·2H₂O as the filler with varying quantities of talc, starch, and magnesium stearate are listed in Table I. The lactose blends were filled to 350 mg.; the CaHPO₄·2H₂O to 400 mg. In addition, disintegration times—range values for six capsules—are shown. The values varied from the rapid, 5–6 min., to the very slow or nondisintegrating capsule, greater than 60 min. Magnesium stearate has the greatest influence on the disintegration times. The filler, lactose or CaHPO₄·2H₂O, also appears to have a measurable effect on disintegration. The starch and the talc at the levels investigated in the blends with and without magnesium stearate did not markedly affect the disintegration times.

Dissolution data shown in Figs. 1 and 2 for several of these same blends confirm this interpretation. The physical nature of the wet capsule contents for several of these powder blends has been noted in Table I. The extended disintegration coincides with the observations that the capsule contents either remain intact or break up into a limited number of wet powder masses. In one instance the compacted powder mass did not wet. This occurred with the CaHPO₄·2H₂O plus 5% magnesium stearate blend.

Additional liquid penetration rate measurements were performed on these same powder blends. Figure 3 shows the decreased penetration rates measured for the lactose-magnesium stearate systems. Figure 4 shows the relatively slight decrease in liquid penetration caused by the addition of starch up to the 10% level. Similar data were obtained with the lactose-talc blends. In blends containing magnesium stearate, the influence of starch or talc on the liquid penetration rate was not detectable. This was true for both the lactose and the CaHPO₄·2H₂O systems. The data in Fig. 5 are for the CaHPO₄·2H₂O–2% magnesium stearate blends with starch.

This first series of experiments has shown that magnesium stearate has the greatest influence on the disintegration/dissolution behavior of the various capsule blends. The nature of the filler has also been shown to be of importance.

The second portion of this study consisted of capsules prepared with a drug at a relatively high concentration (approximately

two-thirds of total weight). The two fillers and the various levels of magnesium stearate found to be of importance in the first portion of the study were studied. The talc and starch were not included in these studies because of their apparently limited role. Dissolution behavior studies in both water and simulated gastric fluid were carried out. Disintegration times were noted in some of the figures.

The dissolution behavior of No. 2 capsules filled with the drug-lactose and drug-dibasic calcium phosphate dihydrate blends in water and in simulated gastric fluids are shown in Fig. 6. The dissolutions were rapid in all cases and essentially the same for the two different dissolution media and the two capsule fillers. The influence of 2% magnesium stearate on these two blends is shown in Fig. 7.

The slowest dissolution was observed for the drug-dibasic calcium phosphate-2% magnesium stearate system tested in water. This was due to the hydrophobic nature of the magnesium stearate and the insolubility of the calcium phosphate in the water. In simulated gastric fluid, this combination dissolved as fast as the comparable lactose system. In acid the dibasic calcium phosphate is soluble and the magnesium stearate is decomposed (26). The drug-lactose-2%

Figure 3—Liquid penetration of packed powder beds. Key: \times , lactose; \circ , lactose + 1% magnesium stearate; \square , lactose + 2% magnesium stearate; Δ , lactose + 5% magnesium stearate.

magnesium stearate system also showed a difference in dissolution rate when tested in gastric fluid and water. The release in water, although slowed, was faster than the comparable dibasic calcium phosphate system. This probably was due to the water solubility of the lactose which permitted a faster erosion of the wet powder mass.

The magnesium stearate was further increased to 5% in both the lactose and dibasic calcium phosphate blends. In water these systems failed to wet after dissolution of the capsule walls. The powder remained as an essentially dry powder pack. Therefore, under these conditions, 5% magnesium stearate prevented dissolution when tested in water. In simulated gastric fluid, the powder beds did wet but remained as a wet mass during the dissolution process with erosion and dissolution slowly occurring. Figures 8 and 9 show the pronounced effect of this higher level of magnesium stearate with both fillers, even in simulated gastric fluid.

Figure 10 gives the dissolution data obtained in simulated gastric fluid by increasing the packing density in the No. 2 capsule with 0 and 5% magnesium stearate formulations (356 mg. versus 400 mg.). The data indicate that the packing density did not influence the dissolution rate in the absence of magnesium stearate. For the 5%

magnesium stearate samples, the 50% dissolution value did increase for both systems with increasing packing density; the dibasic calcium phosphate system showed the greatest increase of the 50% dissolution time, changing from about 7 min. to 23 min.

The behavior of the capsule blends shown in Fig. 6 indicates that the wettability and solubility of the drug used were adequate for rapid dissolution under these test conditions. In the majority of the systems in which the dissolution rate was slowed, the capsule contents—even after solution of the gelatin capsule walls—remained as an intact wet powder mass. Occasionally, this wet powder mass would break into more than one fragment. However, the dissolution

was still essentially occurring from a very limited surface area. Because of these observations on the wet powder mass, further examination of the liquid penetration rates of the powder blends and water contents and viscosities of the wet powder beds were undertaken.

Due to the very limited size of the packed powder beds in an actual capsule, the measurements of liquid penetration, water content, and viscosities could more readily be carried out on larger samples of these powder blends. Using the method of Studebaker and Snow (24), the powder blends were therefore packed into open-ended cylindrical tubes for measurements. This method provided

Figure 7—Dissolution of drug from capsules: left, drug-lactose-2% magnesium stearate; right, drug- $\text{CaHPO}_4 \cdot 2\text{H}_2\text{O}$ -2% magnesium stearate. Key: X, simulated gastric fluid; O, water.

large samples, controlled packing density, and permitted measurements of penetration rates and water content of the wet powder beds.

The liquid penetration rates of the various drug-lactose and drug-dibasic calcium phosphate with magnesium stearate blends are shown in Figs. 11 and 12, respectively. The data were plotted as the square of the depth of liquid penetration *versus* time (25). From these figures, decreased liquid penetration rates are seen with increasing magnesium stearate levels. The dissolution data on some of these systems were shown in Figs. 6-9. It is clear that extended dissolution rates are obtained with powder blends that show reduced liquid penetration rates.

During these liquid penetration measurements, it was observed that the wet powder beds varied quite widely in viscosity when

Figure 9—Dissolution of drug from capsules in simulated gastric fluid (drug- $\text{CaHPO}_4 \cdot 2\text{H}_2\text{O}$ -magnesium stearate). Key: X, 0% magnesium stearate; □, ⊕, 2% magnesium stearate; ●, 5% magnesium stearate.

extruded from the Plexiglas tubes. Some of the wet compacted powders were thick pastes while others were quite fluid, almost to the point of flowing. Since many of the capsule blends remained intact long after the gelatin shells had dissolved, it would appear that these observations might also contribute to the prolonged dissolution rate measured.

Therefore, after completion of the liquid penetration experiments, the wet powder plugs were extruded from the tubes and segmented into two portions. The quantities of water present were

determined and are shown in Fig. 13. It can be seen that the water content did decrease with the added magnesium stearate level. Qualitatively, the physical appearance of the wet powder beds varied from a semifluid mass (no magnesium stearate) to a stiff paste (5% magnesium stearate) for both the lactose and dibasic calcium phosphate systems.

Comparative measurement of these viscosity changes with variable water content in the powder blends was carried out with a penetrometer. Three systems were checked: (a) drug-lactose-2% magnesium stearate; (b) drug- $\text{CaHPO}_4 \cdot 2\text{H}_2\text{O}$; and (c) drug- $\text{CaHPO}_4 \cdot 2\text{H}_2\text{O}$ -2% magnesium stearate. Figure 14 shows the depth of cone penetration *versus* the amount of water in the powder. The samples low in water were more rigid and the depth of penetration was less than in the more fluid samples. The two $\text{CaHPO}_4 \cdot 2\text{H}_2\text{O}$ samples tested (with and without 2% magnesium stearate) described the same curve. This would suggest that the magnesium stearate affected the viscosity of the wet powder bed solely by limiting the water content in the bed.

At any given water content, the lactose-based capsule blend would appear to be more fluid than the $\text{CaHPO}_4 \cdot 2\text{H}_2\text{O}$ blend.

Figure 12—Liquid penetration of packed powder beds (drug- $\text{CaHPO}_4 \cdot 2\text{H}_2\text{O}$ -magnesium stearate blends). Key: X, 0% magnesium stearate; O, 1% magnesium stearate; ●, 2% magnesium stearate; ■, 5% magnesium stearate.

Figure 13—Water contents of the wet powder beds: top, drug- $\text{CaHPO}_4 \cdot 2\text{H}_2\text{O}$ -magnesium stearate blends; bottom, drug-lactose-magnesium stearate blends. Key: X, first segment of bed; O, second segment of bed.

This may be due to partial solution of the lactose or other factors such as particle size and shape.

Figure 14—Penetrometer measurements of powder beds containing varying quantities of water. Key: O, drug-lactose-2% magnesium stearate; □, drug- $\text{CaHPO}_4 \cdot 2\text{H}_2\text{O}$ -0% magnesium stearate; ■, drug- $\text{CaHPO}_4 \cdot 2\text{H}_2\text{O}$ -2% magnesium stearate.

Although these data clearly showed that the comparative viscosity decreased with added water as would be expected, the actual differences in viscosity between the various systems were felt to be greater than the numerical differences in the penetrometer readings. This is because the probe used for the measurements was an inverted cone and at greater penetrations, a greater cross section of the cone would contact the sample. Therefore, for greater penetration, a larger portion of the sample would support the load and prevent further penetration. A better estimate of the difference in relative viscosity of these samples would take into account this change in effective contact area of the probe with the sample. Considering this aspect, it would then be estimated that the sample with 27.5% water would be over 200 times as viscous as the sample with 48.5% water. From Fig. 14, the 5% magnesium stearate sample would therefore approximately correspond to the 27% water sample while the drug- $\text{CaHPO}_4 \cdot 2\text{H}_2\text{O}$ behaved like the 48% water sample.

The combined interpretation of Figs. 13 and 14 would suggest that magnesium stearate did reduce the water content in the powder bed and that this, in turn, yielded a wet powder blend of high viscosity. Dissolution of the drug would then be slowed due to the limited area of contact between the wet powder mass and the fluid. Dissolution would proceed by mechanical erosion, diffusion, and/or solution of drug and filler. *In vivo* it would seem these powder masses might remain intact for a considerable time if the agitation conditions are indeed low. In addition, an *in vivo* pH near neutral would favor stability of the wet powder mass.

Hydrolysis of Lincomycin-2-phosphate and Clindamycin-2-phosphate

T. O. OESTERLING and E. L. ROWE

Abstract □ The aqueous stabilities of lincomycin-2-phosphate and its 7-deoxy-7(S)-chloro analog, clindamycin-2-phosphate, were studied at a variety of temperatures and pH values. The predominant degradative routes of lincomycin-2-phosphate in the pH range 1-10 are thioglycoside and phosphate ester hydrolysis, and pH-rate studies show that it is most stable at pH 6-10. Clindamycin-2-phosphate degrades by three major routes from pH 1 to 10 with phosphate ester and thioglycoside hydrolysis predominating at pH less than 6 and scission of 7(S)-Cl to form the 7(R)-OH analog predominating at pH greater than 6. The rate of 7(S)-Cl to 7(R)-OH conversion was obtained using gas chromatography to measure the disappearance of clindamycin in reaction mixtures prepared under identical conditions as clindamycin-2-phosphate reaction mixtures. Rates of phosphate ester hydrolysis of the two compounds were

measured by spectrophotometric determination of the amount of inorganic phosphate formed in reaction mixtures as a function of time. Apparent first-order rate constants of phosphate ester hydrolysis as well as activation energies (32.1 kcal./mole for lincomycin-2-phosphate and 32.9 kcal./mole for clindamycin-2-phosphate) agree favorably. The rate of lincomycin-2-phosphate hydrolysis in a formulated pediatric syrup at room temperature agrees favorably with extrapolated rates from high temperature hydrolysis in simple solutions.

Keyphrases □ Lincomycin-2- PO_4 —hydrolysis kinetics □ Clindamycin-2- PO_4 —hydrolysis kinetics □ Stability—lincomycin-, clindamycin-2- PO_4 aqueous solutions □ pH effect—lincomycin-, clindamycin-2- PO_4 hydrolysis rates □ Colorimetric analysis—spectrophotometer

The antibiotics lincomycin and clindamycin are highly effective in the treatment of infections caused by Gram-positive organisms (1, 2) and clindamycin possesses marked antiparasitic activity as well (3). At times it is desirable to make derivatives from compounds such as lincomycin and clindamycin in order to circumvent

disadvantages such as bitter taste or poor absorption inherent in the parent molecule. The derivatives must possess the same activity as the parent compound or be rapidly reverted to parent *in vivo*. Lincomycin has a bitter taste which is difficult to mask in pediatric liquid formulations. The C_2 phosphate ester of lincomycin

Although these data clearly showed that the comparative viscosity decreased with added water as would be expected, the actual differences in viscosity between the various systems were felt to be greater than the numerical differences in the penetrometer readings. This is because the probe used for the measurements was an inverted cone and at greater penetrations, a greater cross section of the cone would contact the sample. Therefore, for greater penetration, a larger portion of the sample would support the load and prevent further penetration. A better estimate of the difference in relative viscosity of these samples would take into account this change in effective contact area of the probe with the sample. Considering this aspect, it would then be estimated that the sample with 27.5% water would be over 200 times as viscous as the sample with 48.5% water. From Fig. 14, the 5% magnesium stearate sample would therefore approximately correspond to the 27% water sample while the drug- $\text{CaHPO}_4 \cdot 2\text{H}_2\text{O}$ behaved like the 48% water sample.

The combined interpretation of Figs. 13 and 14 would suggest that magnesium stearate did reduce the water content in the powder bed and that this, in turn, yielded a wet powder blend of high viscosity. Dissolution of the drug would then be slowed due to the limited area of contact between the wet powder mass and the fluid. Dissolution would proceed by mechanical erosion, diffusion, and/or solution of drug and filler. *In vivo* it would seem these powder masses might remain intact for a considerable time if the agitation conditions are indeed low. In addition, an *in vivo* pH near neutral would favor stability of the wet powder mass.

Hydrolysis of Lincomycin-2-phosphate and Clindamycin-2-phosphate

T. O. OESTERLING and E. L. ROWE

Abstract □ The aqueous stabilities of lincomycin-2-phosphate and its 7-deoxy-7(S)-chloro analog, clindamycin-2-phosphate, were studied at a variety of temperatures and pH values. The predominant degradative routes of lincomycin-2-phosphate in the pH range 1-10 are thioglycoside and phosphate ester hydrolysis, and pH-rate studies show that it is most stable at pH 6-10. Clindamycin-2-phosphate degrades by three major routes from pH 1 to 10 with phosphate ester and thioglycoside hydrolysis predominating at pH less than 6 and scission of 7(S)-Cl to form the 7(R)-OH analog predominating at pH greater than 6. The rate of 7(S)-Cl to 7(R)-OH conversion was obtained using gas chromatography to measure the disappearance of clindamycin in reaction mixtures prepared under identical conditions as clindamycin-2-phosphate reaction mixtures. Rates of phosphate ester hydrolysis of the two compounds were

measured by spectrophotometric determination of the amount of inorganic phosphate formed in reaction mixtures as a function of time. Apparent first-order rate constants of phosphate ester hydrolysis as well as activation energies (32.1 kcal./mole for lincomycin-2-phosphate and 32.9 kcal./mole for clindamycin-2-phosphate) agree favorably. The rate of lincomycin-2-phosphate hydrolysis in a formulated pediatric syrup at room temperature agrees favorably with extrapolated rates from high temperature hydrolysis in simple solutions.

Keyphrases □ Lincomycin-2- PO_4 —hydrolysis kinetics □ Clindamycin-2- PO_4 —hydrolysis kinetics □ Stability—lincomycin-, clindamycin-2- PO_4 aqueous solutions □ pH effect—lincomycin-, clindamycin-2- PO_4 hydrolysis rates □ Colorimetric analysis—spectrophotometer

The antibiotics lincomycin and clindamycin are highly effective in the treatment of infections caused by Gram-positive organisms (1, 2) and clindamycin possesses marked antiparasitic activity as well (3). At times it is desirable to make derivatives from compounds such as lincomycin and clindamycin in order to circumvent

disadvantages such as bitter taste or poor absorption inherent in the parent molecule. The derivatives must possess the same activity as the parent compound or be rapidly reverted to parent *in vivo*. Lincomycin has a bitter taste which is difficult to mask in pediatric liquid formulations. The C_2 phosphate ester of lincomycin

was synthesized by Morozowich *et al.* (4) as a potential nonbitter derivative with the same activity as the parent compound. Clindamycin hydrochloride is poorly soluble at pH values above 6 and its C₂ phosphate ester was synthesized (5) to obtain a derivative of high water solubility near neutral pH.

The purpose of this study was to investigate the stability of lincomycin-2-phosphate (I) and clindamycin-2-phosphate (II) in aqueous solutions in order to supply basic information necessary for the successful formulation of these drugs in liquid dosage forms. The effects of pH and temperature on the rate of phosphate ester hydrolysis of lincomycin-2-phosphate and clindamycin-2-phosphate were determined. These data allowed the establishment of maximum stability conditions and the prediction of room temperature stability.

EXPERIMENTAL

Materials—Lincomycin-2-phosphate, clindamycin-2-phosphate, and clindamycin hydrochloride containing less than 2% impurities were supplied by the research laboratories of the Upjohn Company. All other chemicals were reagent grade.

Kinetic Studies—Lincomycin-2-phosphate—The rate of hydrolysis of lincomycin-2-phosphate was studied in the pH range 6–9 at 59.4, 69.6, 79.6, and 93.5° and in the extended pH range 0.1–10 at 90.0°. All reaction mixtures except those of less than pH 2 at 90° were prepared at the temperature of the run by adjusting the pH of 90 ml. of solution containing lincomycin-2-phosphate and sodium chloride to the desired pH by the addition of 1 M HCl or NaOH. After the volume was adjusted to 100 ml., the final concentration of lincomycin-2-phosphate was 0.02 M and that of sodium chloride was 0.1 M. The sodium chloride was added to minimize ionic strength effects. Reaction mixtures adjusted to pH less than 2 at 90° were prepared to contain 0.02 M lincomycin-2-phosphate and 0.1, 0.5, and 1 M HCl, respectively. These reaction mixtures did not contain sodium chloride. After preparation, 5-ml. portions of reaction mixtures were filled into ampuls, sealed, and immersed into the appropriate constant-temperature baths. Ampuls were withdrawn at appropriate

times and frozen until assayed for inorganic phosphate by the procedure described below.

Clindamycin-2-phosphate—The effect of pH on the rate of phosphate ester hydrolysis of clindamycin-2-phosphate was studied in the pH range 6–9 at 90°. It was necessary to buffer clindamycin-2-phosphate reaction mixtures because, unlike lincomycin-2-phosphate, the pH drifted sharply downward as the reaction proceeded. This decrease in pH may be caused by degradation at C₇ of clindamycin-2-phosphate (6). Reaction mixtures were prepared to contain 0.02 M clindamycin-2-phosphate, 0.2 M ethylenediamine, or tris (hydroxymethyl) aminomethane¹ (tromethamine) buffers adjusted to the desired pH at the temperature of the run, and sufficient potassium chloride to adjust the ionic strength to 0.3. Aliquots of the reaction mixtures were filled into ampuls which were sealed and immersed in constant temperature baths. Ampuls were withdrawn at appropriate times and frozen until assayed for inorganic phosphate by the procedure described below.

All reaction mixtures in which phosphate ester hydrolysis was measured were prepared with freshly boiled deionized water. The pH's of the samples from all kinetic runs were measured, and a run was discarded if the pH of the final sample varied by more than 0.2 pH units from the initial sample.

Rates of phosphate ester hydrolysis were determined by least-squares analysis of $\log (P_{i,\infty} - P_{i,t})$ -time data, where $P_{i,\infty}$ is the molar concentration of inorganic phosphate present at completion of hydrolysis which is equivalent to the initial molar concentration of lincomycin-2-phosphate or clindamycin-2-phosphate, and $P_{i,t}$ is the molar concentration of inorganic phosphate present at any time.

A previous study (6) has indicated that in addition to phosphate ester hydrolysis at Position 2, clindamycin-2-phosphate will undergo degradation at C₇ to form the 7-(R)-OH analog in the pH range 6–9. To measure the rate of degradation at Position 7, reaction mixtures containing clindamycin hydrochloride were prepared identical to those containing clindamycin-2-phosphate, and the amount of intact clindamycin remaining with time was determined by GLC (6).

Inorganic Phosphate Assay—The method is essentially that developed for assay of free inorganic phosphate in methylprednisolone phosphate (7). The reagents used were ammonium molybdate, 2.0% solution in double-distilled water, acetate buffer prepared by dissolving 310 ml. glacial acetic acid, 49 g. anhydrous potassium acetate, and 48 mg. anhydrous cupric sulfate in double-distilled water to a total volume of 1000 ml., 2.0% ascorbic acid solution in double-distilled water, and 20% stannous chloride stock solution in concentrated hydrochloric acid. One milliliter of the stock stannous chloride solution was diluted to 100 ml. with double-distilled water just prior to use.

Stability samples were assayed for inorganic phosphate by adding 1.0-ml. aliquots of the reaction mixtures to 50 ml. of acetate buffer in 100-ml. volumetric flasks. After thorough mixing, 5.0 ml. ammonium molybdate solution, 5.0 ml. ascorbic acid solution, and 5.0 ml. of the diluted stannous chloride solution were added with mixing after each addition. The solution was adjusted to 100 ml., mixed again, and allowed to stand 30 min. The absorbance was determined at 740 m μ against a water blank using 1.0-cm. cells within a period of 3 hr. After confirming that Beer's law applied in the concentration range of interest, the concentration of inorganic phosphate was determined by comparing the absorbance of the unknown solutions with that of a standard solution.

RESULTS AND DISCUSSION

The phosphate ester moieties of lincomycin-2-phosphate and clindamycin-2-phosphate hydrolyzed by an apparent first-order process under all experimental conditions. Some typical first-order curves of lincomycin-2-phosphate hydrolysis are shown in Fig. 1.

The effects of pH and temperature on the rate of phosphate ester hydrolysis of lincomycin-2-phosphate are shown in Table I. In general the hydrolysis rate constants from reaction mixtures of similar pH were in good agreement. The discrepancy in the data from the pH 1.1 reaction mixtures at 90° may be due to the high dependency of rate constant on pH in this region. The rates of phosphate ester hydrolysis of clindamycin-2-phosphate as a function of pH and temperature are shown in Table II. Although ionic strengths are different and the clindamycin-2-phosphate reaction mixtures contain buffers, there is good agreement between its rate constants and those of lincomycin-2-phosphate at a given temperature and pH.

¹ TRIS

Figure 1—Hydrolysis of lincomycin-2-phosphate at 93.5°. Key: O, pH 8.4; ▲, pH 8.0; □, pH 7.5; △, pH 7.0; ●, pH 6.2.

The pH-rate relationship for lincomycin-2-phosphate is shown in Fig. 2 for 59.4, 69.6, and 79.6° and in Fig. 3 for 90°. Above pH 5 the dependency of rate on pH is quite similar to that of monoalkyl phosphates such as methyl phosphate (9) and carbohydrate monophosphates such as α -D-glucose-1-phosphate (10). For monoalkyl phosphates and carbohydrate monophosphates the decrease in rate with increasing pH in this pH range is attributed to the decreasing concentration of the monoanionic species, the dianionic species being much less reactive. Since the pK_a values of the phosphate moiety of lincomycin-2-phosphate are roughly 2 and 6 (4), the monoanionic species is present at maximum concentration at about pH 4, and the decrease in rate above pH 5 in Fig. 3 is probably due to decreasing concentration of monoanion.

Below pH 5 the rate of lincomycin-2-phosphate hydrolysis in Fig. 3 appears to be constant to about pH 1. In this pH range the two predominant species are the monoanion and the undissociated form of the phosphate moiety. The monoanion actually exists as a zwitterion and the undissociated form carries a net charge of +1 due to protonation of the amino group. (The pK_a of lincomycin hydrochloride is 7.6.) The monoanion is present at maximum concentration at about pH 4 and decreases with decreasing pH, whereas the undissociated form increases in concentration as pH decreases in this range. The rate of hydrolysis in this pH range is the sum of the rates of hydrolysis of the monoanionic and undissociated form and this sum is a constant between pH 1 and 5. The pH profile of methyl phosphate shows a decrease in rate from pH 4 to pH 1 and this decrease is explained as corresponding to a decrease in the monoanion concentration, the undissociated form being relatively unreactive (9). On the other hand, the rate of glucose-1-phosphate hydrolysis increases rapidly between pH 5 and 1 and this increase is explained as due to the increase in concentration of undissociated glucose-1-phosphate (10) which is much more reactive than the corresponding form of methyl phosphate. Since the reactivities of the monoanionic species of lincomycin-2-phosphate (Table I), methyl phosphate (9), and glucose-1-phosphate (10) as well as hydroxyalkyl and alkyl monophosphates of similar structure (11) are of the same order, the plateau region of the lincomycin-2-phosphate pH profile between pH 1 and 5 indicates that the undissociated form of lincomycin-2-phosphate is more reactive than that of

methyl phosphate but less reactive than the undissociated form of glucose-1-phosphate.

There are at least two possible explanations for the sharp increase in rate of lincomycin-2-phosphate hydrolysis below pH 1 shown in Fig. 3. Both are based on the formation of new species which are more reactive than the undissociated form of lincomycin-2-phosphate. The first of these species may be the conjugated acid form of lincomycin-2-phosphate where conjugate acid is defined as the structure(s) resulting from protonation of the uncharged phosphate moiety. The other reactive species which may be formed at pH less than 1 is lincomycin-1-phosphate. Acid-catalyzed phosphoryl group

migration in monoesters containing suitably placed hydroxyl groups, such as lincomycin-2-phosphate, has been extensively reported (12, 13), and the new reactive species, lincomycin-1-phosphate, may be formed by phosphoryl group migration from C_2 to C_1 . These migrations occur through formation of a five-membered cyclic intermediate (13). Glucose-1-phosphate is much more reactive than glucose-2-phosphate in this pH region (14) and by analogy lincomycin-1-phosphate would be expected to be more reactive than lincomycin-2-phosphate, thus causing the increase in observed hydrolysis rate below pH 1. A prerequisite to migration of the phosphoryl group from C_2 to C_1 in lincomycin-2-phosphate is cleavage of the thioglycoside bond to form the C_1 hydroxy compound. Thioglycoside hydrolysis has been reported as the major route of degradation of clindamycin in the pH range 0.4 to 4 (6). Extrapolation of these reported rate constants of thioglycoside hydrolysis to 90° reveals that the rate of thioglycoside hydrolysis is about five times greater than phosphate ester hydrolysis at pH 1 and falls to about two times greater at pH 4. Thus migration of the phosphoryl group from C_2 to C_1 is possible, and the increase in rate

of lincomycin-2-phosphate hydrolysis below pH 1 may be due to the formation of the more reactive species, lincomycin-1-phosphate.

Migration of the C_2 phosphate group to the other adjacent hydroxyl at C_3 probably also occurs at $pH < 1$ (12), forming another species of the same order of reactivity as the 2-phosphate. However, it is unlikely that any phosphate migration occurs at higher pH since none was detected when lincomycin-2-phosphate was heated in 80% acetic acid (4), and alkaline migration does not occur in monoesters of this type (13).

The pH-rate relationship for phosphate ester hydrolysis of clindamycin-2-phosphate in ethylenediamine and tromethamine buffer in pH range 6–8 is shown in Fig. 4. Similar slopes of the two curves indicate that the rate of hydrolysis changes with pH to approximately the same extent in each buffer; however, nonoverlapping curves indicate that there is a buffer effect since at constant pH the rate is faster in ethylenediamine buffers. In both buffers, however, the pH-rate relationship is similar to that observed with lincomycin-2-phosphate between pH 6–8, i.e., increasing hydrolysis rate as pH decreases.

The apparent first-order rate constants of degradation of clindamycin under conditions identical to clindamycin-2-phosphate are shown in Table III. According to a previous report (6), there are several products of clindamycin degradation in this pH range but the major degradative route is conversion to lincomycin. The influence of the phosphate ester moiety on the rate of lincomycin conversion is unknown when clindamycin alone is reacted; however, the relatively large distance between Positions 2 and 7 and the absence of conjugation minimize any substituent effects. The data in Table III indicate that the sum of the rate constants of lincomycin conversion and the other minor reactions is about 100 times greater than the rate of phosphate ester hydrolysis between pH 6 and 7.85. Thus, the phosphate ester moiety of clindamycin-2-phosphate is not the least stable portion of the molecule in this pH range. Extrapolation of rates of

phosphate ester hydrolysis and rates of degradation of other areas of the clindamycin-2-phosphate molecule to 25° shows that a liquid formulation adjusted to pH 7.4 would not meet stability criteria of less than 10% degradation after 2 years. However, these criteria are satisfied in the pH range 3.5 to about 6.5. Preliminary studies of lincomycin degradation alone indicate that the phosphate ester moiety is the least stable area of lincomycin-2-phosphate in the pH range 1–10. Calculations, using Tables I and IV data, show that lincomycin-2-phosphate meets the above stability criteria in the pH range 3.5–10.

Arrhenius plots of phosphate ester hydrolysis of lincomycin-2-phosphate at a variety of pH values and of clindamycin-2-phosphate at pH 7.5 in tromethamine buffer are shown in Fig. 5. Since clindamycin-2-phosphate was a parenteral product candidate, its activation energy was determined only at optimum physiological pH. Activa-

Temperature, °C.	$k \times 10^{10} \text{ sec.}^{-1}$ Predicted ^a	Found
25	0.239	0.441
40	2.68	5.01
47	9.77	7.54
56	35.9	35.4

^a Calculated from $E_A = 32.1$ kcal./mole and $k = 2.50 \times 10^{-8} \text{ sec.}^{-1}$ at 70°.

tion energies calculated from these curves are shown in Table IV. Good agreement between the activation energies of the two compounds was observed as expected since conversion of clindamycin to lincomycin is about 100 times faster than phosphate ester hydrolysis at this pH. Assuming that the monoanion is the predominant reactive species in the pH range reported in Table IV, the activation energies are in good agreement with values reported for phosphate esters of similar structure (11).

Accelerated stability studies of the type described in this study are useful in the prediction of product stability and determination of optimum formulation parameters. These studies in simple buffered solution provide baseline rate data for comparison with rates of degradation in actual formulations. Any influence of additives in a liquid formulation such as preservative, flavor, color, or solubilizing agent on the rate of drug degradation can be detected and corrected if necessary. Some early data on the hydrolysis of lincomycin-2-phosphate in a pediatric formulation containing sucrose, sorbitol, glycerin, preservatives, alcohol, saccharin, flavor, and color at a pH of 7.5 are shown in Table V along with rate constants predicted from 70° data in simple solution. Although hydrolysis had not occurred to greater than 3%, agreement between simple solution and formulation hydrolysis is reasonable and indicates that none of the formulation ingredients significantly influences lincomycin-2-phosphate hydrolysis.

Influence of Ionic and Nonionic Materials on Thermally-induced Ribonucleic Acid Degradation and Leakage in *Staphylococcus aureus*

M. C. ALLWOOD* and A. D. RUSSELL

Abstract □ Suspensions of *Staphylococcus aureus* were held at 50 or 60° in water, 1 M sucrose, or 0.5 M sodium chloride, and analyses were made of cellular ribonucleic acid (RNA), the content of RNA-like material in the acid-soluble (metabolic) pool and the amount of RNA-like material leaked. In sucrose and sodium chloride, as compared to water, RNA degradation was reduced at 50° and increased at 60°. In comparison to water, Mg^{++} ions reduced RNA-like material leaked at 37 and 50°, but not at 60°. The results are discussed in relation to the effect of thermal damage and loss of viability of the organism.

Keyphrases □ Ribonucleic acid (RNA) degradation, leakage—thermally induced □ Degradation, *Staphylococcus aureus* RNA—temperature effect □ Ionic, nonionic materials effect—RNA degradation □ UV spectrophotometry—analysis

Previous studies (1-4) have been concerned with the reasons for thermally-induced death in *Staphylococcus aureus* strain NCTC 3761. Several changes took place in heated suspensions of this organism: protein co-

agulation, a decrease in cell volume, a breakdown of ribonucleic acid (RNA), an increase in the content of RNA-like material in the acid-soluble (metabolic) pool and leakage of RNA-like material, damage to the cytoplasmic membrane, and leakage of amino acids. Deoxyribonucleic acid (DNA) did not leak from the cells and did not appear to be degraded. RNA degradation may be responsible for thermally-induced death in *Aerobacter aerogenes* (5), *Staphylococcus aureus* (3, 6, 7), and *Streptococcus faecalis* (8).

Some effects of sucrose on thermal death of *Staph. aureus* have also been described (3). These earlier findings are here considered in greater detail, and the effects of sodium chloride and Mg^{++} on RNA degradation or leakage are also presented.

MATERIALS AND METHODS

Materials—Magnesium sulfate, $MgSO_4 \cdot 7H_2O$, sucrose, and sodium chloride were of analytical reagent quality. Solutions were sterilized by heating in an autoclave.

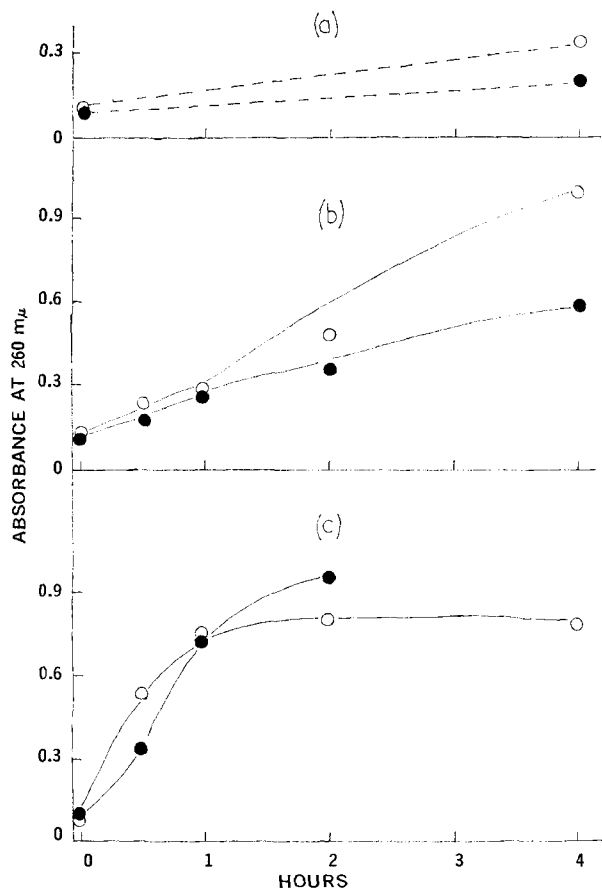

Figure 1—Leakage of 260 mμ-absorbing material from suspensions of *Staph. aureus* stored in water ○—○ and 2×10^{-3} M magnesium sulfate solution ●—● at a 37°, b 50°, and c 60°.

Figure 2—Effect of magnesium sulfate concentration on the amount of 260 mμ-absorbing material from suspensions of *Staph. aureus* held for 4 hr. at a 50°, b 60°.

Organism—*Staph. aureus* was grown for 18 hr. in nutrient broth (Oxoid Laboratories, Ltd., London, England), the culture centrifuged, the pellet washed twice with sterile water, and finally adjusted with sterile water to contain approximately 10^{10} viable cells/ml.

Heating Procedure—One part of a washed suspension was added to nine parts of the desired suspending medium, already at the required temperature ($\pm 0.1^\circ$), in a thermostatically-controlled water bath.

Viable Counts—Samples were removed at intervals, and viable counts made as described previously (3) using the pour-plate method, a plating medium consisting of nutrient agar containing 1% w/v yeast extract (Difco Laboratories, Ltd., Detroit, Mich.) and an incubation period of 48 hr. at 37° .

Analytical Procedure—The breakdown and release of RNA with *Staph. aureus* cells held at 50 or 60° in water, sucrose or sodium chloride were examined. An increase in the content of RNA-like material in the cold perchloric acid-soluble metabolic pool is indicative of breakdown of RNA. Details of the methods of obtaining the cold acid-soluble fraction, and of the RNA fraction, consisting of cellular RNA, i.e., the RNA in the cell except for the small molecular weight RNA material in the metabolic pool, have been considered previously (3). Cellular RNA, RNA-like material in the pool, the RNA-like material leaked were determined by the orcinol technique (9) and by absorbance at $260\text{ m}\mu$, employing yeast RNA (British Drug Houses, Ltd., London, England) as standard. It has previously been found (1, 10) that closely related results were obtained in assaying RNA (or RNA-like material) by these two methods. Moreover, when sucrose was used as suspending medium, the orcinol technique could not be employed. When *Staph. aureus* cells were suspended in magnesium sulfate solutions, leakage of $260\text{ m}\mu$ -absorbing material was measured.

RESULTS AND DISCUSSION

Mg^{++} ions are known to play an important part in membrane stability (11) and Strange (12) suggested that Mg^{++} stabilized bacterial membranes and reduced the lethal influences of chilling. It can be seen from Fig. 1 that, Mg^{++} reduced the amount of leakage at 37 or 50° . There appears to be no influence of Mg^{++} on leakage during storage at 60° , although the rate of loss of $260\text{ m}\mu$ absorbing material may be reduced during the early stages of storage. It is apparent that Mg^{++} ions may influence the loss of intracellular material. The apparent lack of effect of Mg^{++} on leakage from cells stored at 60° was confirmed by storing cell suspensions in suspending fluids containing different concentrations of Mg^{++} for 4 hr. at 50 or 60° . The results are shown in Fig. 2. The total amount of $260\text{ m}\mu$ -absorbing material lost from the cells is directly reduced at 50° as the concentration of Mg^{++} present is increased, but such a reduction is not observed at increasing Mg^{++} concentrations during storage at 60° . It seems unlikely that magnesium sulfate at the highest concentration employed could exert any osmotic influences to reduce the loss of intracellular material.

Mg^{++} ions are known to increase the stability of cellular ribosomes (13) and it was found that magnesium sulfate reduced the leakage of $260\text{ m}\mu$ -absorbing material from heated *Aerobacter aerogenes* (5) and from starved *Sarcina lutea* (14), possibly due to stabilization of ribosomes. Thus, the apparent protective influences of Mg^{++} may be a result of the stabilization of RNA-containing units within the cell as well as the cell membrane. However, the variation in response of *Staph. aureus* stored in the presence of Mg^{++} at 50 and 60° is emphasized by the results presented here.

The changes in RNA in *Staph. aureus* cells suspended in water, 1 M sucrose, or 0.5 M sodium chloride are shown in Figs. 3–5. Cells in water at 50° (Fig. 3a) show a small but rapid initial decrease of cellular RNA, paralleled by a rise in the RNA-like content of the metabolic pool; this is followed by a slower loss of RNA-like

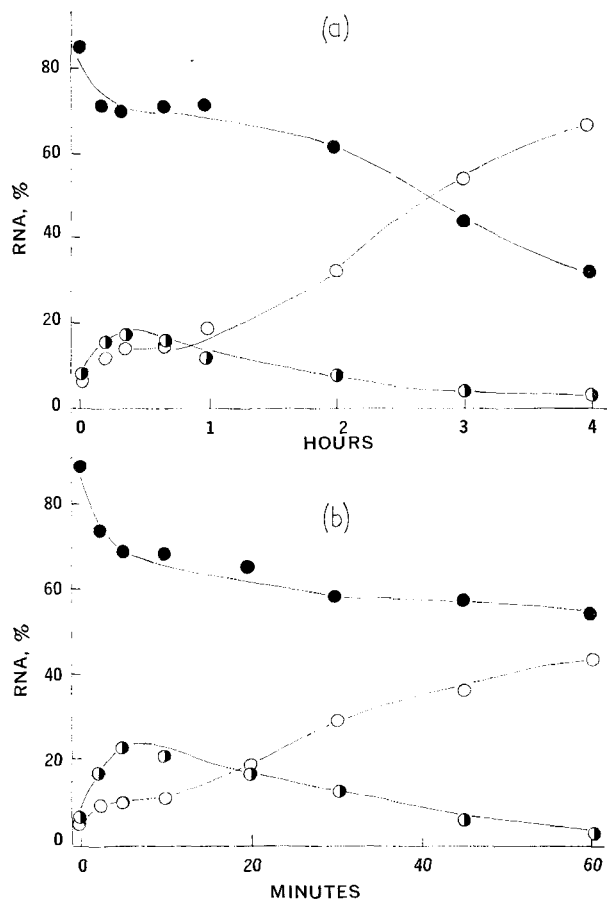

Figure 3—Changes in the composition of RNA-like material in the metabolic pool ○—○, cellular RNA ●—●, and of RNA-like material leaked ○—○, with a suspension of *Staph. aureus* held in water at a 50° , b 60° .

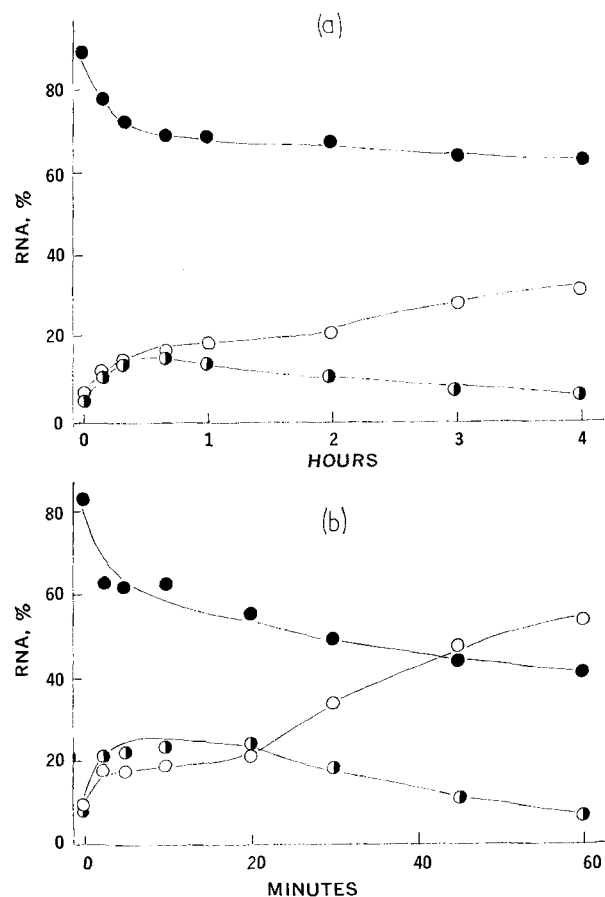

Figure 4—Changes in the composition of RNA-like material in the metabolic pool ○—○, cellular RNA ●—●, and of RNA-like material leaked ○—○, with a suspension of *Staph. aureus* held in 1 M sucrose at a 50° , b 60° .

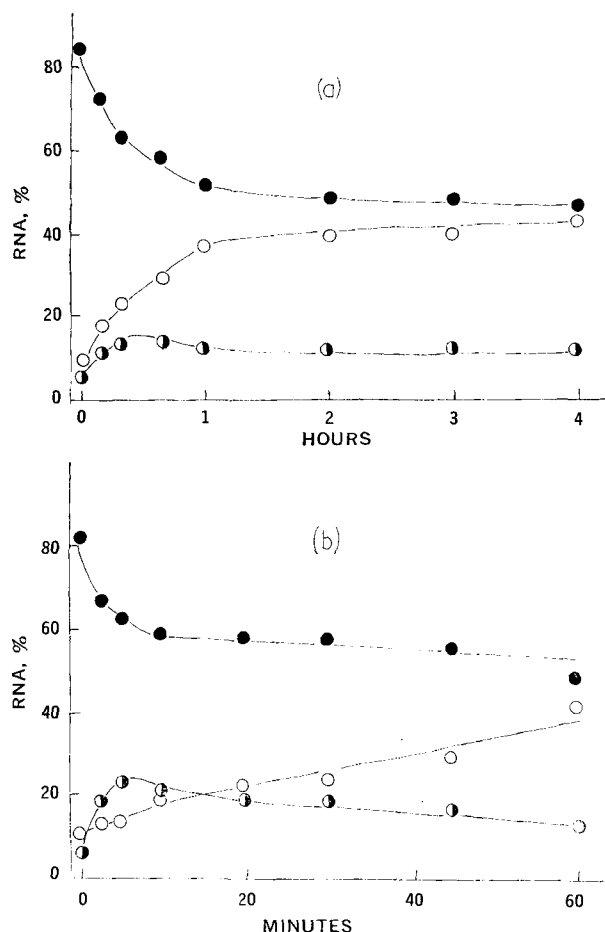

Figure 5—Changes in the composition of RNA-like material in the metabolic pool \circ — \circ , cellular RNA \bullet — \bullet , and of RNA-like material leaked \circ — \circ , with a suspension of *Staph. aureus* held in 0.5 M sodium chloride at a 50°, b 60°.

material into the supernatant fluid, this loss clearly being derived from the degradation of cellular RNA and not principally from the cell pool. Subsequently, there is a decrease in the content of RNA-like material in the pool, and an increased leakage of RNA-like material into the surrounding environment; this diphasic loss of RNA-like material could be the result of enzyme action, as previously discussed (3), although there is no evidence as yet to substantiate this, or could be caused by leakage of large molecular weight RNA through the damaged cytoplasmic membrane. More delicate techniques are needed, however, since the reported techniques do not permit the authors to determine this.

Sodium chloride (Fig. 5a), like sucrose (Fig. 4a) protects *Staph. aureus* at 50° against the leakage of intracellular RNA-like material. It also appears that the loss of RNA-like material from the metabolic pool occurs more slowly in the presence of an osmotic stabilizer than when cells are held in water at 50°. The presence of 1 M sucrose as suspending medium appears to prevent the secondary breakdown (or leakage) of RNA; RNA degradation, or leakage, is higher when cells are held in saline, but again there is no diphasic pattern in the depletion of cellular RNA or in the leakage of this material.

At 60°, with *Staph. aureus* cells held in water (Fig. 3b), the pool content of RNA-like material increases rapidly, the content of cellular RNA falls, but leakage of RNA-like material occurs to a considerably slower extent. Subsequently, there is a decrease in the amount of RNA-like material in the pool, presumably as the membrane control over the pool is lost due to thermal damage, and this material leaks into the environment. Sucrose (Fig. 4b) or sodium chloride (Fig. 5b), at 60°, apparently caused a more rapid degradation of RNA, although a longer period elapses before there is any appreciable loss of material from the metabolic pool. After 1 hr. at 60°, the greatest loss of RNA-like material occurs from

Figure 6—Loss of viability of suspensions of *Staph. aureus* held in water \circ — \circ , 1 M sucrose \bullet — \bullet , and 0.5 M sodium chloride \circ — \circ at a 50°, b 60°.

cells held in sucrose, which confirms previous findings (1, 3); the loss from cells in water and saline appears to be of a similar, but lower, order.

A comparison has been made of the loss of viability of cells stored in water, 1 M sucrose or 0.5 M sodium chloride at 50 or 60°. The results are present in Fig. 6. A statistical analysis of the results was made, using a common regression line calculation, to test if the three regressions could be represented by a common line. During storage at 50° (Fig. 6a) sodium chloride had a significant protective influence on the loss of viability of the *Staph. aureus* suspension, but there was no significant difference in loss of viability of cells held in water or sucrose. During storage at 60° (Fig. 6b), the three regression lines could be represented by one common line, and any differences are thus not significant.

As evidenced by a rise in the content of RNA-like material in the metabolic pool, RNA degradation obviously occurs in heated *Staph. aureus* cells. The rate of degradation increases with temperature, and occurs before leakage takes place (particularly at 60°). Such a degradation may be responsible for thermally-induced death in this strain (1, 3) and in other strains of *Staph. aureus* (6, 7). It is, however, difficult to link this degradation with loss of viability of *Staph. aureus* held in different suspending media (Fig. 6). Moreover, in assessing the primary site of damage in heated cells, other changes in the organism must be considered, including changes in appearance under the electron microscope, in size, and in light-scattering properties (4). Thus, whereas RNA degradation may be the cause of death in heated cells (3, 6, 7) it is apparent that further research is needed to substantiate this contention.

Renal Effects of a Vasodilator: 2-[N-methyl-piperidyl-(4)]-3-amino-5-(4'-pyridyl)-pyrazole HCl (Ciba 31-531 Ba)

RONALD L. WILLIAMS and JAMES E. PEARSON

Abstract □ Acetylcholine (Ach), when infused directly into the renal artery of a kidney, causes unilateral vasodilatation and increased salt excretion. Ciba 31-531 Ba, a nonspecific vasodilator, was infused both directly into the renal artery and given systemically, and the effects were compared to Ach. Infusion of Ach at 0.1 μ g./kg./min. into the left renal artery (LRA) of an anesthetized dog effected a unilaterally increased salt excretion and increased effective renal plasma flow (ERPF) and urine volume, but no demonstrable change in glomerular filtration rate (GFR) or blood pressure. Infusion of Ciba 31-531 Ba (LRA) at 0.1 mg./kg./min. resulted in a similar unilateral saluresis of approximately 50% increase over Ach with an increase in ERPF and urine volume but no change in GFR or blood pressure. The right kidney served as an internal control. When Ach and Ciba 31-531 Ba were given systemically, at higher doses there was a drop in blood pressure, decreased solute excretion, and decreased ERPF and GFR for both drugs. The effects of Ach were reversed with atropine. The effects of Ciba 31-531 Ba were not reversed by atropine or propranolol. The authors believe that the direct renal effects of these drugs are the results of direct tubular effects associated in some way with hemodynamic alterations.

Keyphrases □ 2-[N-methyl-piperidyl-(4)]-3-amino-5-(4'-pyridyl)-pyrazole HCl (Ciba 31-531 Ba)—renal effects □ Renal infusion—Ciba 31-531 Ba □ Acetylcholine, Ciba 31-531 Ba renal effects—comparison □ IV infusion, Ciba 31-531 Ba—renal effects

A new vasodilator, recently synthesized by Ciba (1), given systemically appeared to have contradictory effects on the kidney (2). In some cases it acted as a vasodilator and increased renal blood flow. In other experiments the various systemic effects appeared to predominate and no change or decrease in renal blood flow was observed.

Ciba compound 31-531 Ba, 2-[N-methyl-piperidyl-(4)]-3-amino-5-(4'-pyridyl)-pyrazole HCl, antagonized the effects of epinephrine, norepinephrine, angiotensin II-amide, and histamine on smooth muscle of the guinea pig and the cat. It did not antagonize the effects of BaCl₂, acetylcholine, or bradykinin (1).

When compared to papaverine, nitroglycerin, and isoproterenol in an open-chest cat preparation where it is possible to measure both systemic arterial and venous pressure, isoproterenol and Ciba 31-531 Ba administration caused both arterial and venous pressure to fall.

The direct renal effects of adrenergic and cholinergic agents have recently been reported in the literature (3). It was felt that a study of this rather nonspecific muscle-relaxing drug on renal function as compared to acetylcholine would be of interest. The following experiments were designed to study the effect on sodium excretion and renal hemodynamics when Ciba 31-531 Ba is given directly into the renal artery and when given systemically.

MATERIALS AND METHODS

Eight mongrel dogs were anesthetized with intravenous injections of pentobarbital sodium, 30 mg./kg. Both ureters were cannulated through an abdominal midline incision, and the cannulae were positioned approximately 1.27 cm. (0.5 in.) below the ureteral pelvic junction. A femoral vein and artery were cannulated and the arterial cannula was connected to an E & M linear transducer (E & M Co., Inc.) with a three-way stopcock for recording blood pressure with an E & M polygraph. Arterial blood samples were obtained through the three-way stopcock. The sustaining solution containing 1.8 mg./ml. of creatinine, 0.5 mg./ml. of *p*-aminohippurate (PAH) in normal saline was infused at a rate of 5 ml./min. through the venous system by means of a dual-syringe constant-flow pump. After exposing the left renal artery by the retroperitoneal approach, a 27-gauge hypodermic needle, attached to No. 10 polyethylene tubing, was placed into the left renal artery in the direction of blood flow. Through this renal arterial system, a solution of isotonic sodium chloride was continuously infused at a rate of 0.1 ml./min. Solutions of drugs were also infused at the same rate through the system by changing the renal arterial infusate to one containing test drugs dissolved in normal saline. One to two hours were allowed for equilibration and then collections of 10-min. urine samples from each kidney were begun. Blood samples, drawn every 20 min., were heparinized, centrifuged, and the plasma immediately removed. At

least three control urine samples were collected before test agents were infused into the kidney. Intravenous experiments used the same technique with sham retroperitoneal exposure.

ANALYTICAL

Chloride concentrations in urine and plasma were determined using a Buchler-Cotlove chloridometer, sodium and potassium concentrations in urine and plasma were determined using a Baird-Atomic flame photometer with an internal lithium standard, a modification of the Bonsnes and Taussky (4) method was used in the determination of plasma and urine creatinine, and PAH determinations were made using a modification of the method of Bratton and Marshall (5). The osmolalities were determined with a Fiske osmometer. In addition to the electrolyte excretion rates, the glomerular filtration rates (GFR), the effective renal plasma flow (ERPF), and the tubular rejection fraction (TRF) of sodium were calculated. The tubular rejection fraction is the ratio of the rate of sodium excretion to the filtered load of sodium. The TRF can vary independently of changes in filtered load (6). Because only concentrations are used in the calculation of TRF, its magnitude is independent of the size of the animal and facilitates comparisons between dogs. The absolute rate of tubular reabsorption (T_{Na}) is less useful because it is markedly affected by filtered load, which in turn

is a product of extrarenal as well as renal factors:

$$TRF_{Na} = \frac{U_{Na}V}{P_{Na}GFR} = \frac{U_{Na}P_{creatinine}}{P_{Na}U_{creatinine}}$$

where U is the urine concentration, P is the plasma concentration, V is the urine flow in ml./min., and GFR is the clearance of creatinine.

All drug doses are based on the respective salts: acetylcholine bromide and atropine sulfate. Ciba 31-531 Ba is 2-[N-methyl-piperidyl-(4)]-3-amino-5-(4'-pyridyl)-pyrazole HCl (obtained from Ciba Pharmaceutical Co., Summit, N. J.), propranolol hydrochloride (obtained from Ayerst Lab., Inc., New York, N. Y.).

RESULTS

Direct Renal Effect of Ciba 31-531 Ba Compared to Acetylcholine—The administration of Ciba 31-531 Ba (0.1 mg./kg./min.) by infusion into the left renal artery (LRA) resulted in a diuresis and saluresis similar to acetylcholine (0.1 mcg./kg./min.) (Fig. 1). The response to direct renal infusion of 0.1 mg./kg./min. of Ciba 31-531 Ba was about 50% greater than that to the renal infusion of 0.1 mcg./kg./min. acetylcholine and was the result of an increased tubular rejection of sodium (TRF_{Na^+}). This direct renal response to

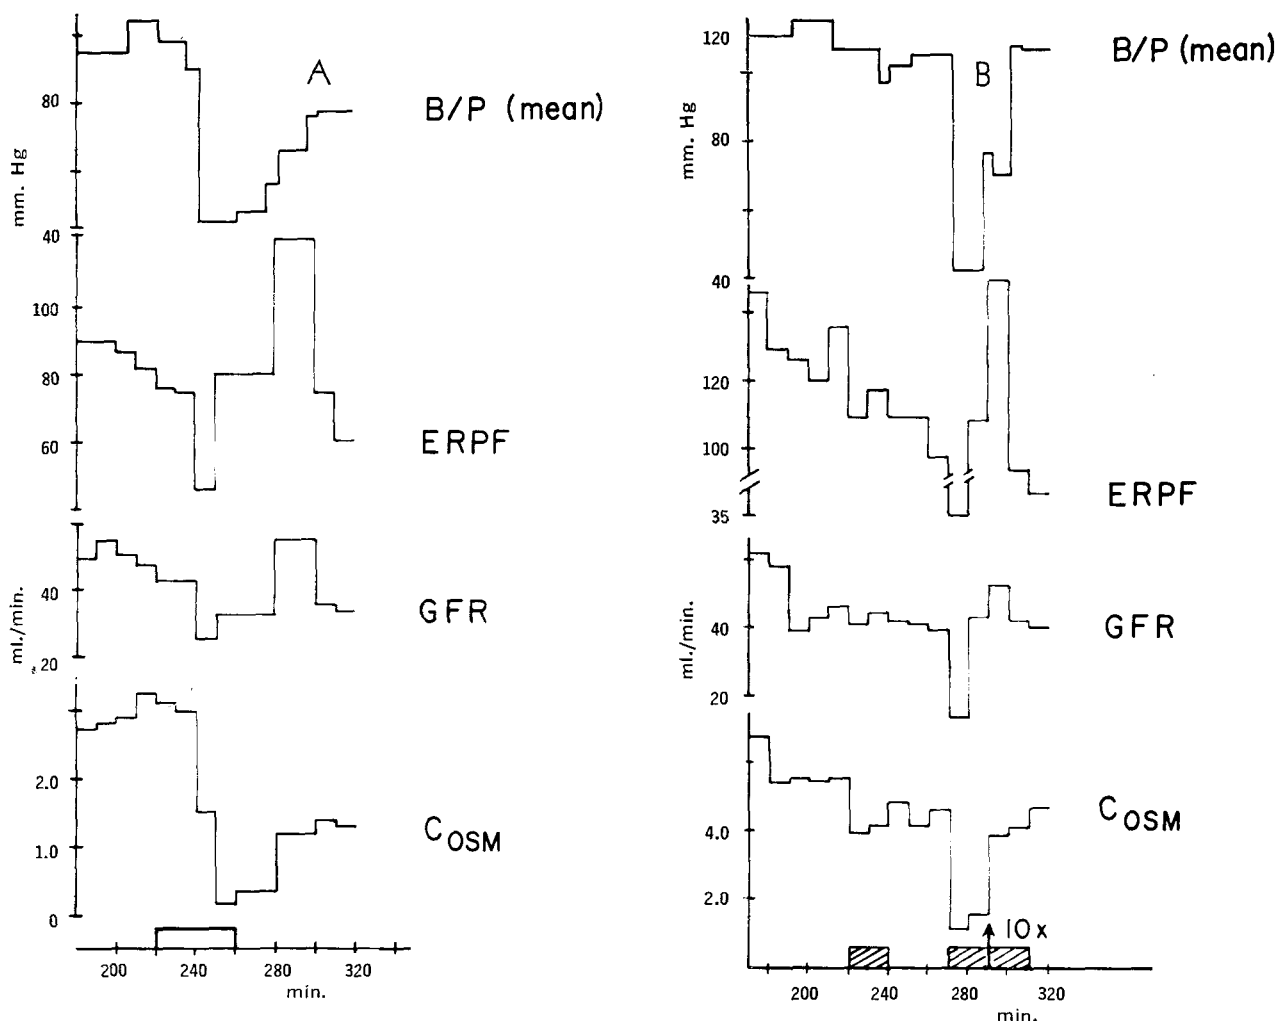

Figure 3—Comparison of the indirect renal effects of Ciba 31-531 Ba given intravenously to a 10-kg. female dog and acetylcholine given intravenously to a 14-kg. female dog. Key: A, □, Ciba 31-531 Ba (20 mg./ml. i.v.); B, ▨, acetylcholine (1 mcg./kg./min.); →, atropine (1 mg./kg. i.v.).

Ciba 31-531 Ba was not blocked by the systemic administration of atropine or propranolol (Fig. 1). The effective renal plasma flow (ERP) was not changed during the first infusion, but it was markedly increased on the experimental side during the second 30-min. infusion. There was no change in glomerular filtration rate (GFR) during the acetylcholine infusion or during the first 10-min. infusion of Ciba 31-531 Ba. There was, however, a unilateral increase in the excretion of Na^+ , K^+ , Cl^- , and water. The osmolar clearance (Cosm) increased with both acetylcholine and Ciba 31-531 Ba, and the sodium contribution to the osmolality also increased with both agents.

There was no significant change in systemic blood pressure during this entire experiment.

Effect in a Dog with Marked Sodium Retention—The administration of Ciba 31-531 Ba (0.1 mg./kg./min.) LRA to a dog with plasma sodium of 168 meq./l. and oliguria resulted in a large unilateral saluresis. This animal had failed to respond with diuresis even when given 6% mannitol in a 2% NaCl solution (Fig. 2). The TRF Na^+ was 58% of filtered load. During this 10-min. infusion period the ERP increased from a depressed 32 ml./min. to only 47 ml./min. with no change in GFR. The osmolar clearance was increased from 3.4 to 6.6 ml./min.

Indirect Renal Effects—Intravenous infusion of Ciba 31-531 Ba (20 mg./ml.) at increasing rates (total infused 400 mg.) until there was a substantial decrease in blood pressure resulted in depressed ERP, GFR, Cosm, Na^+UV , TRFNa^+ , and K^+UV . The infusion was discontinued and the blood pressure returned to 75% of control value with an unusual increase in ERP and GFR during the period from 280–300 min. The osmolar clearance, however, remained

depressed during the same exaggerated increase in ERP and GFR (Fig. 3A).

The intravenous infusion of acetylcholine for two experimental periods is shown in Fig. 3B. The first period of 20 min. at 1 mcg./kg./min. i.v. did not result in a blood pressure depression. The second period of 40 min. at 10 mcg./kg./min. caused a substantial decrease in blood pressure with a decrease in GFR, ERP, Cosm, Na^+UV , TRFNa^+ , and K^+UV . This effect of Ach i.v. was reversed with an injection of atropine, 14 mg. i.v. (1 mg./kg.).

DISCUSSION

Evidence has accumulated that acute increases in GFR *per se* have little effect on sodium excretion (7, 8). Therefore, natriuresis requires changes in fractional tubular reabsorption. However, the performance of the renal tubules are dependent for their several clearance functions upon the blood supply to the kidney. The exact quantitative influences of renal blood flow (9), intrarenal hydrostatic pressure (10), and intrarenal distribution of blood flow (11) on sodium excretion are not understood. Some diuretics such as furosemide and ethacrynic acid, which have no marked vascular effects elsewhere other than on renal vasculature, do increase the renal blood flow in parallel with natriuresis. However, for these diuretics the increased blood flow is not a requirement for the natriuretic response (12, 13). Autonomic drugs such as acetylcholine, which have powerful vascular effects throughout the body, produce natriuresis only when they are infused into a renal artery (14). Such is the case with Ciba 31-531 Ba in these experiments. Ciba 31-531 Ba must be infused into a renal artery to obtain the saluretic

response. However, this does not mean that the saluresis produced by infusing acetylcholine, or other autonomic agents, is simply the result of changes in hemodynamics (15). McGiff *et al.* (16) have shown that the natriuresis produced by angiotensin given intravenously was independent of the magnitude of increases in blood pressure, increases of GFR, and reduction in renal blood flow. Also the degrees of renal concentration and of rates of biotransformation will determine the magnitude of systemic vascular effects. The magnitude of the systemic vascular effects will bring into play various reflex autonomic nervous activities which may enhance or antagonize direct renal effects of autonomic drugs (17). This reflex antagonism of direct renal effects is especially demonstrated by diazoxide which produces salt retention when given systemically but produces salt excretion when infused directly into the renal artery (18).

It appears from the data presented here that Ciba 31-531 Ba has both tubular and hemodynamic effects. Changes in GFR do not seem to be concerned in these phenomena. In the case of the animal with extremely high plasma sodium (Fig. 2) the GFR remained unchanged in spite of 300% increase in TRFNa⁺ and 300% increase in osmolal clearance. During this 300% increase in osmolal clearance, the ERPF increased only by a factor of 47%. In this experiment the animal was retaining sodium in the face of an elevated plasma sodium. This response suggests a proximal site of action since it is improbable that a TRF Na⁺ of 58% could be accounted for by a distal mechanism.

The interpretation of the renal mechanism of action remains complicated even though changes in GFR may be ignored. Saluresis was produced by increased tubular rejection of sodium accompanied by increased renal plasma flow. What the interrelationship is between these two parameters remains unknown. Neither were they always congruent (Fig. 1). Also, Harvey (19) showed that acetylcholine produced a generalized vasodilatation in the kidney along with reduced plasma extraction ratios of PAH and inulin. However, there was also an increased tubular secretion of PAH. Something more is involved than a mere shunting of the blood supply. Williams *et al.* (20) believe that acetylcholine produces its effect by an action mainly upon the renal tubules. Martino and Earley (21) postulate that the hemodynamic alterations are the chief causes for the saluresis. However, they obtained no quantitative correlation between changes in sodium excretion and changes in intrarenal venous pressure. May and Carter (15) infused arecoline into the renal portal system of hens and obtained a marked unilateral saluresis. They postulated a direct effect upon the permeability of the renal tubule since it is unlikely that the slight increases in plasma flowing through the portal system in these preparations could be the cause of the natriuresis. The authors of this article also hesitate to describe the direct renal action of Ciba 31-531 Ba as mere vasodilatation since this agent also antagonizes the effects of norepinephrine which the authors believe to cause salt retention by a tubular action (3).

Perhaps the evidence from the direct renal effects of different pharmacological agents will help in the future understanding of the

relationship between tubular rejection of sodium and peritubular capillary blood flow, distribution, pressure, and permeability.

N-(1,1-dihydroperfluorooctyl)pyridinium Trifluoromethanesulfonate, a New Quaternary Ammonium Antiseptic

D. M. UPDEGRAFF*, D. C. KVAM, and J. E. ROBERTSON

Abstract □ The synthesis and biological evaluation of N-(1,1-dihydroperfluorooctyl)pyridinium trifluoromethanesulfonate (MBR 3092-42), a highly fluorinated quaternary ammonium antiseptic, are described. The material is structurally related to cetylpyridinium chloride. It shows approximately equivalent bacteriostatic activity to cetylpyridinium chloride but somewhat less fungistatic activity. The bactericidal activity of MBR 3092-42 is slightly less than that of cetylpyridinium chloride in equal concentration in distilled water or in 10% blood serum, but is slightly greater in 80% human blood. MBR 3092-42 is also antibacterially equivalent to cetylpyridinium chloride on the resident bacterial flora of human skin. Although this new compound slowly decomposes in water at pH 7 and above, it is stable in weakly acidic aqueous or hydroalcoholic solutions. Solutions of MBR 3092-42 yield much lower surface tension values than equivalent concentrations of cetylpyridinium chloride.

Keyphrases □ N-(1,1-dihydroperfluorooctyl)pyridinium trifluoromethanesulfonate (MBR 3092-42)—synthesis □ Antimicrobial activity—MBR 3092-42 □ Dermal toxicity—MBR 3092-42 □ Acute toxicity—MBR 3092-42 □ Irritation, sensitivity testing—MBR 3092-42

The quaternary ammonium-type germicides, introduced by Domagk (1), are highly effective broad spectrum germicides and fungicides. However, this class of compound suffers from the disadvantage of being inactivated by lecithin, long-chain fatty acids, and other anionic materials. In spite of this, they have been successfully used as antiseptics for general and surgical applications for many years.

In general, quaternary ammonium germicides are nontoxic and nonirritating to skin and mucous membranes at the concentrations used for antiseptic effects (2). At higher concentrations, however, these compounds are toxic and irritating to skin and mucous membranes. Most commercially available compounds of this class show similar toxicological and pharmacological properties (3-6).

This report concerns itself with the synthesis and biological properties of MBR 3092-42, and compares these properties, in most cases, with those of cetylpyridinium chloride, one of the oldest and most active of the quaternary ammonium germicides currently in use.

MBR 3092-42

cetylpyridinium chloride

EXPERIMENTAL

Synthesis—N-(1,1-dihydroperfluorooctyl)pyridinium trifluoromethanesulfonate. 1,1-Dihydroperfluorooctyl trifluoromethanesulfonate (7) (1.30 kg., 2.44 moles) was added over 2 hr. to a solution of 2.59 kg. (3.06 moles) of pyridine in 2.1 l. of acetone. After the solution was warmed at 40° for 24 hr., the product was precipitated by cooling and addition of excess isopropyl ether. The collected solid was purified by reprecipitation from acetone-ether to afford 870 g. (58%) of product, m.p. 112.5–114.5°.

Antimicrobial Activity—Bacteriostatic and fungistatic activities were compared using the filter paper disk-agar plate diffusion assay method of Vincent and Vincent (8). Activity was determined both in the presence and absence of blood or serum. Experiments were carried out at three dosage levels: 40, 4, and 0.4 mcg. per paper disk on PGY agar:

PGY Agar	Concentration, g./l.
NaCl	8.0
KCl	0.4
MgSO ₄ ·7H ₂ O	0.154
CaCl ₂ ·7H ₂ O	0.016
Na ₂ HPO ₄ ·7H ₂ O	0.29
KH ₂ PO ₄	0.15
Phenol Red	0.6 ml. of 0.2% soln.
Yeast extract	1.0
Glucose	2.0
Inoagar	8.5
Deionized water to 1 l.	

Bactericidal properties were assayed using a quantitative kill-rate method similar to that originally described by Chick (9). The test was carried out in three media: deionized water, 10% horse serum, or 80% human blood in deionized water. The test medium was inoculated with the test microorganisms at a rate of approximately 10⁵ cells per ml., and the test chemical was added. Solutions were prepared of the test chemicals at 1% in 20% alcohol (necessary to aid in solubilizing MBR 3092-42), and serial dilutions were prepared in deionized water out to extinction of activity. Dilutions of 1-10 or higher were found not to contain sufficient alcohol to have significant antibacterial activity. At intervals of 1, 5, 30, and 120 min., portions were removed and diluted serially in a dilution medium containing lecithin and polysorbate 80¹ to neutralize the germicide.

	Concentration, g./l.
KH ₂ PO ₄	6.80
K ₂ HPO ₄ ·3H ₂ O	11.4
Na ₂ S ₂ O ₃ ·5H ₂ O	5.0
Lecithin	2.5
Polysorbate 80	15.0
Deionized water to 1 l.	

Plate counts were then made using standard methods agar.

The ability of the compounds to kill the resident bacteria on human skin was compared using a serial skin-stripping method as described by Updegraff (10). For these studies, MBR 3092-42 and cetylpyridinium chloride² were dissolved in water at 1.0%. Solution of MBR 3092-42 was accomplished by warming in a water bath to 40 to 50°, and the solution was kept warm in this bath during the test to prevent precipitation of the compound. Dilutions were made in deionized water to 0.1 and 0.01%. These were not warmed

¹ Tween-80, Atlas Chemical Industries, Wilmington, Del.

² The cetylpyridinium chloride used in this and other studies was purchased from Calbiochem.

in the case of MBR 3092-42 as there was no tendency for the compound to precipitate at the low concentrations. Test solutions were applied to areas of the skin on the plantar surface of the forearm of three experimental human subjects and allowed to remain for 30 min. Residual germicide was washed off with sterile deionized water and the skin was gently patted dry with sterile gauze. Cultural counts were then made for bacteria in sequential layers of skin.

Effects of MBR 3092-42 in Anesthetized Dogs—Mongrel dogs were anesthetized with intravenous pentobarbital sodium, 30 mg./kg., and both vagus nerves were sectioned in the midcervical region. Blood pressure was recorded directly from the femoral artery by means of a P23AA Satham pressure transducer. Respiration was recorded *via* a bellows pneumograph fastened around the chest and connected to a P23BB Satham pressure transducer. A Lead II electrocardiogram was recorded to monitor heart rate. All parameters were recorded on a Type R Beckman Dynagraph. Drugs were administered intravenously in the indicated doses directly into the femoral vein.

Acute Toxicity—Determinations of the acute LD₅₀ were carried out in rats and mice by both the oral and intraperitoneal routes. Calculations of the LD₅₀ values were accomplished by the method of Miller and Tainter (11).

Mice—Simonsen Swiss Webster male mice weighing 18–30 g. were used in all studies. The compounds were administered either orally or intraperitoneally suspended in 4% acacia. Ten mice were used at each dosage level and were group-housed by dosage level in solid bottom plastic cages with food and water available *ad libitum*. The mice were not fasted prior to compound administration. Animals were observed for pharmacodynamic signs and mortality for several hours postdosage and daily thereafter for 14 days.

Rats—Simonsen Sprague Dawley female rats (150–200 g.) were used for all studies. The compounds were administered as a suspension in 4% acacia to fasted animals by either the oral or intraperitoneal route. Eight rats were used for each dosage level and were group-housed by dosage level in suspended screen bottom cages with food and water available *ad libitum*. The rats were observed for pharmacodynamic signs and mortality for several hours after dosing and daily for 14 days thereafter.

Other Species—Oral lethality studies were carried out in dogs and cats by administration of the compound in gelatin capsules to fasted animals of unspecified sex.

Acute Dermal Toxicity—Albino rabbits weighing initially 1630 to 2314 g. were used in this study. The animals were divided into seven groups of four rabbits (two males and two females) each. An area of the back corresponding to approximately 10% of the body surface was prepared by close clipping with an electric clipper. Additionally, one male and one female rabbit in each group were abraded over this area by producing shallow incisions with a scalpel blade. A 10% concentration of the test compound in 70% ethanol was applied to the backs of the rabbits by repeated applications of 4–5 ml. until the animals had received the proper dosage. The area was then covered with surgical gauze which was held in place by wrapping the body with an elastic bandage. Application of compounds was carried out once only at dosage levels of 0.5, 1.0, and 2.0 g./kg. The seventh group of four rabbits was treated with 70% ethanol only in a volume equivalent to that applied to the 2.0 g./kg. group for control purposes.

All of the animals were immobilized for 24 hr. in stocks. After this restraint period the compound was washed off with tap water and animals were observed for dermal irritation. The animals were the housed individually for a 14-day observation period in suspended metal cages. Hematologic examinations and urinalysis were conducted once during the control period and at 24 hr. and 2 weeks after compound administration. Daily observations were made for mortality, food consumption, systemic toxicity, and dermal irritation. Dermal irritation was scored as outlined by Draize (12).

Irritation Tests—Rabbits were utilized for eye irritation assay as follows. Albino rabbits of unspecified sex were placed in a restraining stock until quiet. The test materials in varying concentrations (0.5, 1.0, and 2.0%) were then instilled into the right eye in 0.1-ml. amounts. Isotonic saline was instilled into the left eye which served as control. The lids were gently held together for 1 sec. and then released. The eyes were not washed following instillation of the test material. Two rabbits were utilized for each concentration of material tested. The eyes were examined for degree of irritation and scored at intervals as described under Section 191.12 of the Federal Hazardous Substances Labeling Act Regula-

Table I—Surface Tension of Aqueous Solutions Determined Using a DuNoüy Ring and Instron Tester

Compound	Concentration, % w/v	Surface Tension, dynes/cm.
MBR 3092-42	0.05	34.0
MBR 3092-42	0.10	26.0
Cetylpyridinium chloride	0.05	42.0
Cetylpyridinium chloride	0.10	45.5
Water	—	76.0

tions (13). The lowest concentration producing signs of irritation considered positive under these regulations (ulceration or opacity of cornea, inflammation of iris, or swelling or redness of the conjunctiva) was considered to be the threshold irritation concentration.

Primary dermal irritation was determined utilizing guinea pigs. Twelve male albino guinea pigs weighing from 340 to 441 g. were used in this study. The dorsal hair was removed with an electric clipper over an area of approximately 5.08 cm. (2 in.) square. The animals were separated into two groups and the skin of one-half the guinea pigs in each group was further prepared by abrading the shaved area with a scalpel blade.

The prepared skin was dampened with normal saline, and 0.1 g. of the test compound was then placed on the prepared area of six guinea pigs (three with intact and three with abraded skin). The area was covered with gauze and the body of each animal wrapped with elastic bandage. Twenty-four hours later the bandages were removed and the areas of application washed with tepid tap water and examined for dermal irritation. Seventy-two hours later the areas were again examined. Scoring of irritation was as outlined by Draize (12).

Sensitization Testing—Testing for dermal sensitization was performed on male albino guinea pigs. Twenty guinea pigs weighing from 260 to 336 g. were used for this study. The animals were individually housed in suspended metal cages with food and water available *ad libitum*. The laboratory food³ diet was supplemented with fresh cabbage three times weekly.

The test compounds and the positive control (2,4-dinitro-1-chlorobenzene) were dissolved in sterile distilled water at 0.1% concentration just prior to injection. The back of each guinea pig was prepared by close shaving with an electric clipper. This was repeated as necessary throughout the study.

The positive control and test compounds were injected intradermally (using a 26-gauge needle) into the prepared area every other day, until a total of 10 such sensitizing doses had been given. The volume of the first dose was 0.05 ml. and that for the remaining doses was 0.10 ml. No injection site was used more than once.

Two weeks after the final sensitizing dose had been administered, a challenge dosage of 0.05 ml. of the respective test and positive control compounds was administered intradermally.

The injection sites were examined for diameter, height, and intensity of erythema and edema 24 and 48 hr. following each individual injection. Results were scored as follows: 0.0, normal; 0.5, trace (faint pink); 1.0, pink; 2.0, red; 3.0, yellow-pink; 4.0, yellow (necrosis).

The 24- and 48-hr. readings were averaged and means calculated. Similar measurements were made 24 and 48 hr. after the challenge dosages and averaged.

RESULTS

Analysis of the synthetic product obtained by the procedure described was as follows:

Anal.—Calcd. for C₁₄H₇F₁₈NO₃S: C, 27.53; H, 1.15; F, 55.92; N, 2.30. Found: C, 27.58; H, 1.29; F, 55.87; N, 2.37.

Physical and Chemical Properties—MBR 3092-42 is a white, odorless, crystalline compound, with a bitter taste and somewhat less aftertaste than most quaternaries. In comparative taste tests with cetylpyridinium chloride, it was somewhat less bitter and was judged to have less aftertaste.

It is soluble in water to 0.1% (w/v); ethanol, 24.0%; acetone, 53.0%; hexane, 0.7%; and polyethylene glycol 400, 3.0%. MBR 3092-42 is very effective at lowering the surface tension of water

(Table I) and it is unique in that the concomitant foaming property frequently seen with surfactants is lacking.

Like cetylpyridinium chloride, MBR 3092-42 is decomposed by alkali, producing a brown or yellow solution or precipitate devoid of antibacterial activity, as shown by complete lack of any inhibition zones at the highest test dose, 40 mcg., against any of the test organisms listed in Table II.

Antimicrobial Activity—The bacteriostatic and fungistatic activities of MBR 3092-42 and cetylpyridinium chloride are compared in Table II. From these data, we can conclude that both agents are powerful bacteriostatic agents and moderately potent fungistatic agents.

The bactericidal activities of these agents toward *Staphylococcus aureus*, *Escherichia coli*, and *Pseudomonas aeruginosa* are presented

in Table III and Figs. 1 and 2. It is clear that both agents are powerfully bactericidal. Cetylpyridinium chloride appears to be slightly more active in water and 10% horse serum as indicated by Table III, but when tested in 80% human blood, MBR 3092-42 showed superior activity against both *S. aureus* and *E. coli*, as shown in Figs. 1 and 2.

The ability of MBR 3092-42 to kill the resident flora of the human skin, as compared with cetylpyridinium chloride, is presented in Table IV. The first two experiments, carried out on subjects DMU and RMW, showed complete kills in several cases with 1% solutions of the test materials; therefore, lower concentrations were used in subsequent tests. Control counts were well within the range reported for normal human subjects (10). Both agents are highly effective and comparable in activity within experimental error reported for this procedure (10).

Effects in Anesthetized Dogs—When administered intravenously to anesthetized dogs as single doses, neither MBR 3092-42 nor cetylpyridinium chloride produced marked effects on heart rate, blood pressure, and respiration until the toxic dose level was reached (Table V). High doses of either agent produced bradycardia and a fall in blood pressure. The fatal single doses of MBR 3092-42 and cetylpyridinium chloride were found to be 20 mg./kg. and 40 mg./kg., respectively. Death in both cases was apparently due to res-

piratory failure. Continuous intravenous infusion of these agents at constant rates produced death at an average cumulative dose of 88 mg./kg. with cetylpyridinium chloride and at an average cumulative dose of 97 mg./kg. with MBR 3092-42 (Table VI). Death in both cases was due to respiratory failure preceded by marked bradycardia and hypotension. MBR 3092-42 was found to cause greater

Table V—Effect of Single Intravenous Injections of MBR 3092-42 or Cetylpyridinium Chloride on Heart Rate, Blood Pressure, and Respiration in Anesthetized Dogs^a

Compound	Dose, mg./kg. ^b	Maximum Change, %

	10	-15	-25	0
	20		Fatal ^c	

^a MBR 3092-42 was administered as a 1% solution in distilled water acidified with 0.1 N HCl sufficient to solubilize the compound. Cetylpyridinium chloride was administered as a 4% solution in distilled water. ^b One dog was used for each dosage level administered. ^c Respiration ceased shortly after drug administration with death following from respiratory failure. Bradycardia and hypotension were noted immediately preceding respiratory arrest.

depression of heart rate and blood pressure than cetylpyridinium chloride at doses below the toxic level.

The mechanism for the toxic effect of cetylpyridinium chloride has been found to be a neuromuscular blockade with subsequent paralysis of the muscles of respiration (3). From these experiments

it would appear that a similar mechanism is also responsible for the toxic effect of MBR 3092-42.

Acute Toxicity—The acute LD₅₀ values obtained are summarized in Table VII. MBR 3092-42 proved to be less toxic than cetylpyridinium chloride in rats and mice by most routes, with the exception of the intraperitoneal route in rats. Administration of either compound to dogs or cats produced emesis of such severity as to preclude determination of lethal potential in these species by the oral route.

Results of the acute dermal toxicity studies in rabbits are reported in Table VIII. The degree of dermal irritation produced was much more prominent in those rabbits receiving cetylpyridinium chloride than in those receiving MBR 3092-42. Rabbits receiving cetylpyridinium chloride exhibited erythema, edema, atonia, desquamation, leathery texture, fissuring, necrosis, ulceration, and sloughing of the skin. These signs bore a dose relationship, particularly in relation to the necrosis, sloughing, and ulceration. Rabbits administered MBR 3092-42 exhibited erythema, edema, and atonia of the skin over a 24-48-hr. period following application. However, the skin appeared essentially normal thereafter.

Control rabbits and rabbits administered MBR 3092-42 exhibited essentially normal values in hematology and urinalysis during this study. Rabbits receiving cetylpyridinium chloride exhibited an elevation in nonsegmented neutrophils at the 24-hr. period after treatment which was dose related in severity.

No unusual alterations in body weight or food consumption were noted in animals receiving MBR 3092-42. Rabbits administered cetylpyridinium chloride exhibited partial anorexia for the first week after treatment. This appeared to be dose related and was accompanied by loss of body weight, particularly at the 2.0 g./kg. dose level.

Irritation Testing—In ocular irritation studies in rabbits, the threshold irritation concentrations were found to be 0.5% for cetylpyridinium chloride and 1.0% for MBR 3092-42.

Dermal irritation studies in guinea pigs over a 72-hr. period produced no evidence of skin irritation under the conditions of the

Cetylpyridinium chloride	0.5	0/4	4/4
	1.0	0/4	4/4
	2.0	2/4 ^c	4/4
MBR 3092-42	0.5	0/4	2/4
	1.0	0/4	4/4
	2.0	0/4	4/4

^a Positive animals were those showing any signs of irritation. ^b One rabbit died from a broken neck while restrained in the stock. ^c One rabbit (abraded) died on Day 4 and one (intact) on Day 5.

experiment with either MBR 3092-42 or cetylpyridinium chloride. Due to the negative scores obtained, no table of results is presented.

Sensitization Testing—The results of a dermal sensitization study conducted in guinea pigs are presented in Table IX. These indicate that the test compounds, cetylpyridinium chloride and MBR 3092-42, produced irritation since wheal and flare formation was evident throughout all 10 sensitizing injections. The values obtained from the challenge dosage were similar to the average values obtained with the sensitizing injections. Dinitrochlorobenzene as the positive control also produced evidence of irritation. However, the values obtained from the challenge dosage exceeded those obtained from the sensitizing injections. Thus, it is concluded that MBR 3092-42 and cetylpyridinium chloride produced irritation but not sensitization and that dinitrochlorobenzene produced sensitization as well as irritation.

DISCUSSION

The antibacterial activity of quaternary compounds is believed to be correlated with their surfactant properties (2). Fluorine substitution markedly increases the surface activity of many surfactants, as measured by surface tension reduction (14). This property could

account for the high bactericidal activity of MBR 3092-42 as contrasted with its nonfluorinated homolog *n*-octylpyridinium chloride, which has very slight activity (15).

On the other hand, the introduction of fluorine decreases water solubility and increases formula weight to a value of 611 for MBR 3092-42 versus 358 for cetylpyridinium chloride. Thus, on a molar basis, MBR 3092-42 is proportionately more active than cetylpyridinium chloride.

The relative lack of toxicity and irritation to the skin and mucous membranes with MBR 3092-42 and its effectiveness in the presence of blood would appear to be advantageous for its use as an antiseptic for the skin and surgical wounds. Further, its high surface activity and lack of foaming properties as well as its somewhat less unpleasant taste should prove advantageous for other uses, e.g., as an oral antiseptic. For this purpose, dilute hydroalcoholic solutions could conceivably be preferable to weakly acidic solutions, since acidic solutions might aggravate the formation of dental caries.

Reactions of Acetaminophen in Pharmaceutical Dosage Forms: Its Proposed Acetylation by Acetylsalicylic Acid

E. KALATZIS

Abstract □ Acetylation of acetaminophen (paracetamol) by acetylsalicylic acid to *O,N*-diacetyl-*p*-aminophenol (DAPAP) was not evident in experimental pharmaceutical dosage forms. DAPAP, which was found to be present in small quantities in commercial grade acetaminophen, is unstable in pharmaceutical preparations. The destruction of DAPAP increases rapidly with the temperature and moisture content of the system. Solid DAPAP seems to exist in at least two forms, as shown by their IR spectra.

The observed color darkening of suspensions containing acetaminophen is mainly due to the oxidative degradation of the liberated *p*-aminophenol. The presence of codeine phosphate and caffeine seems to enhance the color deterioration of solid preparations containing acetaminophen kept at 45° and in a humid atmosphere. It is recommended that moisture be excluded, as much as possible, from such preparations.

Keyphrases □ Acetaminophen reactions—dosage forms □ Aspirin—acetaminophen acetylation □ Codeine PO₄, caffeine effect—acetaminophen stability □ Humidity effect—acetaminophen stability □ TLC—analysis □ IR spectrophotometry—identity □ UV spectrophotometry—identity

Previous publications have indicated that drugs containing amino- or phenolic-groups, such as phenylephrine (1) or codeine (2), as well as proteins (3) can be acetylated by acetylsalicylic acid in tablet formulations.

In 1967, it was reported (4) that acetaminophen (*N*-acetyl-*p*-aminophenol) can be acetylated by acetylsalicylic acid in tablet formulations, with the formation of *O,N*-diacetyl-*p*-aminophenol and salicylic acid. The same authors (4) proposed a linear relationship between the rate of formation of salicylic acid and the rate of formation of *O,N*-diacetyl-*p*-aminophenol and indicated the presence of *p*-aminophenol in some tablets, but they did not discuss its formation. However, a study of the kinetics of the formation of *p*-aminophenol by the hydrolysis of acetaminophen in aqueous solutions has been reported earlier (5).

Because there was a strong move in 1967 to have phenacetin removed from analgesic preparations being sold in Australia, many manufacturers replaced the phenacetin in their formulations by the same weight of acetaminophen. In this laboratory, however, it was found that in aspirin-acetaminophen preparations held at 45° under humid conditions or aspirin-acetaminophen suspensions held at 45°, *p*-aminophenol, together with its colored oxidation products, was being produced in a relatively short time.¹ In a number of these aspirin-acetaminophen preparations or suspensions the presence of *O,N*-diacetyl-*p*-aminophenol has also been established.

¹ Part of this work was presented at the I.U.P.A.C. 2nd International Congress on Pharmaceutical Chemistry, held at Münster/Westf. on July 22–26, 1968, in a paper on "Reactions of Acetylsalicylic Acid and Paracetamol in Dosage Forms," by B. G. Boggiano, E. Kalatzis, and F. E. Peters.

The formation of *p*-aminophenol in preparations containing acetaminophen is of some concern, therefore, and the presence of *O,N*-diacetyl-*p*-aminophenol attracted the author's attention, because any acetylation of acetaminophen (APAP) by acetylsalicylic acid (ASA) to the *O,N*-diacetyl-*p*-aminophenol (DAPAP) could, in addition to the direct hydrolysis of acetaminophen, be responsible for an alternative reaction path affecting the rate of the formation of *p*-aminophenol (PAP). However, the results of this paper show also that, contrary to what has been assumed earlier (4), acetylation of APAP by ASA was not evident under the conditions examined.

EXPERIMENTAL

Thin-layer Chromatography (TLC)—Analyses by TLC were carried out on 0.25 mm. Silica Gel GF₂₅₄ (Merck reagent). Solvent systems (4) used in all cases were as follows: (a) chloroform-acetone-acetic acid (80:18:2), and (b) chloroform-ethanol-acetic acid (88:10:2).

TLC plates were usually eluted only once but, when necessary, a second elution (placing the plate in the solvent tank for a second time) improved the separation of spots. The various spots separated on the TLC plate could be easily seen against the green fluorescence of the plate by viewing in the UV light of short wavelength (254 mμ).

Materials—Acetaminophen, phenacetin, and acetylsalicylic acid were commercial (pharmaceutical) grade reagents. Acetaminophen (Winthrop), which showed more than one spot by TLC examination, was recrystallized four times from methyl isobutyl ketone before the spot corresponding to DAPAP disappeared. Figure 1 shows the results of the TLC examination of the residues and of the final product obtained from the recrystallization of acetaminophen; also, it shows that when 2% DAPAP was added before or after purification, only one DAPAP spot was obtained by TLC. The spots which correspond to pure DAPAP have UV and IR spectra identical with those of DAPAP. The UV spectra in ethanol have λ_{max.} at 246 mμ and log ε ≅ 4.20. Solid DAPAP seems to be polymorphic and the form obtained depends on the solvent from which it is recovered. Thus, when it was recrystallized from water, the IR spectrum of the solid showed two carbonyl frequencies at

Figure 1—Thin-layer chromatogram of APAP (Solvent a) Key: 1, residue from the filtrate of the first recrystallization of commercial APAP; 2, same as 1 but from second and third recrystallizations combined; 3, commercial APAP before recrystallization; 4, pure recrystallized APAP; 5, commercial APAP containing 2% DAPAP; 6, *O*-acetyl-*p*-aminophenol; 7, DAPAP; and 8, PAP.

1688 and 1738 cm^{-1} and an N—H frequency at 3364 cm^{-1} . There were a shift and an increase in the complexity of these frequencies when the solid was recovered from other solvents. For example, the solid recovered from alcohol or benzene showed the two carbonyl frequencies at 1665 and 1752 cm^{-1} and what appeared as a number of N—H frequencies in the range of 3074–3292 cm^{-1} . Furthermore, the solid recovered from acetone seemed to be a mixture of the two forms, because its spectrum contained all these frequencies. These changes, which may be due to the presence of the amide group, are reversible and have been observed with commercial DAPAP as well as with that recovered by TLC from commercial APAP. This problem is under investigation.

Phenacetin and acetylsalicylic acid were recrystallized three times from ethylacetate; they were shown by TLC to be pure (one spot). Salicylic acid (AnalaR), acetylsalicylic acid (May & Baker), codeine phosphate (May & Baker), and caffeine (D.H.A.) were used without further purification.

Commercial APAP containing 2% DAPAP was prepared as follows: 0.2 g. of DAPAP (Tokyo Kasei & Co.) together with 10 g. of APAP (commercial grade D.H.A. shown by TLC to contain no DAPAP) were dissolved in alcohol (20 ml.) and the clear solution obtained was then evaporated slowly to dryness under vacuum.

Preparations—Suspensions—Typical suspensions were prepared as follows: 10 g. acetylsalicylic acid, 10 g. acetaminophen, 200 ml. demineralized water, with or without 0.4 g. codeine phosphate or 1.0 g. caffeine, and with or without the following mixture: 4 g. compound powder of tragacanth BP and 20 ml. syrup of orange and 5 ml. concentrate chloroform–water (60% chloroform in 60% ethanol).

Similar suspensions containing phenacetin instead of acetaminophen were also prepared. All suspensions were kept at room temperature (about 25°) or at 45° for 14 weeks.

^a Mixtures 1–9 contain APAP (commercial grade) which was shown by TLC to be free from DAPAP. ^b Mixtures I–IX contain APAP (commercial grade as in Mixtures 1–8) to which 2% DAPAP was added.

Powders—Uncompressed mixtures of powders were prepared by grinding the weighed quantities of the appropriate materials and mixing thoroughly. No excipients were included in these mixtures, as is seen in Tables I–III.

Each uncompressed mixture was divided into six equal parts which were kept at room temperature (about 25°) and at 45° under the following conditions: (a) in sealed vials (dry mixtures), (b) in a desiccator over water (humid mixtures), and (c) in sealed vials in which 1–2 ml. of water was added (moist mixtures).

Samples (25–50 mg.) were taken out at regular intervals of time, dissolved in alcohol (about 2 ml.), and examined by TLC. Satisfactory results were obtained when many applications (about eight each of about 5 $\mu\text{l}.$) were used for each sample, thus ensuring that the minor components, if present, would appear as recognizable spots on the thin-layer chromatograms. The limits of detection lie between 0.2 and 0.4 mcg. of DAPAP spots on the TLC plate by the method described.

Tablets—The tablets examined were commercially manufactured products.

RESULTS AND DISCUSSION

Suspensions—Suspensions containing phenacetin and held at 45° for 14 weeks showed no color change and, as expected, neither DAPAP nor PAP could be detected by TLC.

Suspensions containing acetaminophen (commercial grade, which was shown to contain DAPAP) rapidly turned brown and deposited a black precipitate. Spots indicating the presence of both PAP and DAPAP were observed. While the amount of PAP and its colored oxidation products increased with time, the amount of DAPAP decreased and eventually could not be detected.

The level of PAP in the aqueous phase of these suspensions rose to about 10^{-2} M, as determined spectrophotometrically by using 4-nitrobenzaldehyde and removing the colored oxidation products (6).

Similar, but much slower, changes were observed in suspensions kept at room temperature. For example, at the end of 14 weeks the level of PAP was less than 10^{-4} M and 24 weeks later these suspensions, although discolored, were not as dark as the suspensions kept at 45° for 14 weeks.

Powders—The results obtained after examining the powder mixtures containing recrystallized APAP (Table I) indicate that no DAPAP is formed in the dry mixtures when kept at room temperature for 6 months. Also, no DAPAP is formed in all the other mixtures held at room temperature or at 45° for 2 months.

On the other hand, humid and moist mixtures containing commercial acetaminophen (Table I) and kept at room temperature indicated that the original DAPAP remained almost completely unaffected for 2 months. Similar results were obtained with the dry mixtures kept at room temperature for 6 months and at 45° for 2 months. However, the DAPAP present in the humid and moist mixtures held at 45°, for 6 and 2 weeks, respectively, decreased steadily and at the end it could not be detected, presumably because of hydrolysis to APAP. This view is supported by the fact that no additional spots were revealed by TLC (*O*-acetyl-*p*-aminophenol appears as a different spot than that of APAP, as shown in Fig. 1).

Uncompressed powder mixtures based on two-tablet formulations of the Australian Pharmaceutical Formulary were also prepared. No excipients were added to these mixtures as seen in Table II.

^a Commercial (pharmaceutical) grade acetaminophen, which was shown by TLC to contain DAPAP. ^b Recrystallized acetaminophen and acetylsalicylic acid.

The formulations are: (a) acetylsalicylic acid, 250 mg.; acetaminophen, 250 mg.; and codeine phosphate, 8 mg.; and (b) acetylsalicylic acid, 225 mg.; acetaminophen, 150 mg.; and caffeine, 30 mg.

The APAP used was a commercial grade, but TLC examination showed that it contained no DAPAP. Accordingly, DAPAP was added and thus two series of powder mixtures were prepared: one with APAP free from DAPAP and the other with APAP containing 2% DAPAP (Table II).

All the mixtures were exposed to the same conditions as indicated above. The results have shown that again no DAPAP was formed under any of the conditions examined and that the DAPAP added had a fate similar to that of the DAPAP present in the previous powder mixtures (Table I). These findings hold true for all the mixtures including those containing codeine phosphate or caffeine. Increased quantities of codeine phosphate added in a number of uncompressed powder mixtures (Table III) gave similar results.

No appreciable decrease in the DAPAP was observed in the dry mixtures held at room temperature and at 45° for 2 months (Fig. 2a). The DAPAP present in the humid mixtures which were held at 45° for 2 months decreased steadily to traces and disappeared completely when codeine phosphate was present. This acceleration in the destruction of DAPAP is possibly due to the liberation of phosphoric acid in the presence of moisture.

Only a slow decrease in the DAPAP present in the moist mixture held at room temperature was observed and DAPAP was still present after 2 months. On the other hand, the decrease in the DAPAP in the moist mixtures kept at 45° was rapid and no DAPAP could be seen after about 2 weeks (Figure 2b).

These observations seem to be consistent whether ASA or SA is mixed with APAP. Of course, ASA hydrolyzes to SA and acetic acid, and this can be easily seen by TLC, because ASA appears as a green spot in the UV light (254 mμ) against the fluorescent background of the plate while SA appears as a blue spot. Adequate separation of the ASA from SA can be effected in Solvent b referred to in the *Experimental* section.

Powder mixtures containing phenacetin (Table I) have shown no recognizable changes except that, as in the case of those containing acetaminophen, humid and moist mixtures develop SA rapidly at 45° and more slowly at room temperature.

Because the results of the present work have shown that DAPAP is not stable and that its destruction, like the hydrolysis of ASA, increases with temperature and moisture content of the systems under consideration, the work reported by the earlier authors (4) has been reexamined. Figure 3 shows a plot of the number of moles of free SA against the number of moles of DAPAP based on their data (4).

Such a plot, however, does not seem to support satisfactorily the suggestion made by the above authors (4) that there is a relationship between the rate of formation of SA and the rate of formation of DAPAP. For example, in the case of their results with Product C,

Figure 2—Thin-layer chromatogram of uncompressed powder mixtures. (Solvent a) Key: for 3 to IV and 7 to VIII, see Table II; S, DAPAP; Z, codeine phosphate; W, caffeine; Y, yellow spots (seen in ordinary light); and D, rather dark brown spots. Chromatogram A was eluted once and Chromatogram B was eluted twice. (Dry A and moist B mixtures at 45°).

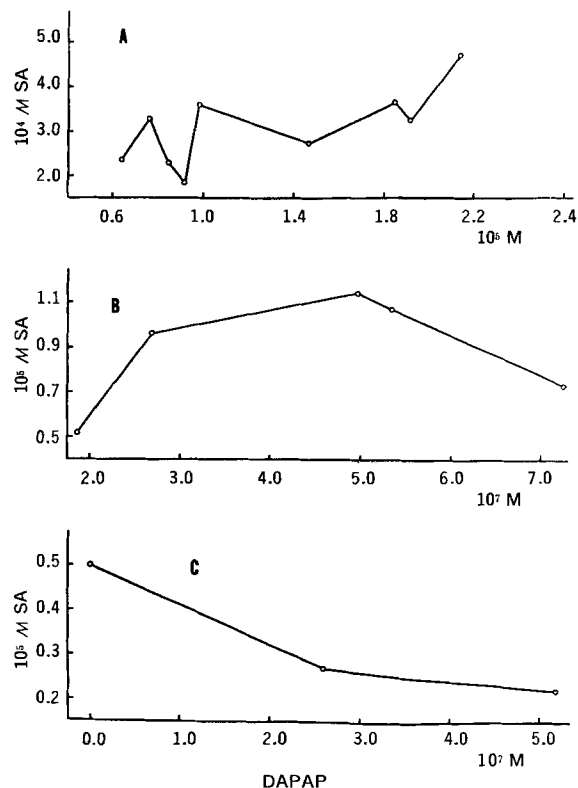

Figure 3—Plot of the number of moles of free SA against number of moles of DAPAP in the samples of products A, B, and C, from the data of Reference 4.

a fivefold increase in the number of moles of DAPAP corresponds to an approximate twofold decrease in that of the free SA.

These results rather suggest a random distribution of DAPAP in the various products. Furthermore, their (4) proposed linear relationship between the amount of DAPAP and that of SA formed with time in tablets from the same batch is not in agreement with the results of the present work, which indicates that the DAPAP is unstable especially under accelerated storage conditions. Since the storage conditions for the different products were probably not identical, the amount of DAPAP determined at a certain time would be expected to vary according to the history of the products concerned and the amount, if any, of DAPAP initially present. Moreover, all the figures quoted by the above authors (4) indicate that the number of moles of SA formed as a result of the proposed acetylation is far greater than that of DAPAP. For example, their (4) proposed linear relationship states that about 6 moles of SA are formed as a direct result of the formation of 1 mole of DAPAP. These results, however, are not in agreement with the proposed acetylation of APAP by ASA when it is considered that the formation of 1 mole of DAPAP is expected to be accompanied by the formation of 1 mole of SA.

An approximate estimation (semiquantitative TLC examination) of the DAPAP in commercial APAP (Table I) indicated that the level of DAPAP is within the range of 1.1–1.3%.

It is interesting to note that when APAP, with or without 2% DAPAP (Table II), was subjected to the same treatment as the previous mixtures, the destruction of DAPAP present in the moist sample held at 45° was complete within 6 weeks. Moreover, no color deterioration was observed.

Tablets—*p*-Aminophenol was detected (6) in very small amounts (less than 0.005%) in tablets containing acetaminophen, but was not detected in tablets containing phenacetin. Tablets containing acetaminophen (codeine phosphate or caffeine present) held at 45° in a humid atmosphere discolored or developed a mottled appearance after about 4 days.

In view of these discolorations, an examination of the color changes taking place in the powder mixtures discussed above in the *Powders* section of *Results and Discussion* is of interest.

None of the mixtures containing phenacetin (Table I) and held at room temperature showed any color deterioration, while at 45°

Table IV—Summary of Main Observations

	DAPAP ^a			Color Deterioration ^a		ASA Hydrolysis, APAP and Phenacetin Mixture
	Formation APAP Mixture, DAPAP Absent	Phenacetin Mixture	Hydrolysis, Complete APAP Mixture, DAPAP Present	APAP Mixture	Phenacetin Mixture

At 45°						
Suspensions	No	No	Yes	Excessive darkening	Slight	Complete
Mixtures						
dry	No	No	No	No	No	Very slight
humid	No	No	Yes	Noticeable mainly in the presence of co- deine phosphate or caffeine	No	Greatly increased
moist	No	No	Yes, 2 weeks	Excessive darkening of all mixtures	Slight	Almost complete
Tablets humid	—	No	No	Rather dark and mottled appearance	Slight	Greatly increased

^a Observations carried out for a period of 2 months, unless otherwise stated.

only the moist ones showed a very slight deterioration. These results are different in many respects from those obtained from mixtures containing APAP.

At room temperature all APAP mixtures showed no color deterioration except for the moist mixtures containing caffeine, which turned light yellow.

At 45° the dry mixtures showed no color deterioration. Of the humid mixtures, those containing codeine phosphate or caffeine became slightly red initially with subsequent darkening of the color. This deterioration was more pronounced in mixtures containing codeine phosphate and SA (Table II). On the other hand, all the moist mixtures turned dark brown and eventually black due mainly to the oxidative degradation of *p*-aminophenol produced from the hydrolysis of APAP, as was observed in the case of the suspensions already discussed.

For comparative purposes, therefore, mixtures containing *p*-aminophenol instead of APAP (Table III) were prepared and examined in the same way as was done above. Color deterioration of these mixtures took place within a day or two, even at room temperature. They were examined periodically by TLC and compared with the moist acetaminophen mixtures, because the darkening of the color was similar in both these groups. The results showed that the darkening of the color of the samples of both groups was due to yellowish, dark brownish, and to some extent reddish products (Fig. 2b). They also showed that PAP can be acetylated by ASA with the formation of APAP and that its oxidation was very pronounced in the presence of SA. However, no DAPAP could be observed under any conditions.

Deterioration in the color of these mixtures greatly increases with temperature and moisture content, and sealed samples kept at room temperature did not show as many dark spots by TLC. It is worth noting, however, that acetylation of PAP to APAP by ASA takes place readily at room temperature also in the dry, humid, or moist mixtures.

In view of the above findings, APAP (1 g.), ASA (1 g.), and SA (1 g.), each containing codeine phosphate (40 mg.) or each containing caffeine (150 mg.), were placed at 45° in a humid atmosphere (above water in a desiccator) for 12 weeks. The color of the mixtures containing APAP deteriorated faster than those containing ASA or SA. Even codeine phosphate or caffeine kept at 45° and in humid atmosphere on their own showed a color deterioration.

On the other hand, when these mixtures were heated at 45° for the same period of time in sealed vials, *i.e.*, in a rather dry atmosphere, no color deterioration could be observed.

It is, therefore, suggested that color deterioration in APAP tablets, kept under accelerated storage conditions, may be due partly to interactions between the codeine phosphate or caffeine, if present, with the other components or breakdown products in the tablets, and partly to the oxidative degradation of *p*-aminophenol formed from APAP.

SUMMARY AND CONCLUSION

A summary of the main observations is presented in Table IV.

From the results it can be seen that acetylation of acetaminophen to *O,N*-diacetyl-*p*-aminophenol by acetylsalicylic acid is not evident under the conditions examined and that the stability of the pharmaceutical preparations containing acetaminophen decreases rapidly with increase in their moisture content and temperature. Furthermore, when the moisture of these preparations is kept to the minimum possible level (without any special drying of the ingredients), their stability is greatly improved. It is, therefore, recommended that such preparations be kept in a dry atmosphere in order to increase their stability during storage.

Partition of Alkylsulfates of Quaternary Ammonium Compounds: Structure Dependence and Transport Study

FOTIOS M. PLAKOGIANNIS*, E. J. LIEN, CHARLES HARRIS†, and JOHN A. BILES

Abstract □ The apparent partition coefficients ($\log K_{app.}$, chloroform-water) of 48 alkylsulfates of substituted quinolinium compounds and 19 alkylsulfates of substituted pyridinium derivatives were correlated with Bondi's group contribution to the surface area ($A_w \times 10^9$), Hansch's π constant, and Hammett's σ constant. The surface area of the ring substituent and the alkyl group appears to be the most important factor in governing the apparent partition coefficient. The kinetic study of the dialysis of nicotinic acid *N*-methyl iodide through Visking cellulose membrane showed an effective rate constant of $1.6 \times 10^{-2} \text{ min.}^{-1}$ in the first hour and a rate constant of $0.3 \times 10^{-2} \text{ min.}^{-1}$ after the first hour. The *in vitro* intestinal absorption of four quaternary ammonium iodides was studied. It was found that the presence of equimolar concentration of sodium decylsulfate inhibited the transfer of the quaternary ammonium compounds.

Keyphrases □ Quaternary ammonium alkylsulfates—apparent partition coefficients □ Partition coefficient correlation—Hansch's π -, Hammett's constants, Bondi's group contribution surface area □ Intestinal absorption, *in vitro*—quaternary ammonium compounds □ Dialysis, kinetics—nicotinic acid *N*-methyl iodide

In 1957–1959, Hogben *et al.* (1, 2) postulated that the gastric mucosa and intestinal blood barrier are essentially lipid in nature and permit the passive diffusion of the unionized lipid-soluble form of a drug. Schanker (3) suggested that the absorption of organic ions might occur by a specialized transport process analogous to those which operate in transport of certain inorganic cations. He further suggested that the organic ions might penetrate the gastrointestinal blood barrier by the diffusion of the ions in the form of a less polar complex formed with some material normally present in the lumen.

Levine *et al.* have studied the transport of quaternary ammonium compounds extensively (4–9). They attributed the poor absorption to the formation of non-absorbable complexes with mucin. They also proposed that a phosphatidopeptide fraction allowed a more efficient absorption of certain quaternary ammonium compounds. Other mechanisms in addition to passive diffusion were proposed by Levine (9).

Although hundreds of partition coefficients have been reported for unionized molecules by Hansch *et al.* (10–13), relatively few data on the charged molecules are available in the literature (11, 14). Biles *et al.* showed that partitioning of organic ions into the organic layer from the aqueous layer could be increased by the addition of organic ions of opposite charge and by the addition of water-insoluble proton donor-type molecules to the organic layer (15–17).

The purposes of this report are to analyze quantitatively which physicochemical parameter is most important in governing the partition of the alkylsulfates of pyridinium and quinolinium derivatives, and to explore whether alkylsulfates would enhance the absorption

of quaternary ammonium compounds by the small intestine.

EXPERIMENTAL

Synthesis of Quaternary Ammonium Iodides—The appropriate tertiary arylamine was reacted with an excess of methyl iodide to form the quaternary ammonium iodide according to the published methods (18). The precipitated crystals were isolated by filtration and recrystallized from methanol or ethanol. Ethyl ether was used as a washing agent. The melting points were checked for all the compounds synthesized and agreed with those recorded in the literature.

Synthesis of the Alkylsulfates—The alkylsulfates were synthesized either by the method previously described (17) or by the method of Dreger *et al.* (19).

Analysis of the Quaternary Ammonium Compounds—The analysis of the quaternary ammonium compounds was performed either by the method previously described (17) or by UV absorption (λ_{max} , 236–322 m μ).

Determination of the Apparent Partition Coefficients—The procedure used was identical with that used for the anticholinergic compounds (17). The $\log K_{app.}$ values (Tables I and II) were obtained from the following expression (16) using the chloroform-water system:

Since the dielectric constant of water is 80.4 and that of chloroform is only 4.8, the ion-pair formation in aqueous phase should be negligible as compared to that in the chloroform phase. It is known that highly polar solvents favor ionization. For example, dilute aqueous solutions of sodium chloride and sodium acetate will have practically 100% ionization. It was felt that the same assumption would be valid in the case of an alkylsulfate of quaternary ammonium compound (a salt of a strong acid and a strong base).

Regression Analysis—The method of least squares was employed to derive the equations using a Honeywell-800 computer. The

^a Calculated value using Eq. 3. ^b Using Hammett's σ constant from H. H. Jaffé, *Chem. Rev.*, **53**, 191(1953). ^c Estimated value. ^d Calculated from the pK_a values of quinoline and 8-hydroxyquinoline, from A. Albert and J. N. Phillips, *J. Chem. Soc.*, **1956**, 1294. ^e Calculated from $4 \times 1.08 - 0.78$ for (CH)₄-H.

log K_{app} values, Hansch's π constant (10–14), Bondi's group contribution to the surface area (A_w cm.²/mole $\times 10^9$) (20), and Hammett's σ constant used in the analysis are assembled in Tables II and III.

Protein-binding Studies and Kinetic Study of the Dialysis Through Artificial Membrane—The static dialysis method of Matsumoto *et al.* (27) was adapted for these studies. Visking cellulose tubing (Visking Corp., Chicago, average pore size of 24 Å.) was used to carry out the equilibrium dialysis for the binding of *N*-methylacridinium iodide and *N*-methyl-2,6-dimethylquinolinium iodide by bovine serum albumin (2.5×10^{-5} M) for a period of 24 hr. Before the binding studies were performed, the Visking tubing was hydrated by soaking it in refrigerated phosphate buffer (pH 6.7) overnight. After soaking, the bag was immediately refilled with 10 ml. of buffer or buffered protein solution and then placed in the bottle which contained 25 ml. of a 6.67×10^{-4} M solution of a quaternary ammonium salt in the same buffer. About a dozen assemblies were kept in the refrigerator during the period of dialysis. At specified time intervals, one of the bottles was removed from the refrigerator and the solutions were assayed for the quaternary

ammonium compound, so no replacement or correction of the volume was necessary.

Equilibrium time was established by subjecting four compounds (nicotinic acid *N*-methyl iodide, *N*-methyl-2,6-dimethylquinolinium iodide, *N*-methyl-2-chloroquinolinium iodide, and *N*-methylacridinium iodide) to dialysis. It was found that 24 hr. were sufficient for equilibrium to be established.

A kinetic study was done on the dialysis of nicotinic acid *N*-methyl iodide and *N*-methylacridinium iodide for the first 6 hr.

In Vitro Intestinal Transport of Some Quaternary Ammonium Compounds—Preliminary studies were performed on a limited number of *N*-methylquinolinium salts. Fasted, male Sprague Dawley rats weighing 215–307 g. were used. Each rat was anesthetized with ethyl ether. A midline incision was made and the intestine was removed and washed with normal saline solution. The intestine was divided into four segments. The first two segments were considered as the jejunum and the other two as ileal segments. Each segment was everted and attached to the modified Wiseman apparatus previously described by Saltman (21). To the luminal side was added 100 ml. of a 0.001 M solution of the quaternary ammonium

^a Calculated value using Eq. 5. ^b Using Hammett's σ constant in benzene ring system, from H. H. Jaffé, *Chem. Rev.*, **53**, 191(1953).

compound in normal saline; to the serosal side was added 50 ml. of normal saline solution. The system was immersed in a 37° bath, and all solutions were adjusted to 37° before using. The solutions were circulated by bubbling oxygen through the serosal and luminal solutions. Samples were removed at 15, 30, 60, 90, and 120-min. intervals. Two milliliters was removed from the serosal solution and 4 ml. was removed from the luminal solution for each assay. The following quaternary ammonium compounds were studied in this phase of the research: *N*-methylquinolinium iodide, *N*-methyl-6-methoxyquinolinium iodide, *N*-methyl-2-iodoquinolinium iodide, *N*-methyl-6-bromoquinolinium iodide, and *N*-methyl-6-methylquinolinium iodide.

RESULTS AND DISCUSSION

The equations obtained by the method of least squares are listed in Table I. The data used to derive the equations are listed in Tables II and III. In Table I, n is the number of data points used in the regression analysis, r is the correlation coefficient, and s is the standard deviation. From Eqs. 2 and 5, it appears that the surface areas of the substituent on the quaternary ammonium compound as well as that of the alkyl group on the sulfate moiety are the most important factors in governing the apparent partition coefficient ($\log K_{app}$). More than 86 and 96% of the variance in the data ($r^2 = 0.86$ and 0.96) can be explained by Eqs. 3 and 5, respectively. This reflects the importance of the van der Waals forces (dipole-induced dipole and induced dipole-induced dipole) of the quaternary ammonium-alkylsulfate in the chloroform phase, and the hydrophobic interactions of the alkyl group with the aromatic ring in the aqueous phase. This agrees with the previous finding that the apparent distribution constant of alkylamine salts of tropeolin 00 was governed by the molecular weight and branching of the aliphatic amine, the relative concentration of the amine and dye, and the dielectric constant of the solvent (15). In fact the $\log K_{app}$ of six amine salts of tropeolin 00 reported previously (15) can be correlated with the surface area or the π of the alkyl groups of the amine. This is illustrated by deriving the mathematical expressions by the method of least squares and the equations obtained are expressed (Eqs. 7 and 8).

$$\log K_{app} = 0.448 (A_{wR} \cdot 10^9) - 4.782 \quad \begin{matrix} n & r & s \\ 6 & 0.992 & 0.150 \end{matrix} \quad (\text{Eq. 7})$$

$$\log K_{app} = 1.177 (\pi_R) - 2.232 \quad \begin{matrix} n & r & s \\ 6 & 0.994 & 0.137 \end{matrix} \quad (\text{Eq. 8})$$

Addition of the electronic parameter σ in Eq. 3 gives a better correlation ($r = 0.931$, $s = 0.263$). This term is significant at the 95-percentile level ($F_{1,44} = 4.02$). The positive dependence on σ in Eq. 3 suggests that electron withdrawing groups would enhance the $\log K_{app}$; this is explainable since an electron withdrawer makes the quaternary ammonium ion more positive and attracts the alkylsulfate ion more strongly.

Addition of a σ term to Eq. 5 does not result in an improved correlation. This is probably due to the fact that only two substituents studied have minus σ values and 16 molecules have very close σ values (0.28–0.40). A better selection of the substituents may reveal the role of the electronic effect.

The $\log K_{app}$ values calculated from Eqs. 3 and 5 are in good agreement with the observed values. The calculated and observed values are listed in Tables II and III.

The use of Hansch's π constant has been explored in view of the fact that $\log P_1$ obtained from one solvent system can be related to $\log P_2$ obtained from another system by the linear equation (22): $\log P_1 = a \log P_2 + b$, where a and b are constants. For the quinolinium compounds (Eqs. 2–4) the correlation obtained by using π is not as good as what is obtained by using A_w ($r = 0.83$ versus 0.93), although for the pyridinium compounds (Eqs. 5 and 6) both A_w and π give good correlations ($r = 0.98$ and 0.97 , respectively). This may be due to somewhat different π values of the substituents in the quinolinium system from what were obtained from phenoxyacetic acid system (10).

Equilibrium dialysis studies showed that 24 hr. is sufficient for equilibrium to be established for the compounds studied. Since both solutions were assayed at the same time, it appears that no protein binding occurred with the quaternary compounds investigated. The Student t test revealed that no binding occurred to *N*-methyl-2,6-dimethylquinolinium iodide at $P = 0.01$ level. The kinetics of the dialysis of nicotinic acid *N*-methyl iodide through Visking cellulose membrane is shown in Fig. 1, using the reversible model (28). In Fig. 1, A_0 is the initial concentration of the drug ($5.0 \times 10^{-4} M$), A is the outside drug concentration at time t , A_e is the theoretical equilibrium concentration ($3.57 \times 10^{-4} M$). It is most interesting to note in Fig. 1 that within the 1st hr. the effective rate constant, $k + k'$ (the slope of the regression line) is $(1.62 \pm 0.9) \times 10^{-2} \text{ min.}^{-1}$, and that following the 1st hr. is $(0.3 \pm 0.15) \times 10^{-2} \text{ min.}^{-1}$, with the 95% confidence interval

Figure 1—The kinetic study of the dialysis of nicotinic acid *N*-methyl iodide through Visking cellulose membrane.

given. The change in the effective rate constant may be due to plugging of some of the smaller pores of the cellulose membrane by the quaternary ammonium compound leaving fewer pores available for transport, and this process appears to be completed within the first hour.

The authors' results on the transport of *N*-methylacridinium iodide showed that this compound might bind on the dialysis membrane since the assay, after a given period of time, resulted in an overall value less than the original value.

The regression lines for the *in vitro* intestinal absorption of some quaternary ammonium salts are given as Eqs. 9–12, where *C* (micromoles) is the amount of quaternary ammonium salt transferred from the mucosal to the serosal side of the intestinal segment, and *t* is time in minutes. Each data point represents the average of four determinations. No transference of *N*-methyl-2-iodoquinolinium iodide was detected. This may be due to steric inhibition because of the presence of the fairly bulky iodo group next to the quaternary ammonium head. The equations expressing the intestinal absorption of the compounds are shown in Table IV.

From the slopes of Eqs. 9–12, it is evident that 6-methylquinoline *N*-methyl iodide and quinoline *N*-methyl iodide were transferred more rapidly. The rate of transfer of 6-bromo-quinoline *N*-methyl iodide and 6-methoxyquinoline *N*-methyl iodide was lower.

The transference of the quaternary ammonium salts was then investigated with the addition of an equimolar concentration of sodium decylsulfate to determine if the ion-ion pair, which is more nonpolar soluble than the iodide salt, occurred at a greater rate. The results showed that no transfer of any of the alkyl salts occurred. This may be due to steric inhibition and/or hydrophobic interactions of the decyl group and the aryl group of the quaternary ammonium moiety with the lipoprotein membrane since it is known that the strength of hydrophobic interaction is about 0.37–1.00 kcal./CH₂ (23–25) and an alkyl group of 10 or more carbon atoms will bind to another hydrophobic counterpart as strongly as an ion pair in the biological system (5 kcal./mole) (26).

Although the apparent partition coefficients of some alkyl-sulfates of quaternary ammonium compounds were correlated

with their molecular structure, it was found that the rate of transfer of these same compounds across the intestinal wall could not be predicted on the basis of their partition coefficients since the presence of equimolar concentration of alkylsulfate inhibited the transfer of the quaternary ammonium compounds. The possible explanations for the failure of absorption of the alkylsulfates of the quaternary ammonium compounds by intestine may be due to: (a) steric hindrance because of the attachment of the long alkylsulfate moiety, (b) the increased hydrophobic interactions of the alkyl group with the lipoprotein membrane, or (c) the absence of the positive charge which is necessary for binding with a carrier.

Absorptiometric, Polarographic, and Gas Chromatographic Assays for the Determination of *N*-1-substituted Nitroimidazoles in Blood and Urine

J. A. F. de SILVA, N. MUNNO, and N. STROJNY

Abstract □ This report describes an absorptiometric, a polarographic, and a gas-liquid chromatographic assay procedure for the quantitative determination of an *N*-1-substituted 2- and 5-nitroimidazole in blood and urine. Using the same selective extraction procedure and thin-layer chromatographic separation of the ethyl acetate extracts of blood and urine, the compounds are eluted from the silica gel into methanol. A suitable aliquot of this methanolic extract can be assayed sequentially using the absorptiometric (Bratton-Marshall) assay which has a sensitivity limit of 0.5–1.0 mcg./ml., or the pulsed polarographic assay (sensitivity limit 0.2–0.3 mcg./ml.) or the electron capture–GLC assay using the trimethyl silyl (TMS) derivatives of these compounds (sensitivity limit 0.01–0.02 mcg./ml.) for quantitation. Thus the sequential analysis of a specimen of blood or urine covers a sensitivity range of three orders of magnitude (*i.e.*, from 0.01 to 10 mcg./ml. of sample). The absorptiometric assay was used in the determination of blood level fall-off curves and urinary excretion of each compound in a dog following the administration of single 10-mg./kg. doses by oral and *i.v.* routes, while the GLC assay was used to extend the limits of detection of the absorptiometric assay and to determine the blood level fall-off curve in man following a single oral 50-mg. dose of Compound I.

Keyphrases □ Nitroimidazoles, *N*-1-substituted—determination in blood, urine □ Blood, urine analysis—*N*-1-substituted nitroimidazoles □ Polarography—analysis □ GLC—analysis □ TLC—analysis □ UV spectrophotometry—analysis

The nitroimidazole class of compounds has yielded several antimicrobial agents that are currently in use as trichomonacides (metronidazole)¹ and amebicides (dimetridazole).² The above agents are 5-nitroimidazoles with antimicrobial activity. The synthesis of 2-nitroimidazole by Beaman *et al.* (1) and by Lancini and Lazzari (2) represents the first total chemical synthesis of this antibiotic agent hitherto isolated from a microbial strain resembling *Nocardia mesenterica*. This led to the synthesis of several *N*-1-substituted 2- and 5-nitroimidazoles which were screened for antimicrobial properties.

From among these 1-(2-nitro-1-imidazolyl)-3-methoxy-2-propanol (hereafter referred to as Compound I) was synthesized by Beaman (3) and is under clinical investigation as a trichomonacidal agent, whereas α -chloromethyl-2-methyl-5-nitro-1-imidazoleethanol (hereafter referred to as Compound II) was synthesized by Hoffer (4) and is under clinical investigation as an amebicide. The chemical reactions of I and II are shown in Scheme I, and the analytical parameters used in the sequential analysis of the compounds by absorptiometric, polarographic, and gas chromatographic (GLC) methods are shown in Fig. 1.

The Ehrlich diazo coupling reaction between diazobenzene sulfonic acid and imidazole or phenol derivatives in acidic media to produce colored azo dye-chromophores has been widely used in biological chemistry for the detection of these physiologically important compounds. However, the reaction is inhibited by *N*-substitution or the presence of strong electro-negative substituents such as the nitro group on the imidazole ring. Nitroimidazoles can be detected by the Bratton-Marshall method (5) following reduction of the nitro group to the corresponding amine. Stambaugh and Manthei (6) used this principle of reducing nitroimidazoles to their amino derivatives, followed by coupling with either diazotized sulfanilic acid, *p*-dimethylaminobenzaldehyde, or ninhydrin to produce a chromophore characteristic of the coupling agent used as a means of differentiating nitroimidazoles. These reactions were found to be unsatisfactory for use in solvent extracts of blood or urine due to the presence of many interfering substances of biological origin.

The most widely used analytical procedures for the analysis of nitroimidazoles in pharmaceutical or agricultural products has been by the use of polarographic techniques (7–10), which are sufficiently sensitive and specific but complicated because of the need of specialized instrumentation. The analytical parameters for the polarographic assay were developed by MacDonald *et al.* (11), and applied directly in the analysis of Compounds I and II in blood. The method was, however, not used for the analysis of biological specimens because of the superiority of the GLC assay.

A rapid and sensitive absorptiometric assay was reported by Lau *et al.* (12). It is based on the alkaline hydrolysis of *N*-1-substituted 5-nitroimidazoles to yield stoichiometric amounts of the nitrite (-NO_2) ion which after acidification is used to diazotize sulfanilamide and couple it to *N*-(1-naphthyl)ethylenediamine to produce the characteristic Bratton-Marshall azo dye chromophore (5). The authors found, however, that *N*-1-substituted 2-nitroimidazoles also undergo a similar reaction, and this principle was used to develop the absorptiometric assay described for the determination of both I and II in blood and urine with a sensitivity limit of 0.5–1.0 mcg. of compound/ml. of blood or urine and an overall recovery of about 70%. The TLC separation of the ethyl acetate extract was required to ensure the specificity of the assay.

The highly sensitive and specific polarographic and GLC assays described use the same extraction, thin-layer chromatographic separation, and methanolic elution steps described in the absorptiometric assay. Suitable aliquots of the methanolic solution are evaporated to dryness and analyzed sequentially by the polaro-

¹1-(2-Hydroxyethyl)-2-methyl-5-nitroimidazole (Flagyl, G. D. Searle & Co).

²1,2-Dimethyl-5-nitroimidazole (Emtryl).

Scheme I

graphic and/or GLC assays as shown in Fig. 1. The GLC assay requires that both I and II be reacted with the silylating reagents at room temperature for 15 min. to produce their respective trimethyl silyl (TMS) derivatives (Scheme I). These derivatives are very sensitive to detection by electron-capture GLC and can be quantitated in the nanogram (10^{-9} g.) to picogram (10^{-12} g.) range. The GLC method has an overall recovery of 83% and a sensitivity limit of 0.01–0.02 mcg. of Compound I/ml. of blood. The method was applied to the determination of a blood level fall-off curve of Compound I in man, following a single oral 50-mg. dose and in extending the limits of detection of the absorptiometric assay.

EXPERIMENTAL

Absorptiometric Assay in Blood and Urine

Standard Solutions of Compounds I and II—Compound I—

Compound II—

A. Stock Solution—Dissolve 10 mg. of Compound I in 100 ml. of methanol (100 mcg./ml.) in an actinic flask, store refrigerated, and make fresh weekly.

B. Working Solution—Dilute 1 ml. of A to 10.0 ml. with methanol (concentration 10 mcg./ml.). Make fresh daily. Aliquots of this solution (B) are evaporated to dryness and the residues are redissolved in blood and used as internal standards. Stock solution A' and working solution B' for Compound II are also prepared as described above.

Reagents—All reagents used were of analytical reagent grade purity (>98%) and all inorganic reagents were made up in distilled deionized water (d.d.w.).

1.0 M (pH 9.0) H_3BO_3 – Na_2CO_3 –KCl buffer solution: dissolve 62.8 g. of orthoboric acid (H_3BO_3) and 74.6 g. of KCl/l. of distilled deionized water. Dissolve 106 g. of Na_2CO_3 /l. of distilled water. To 630 ml. of the boric acid–KCl solution, add 370 ml. of the Na_2CO_3 solution to make 1 l. of buffer solution. Shake well, check the pH, and adjust it to pH 9.0 if necessary with the Na_2CO_3 solution. The

final solution is 1 M with respect to H_3BO_3 – Na_2CO_3 –KCl and should be stored at 37° to prevent the salts from crystallizing out of solution. The following are also used: methanol, absolute, reagent grade; NaCl, reagent grade crystalline salt; 0.1 N NaOH in distilled deionized water; and 4.0 N HCl in distilled deionized water. To make the 0.1% sulfanilamide solution, use *p*-aminobenzene-sulfonamide, mol. wt. 172.21, m.p. 163° (Matheson). Dissolve 100 mg. sulfanilamide in 5 ml. of glacial acetic acid and bring to 100 ml. with distilled deionized water. Bratton-Marshall coupling reagent *N*-(1-naphthyl)ethylenediamine·2HCl (Eastman), mol. wt. 259.25, m.p. 190°. Dissolve 100 mg. in 100 ml. of distilled deionized water. Ethyl acetate, reagent grade (Mallinckrodt) was the extracting solvent.

Procedure—Into a 40-ml. glass-stoppered centrifuge tube, add 2 ml. of blood or urine specimen, 4.0 ml. of pH 9.0 buffer solution, 5 g. of NaCl, and 15 ml. of ethyl acetate.

With each series of samples, run a 2.0-ml. specimen of control blood or urine (preferably taken from the subject prior to medication or from a pooled control source) and a set of internal standards consisting of 2.0-ml. specimens of control blood or urine added to 2.5, 5.0, and 10.0 mcg. each of Compound I or II [0.25, 0.50, and 1.0 ml. of the methanol working solution (B or B'), respectively, is evaporated to dryness under a stream of nitrogen at 35–40°]. Stopper the tubes (seal with a drop of distilled water), shake for 10 min. on a reciprocating shaker, centrifuge (0–5°) for 10 min. at 2000 r.p.m., and transfer the clear supernatant into a 15-ml. centrifuge tube. Repeat the extraction with another 10-ml. aliquot of ethyl acetate and centrifuge. While this step is in progress, evaporate the first ethyl acetate extraction in a 50° water bath under nitrogen to a small volume \approx 1 ml. Combine the second extraction with the first and evaporate to dryness at 50° under nitrogen. Dissolve the residue in 100 μ l. of ethyl acetate and transfer quantitatively onto a 20 \times 20-cm. precoated (Silica Gel F₂₅₄) Brinkmann TLC plate. The TLC plate should be ruled into strips 2.54 cm. (1 in.) in width prior to the application of the samples. This is done to prevent the samples from diffusing into each other and also for a more uniform development of the chromatogram. Rinse the tube with 50 μ l. of methanol and combine the wash on the TLC plate. External standards of 50 mcg. of Compounds I and II [0.5 ml. of stock solution (A or A'), respectively, are evaporated to dryness under nitrogen, the residue dissolved in 100 μ l. of ethyl acetate, and transferred onto the TLC plate] are run alongside the sample extracts. The plate is developed in a vapor-saturated tank in chloroform–acetone–glacial acetic acid (85:10:7.5) until the solvent front has ascended 12–15 cm. The area on the TLC plate corresponding in R_f to that of the external standards of Compound I (R_f = 0.25–0.30) or Compound II (R_f = 0.35–0.40), respectively, is delineated using a sharp stylus.

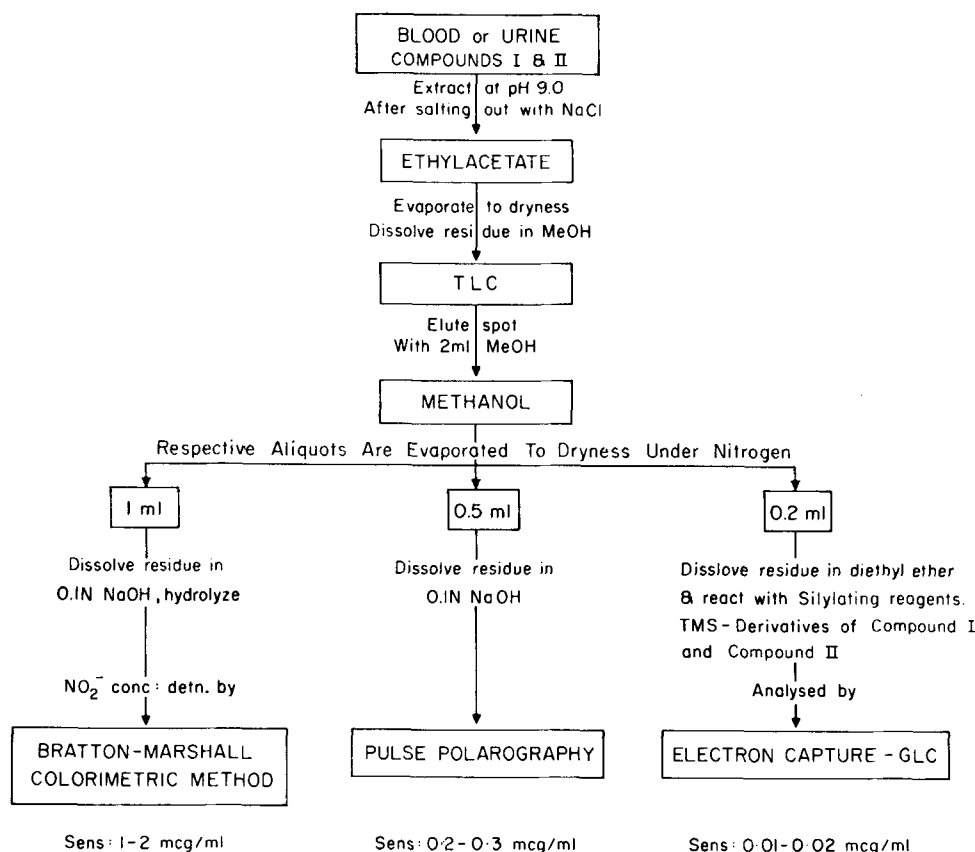

Figure 1—Flow diagram of the sequential analysis of blood and urine for the determination of Compounds I and II.

It must be noted that the visibly detectable limit of either Compound I or II on the TLC plate under shortwave UV is about 5–15 mcg. Amounts below this cannot be visibly defined; hence an area on the TLC plate 6.451 cm.² (1 in.²) corresponding to the R_f of the authentic standard is delineated, the silica gel is carefully scraped off, and transferred quantitatively into a 15-ml. centrifuge tube. The silica gel is eluted with 2 ml. of absolute methanol by slurring for 1 min. on a vortex high-speed supermixer. The sample is centrifuged and the supernatant is decanted off carefully into another 15-ml. tube. The silica gel is reeluted with another 2-ml. aliquot of methanol as before, centrifuged, and the supernatants are combined. A 1.0-ml. aliquot of the methanolic solution is set aside for polarographic or GLC assay (if desired). The remaining supernatant (≈ 3.0 ml.) is evaporated to dryness under nitrogen in a 50° water bath and the residue is dissolved in 2.0 ml. of 0.1 N NaOH. However, if the sequential analysis of the sample using the polarographic and/or GLC assays is not required, then the entire sample is used for the absorptimetric assay.

At this stage external standards of Compound I or II in amounts of 2.5, 5.0, and 10.0 mcg. (0.25, 0.50, and 1.0 ml. of standard solution B or B', respectively, are evaporated to dryness under nitrogen in a 50° water bath and the residues dissolved in 2.0 ml. of 0.1 N NaOH) are included for the determination of percent recovery and for establishing an analytical standard curve, Fig. 2A and B.

In the assay for Compound I only, transfer all the sample tubes and the external standards to a 100° water bath, allow to equilibrate for 5 min., stopper the tubes by sealing them with a drop of distilled water, and hydrolyze for 45 min. at 100°. In the assay for Compound II, however, all the sample tubes and external standards are hydrolyzed photolytically by irradiating them for 60 min. with UV energy from a Pyro Lux R-57 lamp (Luxor Corp., N. Y.). The samples are placed in a single row 30.48 cm. (12 in.) in front of the lamp which is housed in a aluminum foil-lined reflector box.

After hydrolysis, the samples are cooled in ice and acidified by adding 1.0 ml. of 4 N HCl. The samples are swirled on the vortex supermixer for 1 min. while cold, 0.5 ml. of 0.1% sulfanilamide solution is added, and the samples swirled again for 1 min. on the supermixer. Finally, 0.5 ml. of the coupling agent is added, the samples are swirled again on the supermixer for 1 min., and then allowed to stand at room temperature in the dark for 15 min. (minimum) to 30 min. (maximum) for full color development.

The absorbance of the Bratton-Marshall chromophore produced in each solution (final volume = 4.0 ml.) is measured in a 1-cm. path cell at 545 m μ in a Beckman DU or equivalent spectrophotometer.

Calculations—All biological samples are corrected for control (blank) values, and the external standards are corrected for reagent blank values.

Determination of Unknowns—The concentration of Compound I or II in the unknowns is determined by direct comparison of the absorbance of the unknowns to the mean absorptivity value of the three concentrations of the respective recovered internal standards thus:

$$\frac{A_{545} \text{ unknowns}}{[a/\text{mcg./ml.}] \text{ int. std.}} \times \frac{1}{\text{ml. of sample}} = \text{mcg. of Compound I or II/ml. of blood or urine}$$

Determine the $A/\text{mcg./ml.}$ value of each of the three concentrations of recovered internal standards and calculate the mean $A/\text{mcg./ml.}$ value of those standards. Use the mean value for determining the concentration in the unknowns.

Determination of Percent Recovery—The percent recovery of each internal standard is determined by direct comparison of the absorbance of the recovered internal standard against that of the corresponding external standards thus:

$$\frac{[A/\text{mcg./ml.}] \text{ of int. std.}}{[A/\text{mcg./ml.}] \text{ of ext. std.}} \times 100 = \text{percent recovery}$$

Polarographic Analysis

Procedure—The sample preparation was carried out as described for the absorptimetric assay up to the point where the compound is eluted off the silica gel successively with 2 \times 2 ml. of methanol, the sample is centrifuged, and the supernatants are combined in a 15-ml. tube and a 1.0-ml. aliquot is set aside for polarographic or GLC assay (if desired). A 0.2-ml. aliquot of this sample is set aside for GLC analysis and the rest is evaporated to dryness under nitrogen. The residue is dissolved in 5 ml. of 0.1 N NaOH and then transferred into the polarographic cell. The three-electrode assembly is placed in the sample solution and the sample is deoxygenated with nitrogen for 2 min. The solution was analyzed in the differential pulse

Figure 2A—Standard curves of Bratton-Marshall chromophores of nitrite ion released by the alkaline hydrolysis of Compound I (external standards and internal standards recovered from blood including TLC) compared against an equivalent NaNO_2 reference curve.

mode using instrumental parameters which will be published elsewhere (11).

The halfwave potential $E_{1/2} = -0.50$ v. for the nitro group reduction of Compound I and -0.59 v. for the nitro group reduction of Compound II, respectively. The peak area was calculated using height \times width at half-height (cm.) and the sensitivity limit was 0.30 mcg. of I or II/ml. of final solution. A typical polarogram of the reference standard *versus* that of an internal standard of 5 mcg. each of Compound I or II recovered from blood is shown in Fig. 3.

Gas Chromatographic Assay in Blood and Urine

Principle—The GLC assay uses the same extraction procedure from blood or urine and the same TLC separation step as the

Figure 2B—Standard curves of Bratton-Marshall chromophores of nitrite ion released by the photolysis in alkali of Compound II (external standards and internal standards recovered from blood including TLC) compared against an equivalent NaNO_2 reference curve.

absorptiometric assay. The silica gel covering a 6.45 cm.^2 (1 in.^2) area corresponding in R_f to that of an external standard of Compound I or II is scraped off and eluted with methanol; the eluate is transferred to a fresh tube, evaporated to dryness, and the residue is vacuum dried. The residue is reacted with the silylating reagents to yield the trimethyl silyl (TMS) derivatives of I and II, respectively (Scheme I) and is quantitated by electron-capture GLC. The sensitivity limit of detection is of the order of 10–20 ng. of compound/ml. of blood or urine.

Reference Standard for GLC Assay—Since the assay involves several steps at which losses of compound are unavoidable, such as a TLC separation and a TMS derivatization step prior to quantitation, the use of a reference standard as a means of correcting for individual variations in recovery is good analytical practice. For this

Figure 3—Polarograms of standard solutions (A and C) and blood extracts (B and D) containing an added amount of Compounds I and II, respectively.

purpose in the analysis of Compound I from biological media, an analogous nitroimidazole Compound II is used as the reference analytical standard and vice versa.

Standard Solutions—Compound I—Use working solution B from the absorptiometric assay (10 mcg./ml.). Suitable aliquots of solution B are evaporated to dryness and used as internal standards added to blood or urine for the determination of percent recovery. Aliquots of the same solution B are evaporated to dryness and used as external standards for determining the GLC standard curve.

Compound II Reference Standard—1-(3-Chloro-2-hydroxypropyl)-2-methyl-5-nitroimidazole, empirical formula $C_7H_{10}N_2O_3Cl$, mol. wt. 219.5, m.p. 77–78°. The stock solution (A') and the working solution (B') are made up as described for Compound I (see *Absorptiometric Assay*).

Parameters for GLC Analysis—Column—The column packing was a preconditioned phase containing 3% OV-17 on a 60/80 mesh Gas Chrom Q (Applied Sciences, State Park, Pa.) packed in a U-shaped 1.83-m. (6-ft.), 4-mm. i.d. borosilicate glass column.

Instrumental Parameters for GLC—A Micro-Tek gas chromatograph, model MT-220 (biomedical), was used equipped with a ^{63}Ni electron-capture detector containing a 10 mc. ^{63}Ni β -ionization source. Argon-methane (90:10) (oil pumped and dry) was used as the carrier gas, the column head pressure being adjusted to 40 psig. and the flow rate to 115–120 ml./min. The temperature settings were as follows: oven, 180°; injection port, 220°; detector, 290°. The conditions of column head pressure, flow rate, and oven temperature must be adjusted so as to obtain retention times of 5 and 6.5 min., respectively, for the TMS derivatives of Compounds I and II. A typical chromatogram is shown in Fig. 4. The solid-state electrometer (model No. 8169) input was set at 10^2 and the output attenuation was 16, giving a response of about 1.0×10^{-9} amp. for full-scale deflection (fsd); the chart speed was 76.2 cm./hr. (30 in.); and the time constant on the 1.0 mv. Honeywell recorder (model No. 194) was 1 sec. (fsd). The response of the ^{63}Ni electron-capture detector (operated in the pulsed d.c. mode) to the TMS derivatives of Compounds I and II showed maximum sensitivity at 30 v., at a 270- μ sec. pulse rate and a 3- μ sec. pulse width. Under these conditions a concentration of the TMS derivatives of 1 ng. of I:1.25 ng. of II gives nearly full-scale pen response on the 1.0-mv. recorder.

Calibration of Compound I by GLC—A calibration (external standard) curve of the peak area ratio of TMS-Compound I/TMS-

Compound II versus concentration of Compound I/ml. of *n*-hexane (final solution) is constructed as shown in Fig. 5A. Determine the electron-capture detector response ratio of the TMS derivatives of Compounds I and II using the formula:

$$\frac{\text{response of Compound I}}{\text{response of Compound II}} =$$

$$\frac{\text{peak area [height (cm.)} \times \text{width at half-height (cm.)] of Compound I}}{\text{peak area [height (cm.)} \times \text{width at half-height (cm.)] of Compound II}}$$

A fresh calibration curve is prepared for each day of analysis to establish the reproducibility of the GLC system. A similar curve of the added internal standards recovered from blood is also constructed. The amount of Compound I per aliquot of the unknown sample injected is calculated from the internal standard curve. In the analysis of Compound II, an external standard curve of the compound is constructed as shown in Fig. 5C using Compound I as the reference standard.

Since the peak area response ratio of Compound I:Compound II in any given sample is constant irrespective of the actual volume of sample injected, the concentration in the unknowns is obtained directly from the internal standard curve. Since the internal standards and unknowns are all dissolved in 1 ml. of *n*-hexane, there is no dilution or aliquot factor to be considered, unless the sequential analysis of the sample is employed (Fig. 1). The recovery factor for both internal and reference standards remains constant throughout and is not needed for the calculation of the unknowns.

Calculation of Unknowns—

$$\frac{\text{concn. (ng.) in unknown (extrapolated from int. std. curve)}}{\text{ml. of sample assayed}}$$

$$\times \frac{\text{dilution factor}}{10^{-3}} = \text{mcg. compound/ml. of blood or urine}$$

where ng. compound = amount in the aliquot of sample injected extrapolated from the internal standard curve; dilution (aliquot) factor = sample aliquot (from sequential analysis if employed); and 10^{-3} = conversion factor for nanograms to micrograms.

Figure 4—Chromatograms showing the electron-capture GLC analysis of the TMS derivatives of: (A and B) the authentic standards of I and II and (C and D) Compounds I and II recovered from blood in vitro and in vivo.

Figure 5—Standard curves of the electron-capture detector response to the TMS derivatives of Compound I using Compound II as the reference standard (A/B) and vice versa (C/D).

Sample Preparation for GLC Analysis of Blood and Urine—Reagents—Same as for the *Absorptiometric Assay*. In addition the following silylating reagents are required: hexamethyldisilazane (HMDS); trimethylchlorosilane (TMCS, Applied Science Labs, State College, Pa.); *n*-hexane, Fisher Spectrograde reagent (anhydrous).

Procedure for Blood and Urine—Into a 40-ml. glass-stoppered centrifuge tube, add 50 μ l. of reference standard solution B' of Compound II equivalent to 500 ng. and evaporate off the ethanol under nitrogen. Add a 2-ml. specimen of blood or urine and mix sample for 1 min. on a vortex high-speed mixer. Then add 4.0 ml. of pH 9.0 borate buffer, 5.0 g. of NaCl, and 15 ml. of ethyl acetate to the sample tube. Stopper the tube (sealing it with a drop of distilled water). Along with the unknowns, run a 2-ml. control specimen of blood or urine (taken prior to medication) and triplicate control specimen added to the residues of 250, 500, and 750 ng. of Compound I (25, 50, and 75 μ l. of solution B) as the internal standard and 500 ng. of Compound II (50 μ l. solution B') as the reference standard. If the sequential analysis of the samples is used (Fig. 1), then 500 ng. of Compound II must be added to the aliquots taken of both internal standards and unknowns, the methanol evaporated to dryness, and the residues silylated as described. Follow the entire extraction procedure, TLC separation of the ethyl acetate residue, and methanol elution of the respective silica gel areas corresponding to Compound I ($R_f = 0.3$) and Compound II ($R_f = 0.4$) as described in the absorptiometric assay. However, in the GLC assay *only*, the silica gel areas of Compounds I and II are combined in a 15-ml. centrifuge tube prior to elution into methanol. The samples are then eluted successively with 2-ml. portions of methanol by slurrying for 60 sec. on a vortex high-speed supermixer. The samples are centrifuged, the clear supernatant transferred quantitatively (by decanting) into another 15-ml. centrifuge tube, evaporated to dryness at 50° under nitrogen, and vacuum-dried for 15 min. (under mild vacuum) to remove all traces of moisture.

At this point in the assay a series of external standard solutions of Compound I covering the concentration range of 100 to 750 ng. in suitable increments are prepared for the determination of the external standard curve. Suitable aliquots of standard solution B, Compound I, are pipetted into 15-ml. centrifuge tubes into which 50 μ l. of solution B' containing 500 ng. of Compound II (the reference standard) are added. The methanol is evaporated to dryness and vacuum-dried to remove all traces of moisture. These standards are processed along with the sample extracts to standardize the silylation process.

The residues are dissolved in 250 μ l. of diethyl ether followed immediately by the successive addition of 40 μ l. of HMDS and by 20 μ l. of TMCS (silylating reagents) into the ether solutions. The tubes are stoppered immediately and mixed vigorously on a vortex supermixer for 60 sec. and then allowed to stand at room temperature (25°) for 15 min. to effect complete silylation of the two compounds. During this time period the samples are mixed again on the vortex mixer about 5–6 min. after the addition of the reagents. The sample tubes will develop a white precipitate of NH_4Cl due to the silylation reaction. This precipitate does not affect the reaction since the silylating reagents are present in a large excess relative to the amount of compound to be silylated.

After the 15-min. reaction period, the tubes are unstoppered and the solvent is evaporated to dryness under nitrogen at room temperature to remove the ether and all of the silylating reagents. The TMS derivatives are dissolved in 1 ml. of *n*-hexane and suitable aliquots of these standards are injected into the GLC instrument for preparing the external standard curve. This standard curve is required to establish the reproducibility of the GLC system and also for recovery determination. All the sample residues are also dissolved in 1 ml. of *n*-hexane (anhydrous) added to each tube, stoppered, and mixed well for 60 sec. on a vortex supermixer to dissolve the TMS derivatives. A suitable aliquot of this *n*-hexane extract (1–10 μ l.) is injected into the gas chromatograph for the quantitation of Compound I. The large dilution is necessary because of the high sensitivity of the electron-capture detector to the TMS derivatives of these compounds and also to reduce the sample blank.

Determination of Percent Recovery—The use of a reference standard (Compound II) in the analysis, together with the internal standard (Compound I) added to blood or urine, eliminates the need to determine the percent recovery obtained with each run. Once the actual recovery factor has been experimentally determined by GLC (*viz.*, $83 \pm 2.5\%$ for Compound I and $65 \pm 5.0\%$ for Compound II), this factor can be assumed to be constant throughout. Since the relative recovery of each compound is assumed to remain constant, any change in the overall recovery of one would be automatically reflected in the recovery of the other to the same degree. Hence, irrespective of the actual recovery of each, the response ratio of the electron-capture detector would be constant and thus compensate for any variations incurred in sample processing. Consequently the response ratio of the TMS derivatives of Compound I/Compound II in the recovered internal standards and in the unknowns would reflect the relative amounts of each compound present irrespective of the actual recovery obtained.

If the determination of the actual recovery is desired, then proceed as follows: prepare a series of standards of either Compound I or II (100 to 1000 ng.) added to blood or urine as before but *without* the addition of the appropriate reference standard. Prepare the samples as described up to the silylation reaction step. At this point, add 250 ng. of Compound I or 500 ng. of Compound II (reference standard) to the appropriate series of samples and vacuum dry the residues. Continue with the silylation reaction as described previously, dissolving the final residue containing the respective TMS derivatives in 1 ml. of *n*-hexane. A suitable aliquot of this solution (1–10 μ l.) is analyzed by GLC. The peak area response ratio of the recovered standards is directly compared against that of the external standards to determine the percent recovery of Compound I or II, respectively.

Calculation of Percent Recovery of Added Standards—The peak area response ratio of the recovered standards is plotted against concentration of the added standards of Compound I (Fig. 5B) to construct a blood-recovery curve. The slope of this curve is compared directly with that of the external standard curve of Compound I (Fig. 5A) to obtain the overall percent recovery. The same procedure is applied in the determination of the recovery of Compound II using Compound I as the reference standard. The slope of the blood-recovery curve of II (Fig. 5D) is compared directly with that

of the external standard curve (Fig. 5C) to determine the overall recovery. Alternatively, the response ratio of any one recovered standard is compared directly with that of the same concentration of the external standard, thus:

$$\frac{[\text{peak area response ratio}] \text{ rec. std.}}{[\text{peak area response ratio}] \text{ ext. std.}} \times 100 = \% \text{ recovery}$$

The sensitivity of the GLC method is of the order of 0.01–0.02 mcg. of either Compound I or Compound II/ml. of blood or urine, but the overall recovery from blood of Compound I is of the order of $83 \pm 2.5\%$, whereas that for Compound II is $65 \pm 5.0\%$ (Table I).

RESULTS AND DISCUSSION

A systematic investigation of suitable analytical parameters for use in the quantitation of *N*-1-substituted nitroimidazoles was undertaken in the development of suitable analytical procedures.

The UV absorption spectra of the two compounds determined in 0.1 *N* HCl showed absorption maxima at 325 $m\mu$ (*A*/mcg./ml. = 0.038) for Compound I and at 278 $m\mu$ (*A*/mcg./ml. = 0.029) for Compound II, respectively. The specific absorptivity was sufficient to quantitate 10–100 mcg. of each compound/ml. of final solution. The determination of the extractability of these compounds into organic solvents from blood buffered at different pH values was done initially using the UV absorption of these compounds in 0.1 *N* HCl for quantitation. It was determined that using ethyl acetate as the extracting solvent gave better than 90% recovery of these nitroimidazoles from blood buffered to pH 9.0. The recovery declined significantly at pH values greater or less than 9.0.

The ethyl acetate extract was evaporated to dryness, the residue dissolved in 0.1 *N* HCl, and backwashed with diethyl ether as a cleanup step prior to quantitation in the UV. Notwithstanding the cleanup of the sample, high UV absorption values from control blood suggested the incorporation of a TLC separation step for specificity and additional cleanup of the sample prior to quantitation. The sensitivity limits of the UV assay were unsatisfactory for use as a routine method due to high blank values from control blood and urine.

The principle of the sensitive absorptiometric assay reported by Lau *et al.* (12) was used to advantage in the absorptiometric assay described for the quantitation of these nitroimidazoles in blood and urine. The kinetics of the hydrolysis (at 100°) of Compound I to the -NO₂ ion indicated that the reaction was complete in 45 min., giving a >80% yield of nitrite ion. The yield was linear with concentration (2.5–25 mcg./4 ml.) measured against an external standard curve of NaNO₂ in concentrations equivalent to a theoretical 100% yield of -NO₂ from Compound I (Fig. 2A). Following diazotization of sulfanilamide with the released -NO₂ ions, coupling of the diazonium salt with *N*-(1-naphthyl) ethylenediamine · 2 HCl to form the characteristic Bratton-Marshall azo dye chromophore was complete in 30 min. The hydrolysis of Compound II (at 100°) to the -NO₂ ion however was erratic. Although the overall yield was >70% it was not very reproducible. The compound was noted to be unstable to light exposure, the investigation of which led to the finding that the compound undergoes photolysis to the -NO₂ ion in alkali when irradiated with UV energy from a Pyro Lux R-57 lamp. The kinetics of the photolysis of Compound II in alkali to yield -NO₂ indicated that the reaction was complete in 60 min., giving a >80% yield of nitrite ion. The yield was also linear with concentration (2.5–25 mcg./4 ml.) (Fig. 2B).

Due to the intense color of the chromophore and its high absorption, the useful range for quantitation was in the concentration range of 0.25–5.00 mcg./ml. of final solution, Fig. 2A and 2B, respectively. Concentrations of either compound greater than 5.0 mcg./ml. should be diluted.

Initial recovery experiments were conducted from blood buffered to pH 9.0, extracted into ethyl acetate, the residue of which was hydrolyzed directly in alkali and quantitated by the Bratton-Marshall procedure. The erratic recoveries and high blank values obtained indicated the need for extensive cleanup of the sample prior to quantitation. The incorporation of a TLC separation step to ensure specificity and sample cleanup, the use of deionized distilled water to reduce possible contamination with nitrite or nitrate ions in preparing the reagents, and the use of NaCl to salt out the lipoproteins after buffering the blood or urine to pH 9.0 with 1.0 *M* borate buffer achieved the necessary cleanup of the sample. The residues of the ethyl acetate extracts on TLC analysis were free of

interfering substances, especially in the areas on the chromatoplate corresponding in *R_f* to that of Compounds I and II.

The final procedure yielded an overall recovery for Compounds I and II of $72 \pm 5.7\%$ and $70 \pm 7.2\%$ from blood, respectively (Table II, A and C). The recovery from blood was linear in the concentration range of 2.5–25 mcg./4 ml. of final solution (Fig. 2A and 2B). The recovery from urine was of the order of 59 and 53%, respectively (Table II, B and D). The sensitivity limit of the assay is 0.50–0.60 mcg. of Compound I or 1–2 mcg. of Compound II/ml. of blood or urine using a 2-ml. specimen per assay and a 2:1 sample-blank absorbance ratio as the limit of detectability.

The sensitivity limits of the absorptiometric assay can be extended into the submicrogram range using the polarographic assay and further extended into the nanogram range using the GLC assay. Therefore, if the sequential analysis of a specimen of blood or urine is undertaken as shown in Fig. 1, the ultimate sensitivity limit of quantitation obtained is of the order of 10–20 ng. of compound/ml. of blood or urine by electron-capture GLC. The polarographic assay was not investigated in any great detail since its usefulness in the analysis of nitroimidazoles in general has already been demonstrated (7–11). However the recovery of 5–15 mcg. of Compounds I and II was determined to be of the order of 47 and 60%, respectively, with a limit of detectability of 0.3 mcg. of compound/ml. of blood.

The relatively low melting point and the presence of the -NO₂ group in the imidazole ring of these compounds suggested that they could be readily quantitated by electron-capture GLC with potential sensitivities in the nanogram range. However, initial attempts at GLC analysis revealed very poor response characteristics with minimum detectability in the 1–5-mcg. range together with tailing peaks. It was apparent that the polar hydroxyl groups present in the side chain of the molecules (Scheme I) were interacting with the polar liquid phase to cause tailing and also possibly reduce the electron-capture response of the -NO₂ group due to inductive effects on the imidazole ring. The silylating of hydroxyl groups on aliphatic side chains and in sterically unhindered aromatic rings is known to proceed readily at room temperature (13). The preparation of suitable silyl derivatives of these compounds was effected using diethyl ether as the solvent and was found to proceed almost instantaneously at room temperature when reacted with hexamethyldisilazane (HMDS) synergized by trimethylchlorosilane (TMCS). The reaction products were analyzed by TLC using the solvent system heptane-CHCl₃-ethanol, 50:50:10 (v/v). The chromatoplate showed the presence of a single UV absorbing spot (*R_f* = 0.50) for the trimethyl silyl (TMS) derivatives of Compounds I and II. No residual I (*R_f* = 0.20) or II (*R_f* = 0.25) was seen on the plate, indicating complete reaction. The TMS derivatives when eluted off the silica gel with diethyl ether and analyzed by GLC gave excellent response to the electron-capture detector with nanogram range sensitivity with well-resolved peaks demonstrating the feasibility of the method. An aliquot of the *n*-hexane solution of the reaction mixtures when analyzed directly by GLC also gave a single sharp well-resolved peak with the same retention time and sensitivity as the respective TLC-

^a Compound I is 1-(3-methoxy-2-hydroxypropyl)-2-nitroimidazole; Compound II is 1-(3-chloro-2-hydroxypropyl)-2-methyl-5-nitroimidazole.

isolated TMS derivatives, indicating that the reaction products were homogeneous and free from contaminating impurities. The silica gel area on the TLC plate corresponding in R_f to that of any unreacted residual parent compound that may have been present in the reaction mixture but undetectable by UV was eluted with methanol, evaporated to dryness, resilylated using the HMDS-TMCS mixture, and reanalyzed directly by electron-capture GLC. The chromatogram did not show any residual TMS derivatives, indicating that the initial silylation reaction was quantitative at room temperature.

Optimum conditions for the concomitant silylation of both compounds were obtained in diethyl ether as solvent using a 2:1 ratio of HMDS:TMCS and a total reaction time of 15 min. at room temperature for quantitative reaction. It is essential that the two silylating agents be added successively into the reaction mixture rather than from a synthetic mixture of the two reagents and that they also be vigorously mixed immediately after addition. The reaction mixture is also mixed vigorously at intervals of 5 and 10 min. after the addition of the reagents during the 15-min. reaction period. The reaction mixture is evaporated to dryness under nitrogen and the residue is dissolved immediately in anhydrous *n*-hexane without any vacuum drying. Although the TMS derivatives are stable in anhydrous *n*-hexane, they should nevertheless be analyzed by GLC as soon as possible. These derivatives are easily hydrolyzed by traces of moisture; hence it is of the utmost importance to maintain an anhydrous

environment during their preparation and subsequent analysis by electron-capture GLC. The response of the electron-capture detector operated in the pulsed d.c. mode to the TMS derivatives of I and II is linear with concentration in the range of 0.1 to 1.0 mcg. of compound/ml. of *n*-hexane equivalent to 1.0 to 10 ng./10 μ l. of sample injected. The sensitivity of the detector was such that 1.00 ng. of TMS-I and 1.25 ng. of TMS-II gave peak heights equivalent to nearly full-scale pen response for each compound on the recorder at the electrometer settings described. Since the response of the electron-capture detector to nearly equal (nanogram) amounts of the TMS derivatives of both compounds was comparable, i.e.,

$$\left[\frac{\text{peak area of TMS-I}}{\text{peak area of TMS-II}} \approx \frac{1.0}{0.8} \approx 1.25 \right]$$

the peak area ratio of the two was used as the index of detector performance and overall efficiency of the analytical procedure. Thus the external standard curve and the blood- or urine-recovered internal standard curves were constructed by plotting the peak area response ratios of TMS-I/TMS-II versus concentration of I containing a constant amount of II as the reference standard/ml. of *n*-hexane or vice versa when Compound II is the analytical peak and Compound I the reference standard. The overall recovery of 250–1000 ng. of Compound I or II from blood was of the order of 83 ± 2.5% and 65 ± 5.0%, respectively (Table I, A and B), whereas that of Compound II from urine was 82 ± 5.4% (Table I, C). The GLC method was used to extend the range of sensitivity of detection of the absorptiometric assay in the determination of blood level fall-off curves in the dog and in man.

Application of the Absorptiometric Assay in Biological Specimens—The Bratton-Marshall absorptiometric assay was applied to the determination of blood and urine levels of I and II in a dog following the administration of a single 138-mg. dose of I and a 122-mg. dose of II (equivalent to 10 mg./kg.) by i.v. and oral routes, respectively.

The blood level fall-off curves of Compounds I and II are shown in Figs. 6 and 7, respectively. Following administration by both oral and i.v. routes, blood levels were measurable for up to 12 hr. by the absorptiometric assay, beyond which time period they were non-measurable by this method (i.e., <0.5–1.0 mcg./ml.). Both compounds showed a typical biphasic i.v. blood level fall-off curve with a rapid initial distribution phase (half-life ≈ 20–30 min.) followed by a linear elimination phase with a half-life of 2.51 and 6.10 hr. for Compounds I and II, respectively.

The oral blood level fall-off curves of both compounds indicate good absorbability, Compound II showing a rapid absorption pattern with a blood level peak at 1 hr. of 11.5 mcg./ml. while Compound I showed a slower absorption pattern with a blood level peak at 2 hr. of 9.0 mcg./ml. Both compounds showed a linear elimination phase, Compound I having a faster elimination (half-life ≈ 2.55 hr.) running almost parallel with its i.v. elimination, while Compound II showed a slower elimination pattern (half-life ≈ 5.30 hr.). The blood levels in the 12–72-hr. postmedication period, where measurable, could only be determined by the electron-capture GLC assay with a sensitivity limit of the order of 0.01–0.02 mcg./ml. of blood.

The urinary excretion data following i.v. and oral administration of Compounds I and II are given in Table III, A and B, respectively. The data indicate that approximately equal amounts of both Compound I or II are recovered in the 0–72-hr. collection period following either i.v. or oral administration. This amounts to a recovery of 6.2 and 6.9% of Compound I and 7.1 and 6.6% of Compound II following i.v. and oral administration, respectively. The low percent recovery of the administered dose indicates either extensive biotransformation, tissue distribution, and/or alternate routes of elimination.

Application of the GLC Assay to Biological Samples—A blood level fall-off study on Compound I was conducted in a human subject following the administration of a single 50-mg. oral dose (0.67 mg./kg.). This study was primarily designed to test the capabilities of the GLC assay in the determination of blood levels following therapeutic doses.

The blood level fall-off curve, Fig. 8, indicates rapid absorption of the drug with a blood level peak of 1.0 mcg./ml. at 30 min. post-dosing. The levels declined to 0.5 mcg./ml. at 1 hr. followed by a plateau in the levels up to 11.5 hr. Between 11.5 and 48 hr. the levels declined progressively, with a half-life of about 8 to 9 hr. Because of

Oral	0-24	18.1	4440	4440	185.0	3.64
	24-48	15.1	3650	8090	152.1	6.63
	48-72	n.m.	—	—	—	—

^a Following single 138-mg. doses by i.v. and oral routes. ^b n.m. = not measurable, i.e., <0.5–0.6 mcg. l/ml. urine using a 2-ml. specimen per assay. ^c Following single 122-mg. doses by i.v. and oral routes. ^d n.m. = not measurable, i.e., <1.0 mcg. II/ml.

its inherent sensitivity the GLC assay thus can be used to determine blood levels in man up to 48 hr. postoral dosing following a single 50-mg. dose, and also in extending the limits of detection of the absorptiometric assay in determining blood levels in the nanogram (10^{-9} g.) range of sensitivity. This was demonstrated in the blood level fall-off curve of Compound II in a dog (Fig. 7) which indicates the range of detectability of the two assays.

Specificity of the Assay—Studies on the metabolism of the 5-nitroimidazole, metronidazole (14), have indicated that the $-\text{NO}_2$ group is stable to metabolic reduction *in vivo* and that metabolism occurs preferentially on the alkyl substituents resulting mostly in the excretion of the resulting alcohol, as such, and as the glucuronide and sulfate esters.

Since the $-\text{NO}_2$ group is left intact the presence of any metabolites in blood or urine would interfere with the specificity of the absorptiometric assay since they too would yield $-\text{NO}_2$ ion upon alkaline hydrolysis. The specificity of the three assays described

Figure 6—Blood level fall-off curves of Compound I in a dog following the administration of a single 138-mg. dose by i.v. and oral routes.

Figure 7—Blood level fall-off curves of Compound II in a dog following the administration of a single 122-mg. dose by i.v. and oral routes.

for Compounds I and II is ensured by the inclusion of the TLC-separation step which effectively resolves the intact drug from other possible metabolites and from extracted impurities. Two-dimensional TLC examination of the silica gel eluates of the spots corresponding in R_f to the intact compound (I and II) migrate as one component when cochromatographed with the respective authentic standard. Thus the spot assayed following one-dimensional TLC represents the respective intact compound only. This was further verified using the GLC assay of the compounds as their respective TMS derivatives following elution from the silica gel.

No metabolites were seen in either the blood or urine specimens in a dog following the administration of Compound I. However, several metabolites were seen in blood and urine in a dog following the administration of Compound II. Since they were all well resolved from the intact compound by TLC analysis, they do not interfere with the specificity of the three assays for Compound II.

Figure 8—Blood level fall-off curve of Compound I in man following the administration of a single oral 50-mg. dose.

Estimation of Mean Potency and Content Uniformity of Tablets: A New Approach

J. P. COMER, H. L. BREUNIG, D. E. BROADLICK, and C. B. SAMPSON

Abstract □ Current official procedures for the estimation of mean drug level and of content uniformity in individual tablets do not efficiently utilize all information available to the analyst, nor can confidence statements be made concerning the reported results. The authors present here a plan for combining readily available weight data with that from assays to generate distributions of potency per tablet. Tolerance limits on these distributions reflect not only the proportion of tablets bracketed, but also the degree of confidence to be placed in the finding. Reference is made to Monte Carlo studies on theoretical distributions as well as to examples from production lots of certain tablet items. The efficient utilization of this combined information leads to an improved method for estimating mean potency and content uniformity.

Keyphrases □ Tablets—mean potency, content uniformity □ Drug content uniformity, mean potency estimations—tablets □ Equations—tablet drug uniformity, mean potency □ Computer simulation—drug distribution, tablets

When considering drug dosage forms, the primary concern of the ethical pharmaceutical industry is that the patient receive in his individual dose an amount of medicament close to that claimed on the label. If this is so, the physician may prescribe the product with confidence that the desired drug substance will be available to perform its intended function. There are many facets to pharmaceutical quality assurance but all lead toward ensuring the identity, safety, and bioavailability of the drug of interest. This paper is solely concerned with the amount of drug substance in the unit dose. Such considerations as particle size, rates of dissolution and of absorption, freedom from impurities, and numerous others, while understood to be parts of pharmaceutical quality assurance, are not directly considered here.

Although this paper refers to compressed tablets, the techniques presented could also apply to filled capsules, ampuls, and other dry product dosage forms. Because of variation in homogeneity of granulation and in individual tablet weights, it is obviously unrealistic to expect every unit of product to possess *exactly* the same amount of physiologically active drug, but with good manufacturing practice these variations may be controlled. The subject of drug substance variability has been considered by a number of authors. Olson and Lee (1) have summarized much of the discussion and present an extensive list of references. A more recent paper is that by French *et al.* (2). Breunig (3) has emphasized the importance of weight control for individual units of product. Roberts (4) points out how easily many tablets (and filled capsules and sterile solids) may fail the USP weight variation test when based upon a sample of 20. He develops four rules for acceptance based upon the coefficient of variation of unit weights and provides charts which may be used for evaluation.

PRODUCT SPECIFICATIONS

The existence of variability in pharmaceutical products is recognized by USP XVII (5) and NF XII (6). These official compendia include at least three types of product specifications:

Rubric Limits—Referred to in the separate monographs, they are the bounds within which the mean response of samples of *N* units of product must fall based upon physiological, biological, or chemical assay. This response is in terms of the weight of drug substance per unit of product as determined upon individual units or as drug substance weight per average unit where test methods applicable to single units are not available. The bounds and the

ACKNOWLEDGMENTS AND ADDRESSES

Received July 22, 1969, from *Hoffmann-La Roche Inc.*, Nutley, NJ 07110

Accepted for publication September 15, 1969.

The authors thank Drs. B. A. Koechlin and W. B. Abrams for their interest in this study and for their critical review of the manuscript. Thanks are also due to Dr. S. A. Kaplan and Mr. S. Cotler for conducting the animal experiments, to Dr. A. S. Leon for the clinical specimens from his patient, to Dr. A. MacDonald for conducting the polarographic investigations, and to T. Danielian and R. McGlynn for the drawings of the figures.

Estimation of Mean Potency and Content Uniformity of Tablets: A New Approach

J. P. COMER, H. L. BREUNIG, D. E. BROADLICK, and C. B. SAMPSON

Abstract □ Current official procedures for the estimation of mean drug level and of content uniformity in individual tablets do not efficiently utilize all information available to the analyst, nor can confidence statements be made concerning the reported results. The authors present here a plan for combining readily available weight data with that from assays to generate distributions of potency per tablet. Tolerance limits on these distributions reflect not only the proportion of tablets bracketed, but also the degree of confidence to be placed in the finding. Reference is made to Monte Carlo studies on theoretical distributions as well as to examples from production lots of certain tablet items. The efficient utilization of this combined information leads to an improved method for estimating mean potency and content uniformity.

Keyphrases □ Tablets—mean potency, content uniformity □ Drug content uniformity, mean potency estimations—tablets □ Equations—tablet drug uniformity, mean potency □ Computer simulation—drug distribution, tablets

When considering drug dosage forms, the primary concern of the ethical pharmaceutical industry is that the patient receive in his individual dose an amount of medicament close to that claimed on the label. If this is so, the physician may prescribe the product with confidence that the desired drug substance will be available to perform its intended function. There are many facets to pharmaceutical quality assurance but all lead toward ensuring the identity, safety, and bioavailability of the drug of interest. This paper is solely concerned with the amount of drug substance in the unit dose. Such considerations as particle size, rates of dissolution and of absorption, freedom from impurities, and numerous others, while understood to be parts of pharmaceutical quality assurance, are not directly considered here.

Although this paper refers to compressed tablets, the techniques presented could also apply to filled capsules, ampuls, and other dry product dosage forms. Because of variation in homogeneity of granulation and in individual tablet weights, it is obviously unrealistic to expect every unit of product to possess *exactly* the same amount of physiologically active drug, but with good manufacturing practice these variations may be controlled. The subject of drug substance variability has been considered by a number of authors. Olson and Lee (1) have summarized much of the discussion and present an extensive list of references. A more recent paper is that by French *et al.* (2). Breunig (3) has emphasized the importance of weight control for individual units of product. Roberts (4) points out how easily many tablets (and filled capsules and sterile solids) may fail the USP weight variation test when based upon a sample of 20. He develops four rules for acceptance based upon the coefficient of variation of unit weights and provides charts which may be used for evaluation.

PRODUCT SPECIFICATIONS

The existence of variability in pharmaceutical products is recognized by USP XVII (5) and NF XII (6). These official compendia include at least three types of product specifications:

Rubric Limits—Referred to in the separate monographs, they are the bounds within which the mean response of samples of *N* units of product must fall based upon physiological, biological, or chemical assay. This response is in terms of the weight of drug substance per unit of product as determined upon individual units or as drug substance weight per average unit where test methods applicable to single units are not available. The bounds and the

mean response are generally given in terms of percentage of the labelled amount of drug.

Weight Variation Requirements—These are sampling plans for controlling the variation in weight of units of product about their sample mean. A certain proportion of the sample is expected to fall within various percentages of the mean sample weight, according to the weight class of the item. In the case of dry products, no statement is made relating the mean sample weight to the expected weight for the batch.

Content Uniformity Limits—Official at this time for certain tablet items only, these limits are specifications on drug substance weight present in individual units of product such that at least 96.7% of the assayed units are expected to fall between 85 and 115% of the mean of the rubric limits "average of the tolerances" (see Reference 5, p. 906).

None of the above specifications contains any provision for stating the degree of confidence to be placed on the experimental finding. Depending on how a sample is taken, the requirements listed may or may not characterize the population, *i.e.*, the batch or lot from which it is drawn.

PRESENT PROPOSAL

A major unexplored area in this field has been the effective utilization of information from two sources: (a) the distribution statistics obtained from large (100–200) numbers of tablets weighed on automatic recording balances, and (b) the information recorded for single unit assays on smaller numbers (3–10) of units from the same lot.

A plan is presented for combining the information from these two sources to place approximate tolerance limits on the drug substance weight in individual dosage units of the product from a lot. Several computer simulation studies have been completed. The results of these studies suggest that the proposed method for setting tolerance limits is reasonable. Since this paper is directed towards the pharmaceutical scientist, it contains no mathematical derivations. These may be the subject of a subsequent paper.

THEORY AND REFERENCES

Tolerance limits for normal distributions are discussed by several authors, including Hald (7) and Dixon and Massey (8). The assumption of normality was made for both types of populations under consideration. This assumption should be checked for a particular item by any of the usual tests for normality that the reader may judge pertinent. The following populations are considered: (a) tablet weights, say Y , and (b) drug substance in formulation material, say P .

Y is measured in milligrams per tablet (mg./tablet) and P in milligrams of drug substance per milligram of formulation material. It is also assumed that the concentration of drug, P , is independent of the weight of the tablet, Y . The relevant distribution statistics are the sample means, \bar{Y} and \bar{P} , and the sample variances, S_Y^2 and S_P^2 . These estimates are based on N_Y observations of the Y -distribution and N_P observations of the P -distribution.

The variable of interest is YP , the weight of drug substance per tablet. The unbiased estimates of the population mean and variance of YP are easily shown to be

$$\bar{Y}\bar{P} \quad (\text{Eq. 1})$$

and

$$S_{YP}^2 = \bar{Y}^2 S_P^2 + \bar{P}^2 S_Y^2 + \left(1 - \frac{1}{N_Y} - \frac{1}{N_P}\right) S_Y^2 S_P^2 \quad (\text{Eq. 2})$$

respectively, *e.g.*, Goodman (9).

The distribution of YP (even when P and Y are both normally distributed) is, in general, somewhat unmanageable, but Aroian (10) has shown that as the population coefficients of variation, of which S_Y/\bar{Y} and S_P/\bar{P} are estimates either singly or together, become small, then the distribution of YP is approximately normal. This being so, normal theory can be utilized and approximations thereof to set tolerance limits on the distribution of YP by constructing the interval

$$\bar{Y}\bar{P} \pm K(\gamma_1, \gamma_2, F) S_{YP} \quad (\text{Eq. 3})$$

where $K(\gamma_1, \gamma_2, F)$ is the multiplicative factor indexed by the degree of confidence, γ_1 , the proportion of distribution covered, γ_2 , and the degrees of freedom, F . For values of K see References 7, p. 315, and 8, p. 436. In other words,

$$\bar{Y}\bar{P} \pm K S_{YP} \quad (\text{Eq. 3a})$$

gives approximate γ_1/γ_2 tolerance limits on the distribution of values of YP , based on F degrees of freedom. For instance, if $\gamma_1 = 0.95$ and $\gamma_2 = 0.99$, the expression 95/99 indicates that one can expect, with 95% confidence, that 99% of the individual values of YP are bounded by $\bar{Y}\bar{P} \pm K S_{YP}$ utilizing the amount of information provided by F . In this case, F is not simply some linear function of N_Y and N_P , but is approximately given by

$$F = \frac{(\bar{P}^2 S_Y^2 + \bar{Y}^2 S_P^2)}{[(\bar{P}^2 S_Y^2)/(N_Y - 1)] + [(\bar{Y}^2 S_P^2)/(N_P - 1)]} \quad (\text{Eq. 4})$$

Equation 4 may be rewritten

$$F = \frac{(C_P^2 + C_Y^2)}{[(C_P^2)/(N_P - 1)] + [(C_Y^2)/(N_Y - 1)]} \quad (\text{Eq. 5})$$

where C_Y and C_P are sample coefficients of variation (also called relative standard deviation), derived from either past data, current data, or both. This formula for F was adapted from the results of Welch (11).

Additional Monte Carlo studies suggest that F , as computed in Eq. 5, will be, on the average, too large in some parametric situations. A more comprehensive treatment of the theory, as well as some suggested improvements, will be the subject of a future paper as previously mentioned.

In the next sections some of the Monte Carlo results and the application of the above equations are reported, using actual control laboratory data.

COMPUTER SIMULATIONS

As mentioned in the previous section, Aroian has shown that the distribution of YP is approximately normal if the coefficients of variation of Y and P are "small." To examine this empirically, several Monte Carlo simulations were carried out on an IBM 360-30 computer with various population coefficients of variation. As an illustrative example, the following are presented.

Initially, the histogram (Y -distribution) of 2000 hypothetical tablet weight observations shown in Fig. 1 was generated from a normal distribution with a population mean of 122.58 and variance of 4.0466. The sample mean and variance from these data were calculated to be 122.55 and 4.1299, respectively. The population coefficient of variation is 1.64%.

Secondly, the histogram (P -distribution) of 2000 hypothetical assays shown in Fig. 2 was generated from a normal distribution with a population mean of 0.7106×10^{-3} and a population variance of 0.2760×10^{-10} . The sample mean and sample variance from these data were calculated to be 0.7104×10^{-3} and 0.2730×10^{-10} , respectively. The population coefficient of variation is 0.757%.

Finally, the histogram shown in Fig. 3 is that of the products of the two random variables, Y and P , *i.e.*, YP -distribution. From the data thus generated, the sample mean and variance are 87.065×10^{-3} and 2.4610×10^{-6} , respectively. The theoretical mean and variance obtained by the proposed calculation are 87.105×10^{-3} and 2.490×10^{-6} , respectively. The population coefficient of variation is 1.81%.

It should be noted that the sample estimates of skewness and kurtosis for the YP -histogram are of the same magnitude as those for the Y - and P -histograms, thus supporting Aroian's work. Neither of these two latter sample statistics is significantly different from zero in any of the cases illustrated by Figs. 1–3.

These sampling results, in addition to Aroian's work, provide justification for using normal theory approximations for the YP -distribution.

APPLICATIONS

To test the calculations further, sufficient data from a tablet product were needed to obtain reliable estimates of sample mean potency and tolerance intervals. Fortunately, such data were available on a steroid tablet assayed by a method described in the

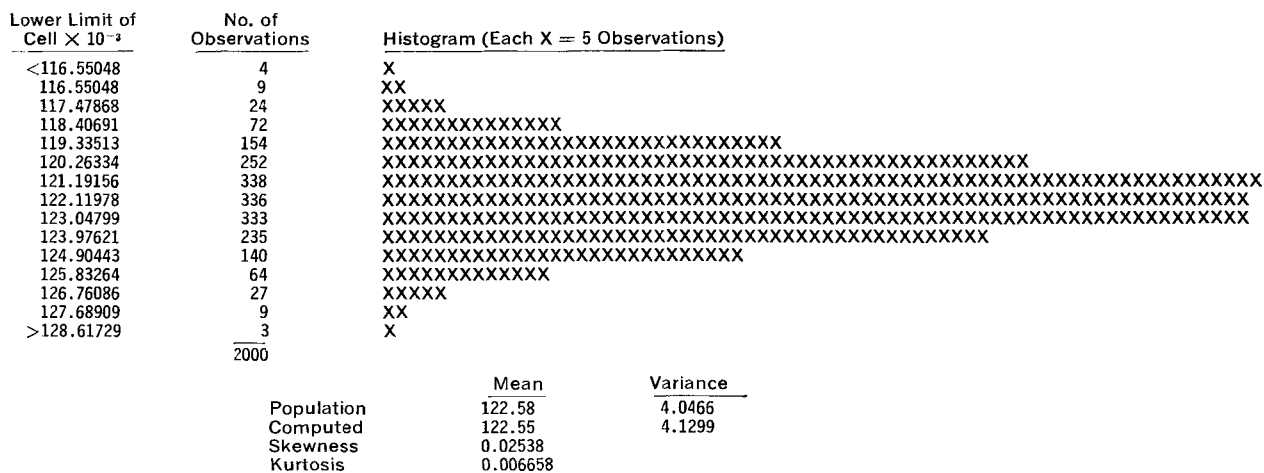

Figure 1—Histogram and distribution statistics for variable Y.

Analytical Methods section under *Mestranol Assay*. The assay has been found to be very precise and accurate. Routine control computer computations for S_V and S_P had been made on 200 lots of this product. A summary of the information from these lots is presented in Table I. There were 103 lots with a target dose of 84 mcg./tablet and 97 lots with a target dose of 86 mcg./tablet. Nine tablets per lot were assayed and this information was used to calculate drug dosage. The results of this method are reported under column heading A. The results under B are from the calculations recommended in this paper; *i.e.*, there is information from 100 tablet weighings per lot which were ignored in the A calculations but were utilized in the B calculations. When this information was combined with assay information, the 95/99 tolerance limits (in percentages of sample means) were reduced considerably by the additional degrees of freedom gained from including the tablet weight data. The mean potencies found by the two methods were not significantly different from each other.

Table II summarizes data taken from routine computer printouts for production lots of several official and proprietary items. These printouts display results computed for the conventional assay procedure as well as for the composite procedure, described in this paper. In the conventional procedure, N_x tablets are weighed and the mean weight \bar{Y}_{N_x} is obtained. These N_x tablets are assayed and the mean drug weight per tablet, \bar{x} , and the standard deviation, S_x , reported. From these are computed the 95/99 tolerance limits

$$\bar{x} \pm KS_x$$

with $F_x = N_x - 1$ degrees of freedom. It should be noted that these N_x assays are the same ones which give N_P values of P , the proportion of drug in the tablet substance, so that $N_x = N_P$. Table

II thus compares the several statistics calculated from both the conventional procedure and the authors' composite procedure. It is noted that, as a rule, the composite procedure results in shorter tolerance intervals. In the isoniazid examples, this represents the difference between rejecting and passing a lot.

Table III gives some guidance to the average number of assays and tablet weights required in order to set 95/99 tolerance limits to $\pm 15\%$ of label claim if the target is label claim and if the process is running at label claim with the population coefficients of variation, λ_Y and λ_P , listed in the first two columns of the table. This table should be used only as a rough guideline. Equations 1 through 5 may be used to prepare similar tables for various confidence levels, portions of population distribution, and postulated tolerance limits.

ANALYTICAL METHODS

Mestranol Assay—A direct reference standard tablet method previously published (12) for the determination of a 17 α -ethynyl-estradiol 3-methyl ether (mestranol) was selected for this study because of its good precision and accuracy as used in these laboratories. In the course of development and production, both domestic and foreign, more than 17,000 determinations have been made by this procedure. Nine test tablets plus three reference tablets may be assayed in 1 hr. of analyst's time. The average difference in the means of single tablet assays comparing this direct method with a manual extraction method on composite samples for a series of 260 assays was 0.56%. During an 18-month period the absorbance values per gram of the reference tablets were found to change no more than absorbance values from color reactions on freshly prepared standard solutions of mestranol. The average assay relative standard deviation for the 1800 determinations on the 200 lots

^a Average results from estimating mean and content uniformity by weighing and assaying nine tablets. ^b Average estimates from the use of the procedure recommended in this paper.

of Table I was less than 0.7%. The direct method cannot be used with tablets whose excipients react with sulfuric acid to form colored components. For such tablets, a selective method such as that reported by Tsilifonis and Chafetz (13) may be used.

Isoniazid Assay—The isoniazid from a single tablet was dissolved in water and filtered. An aliquot of filtrate was diluted with 0.003 N

HCl. The absorbance of the sample solution at 265 mμ was compared to that of a standard solution similarly prepared using 0.003 N HCl as the blank. The relative standard deviation of the method was found to be about 0.6%.

Diethylstilbestrol Assay—The diethylstilbestrol tablets were assayed by the USP procedure (5).

Atropine Sulfate—The atropine sulfate tablets were assayed by a modification (14) of an automated procedure (15) using a bromocresol purple dye complex. The tablets were dissolved in 10 ml. water and placed in the liquid sampler. Ethylene dichloride was used as the extraction solvent.

Methyltestosterone Assay—The methyltestosterone tablets were assayed by the NF procedure (6).

Phenobarbital Assay—A single tablet was disintegrated in water, made alkaline, and filtered. An aliquot of the filtered solution was diluted to a concentration of 8 mcg. of phenobarbital per ml. of 0.04% sodium hydroxide solution. The absorbance at 241 mμ of the sample solution was compared to that of a standard solution similarly prepared using 0.04% sodium hydroxide as the blank. The relative standard deviation of the method was found to be about 1.2%.

Caffeine Assay—The caffeine from a single tablet of aspirin, phenacetin, and caffeine tablets (NF XII) was dissolved in chloroform and determined by an IR spectrophotometric procedure previously published (16). The relative standard deviation of the method was found to be about 1.1%.

Paramethasone Acetate—The paramethasone acetate tablets were dissolved in 50 ml. of 50% methanol and determined by the semiautomated procedure using only the steroid manifold in the previously published method for propoxyphene hydrochloride and paramethasone acetate (17).

CONCLUSIONS

Formulas have been proposed for combining tablet weight and assay data into estimates of mean potency and content uniformity. Based on Monte Carlo simulations and also 20,000 tablet weighings and 1800 assays on 200 lots of a steroid tablet, this approach was found to be reasonable. More specific information on tolerance

intervals is obtained by the proposed method than by existing or suggested tests for content uniformity in the official compendia.

Complexes of Ergot Alkaloids and Derivatives II: Interaction of Dihydroergotoxine with Certain Xanthines

MICHAEL A. ZOGLIO and HAWKINS V. MAULDING

Abstract □ Intermolecular complexation between a mixture of the comparatively water-insoluble alkaloids comprising 9,10-dihydroergotoxine and several xanthines was investigated. Substantial elevations of aqueous solubility of dihydroergotoxine in 0.1 *N* HCl and in pH 6.65 phosphate buffer was observed in most of the cases examined. This incongruity in the normally expected solubility data may be attributed to a mutual influence between the ergot derivative and the xanthine under consideration. Dissolution studies indicated a generally enhanced first-order rate of solution in the presence of xanthine which seems to evidence some "driving force" pulling the drug into solution. Partitioning rates (aqueous to chloroform) are usually increased when xanthine is added to the 9,10-dihydroergotoxine at pH 6.65 and the reverse is true in 0.1 *N* HCl. Biological data in cats and humans are in good agreement with physicochemical work.

Keyphrases □ Ergot alkaloids, derivatives—complex formation □ Dihydroergotoxine—xanthines—interactions □ Xanthines effect—dihydroergotoxine dissolution □ Partitioning rate, dihydroergotoxine—xanthine effect □ Biological activity correlation—physicochemical data

Caffeine and other naturally occurring xanthines have previously been shown to exhibit exceptional ability for formation of stable complexes with a wide variety of substances (1–3).

Mixtures of ergot alkaloids themselves have been stated to possess a tendency toward facile intermolecular complexation (4).

The interaction of caffeine and ergotamine tartrate in aqueous solution was observed in this laboratory and is exemplified by: (a) an increased solubility of the alkaloid in the presence of caffeine; (b) an increased dissolution rate constant for the ergot alkaloid in the combination over pure ergotamine; and (c) increased or decreased partitioning rates (aqueous to chloroform) of the alkaloid in the presence of caffeine relative to ergotamine tartrate alone depending on the pH studied (5).

This attraction between ergotamine tartrate and caffeine appeared to be an extremely weak one. The isolation of the complex eluded the authors (5). These ill-defined forces may be on the order of those found in dipole-dipole, dipole-induced dipole, and induced dipole-induced dipole systems, but have not been delineated. The two component solubility curves do not lend themselves to stoichiometric analysis (5).

It was speculated at the time that these *in vitro* results might correlate to some extent with the stated clinical effectiveness (6, 7) of orally administered caffeine, ergotamine tablets,¹ and the caffeine present was functioning by holding the ergotamine in solution in the gut. Consequently, this solubilization of the complex in enteral media was thought probably to provide increased drug activity through ease of absorp-

tion (5). If the above hypothesis were correct, it was hoped that judicious selection of new potential complexing agents and their *in vitro* study and comparison might lead to more potent and efficacious substances. In the light of presently available animal and human data, this theory has been corroborated.

An investigation was carried out on the naturally occurring xanthines, caffeine, theophylline, and theobromine, as well as several of their closely related and commercially available analogs in an endeavor to discover a more suitable solubilizing agent for ergotamine tartrate and other medicinally active bases derived from ergot. The ergot alkaloid under consideration in this work was 9,10-dihydroergotoxine.² This substance is an approximately equimolar mixture of the methanesulfonate salt of three alkaloids: dihydroergocristine, dihydroergokryptine, and dihydroergocornine. These three compounds are difficult to separate and the salts thereof display only slight water solubility, although they are not as insoluble as ergotamine. The three are closely related structurally, the only deviation being in amino acid composition of the peptide side chain attached to the lysergic acid nucleus.

The simplest basic structural requirements for this specific type of complexing agent were thought to be: (a) a planar ring system or single ring; (b) absence of acid or basic functions (the comparative electrical neutrality and lack of acidic hydrogen); and (c) some degree of water solubility. This premise has shown itself to be generally correct. Pharmacologically speaking, an innocuous substance is demanded. Caffeine, theophylline, and theobromine present major drawbacks as is evidenced by their own pharmacology represented by their important clinical applications.

In most of the compounds surveyed in this project the basic xanthine prototype was maintained, and it was believed that specific structural modification of this moiety might lead to more appropriate compounds. Commercially available materials were examined with the exception of trimethyl-isocyanurate ester which was prepared (8). This is not to imply that many other molecules should not possess the ability of complexation with ergot alkaloids as many systems fit the stipulations presented in the previous paragraph.

BIOLOGICAL

The onset and duration of action upon enteral administration of dihydroergotoxine and other ergot alkaloids were recently reported to be enhanced by several of the xanthine derivatives mentioned in this study. The pharmacological parameter employed was α -adrenergic blocking activity of ergot alkaloids in cats. The data clearly show the increased activity of some ergot alkaloids when used together with suitable xanthine derivatives. This appears

Figure 1—Solubilizing action of xanthines on 9,10-dihydroergotoxine in 0.1 N HCl (pH 1.25) at 30° for 24 hr. Key: ○, caffeine; ○—, complete solution; △, theophylline; □, theobromine.

to point toward the fact that this phenomenon is due to an improved absorption picture for these compounds in cats (9).

In humans the oral absorption of tritiated dihydroergocristine—one of the three alkaloidal components of dihydroergotoxine—was both faster and more complete for a 24-hr. period on administration with 7-β-hydroxypropyltheophylline. Upon the utilization in combination with the theophylline analog this was evidenced by appreciably higher and longer lasting blood levels when the xanthine

Figure 2—Solubilizing action of xanthines on 9,10-dihydroergotoxine in phosphate buffer (pH 6.65; ionic strength 0.2) at 30° for 24 hr. Key: ○, caffeine; △, theophylline; □, theobromine.

was present compared to when the drug alone was given. It was concomitantly noted that tritiated dihydroergocristine exhibited a significant increase in the cumulative urinary excretion of tritium when the alkaloid was administered in combination with 7-β-hydroxypropyltheophylline relative to dihydroergocristine itself (9).

EXPERIMENTAL

Materials—Dihydroergotoxine substance² is a mixture of equal parts by weight of dihydroergocristine methanesulfonate, dihydroergokryptine methanesulfonate, and dihydroergocornine methanesulfonate, which melted with decomposition at 196–206°. The various xanthines employed were obtained from the following sources: theophylline, m.p. 272–274° (Matheson, Coleman & Bell); theobromine (Mallinckrodt Chemical Works); caffeine anhydrous powder USP, m.p. 238° (Pfizer); 7-β-hydroxypropyltheophylline, m.p. 135–138° (Gane's Chemical Works, Inc.); 7-(2,3-dihydroxypropyl)-theophylline, m.p. 163–166° (Aldrich Chemical Co.). Melting points are uncorrected. Reagent grade chloroform (Mallinckrodt) was employed in the partitioning studies, and 0.1 N HCl and pH 6.65 phosphate buffer were prepared in the usual manner. All pH values were measured on a Metrom pH meter and spectrophotometric data obtained from a Cary model 14 spectrophotometer.

Solubility Studies—Watertight screw-capped vials (18 ml.) containing exactly 10 ml. of solvent, dihydroergotoxine (100 mg. with pH 6.65 buffer and 400 mg. with 0.1 N HCl) and varying amounts of the xanthine, were clamped onto the edge of metal disks (15-cm. diameter) mounted on a motor-driven shaft and rotated vertically at 6 r.p.m. in a constant-temperature bath at 30 ± 0.1°. After exactly 24 hr., samples were withdrawn using pipet with filters attached and analyzed for dihydroergotoxine by the Van Urk method (10).

Dissolution Rates—Either a 25 or 60 r.p.m. stirrer motor fitted with a 2.54-cm. propeller blade placed 4 cm. from the bottom of an 800-ml. beaker containing 500 ml. 0.1 N HCl solution was used in determining these rates. The ergot alkaloid (50 mg.) or alkaloid in combination with xanthine (50 mg.:5 g.) was placed into the stirred solution from a height of about 1.5 cm. The temperature of

Figure 3—Solubilizing action of compounds on 9,10-dihydroergotoxine (100 mg.) in phosphate buffer (10 ml.; pH 6.75; ionic strength 0.2) at 30° for 24 hr. Key: ●, trimethyl-isocyanurate ester; ▲, 7-β-hydroxypropyltheophylline; □, 7-(2,3-dihydroxypropyl)-theophylline.

the dissolution rate media was kept at $37 \pm 0.1^\circ$ by immersing the beaker in a constant-temperature bath. Samples were withdrawn for analysis for dihydroergotoxine content by the Van Urk method (10).

Partitioning Studies—Fifteen milliliters of an aqueous phase (0.1 *N* HCl or phosphate buffer, pH 6.65 ionic strength of 0.20) containing alkaloid or alkaloid and xanthine (1:100) made by dissolution of dihydroergotoxine, Van Urk analysis, and addition of xanthine was added carefully to 15 ml. chloroform in screw-capped vials. The vials were sealed and rotated at 6 r.p.m. in a $30 \pm 0.1^\circ$ constant-temperature bath using the same apparatus as described for solubility studies. Five-milliliter samples were taken at 1, 3, 5, 7, and 9-min. intervals from the aqueous phase and analyzed for alkaloidal content by the Van Urk method (10).

RESULTS AND DISCUSSION

The solubility of 9,10-dihydroergotoxine methanesulfonate varies with hydrogen ion concentration as can be seen from Figs. 1 and 2. Changes in apparent solubility of the alkaloid when caffeine is added are also a function of pH up to the point of complete solution in 0.1 *N* HCl and the downward trend evidenced in Fig. 2 (pH 6.65, phosphate buffer) after addition of 35 mg./ml. caffeine. This latter phenomenon is possibly the result of saturation of the solution with the solubilized species. It is evident from Fig. 2 that solubility of the ergot derivative is raised twentyfold through interaction with caffeine at near neutral pH and 30° . The ratio of caffeine to alkaloid which can accomplish this increase is about 10:1 on a weight basis and the molar ratio is 35:1 which brings about maximum solubilization at pH 6.65. Theophylline shows a great deal less complexation in the phosphate buffer. The plateau in Fig. 2 is conceivably caused by solubility limitations of theophylline; however, the picture in 0.1 *N* HCl generally parallels caffeine. Theobromine does not appear to form a complex as may be noted in Figs. 1 and 2. This is likely a result of the poor solubility of theobromine, about 1/40 that of caffeine.

Figure 3 illustrates the interaction of three synthetic compounds and caffeine with 9,10-dihydroergotoxine methanesulfonate in phosphate buffer. Two theophylline derivatives, 7-(2,3-dihydroxypropyl)-theophylline and 7- β -hydroxypropyltheophylline, were employed, with each exhibiting comparable solubilizing properties to caffeine. Both of these compounds have good water solubilities relative to the other xanthines. The dihydroxy derivative elevates the 9,10-dihydroergotoxine methanesulfonate solubility up to a maximum of 1.5 mg./ml. under the conditions employed, while the 7- β -hydroxy derivative gives somewhat less solubilization. Trimethyl-isocyanurate ester (1,3,5-trimethyl-2,4,6-trioxo-1,3,5-triazine) (8) showed the least interaction. This may be because of its low water solubility in addition to absence of the second ring as is found in all xanthines followed by the consequent lowering of its affinity for the ergot alkaloid.

From Fig. 2 it seems the presence of less xanthine molecules is needed to solubilize each molecule of the ergot compound than was the situation with ergotamine tartrate (5).

The question as to the species comprising the complex as well as its stoichiometry is in doubt, but protonation of one or both species is likely in 0.1 *N* HCl, while at pH 6.65 almost all the caffeine and a good percentage of the dihydroergotoxine (pK_a around 6.5) is present as the neutral molecule.

The exact nature of the complex between these ergot alkaloids possessing the unusual cyclic tripeptide attached to the lysergic acid portion has not been elucidated, but work is continuing along these lines.

Complete solubility studies were not carried out in 0.1 *N* HCl as most of the alkaloid and some of the xanthine would exist as the hydrochloride salt under these conditions, and even though the amount in solution is considerable, absorption of these ionic species is doubtful (11).

The dissolution rate of poorly water-soluble drugs is considered by some to be the rate-limiting step in absorption (12-14). Dissolution rates were run on 9,10-dihydroergotoxine methanesulfonate with and without xanthine present to determine if there were any differences in rate constants. These tests were done in a relatively large volume of 0.1 *N* HCl (500 ml.) to effect "sink" conditions and allow approximation of a first-order process. A 100:1 ratio of xanthine to alkaloid was employed to correspond to the quantities found in the commercial product (6). Figure 4 gives an example of a

Figure 4—Effect of caffeine on the dissolution rate of 9,10-dihydroergotoxine in 0.1 *N* HCl (500 ml.) at 37° and 60 r.p.m. Key: ●, dissolution of 9,10-dihydroergotoxine, 50 mg.; ○, dissolution of 9,10-dihydroergotoxine, 50 mg., and caffeine, 5.0 g.

system of this kind and substantial variation may be noted in the two rate constants (a factor of three). The sizable variances in the relative rate constants are again evidenced in Fig. 5 with the ex-

Figure 5—Effect of naturally occurring xanthines on the dissolution rate of 9,10-dihydroergotoxine in 0.1 *N* HCl (500 ml.) at 37° , stirring speed 25 r.p.m. Key: ●, 50 mg. dihydroergotoxine; ○, 50 mg. dihydroergotoxine and caffeine, 5.0 g.; △, 50 mg. dihydroergotoxine and theophylline, 5.0 g.; ◻, 50 mg. dihydroergotoxine and theobromine, 5.0 g.

Figure 6—Effect of synthetic xanthines on the dissolution rate of 9,10-dihydroergotoxine in 0.1 N HCl (500 ml.) at 37°, stirring speed 25 r.p.m. Key: ●, 50 mg. dihydroergotoxine; □, 50 mg. dihydroergotoxine and 5.0 g. 7-(2,3-dihydroxypropyl)-theophylline; ■, 50 mg. dihydroergotoxine and 5.0 g. 7-β-hydroxypropyltheophylline.

ception of theobromine where the deviation from the 9,10-dihydroergotoxine standard is negligible. It is obvious that caffeine and theophylline have a large influence on the dissolution rate of the ergot alkaloid. Figure 6 shows the same phenomena of increase in dissolution rate on addition of the two theophylline derivatives to the alkaloid, with the extremely water-soluble 7-β-hydroxypropyltheophylline showing the largest rate increase as expected.

Figure 7—Plot of amount of 9,10-dihydroergotoxine remaining on partitioning of 10 ml. pH 6.65 buffer with 10 ml. chloroform in a water bath at 6 r.p.m. and 30°. Key: ●, 0.15 mg./ml. dihydroergotoxine; ○, 0.15 mg./ml. dihydroergotoxine plus 15 mg./ml. caffeine.

Figures 4–6 were derived from a typical experimental run with the only variation being a stirrer speed of 60 r.p.m. in Fig. 4 compared to 25 r.p.m. for the latter two.

Overemphasis should rarely be placed on dissolution rate data alone, but it is plain in this instance that there are significant changes in the dissolution rates on addition of xanthines, excepting theobromine. This information complements the solubility data.

During the course of investigation of the equilibrium distribution between an aqueous phase and chloroform of 9,10-dihydroergotoxine methanesulfonate with and without caffeine, it was noted that the time required for attaining this equilibrium was 15 min. in the former instance and 45 min. in the latter (Fig. 7). These data suggested perhaps the way to relate *in vitro* results to drug absorption was to study the rate of migration from one phase to another rather than look at the equilibrium distribution. The rate at which a drug distributes itself between phases does not necessarily parallel its equilibrium distribution coefficient.

A representative partitioning experiment involving the alkaloid and caffeine is illustrated in Fig. 8. The log of the 9,10-dihydroxyergotoxine methanesulfonate percentage remaining in the aqueous layer (phosphate buffer, pH 6.65) is plotted *versus* time. The graph shows that the rate for the first-order transfer of drug from aqueous phase to chloroform is substantially larger in the presence of caffeine than in its absence. The rate of caffeine partitioning from aqueous to organic phase is apparently the same with and without alkaloid. A 100:1 ratio of caffeine to 9,10-dihydroergotoxine was utilized.

In all instances of partitioning rates determined at pH 1.25 (0.1 N HCl), a retardation of transfer of 9,10-dihydroergotoxine from aqueous to organic phase was noted upon inclusion of xanthine (Fig. 9). This phenomenon is unexplained but may be due to some combination of protonation of both species coupled with interaction in acidic media. As drug absorption at this pH is rather unlikely, it was not examined further.

Partitioning rates were run in duplicate—ergotoxine *versus* ergotoxine plus xanthine—and each repeated several times. The experimental conditions approach a first-order process (see *Experimental* section) and give good results for this system. The results paralleled those found with caffeine–ergotamine with the exception of the combination 7-(2,3-dihydroxypropyl)-theophylline:dihydroergotoxine at pH 6.65. This combination exhibited no difference in partitioning rate when compared to dihydroergotoxine. This particular xanthine is insoluble in chloroform which in some way

Figure 8—Effect of caffeine on the partitioning rate of dihydroergotoxine methanesulfonate from an aqueous (phosphate buffer, pH 6.65) to an organic phase (chloroform). Key: ●, dihydroergotoxine, 0.1 mg./ml.; ○, dihydroergotoxine, 0.1 mg./ml.; and caffeine, 10.0 mg./ml.

Figure 9—Effect of 7-(2,3-dihydroxypropyl)-theophylline on the partitioning rate of dihydroergotoxine methanesulfonate from an aqueous phase (0.1 N HCl) to an organic phase (chloroform). Key: O, dihydroergotoxine methanesulfonate, 0.1 mg./ml.; □, dihydroergotoxine methanesulfonate, 0.1 mg./ml.; and 7-(2,3-dihydroxypropyl)-theophylline, 10.0 mg./ml.

relates to its inability to affect partitioning at this pH. Solubility problems precluded use of theobromine at this almost neutral pH. The 7- β -hydroxypropyltheophylline was tested in humans with dihydroergocristine, and the same relative results were obtained and are listed in the *Biological* section.

It has been reported by the authors (5) that when a complexing agent is present in partitioning studies, the alkaloid is transferred directly to the organic phase, while in cases of the alkaloid alone a precipitation step precedes this transfer. The increased partitioning at enteral pH (6.65) was probably not due to transfer of complex between phases, but rather to partial prevention of a precipitation step which occurred when the alkaloid itself was present in the aqueous phase.

CONCLUSIONS

The utilization of simple physicochemical studies as a rapid ranking or screening device of known or suspected biologically active agents preceding the tedious and expensive animal and human work is an ultimate goal of these investigations.

In general, the *in vitro* partitioning rate data obtained thus far indicate absorption potentiation at neutral pH should be observed

with ergot alkaloids having the polypeptide moiety intact upon addition of certain xanthines such as caffeine. This phenomenon has been examined both for 9,10-dihydroergotoxine methanesulfonate and ergotamine tartrate (5). The rate effect, however, is reversed at gastric pH. Dissolution rate constants are usually increased in 0.1 N HCl solutions upon inclusion of xanthine while solubility of the alkaloid at enteral and gastric pH is elevated by most xanthines discussed.

An exceptional degree of success has been achieved in correlation of *in vitro* data with the increased clinical effectiveness of ergot alkaloids in the presence of complexing agents (6, 7). Recent clinical and animal evidence has substantiated the previously obtained *in vitro* results stated in this communication (9).

This ergot alkaloid:xanthine interaction is somewhat unusual as it is an exceptional example where complexation in the gastrointestinal tract leads to enhanced rather than decreased absorption of a medicinal agent.

Micellar Solubilization of Barbiturates I: Solubilities of Certain Barbiturates in Polysorbates of Varying Hydrophobic Chain Length

A. A. ISMAIL*, M. WAFIK GOUDA†, and M. M. MOTAWI*

Abstract □ The effect of the hydrophobic chain length of the non-ionic surfactants, polysorbates, on the degree of solubilization of a series of 5,5-disubstituted barbituric acid derivatives was studied. The solubilities were found to increase as the hydrophobic chain length increases. A pseudo two-phase model, according to which the drug molecule is partitioned between an aqueous phase and a micellar phase, was selected to determine the effect of the chemical structure of the solubilize on the degree of solubilization. The number of carbon atoms of the substituents on the 5-position, as well as their inductive effects, was found to determine the extent of solubilization.

Keyphrases □ Barbiturates—solubilization □ Micellar solubilization—5,5-disubstituted barbituric acid derivatives □ Polysorbates, barbiturate solubilization—hydrophobic chain length effect □ UV spectrophotometry—analysis

Molecules of materials classed as surface-active agents possess polar and nonpolar characteristics. They are able to remain in solution at higher concentrations by orienting themselves in aggregates known as micelles (1). Surface-active agents, at a concentration above the CMC, are widely used as a means of producing aqueous solutions of insoluble or poorly soluble drugs (2). This phenomenon is known as micellar solubilization. Non-ionic agents are by far the most popular in pharmaceutical formulations. This is due mainly to their low toxicity combined with their good solvent action. Although a wide range of nonionic surfactants are available, those most frequently employed are the polyoxyethylene sorbitan fatty acid esters and the polyoxyethylene monoalkyl ethers. Numerous studies on the solubilities of various drugs in these nonionic surfactants were reported (2).

The barbiturates are among the most frequently employed hypnotic and sedative drugs. They are used both as the free acids and as salts (usually sodium or calcium). Because of the instabilities and incompatibilities of the salts, the free acids are recommended to be used with other soluble drugs. These acids are slightly soluble in cold water. This limited solubility represents a problem in formulating aqueous preparations and elixirs (3). Polysorbate 80 was used to prepare aqueous solutions of phenobarbital (4). Gusiakov *et al.* found that the solubility of barbital increases in 2% solutions of polysorbates 20, 40, 60, and 80¹ (5). Küttel (6, 7) reported the solubilities of phenobarbital, barbital, and butabarbital in solutions of polysorbates 20, 60, and 80 at room temperature (16–24°). None of these reports have presented quantitative information concerning the effect of the chemical structure of the solubilizer or

solubilize on the degree of solubilization. This paper deals with the study of the solubilization of certain 5,5-disubstituted barbituric acids, which differ from one another only in carbon content of their substituents, in aqueous solutions of polysorbates of varying hydrophobic chain lengths. The data presented might help in gaining some insight into the mechanism of solubilization of such semipolar pharmaceuticals.

EXPERIMENTAL

Materials—The following surfactants were used as received: polysorbate 20, polyoxyethylene 20 sorbitan monolaurate; polysorbate 40, polyoxyethylene 20 sorbitan monopalmitate; polysorbate 60, polyoxyethylene 20 sorbitan monostearate; polysorbate 80, polyoxyethylene 20 sorbitan monooleate.

The barbiturates used and their melting points² were: phenobarbital, 5-ethyl-5-phenylbarbituric acid, m.p. 173–174°; barbital, 5,5-diethylbarbituric acid, m.p. 185–187°; amobarbital, 5-ethyl-5-isoamylbarbituric acid, m.p. 153–155°; diallylbarbituric, 5,5-diallylbarbituric acid, m.p. 169–170°; cyclobarbital, 5-(1-cyclohexenyl)-5-ethylbarbituric acid, m.p. 170–171°; butethal, 5-ethyl-5-butylbarbituric acid, m.p. 120–122°; secobarbital, 5-allyl-5-(1-methylbutyl)barbituric acid, m.p. 89–91°.

Assay Procedure—All barbiturates were assayed by the differential UV spectrophotometric procedure of Walker *et al.* (8) using a Unicam SP 500 spectrophotometer. The presence of surfactants did not interfere with this method.

Solubility Determinations—Excess quantities of the solid barbiturate were placed in 50-ml. rubber-stoppered bottles together with varying concentrations of 25-ml. solutions of the polysorbates in 0.003 *N* sulfuric acid. The weakly acidic solution was employed as the solvent to suppress any dissociation of the barbituric acid derivatives. The bottles were rotated in a constant temperature water bath at 30 ± 0.2° for 24 hr. This time was found to be sufficient for equilibrium to be attained. After equilibrium, aliquot portions of the supernatant liquid were removed and assayed for their barbiturate contents.

RESULTS AND DISCUSSION

Solubilization of the Barbiturates—The solubility curves for the barbituric acid derivatives are shown in Figs. 1–7. The curves show the effect of concentrations of polysorbates, well beyond the reported CMC (9–11), on the apparent solubilities of the drugs. All barbiturates studied showed increased solubilities in the presence of the polysorbates. This increase in solubility is looked upon here as due to true or micellar solubilization. Other workers (12–14) have found increased solubilities of similar semipolar drugs in solutions of various nonionic surfactants due to the same phenomenon. The apparent solubility increased linearly with the concentration of the surfactant as would be expected of micellar solubilization of such polar solubilizates (11, 12, 15, 16, 18).

Effect of Hydrophobic Chain of Solubilizer—In comparing the solubilizing power of different homologs of solubilizers, the ratio of moles of solubilize:moles of micelles is the sensible criterion for comparison (17). This comparison involves the assumption that all the surfactant in excess of the CMC is in the form of micelles and

¹ Marketed as Tween 20, 40, 60, and 80 by Atlas Chemical Industries, Inc., Wilmington, Del.

² Uncorrected melting points determined with a Thomas-Hoover Unimelt.

that the number of units in the micelle remains constant. Although this is an approximation, it still has practical merit (17). Polysorbates 20, 40, 60, and 80 have the same hydrophilic portion in their molecule but differ in the length of the carbon atom chain of their lipophilic portion. The solubilizing capacity of the different polysorbates could be compared by calculating the slopes of the solubilization isotherms beyond the CMC. These slopes were calculated using the method of least squares. Table I shows the solubilizing capacities expressed as milligram drug per gram polysorbate and as mole drug per mole micellar solubilizer. The weight of each barbiturate solubilized per gram of polysorbate has its practical usefulness. The molar concentrations of polysorbates were calculated from the following molecular weights: polysorbate 20, 1226; polysorbate 40, 1282; polysorbate 60, 1310; polysorbate 80, 1308. Since polysorbates are heterogeneous, the significance of the molar values has its limitation.

On examining the slopes of the isotherms expressed on molar basis, it is found that all barbiturates showed a slight but gradual increase in solubility as the hydrophobic chain length of the solubilizer is increased. This increase in solubility is considered to be due to increase in the volume of the hydrocarbon in the micelle interior. In an idealized picture of spherical micelles the alkyl portions may be visualized as being directed inward. An increase in their length would result in micelles of larger size, and larger micelles will accommodate more solubilize (16). Similar results were obtained by other workers when examining the solubilities of other semipolar pharmaceuticals (11, 14).

Effect of Chemical Structure of Solubilize—In order to compare the effect of the chemical structure of the solubilize on the degree of solubilization, a pseudo two-phase model was selected. According to this model, the solubilize molecule is partitioned between an aqueous phase and a micellar phase. McBain and Hutchinson (17) suggested that a truer view is seen if solubilization is regarded as a partition between the micelle and water. The formation of hydrocarbon regions in micelles is a good justification for treating the micelles as a separate phase. The partition coefficient K , associated with this process, was determined according to the following equation:

$$K = \frac{[D_M]}{[D_{NM}]}$$

where $[D_M]$ and $[D_{NM}]$ are the concentrations of drug, expressed as moles per moles, in the micellar and nonmicellar phases, respectively. The slopes of the solubilization isotherms expressed on molar

basis will give the values for $[D_M]$. The number of moles of drug solubilized per mole of acidified water at 30° will give the values for $[D_{NM}]$. Table II lists the values of K for the various barbiturates in the different polysorbates studied. In a series of compounds such as the 5,5-substituted barbituric acids, which differ from one another only in carbon content of their substituents, the distribution coefficient would be expected to change with the alteration of the lipophilic character of the substituents as well as the influence these groups exert on the rest of the molecule. This influence will be mainly in the form of polar or inductive effects (19). The partition coefficients of the barbiturates between the micellar pseudophase and the aqueous phase in decreasing order are: secobarbital > amobarbital > phenobarbital > cyclobarbitol > butethal > diallylbarbituric acid > barbital. As seen, the value of K increased with increasing the

number of carbon atoms in the substituents on the 5-position. These results compare favorably with the distribution coefficients of the same compounds between 1-octanol and water as determined by Hansch and Anderson (20). In their report the values of the distribution coefficients of the barbiturates between 1-octanol and water were in the following order: secobarbital > amobarbital > butethal > phenobarbital > cyclobarbitol > diallylbarbituric acid > barbital. In comparing their results to the degree of solubilization of the barbiturates, as expressed by K , the authors found that phenobarbital and cyclobarbitol show a higher degree of solubilization than what would be expected from their distribution between 1-octanol and

^a Limited supply of the drug necessitated the use of a lesser number of surfactants.

water. As a result, phenobarbital and cyclobarbitol showed higher K values than butethal which is reported to have a higher distribution coefficient. The increase in the extent of solubilization of these two barbiturates is attributed to the polar effect the phenyl and cyclohexenyl group exert on the hydrophilic portion of the barbiturate molecule. This polar effect will act in such a way as to increase the interaction between the hydrophilic portion of the barbiturate molecule and the hydrophilic portion of the polysorbate molecule. Such interaction may enhance the solubilization process. Further evidence for the effect of the phenyl group in enhancing the extent of interaction of the hydrophilic portion of the barbiturate molecule was obtained when the authors carried out an investigation of the solubilities of the same barbiturates in solutions of polyoxyethylene stearates of varying hydrophilic portion in their molecule. Phenobarbital was the

^a Limited supply of the drug necessitated the use of a lesser number of surfactants.

only barbiturate to form an insoluble precipitate complex indicative of a greater extent of interaction. The results of this investigation will be the subject of a future communication.

Solubilization Type—Micellar solubilization was broadly classified into three types (16): first, adsorption on the surface of the micelle; second, incorporation in the hydrocarbon center of the micelle, a form of solution; and third, incorporation by penetration into the palisade layer of the micelle with the solubilize oriented in approximately the same manner as is the surfactant molecule in the micelle. Mulley (1) suggests that solubilization even of polar materials in nonionic surfactants is probably due mainly to a solution process within the micelles rather than due to specific factors such as complex formation or adsorption on the surface of the micelles. He

states that other factors obviously play a part but a solution process still predominates. The results obtained in this work support the assumption that the solubilization of the semipolar molecules, the barbiturates, in polysorbate solutions is essentially a micellar solubilization.

The order of the partition coefficient *K*, calculated from the solubility data of the various barbiturates studied, lends support to the suggestion of Mulley and leads the authors to believe that here also the type of solubilization is mainly a solution within the micelles together with some other factors playing a minor role. In the case of the barbiturates these factors are probably interactions between the hydrophilic portion of the solubilizer and that of the solubilize.

SUMMARY

1. All barbiturates studied showed increased solubilities in the presence of the nonionic surfactants, polysorbates.
2. The amount of barbiturate solubilized was a linear function of the concentration of the polysorbates, characteristic of micellar solubilization of semipolar molecules.
3. The degree of solubilization increased with increase of the hydrophobic chain length of the solubilizer due to formation of larger micelles.
4. The increase in the number of carbon atoms in the substituents on the 5-position of the barbituric acid molecule, together with the polar or inductive effects of such substituents, determined the extent of solubilization.
5. The order of solubilization of the drugs compared favorably with the order of their distribution coefficients between 1-octanol and water.
6. Phenobarbital and cyclobarbital showed a greater extent of solubilization due to the inductive effect of the phenyl and cyclohexenyl groups resulting in a greater interaction between the hydrophilic portion of the solubilizer and that of the solubilize.
7. The mechanism of solubilization is thought to be mainly a solution within the micelles together with other factors playing a role in the solubilization.

Improved Thin-layer Chromatographic Identification of Tetracyclines and Their Degradation Products: Application to an Epimerization Study

N. D. GYANCHANDANI*, I. J. MCGILVERAY, and D. W. HUGHES

Abstract □ An improved thin-layer chromatographic method for the identification of pharmaceutically important tetracyclines and their degradation products is presented. A process is used which conditions the plates with optimum moisture content so that they may be stored without special precautions for as long as 4 weeks before use. Two solvent systems and four spray reagents for the separation and detection of tetracyclines and their degradation products are also presented. Tetracycline hydrochloride and chlortetracycline hydrochloride were allowed to epimerize in phosphate and acetate solutions, respectively. With the aid of UV spectroscopy and TLC analysis, it is demonstrated that epimerization is accompanied by extensive degradation.

Keyphrases □ Tetracyclines, degradation products—identification □ Epimerization, tetracyclines—reaction products separation, identification □ TLC—separation, identification □ UV light—TLC spot visualization

Thin-layer chromatography (TLC) has been used by a number of workers to separate and characterize certain tetracyclines of pharmaceutical importance (Table I) using adsorbent layers of silica gel (1, 2), kieselguhr (3–5), and microcrystalline cellulose (6). Difficulties encountered in these separations have been attributed to the property of tetracyclines to form chelate complexes with metallic ions and to lack of moisture in the support. Hence, sequestering agents (1–5) and glycerin (7) or mixtures of glycerin with polyethylene glycol 400 (PEG 400) (4) have been added to the support.

Of the various methods reported, two (3, 4) are most useful since they can resolve two or more tetracyclines in a single system on one chromatogram. Of these, the one employing the coating of kieselguhr containing

EDTA and a developing solvent consisting of methyl ethyl ketone saturated with McIlvaine's buffer (pH 4.7) (3) was especially good for the separation of various degradation products of the tetracyclines. The other method (4), which employs acid-washed diatomaceous earth impregnated with EDTA at pH 7.0 and a glycerin-PEG 400 mixture, and which uses ethyl acetate as the developing solvent, was found satisfactory for the resolution of tetracyclines, though often it was necessary to chromatograph two to four times. In both cases, however, problems in their application were encountered. The most serious difficulty with the former method (3) was the frequent and erratic splitting and streaking of the tetracycline spots. The latter method (4) involves rigid adherence to a lengthy procedure in which the diatomaceous earth is repeatedly washed to remove binder and other acid-soluble materials. This was found not to be reproducible without considerable experience. Furthermore, the plates must be freshly prepared and used immediately. The method is, therefore, particularly inappropriate in situations where a large number of chromatograms must be run in a short time.

The tetracyclines have most commonly been detected on chromatograms by their fluorescence under long-wave UV light, either with or without exposure of the chromatograms to ammonia vapor (1, 3–5, 8). A few chromogenic spray reagents were described in the earlier literature (1) but have been largely abandoned in recent publications.

This communication describes a simple, rapid, and reproducible method for the separation of six tetracyclines presently marketed in numerous dosage forms.

Anhydrotetracycline (ATC)	(II)	H	—	—	—	N(CH ₃) ₂	H	—
Epianhydrotetracycline (EATC)	(II)	H	—	—	—	H	N(CH ₃) ₂	—
Anhydrochlortetracycline (ACTC)	(II)	Cl	—	—	—	N(CH ₃) ₂	H	—

Various degradation and reaction products are also well separated, even when chromatographed on 4-week old plates. Four spray reagents for the detection of these antibiotics are presented. This TLC method has been used in a preliminary qualitative study of degradation products, other than epimers, formed when tetracycline hydrochloride (TC·HCl) and chlortetracycline hydrochloride (CTC·HCl) (see Table I) were allowed to epimerize at three different pH values at room temperature.

EXPERIMENTAL

Reagents—EDTA disodium salt, glycerin, PEG 400, methyl ethyl ketone, dichloromethane, ethyl formate, sodium phosphate monobasic, sodium acetate, all analytical grade reagents.

Preparation of Plates—With the aid of an applicator, five glass plates (20 × 20 cm.) were coated with 0.25-mm. layers of a slurry of 50 g. kieselguhr G (Merck) in a homogeneous mixture consisting of 95 ml. 0.1 M EDTA in water and 5 ml. 20% v/v PEG 400 in glycerin. The plates were allowed to dry at room temperature for at least 4 hr. (preferably overnight), then developed in the Solvent System I (see below) up to the top of the plate. They were then dried and stored in a dust-free atmosphere with no drying agent.

Spotting the Solution—Two microliters of 2 mg./ml. methanolic solutions of the tetracyclines [aqueous solutions in case of rolitetracycline (RTC)] were spotted as usual, 2 cm. from the edge of the plate.

Solvent Systems—I—Methyl ethyl ketone saturated with McIlvaine's buffer (pH 4.7) (3).

II—Dichloromethane-ethyl formate-ethanol (9:9:2) saturated with McIlvaine's buffer (pH 4.7).

Spray Reagents—I—Fast Blue B (Diazo-Reagent)—Spray Solution A: 0.5% aqueous, freshly prepared solution of fast blue B; Spray Solution B: 0.1 N NaOH (aqueous) (1a).

II—Diazotized *p*-Nitroaniline (1b)—Spray Solution A: just before spraying, 5% aqueous sodium nitrite solution (1.5 ml.) is

added to 0.3% *p*-nitroaniline in 8% HCl (25 ml.); Spray Solution B: 20% aqueous sodium carbonate solution. After spraying with Solution A, the developed chromatogram is sprayed with Solution B, taking care not to make the plate transparent with an excess of the sprays.

III—Modified Sakaguchi Reagent (9)—Boric acid (5 g.) is dissolved in water (150 ml.) and concentrated sulfuric acid (350 ml.). The reagent is stored in a glass-stoppered bottle in a refrigerator and is used cold.

IV—Diphenylpicrylhydrazyl (DPPH) Reagent (10)—Solution A: methanolic solution of DPPH (~1 mg./2 ml.); Solution B: 25% aqueous NaOH solution.

Detection—All the tetracyclines and many of their degradation products could be detected by their fluorescence in longwave UV light (Black Ray UVL-22). For the visualization of the spots in daylight the dried chromatogram was sprayed with one of the spray reagents I-IV. With the first three reagents, colored spots are observed on a nearly white background but with spray reagent IV yellow spots on a bluish white background are obtained (Table II).

Epimerization Experiments—Five milliliters each of 1% aqueous solutions of TC·HCl and CTC·HCl were separately diluted to 25 ml. with distilled water (reference solution), 0.1 M sodium dihydrogen phosphate (aqueous) (pH 4.1), and 0.1 M sodium acetate (aqueous) (pH 7.3). The solutions were kept at room temperature in 25-ml. volumetric flasks and wrapped in aluminum foil for protection from light. At convenient time intervals, 2 μl. of each solution was examined by TLC using Solvent Systems I and II. Simultaneously, 0.2 ml. of each solution was diluted to 25 ml. with 0.1 N H₂SO₄ and immediately scanned between 210 and 400 mμ,¹ noting the absorbance at 254, 267, 298, and 355 mμ. The UV spectra (210–400 mμ) of the three TC·HCl solutions at 0 and 620 hr. are shown in Fig. 1. The corresponding spectra for CTC·HCl are presented in Fig. 2. The TLC of these solutions at 0, 24, and 620 hr. are schematically represented in Fig. 3.

^a R_f values vary considerably with tank temperature, especially in case of stored plates. If very low R_f values are obtained, the chromatograms, after brief drying may be rechromatographed in the same solvent system. ^b Pk = pink, Y = yellow, Br = brown. ^c Colors change with excess of spray reagent and with time. ^d Limit of detection is not given since very pure samples were not available.

RESULTS AND DISCUSSION

In the procedure of Ascione *et al.* (4) the support of diatomaceous earth is washed with hot 6 *N* HCl until the washings no longer show the presence of calcium or iron. It is then washed with water until a neutral pH is obtained and dried at 105°. This somewhat tedious process required considerable experience to obtain an acid-washed neutral support, and some batches, perhaps less well washed or dried, gave chromatograms with streaks and tails. Thus, it was decided to use as support the commercially available kieselguhr G (Merck) without treatment other than impregnation with EDTA and glycerin-PEG 400 mixture. Though the tetracyclines with R_f 0.4 and lower gave well-shaped spots, those with higher R_f values showed irregular zig-zag patterns, which appeared to be due to the glycerin-PEG mixture which was also moving with the solvent.

The same results were obtained when the amount of glycerin-PEG mixture in the preparation of the slurry was greatly reduced. This defect was, however, completely remedied when the plates were first developed in Solvent System I and allowed to dry before spotting. This process also conditioned the plates with optimum moisture content and allowed a satisfactory resolution of the tetracycline spots, even after the plates were stored up to 4 weeks. In this system, one run with the solvent gave satisfactory resolution of the various spots, in contrast to the published method (4) where it is almost always necessary to chromatograph two to four times. It was ascertained by two-dimensional TLC that no degradation of the tetracyclines occurred on the plates.

Though a few spray reagents for the detection of tetracyclines have been reported by earlier authors (1), they proved unsatisfactory under chromatographic conditions in this laboratory. Recent

authors have exclusively made use of longwave UV light for the detection of these compounds (2-8). In an attempt to find a spray reagent which might be useful for the quantitation of tetracyclines by densitometric methods, several sprays used for the detection of phenols and amines (1c) were tried. Of these, the four described in the experimental section were found to give colored spots with various tetracyclines and their degradation products (Table II). Though these spray reagents are not as sensitive as the use of UV light, they are satisfactory for most detection purposes.

TLC of Tetracyclines—The chromatography of tetracyclines in Solvent Systems I and II is schematically represented in Fig. 4 and a compilation of approximate R_f values obtained with both the solvent systems is shown in Table II. With the exception of CTC and doxycycline (DOXY) all other tetracyclines are well separated

Figure 4—Schematic chromatogram of tetracyclines in Solvent Systems I (left) and II (right). Samples: 1, CTC; 2, DOXY; 3, OTC; 4, DMCTC, TC, and MC; 5, CTC, DMCTC, MC, and OTC; 6, DOXY and TC.

from one another in Solvent System II. CTC and DOXY can also be separated from each other in a system composed of dichloromethane-ethyl alcohol (18:1) saturated with the above-mentioned McIlvaine buffer. Though oxytetracycline (OTC) moves higher than TC or methacycline (MC) in System I, it has an R_f value lower than these compounds in System II. Rolitetracycline (RTC), which carries the pyrrolidinomethyl moiety in Position 2 (Table I), did not move in these systems but did so when the alcohol content in System II was increased [dichloromethane-ethylformate-ethanol (2:2:1), R_f = 0.15]. Furthermore, any tetracyclines formed by hydrolysis of RTC can be easily detected by employing System I or II.

TLC of Degradation Products—Following the reports of a Fanconi-like syndrome that developed in patients after the ingestion of outdated or degraded tetracycline capsules (6, 10, and references contained therein), concern was expressed over impurities and degradation products in tetracyclines. 4-Epi-, anhydro-, and 4-epianhydro-derivatives of tetracycline (Table I) have been implicated as the most toxic degradation products accompanying tetracycline (11). 4-Epianhydrotetracycline in relatively large doses was the causative agent of renal tubular damage in the rat and the dog, producing urinary findings suggestive of Fanconi-type syndrome (11). Furthermore, the epimers have been found to possess less than 5% of the antibiotic activity of the parent tetracycline (11).

Solvent Systems I and II are suitable for the separation of epitetraclines from their parents and of epianhydrotetracycline from tetracycline. Anhydrotetracycline and anhydrochlortetracycline both move to the solvent front in Position 1 but have reasonable mobilities in System II (see Table II).

Epimerization Experiments—The TLC method was successfully applied to a qualitative study of degradation products other than the epimers that may be formed in solutions of tetracyclines. Previously, the process of epimerization has been studied spectroscopically (12–14) and use has been made of 254 $m\mu$ /267 $m\mu$ and 355 $m\mu$ /298 $m\mu$ absorbance ratios (14) to follow the epimerization. The decrease in absorbance in the 300–380 $m\mu$ region in the spectra of tetracyclines has been regarded as an indicator for degradation other than epimerization.

In this study, TC·HCl and CTC·HCl were separately allowed to epimerize in phosphate and acetate solutions side by side with the corresponding aqueous solutions at room temperature, and the reaction products were studied at suitable time intervals both spectroscopically and by TLC.

The results obtained by spectrophotometric study were in accordance with the earlier epimerization studies (12–14). The UV spectra of TC·HCl and CTC·HCl in the three systems (aqueous, phosphate, and acetate) are shown in Figs. 1 and 2, respectively, and the corresponding TLC results are represented schematically in Figs. 3A and 3B, respectively. It was evident from both the chromatographic and spectroscopic evidence that there was considerable degradation other than epimerization occurring in each system. TLC analysis, however, appears capable of giving more detailed information on the excessive degradation than does the absorbance ratio analysis or the UV absorbance in the 300–380- $m\mu$ region.

In addition to the gradual change in color of the phosphate solutions, yellowish-gray deposits also formed and were collected at the end of about 620 hr. They were dissolved in mixtures of ethyl acetate-methanol (~1:3) and on TLC each showed at least four minor spots, beside the one major spot corresponding in R_f values (Sys-

tems I and II) to that of the parent tetracycline. Though no further study of these spots was undertaken, it seemed probable that during the process of epimerization, some of the antibiotic was precipitated out of the solution perhaps in the form of phosphate complex. In the acetate system the corresponding deposit was gray in each case and was dissolved in formic acid-methanol (~1:3). On TLC it showed at least seven spots, none of them corresponding to those reported earlier.

The TLC methods described here thus indicated the extensive degradation which occurs in solutions of tetracyclines and may be of value in studying the stability of liquid pharmaceutical preparations containing tetracyclines. If products similar to those detected in the epimerization study are found, it will be important to determine their nature and toxicity.

Effect of Silica Gel on Stability and Biological Availability of Ascorbic Acid

E. De RITTER, L. MAGID, M. OSADCA, and S. H. RUBIN

Abstract □ The alleged interaction of silica gel and ascorbic acid has been investigated in model experiments and in practical tablet trials, using wet granulation procedures. In simple mixtures stored for 3 weeks at 45° in closed tubes, losses of ascorbic acid increase progressively with increasing moisture content, whether or not silica gel is present, although losses are higher in the presence of silica gel. At an equivalent percentage of water in such mixtures, the amount of silica gel or the prior adsorption of 1½ times its weight of vitamin E on the silica gel, did not influence the loss of ascorbic acid. The data show that silica gel binds a certain fraction of the water present and that the loss of ascorbic acid is directly proportional to the amount of unbound water in the system. Sodium ascorbate is more sensitive than ascorbic acid to aerobic oxidation in the presence of moisture. Other commonly used tablet excipients, as well as silica gel, enhance losses of ascorbate. However, proper technology applied to wet granulation procedures yields excellent recoveries and stability of ascorbic acid or sodium ascorbate in dried granulations and in finished multivitamin tablets. The human bioassay technique, in which extra urinary excretion of ascorbic acid after tablet dosage is compared to that after dosage of ascorbic acid in water, has been used to demonstrate the full physiological availability of ascorbic acid in the presence of silica gel. Storage of such tablets for 3 months at 45° did not alter the complete bioavailability of the ascorbic acid.

Keyphrases □ Ascorbic acid—stability, biological availability □ Stability, ascorbic acid—humidity, excipient effects □ Silica gel effect—ascorbic acid stability, bioavailability □ Moisture concentration—ascorbic acid stability □ Biological availability, ascorbic acid—silica gel effect

Diffuse reflectance spectroscopy has been used by Lach and Bornstein (1-3) to study interactions of a number of drugs with various adjuvants after treatment of the mixtures by equilibration in aqueous or nonaqueous media, by compression, and by exposure to controlled humidity conditions. Such an interaction of ascorbic acid and silica gel has been claimed by Lach (4). Since silica gel is a useful adsorbent for converting liquid vitamins such as vitamin E and panthenol into free-flowing, dry powders, it became important to evaluate this alleged interaction of silica gel with ascorbic acid. This has been done in model experiments with simple mixtures and under practical conditions of formulating multivitamin dosage forms. In addition, physiological availability tests in humans have been utilized to check for possible influence of silica gel contained in multivitamin tablets on the biochemical behavior of ascorbic acid.

EXPERIMENTAL

Model Experiments—(a) *Effect of Graded Moisture Levels*—Experimental mixtures of ascorbic acid with silica gel¹ and with 60% adsorbate of *d,l*- α -tocopheryl acetate on silica gel were prepared both at normal use ratios and at an eightfold higher than normal

adsorbent/vitamin ratio. Ascorbic acid alone and the various mixtures were adjusted with distilled water to graded moisture levels up to 40% and stored in closed tubes for 21 days at 45°. The percentage of water added was based in each case on the total weight of the tube contents, except for the vitamin E adsorbate mixtures where the weight of the oil phase was not included. The compositions of the mixtures before addition of water are shown in the legend of Fig. 1. Ascorbic acid was determined after storage by titration with about 0.1 *N* standard iodine solution and starch indicator.

(b) *Rate of Loss of Ascorbic Acid and Sodium Ascorbate at 45° with 11.6% Water*—The stress conditions used in Experiment (a), namely 3 weeks at 45° at high moisture levels, are obviously much more strenuous than those normally encountered in pharmaceutical manufacturing operations, such as wet granulation procedures, in which drying is completed in a much shorter period. It was of interest, therefore, to check the rate of decomposition of ascorbic acid in similar mixtures stored for 1, 2, and 3 days at 45° at one of the lower levels of moisture, namely 11.6%.

Ascorbic acid and the ascorbic acid plus silica gel mixture used in this test, when shaken with water at a concentration of about 20 mg. of vitamin C per ml., yielded a pH of 2.3 and 2.4, respectively. Sodium ascorbate with and without silica gel, at similar dilutions in water, gave a pH of 6.7 with silica gel and 7.2 without. The same stability tests were set up with sodium ascorbate with and without silica gel at 11.6% water.

(c) *Effect of Other Tablet Excipients*—The relative effect of other excipients commonly used in tablets has been compared to that of silica gel in a test similar to that in (b). Three hundred milligrams of sodium ascorbate were mixed with 80 mg. of the particular excipient and water added to give 11.6% by weight. The mixtures were stored in closed tubes for 3 days at 45° and ascorbate determined by iodine titration.

Granulation and Tablet Trials—Multivitamin mixtures containing ascorbic acid or sodium ascorbate and silica gel adsorbates of vitamin E were made by wet granulation procedures with and without iron. To minimize exposure to moisture stress, the granulations were milled through a No. 6, round-hole screen to the minimum practical particle size and dried in layers of 1.27 cm. (0.5 in.) or less with rapidly moving, 45° air. Vitamin C recoveries were determined for the granulations and finished tablets made from these granulations, using iodometric titrations. Stability of vitamin C was determined similarly after accelerated and room temperature storage.

Availability Studies in Men—It has been pointed out (1-3) that drug-adjuvant interactions possibly may result in significant altera-

tions of the biochemical behavior of a medicament. Although such effects are more likely to occur at low drug to adjuvant ratios, the possible existence of the excipient as a chemisorbed layer on the drug has been mentioned as a factor that might cause similar effects at high drug to adjuvant ratios (2). To determine whether silica gel in a tablet would influence the physiological availability of ascorbic acid, the human bioassay technique described by Melnick *et al.* (9) was applied to several tablet formulations. In this test, comparison is made between the extra urinary excretion of the vitamin following dosage with the test sample and that following administration of the vitamin in pure form.

Five male subjects were saturated with ascorbic acid by daily dosing with 500 mg. for 3 weeks. Dosing with test samples and standard was not initiated until a stable plateau had been obtained for the 24-hr. urinary excretions following a 500-mg. dose, given after 2 days without dosing. Two different tablet formulations as listed in Table VI were tested, both containing vitamin E at a level of 30 mg. per tablet in the form of silica gel adsorbate. The standard dose of pure ascorbic acid taken in water was 450 mg. For the initial test, the dose taken was six tablets (453 and 466 mg. ascorbic acid for the Lot Nos. 73-69/1 and 73-69/3, respectively). For the aged sample, seven tablets (430 mg. ascorbic acid) were given.

One test was performed each week with basal urine collected on the day prior to taking each test dose. After dosage with ascorbic acid alone or in tablets, respectively, urine was collected for the periods 0–6 hr. and 6–24 hr., except for Dose 2 of ascorbic acid where only total 24-hr. collections were made. Basal urines were collected in each case according to the same schedule. Ascorbic acid in urine was determined by the dichlorophenol–indophenol–xylene extraction method, as previously described (10). In each case the extra excretion due to dose was calculated by subtracting the corresponding basal excretion value from the value after dose.

RESULTS AND DISCUSSION

Model Experiments—Effect of Graded Moisture Levels—The results of storage tests on the ascorbic acid plus silica gel mixtures at graded moisture levels for 3 weeks at 45° are shown in Fig. 1. Ascorbic acid alone shows progressively increasing storage losses with increasing moisture content. At low moisture levels (below 6%), no significant difference could be determined between samples with or without silica gel. At higher moisture levels, the losses increase with increasing moisture content in mixtures containing silica gel and are higher than those found with ascorbic acid alone. It is noteworthy, however, that at any percentage moisture level, an eightfold increase in the ratio of silica gel to ascorbic acid caused no

Figure 3—Effect of free water level on stability of ascorbic acid in mixtures with or without silica gel; storage in closed tubes for 3 weeks at 45°. Key: ○, 300 mg. ascorbic acid alone; ●, 300 mg. ascorbic acid + 80 or 640 mg. silica gel.

further increase in the ascorbic acid loss above that observed at the lower silica gel level in the 3 weeks at 45° storage tests. This lack of concentration effect of silica gel suggests strongly that the degradation of ascorbic acid is not due to surface interaction. Further, when 60% vitamin E oil was adsorbed on the silica gel, no change in the stability of ascorbic acid was observed. Thus is due undoubtedly to the strongly hydrophilic nature of this adsorbent.

It is of interest to examine the data in Fig. 1 in terms of the losses of ascorbic acid found at equivalent weights of water in the mixtures, rather than at equivalent percentages of water. This type of plot is given in Fig. 2. The circumstance that the higher proportion of silica gel exerts a protective effect indicates that some binding of water by the silica gel is taking place and suggests that the ascorbic acid losses are related to the amount of unbound or free water in the various mixtures. If this is true, then the equivalence of the ascorbic acid losses at the high and low silica gel levels at any particular percentage of moisture would indicate an equivalent amount of free water in these two mixtures.

Assuming that the silica gel binds water as a fixed fraction of its own weight at any given percentage of water, calculation has been made of the fraction that must be bound at both the 80 and 640-mg. silica gel levels in order to yield equal weights of free water at these two levels. A typical calculation is given below for the 25% water level in both mixtures, the compositions of which are as follows: (a) 80 mg. silica gel, 300 mg. ascorbic acid, and 127 mg. water; (b) 640 mg. silica gel, 300 mg. ascorbic acid, and 313 mg. water. If X = bound water level (expressed as percent of silica gel weight) which will yield the same weight of free water for both mixtures, then in both cases the total water minus bound water = free water, and

$$127 - 80 \times \frac{X}{100} = 313 - 640 \times \frac{X}{100}$$

from which $X = 33.2$. Then milligrams of bound water are: (a) $80 \times 0.332 = 26.6$ and (b) $640 \times 0.332 = 212.6$, and milligrams of free water are: (a) $127 - 26.6 = 100.4$ and (b) $313 - 212.6 = 100.4$.

These percentages of bound water and the corresponding weights of free water at the various total water levels are listed in Table I, together with the respective losses of ascorbic acid taken from the curve in Fig. 1. Values at the lower moisture levels are not included in Table I since the magnitude of the ascorbic acid losses in this range of water content is not sharply defined, due to the difficulty of mixing the small quantities of water uniformly, the greater error inherent in the small differences in titrations before and after storage, and the possible effect in some cases of a moisture loss during storage.

Table I—Effect of Moisture Content on Stability of Ascorbic Acid in Presence of Silica Gel^a

^a Ascorbic acid (A.A.), 300 mg. + 80 or 640 mg. silica gel (S.G.) + indicated percent H₂O—storage in closed tubes for 3 weeks at 45°.

Figure 4—Rate of loss of vitamin C in presence of silica gel; storage in closed tubes at 45° with 11.6% water. Key: Δ , 300 mg. ascorbic acid alone; \blacktriangle , 300 mg. ascorbic acid + 80 mg. silica gel; \circ , 300 mg. sodium ascorbate alone; \bullet , 300 mg. sodium ascorbate + 80 mg. silica gel.

The excellent correlation between weights of free water in the mixtures and losses of ascorbic acid is shown by the plot of Fig. 3. The losses of ascorbic acid are directly proportional to the calculated amounts of free water in the mixtures. For the sake of comparison, the data on the ascorbic acid plus water mixtures without silica gel are plotted in Fig. 3. The slope of the latter line is smaller than that of the ascorbic acid + silica gel + water mixtures. Again, in view of the fact that equal losses are found with a given weight of ascorbic acid over an eightfold range of silica gel plus bound water weights, it appears highly unlikely that surface reaction is a significant factor responsible for the higher losses of ascorbic acid in the presence of silica gel. It is believed more likely that trace metals such as iron and copper, which are present in silica gel to the extent of 110 and 1 p.p.m., respectively, are dissolved by the water and exert their well-known catalytic effect on ascorbic acid decomposition in solution (5, 6). Trace metals in the ascorbic acid (less than 10 p.p.m.) are present to the same extent in the tubes with or without silica gel. This mode of decomposition of ascorbic acid is in contrast to that reported by Carstensen *et al.* (7) for thiamine in solid dosage forms, where losses occur in an adsorbed surface monolayer of thiamine dissolved in water.

Rate of Loss of Ascorbic Acid and Sodium Ascorbate at 45° with 11.6% Water—These data are shown in Fig. 4. The loss of ascorbic acid alone in 3 days at 45° is only about 1%; in the mixture with silica gel the loss in this period is 3.6%. This small effect of silica gel in the 3-day test shows the same trend as described previously for the 3-week test.

The losses of sodium ascorbate, both with and without silica gel, are considerably higher than those found with ascorbic acid. This is to be expected in view of the fact that aerobic oxidation of ascorbic

acid in the presence of metallic catalysts proceeds more slowly in acid solution than in neutral solution (8).

Effect of Other Tablet Excipients—The losses of ascorbate in the presence of the various excipients at 11.6% water are listed in Table II. Like silica gel, all these other excipients also increase the loss of ascorbate. The magnitude of the effect is undoubtedly dependent on the factors discussed above, including pH, water-binding capacity of the adjuvant, and trace metal content.

Granulation and Tablet Trials—Table III shows the excellent recoveries of ascorbic acid in dried granulations properly formulated with high levels of vitamin E in the form of silica gel adsorbates. Table IV similarly shows the excellent stability of sodium ascorbate in two dried granulations.

Finished tablets prepared by suitable techniques also show good stability of vitamin C in the presence of silica gel. This is demonstrated by the data in Table V on ascorbic acid stability in tablets prepared with 33 and 60% adsorbates of *d,l*- α -tocopheryl acetate on silica gel.

It has long been known that the sensitivity of vitamin C to oxidation in the presence of moisture is a factor that must be considered in the preparation of multivitamin tablets by wet granulation procedures. This is true whether or not silica gel is present in the granulation. In granulations containing appreciable quantities of silica gel and/or excipients, which are also potential contributors to vitamin C breakdown, it is possible to obtain excellent recovery of either ascorbic acid or sodium ascorbate by suitable wet granulation procedures. However, it is essential that the moisture level be held to the minimum level for effective granulation and that drying be carried out promptly and efficiently.

Experiences with wet granulation formulations containing ascorbic acid or sodium ascorbate indicate that excellent stability can be achieved if the wet granulation is dried to about 10% moisture within a few hours and to the final, low moisture content within 24 hr.

Order of mixing of ingredients and especially the mode of addition of water can be important. The vitamin C stability may be influenced by the presence of adsorbents that bind water or soluble ingredients that serve as emulsifiers or influence the solubility or reactivity of vitamin C.

Availability Studies in Men—The results of bioavailability tests in men of ascorbic acid in tablets containing silica gel have been calculated on the basis of 24-hr. excretions of test doses. These results are summarized in Table VI. Both lots of tablets show complete bioavailability of the ascorbic acid, and this was not changed by storage for 3 months at 45°. In order to provide information on the question of whether or not silica gel reduces the rate of absorp-

tion of ascorbic acid *in vivo*, calculations of physiological availability also were made on the basis of urinary excretions in the first 6 hr. after dose. These data are given in Table VII. Again, the results show complete availability of ascorbic acid in all three tablet trials, indicating that the ascorbic acid is absorbed normally in the presence of silica gel.

Interfacial Barriers in Interphase Transport II: Influence of Additives upon the Transport of Diethylphthalate Across the Hexadecane-Gelatin-Water Interface

ABDEL-HALIM GHANEM, W. I. HIGUCHI, and A. P. SIMONELLI

Abstract □ The authors recently described a novel method for investigating the effects of an interfacial barrier in interphase transport. The procedures, both theoretical and experimental, were applied to the study of the effects of an adsorbed gelatin at the hexadecane-water interface upon the transport of diethylphthalate between the two phases. The present paper describes the influences of surfactants, electrolyte type, and concentration upon the permeability coefficient for the interfacial barrier. Experiments were conducted as before, employing diethylphthalate as the solute. The transport data were analyzed by the physical model described earlier. The results showed that the two ionic surfactants, sodium lauryl sulfate and dodecylpyridinium chloride, markedly decreased (2 to 12 times) the interfacial barrier even at low concentration

(0.001–0.10% in the stock emulsion). Furthermore, the analysis showed that neither the electrolyte type nor concentration influenced the permeability coefficients, although they significantly altered the interphase transport rates themselves by changing the partition coefficients. These findings are particularly interesting as they may represent types of nonspecific situations that give rise to important barriers in *in vivo* drug transport.

Keyphrases □ Transport, interphase—interfacial barriers □ Diethylphthalate transport—hexadecane-gelatin-water interface □ Electrolyte effect—diethylphthalate transport, hexadecane-gelatin-water interface □ Surfactant effect—diethylphthalate transport, hexadecane-gelatin-water interface □ Permeability coefficients, interfacial barriers—surfactant, electrolyte type, concentration effect.

Recent studies from these laboratories (1, 2) involving the use of a novel method for investigating interfacial barriers in interphase transport have shown that substances adsorbed at the oil-water interface may control the interphase transport rates of solutes. Gelatin ad-

sorbed at the hexadecane-water interface has been shown (1) to give an interphase transport rate for diethylphthalate that is about 1×10^4 times slower than diffusion controlled. A significant reduction in the aqueous to lipid transport rate of cholesterol by an

adsorbed polysorbate 80 film has also been observed (2). These findings have suggested that such barriers, which are probably nonspecific in nature from the biopharmaceutical standpoint, may play important rate-determining roles in the transport of drug molecules across biological membranes and into tissues.

In order to better understand the nature of these barriers, the present studies were undertaken. This article describes the results of the experiment on the effects of the different gelatin fractions of Pharmagel A,¹ the influences of electrolyte types and concentration, and the effect of surfactants on the transport rate of diethylphthalate. The data have been mechanistically analyzed and reported in terms of the permeability coefficients for the interfacial barriers.

EXPERIMENTAL

Consideration in the Design of the Experiment—A discussion of the basic design and the advantages of the multiparticulate dispersion technique has already been given (1, 3). In the present study the same general approach was essentially employed.

The previous procedure for preparing the emulsion system was slightly modified in the direction of greater flexibility. Instead of preparing stock hexadecane-in-water emulsions near the interfacial coacervation point (1, 4) of gelatin sodium sulfate, lower electrolyte concentrations were used and the temperature was kept at 40° for the whole period of equilibration of the emulsion systems. This provided the means for varying the concentrations of the additives used in these studies without droplet-droplet aggregation taking place.

Materials—The gelatin used was Pharmagel A. Fractionation of the gelatin was accomplished (5) by adding successive amounts of ethanol to the gelatin solution adjusted to pH 7 at 40°. The hexadecane² was purified (6) and the diethylphthalate³ was used without further purification. Sodium sulfate,⁴ sodium chloride,⁵ calcium chloride dihydrate,⁴ magnesium chloride hexahydrate,⁶ and magnesium sulfate⁴ were used without further purification. Pure samples of sodium lauryl sulfate⁷ and polysorbate 80⁸ were used. Dodecylpyridinium chloride³ was purified by recrystallizing three times from acetone. Spectroquality cyclohexane⁹ was used in the UV analysis.

Key: experimental points, ○, 0.352 M sodium chloride; □, 0.176 M sodium chloride; Δ, water. Curves are theoretical values computed using Eqs. 1 and 2 with $P = 5 \times 10^{-6}$ cm./sec.

the particle size distribution taken from the Fig. 2 photograph. This information was used in the calculation of the permeability coefficients.

The hexadecane-water partition coefficients for diethylphthalate were determined in two ways as previously discussed (1) with and without gelatin present. Table II gives the partition coefficients obtained in different electrolyte media. It is clear that the partition coefficients obtained with and without gelatin at the interface are the same within the experimental error. However, the partition coefficients were found to be dependent on the nature and the concentration of the electrolytes used. This can be attributed to the salting-out effect (7).

The interphase transport experiments were carried out as described previously (1). A 3-ml. aliquot of the stock emulsion system containing the diethylphthalate was pipetted into 100 ml. of the aqueous release medium at zero time, and the amounts released to the aqueous phase were determined as a function of time.

EXPERIMENTAL RESULTS

Effect of Different Gelatin Fractions—Figure 3 gives the experimental results of diethylphthalate release obtained using whole

gelatin and two fractions of gelatin (second and third fraction) under similar conditions. These stock emulsions were pretreated with 0.352 M sodium sulfate for 24 hr. prior to the release experiments in the various electrolyte concentrations. The differences in the release-rate data among the three fractions of gelatin used were within experimental error.

Effect of Electrolytes—The experimental results obtained with five electrolytes—sodium sulfate, sodium chloride, calcium chloride, magnesium chloride, and magnesium sulfate—are shown in Figs. 4–8. In these runs an emulsion system of essentially the same particle size distribution was pretreated with a 0.352 M solution of the particular electrolyte for 24 hr. at 40°. The release medium was either 0.352 M, 0.176 M electrolyte, or water at 23°.

These experiments showed that both electrolyte type and concentration have significant influences upon the transport rate.

Figure 7—Influence of electrolyte and the comparison of experimental release data with the theoretically computed ones. C_a is the amount of diethylphthalate released, ml./ml., versus time in minutes. A 3.0-ml. aliquot of the emulsion system pretreated with 0.352 M magnesium chloride was added to 100 ml. of aqueous medium at 23°. Key: experimental points, \circ , 0.352 M magnesium chloride; \square , 0.176 M magnesium chloride; Δ , water. Curves are theoretical values computed using Eqs. 1 and 2 with $P = 5 \times 10^{-6}$ cm./sec.

However, as will be seen, the effects may be attributed entirely to the influences of salts upon the partition coefficient (see Table II) and not the permeability coefficients.

Figure 9 gives the results obtained employing different electrolyte concentrations in the pretreatment media prior to the release runs. As can be seen, little or no influence of the pretreatment was found. This suggested that, as far as salt interactions were concerned, essentially equilibrium conditions were present during the release period.

Effect of Surfactants—The influences of two ionic surfactants, sodium lauryl sulfate and dodecylpyridinium chloride, upon the release rate in sodium sulfate solutions are shown in Figs. 10–13. The effects of both of these surfactants were found to be similar

Figure 9—Comparison of the experimental release of diethylphthalate from emulsion systems pretreated with different electrolyte concentrations. Three milliliters of emulsion system was added to 100 ml. of aqueous medium at 23°. Emulsion system was pretreated with 0.352 M sodium sulfate and released in: \bullet , 0.352 M sodium sulfate; \blacksquare , 0.176 M sodium sulfate; \blacktriangle , water. Emulsion system was pretreated with 0.176 M sodium sulfate and released in: \circ , 0.352 M sodium sulfate; \square , 0.176 M sodium sulfate; \triangle , water. Emulsion system was without electrolyte pretreatment and released in: \circ , 0.352 M sodium sulfate; \square , 0.176 M sodium sulfate; \triangle , water.

Figure 10—Influence of sodium lauryl sulfate and comparison of the experimental release data with theory. C_a is amount of diethylphthalate released, ml./ml., versus time in minutes. Three milliliters of emulsion system pretreated with 0.352 M sodium sulfate and 0.1% sodium lauryl sulfate was added to 100 ml. of aqueous medium at 23°. Key: experimental points, ●, 0.493 M sodium sulfate; ○, 0.352 M sodium sulfate; □, 0.176 M sodium sulfate; △, water. The curves are theoretical values computed using Eqs. 1 and 2 and $P = 6 \times 10^{-4}$ cm./sec.

and showed marked enhancement of the release rates at relatively low concentrations.

Experiments with polysorbate 80 were also attempted. However, the emulsions containing this material were found to be unstable with respect to coalescence. During the pretreatment stage, extensive cracking of the emulsion containing polysorbate 80 was observed.

TREATMENT OF THE DATA AND DISCUSSION

The experimental results presented in Figs. 4–13 may be analyzed by the theoretical methods discussed previously (1). Equations 1 and 2,

$$\frac{-dC_{0i}}{dt} = \frac{3DP(C_{0i}/K - C_a)}{a_i(D + a_iP)} \quad (\text{Eq. 1})$$

$$(C_a - E) V_a = \sum_{i=1}^L 4/3\pi a_i^3 n_i (C_0^* - C_{0i}) \quad (\text{Eq. 2})$$

give the two basic relations that can be used in the treatment of the data obtained in these studies. Here C_{0i} is the solute concentration in the droplet of radius a_i , C_a is the aqueous concentration, D is the diffusion coefficient of the solute in water, P is the interfacial barrier permeability coefficient, C_0^* and E are the solute concentrations in the oil and aqueous phases at zero time, V_a is the volume of the aqueous phase, K is the oil-water partition coefficient for the solute, n_i is the number of droplets of sizes between a_i and $a_i + 1$, and t is time. Equation 2 assumes (1) that no binding of the solute occurs at the oil-water interface. This assumption should be reasonable in view of the partition coefficient data in Table II which shows that the presence of gelatin at the interface does not significantly alter the experimental partition coefficients. In the previous study (1), because of the higher electrolyte concentrations used, adsorption of diethylphthalate was found to be significant, and a modified form of Eq. 2 was found to be necessary for explaining the experimental data.

Influence of Electrolytes—The results of theoretical computations employing Eqs. 1 and 2 and the computer program previously given (1) are presented as the curves in Figs. 4–8. The partition coefficients used were taken from Table II and the particle size distribution function, $n_i(a_i)$, was taken from Table I. A value of 6×10^{-6}

Figure 11—Influence of sodium lauryl sulfate and comparison of the experimental release data with theory. C_a is amount of diethylphthalate released, ml./ml., versus time in minutes. Three milliliters of emulsion system pretreated with 0.352 M sodium sulfate and 0.01% sodium lauryl sulfate was added to 100 ml. of aqueous medium at 23°. Key: experimental points, ●, 0.493 M sodium sulfate; ○, 0.352 M sodium sulfate; □, 0.176 M sodium sulfate; △, water. The curves are theoretical values computed using Eqs. 1 and 2 and $P = 2.5 \times 10^{-4}$ cm./sec.

cm.²/sec. was used for the diffusion coefficient. The theoretical release-time profiles were fitted to the experimental data by varying the parameter, P , the permeability coefficient for the interfacial barrier.

First it should be noted that the time-dependence agreement between experiment and theory is generally good in all cases (Figs. 4–8). The slight deviations are always in the direction of somewhat faster experimental release rates at early times.

The most significant aspects of the comparison of experiments with theory is that a single P value of 5×10^{-6} cm./sec. quantita-

Figure 12—Influence of sodium lauryl sulfate and comparison of the experimental release data with theory. C_a is amount of diethylphthalate released, ml./ml., versus time in minutes. Key: experimental points, ●, 0.493 M sodium sulfate; ○, 0.352 M sodium sulfate; □, 0.176 M sodium sulfate; △, water. The curves are theoretical values computed using Eqs. 1 and 2 and $P = 1.2 \times 10^{-4}$ cm./sec.

Figure 13—Influence of dodecylpyridinium chloride (DDPCI) and the comparison of the experimental release with theory. C_a is amount of diethylphthalate released, ml./ml., versus time in minutes. Three milliliters of emulsion system pretreated with 0.352 M sodium sulfate and different concentrations of DDPCI was added to 100 ml. 0.352 M sodium sulfate at 23°. Key: Δ , pretreated with 0.1%; \square , pretreated with 0.01%; \circ , pretreated with 0.001% DDPCI. The curves are theoretical values computed using Eqs. 1 and 2 and P values of 6×10^{-4} , 2.5×10^{-4} , and 1.2×10^{-4} cm./sec. for the three concentrations of DDPCI, respectively.

tively describes the data. This was unexpected in view of the large differences in the rates found in the different electrolyte media. This can only mean that the observed differences in the rate may be attributed entirely to the effect of salts upon K , the partition coefficient. The K values given in Table II show that a significant salt effect upon K exists which may be explained on the basis of a salting-out effect (7).

The absence of the salt effect upon the permeability coefficient is somewhat surprising in view of the polyelectrolytic nature of gelatin. This effect may, however, be related in part to Veis' interpretation (8) of acid-precursor gelatin having a relatively compact structure and its configuration being less readily altered by environmental conditions. The absence of the salt effect may also be related to the concept that the main contribution to the interfacial barrier should arise from those interactions between gelatin, hexadecane, and water at the hexadecane side of the gelatin film. This effect may be enhanced by the possibility of surface denaturation (9) of the polymer at the oil interface.

Influence of Surfactants—The results of theoretical computations employing the same procedure previously mentioned are shown as the curves in Figs. 10–13. For these calculations the partition coefficients used were obtained from the terminal aqueous concentrations of the rate runs themselves. These values were generally slightly lower than those given in Table II.

First it should be noted that the shapes of the curves compare very well with the experimental results. The theoretical analysis of the surfactant effects was quite significant (Figs. 10–13). The P values obtained were 6×10^{-4} , 2.5×10^{-4} , and 1.2×10^{-4} cm./sec. for emulsion systems pretreated with 0.1, 0.01, and 0.001% surfactants, respectively. These P values were found to be independent of the electrolyte concentration.

The permeability coefficients obtained with sodium lauryl sulfate and dodecylpyridinium chloride were found to be about the same at

the same percent surfactant concentration levels. Thus, it appears that both anionic and cationic surfactants operate by a similar general mechanism in influencing the permeability of diethylphthalate. These findings might be related to Pearson's studies (10, 11) which showed that cationic and anionic surfactants affect the surface viscosity of adsorbed protein films in a similar manner.

Biopharmaceutical Significance—It is noteworthy that these values for interfacial resistance are of the same order of magnitude as those observed (12) in lipid bilayer transfer studies and therefore generate the idea that biological membrane barriers might be largely of interfacial nature. Also, as pointed out by Ghanem *et al.* (1), the low apparent diffusion coefficient (10^{-9} – 10^{-16} cm.² sec.⁻¹) observed by Blank *et al.* (13) for the stratum corneum is of the same order of magnitude expected from the data obtained in these experiments. Other noteworthy results of this study are that the role of ionic surfactants in enhancing interfacial transport may closely parallel the influence of ionic surfactant in, for example, erythrocyte membrane permeability (14) or in enhancing transfer of drugs through the stratum corneum (15).

Gas Chromatographic Determination of Glycerol Guaiacolate in Pharmaceutical Preparations

JOSEPH HUDANICK

Abstract □ A sensitive gas chromatographic method was developed for the assay of glycerol guaiacolate contained in various pharmaceutical preparations. The method, based upon the chromatography of the trimethylsilyl derivative, has good precision and the desired specificity. A choice of columns and operating conditions is given in order to facilitate assaying a variety of formulations.

Keyphrases □ Glycerol guaiacolate dosage forms—analysis □ Salicylate-glycerol guaiacolate dosage forms—analysis □ GLC—analysis

Glycerol guaiacolate, 3-(*o*-methoxyphenoxy)-1,2-propanediol, is used in various asthma, cough-preventive, and similar preparations as the expectorant-antitussive ingredient.

Its determination is difficult since it is usually found in formulations containing several ingredients and a satisfactory specific color reaction has not been reported. A separation of the compound from the other ingredients is generally required prior to assay. Among the assay methods reported in the literature are: a thin-layer method (1), a paper chromatographic method (2, 3), and a gas chromatographic (4) method *via* the acetate derivative, with all of the methods being time consuming even though they do have a measure of specificity. The gas chromatographic method requires a 90-min. esterification step in addition to extraction.

A simpler and more rapid method was needed in the author's laboratory for the assay of the compound in a variety of formulations, and it was found that the most suitable one was a gas chromatographic determination *via* the trimethylsilyl derivative. Using this approach, it was found that ingredients commonly found associated with glycerol guaiacolate such as ephedrine sulfate, theophylline, chlorpheniramine maleate, and phenobarbital did not interfere. Interference from salicylates is eliminated by extracting glycerol guaiacolate from an alkaline solution with chloroform prior to formation of the derivative.

For the chromatography of the trimethylsilyl derivative, either a 45.72-cm. (1.5-ft.) column packed with 5% SE-52 on diatomaceous earth¹ or a 152.4-cm. (5-ft.) column packed with 5% SE-30 on diatomaceous earth¹ is satisfactory for use with a flame ionization-equipped gas chromatograph. The trimethylsilyl

derivative of *n*-butyl-*p*-hydroxybenzoate is used as an internal standard when assaying for glycerol guaiacolate. Typical chromatograms are shown in Figs. 1 and 2. The retention times for the glycerol guaiacolate trimethylsilyl derivative are 8.5 min. on the SE-30 column at 150° and 7.5 min. on the SE-52 column at 130°. The *n*-butyl-*p*-hydroxybenzoate derivative has a retention time of 5.5 min. on the SE-30 column at 150° and 5.5 min. on the SE-52 column at 130°.

EXPERIMENTAL

Instrumentation—For the chromatography of the derivative, a gas chromatograph equipped with flame ionization detectors (Aerograph 1520, Varian) and operated in the isothermal mode is suitable. Either a 152.71-cm. (5-ft.) long, 0.38-cm. (0.125-in.) internal diameter stainless steel column packed with 5% SE-30 on diatomaceous earth or a 46.03-cm. (1.5-ft.) long, 0.38-cm. (0.125-in.) internal diameter stainless steel column packed with 5% SE-52 on diatomaceous earth is used. The SE-30 column is used with an oven temperature of 150° and the SE-52 column is operated at 130°. In either case, the injector temperature is 225° and the detector temperature is 250° with helium as the carrier gas at a flow rate of about 50 ml./min. The detector response is recorded on a strip-chart recorder (Sargent S.R.) having a 1.0-mv. span and a chart speed of 0.2 in./min.

Reagents—Commercial catalyst reagent (Tri-Syl, Pierce Chemical Co., Rockford, Ill.), acetone, chloroform, saturated aqueous sodium chloride solution, sodium hydroxide, *n*-butyl-*p*-hydroxybenzoate (Eastman Kodak), and anhydrous sodium sulfate. All chemicals are reagent grade and the solvents are redistilled.

Relative Responses of the Trimethylsilyl Derivatives of Glycerol Guaiacolate and *n*-Butyl-*p*-hydroxybenzoate—From a chloroform solution of glycerol guaiacolate (concentration of 10 mg./ml.), transfer aliquots representing 30, 40, and 50 mg. of glycerol guaiacolate to separate 15-ml. centrifuge tubes. To each add 40 mg. of *n*-butyl-*p*-hydroxybenzoate (from a chloroform solution) and evaporate to dryness on a steam bath under a gentle current of air. Add to each tube 0.5 ml. of Tri-Syl reagent, stopper, mix thoroughly, and allow to stand for about 2–3 min. Dilute each to 10 ml. with acetone and mix thoroughly.

Inject a 2.0-μl. aliquot of each solution into the chromatograph, using either the SE-30 or SE-52 column under the conditions previously described. Record the detector response using a chart speed

Table I—Recovery of Glycerol Guaiacolate from Prepared Mixtures

Batch No.	Glycerol Guaiacolate Added, mg.	Recovery, %
1	100	98.5
1	100	100.0
2	100	98.1
2	100	101.0
3	100	98.0
3	100	99.0

¹ Gas Chrom Q, Applied Science Laboratories, Inc., State College, Pa.

Figure 1—Gas chromatogram of TMS derivatives of glycerol guaiacolate (C) and *n*-butyl-*p*-hydroxybenzoate (B) on 5% SE-30 at 150°. Peak A is the solvent.

of 0.2 in./min. and a span voltage of 1.0 mv. Attenuation is about 32×. Calculate the relative response factor *F* using the equation:

$$F = (P_o/P_i) \times (W_i/W_o)$$

where *P_i* is the peak height of the *n*-butyl-*p*-hydroxybenzoate derivative, *P_o* is the peak height of the glycerol guaiacolate derivative, *W_i* is the weight of the *n*-butyl-*p*-hydroxybenzoate injected, and *W_o* is the weight of the glycerol guaiacolate injected.

The *F* factor used in subsequent analytical calculations is the average of the *F*'s found.

Determination in Tablets Not Containing Salicylates—Thoroughly grind the tablets to a fine powder, weigh accurately a portion equivalent to about 100 mg. of glycerol guaiacolate, and transfer to a glass-stoppered conical flask containing 100 ml. of chloroform. Shake thoroughly for about 30 min. and then filter or centrifuge to obtain a clear solution. Transfer an aliquot containing the equivalent of about 40 mg. of glycerol guaiacolate to a glass-stoppered conical flask, add 40 mg. of the internal standard, and evaporate to dryness. Then add 0.5 ml. of Tri-Syl, stopper, and allow to stand for 2–3 min. Dilute the mixture to 10 ml. with acetone and mix thoroughly. Inject a 2.0-μl. aliquot into the chromatograph and record the response as previously described. Calculate the amount of glycerol guaiacolate per tablet as follows: glycerol guaiacolate mg./tablet = $(P_o/P_i) \times (W_i/F) \times (D/S)$, where *P_o* is the peak height of the glycerol guaiacolate, *P_i* is the peak height of the internal standard, *W_i* is the weight of the internal standard, *D* is the dilution factor, *S* is the sample weight, and *F* is the average response factor.

Determination in Tablets and Fluids Containing Salicylates—Transfer an accurately measured sample equivalent to about 200 mg. of glycerol guaiacolate to a separator, dilute to about 25 ml. with water, add 25 ml. of saturated sodium chloride, and make alkaline with sodium hydroxide. Extract with five 45-ml. portions of chloroform, filter through anhydrous sodium sulfate, and combine the chloroform extracts in a 250-ml. volumetric flask. Dilute to volume with chloroform. Withdraw an aliquot containing about 40 mg. of glycerol guaiacolate, add 40 mg. of internal standard, and proceed as previously described.

Recovery of Glycerol Guaiacolate from Mixtures—In order to test the recovery of glycerol guaiacolate when compounded into

Figure 2—Gas chromatogram of TMS derivatives of glycerol guaiacolate (C) and *n*-butyl-*p*-hydroxybenzoate (B) on 5% SE-52 at 130°. Peak A is the solvent.

various mixtures, three batches of tablets were made containing the following ingredients: Batch 1, glycerol guaiacolate 100 mg., phenobarbital 16.25 mg. (0.25 grain), theophylline 162.5 mg. (2.5 grains), ephedrine sulfate 25 mg., and excipient. Batch 2, glycerol guaiacolate 100 mg., theophylline 162.5 mg. (2.5 grains), ephedrine sulfate 25 mg., chlorpheniramine maleate 2.0 mg., and excipient. Batch 3, glycerol guaiacolate 100 mg., sodium salicylate 130 mg. (2.0 grains), ephedrine sulfate 25 mg., theophylline 130 mg. (2.0 grains), and excipient.

The results of the assays are shown in Table I.

CONCLUSIONS

An average recovery of 99.1% (*SD* = 1.1) may be achieved by the gas chromatographic method of assay of fluids and tablets. The method is straightforward, rapid, and has the desired specificity. A choice of columns and operating conditions is given for assaying various formulations. The amount of glycerol guaiacolate that can be estimated may be quite small by using the gas chromatograph to the limit of its sensitivity and by manipulation of the sample size.

A Column Chromatographic Method for the Determination of Sulfanilamide in Pharmaceutical Preparations Containing Sulfacetamide or Its Sodium Salt

EDWARD J. WOJTOWICZ

Abstract □ A simple and rapid method, using column-adsorption chromatography on alumina and UV spectrophotometry, has been developed for the separation and determination of sulfanilamide in ophthalmic solutions and tablets containing sulfacetamide or its sodium salt.

Keyphrases □ Sulfacetamide formulation—sulfanilamide determination □ Sulfanilamide—sulfacetamide degradation product □ Column chromatography—separation □ UV spectrophotometry—identity

The presence of undeclared sulfanilamide in preparations containing sulfacetamide has been reported (1-4). Hayden (1) found 17% sulfanilamide in a commercial sample of sulfacetamide powder, using paper chromatography and IR spectroscopy. Klein and Kho (2) reported undeclared sulfanilamide in suspensions of mixed sulfas containing sulfacetamide, using TLC. Previous work has shown that sulfacetamide preparations form sulfanilamide as a degradation product when exposed to light, extremes of temperature, or prolonged storage (3, 4). Gruber and Klein (4) used TLC on silica gel to separate the degradation product from the parent compound; the amount of sulfanilamide present was determined colorimetrically with the Bratton-Marshall reagent. Ophthalmic solutions contained contamination of 13% sulfanilamide, but tablets showed no detectable degradation over a period of 4 months.

Alexander and Stanley (5) used alumina for qualitative thin-layer chromatographic determination of sulfas in feeds. The separation of sulfanilamide from sulfacetamide or its sodium salt was much greater in this system using alumina than in the silica gel system used by Gruber and Klein (4). (In both systems sulfanilamide has the greater R_f .) This large separation was the basis for adapting the qualitative thin-layer chromatographic procedure to a quantitative column chromatographic determination for sulfanilamide.

Sulfanilamide was easily separated and collected from a neutral alumina column, using the thin-layer developing solvent system of Alexander and Stanley (5). The sulfanilamide in the column eluate was quantified by UV absorption. The residue from the column eluate was also identified qualitatively as sulfanilamide by IR spectroscopy.

EXPERIMENTAL

Apparatus and Reagents—The following apparatus and reagents were used: 1-cm. (i.d.) glass columns fitted with Teflon stopcocks and sintered-glass frits (Kontes); aluminum oxide, neutral, suitable for chromatographic adsorption (Merck)¹; spectrophotometric grade methanol and chloroform (Burdick and Jackson); USP

sulfanilamide reference standard solution, 5 mcg./ml. in chloroform-methanol (70:30); a suitable recording UV spectrophotometer.

Preparation of Chromatographic Column—Heat the aluminum oxide for 30 min. at 100° before use. With the stopcock open, transfer 5.0 g. of aluminum oxide to the column in a slurry with chloroform-methanol (70:30). The solvent should drain quickly as the adsorbent settles. Wash the column with 20-25 ml. of the solvent mixture, and cover the top of the column with a pledget of glass wool. Drain the solvent to a level of 1 cm. above the glass wool.

If a flow rate of 1-2 drops per 10 sec. is encountered due to an excess of fine particles in the alumina, the column can be packed by the following procedure: place 10-15 g. of the alumina into a 250-ml. separator. Add 50 ml. of the solvent mixture and shake. The fine particles will stay suspended in the solvent. Open the stopcock of the column and add the alumina slurry from the separator to the predetermined height for 5 g. (about 7 cm.). Maintain a level of solvent above the alumina and wash with 20-25 ml. of the solvent mixture as in the previous column-packing procedure.

Sample Preparation—Transfer an accurately measured volume of ophthalmic solution or an accurately weighed portion of ground solid sample equivalent to about 200 mg. of sulfacetamide to a 100-ml. volumetric flask. Add 30 ml. of methanol and mix thoroughly. Dilute to volume with chloroform and mix again.

Procedure and Analysis—Pipet a 5-ml. aliquot of the sample solution onto the column; collect the eluate in a 50-ml. volumetric flask. After all the sample aliquot has entered the column, elute to volume with chloroform-methanol (70:30). Maintain a liquid level about 5 cm. above the alumina so that the time for collecting the 50 ml. is about 30 min. Obtain the absorbance of the sample at

262 $m\mu$ against the elution solvent blank. Compare the absorbance of the sample to that of the sulfanilamide reference standard solution.

RESULTS AND DISCUSSION

Proprietary standards of sulfacetamide and sodium sulfacetamide were analyzed by the column chromatographic procedure. A portion of the sodium sulfacetamide was recrystallized and also analyzed. All three standards were eluted with an additional 30 ml. of elution solvent after the first 50 ml. was collected. The 50-ml. fraction exhibited absorbance maxima at 262 $m\mu$; the subsequent eluates did not show UV absorbance. Therefore, the sulfanilamide was completely eluted and no additional sulfanilamide or any sulfacetamide was present in subsequent 30-ml. eluates. However, each batch of alumina should be tested to ensure that the desired separation occurs in the first 50 ml. of eluting solvent.

Sulfanilamide was added to the free sulfacetamide and to the recrystallized sodium salt, and recoveries were obtained. Data from analyses using these standards are reported in Table I.

Two buffered ophthalmic solutions of 10 and 30% sodium sulfacetamide and a tablet form of sulfacetamide, 500-mg. label declaration, were assayed for their sulfanilamide content. Known amounts of sulfanilamide were added and percent recoveries were determined. Data from these analyses showed that the ophthalmic solutions contained a larger percentage of sulfanilamide than the tablets. This agrees with the quantitative findings of Gruber and Klein (4).

The USP XVII (6) or NF XII (7) procedure failed to detect any degradation of sulfacetamide preparations since it is a general titrimetric procedure for sulfonamides.

The residue left after evaporation of the column eluate was confirmed as sulfanilamide by IR spectroscopy, employing micro-KBr disk techniques.

All standards and samples used in this study were analyzed by the screening procedure of Gruber and Klein (4) on silica gel. Amounts were spotted to yield about 0.1 mcg. of sulfanilamide as determined by the column chromatographic procedure. Sulfanilamide was detected in all cases except in the sulfacetamide standard and the tablet form of sulfacetamide. These also gave the lowest results by the column chromatographic procedure.

The method described in this paper can also be used to determine purity of reference standards of the free sulfa or its sodium salt to meet compendial requirements. Levels of sulfanilamide below 1% can be quantitated.

Selective Determination of Isoproterenol and Isoproterenol Sulfonic Acid in Pharmaceutical Dosage Forms

K. K. KAISTHA

Abstract □ Two simple, precise, and specific methods for the determination of isoproterenol in decomposed formulations are described. DEHP shakeout procedure, which depends upon ion-pair formation with the unchanged drug at a suitable pH, enables the quantitative determination of isoproterenol from the DEHP-ether phase and of its sulfonic acid from the aqueous buffer phase. Isoproterenol sulfonic acid can then be determined selectively by treating the aqueous buffer phase with Doty's reagents. The sodium metaperiodate method has been developed as an alternate checking procedure to validate the results obtained by the DEHP method and involves the quantitative formation of an aryl aldehyde of the unchanged drug. The merits of both the procedures over the conventional UV and visible spectrophotometric procedures are shown

by their application to the analysis of simulated decomposed formulation, aged simulated inhalations and injections, and commercial formulations. A thin-layer chromatographic procedure for the separation and detection of isoproterenol and its sulfonic acid and other artifacts is described.

Keyphrases □ Isoproterenol dosage forms—analysis □ Isoproterenol sulfonic acid formed in products—analysis □ Degradation products presence—isoproterenol determination □ Di-(2-ethylhexyl)phosphoric acid extraction method—isoproterenol determination □ Metaperiodate sodium method—isoproterenol determination □ UV spectrophotometry—analysis □ TLC—analysis

The selective determination of isoproterenol (3,4-dihydroxy- α -[(isopropylamino)methyl]-benzyl alcohol hydrochloride), in the presence of isoproterenol sulfonic acid and other decomposition products or vice versa, presents an unusually difficult analytical problem. Recently it became evident that the composition of

pharmaceutical dosage forms, especially inhalations and injections containing isoproterenol hydrochloride, can change with aging. The change is attributed to the interaction of isoproterenol with the bisulfite antioxidant, by which the alcoholic hydroxyl group of the drug is replaced by a sulfonic acid group (1) as shown in

262 $m\mu$ against the elution solvent blank. Compare the absorbance of the sample to that of the sulfanilamide reference standard solution.

RESULTS AND DISCUSSION

Proprietary standards of sulfacetamide and sodium sulfacetamide were analyzed by the column chromatographic procedure. A portion of the sodium sulfacetamide was recrystallized and also analyzed. Selective Determination of Isoproterenol and Isoproterenol Sulfonic Acid in Pharmaceutical Dosage Forms

K. K. KAISTHA

Abstract □ Two simple, precise, and specific methods for the determination of isoproterenol in decomposed formulations are described. DEHP shakeout procedure, which depends upon ion-pair formation with the unchanged drug at a suitable pH, enables the quantitative determination of isoproterenol from the DEHP-ether phase and of its sulfonic acid from the aqueous buffer phase. Isoproterenol sulfonic acid can then be determined selectively by treating the aqueous buffer phase with Doty's reagents. The sodium metaperiodate method has been developed as an alternate checking procedure to validate the results obtained by the DEHP method and involves the quantitative formation of an aryl aldehyde of the unchanged drug. The merits of both the procedures over the conventional UV and visible spectrophotometric procedures are shown

by their application to the analysis of simulated decomposed formulations, aged simulated inhalations and injections, and commercial formulations. A thin-layer chromatographic procedure for the separation and detection of isoproterenol and its sulfonic acid and other artifacts is described.

Keyphrases □ Isoproterenol dosage forms—analysis □ Isoproterenol sulfonic acid formed in products—analysis □ Degradation products presence—isoproterenol determination □ Di-(2-ethylhexyl)phosphoric acid extraction method—isoproterenol determination □ Metaperiodate sodium method—isoproterenol determination □ UV spectrophotometry—analysis □ TLC—analysis

The selective determination of isoproterenol (3,4-dihydroxy- α -(isopropylamino)methyl-benzyl alcohol hydrochloride), in the presence of isoproterenol sulfonic acid and other decomposition products or vice versa, presents an unusually difficult analytical problem. Recently it became evident that the composition of

pharmaceutical dosage forms, especially inhalations and injections containing isoproterenol hydrochloride, can change with aging. The change is attributed to the interaction of isoproterenol with the bisulfite antioxidant, by which the alcoholic hydroxyl group of the drug is replaced by a sulfonic acid group (1) as shown in

Scheme I

Scheme I. Higuchi *et al.* (2, 3) have reported a similar type of reaction between bisulfite and epinephrine and other suitably substituted benzyl alcohol derivatives. The UV spectrum of the physiologically inactive product has the same absorption maximum as that of isoproterenol. Thus the current USP XVII (4) assay procedure based on spectrophotometric measurement of the active drug at 279 $m\mu$ will not yield true values for the unchanged drug in decomposed formulations. Similarly the colorimetric procedure, as described in the BP 1968 (5) for tablets is not specific for isoproterenol, as any impurity such as isoproterenol sulfonic acid possessing at least two phenolic groups attached to adjacent carbon atoms will undergo this color reaction (6).

Recently, a notable improvement in the determination of unchanged isoproterenol in pharmaceutical dosage forms was achieved by Welsh and Sammul (1), who used the principle of ion-pair formation of the drug with di-(2-ethylhexyl)phosphoric acid (DEHP) at a suitable pH. This idea of DEHP-organic base ion-pair formation was originally contributed by Temple (7) and Temple and Gillespie (8), who reported that several phenolic phenethylamines, including isoproterenol, show partition coefficients favoring their extraction into a chloroform phase containing DEHP from an aqueous phase adjusted to a suitable pH. Levine and Doyle (9) extracted phenylephrine quantitatively as its DEHP ion-pair, using partition chromatography and an ether solution of DEHP as a mobile phase. In the method proposed by Welsh and Sammul (1), a portion of the sample buffered to pH 5.8 is used as a stationary phase supported on a diatomaceous earth¹ column. The passage of an ether solution of DEHP through the column extracts the DEHP-isoproterenol ion-pair while the sulfonic acid is retained in the stationary phase. This method, when applied to simulated preparations, gave higher values for isoproterenol. The results could not be reproduced unless a step to wash the DEHP-ether effluent (from the diatomaceous earth column) with buffer was introduced prior to the extraction with 0.1 *N* sulfuric acid. Although the method as modified was found specific in the presence of Compound II (Scheme I), the recoveries for unchanged drug in the aged simulated inhalations were found higher due to some additionally encountered decomposition products.

By modification of Hellberg's fluorimetric assay for

epinephrine (10), Pratt *et al.* (referred to in Reference 1) were able to analyze aged isoproterenol solutions in the presence of Compound II. No published data are yet available about the variability or about the inherent instability of this lutin method when applied to aged pharmaceutical dosage forms of isoproterenol.

The purpose of this communication is to present two simple, rapid, accurate, and selective assay procedures for the quantitative determination of unchanged isoproterenol in aged formulations. The chromatographic method of Welsh and Sammul (1) based on ion-pair formation with DEHP has been modified to a simple shakeout procedure. An aliquot of the formulation (without dilution) is transferred to a separator containing potassium phosphate buffer and extracted with DEHP-ether solution. The DEHP-ether solution after washing with buffer and water, respectively, is extracted with dilute sulfuric acid to partition the unchanged isoproterenol as its sulfate into the aqueous phase. The UV absorbance of the sulfate is then determined. The aqueous-buffer phase left after DEHP-ether extraction is diluted to a definite volume. The UV absorbance is measured in order to calculate the amount of total water-soluble decomposition products. Subsequently, an aliquot of this is treated with aminoacetate buffer and ferrous sulfate-citrate reagent (Doty reaction) (6) to determine quantitatively the amount of isoproterenol sulfonic acid (Compound II) present in the formulation. The second method developed in these laboratories consists of treating a suitably diluted aliquot of the preparation with 2% aqueous solution of sodium metaperiodate, extracting the resulting aryl aldehyde of the unchanged drug with chloroform, and then measuring its UV absorption at 270 $m\mu$. This reaction is specific to those compounds having two vicinal hydroxyl groups; thus Compound II or amino-chrome-type oxidation products analogous to adrenaline (11) do not yield this aldehyde. This reagent was first used by Heimlich *et al.* for the determination of phenylpropanolamine in the urine (12) and later on by Chafetz (13) for the determination of some phenethanolamine drugs having one or no phenolic group. However, as far as the author is aware, there is no reference in the literature which describes an assay procedure for the determination of catecholamines using this reagent.

EXPERIMENTAL

Preparation of Isoproterenol Sulfonic Acid—This was prepared by the modification of the Schroeter and Higuchi method described for the preparation of 1-(3,4-dihydroxyphenyl)-2-methylaminoethane sulfonic acid from epinephrine (14). Isoproterenol sulfate, 0.018 mole (5.0 g.), and sodium bisulfite, 0.018 mole (1.869 g.), were dissolved in about 25 ml. of water (pH of the reaction solution was 5.0). The solution was heated on a steam bath while keeping it flushed with nitrogen. After 1.50 hr., the flask was removed from the steam bath (pH of the yellowish solution was 6.4) and stored in the dark after flushing with nitrogen. At the end of 3 days, the excess water (about 15 ml.) was removed with a rotary evaporator and the residual solution was stored in the dark at room temperature for a further period of 6 days. The white crystalline precipitate that separated during storage was collected on a Büchner funnel, was washed with water to remove unchanged isoproterenol sulfate, and was dried under vacuum at 60° for 2 hr. Yield: 4.90 g. (70%). The product was recrystallized once from 1 *N* HCl and twice from water to give prisms, m.p. 191–194° with decomposition (Fisher-John hot stage).

Anal.—Calcd. for $C_{11}H_{17}NO_3S \cdot H_2O$: C, 45.1; H, 6.18; N, 4.78; O, 32.76; S, 10.92. Found: C, 45.24; H, 6.12; N, 4.75; O, 32.75; S, 11.13. (Analysis was performed after drying the sample for 7 hr. under vacuum at 100°.)

ANALYTICAL METHODS

Reagents—*DEHP-Ether Solution*—Five milliliters DEHP in 140 ml. ether, washed with four 10-ml. portions of water (water washings discarded).

Potassium Phosphate Buffer—Two volumes of 1 *M* K_2HPO_4 (dibasic potassium phosphate) were mixed with eight volumes of 1 *M* KH_2PO_4 (monobasic potassium phosphate), and the pH was adjusted to 5.8 ± 0.05 with a pH meter.

Iron Reagents—(a) Ferrous sulfate heptahydrate (1.5 g.) in 200 ml. of distilled water to which 1 ml. of 1 *N* HCl had been added. (b) Ferrous sulfate-citrate solution prepared by adding 0.5 g. of sodium citrate to 10 ml. of ferrous solution (a) (freshly prepared before use).

Aminoacetate Buffer—Solution of sodium bicarbonate (42 g.) and potassium bicarbonate (50 g.) in 180 ml. of water was mixed with solution of aminoacetic acid (37.5 g.) and strong ammonia (17 ml.) in 180 ml. of water, and volume was adjusted to 500 ml. with water (6).

Sodium Metaperiodate Solution—Sodium metaperiodate (2%) (reagent grade) in water (freshly prepared).

Sodium Bisulfite Solution—Sodium bisulfite (0.024%) (reagent grade) in water.

Standard Isoproterenol HCl Solution (A)—Isoproterenol HCl USP reference standard (125 mg.) in water (25 ml.) (freshly prepared). For inhalations a 2-ml. aliquot was carried through the DEHP assay procedure along with the sample solution. For tablets a 2-ml. aliquot diluted with 3 ml. of water was carried through the DEHP assay procedure along with the sample solution.

Dilute Solution (B)—A 4-ml. aliquot of Solution A diluted to 100 ml. with water. For injections a 10-ml. aliquot of this solution was carried through the DEHP assay procedure along with the sample solution. For the $NaIO_4$ method a 4–6-ml. aliquot of this solution was carried through the assay procedure along with the sample solution.

Standard Isoproterenol Sulfonic Acid Solution—Isoproterenol sulfonic acid (30 mg.) in 30 ml. of water was shaken mechanically for 20 min. Then 120 mg. $NaHSO_3$ was added to the clear solution, which was made to 50 ml. with water and mixed.

Sample Preparation—*Inhalations (0.5% Isoproterenol HCl)*—A 2-ml. aliquot of the undiluted sample (equivalent to about 10 mg. of isoproterenol HCl) was used for the DEHP method (Procedure A). A 4-ml. aliquot was diluted to 100 ml. with water and a 4–6-ml. aliquot of this diluted solution (equivalent to 0.8–1.2 mg. of isoproterenol HCl) was used for the $NaIO_4$ method (Procedure B).

Injections (0.02% Isoproterenol HCl)—A 10-ml. aliquot of the undiluted sample (equivalent to 2.0 mg. of isoproterenol HCl) was used for the DEHP method and a 4-ml. aliquot (equivalent to 0.8 mg. of isoproterenol HCl) was used for the $NaIO_4$ method.

Tablets (10 mg. Isoproterenol HCl per Dosage Unit)—Twenty tablets were weighed and finely powdered. An accurately weighed aliquot containing about 50 mg. of isoproterenol HCl was quantitatively transferred to a 25-ml. volumetric flask with the aid of water (20 ml.). The mixture was shaken on a mechanical shaker for 20 min., made to volume with water, mixed, and filtered. A 5-ml. aliquot of the filtrate (equivalent to 10 mg. of isoproterenol HCl) was used for the DEHP method. A 10-ml. aliquot of the filtrate was diluted to 100 ml. with water and a 4-ml. aliquot of the diluted solution (equivalent to 0.8 mg. of isoproterenol HCl) was used for the $NaIO_4$ method.

Determination of Unchanged Isoproterenol—*DEHP Method (A)*—A 2-ml. (inhalations) or 10-ml. (injections) aliquot of the undiluted sample or 5-ml. aliquot of the aqueous filtrate in the case of tablets (prepared as already described) was transferred to a 250-ml. separator containing 3 ml. of potassium phosphate buffer (pH 5.8) and extracted with 50 ml. of DEHP-ether solution. The aqueous buffer phase was transferred to a 60-ml. separator and, after extracting successively with four 20-ml. portions of DEHP-ether solution, was drained into a 25-ml. volumetric flask. The DEHP-ether solutions were combined and washed first with two 1-ml. portions of potassium phosphate buffer and then with 2 ml. of water. These washings were combined with the aqueous buffer phase

in the volumetric flask, made to volume with distilled water, and mixed (reserved for the determination of total water-soluble degradation products).

The combined residual DEHP-ether solutions were then extracted with five 25-ml. portions of 0.1 *N* H_2SO_4 . Acid extracts were combined in a 200-ml. volumetric flask, made to volume with 0.1 *N* H_2SO_4 , and mixed. The absorbance of the acid solution of the sample and that of the standard isoproterenol HCl carried simultaneously through the assay procedure were measured at 279 $m\mu$ against 0.1 *N* H_2SO_4 blank obtained by carrying a reagent blank through the assay procedure.

Calculations—*For Inhalations and Injections (a)*—

mg. isoproterenol HCl/100 ml. formulation =

$$\frac{Au}{As} \times Cs \times 200 \times \frac{100}{Vu}$$

where Au = absorbance of acid solution of the sample after dilution to final volume, As = absorbance of acid solution of the standard after dilution to final volume, Cs = final concentration of isoproterenol HCl standard (mg./ml.) in acid solution after dilution to volume, and Vu = milliliters of the formulation taken.

For Tablets (b)—

$$\text{mg. isoproterenol HCl/tablet} = \frac{Au}{As} \times \frac{Ws \times Wo}{Wu}$$

where Au = absorbance of acid solution of the sample after dilution to final volume, As = absorbance of acid solution of the standard after dilution to final volume, Ws = weight of standard isoproterenol HCl (mg.), Wu = weight of sample (mg.), and Wo = tablet average weight (mg.).

Sodium Metaperiodate Method (B)—A 4-ml. aliquot of the diluted sample solution (for inhalations or tablets) or 4-ml. aliquot of the undiluted sample (for injections) was transferred to a 60-ml. separator, treated with 6 ml. of 2% sodium metaperiodate, mixed, stoppered, and allowed to stand overnight at room temperature. After 18 hr., the reaction solution was extracted successively with two 3-ml. and one 3.8-ml. portions of chloroform. The chloroform solutions were combined in a 10-ml. volumetric flask, made to volume with chloroform, and mixed. A 4-ml. aliquot of the dilute solution (Solution B) of isoproterenol HCl standard, after treating with appropriate volume of $NaHSO_3$ solution (containing $NaHSO_3$ equivalent to the amount present in the sample solution, i.e., 2 ml. for inhalations containing 0.3% $NaHSO_3$; 1.3 ml. for inhalations containing 0.2% $NaHSO_3$; 1.0 ml. for injection containing 0.1% $NaHSO_3$; 0.67 ml. for tablets containing 2 mg. of $NaHSO_3$ per dosage unit), and 6 ml. of sodium metaperiodate solution were simultaneously carried through the assay procedure. The absorbance of the chloroform solution of the sample and that of the standard were measured concomitantly at 270 $m\mu$ after allowing the solutions to stand in the cells for 1 min. The chloroform solution used in the reference cell was obtained by carrying the reagent blank, i.e., sodium metaperiodate and sodium bisulfite solutions, through the assay procedure.

Calculations—*For Inhalations (a)*—

mg. isoproterenol HCl/100 ml. of formulation =

$$\frac{Au}{As} \times Cs \times 10 \times \frac{100}{4} \times \frac{100}{Vu}$$

where Au = absorbance of chloroform solution of the sample after dilution to final volume, As = absorbance of chloroform solution of the standard after dilution to final volume, Cs = final concentration of isoproterenol HCl standard (mg./ml.) in $CHCl_3$ after dilution to final volume, and Vu = milliliters of the formulation taken for dilution.

For Injections (b)—

mg. isoproterenol HCl/100 ml. of formulation =

$$\frac{Au}{As} \times Cs \times 10 \times \frac{100}{Vu}$$

where Vu = milliliters of the formulation treated with $NaIO_4$ and the rest same as above.

For Tablets (c)—Same as given in Procedure A for tablets.

Determination of Isoproterenol Sulfonic Acid—A 2-ml. aliquot of the isoproterenol sulfonic acid standard (for inhalations) or 2-ml. aliquot diluted with 8 ml. of water (for injections) or 2-ml. aliquot diluted with 3 ml. of water (for tablets) was carried through the DEHP assay (Method A) simultaneously with the formulation. The absorbance of the aqueous buffer phase of the standard and that of the sample solution as obtained under *Determination of Unchanged Isoproterenol* (Method A) were measured at 279 $m\mu$. The aqueous buffer solution used in the reference cell was obtained by carrying a reagent blank (potassium phosphate buffer and the appropriate volume of the distilled water containing sodium bisulfite) through the assay procedure. These absorbance values were used to deduce the amount of total water-soluble degradation products with reference to isoproterenol sulfonic acid.

Isoproterenol sulfonic acid was then determined colorimetrically by treating a 6-ml. aliquot each of the aqueous buffer solution of the sample and that of the standard (aqueous buffer solutions left after UV determination) with 3.9 ml. of aminoacetate buffer and 0.1 ml. of ferrous sulfate-citrate reagent. The purple color formed was measured after 2.50 hr. at 530 $m\mu$ against the reagent blank. Alternatively, a 2-ml. (inhalation) or 10-ml. (injection) aliquot of the undiluted sample was carried through the DEHP assay (Method A) starting at: "A 2-ml. (inhalations) or 10-ml. (injections) aliquot of the undiluted..." and ending at "these washings were combined with aqueous buffer phase." These combined aqueous buffer solutions were treated with 10 ml. of aminoacetate buffer and 0.1 ml. of ferrous sulfate-citrate reagent, made to 25 ml. with water, and mixed. The absorbance of the sample solution and that of the isoproterenol sulfonic acid standard (a 2-ml. aliquot) carried simultaneously through the assay procedure were measured at 530 $m\mu$ against the reagent blank. The amount of isoproterenol sulfonic acid (mg./100 ml. of formulation) was calculated from the respective absorbance values.

Determination of Total Catechols as Isoproterenol—Modified Colorimetric Method—A 3-ml. aliquot of the diluted sample solution (for inhalations or tablets) or 3-ml. aliquot of the undiluted sample solution (for injections) containing the equivalent of 0.6 mg. of isoproterenol HCl was treated with 1.9 ml. of aminoacetate buffer and 0.1 ml. of ferrous sulfate-citrate solution in a 10-ml. volumetric flask, made to volume with distilled water, and mixed. A 3-ml. aliquot of the dilute solution of isoproterenol HCl standard (Solution B), after treating with appropriate volume of NaHSO_3 solution (containing NaHSO_3 equivalent to the amount present in the sample solution, i.e., 1.5 ml. for inhalations containing 0.3% NaHSO_3 ; 1.0 ml. for inhalations and injections containing 0.2% NaHSO_3 or 0.1% NaHSO_3 , respectively; 0.51 ml. for tablets containing 2 mg. of NaHSO_3 per dosage unit) was concurrently carried through the assay procedure. The absorbance of the colored solutions of the sample and that of the standard were measured after 2.50 hr. at 530 $m\mu$ against the reagent blank.

USP Method—An aliquot of the inhalation (equivalent to 50 mg. of isoproterenol HCl) or injection (equivalent to 50 mg. of isoproterenol HCl) or tablet powder (equivalent to 50 mg. of isoproterenol HCl) was carried through the assay procedure as described in USP XVII, pp. 330–332. The absorbance of the sample and that of the standard solution were measured at 279 $m\mu$.

Thin-Layer Chromatography (TLC)—Preparation of Layers—The chromatoplates were prepared using standard equipment (15). Cellulose MN300 and silica gel G were used as adsorbents. To obtain five plates 20×20 cm., 10 g. of cellulose powder containing 20 mg. of fluorescent indicator was mixed with 70 ml. of water and 10 ml. of 1% aqueous solution of sodium carboxymethylcellulose (CMC). For silica gel G, five plates were obtained from 25 g. of powder in 55 ml. of water. A layer-thickness of 250 μ was used throughout. Cellulose plates were activated by heating at 110° for 30 min. and stored in a desiccator until use; silica gel plates were air dried and used without activation.

Solvent Systems—The following solvent systems were used: (a) *n*-butanol-acetic acid-water (4:1:5) (16) were shaken together in a separator and set aside for 2 hr.; the upper organic layer was separated and used as the running solvent for cellulose plates. (b) *n*-Butanol-acetic acid-water (60:10:25) were mixed together to form a clear solution and used as the developing solvent for silica gel plates.

Detection Reagents—(a) Short wavelength and long wavelength UV light. (b) Potassium ferricyanide and ferric chloride solution: 5 ml. of 5% aqueous solution of potassium ferricyanide and 10

ml. of 10% aqueous solution of FeCl_3 were mixed and made to 50 ml. with water. This was used to spray cellulose plates. (c) Sodium metaperiodate 2% aqueous solution. (d) Doty's reagent: mix immediately before use equal volumes of ferrous sulfate-citrate solution and aminoacetate buffer. (For preparation of solutions, refer to *Analytical Methods* of this paper.) (e) Folin-Ciocalteu reagent (FCR) (17). This reagent was used for silica gel plates; the plates were first sprayed with FCR solution, air dried, and then sprayed with 10% aqueous Na_2CO_3 solution.

Chromatographic Procedure—A solution of isoproterenol HCl (230 mg.) and isoproterenol sulfonic acid (20 mg.) in about 30 ml. of water was prepared by mechanical shaking for 20 min., adding 139 mg. of sodium bisulfite to the clear solution, and making it to 50 ml. in a volumetric flask. Quantities of this standard solution (1–5 μ l.) containing equivalent of 4.6–23 mcg. of isoproterenol HCl and 0.4–2.0 mcg. of isoproterenol sulfonic acid were spotted adjacent to the aqueous solutions of the simulated formulations and/or commercial formulations (5 μ l.) containing equivalent to 25 mcg. of isoproterenol HCl. The plate was inserted in a solvent jar previously equilibrated with solvent [solvent system (a) for cellulose plates and solvent system (b) for silica gel plates] which was allowed to rise to a height of 10 cm. for cellulose plates and 15 cm. for silica gel plates (time about 120 min. for cellulose plates and 135 min. for silica gel plates). The plate was then air dried and examined under short and long wavelength UV light.

Examination of cellulose plates under short wavelength UV light showed a spot at the origin having a blue fluorescence (indicative of NaHSO_3 presence) and long wavelength UV light showed an additional spot having a strong blue fluorescence (R_f about 0.26) both for simulated and commercial formulations but not seen for the standard solution. Spraying the plate with DR (b) (potassium ferricyanide and FeCl_3 solution) caused the immediate formation of blue spots for isoproterenol HCl (R_f about 0.53) and isoproterenol sulfonic acid (R_f about 0.33). The spot seen under long wavelength UV light also stained blue after about half a minute, and thus the whole area from about 0.33 to 0.53 R_f values was seen as a single blue spot (limiting sensitivity of this spray for isoproterenol sulfonic acid 0.4 mcg.). Citric acid and sodium citrate present in a few commercial formulations also gave a blue spot of minor intensity after 2–5 min.; glycerin, another excipient, gave a minor blue spot after 5–10 min. Thus these spots due to their late formation did not interfere with the detection of the decomposition products. Spraying the second half of the plate with DR (c) or (d) caused the formation of reddish-colored spots for isoproterenol HCl and isoproterenol sulfonic acid with sodium metaperiodate spray and mauve-colored spots with Doty's reagent. The reddish-colored spot formed with NaIO_4 for isoproterenol sulfonic acid disappeared within 1 min. of its formation but that of Doty's reagent (mauve-colored spot) did not disappear. (Limiting sensitivity of both of these sprays was 2.0 mcg. for isoproterenol sulfonic acid.)

Examination of silica gel G plates under short wavelength UV light did not show any spot; long wavelength UV light showed two spots having blue fluorescence for inhalations containing 0.3% NaHSO_3 (R_f values of 0.03 and 0.1); three spots for inhalations containing 0.2% NaHSO_3 (R_f values 0.03, 0.1, and 0.16) and two spots for injections (depending upon the quantity spotted) at R_f of 0.1 and 0.16. Simulated formulations stored in the dark over a period of 4 months showed almost the same pattern, while a freshly prepared standard solution did not show any of these spots. Spraying the plate with DR(e)-FCR reagent followed by Na_2CO_3 spray caused the formation of purple spots for isoproterenol HCl (R_f about 0.4) and isoproterenol sulfonic acid (R_f about 0.26) (limiting sensitivity 0.6 mcg. for isoproterenol sulfonic acid). Among the spots seen under long wavelength UV, spots at R_f 0.1 gave coloration with this reagent for all formulations, while the spot at 0.16 R_f gave coloration for formulations having 0.2% NaHSO_3 . An additional bluish-purple spot at R_f 0.43 was also seen in some formulations. A freshly prepared standard solution mixture showed only two purple spots at R_f 0.4 and 0.26 for isoproterenol HCl and isoproterenol sulfonic acid, respectively.

RESULTS AND DISCUSSION

The TLC of simulated inhalations and injections stored in the dark over a period of 4 months showed that in addition to Compound II (Scheme 1), the drug can give rise to two to

^a Modified USP XVII method for the determination of epinephrine in procaine hydrochloride injection (determines total catechols as isoproterenol). ^b Isoproterenol HCl 115 mg., isoproterenol sulfonic acid 10 mg. (8.0%), and sodium bisulfite 65 mg. (0.3% w/v) in 25 ml. water. ^c Isoproterenol HCl 10 mg., sodium bisulfite 2 mg. plus excipients such as starch, lactose, saccharin, and talcum per tablet of average weight of 100 mg. ^d Isoproterenol HCl 125 mg., sodium bisulfite 75 mg. (0.3% w/v) plus excipients such as sodium chloride, citric acid, glycerin, and chlorobutanol dissolved in water to 25 ml. The pH was adjusted to 3.75 with 1 N sodium hydroxide. Molar ratio of sodium bisulfite to isoproterenol HCl is 1.42:1. ^e Isoproterenol HCl 125 mg., sodium bisulfite 50 mg. (0.2% w/v) plus excipients such as chlorobutanol and sodium chloride dissolved in water to 25 ml. The pH of the formulation was 2.8 (without adjustment). Molar ratio of sodium bisulfite to isoproterenol is 0.95:1. ^f Isoproterenol HCl 20 mg., sodium bisulfite 100 mg. (0.1% w/v) plus excipients such as lactic acid, sodium lactate, and sodium chloride dissolved in water to 100 ml. The pH of the formulation was 2.8 (without adjustment). Molar ratio of sodium bisulfite to isoproterenol is 11.9:1. ^{g,h,i,j} Labeled to contain active ingredients and sodium bisulfite in the same amounts as in simulated formulations ^{d,e,f}, and ^e, respectively. Formulations ^{g,h}, and ⁱ were found to have the pH values of 3.75, 3.35, and 3.75, respectively.

three decomposition products. The exact chemical nature of these additionally encountered artifacts could not be established but one of them can be envisaged as an aminochrome-sodium bisulfite addition compound by analogy with the similar compound described by Oesterling and Tse (18) in their procedure for the determination of total content of catecholamines in the urine. The total percent ratio of these to Compound II was found to be about 1:4 depending upon the molar ratio of sodium bisulfite to isoproterenol used in a formulation. In addition, other factors including conditions of storage and its length and the pH of the formulation may affect the relative formation of these components.

A method of analysis, to be completely reliable, therefore, should be capable of differentiating between the parent drug and the closely related sodium bisulfite addition product. Both isoproterenol and sulfonic acid II exhibit maximum absorption at 279 mμ and have similar molar absorptivity values. Although the method of Welsh and Sammul (1) based on the DEHP ion-pair and utilizing a diatomaceous earth column represents a major step in solving the problem, the technique suffers from certain disadvantages. When applied to a synthetic preparation containing known amounts of Compound II and sodium bisulfite, this method gave higher and inconsistent values for the parent drug. This discrepancy was reconciled by introducing a step to wash the ether effluent from the column with potassium phosphate buffer prior to the acid extraction. The aged simulated formulations containing artifacts in addition to Compound II (as shown by TLC) showed higher

recoveries for the unchanged drug due to carrying over some of the degradation products other than sulfonic acid to the DEHP-ether phase. The above shortcomings and the cumbersome steps of column packing and its elution were overcome by modifying the column method to a simple shakeout procedure and by washing the combined DEHP-ether solutions first with potassium phosphate buffer and then with water prior to the extraction of the unchanged drug with 0.1 N H₂SO₄. These modifications not only resulted in the increased specificity of the method (by removing some of the water-soluble degradation products) but also permitted the quantitative determination of isoproterenol sulfonic acid which is retained in the aqueous buffer phase. Thus the Compound II (sulfonic acid) is then determined selectively by treating the aqueous phase with Doty's reagents.

Application of the modified procedure to the simulated isoproterenol tablets and to the simulated decomposed sample containing 8% Compound II and 0.3% NaHSO₃ gave the results shown in Table I. Analytical range and standard deviation values demonstrate the accuracy and precision of the method. A batch of commercial isoproterenol tablets was analyzed by this method and the results (Table I) appear satisfactory in comparison with those obtained from the USP analyses and with data obtained with simulated tablets.

Data in Table II show the recoveries of isoproterenol sulfonic acid II from a simulated decomposed sample by the procedure described under *Determination of Isoproterenol Sulfonic Acid*.

Table II—Amount of Degradation Products and Isoproterenol Sulfonic Acid in Simulated and Commercial Formulations

Formulation	Assay Values for Isoproterenol, ^a % ^d	Total Water Soluble Degradation Products, ^b % ^d	Isoproterenol Sulfonic Acid, ^c % ^d	Isoproterenol HCl Undergone Degradation, % ^d
Simulated Formulations				
Inhalation ^e	89.6	12.4	11.6	11.1
Inhalation ^f	88.6	12.0	9.0	10.7
Injection ^g	84.3	19.1	15.0	17.2
Decomposed ^h	92.6	8.1	8.2	—
Commercial Formulations				
Inhalation ⁱ	106.8	7.5	4.7	6.8
Inhalation ^j	106.1	5.5	3.4	4.9
Injection ^k	100.0	15.6	15.5	14.0

^a Values quoted have been obtained by NaIO₄ method. ^b Values quoted for total water soluble degradation products have been obtained by measuring UV absorbance of the aqueous-buffer phase, and calculated as isoproterenol sulfonic acid. ^c Values quoted for isoproterenol sulfonic acid were obtained by the spectrophotometric quantitative measurement of the purple color formed by treating the aqueous phase with ferro-citrate solution and buffer. The reaction is specific for catechol nucleus only. ^d Calculated relative to the label claim. ^{e,f,g} Formulations same as ^{d,e,f} in Table I; assay values for ^e and ^f were obtained after 83 days of storage at room temperature, and for ^g after 88 days of storage. ^h Formulation same as ^b in Table I containing 8% isoproterenol sulfonic acid. ^{i,j,k} Commercial formulations same as ^{e,h,i} in Table I.

Simulated formulations which had been stored in the dark over a period of 3 months were also analyzed by this procedure. Table II also depicts the amounts of Compound II in the aged simulated formulations and in commercial formulations. One of the commercial formulations having a molar ratio of 11.9:1 of sodium bisulfite to isoproterenol was found to contain a considerable percentage of Compound II when it was analyzed 8–9 months after its procurement from the factory premises. The logic of using such a higher molar ratio of sodium bisulfite is not clearly understood, especially when the injection is to be administered by the intravenous route.

An alternate checking procedure to validate the results obtained by the DEHP method was sought. Consequently, sodium metaperiodate which is known to cleave carbon-carbon bonds of vicglycols, α -aminoalcohols where the amine is primary or secondary, and α -hydroxyketones (19), was used for the selective determination of the unchanged drug. This treatment results in the formation of an aryl aldehyde of the parent drug, and the Compound II or amino-chrome-type oxidation products do not yield this aldehyde. The aryl aldehyde is extracted into chloroform and UV-determined at 270 m μ . The typical UV spectrum of the reaction product is given in Fig. 1.

Figure 1—Absorption spectrum of the reaction product in chloroform (concentration equivalent to 140 mg. of isoproterenol HCl per milliliter of final chloroform solution).

Figure 2—Effect of time on the completion of reaction (concentration equivalent to 120 mg. of isoproterenol HCl per milliliter of final chloroform solution).

Figure 3—Effect of varying concentration of sodium metaperiodate on the formation of reaction product.

Experiments undertaken to obtain the quantitative yield of the reaction product indicated that (a) the sample and reagent be allowed to react for about 17–18 hr. (overnight) at room temperature, although periods up to 30 hr. did not adversely affect the reaction (Fig. 2); (b) a molar ratio, 116:1, of sodium metaperiodate to isoproterenol was satisfactory for analysis but a molar ratio of 82:1 was insufficient. On the other hand, a molar ratio as high as 165:1 did not show any untoward effect on the yield of the reaction product (Fig. 3); (c) the standard solution of isoproterenol HCl should contain approximately the same amount of sodium bisulfite as is present in the formulation. A 4–6-ml. aliquot of the diluted formulation used for NaIO₄ assay will contain about 0.48–0.72 mg. of NaHSO₃ and as shown in Fig. 4, the NaHSO₃ concentration from 0.48–0.96 mg. in the isoproterenol HCl standard did not affect the yield of the reaction product. Under these conditions, Beer's law was obeyed for a concentration of at least 140 mcg. of isoproterenol HCl per milliliter of final solution (Fig. 5). The effect of varying concentrations of Compound II on the recoveries of isoproterenol is shown in Fig. 6; the recoveries were not affected up to 28% concentration of the decomposition product.

When applied to the simulated isoproterenol tablets and to a simulated decomposed sample containing 8% Compound II and 0.3%

Figure 4—Effect of varying concentration of sodium bisulfite on the formation of reaction product.

Figure 5—Relationship between concentration and absorbance (absorbance of the reaction product in chloroform at 270 $m\mu$).

NaHSO_3 , the NaIO_4 method gave results (Table I) virtually identical with those obtained by the DEHP method. Results obtained by applying the NaIO_4 method to four commercial products containing isoproterenol are shown in Table I. The comparison of the experimental data with those obtained by the DEHP method shows a good correlation between the two, with comparable precision for three formulations. Only one formulation showed higher values by the DEHP method which were explicable by additionally encountered artifacts other than Compound II. The data show that although inhalations and injections sold on the market conform to the USP limits, the formulations may contain considerably large amounts of decomposition products. The accuracy and the precision of this method are demonstrated by the analytical range and standard deviation values obtained (Table I) by its application to the freshly prepared inhalations and injections. A simulated injection containing a molar ratio of 11.9:1 of NaHSO_3 to isoproterenol (identical to the commercial formulation) showed only 86% of the added isoproterenol content. Virtually no further deterioration of the isoproterenol content was noticed, even when the formulation was analyzed after 88 days of storage in the dark at room temperature (Tables II and III). Lower values were ascribable to the formation of 15% isoproterenol sulfonic acid.

The isoproterenol content found by the ferro-citrate colorimetric method (6, 20) and by the USP XVII UV spectrophotometric method (4) is a measure of the isoproterenol present at the time the solutions were manufactured. Values obtained by the two methods are satisfactory and in close agreement (Table I). The colorimetric method reported in the paper is a modification of the USP XVII procedure described for the determination of epinephrine in procaine hydrochloride injection (20). It was found that the amounts of NaHSO_3 as specified in the USP were too high and a substantial decrease in the color intensity was noticed. The amount of NaHSO_3 present in the commercial formulations was found adequate for reproducible color development. The order of adding reagents was another variable considered to be important, and thus the maximum reproducibility was obtained by adding ferrous sulfate reagent to the reaction solution to which the appropriate volume of the aminoacetate buffer had already been added. Time for color development was changed from 30 min. to 2.50 hr.

Table III shows the stability data of the simulated inhalations and injections stored in the dark at room temperature over a period of 88 days. The data indicate that the inhalation having a molar ratio of 1.42:1 of NaHSO_3 to isoproterenol did not show further deterioration of the isoproterenol content after 39 days. The data also revealed that no consistent pattern of degradation was followed

Figure 6—Effect of varying concentration of isoproterenol sulfonic acid on the recovery of isoproterenol HCl.

Table III—Analysis of Isoproterenol in Aged Simulated Formulations^a

Formulations	Storage Period, days	Assay Values for Isoproterenol ^b		
		NaIO_4 Method, %	DEHP Method, %	USP Method, %
Inhalation ^c	0	98.4	—	102.0
	39	89.5	—	—
	83	89.6	95.4 ^d	102.6
Inhalation ^e	0	98.9	—	100.3
	39	96.7	—	—
	83	88.6	95.9 ^d	100.8
Injection ^f	0	86.0	—	—
	39	86.0	—	—
	88	84.3	82.7 ^g	101.8

^a Stored in dark at room temperature. ^b Calculated relative to the label claim. ^{c,e,f} Formulations same as ^{d,e,f} in Table I. ^d Higher values for unchanged drug were obtained due to carrying over of certain decomposition products into DEHP-ether phase. ^e Values for unchanged drug in this formulation agreed very well to that of NaIO_4 method due to formation of isoproterenol sulfonic acid as the main degradation product. Formation of isoproterenol sulfonic acid as the main degradation product was favored due to high molar ratio of sodium bisulfite to isoproterenol, i.e., 11.9:1 and DEHP method has been found to be specific if the main degradation product formed is only sulfonic acid.

in all three formulations. These findings agree well with those made by Chafetz *et al.* (21).

The investigation showed that although solvent system (a) on cellulose was satisfactory for resolving isoproterenol and its sulfonic acid II, the solvent system (b) on silica gel G was an ideal one for the complete separation and detection of isoproterenol and its artifacts. Despite the specificity of NaIO_4 spray (formation of reddish color for isoproterenol and transient coloration for sulfonic acid) and Doty's reagent spray (mauve coloration for isoproterenol and its sulfonic acid), these are not suitable to detect the presence of isoproterenol sulfonic acid due to their low sensitivity (2 mcg. or more is required for color formation). Potassium ferricyanide- FeCl_3 spray (though less specific but having a sensitivity of less than 0.4 mcg.) and FCR spray (more specific having a sensitivity of 0.6 mcg.) were found very satisfactory to detect the presence of Compound II even in minor concentrations. Under the conditions used, the problem of an apparent second front as described by Choulis (16) and Chafetz *et al.* (21) was not encountered for the standard solution containing isoproterenol and its sulfonic acid and NaHSO_3 .

It is recommended that the DEHP shakeout method as described in the paper may be adopted as the official procedure in the USP XVIII for the analysis of isoproterenol formulations. This procedure has overcome the shortcomings of the method reported by Welsh and Sammul (1). Procedure with these modifications achieves all the essential criteria required for its inclusion in various official compendia by its simplicity, precision, accuracy, and specificity. It is further suggested that the limits (maximum and minimum) for isoproterenol sulfonic acid may be delineated for all the formulations containing sodium bisulfite as an antioxidant. TLC using silica gel G and *n*-butanol-acetic acid-water (60:10:25) as an ideal solvent may be included in the monograph to detect the presence of isoproterenol sulfonic acid and other artifacts.

The sodium metaperiodate method is also very specific and simple and can be automated very easily using the currently available Liquid Prep. Technicon Auto-Analyzer equipment. The method can be of potential value to the pharmaceutical industry to be utilized as a routine-monitoring and stability-indicating procedure for the unchanged drug in drug quality control.

TECHNICAL ARTICLES

Construction and Operation of an Automated Dispensing Analyzer for the Assay of Individual Tablets

WILLIAM F. BEYER* and EDWIN W. SMITH†

Abstract □ An automated system of modular design has been developed for the assay of single tablets. Commercially available proportioning pumps, continuous filter, tablet homogenizer, spectrophotometer, and recorder are mated to specially designed components for unattended operation. The system is constructed to analyze automatically up to 300 identifiable tablets with standards inserted prior to tablets, after any selected number of tablets, and at the end of the particular type of tablet being assayed. Up to six different concentrations or types of tablets can be automatically processed sequentially, each with its own standard insertion. Provisions are made to alter automatically the dilution of samples as tablet strengths vary. Under normal program conditions the system can operate unattended for approximately 18 hr.

Keyphrases □ Tablets, individual—automated analysis □ Automated dispensing analyzer, tablet—construction, operation □ Diagram—automated analyzer, individual tablets □ UV spectrophotometry—analysis

The assay of single tablets and single units in other dosage forms is recognized as an important feature in the quality control of manufacturing processes. Compendia requirements for content uniformity of selected tablets containing 50 mg. or less of drug substance has

placed additional burdens on the quality control chemist. To make data available in the quantity needed for statistically valid results, analytical procedures have been automated to varying degrees. The majority of automated assay systems that include sample preparation have incorporated a commercially available solid sampler,¹ as evidenced by symposia of the New York Academy of Sciences and Technicon Corp. (1–5). Papers presented at the 1967 New York Academy of Sciences included a presentation by Rehm *et al.* (2) describing an automated system for the UV analysis of single tablets.²

An automated system constructed in these laboratories for UV analyses of individual tablets has been in routine operation for more than a year. The system is of modular design and consists of commercially available components wherever possible. Provisions have been made for the introduction of liquid standards, dilution, and

Figure 2—Instruments comprising the automated dispensing analyzer, showing its modular design.

the mixing block is replaced with a polyethylene tube having a capillary opening and attached to a pulse suppressor (PCI),³ into which diluting lines are fed (Fig. 1).

Solid Sampler—An externally mounted solenoid valve⁴ replaces the internal wash water distribution solenoid valve carrying three associated rinsing lines. Two check valves⁵ replace the check valve for solvent introduction. Only the cup rinsing jet and the hopper jet nearest the cabinet of the solid sampler are used.

Heating Bath, 65°⁶—The diluent passes through 0.95-cm. (0.375-in.) copper tubing fashioned into a 12-turn, 11.43-cm. (4.5-in.) coil, immersed in a 65° water bath. The temperature of the diluent remains above 55° while in the blender.

UV-Visible Spectrophotometer⁷ with 1.0-cm. flow cell.⁸

Absorbance Recorder with event marker.⁹

Constructed Modules—Instream Diluting System—Four explosion-proof three-way solenoid valves⁴ are mounted in an elevated stand to match the height of the proportioning pump. Stainless steel fittings to accommodate approximately 0.32-cm. (0.125-in.) tubing were made for all ports of the solenoid valves. Entrance ports are connected to Solvaflex pumping tubes³ and exit ports to Teflon tubing leading either to the continuous filter or to waste.

Tablet-holding Disk and Tablet-dispensing Apparatus—Six disks of 50-tablet capacity were fabricated from 0.32-cm. (0.125-in.) and 1.27-cm. (0.5-in.) Plexiglas sheet stock. Numbered slots in the tablet-holding disk accommodate nearly all tablet shapes currently produced at the authors' company. Embedded in the rim of each tablet-holding disk is a strip of brass, sensed by a proximity probe, to signal that the last tablet has been dispensed. The disks, dispensing mechanism, turret, and proximity probe are shown in Fig. 3. The

Figure 3—Sample preparation and dispensing system: solid sampler; turret with six tablet disks, dispensing mechanism, and proximity probe; and the seven-figured tubing attachment unit for standards and tablet-wetting lines.

Commercially Available Modules, Modified in Some Instances—Proportioning Pumps (Two)³ and **Continuous Filter with Paper T-014**³—The chamber of the mixing block is enlarged to accommodate the large volumes of diluent required on occasion. The small nipple used to attach the sample line to the mixing block is replaced with a larger one (N-4)³ to prevent plugging of the nipple with tablet excipients after prolonged pumping of sample. The upper nipple of

tablet-dispensing mechanism is powered by a synchronous motor.¹⁰ A pulse signal from the programmer causes the motor to rotate the

^a Blue tetrazolium.

which determines the extent of sample dilution after aspiration from the homogenizer; and (e) the event pen of the recorder, energized upon delivery of standard.

The preparator control automatically governs functions of the system once started, yet permits the following actions manually by the operator: (a) selection of the number of standards dispensed prior to any tablets, numbers of tablets dispensed between the introduction of additional standards, and whether or not a standard is dispensed after the last tablet in each tablet-holding disk; (b) selection of the proper times for diluting valves to open or close in order that exact correspondence may be maintained after the introduction of a new series of tablets; (c) rotation of the turret to any one of the six tablet-holding disks for correct startings; (d) dispensing of standards and tablet-wetting medium prior to initiation of a run in order to purge the lines; and (e) testing for malfunction of individual components by activating selected switches or observing pilot lights as the entire sequence of operational events is simulated.

OPERATING PROCEDURE

A zero base line with 75% 3A alcohol is established using the manifold flow system of Fig. 1 and with all instruments operating (recorder, UV spectrophotometer at a wavelength at 242 mμ, two proportioning pumps, vacuum pump, continuous filter, 65° heating bath, solid sampler, and preparator control). Sixty milliliters of 75% 3A alcohol is used in the solid sampler. From 1–50 tablets are placed in numbered slots of each of the six disks, and the disks are mounted on the turret and secured. The tablet-wetting pump and all standard pumps used in the analysis are rinsed with solutions to be used to ensure that the lines are free of air and previous liquid. Programs for the standard pumps and associated tablet disks, diluent valves, and number of disks used in the assay are selected on the preparator control panel.

The recorded peak heights resulting from tablets and standards bracketing the tablets are used in conjunction with the concentrations of the standards to calculate the amount of active ingredient in each tablet.

RESULTS AND DISCUSSION

The manifold tubing and flow system of the automated dispensing analyzer is very similar to that reported for the automated UV assay of tolbutamide tablets (7). The durability of Solvaflex tubes during prolonged pumping with 75% 3A alcohol and the ability of this solvent to remove or minimize UV-absorbing material from the tubes were established in the tolbutamide studies (7).

A much better flow of liquid and more uniform air segmentation of the sample stream occurred when the diluent and air lines connected to the blender assembly of the solid sampler were interchanged in the manner described by Kuzel (8). The ratio of rinse to sample was increased (also suggested by Kuzel) so that during the wash cycle a portion of the rinse enters the sample line and the remainder enters the blender, blocking off seepage of sample. Directing the diluent from the solenoid valves to the mixing block of the continuous filter permitted the addition or interruption of diluent without changing sample flow rate. This was particularly important in programming the correct moment for the solenoid diluting valves to be activated. Placing a pulse suppressor in the diluent line at the mixing block of the continuous filter eliminated surging which gave poor mixing of unfiltered sample and diluent.

Standards, tablets, and tablet-wetting diluent are dispensed into the sample cups of the solid sampler 45 min. prior to homogenization. Complete dissolution of drug from the tablet is ensured by a combination of the 45-min. period and by the use of heated diluent in the homogenizing vessel of the solid sample. Delivery volumes of the six standards and one tablet-wetting pump were adjusted so that each pump filled ten 10-ml. volumetric flasks to the mark. Automatic addition of standards and manual pipeting gave equivalent results for steroids when analyzed by ADA.

Table I gives results for six levels of various steroids, four of which require the use of diluting valves. The data are the result of 10 replicate analyses with the automated system. The coefficients of variation ranged from 0.62% for prednisolone to 1.23% for hydrocortisone at concentrations of 2.5 mg./10 ml. and 20.0 mg./10.0 ml., respectively.

Table III—Statistical Results of Single Tablet Potency Assays

Numerous individual steroid tablet assays were carried out with the automated UV system. Representative data of prednisone, 5 mg., and methylprednisolone, 4 mg., are given in Table II. Approximately 50 tablets from each of 20 lots are shown with high and low tablets well within NF (9) and USP (10) limits for content uniformity (85-115% of the average of specified tolerances). Blue tetrazolium assays of composite samples of pulverized tablets are also shown in Table II.

Table III gives statistical data for individual tablet assays, with the steroid content varying from 0.75 mg. fluprednisolone to 25 mg. cortisone acetate. Steroid content, coefficients of variation, and 95% confidence limits were calculated for this series of tablets. Both production and assay precision determine the magnitude of the coefficient of variation and the spread of the 95% confidence limits. The highest coefficient of variation was 3.74% for 0.75 mg. fluprednisolone; the lowest was 0.92% for 1.0 mg. fluoxymesterone.

The tablet data of Tables II and III demonstrate the application of the automated system for unattended UV analysis of individual tablets. Changes only in manifold tubing and the addition or elimination of particular modules should permit the use of other end-point detection methods.

Uniformity of Distribution of Cyanocobalamin in Tablet Formulations

R. J. NESSEL, H. M. APELIAN, and J. BLODINGER

Abstract □ Some of the distribution characteristics of three commercially available, protected cyanocobalamin forms were demonstrated in each of two vitamin formulations of dissimilar particle size. The incorporation of ^{57}Co cyanocobalamin into each of these protected forms permitted rapid, precise measurements of the distribution on individual unit doses. Statistical analysis of the data confirmed the visual observations of improved distribution of the 1% gelatin product.

Keyphrases □ Cyanocobalamin- ^{57}Co —formulation distribution □ Distribution characteristics—cyanocobalamin- ^{57}Co in tablets □ Wet granulation, direct compression—cyanocobalamin- ^{57}Co distribution comparison □ Scintillometry—analysis

Solids mixing has undergone a great deal of scrutiny during the past 20 years, with particular emphasis on rates and mechanisms of the mixing process and on equipment evaluation.

Reviews on these subjects have been made by Weidenbaum (1), Jameson (2), Valentin (3), and Scarlett (4). Few workers, however, have published on the conditions, factors, and properties of the particles themselves or on the particulate system, especially those factors which influence uniform distribution of the active ingredient within a batch and thus affect accurate dosage within each unit dose.

Train (5, 6), in his review articles, considers such factors as particle bed dilation, induced forces, particulate physical properties, and surface forces of particles and their effect on the results of a mixing operation.

He states that particle bed dilation and induced forces are necessary to permit movement of the components in all directions, thus preventing (a) dead zones within a system, and (b) movement of aggregates as compound entities. In addition, such physical properties as particle size, shape, and density of the various components are key factors in obtaining a uniform mix without segregation tendencies.

The presence of surface-active forces causes aggregation of particles which are difficult to disperse evenly throughout the other components during the normal mixing time.

Rippie *et al.* (7-9) have investigated the properties which contribute to the mixing and unmixing of particulate systems.

The constantly increasing number of high-potency, low-dosage drugs being developed emphasizes the necessity for obtaining proper distribution of particles within a batch.

One of the most potent products of this type in wide use today is cyanocobalamin (vitamin B-12), which is marketed in several protected forms so as to prevent instability of the cyanocobalamin in the presence of

Table I—Mesh Distribution of Vitamin Formulations

certain other active components or their degradation products. The quantity of protected vitamin B-12 necessary to provide the required potency-per-unit dose is extremely low and is usually in the range of 0.05 to 0.15% in relation to the total batch.

The purpose of this investigation is to compare some of the distribution properties of three commercially available, protected forms of vitamin B-12. These properties are examined in multiple vitamin formulations prepared by wet granulation and by direct compression methods.

Presently, there are three methods of assay available for vitamin B-12 in multicomponent tablets: microbiological (10), radiotracer (11), and cyanide measurement (12).

These methods, although valid, do not present a precise picture of the distribution of the vitamin in the final dosage, since the sample required is in excess of a single dose.

The tracer method requires a sample size sufficient to contain 200 to 400 mcg. of the vitamin, thus encompassing as many as 400 dosage units. The result, therefore, is an average potency-per-unit dose.

The microbiological procedure, although not as precise as the previous method, requires a minimum of five doses for proper sampling. Thus, as with the tracer

^a Portion of compression cycle.

method, only an average potency-per-dosage unit is obtained.

The cyanide measurement method, while being one of the most sensitive chemical methods for cyanocobalamin, is not specific because other nonvitamin materials may also liberate trace amounts of cyanide.

Although the last two procedures could be adapted to single tablet assays, the time required for each determination is excessive.

For this study, the protected cyanocobalamin forms were radioactively labeled, permitting rapid, precise measurements of the vitamin B-12 content on a unit dose.

EXPERIMENTAL

Preparation of Radioactive Materials—Cyanocobalamin-⁵⁷Co solution, USP,¹ equivalent to 50 and 500 μ c., respectively, of radioactivity was used in the preparation of the 0.1%² and 1%³ cyanocobalamin in gelatin products by adding it to the solution prior to the drying process.

Commercially available 1% cyanocobalamin on resin⁴ was slurried for 8 hr. with USP ⁵⁷Co cyanocobalamin solution, equivalent to 500 μ c. of the radioactive compound, and dried overnight at 40° in a circulating air oven. The dried powder was passed through an 80-mesh standard sieve to break up any soft agglomerates which formed. Mesh analysis performed before and after labeling revealed that no change in particle size was evident.

Preparation of Basic Formulations—The distributive properties of the cyanocobalamin forms were studied in each of two vitamin formulations: (a) a granulated formula, prepared by wet granulation procedures, representing a formulation having diversified particle size; (b) a dry blend, directly compressible, representing a formulation of materials in the fine-particle-size range.

The mesh distribution of each of the formulations is shown in Table I.

Mixing Evaluation—The procedure for blending the labeled compounds varied only with respect to the premix step.

In the case of the granulation, 85 g. of finer-than-80-mesh material was removed by screening. The radioactive material was added to

the fines, coarsely blended, passed through a 40-mesh screen, and reblended for 5 min. in a rotating bottle.

The premix for the direct compression formulation was prepared by coarsely blending the labeled material with 95 g. of the mixture containing vitamins and diluents normally added after a milling operation, passing this blend through a 30-mesh screen, and reblending for 5 min. in a rotating bottle.

Final blending of all formulations was accomplished by adding the premix to approximately half of the material in a Twin Shell blender,⁵ blending for 5 min., adding the remainder of the formula, and blending an additional 10 min.

Samples equivalent to the theoretical tablet weight were then removed for counting from the top and bottom sections of the blender to determine the efficiency of the operation.

Each formulation was compressed on a Rotary B-2 tableting machine⁶ at a maximum speed of 700 tablets per minute.

Once the theoretical tablet weight was attained, samples were removed from the beginning, middle, and end of the tableting run. Twenty tablets were selected at random from each of the three samples and individually weighed on a single-pan Mettler balance.

All radioactivity counts were made on a Model SC 530 gamma spectrometer.⁷

RESULTS AND DISCUSSION

The quantities of radioactivity were utilized in the preparation of the labeled forms to provide a minimum of 5000 counts per minute when 5 mcg., plus a 10% excess of cyanocobalamin, were incorporated per tablet.

The degree of mixedness of each of the formulations prior to compression, as shown in Table II, reflects satisfactory blending in all cases.

A radioactive count was performed on tablet samples before and after disintegration in water to ascertain counting efficiency in the dry state as opposed to the wet state. Since the radioactivity count on both samples varied by less than 1%, all future counts were made on intact tablets. Each sample counted in duplicate for 1 min. yielded 6000–7500 counts, with a 10-min. background count of 1000. The average count was corrected for background interference and converted to counts per minute per milligram of tablet weight to provide an accurate determination of the distribution of the vitamin B-12 form on a unit weight basis. The results are shown in Tables III and IV.

Table V—Variances by Formulation by Position in Batch

Position	1% Gelatin	1% Resinate	0.1% Gelatin
Wet Granulated Formulation			
Beginning	0.0573	0.2129	0.1709
Middle	0.0408	0.1653	0.0655
End	0.0398	0.2737	0.1275
Dry Blend Formulation			
Beginning	0.0287	0.1640	0.0127
Middle	0.0363	0.1637	0.0158
End	0.0270	0.1060	0.0120

The variances by formulation and position in batch were calculated from the data and are shown in Table V. The analysis of variance for each formulation was made on the logarithms of the individual cell variance and is shown in Table VI. Statistically significant differences in variation were exhibited between formulations. These differences in variability were of such high levels of significance that individual *F* ratios were computed for the three types of formulations. In all cases, the difference in variability between the 1% gelatin products and the 1% resin adsorbate was more statistically significant than that between the 1% and the 0.1% gelatin products.

The significantly lower variability of the 0.1% product, as compared to the 1% gelatin form in the dry mix formulation, may probably be attributed to a dilution effect caused by the tenfold increase in quantity required to obtain the same potency. This may also be true for the significantly lower variability in both formulations obtained for the 0.1% gelatin product, as compared to the 1% resinate. Table VII depicts the significance levels of the *F* ratios. These were computed from the ratios of the variances shown in Table V.

Table VI—Analysis-of-variance Calculations on the Logarithms of the Variances

Source of Variation	DF	SS	MS	F
Wet Granulated Formulation				
Position of batch	2	0.08139	0.04069	3.30
Formulation	2	0.68376	0.34188	25.65
Pos. X form.	4	0.04932	0.01233	
Total	8	0.81447		
Dry Blend Formulation				
Position of batch	2	0.03191	0.01595	7.03
Formulation	2	1.62227	0.81113	238.22
Pos. X form.	4	0.00911	0.00227	
Total	8	1.66329		

Table VII—Significance Levels of *F* Ratios

Position	1% Gelatin vs. 1% Resinate	1% Gelatin vs. 0.1% Gelatin	0.1% Gelatin vs. 1% Resinate
Wet Granulated Formulation			
Beginning	99.5%	97.5%	<75.0%
Middle	99.5%	90.0%	97.5%
End	99.9%	99.0%	95.0%
Dry Blend Formulation			
Beginning	99.9%	95.0%	99.9%
Middle	99.9%	95.0%	99.9%
End	99.5%	97.5%	99.9%

It is interesting to note that in comparing the actual variances for both 1% products, the individual position values for the resin product were about 4 to 7 times greater than those for the gelatin product.

SUMMARY AND CONCLUSIONS

Three commercially available protected vitamin B-12 products were labeled with ⁵⁷Co cyanocobalamin. Each was then blended with both a granulated and a dry mix vitamin formulation and compressed into tablets.

The distribution characteristics for each form were evaluated by measuring the radioactivity of individual tablets obtained from different portions of the compression run.

Statistical analysis of the data showed that in all cases, variations in ⁵⁷Co labeled cyanocobalamin content throughout both formulations were significantly lower for the 1% gelatin product than for the resin product, indicating that it distributes more uniformly in tablet formulations.

For the granulated formulation, the variation of the 1% gelatin form was also less than its 0.1% counterpart. For the dry blend, however, the variation in the 0.1% product was lower, although the difference was less significant than that found when the two 1% products were compared. A significantly lower variability was also evident in both formulations for the 0.1% gelatin product, as compared to the 1% resinate.

These latter results may possibly be attributed to the fact that the quantity requirement of the 0.1% product is 10 times that of the 1% material.

NOTES

Metabolic Fate of 2,3,5-Triiodobenzoic Acid in Laying Hens

SUSAN G. ROWLES, GORDON S. BORN, JOHN E. CHRISTIAN, and WAYNE V. KESSLER

Abstract □ The whole body retention, distribution, and metabolism of carboxyl-¹⁴C-labeled 2,3,5-triiodobenzoic acid (TIBA*) were studied in five laying hens. A single oral dose of TIBA* showed a 22-hr. biological half-life. No organ concentration of TIBA* was noted. TIBA* and seven labeled metabolites were found in excreta collected 6 to 12 hr. after the dose, with TIBA* representing the major end product. TIBA* and four labeled metabolites were detected in excreta collected during the 78 to 90-hr. interval; the metabolites occurred in greater proportion than did TIBA* in this sample.

Keyphrases □ 2,3,5-Triiodobenzoic acid (TIBA), carboxyl-¹⁴C-labeled—metabolic fate □ Distribution, metabolism, whole body retention—TIBA, carboxyl-¹⁴C-labeled □ Metabolites—TIBA, carboxyl-¹⁴C-labeled □ Thick-layer chromatography—separation, identification

Greer and Anderson (1) reported that treatment of soybean plants with 2,3,5-triiodobenzoic acid (TIBA) at the beginning of flowering resulted in an increased seed yield due to two major types of effects. Their studies showed that TIBA caused the plants to change from vegetative to reproductive development more rapidly and also caused morphological changes which permitted more efficient utilization of sunlight by the plants. Since a residue of TIBA remains in soybeans grown from treated plants (2), the potential environmental health hazard of TIBA should be investigated prior to the general usage of the compound in agriculture. For this reason, a study of the retention, distribution, and metabolism of TIBA in laying hens was of interest.

Ice *et al.* (3, 4) employed TIBA labeled with ¹³¹I in Position 2 (TI*BA) for metabolism studies in rats and lactating animals. In both studies, a significant thyroid concentration of ¹³¹I was noted, and metabolism by

deiodination was indicated. In rats and in lactating animals, the whole body retention of TI*BA was characterized by a two-component system.

Ware and Barker (5) administered carboxyl-¹⁴C-labeled TIBA (TIBA*) orally to rats and found TIBA* and/or its labeled metabolites in all organs analyzed. Excretion of the compound was primarily through the urine, in which both TIBA and 2,5-diiodobenzoic acid were detected.

The metabolism of TIBA by chickens was investigated by Barker *et al.* (6) who employed TIBA labeled with ¹²⁵I in Positions 3 and 5. They found that 90% of the orally administered radioactivity was excreted within 48 hr. and that TIBA and 2,5-diiodobenzoic acid were present in the excreta. The same investigators dosed chickens and pigs with unlabeled TIBA and detected, by using gas chromatography, the presence of TIBA, 2,5-diiodobenzoic acid, and 3,5-diiodobenzoic acid in the chicken brains and in the thyroids of both chickens and pigs.

EXPERIMENTAL

Administration of TIBA*—Carboxyl-¹⁴C-labeled TIBA (TIBA*) was available from the work reported by Spitznagle (2) and was purified immediately prior to use in this study by a method similar to that reported by Jarboe (7). An ethanolic solution of the impure TIBA* was applied to thick-layer plates (1.0 mm.) of purified silica gel¹ which were then developed three times each (12 cm. per development) in petroleum ether (30 to 60° fraction)—propionic acid (10:1 v/v) (8). The silica containing the pure TIBA*, located on the chromatograms by autoradiography, was removed from the plates and extracted with anhydrous ethyl ether, using a continuous extraction apparatus. The ether was allowed to evaporate at room

Thyroid	7.4	0.9

^a Mean of five hens.

temperature, giving crystals of purified TIBA*. The radiochemical purity of the purified TIBA* was greater than 99%, as determined by thin-layer chromatography, autoradiography, and ¹⁴C assay of the chromatogram.

Five laying single comb white leghorn hens were given, by oral intubation, a single dose of a 2.23% solution of TIBA* in ethanol and glycerin (1:1 v/v). This dose contained 7.7 mg. of TIBA* and 57.1 μ C of ¹⁴C per kilogram of body weight.

Sample Collection and Analysis—The animals were housed individually in metabolism cages and were supplied a breeder laying mash and tap water *ad libitum*. Total excreta samples were collected from each hen at 6, 12, 18, 24, 30, 42, 54, 66, 78, 90, and 96 hr. Eggs were collected immediately after they were laid and were hard-cooked prior to analysis. The animals were sacrificed by decapitation 96 hr. after the dosage, and samples of the brain, breast muscle, fat, gizzard, heart, kidney, liver, thigh muscle, and the thyroids were obtained. Representative aliquots of the excreta, egg albumin, egg yolk, and tissue samples were digested with a 1 M methanolic solution of hyamine hydroxide² and mixed with 15 ml. of a liquid scintillator containing: PPO, 10.0 g.; naphthalene, 80.0 g.; *p*-xylene, 143 ml.; *p*-dioxane, 429 ml.; and a sufficient quantity of 2-ethoxy-ethanol to make 1 l. The samples were then assayed for ¹⁴C in an internal sample liquid scintillation spectrometer. Internal standardization with benzoic acid-¹⁴C was employed to correct for quenching. Sample-counting efficiencies of approximately 50% were obtained.

Metabolism—Twelve-gram aliquots of the 6 to 12-hr. and 78 to 90-hr. excreta samples from the one hen whose egg-laying pattern was most regular were extracted separately with anhydrous ether using a continuous extraction apparatus. After a 48-hr. extraction period, 60% of the ¹⁴C present in the samples was extracted. Following this extraction, portions of the extracted samples were then hydrolyzed separately with 85% *o*-phosphoric acid and 2 N nitric acid. Less than 2% of the remaining ¹⁴C could be extracted from the acid-treated samples with ether.

^a Determined by thick-layer chromatography on purified silica gel plates (1 mm.) developed in petroleum ether (30 to 60° fraction)–propionic acid (10 to 1 v/v). ^b Based on cochromatography with reference standards.

The ether extracts were concentrated and applied to thick-layer (1.0 mm.) plates of purified silica gel. The plates were developed three times each (12 cm. per development) in petroleum ether (30 to 60° fraction)–propionic acid (10:1 v/v) (9), air-dried, and autoradiographed. Reference standards of unlabeled TIBA and six suspected metabolites were chromatographed simultaneously on the same plates and were then visualized by spraying with a 0.1% solution of bromocresol green in acetone.

The radioactive zones located by autoradiography were scraped individually from the chromatograms and added to 18 ml. of a scintillator gel,³ mixed thoroughly, and assayed for ¹⁴C to determine their relative occurrence.

RESULTS AND DISCUSSION

The retention of TIBA* and/or its labeled metabolites at various intervals following oral administration of TIBA* is given in Table I. Mathematical analysis of these data suggests that TIBA* and/or its labeled metabolites have a single component retention system with a biological half-life of approximately 22 hr. This is in contrast to the two-component systems observed in studies using ¹²⁵I-labeled TIBA (3, 4). At the end of the 96-hr. study, 95.3% of the administered ¹⁴C was recovered in the excreta.

Very small quantities of TIBA* and/or its labeled metabolites were detected in the tissues, as shown in Table II. At the end of the 96-hr. study, the maximum ¹⁴C level detected in any tissue corresponded to less than 0.004% of the administered dose per gram of tissue. Fairly wide variations of tissue ¹⁴C levels were noted among the five animals, as seen by the magnitude of the mean standard errors reported in Table II. This may be due in part to the very low level of activity present in all tissues and to biological variation among the hens. No organ concentration of ¹⁴C was noted. This result is significant because of its contrast to studies in rats, cows, and goats which showed that the thyroid concentrated ¹²⁵I-labeled TIBA and/or its labeled metabolites, most probably in the form of ¹²⁵I[−] ion (3, 4).

The level of ¹⁴C present in all eggs collected during the 96-hr. study was very low. The maximum amount of ¹⁴C detected in any yolk or albumin fraction corresponded to less than 0.008% of the administered dose per gram of egg fraction.

The TIBA* and its labeled metabolites present in the 6 to 12-hr. excreta extract were separated by thick-layer chromatography into eight fractions corresponding to four unknowns, TIBA, 2,3-diiodobenzoic acid (2,3-DIBA), 2,5-diiodobenzoic acid (2,5-DIBA), and 3,5-diiodobenzoic acid (3,5-DIBA). The ether extract of the 78 to 90-hr. excreta sample contained two unknowns, TIBA, 2,3-DIBA, and 2,5-DIBA, as determined by thick-layer chromatography. The relative occurrence of TIBA* and its labeled metabolites in the excreta extracts is given in Table III. These results show that the major labeled compound detected in the 6 to 12-hr. excreta sample was TIBA, which accounted for 52.6% of the ether extracted radioactivity. Metabolites present in smaller quantities included

³ A 4% w/w solution of Cab-O-Sil Thixotropic Gel Powder, Packard Instrument Co., Downers Grove, Ill., and the liquid scintillator described above.

2,5-DIBA, 3,5-DIBA, and 2,3-DIBA. TIBA was present in the 78 to 90-hr. sample in a smaller proportion than in the 6 to 12-hr. sample, and accounted for only 10.2% of the extracted ^{14}C . However, the metabolites occurred in larger proportions in the later sample. The results of the metabolite study indicate that TIBA is metabolized to a significant extent by deiodination.

SUMMARY

In the authors' opinion, TIBA has a low probability of becoming an environmental health hazard for a number of reasons. Other investigators have reported the following: TIBA is applied to soybeans in very small quantities and only a minute fraction of the amount applied can be detected in the harvested beans; the toxicity of TIBA is relatively low in humans; and the major portion of TIBA ingested orally by rats, cows, goats, and chickens is excreted rapidly. The work reported here also shows rapid excretion of TIBA in chickens, and no egg or organ concentration of the compound.

N-acyl Derivatives of Bis-(4-aminophenyl) Disulfide and its Thiolsulfinate

WILLIAM O. FOYE and JOSEPH P. SPERANZA

Abstract □ Bis-(4-aminophenyl)-sulfone and several N,N' -diacyl derivatives have shown appreciable activity as antimalarials. With the assumption that a molecule more readily cleaved to a p -aminophenyl sulfur or oxidized sulfur anion, as a potential anti-PAB substance, might be a more effective antimalarial, a series of N,N' -diacyl derivatives of bis-(4-aminophenyl) disulfide was synthesized. Oxidation with peroxide followed by acylation gave the corresponding thiolsulfonates. Antimalarial activity was found for bis-(4- p -acetamidobenzenesulfonamidophenyl) disulfide and N,N' -bis-(α -aminoacyl) derivatives of bis-(4-aminophenyl)-sulfone.

Keyphrases □ Bis-(4-aminophenyl) disulfide and thiosulfinate— N -acyl derivatives synthesis □ Antimalarial activity—bis-(4-aminophenyl) disulfide derivatives □ IR spectrophotometry—structure □ UV spectrophotometry—structure

Diaminodiphenylsulfone (DDS) (1) and its N,N' -diacetyl derivative (2) have both shown appreciable antimalarial activity, particularly against strains of *P. falciparum* resistant to chloroquine and other widely used antimalarials. Evidence has been found to suggest that these compounds are effective by interfering with the utilization of PABA by the parasites (3). If this is the case, then compounds more readily cleaved *in vivo* to a p -aminophenyl sulfur or oxidized sulfur moiety might interfere more effectively with PABA utilization. Accordingly, a series of N,N' -diacyl derivatives of bis-(4-aminophenyl) disulfide and S -oxidized derivatives has been prepared for antimalarial evaluation.

Other disulfides, including 5,5'-diacetamido-8,8'-diquinolyl disulfide, have shown antimalarial activity (4, 5).

Bis-(4-aminophenyl) disulfide was obtained by the procedure of Price and Stacy (6), in which sodium 4-aminophenylmercaptide was oxidized by 30% hydrogen peroxide to the disulfide. The product showed the expected IR absorption bands for an aromatic amine, in addition to two sharp bands at 1175 and 1065 cm^{-1} . Brederick (7) has attributed the presence of these bands in aromatic disulfides to the disulfide linkage and a 1,4-disubstituted aromatic ring, respectively. However, aliphatic disulfides have shown similar peaks in the 1050–1250 cm^{-1} region which were believed due to CH wag on the carbon adjacent to sulfur (8). UV absorption showed a peak at 256 $\text{m}\mu$, characteristic of disulfides (9), with a shoulder at 290–295 $\text{m}\mu$.

Peroxide oxidation of aliphatic disulfides has led to formation of thiolsulfonates, thiosulfonates, and α -disulfones, depending on reaction conditions (10). Also, percamphoric acid oxidation of alkyl or aryl disulfides gave mixtures of disulfides, thiolsulfonates, and thiosulfonates (11). With bis-(4-aminophenyl) disulfide, peroxide oxidation gave only the thiolsulfinate, even on long standing. Heating resulted in decomposition. IR absorption of the product showed a peak at 1050 cm^{-1} , in addition to those present for the disulfide, which is characteristic of thiolsulfonates (8, 12). UV

2,5-DIBA, 3,5-DIBA, and 2,3-DIBA. TIBA was present in the 78 to 90-hr. sample in a smaller proportion than in the 6 to 12-hr. sample, and accounted for only 10.2% of the extracted ^{14}C . However, the metabolites occurred in larger proportions in the later sample. The results of the metabolite study indicate that TIBA is metabolized to a significant extent by deiodination.

SUMMARY

In the authors' opinion, TIBA has a low probability of becoming an environmental health hazard for a number of reasons. Other investigators have reported the following: TIBA is applied to soybeans in very small quantities and only a minute fraction of the amount applied can be detected in the harvested beans; the toxicity of TIBA is relatively low in humans; and the major portion of TIBA ingested orally by rats, cows, goats, and chickens is excreted rapidly. The work reported here also shows rapid excretion of TIBA in chickens, and no egg or organ concentration of the compound.

N-acyl Derivatives of Bis-(4-aminophenyl) Disulfide and its Thiolsulfinate

WILLIAM O. FOYE and JOSEPH P. SPERANZA

Abstract □ Bis-(4-aminophenyl)-sulfone and several *N,N'*-diacyl derivatives have shown appreciable activity as antimalarials. With the assumption that a molecule more readily cleaved to a *p*-aminophenyl sulfur or oxidized sulfur anion, as a potential anti-PAB substance, might be a more effective antimalarial, a series of *N,N'*-diacyl derivatives of bis-(4-aminophenyl) disulfide was synthesized. Oxidation with peroxide followed by acylation gave the corresponding thiolsulfonates. Antimalarial activity was found for bis-(4-*p*-acetamidobenzenesulfonamidophenyl) disulfide and *N,N'*-bis-(α -aminoacyl) derivatives of bis-(4-aminophenyl)-sulfone.

Keyphrases □ Bis-(4-aminophenyl) disulfide and thiosulfinate—*N*-acyl derivatives synthesis □ Antimalarial activity—bis-(4-aminophenyl) disulfide derivatives □ IR spectrophotometry—structure □ UV spectrophotometry—structure

Diaminodiphenylsulfone (DDS) (1) and its *N,N'*-diacetyl derivative (2) have both shown appreciable antimalarial activity, particularly against strains of *P. falciparum* resistant to chloroquine and other widely used antimalarials. Evidence has been found to suggest that these compounds are effective by interfering with the utilization of PABA by the parasites (3). If this is the case, then compounds more readily cleaved *in vivo* to a *p*-aminophenyl sulfur or oxidized sulfur moiety might interfere more effectively with PABA utilization. Accordingly, a series of *N,N'*-diacyl derivatives of bis-(4-aminophenyl) disulfide and *S*-oxidized derivatives has been prepared for antimalarial evaluation.

Other disulfides, including 5,5'-diacetamido-8,8'-diquinolyl disulfide, have shown antimalarial activity (4, 5).

Bis-(4-aminophenyl) disulfide was obtained by the procedure of Price and Stacy (6), in which sodium 4-aminophenylmercaptide was oxidized by 30% hydrogen peroxide to the disulfide. The product showed the expected IR absorption bands for an aromatic amine, in addition to two sharp bands at 1175 and 1065 cm^{-1} . Brederick (7) has attributed the presence of these bands in aromatic disulfides to the disulfide linkage and a 1,4-disubstituted aromatic ring, respectively. However, aliphatic disulfides have shown similar peaks in the 1050–1250 cm^{-1} region which were believed due to CH wag on the carbon adjacent to sulfur (8). UV absorption showed a peak at 256 $\text{m}\mu$, characteristic of disulfides (9), with a shoulder at 290–295 $\text{m}\mu$.

Peroxide oxidation of aliphatic disulfides has led to formation of thiolsulfonates, thiosulfonates, and α -disulfones, depending on reaction conditions (10). Also, percamphoric acid oxidation of alkyl or aryl disulfides gave mixtures of disulfides, thiolsulfonates, and thiosulfonates (11). With bis-(4-aminophenyl) disulfide, peroxide oxidation gave only the thiolsulfinate, even on long standing. Heating resulted in decomposition. IR absorption of the product showed a peak at 1050 cm^{-1} , in addition to those present for the disulfide, which is characteristic of thiolsulfonates (8, 12). UV

absorption was found at 254 $m\mu$, but lacked the shoulder at 290 $m\mu$ of the disulfide.

Oxidation of bis-(4-nitrophenyl) disulfide at room temperature with 30% peroxide returned only starting material, but in refluxing acetic acid, an oxidation product was obtained. A low yield of bis-(4-nitrophenyl) sulfone was isolated; this result agrees with previous observations on the oxidation of either *p*-nitrothiophenol (13, 14) or bis-(4-nitrophenyl) disulfide (15) where only the sulfone was isolated. This unexpected product has been attributed both to the presence of bis-(4-nitrophenyl) sulfide as an impurity (15) and to cleavage of the C—S bond (14).

Since the toxicity of bis-(4-aminophenyl) sulfone was diminished by *N*-acylation (16), various acylation products of bis-(4-aminophenyl) disulfide and its thiolsulfinate were prepared. These included the acetyl, methanesulfonyl, *p*-toluenesulfonyl, *p*-acetamidobenzenesulfonyl, glyceryl, α -phthalimidoacyl, and *N*-carbodithioate. Previously, introduction of α -aminoacyl and α -phthalimidoacyl groups reduced the toxicity of bis-(4-aminophenyl) sulfone without affecting antibacterial activity appreciably (17). The dithiocarbamate of bis-(4-aminophenyl) disulfide was obtained in the presence of a large excess of triethylamine, and showed characteristic IR absorption at 990 and 1010 cm^{-1} for the dithiocarbamate group (18). Similar IR absorption was shown by the dithiocarbamate of the thiolsulfinate, but confirming analytical data were not obtained for this compound.

Antimalarial Test Results—Antimalarial screening in mice using *Plasmodium berghei* has been carried out by the Walter Reed Army Institute of Research and reported to us by Dr. D. P. Jacobus. Bis-(4-*p*-acetamidobenzenesulfonamidophenyl) disulfide effected a cure in one of five mice (60-day survival) (three dying of drug toxicity) at a dose of 640 mg./kg. No activity was found for bis-(4-aminophenyl) disulfide, bis-(4-*p*-tolylsulfonamidophenyl) disulfide or the bis-(*N*-phthalimidoacetyl), bis-[*N*-(2-phthalimido-3-phenyl)-propionyl] or bis-(*N*-carbodithioate) derivatives of bis-(4-aminophenyl) disulfide. Also, of the thiolsulfonates, the 4-acetamidophenyl, 4-methylsulfonamidophenyl, 4-phthalimidoacetamidophenyl, and 4-(2-phthalimido-3-phenyl)-propionamidophenyl derivatives were inactive.

The bis-glyceryl and bis-phenylalanyl derivatives of DDS, previously prepared (17), were described as curative, however. Bis-(4-nitrophenyl) sulfone was also curative.

EXPERIMENTAL

Analyses for carbon, hydrogen, and nitrogen were done by Weiler and Strauss, Oxford, England. Sulfur analyses were done by Parr bomb peroxide fusion. Melting points were taken on a Mel-Temp block and are uncorrected. IR absorption spectra were obtained with a Perkin-Elmer model 137B spectrometer.

Bis-(4-phthalimidoacetamidophenyl) Disulfide—To a solution of 2.5 g. (0.01 mole) of bis-(4-aminophenyl) disulfide (6) in 50 ml. of dry pyridine at 0° was added with stirring 4.5 g. (0.02 mole) of phthalimidoacetyl chloride (19) during a period of 10 min. The mixture was stirred for 4 hr. at 0°, and the resulting solution was poured into 250 ml. of cold water containing 25 ml. of sulfuric acid. The solid product was collected, washed with water, and digested in a mixture of 2-ethoxyethanol and water (4:1), giving 2.8 g. (45%) of cream-colored solid, m.p. 302–305° (dec.).

Anal.—Calcd. for $\text{C}_{32}\text{H}_{22}\text{N}_4\text{O}_6\text{S}_2$: C, 61.74; H, 3.57; N, 8.99; S, 10.29. Found: C, 62.13; H, 3.44; N, 9.19; S, 10.83.

Bis-(4-aminoacetamidophenyl) Disulfide Dihydrochloride—To a suspension of 0.62 g. (0.001 mole) of bis-(4-phthalimidoacetamidophenyl) disulfide in a mixture of 20 ml. of dimethylformamide and 5 ml. of water was added with stirring 3.0 ml. (0.0026 mole) of alcoholic hydrazine hydrate (1 *M*). Stirring was continued for 1 hr. and concentrated hydrochloric acid was added dropwise to distinct acidity. Water (50 ml.) was added, the mixture was chilled, and phthalazine-1,4-dione was removed. The filtrate was distilled under reduced pressure to a volume of 10 ml., methylene chloride was added, and the precipitate was collected and recrystallized from dilute hydrochloric acid, giving 0.1 g. of yellow solid, m.p. 255–257° (dec.).

Anal.—Calcd. for $\text{C}_{16}\text{H}_{20}\text{Cl}_2\text{N}_4\text{O}_6\text{S}_2$: C, 44.14; H, 4.63; N, 12.87. Found: C, 43.51; H, 4.65; N, 13.35.

Bis-[4-(2-phthalimido-3-phenyl)-propionamidophenyl] Disulfide—To a solution of 2.5 g. (0.01 mole) of bis-(4-aminophenyl) disulfide in 50 ml. of dry pyridine at 0° was added with stirring 6.4 g. (0.02 mole) of 2-phthalimido-3-phenylpropionyl chloride (19) during 10 min. The reaction was carried out as above, and 4.5 g. (56%) of pale yellow product was obtained; m.p. 267–269° (dec.).

Anal.—Calcd. for $\text{C}_{46}\text{H}_{34}\text{N}_4\text{O}_6\text{S}_2$: C, 68.80; H, 4.27; N, 6.97; S, 7.98. Found: C, 68.89; H, 4.30; N, 7.05; S, 8.24.

Bis-(4-methanesulfonamidophenyl) Disulfide—To a solution of 0.73 g. (0.003 mole) of bis-(4-aminophenyl) disulfide in 15 ml. of dry pyridine was added with stirring 1.0 ml. (0.012 mole) of methanesulfonyl chloride. The mixture was stirred for 15 min. and poured into cold water, and the precipitate was collected and digested in hot 95% ethanol, giving 1.0 g. (83%) of pale pink solid, m.p. 212–215°.

Anal.—Calcd. for $\text{C}_{14}\text{H}_{16}\text{N}_2\text{O}_4\text{S}_4$: C, 41.57; H, 3.99; N, 6.93; S, 31.70. Found: C, 41.23; H, 3.78; N, 7.10; S, 31.90.

Bis-(4-*p*-tolylsulfonamidophenyl) Disulfide—To a solution of 1.25 g. (0.005 mole) of bis-(4-aminophenyl) disulfide in 20 ml. of dry pyridine at 0° was added with stirring 1.91 g. (0.01 mole) of *p*-toluenesulfonyl chloride during 10 min. The reaction was carried out in the same fashion as with the phthalimidoacyl chlorides. The red solid which separated from dilute sulfuric acid was purified by dissolving in 5% sodium hydroxide solution, filtering, neutralizing with 5% hydrochloric acid, and removing all material which precipitated above pH 7. The resulting cream-colored solid was collected, giving 2.2 g. (80%), m.p. 300° (dec.).

Anal.—Calcd. for $\text{C}_{26}\text{H}_{24}\text{N}_2\text{O}_4\text{S}_4$: C, 56.09; H, 4.34; N, 5.03. Found: C, 56.24; H, 4.61; N, 5.11.

Bis-(4-*p*-acetamidobenzenesulfonamidophenyl) Disulfide—To a solution of 2.5 g. (0.01 mole) of bis-(4-aminophenyl) disulfide in 40 ml. of dry pyridine at 0° was added with stirring 4.7 g. (0.02 mole) of *p*-acetamidobenzenesulfonyl chloride during 10 min. The reaction was carried out as in the previous case, and 2.5 g. (40%) of cream-colored solid was obtained, m.p. 140° (with previous softening).

Anal.—Calcd. for $\text{C}_{28}\text{H}_{26}\text{N}_4\text{O}_6\text{S}_4$: C, 52.33; H, 4.08; N, 8.72; S, 19.96. Found: C, 52.27; H, 3.99; N, 8.72; S, 20.18.

Bis-(triethylammonium) Bis-[4-amino-(*N*-carbodithioate)-phenyl] Disulfide—To a solution of 2.5 g. (0.01 mole) of bis-(4-aminophenyl) disulfide in 25 ml. of absolute ethanol was added a 15-mole excess of carbon disulfide and 10-mole excess of triethylamine at room temperature. After the mixture was stirred and refrigerated overnight, the supernatant liquid was discarded and the residual oil was mixed repeatedly with ether–acetone (3:1). The oil was spread thinly on an evaporating dish, placed under vacuum, and the resulting yellow solid was triturated with ether–acetone (3:1) and filtered, giving 3.2 g. (52%) of product, m.p. 94–96°.

Anal.—Calcd. for $\text{C}_{26}\text{H}_{42}\text{N}_4\text{S}_6$: C, 51.80; H, 7.02; N, 9.29. Found: C, 52.06; H, 6.78; N, 8.98.

4-Aminophenyl 4-Aminobenzenethiolsulfinate—To a solution of 5.0 g. (0.02 mole) of bis-(4-aminophenyl) disulfide in 50 ml. of 95% ethanol was added an excess of 30% hydrogen peroxide. The flask was stoppered and allowed to stand at room temperature for 1 week. The precipitate was collected and purified by digesting in hot 95% ethanol, giving 3.6 g. (69%) of golden-brown product, m.p. 140–142°.

Anal.—Calcd. for $\text{C}_{12}\text{H}_{12}\text{N}_2\text{OS}_2$: C, 54.50; H, 4.58; N, 10.60. Found: C, 55.04; H, 4.82; N, 10.78.

The dihydrochloride was obtained by addition of absolute ethanol to its aqueous solution; m.p. 235° (dec.).

Anal.—Calcd. for $C_{12}H_{14}Cl_2N_2OS_2$: C, 42.73; H, 4.18; N, 8.31. Found: C, 42.90; H, 3.83; N, 8.12.

4-Phthalimidoacetamidophenyl 4-Phthalimidoacetamidobenzenethiolsulfinate—To a mixture of 20 ml. of dimethylformamide and 20 ml. of pyridine at 0° were added 1.32 g. (0.005 mole) of 4-aminophenyl 4-aminobenzenethiolsulfinate and 2.24 g. (0.01 mole) of phthalimidoacetyl chloride (19) during 10 min. The reaction was carried out in the same manner as for the corresponding disulfide, and 1.0 g. (32%) of product was obtained, m.p. 258–263° (dec.).

Anal.—Calcd. for $C_{32}H_{22}N_4O_7S_2$: C, 60.19; H, 3.47; N, 8.78. Found: C, 59.95; H, 3.75; N, 8.51.

4-(2-Phthalimido-3-phenyl)-propionamidophenyl 4-(2-Phthalimido-3-phenyl)-propionamidobenzenethiolsulfinate—To a mixture of 20 ml. of dimethylformamide and 20 ml. of pyridine at 0° were added 1.32 g. (0.005 mole) of 4-aminophenyl 4-aminobenzenethiolsulfinate and 3.15 g. (0.01 mole) of 2-phthalimido-3-phenylpropionyl chloride (19) during 10 min. The reaction was carried out as in the preceding case, and 3.3 g. (78%) of pale yellow product was obtained; m.p. 268–271° (dec.).

Anal.—Calcd. for $C_{46}H_{34}N_4O_7S_2$: C, 67.45; H, 4.19; N, 6.84. Found: C, 67.52; H, 4.43; N, 6.93.

4-Acetamidophenyl 4-Acetamidobenzenethiolsulfinate—To a solution of 1.32 g. (0.005 mole) of 4-aminophenyl 4-aminobenzenethiolsulfinate in 20 ml. of dimethylformamide was added an excess of acetic anhydride. The mixture was stirred for 15 min. and poured into cold water; further stirring coagulated the product. It was collected and recrystallized from glacial acetic acid, giving 1.0 g. (60%) of yellow solid, m.p. 200° (dec.).

Anal.—Calcd. for $C_{16}H_{16}N_2O_3S_2$: C, 55.15; H, 4.63; N, 8.04. Found: C, 55.08; H, 4.59; N, 8.26.

4-Methanesulfonamidophenyl 4-Methanesulfonamidobenzenethiolsulfinate—To a solution of 0.4 g. (0.0015 mole) of 4-aminophenyl 4-aminobenzenethiolsulfinate in 30 ml. of dry pyridine was added with stirring 0.5 ml. (0.006 mole) of methanesulfonyl chloride. The mixture was stirred for 15 min. and poured into cold water; the yellow product (0.47 g., 75%) was collected; m.p. 205–208° (dec.).

Anal.—Calcd. for $C_{14}H_{16}N_2O_5S_4$: C, 39.98; H, 3.83; N, 6.66. Found: C, 40.65; H, 3.90; N, 7.20.

Bis-(4-nitrophenyl) Sulfone—To a refluxing solution of 15.4 g. (0.05 mole) of bis-(4-nitrophenyl) disulfide (Eastman Organic Chemicals) (recrystallized from glacial acetic acid) in 100 ml. of glacial acetic acid was added 6.0 ml. of 30% hydrogen peroxide. An additional 6.0 ml. of 30% hydrogen peroxide was added after 2 hr. The reaction mixture was allowed to cool after 12 hr. of refluxing, and the precipitate was isolated. The pale yellow crystals were washed several times with water and dried *in vacuo*, giving 1.5 g. (10%) of product, m.p. 251–255° (lit. 252–253°) (14, 15).

Anal.—Calcd. for $C_{12}H_8N_2O_6S$: C, 46.75; H, 2.62; N, 9.09; S, 10.40. Found: C, 47.04; H, 2.78; N, 9.17; S, 10.90.

ACKNOWLEDGMENTS AND ADDRESSES

Received March 14, 1969, from the *Department of Chemistry, Massachusetts College of Pharmacy, Boston, MA 02115*

Accepted for publication August 13, 1969.

Presented at the First Northeast Regional Meeting, ACS, Boston, Mass., October, 1968.

Abstracted from a thesis submitted by J. P. Speranza to the Massachusetts College of Pharmacy in partial fulfillment of M.S. degree requirements.

Potentiating Effect of Organomercurials on Bisphenols

FRED S. BARR, G. W. MOORE, and B. J. GRAGG

Abstract □ The activity of organomercurial-bisphenol combinations was checked by *in vitro* methods against *C. albicans*, *S. aureus*, *E. coli*, *B. subtilis*, and *S. faecalis*. The *in vivo* activity of these combinations was determined against *M. canis* and *T. mentagrophytes* in guinea pig infections. The methods for both *in vitro* and *in vivo* testings are given. A potentiating effect was observed both *in vitro* and *in vivo* when phenylmercuric acetate is added to hexachlorophene or dichlorophene.

Keyphrases □ Hexachlorophene, dichlorophene activity, potentiation—organomercurials □ Antimicrobial activity—bisphenol—organomercurial combinations □ Optical density—microbial culture concentration

Recent Food and Drug Administration regulations, which prohibit the use of most antibiotics in topical ointments, and the failure of most systemic medication in the treatment of topical fungal infections have brought about a renewed interest in some of the older antimicrobial agents. These agents, while active against specific organisms, did not inhibit a broad spectrum of infective microorganisms.

Earlier experiments in this laboratory indicated that by the combination of two of these agents the desired results could be obtained *in vitro* (1). In an earlier report the activity of phenylmercuric acetate and a bisphenol was reported. While Barker (2) reported that some cationic and some anionic agents such as surfactants tend to inactivate phenylmercuric compounds, later findings (3) show that the mercury is not inactivated by all such compounds and, in particular, the nonionic surfactants actually may potentiate the activity of the mercurials. It has been established that the surfactants potentiate the activity of the bisphenols.

This study was a continuation of earlier work at the laboratory (4) which reported on the activity of the potentiating effect of organomercurials upon the bisphenols *in vitro* and *in vivo*. In this study the active ingredients were combined in a cream base and checked for activity *in vitro* and *in vivo* in animals that were infected with *Microsporum canis* and *Trichophyton mentagrophytes*.

METHODS AND MATERIALS

In Vitro—The test organisms used in this experiment were *Staphylococcus aureus* (ATCC 9144), *Candida albicans* (ATCC 10231) *Escherichia coli* (ATCC 8330), *Bacillus subtilis* (ATCC 6633), and *Streptococcus faecalis* (ATCC 10541). The organisms were incubated in Trypticase soy broth¹ for 18 hr. at 37°. The cultures were then centrifuged and washed twice with sterile 0.85% saline and finally resuspended in sterile saline. The cultures then were diluted with sterile saline to give 75% light transmission at the 550 mμ wavelength on the Spectronic 20 colorimeter.² In all cases exactly 0.1 ml. of this standardized culture was used for the inoculum, and fresh suspensions were prepared daily.

¹ Baltimore Biological Laboratories.

² Bausch & Lomb, Inc., Rochester, N. Y.

The compounds tested were phenylmercuric acetate, nitromersol, dichlorophene, hexachlorophene, and combinations of the mercury salts with the bisphenols. The solutions were dissolved in ethanol and sterilized by filtration. Following the sterilization they were diluted in sterile distilled water. The agents were then serially diluted through sterile Trypticase soy broth, in 18- × 150-mm. metal cap tubes, and inoculated with 0.1 ml. of the above suspension of organisms. The tubes were incubated at 35–37° for 24 hr. and observed for growth. Control tubes using only the solvent were also tested and found to have no inhibitory properties at the levels used in these tests.

In Vivo—The test organisms in this study were *Microsporum canis* and *Trichophyton mentagrophytes*. The cultures were prepared by inoculating Sabouraud dextrose agar (Difco) with the test organism and incubating at 28° for 7 days. The mycelial mat was removed and placed in 10 ml. of sterile physiological saline in a ground-glass homogenizer and macerated until there was an even suspension of the culture. The inoculum used for each guinea pig was 0.5 ml. of this suspension.

Seventy male guinea pigs weighing 225–275 g. were infected with *Microsporum canis* and 70 were infected with *Trichophyton mentagrophytes*. The method used to infect the animals was to remove the hair from the right side of each animal by use of electric clippers and a safety razor. The culture was then placed on the cleared area and ground into the tissue by use of No. 1 sandpaper. The animals were unmedicated for 5 days to allow the infection to become established. Following this period, cultures were made by skin scrapings onto Mycobiotic agar (Difco) and incubated at 28° for 7 days. After cultures were made, each of the 10 animals in each group were treated twice daily, with a vanishing cream³ containing the test substance, for a period of 7 days with one of the five test substances. Ten animals were unmedicated and served as controls. The vanishing cream base was selected after it was determined that there was no antagonism between the base and the active ingredients.

Following the last day of treatment, any remaining drug was removed by washing the treated area with warm tap water. Cultures of skin scrapings were made on Mycobiotic agar immediately following the washing and again at 7 and 14 days posttreatment. At the time each culture was made, scales and newly grown hairs from the infected site of each animal were examined microscopically.

RESULTS

The *in vitro* results are recorded in Table I. It is evident from the data in this table that phenylmercuric acetate exerts an effect in combination with the bisphenols which one would not expect from an additive effect alone. Against *Candida albicans* and *Escherichia coli*, the phenylmercuric acetate–dichlorophene combination was the most active, while the most active combination against the Gram-positive organisms was phenylmercuric acetate–hexachlorophene. The combination of nitromersol with the bisphenols displays a potentiating effect; it is less than that observed with the other combinations.

The *in vivo* results are recorded in Table II. The data indicates that the combinations of phenylmercuric acetate–bisphenol is more active against *Microsporum canis* than it is against *Trichophyton mentagrophytes*. The combinations are more effective than either agent alone.

DISCUSSION

The data obtained in this study indicate that a product containing phenylmercuric acetate and a bisphenol such as dichlorophene would be of use in the treatment of superficial fungus infections such

³ Contains boric acid, glycerin, cetyl alcohol, stearyl alcohol, Span 20, Tween 20, sodium lauryl sulfate, and water.

Table II—Efficacy of Products Tested; Number Animals Infected/Number Treated

Compound Tested	<i>Microsporum canis</i>			Efficacy, %	<i>Trichophyton mentagrophytes</i>			Efficacy, %
	Day 1 Post-Treatment	Day 7 Post-Treatment	Day 14 Post-Treatment		Day 1 Post-Treatment	Day 7 Post-Treatment	Day 14 Post-Treatment	
Phenylmercuric acetate (0.05%)	7/10	7/10	7/10	30	7/10	8/10	8/10	20
Hexachlorophene (0.5%)	9/10	9/10	8/10	20	10/10	10/10	9/10	10
Dichlorophene (0.5%)	8/10	8/10	8/10	20	8/10	8/10	8/10	20
Phenylmercuric acetate (0.05%)	3/10	2/10	2/10	80	4/10	4/10	4/10	60
Hexachlorophene (0.5%)								
Phenylmercuric acetate (0.05%)	2/10	2/10	2/10	80	7/10	6/10	6/10	40
Vanishing cream base	10/10	10/10	9/10	10	10/10	10/10	10/10	0
Control	10/10	10/10	10/10	0	10/10	10/10	10/10	0

as ringworm and athlete's foot. This combination displayed good activity when tested *in vitro* and the potentiated activity remained when the product, in ointment form, was checked *in vivo*.

While this study indicates that excellent results were obtained with twice-daily treatment for a period of 7 days, it must be remembered that these were fresh infections and treatment of longstanding infections of *Microsporum canis* might require treatment of 14 days or even longer in some cases. The results obtained also indicate that a treatment period longer than 7 days would have increased the percentage efficacy of the tested products; however, it has been found that at 21–28 days some of the control animals do not give positive cultures from one test period to another and for this reason the test must be shortened.

The *in vitro* data obtained along with the fact that these combinations are not inactivated *in vivo* would indicate that a product for the treatment of *Candida albicans* both topically and intravaginally can be developed using the tested agents.

Drug-Plastic Interactions II: Sorption of *p*-Hydroxybenzoic Acid Esters by Capran Polyamide and *In Vitro* Biologic Activity

NAGIN K. PATEL* and NAGAMANI NAGABHUSHAN

Abstract □ Sorption of methyl- and propylparaben by capran polyamide was determined by means of an equilibrium sorption method. Data are presented to show that the antimicrobial activity of the parabens for *Aspergillus niger*, *Aerobacter aerogenes*, and *Pseudomonas aeruginosa* is diminished in the presence of capran polyamide. The *in vitro* biologic activity of the parabens in the presence of the nylon was shown to be related to the concentration of "free" or the drug in equilibrium with the plastic.

Keyphrases □ *p*-Hydroxybenzoic acid ester—capran polyamide film, sorption □ Capran polyamide sorption effect—paraben antimicrobial activity □ Antimicrobial activity, parabens—capran polyamide sorption effect

It is generally recognized that the biologic activity of the sorbed drug would be reduced in proportion to the amount sorbed (1-3) and *a priori* observation by Autian *et al.* (4, 5) that preservatives such as *p*-hydroxybenzoic acid esters (parabens) are sorbed by nylon (6) from aqueous solution and hence proportionately inactivated, should be justifiable. In contrast, Myers and Lefebvre reported that nylon in concentrations up to 5% had no adverse effect on the antibacterial activity of benzalkonium chloride (7). Adsorption of drugs by insoluble fillers has been recognized, and Deutsch *et al.* noted that the biologic activity of a vitamin was reduced significantly due to its adsorption on the fillers used in capsules and tablets (8). No direct report could be found on a correlation of drug-plastic sorption data with *in vitro* antimicrobial activity of *p*-hydroxybenzoates.

This report will show that the antibacterial and antifungal activity of methyl- and propylparaben is reduced due to their sorption by capran polyamide.¹ A correlation between the sorption data and *in vitro* biologic activity will also be presented.

EXPERIMENTAL

Materials—Methyl- and propylparaben and the synthetic culture medium were the same as employed in a previous communication (3). Capran polyamide was washed with 50% aqueous ethanol and then rinsed several times with distilled water in order to remove surface contaminants. The nylon samples were dried at $65 \pm 1^\circ$ for 8 hr. and stored in a desiccator until used.

Equilibrium Sorption Studies—The experimental technique has been described (9) in Part I. An accurately weighed sample of capran polyamide [about 1.2 g.; one 10.2×15.2 -cm. (4×6 -in.) sheet] was placed in 150-ml. bottles,² each containing 90 ml. of varying concentrations of the paraben under study. The bottles were closed tightly using plastic (Bakelite) screw caps lined with thin polyethylene³ film. Preliminary studies showed that under experi-

Figure 1—Sorption of methylparaben by capran polyamide at 30° , showing the total methylparaben concentration in the system as a function of equilibrium or free methylparaben concentration. Key: ●, in culture medium; ▲, in distilled water.

mental conditions there was no sorption of the parabens by the polyethylene. The bottles were agitated in a general-purpose shaking bath.⁴ The drug content at equilibrium was determined spectrophotometrically (5). The decrease in concentration of the drug in solution was a measure of sorption, and the equilibrium was established at the end of 24 hr. agitation.

Microbiological Studies—The general procedure consisted of equilibrating varying concentrations of a paraben in culture medium with a known weight of capran polyamide and determining the inhibitory concentration for one of the organisms. A simple, chemically defined synthetic culture medium as described earlier (3) was used with the exception that 2% dextrose was employed in the place of 5% dextrose. Preliminary experimentation showed that the magnitude of growth of *A. niger* (10), *A. aerogenes* (10), and *Ps. aeruginosa*⁵ in the culture medium containing 5% dextrose was about the same as in that containing 2% dextrose. This work also indicated that dextrose, lactose, or sucrose at 2% concentration supported the growth of the above organisms equally well. It was noticed that the lower concentration of sugar was less apt to caramelize at autoclaving temperature. Sterile distilled water was used to prepare all the solutions for microbiological work.

The nylon samples of a definite weight (0.600 g. methylparaben or 0.100 g. propylparaben) were placed in the bottles, each containing 45 ml. of varying known concentrations of the drug. A series of

⁵ Mac-264. The stock culture was grown on slants of nutrient agar and it was supplied by Dr. D. W. Westlake of the Department of Microbiology.

Figure 2—Sorption of propylparaben by capran polyamide at 30°, showing the total propylparaben concentration in the system as a function of equilibrium or free methylparaben concentration. Key: ●, in culture medium; ▲, in distilled water.

concentrations of the parabens was prepared in the media, differing by 0.05%. In this manner a paraben solution was prepared containing total paraben as predicted by the procedure described under *Results and Discussion*. Four additional concentrations of the agent were prepared, two of which were lower than the computed value and the other two higher. These solutions were prepared in duplicate. The bottles were closed loosely with plastic caps and sterilized by autoclaving at 15 lb. pressure for 15 min.

The bottles were allowed to attain room temperature in an aseptic area. They were closed tightly and equilibrated by agitation in a water bath at 30° for about 24 hr.

Methyl- and propylparaben were apparently stable under experimental conditions (3). The sorption capacities of the autoclaved and unautoclaved samples of the capran polyamide were the same.

Each of the above bottles was then inoculated with two loopful of either a spore suspension of the fungus or 48-hr. cultured suspension (3) of the bacteria. In order to maintain a constant concentration of bacteria, the optical density of the bacterial suspension was kept to a value of 0.50 by diluting the contents with sterile medium if necessary. The bottles were incubated at 30° and observed visually for growth in the form of mycelial hyphae in the case of *A. niger* and turbidity in the cases of *A. aerogenes* and *Ps. aeruginosa*.

RESULTS AND DISCUSSION

Sorption of Parabens by Capran Polyamide—The sorption of parabens by nylons has been reported in the literature (4–6). Sorption of methyl- and propylparaben is shown in Figs. 1 and 2, and it is included here for correlation with antimicrobial activity. Similar sorption data have been reported, based on the undergraduate physical pharmacy experimentation (10). Additional results are plotted in Figs. 1–3, showing that there is a fairly good correlation between sorption and microbiological data. The data of Figs. 1 and 2 also illustrate that the sorption of methyl- and propylparaben by capran polyamide in the media of distilled water and synthetic culture is essentially the same. The data are plotted to show that total (sorbed + free) paraben concentration was a function of equilibrium or free paraben concentration. This type of plot is useful for predicting the biologic activity of the drug in the presence of the nylon as explained in the following section.

Figure 3—Comparison of predicted and experimental minimum inhibitory concentrations (M.I.C.'s) of parabens in the presence of capran polyamide. The concentrations of the plastic were 1.33 and 0.222% for methyl- and propylparaben, respectively. Key: A, M.I.C. in absence of capran polyamide; B, experimental M.I.C. in presence of capran polyamide; and C, predicted (from Figs. 1 and 2) M.I.C. in presence of the plastic.

Method of Prediction of Microbiological Action—If the biologic activity of a paraben can be assumed to be due to equilibrium or free drug in the presence of capran polyamide, and if the minimum inhibitory concentration (M.I.C.) of the paraben in the absence of the plastic is known, then the plots as depicted in Figs. 1 and 2 can be used to predict the total concentration of the drug required for the desired antimicrobial activity. (This assumption supports the theory that the paraben sorbed by capran polyamide is biologically unavailable.) For any desired free concentration, one can obtain the total concentration of the paraben from the ordinates of Figs. 1 and 2. The terms free concentration and M.I.C. in the absence of capran polyamide are assumed to be synonymous for the purpose of prediction.

Inactivation by Capran Polyamide Related to Sorption—The M.I.C.'s of the parabens in the culture medium in the absence of capran polyamide are as follows: methylparaben, 0.065% for *A. niger*, 0.10% for *A. aerogenes*, and 0.13% for *Ps. aeruginosa*; propylparaben, 0.020% for *A. niger*, and 0.034% for *A. aerogenes*. Propylparaben was ineffective in preventing the growth of *Ps. aeruginosa* in a concentration of 0.048%. Based on these M.I.C. values, the inhibitory paraben concentrations in the presence of definite weights of capran polyamide were predicted from Figs. 1 and 2. These predicted values together with experimental inhibitory concentrations in the presence of capran polyamide are portrayed in Fig. 3. It is to be noted that the predicted value (0.052%) of propylparaben for *A. aerogenes* exceeds solubility; therefore, it was not possible to conduct a growth study using this organism in the presence of capran polyamide.

As illustrated in Figs. 1 and 2 the components of the culture medium do not compete for sorption. Thus, any reduction in the biologic activity of the paraben in the presence of the capran polyamide can be attributed to the sorption. Figure 3 demonstrates that there is a good correlation between predicted M.I.C. and experimental antifungal and antibacterial concentrations for the parabens. It is therefore concluded that the plastic-sorbed paraben is devoid of *in vitro* biologic activity.

Polyamide-Silica Gel Layer Chromatography of Yellow Food Dyes

HUNG-CHEH CHIANG and CHWAN-HWAI CHEN

Abstract □ The separation of five yellow food dyes and three toxic yellow dyes by mixed polyamide-silica gel thin-layer is described. The method shows good separation and sharp spots. For comparison, the thin-layer chromatography (TLC) on only polyamide and on only kieselguhr is also carried out.

Keyphrases □ Yellow dyes—analysis □ Dyes, yellow—separation, identification □ Polyamide-silica gel chromatography—analysis

The separation of synthetic food dyes on a thin-layer of cellulose (1), silica gel (2), aluminum oxide (3), starch (4), polyamide (5), and paper chromatography (6) has been reported, but none of these techniques gave entirely satisfactory results. Recently, the separation of 11 red food dyes on polyamide (12%)—silica gel G (88%) mixed thin-layers has been successfully applied by Chiang (7). Therefore, further application of this method was tried. In this note, the separation of five yellow food dyes and three toxic yellow dyes (auramine, metanil yellow, and picric acid) by mixed polyamide-silica gel TLC is described. For comparison, the TLC of only polyamide and of only silica gel is also reported.

EXPERIMENTAL

Material—The solvents and chemicals are the reagent grade of Wako Pure Chemical Industries, Ltd., Osaka, Japan.

Preparation of Polyamide-Silica Gel Mixed Layer—Eight grams of polyamide chip (Nylon 6, type 1022B of UBE Industrial Ltd., Osaka, Japan) was dissolved in 80 ml. of 90% formic acid, and then 20 ml. of distilled water was added. After gentle warming (below 40°) and stirring, a homogeneous solution was obtained; this was cooled to the room temperature and 52 g. of silica gel G (E. Merck) was added. Two hundred milliliters of the above-mentioned solution was poured into a dish (14.5 × 19.5 × 2.5 cm.) and a glass plate (12 × 14 × 0.1 cm.) was dipped into it. Both sides of the glass were covered homogeneously. The glass was

7	Auramine	0.37 (0.71, 0.36)	0.62 (0.71, 0.89)				
8	Picric acid	0.40 (0.97, 0.22)	0.53 (0.84, 0.22)				
	Time required, ^g (min.)	50	30	200	90	70	600

^a Solvent I: methanol-23% ammonium chloride solution-chloroform (30:20:1.3). ^b Solvent II: isobutanol-ethanol-0.45% sodium chloride solution (3:5:1). ^c P-S, *R_f* value on polyamide-silica gel mixed layer. ^d S, on silica gel layer. ^e P, on polyamide layer. ^f Tailing. ^g Time required to ascend 10 cm. from origin.

placed over the dish for 2 min. to let the excess solution drain back. It was then air dried for 3 hr. and heated at 100° for 30 min.

Preparation of Polyamide Layer—Twenty grams of polyamide was dissolved; then the procedure as described in the previous method, but without adding silica gel G, was followed.

Preparation of Silica Gel Layer—Dilute slurries of silica gel G (45 g. in 100 ml. of water) were sprayed at 2 kg./cm.² pressure from a distance of 20 cm. onto eight sheets of glass plates (12 × 14 cm.) in a horizontal position, then dried at 100° for 30 min. The thickness of the layers was about 250 μ.

Chromatographic Procedure—One microliter of 0.3% alcoholic solution of yellow AB, yellow OB, and auramine, and 0.3% water solution of other dyes was applied to the start line 1.5 cm. from the bottom of the layer, and the plate was developed by ascending techniques. The chamber had been equilibrated with the respective solvent for 30 min. before use.

RESULTS AND DISCUSSION

R_f values obtained with two solvent systems are given in Table I. It has been found that the results obtained by the mixed polyamide-silica gel layers show better separation and sharper spots than that obtained by polyamide and silica gel layers. Also the time required to ascend 10 cm. from origin for the mixed layers is shorter than that for the polyamide layers. Separation mechanism on the mixed layers is based on the formation of hydrogen bonds between

Preparation of Silica Gel Layer—Dilute slurries of silica gel G (45 g. in 100 ml. of water) were sprayed at 2 kg./cm.² pressure from a distance of 20 cm. onto eight sheets of glass plates (12 × 14 cm.) in a horizontal position, then dried at 100° for 30 min. The thickness of the layers was about 250 μ.

Chromatographic Procedure—One microliter of 0.3% alcoholic solution of yellow AB, yellow OB, and auramine, and 0.3% water solution of other dyes was applied to the start line 1.5 cm. from the bottom of the layer, and the plate was developed by ascending techniques. The chamber had been equilibrated with the respective solvent for 30 min. before use.

RESULTS AND DISCUSSION

R_f values obtained with two solvent systems are given in Table I. It has been found that the results obtained by the mixed polyamide-silica gel layers show better separation and sharper spots than that obtained by polyamide and silica gel layers. Also the time required to ascend 10 cm. from origin for the mixed layers is shorter than that for the polyamide layers. Separation mechanism on the mixed layers is based on the formation of hydrogen bonds between

¹ U. S. manufacturer: American Enka Corp.

the CONH group of polyamide and the sample and adsorption or partition between the silica gel and the sample. In the mixed layer, polyamide also serves as a strong binder and makes the layer very durable and easy to handle. Also the layer did not crack or peel and could be stored easily. Both sides of the glass are independent of each other and chromatography can be performed simultaneously on both sides. The addition of a small amount of salt (about 0.05% sodium chloride or 0.4% ammonium chloride) in the solvent mixture is essential to break hydrogen bonding between the polyamide and the dyes. Oil-soluble dyes of yellow AB and yellow OB are rather difficult to separate because of the close similarity of their structures (different only in one methyl group). The content of polyamide (13.6%) in this mixed layer was above that of the previous report (12%) (7) in order to obtain a more durable layer.

Modified Granuloma Pouch Procedure for the Evaluation of Topically Applied Anti-inflammatory Steroids

G. DiPASQUALE, CHARLES L. RASSAERT, and EDWARD McDOUGALL

Abstract □ A laboratory procedure for evaluating topically applied anti-inflammatory preparations has been described. A modified croton oil-induced granuloma pouch served as the site of drug application and also as a physical barrier to avoid drug ingestion. Increasing concentrations and/or doses of test compounds are correlated with thymolysis, catabolism, and reduced exudate formation. The procedure can differentiate steroidal modifications, percutaneous absorption, and alterations of the vehicle. However, it is difficult to ascertain how much of the action of the test compound is due to its local and how much to its systemic properties. The assay also evaluated test compounds as pharmaceutical preparations. The order of increasing activity of the test substances can be listed as hydrocortisone acetate (1% cream) < methylprednisolone acetate (0.25% cream) < betamethasone 17-valerate (0.025% cream) < triamcinolone 16,17-acetonide (0.025% cream) < betamethasone (0.2% cream) < fluocinolone acetonide (0.025% alcoholic gel or cream).

Keyphrases □ Steroids, anti-inflammatory—topical activity determination □ Granuloma pouch test procedure—topical steroid activity □ Croton oil-air—granuloma pouch formation

Potential anti-inflammatory substances, topical or systemic, have been evaluated in a variety of procedures which apparently represent different modes of actions and/or different stages of the inflammatory process. Some of these procedures include: cotton pellet, granuloma pouch, paw edema, adjuvant-induced polyarthritis, cell cultures, uncoupling of mitochondrial oxidative phosphorylation, plasma protein changes, ear test, lung inflammation, and inhibition of erythema (1-4). It is evident that each test procedure has some merit; however, one cannot avoid nor explain discrepancies which occur between the various animal *in vitro* and clinical procedures. Nevertheless, most clinically efficacious drugs are active in most procedures, although in some assays a divergence may occur between steroidal and nonsteroidal drugs. Avoidance of

ingestion of topically applied drugs in animals has presented some perplexing problems. Alternatives appear to introduce other problems; for example the use of occlusive dressings may alter absorption whereas the use of collars and other restraining devices produces stress which elaborates endogenous adrenocorticosteroids. The use of an air pouch which serves as the site of drug application and a physical barrier to avoid ingestion has been tried by the authors. They have also tried to observe whether or not the modified granuloma pouch procedure will distinguish steroidal modifications and/or alterations of the vehicle. It is known that these changes will affect drug absorption, retention, and biological activity (5, 6). It should also be mentioned that most animal (*in vivo* and/or *in vitro*) procedures require a solubilized test compound which requires organic solvents. The present study also evaluated drugs as pharmaceutical preparations.

MATERIALS AND METHODS

The method used was a modification of Selye's procedure (7). Male rats weighing 150-170 g. were individually housed and arranged in groups as indicated in the tables. The dorsal surface of the animal was shaved with animal clippers and the pouches were formed with the subcutaneous injection of 25 ml. of air followed by an injection of 0.5 ml. of a 1% solution of croton oil in sesame oil directly into the pouch. The test compounds included the commercial preparations: fluocinolone acetonide (Synalar cream, Syntex Laboratories Inc.); betamethasone (Celestone cream, Schering Corp.); methylprednisolone acetate (Medrol acetate cream, The Upjohn Co.); triamcinolone 16,17-acetonide (Kenalog cream, E. R. Squibb & Sons, Inc.); and also these laboratory preparations: hydrocortisone acetate in a cream base; betamethasone 17-valerate in a cream base; triamcinolone in a cream base; triamcinolone 16,17-acetonide in a cream base; and fluocinolone acetonide in an alcoholic gel base.

I = Initial number, F = Final number. ^a Significantly different from cream control of alcoholic gel, $p < 0.05$. ^b Significantly different from corresponding cream base preparation (Test 2). ^c Kenalog.

The control creams¹ and the test compounds in either creams or alcoholic gel² were applied topically to the surface of the pouch and spread evenly over a controlled area (35 mm. diameter) daily for 8 days starting on Day 2.

On Day 4, all the pouches were reshaped and slightly reinflated to original turgidity and 0.5 ml. of a 3% croton oil solution was injected directly into the pouch. All the animals were killed on Day 10 and the exudate volume was measured. The final body weights and adrenal and thymus weights were also recorded. The groups and their respective treatments are described in the tables. The significance between the control and treated groups was estimated by determining the standard error of the means and application of Student's *t* test.

RESULTS

Topically applied fluocinolone acetonide-alcoholic gel base (0.025%) at 5 mg./animal/day significantly inhibited thymus weights and the normal rate of body weight gain. On the other hand, 25 and 100 mg./animal/day significantly decreased exudate formation, thymus weights, and the normal rates of body weight gain. The comparison of fluocinolone acetonide in an alcoholic gel vehicle (0.025%) with fluocinolone acetonide in a cream vehicle (0.025%) indicates that although the latter also inhibited the same parameters, the former is more active in all the test parameters. Application of various concentrations of fluocinolone acetonide or various amounts of the cream preparations indicates that a dose-related response is obtained with fluocinolone acetonide. The biological activity is directly related to the amount of steroid and not to the quantity of the cream preparation applied (Test 2, Table I). Creams, which contained 1 or 2% hydrocortisone acetate when administered at 250 mg./animal/day significantly reduced exudate formation, thymus weights, and the body weight gain. At 125 mg./animal/day, both concentrations inhibited only the thymus weights and exudate formation whereas the 2% concentration also inhibited the body weight gain. It should be noted that the adrenal weights appeared to be the least sensitive test parameter and no dose-related response was evident.

It is also interesting to note that triamcinolone cream (0.025%) at 100 mg./animal/day significantly inhibited the thymus weight whereas triamcinolone 16,17-acetonide cream (0.025%) at all dose schedules inhibited the thymus weights and the body weight gain. Similarly, triamcinolone 16,17-acetonide (0.025%) at 100 mg./animal/day inhibited exudate formation. At equivalent concentrations the laboratory prepared triamcinolone 16,17-acetonide cream base was comparable to the commercially obtained preparation (Kenalog, 0.025%). Methylprednisolone acetate cream (0.25%) at 125 mg./animal/day had a similar activity whereas betamethasone cream (0.2%) caused a further reduction of the normal rate of

body weight gain, thymus weight, and exudate formation. Betamethasone 17-valerate (0.025%) at 250 mg./animal/day significantly inhibited exudate formation, the body weight gain, and the thymus weights. At one-half the dose, only the thymus weights were inhibited.

CONCLUSIONS

The test procedure is capable of evaluating topically applied anti-inflammatory preparations and apparently percutaneous absorption. It should be mentioned that although the air pouch makes the test substances inaccessible to licking and cleaning, one cannot exclude the possibility that the rat may rub the air pouch and the test compound onto the top of the cage and then lick or ingest the steroids. However, this does not appear to be an important factor since the larger cream doses would have been more accessible for ingestion and yet one observes that the biological activity is related to the amount of active ingredient and not to the amount of the cream base applied. As with all other local/topical anti-inflammatory assays, it is difficult to ascertain how much of the action of the test compound is due to its local and how much to its systemic properties since the anti-inflammatory effect is usually associated with thymolysis and a reduced rate of body weight gain.

Katz and Shaikh (8) indicated that the relative percutaneous absorption produced by the molecular modification of corticosteroids is related to changes in solubility and partition coefficient. The physical properties of the vehicle also influence percutaneous absorption and biological activity (9, 10). It should also be kept in mind that the biological activity is also dependent upon many other factors such as plasma protein binding, receptor specificity, rate of metabolic transformation or inaction, and tissue retention subsequent to absorption to produce a more efficient local therapeutic action (8-10). The results demonstrate that an alcoholic gel vehicle for fluocinolone acetonide or the addition of 16,17-acetonide to triamcinolone enhances the biological activity when compared, respectively, to the fluocinolone acetonide cream or the triamcinolone cream. It appears that the alcoholic gel vehicle (fluocinolone acetonide) increases percutaneous absorption as indicated by the greater effect on the body weight and thymus weights. The correlation between biological activity and drug penetration was previously shown clinically where commercially available drugs were reported to be more active when applied to abraded skin or under occlusive dressing (5, 6, 11, 12).

The molecular modification of the test compound such as the formation of the acetonide apparently also leads to an enhanced percutaneous absorption. McKenzie (6) indicated that the addition of a 16,17-acetonide to specific steroids promotes a greater rat skin penetration and that the acetate is also better absorbed than the parent alcohol. The authors also observed that triamcinolone 16,17-acetonide cream base is more active in all the test parameters than triamcinolone, and the laboratory preparation is comparable to commercially obtained triamcinolone 16,17-acetonide (Kenalog). Similarly, commercially obtained methylprednisolone acetate and

¹ The laboratory creams were prepared to be similar to that employed in Synalar cream.

² Contains Carbopol (1.75%), diisopropanolamine (0.18%), methylparaben (0.2%), propyleneglycol (5%), alcohol (40%), and water (52.87%).

betamethasone also inhibited exudate formation, body weight gain, and the thymus weights. It is difficult to obtain a relative activity of betamethasone since the concentration used was high and may represent a maximum response.

Unlike clinical observations of topical activity in dermatologic diseases (13-15) in which betamethasone 17-valerate is generally described as comparable to fluocinolone acetonide, the authors' test procedure indicates that fluocinolone acetonide is more active. An attempt to grade the order of activity from the experimental results indicates that fluocinolone acetonide (0.025%) > betamethasone (0.2%) > triamcinolone 16,17-acetonide (0.025%) > betamethasone 17-valerate (0.025%) > methylprednisolone acetate (0.25%) > hydrocortisone acetate (1.0%). This order of decreasing activity is closely related to that described by others (16, 17). Similarly, one may also correlate steroidal modifications such as the addition of Δ^1 , 6-methyl, 6-fluoro, 9-fluoro, 6,9-difluoro, 16-methyl, and 16,17-acetonide to the increasing order of biological activity (5, 16, 18, 19).

In conclusion, the modified granuloma pouch procedure not only serves as a site for drug application but is also useful for the evaluation of commercially available corticosteroids. The assay can also distinguish structural modifications and alteration of the vehicle. However, these changes did not always reflect potency differences observed in the clinic.

Gas-Liquid Chromatography of Salicylate Metabolites

CLARENCE H. MORRIS, JOHN E. CHRISTIAN, ROBERT R. LANDOLT, and WARREN G. HANSEN

Abstract □ A gas-liquid chromatographic separation of the methyl ester-methyl ether derivatives of acetylsalicylic acid, salicylic acid, 2,3-dihydroxybenzoic acid, 2,5-dihydroxybenzoic acid, and 2,3,4-trihydroxybenzoic acid is described. Separations were carried out at 155° on a column packed with 5% SE-30 on diatomaceous earth. A hydrogen-flame ionization detector was used.

Keyphrases □ Salicylate metabolites—separation, determination □ Column chromatography—separation □ GLC—analysis

It was decided to develop a gas-liquid chromatographic technique, for possible use by the authors and others, which would effect the separation and identification of acetylsalicylic acid, salicylic acid, 2,3-dihydroxybenzoic acid, 2,5-dihydroxybenzoic acid, and 2,3,4-trihydroxybenzoic acid. Horning *et al.* (1) report retention times for trimethylsilyl ether (TMS)-methyl ester derivatives of acetylsalicylic acid, salicylic acid, gentisic acid (2,5-dihydroxybenzoic acid), and salicylic acid, but they do not mention either 2,3-dihydroxybenzoic acid, or 2,3,5-trihydroxybenzoic acid. Williams (2) reports retention times for methyl ester and methyl ester-methyl ether derivatives of several dihydroxybenzoic acids including 2,3- and 2,5-dihydroxybenzoic acids but he presents no data for acetylsalicylic acid, salicylic acid, or 2,3,5-trihydroxy-

Table I—Relative Retention Times

Methyl Ester-Methyl Ether Derivative of	Relative Retention Time
Benzoic acid (internal standard)	— 1.00 ^a
Salicylic acid	1.240 2.12
Acetylsalicylic acid	— 2.91
2,5-Dihydroxybenzoic acid	— 3.37
2,3-Dihydroxybenzoic acid	— 3.91
2,3,4-Trihydroxybenzoic acid	— 8.43

^a Retention time = 1.026 min.

benzoic acid. The following technique will effectively separate acetylsalicylic acid from its hydroxy metabolites.

MATERIALS AND METHODS

Identity of the individual compounds used was established by melting point.

An ethereal alcoholic solution of diazomethane was prepared by reacting an ethereal solution of *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide with ethanolic potassium hydroxide in a distilling apparatus (3). The resulting ethereal distillate contained approximately 3 g. of diazomethane.

The methyl ester-methyl ether derivatives of the respective compounds were prepared as follows. Approximately 0.25 g. of each compound was dissolved in a minimum amount of absolute ethanol. Ethereal diazomethane was added dropwise until a yellow color

betamethasone also inhibited exudate formation, body weight gain, and the thymus weights. It is difficult to obtain a relative activity of betamethasone since the concentration used was high and may represent a maximum response.

Unlike clinical observations of topical activity in dermatologic diseases (13-15) in which betamethasone 17-valerate is generally described as comparable to fluocinolone acetonide, the authors' test procedure indicates that fluocinolone acetonide is more active. An attempt to grade the order of activity from the experimental results indicates that fluocinolone acetonide (0.025%) > betamethasone (0.2%) > triamcinolone 16,17-acetonide (0.025%) > betamethasone 17-valerate (0.025%) > methylprednisolone acetate (0.25%) > hydrocortisone acetate (1.0%). This order of decreasing activity is closely related to that described by others (16, 17). Similarly, one may also correlate steroidal modifications such as the addition of Δ^1 , 6-methyl, 6-fluoro, 9-fluoro, 6,9-difluoro, 16-methyl, and 16,17-acetonide to the increasing order of biological activity (5, 16, 18, 19).

In conclusion, the modified granuloma pouch procedure not only serves as a site for drug application but is also useful for the evaluation of commercially available corticosteroids. The assay can also distinguish structural modifications and alteration of the vehicle. However, these changes did not always reflect potency differences observed in the clinic.

Gas-Liquid Chromatography of Salicylate Metabolites

CLARENCE H. MORRIS, JOHN E. CHRISTIAN, ROBERT R. LANDOLT, and WARREN G. HANSEN

Abstract □ A gas-liquid chromatographic separation of the methyl ester-methyl ether derivatives of acetylsalicylic acid, salicylic acid, 2,3-dihydroxybenzoic acid, 2,5-dihydroxybenzoic acid, and 2,3,4-trihydroxybenzoic acid is described. Separations were carried out at 155° on a column packed with 5% SE-30 on diatomaceous earth. A hydrogen-flame ionization detector was used.

Keyphrases □ Salicylate metabolites—separation, determination □ Column chromatography—separation □ GLC—analysis

It was decided to develop a gas-liquid chromatographic technique, for possible use by the authors and others, which would effect the separation and identification of acetylsalicylic acid, salicylic acid, 2,3-dihydroxybenzoic acid, 2,5-dihydroxybenzoic acid, and 2,3,4-trihydroxybenzoic acid. Horning *et al.* (1) report retention times for trimethylsilyl ether (TMS)-methyl ester derivatives of acetylsalicylic acid, salicylic acid, gentisic acid (2,5-dihydroxybenzoic acid), and salicylic acid, but they do not mention either 2,3-dihydroxybenzoic acid, or 2,3,5-trihydroxybenzoic acid. Williams (2) reports retention times for methyl ester and methyl ester-methyl ether derivatives of several dihydroxybenzoic acids including 2,3- and 2,5-dihydroxybenzoic acids but he presents no data for acetylsalicylic acid, salicylic acid, or 2,3,5-trihydroxy-

Table I—Relative Retention Times

Methyl Ester-Methyl Ether Derivative of	Relative	Retention Time
Benzoic acid (internal standard)	—	1.00 ^a
Salicylic acid	1.240	2.12
Acetylsalicylic acid	—	2.91
2,5-Dihydroxybenzoic acid	—	3.37
2,3-Dihydroxybenzoic acid	—	3.91
2,3,4-Trihydroxybenzoic acid	—	8.43

^a Retention time = 1.026 min.

benzoic acid. The following technique will effectively separate acetylsalicylic acid from its hydroxy metabolites.

MATERIALS AND METHODS

Identity of the individual compounds used was established by melting point.

An ethereal alcoholic solution of diazomethane was prepared by reacting an ethereal solution of *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide with ethanolic potassium hydroxide in a distilling apparatus (3). The resulting ethereal distillate contained approximately 3 g. of diazomethane.

The methyl ester-methyl ether derivatives of the respective compounds were prepared as follows. Approximately 0.25 g. of each compound was dissolved in a minimum amount of absolute ethanol. Ethereal diazomethane was added dropwise until a yellow color

Figure 1—Gas chromatograph showing: (1) solvent peak; derivatives of: (2) benzoic acid; (3 and 4) salicylic acid; (5) acetylsalicylic acid; (6) 2,5-dihydroxybenzoic acid; (7) 2,3-dihydroxybenzoic acid; and (8) 2,3,4-trihydroxybenzoic acid.

persisted, after which approximately a 20% excess by volume of ethereal diazomethane was added. The reactions were allowed to proceed at room temperature for 48 hr. in stoppered flasks. Additional ethereal diazomethane was added periodically if the resulting solutions became clear. After the reaction was completed, the solvent was evaporated at room temperature under a stream of dry nitrogen. The residual yellow viscous methyl ester–methyl ether derivatives were transferred quantitatively to 10-ml. volumetric flasks and brought to volume with pyridine.

An Aerograph 200, model 2041B (Wilkins Instrument and Research Inc., Walnut Creek, Calif.) equipped with a hydrogen-flame

ionization detection system was used. Separations were carried out at 155° with a 1.524 m. (5 ft.) \times 1.75 mm. i.d. stainless steel column packed with 5% SE-30 on diatomaceous earth¹ 60-80 mesh. Injector and detector temperatures were maintained at 205°. The helium carrier gas flow rate was 25 ml. per minute and the hydrogen pressure was maintained at 10 p.s.i.

RESULTS AND DISCUSSION

The relative retention times of the respective derivatives, as compared with the retention time of the methyl ester of benzoic acid, are reported in Table I. Figure 1 represents a chromatograph of a mixture of the respective compounds. Salicylic acid yielded two peaks with the same relative retention times following three separate derivative preparations. The purity of the salicylic acid was confirmed by TLC. 2,3,4-Trihydroxybenzoic acid was used as a model for the behavior of the 2,3,5-trihydroxybenzoic acid metabolite. It is not unreasonable to assume that the two compounds would demonstrate similar behavior toward the GLC system used. Since the retention time of the trihydroxy derivative is much longer than any of the other hydroxy derivatives, one would not expect the 2,3,5-trihydroxy metabolite to interfere with the analysis of the other compounds. The derivatives were found to be stable for a period of several weeks when stored at 4°.

New Synthesis of *rac.* Anhalonidine and *rac.* Pellotine

M. TAKIDO, K. L. KHANNA, and A. G. PAUL

Abstract □ A new synthesis of *rac.* anhalonidine and *rac.* pellotine is reported. The procedure, a modification of the method of Bobbitt *et al.* (5) for the synthesis of 1,2,3,4-tetrahydroisoquinolines, is simpler and gives better yields than those previously reported.

Keyphrases □ Anhalonidine, racemic—synthesis □ Pellotine, racemic—synthesis □ IR spectrophotometry—structure □ NMR spectroscopy—structure

The need for quantities of anhalonidine and pellotine for use in the biosynthesis of the peyote alkaloids and the inability to obtain them commercially or in sufficient quantities from the peyote cactus required

that they be synthesized. Reported syntheses (1-4) are either lengthy or the yields are low. The method of Bobbitt *et al.* (5) for the synthesis of related tetrahydroisoquinolines was modified for the synthesis of these alkaloids as shown in Fig. 1.

3,4-Dimethoxygalloacetophenone (I), prepared by the method of David and Kostanecki (6), was condensed with aminoacetaldehyde diethylacetal to give Schiff's base (II) which was conveniently reduced at room temperature with sodium borohydride to yield *N*-[2-(3',4'-dimethoxy-2'-hydroxyphenyl)ethyl]aminoacetaldehyde diethylacetal (III). Compound III was cyclized in 8 *N* HCl at room temperature to yield 4,8-dihy-

Figure 1—Gas chromatograph showing: (1) solvent peak; derivatives of: (2) benzoic acid; (3 and 4) salicylic acid; (5) acetylsalicylic acid; (6) 2,5-dihydroxybenzoic acid; (7) 2,3-dihydroxybenzoic acid; and (8) 2,3,4-trihydroxybenzoic acid.

persisted, after which approximately a 20% excess by volume of ethereal diazomethane was added. The reactions were allowed to proceed at room temperature for 48 hr. in stoppered flasks. New Synthesis of *rac.* Anhalonidine and *rac.* Pellotine

M. TAKIDO, K. L. KHANNA, and A. G. PAUL

Abstract □ A new synthesis of *rac.* anhalonidine and *rac.* pellotine is reported. The procedure, a modification of the method of Bobbitt *et al.* (5) for the synthesis of 1,2,3,4-tetrahydroisoquinolines, is simpler and gives better yields than those previously reported.

Keyphrases □ Anhalonidine, racemic—synthesis □ Pellotine, racemic—synthesis □ IR spectrophotometry—structure □ NMR spectroscopy—structure

The need for quantities of anhalonidine and pellotine for use in the biosynthesis of the peyote alkaloids and the inability to obtain them commercially or in sufficient quantities from the peyote cactus required

that they be synthesized. Reported syntheses (1-4) are either lengthy or the yields are low. The method of Bobbitt *et al.* (5) for the synthesis of related tetrahydroisoquinolines was modified for the synthesis of these alkaloids as shown in Fig. 1.

3,4-Dimethoxygalloacetophenone (I), prepared by the method of David and Kostanecki (6), was condensed with aminoacetaldehyde diethylacetal to give Schiff's base (II) which was conveniently reduced at room temperature with sodium borohydride to yield *N*-[2-(3',4'-dimethoxy-2'-hydroxyphenyl)ethyl]aminoacetaldehyde diethylacetal (III). Compound III was cyclized in 8 *N* HCl at room temperature to yield 4,8-dihy-

Figure 1—Synthesis of rac. anhalonidine and rac. pellotine.

droxy-6,7-dimethoxy-1-methyl-1,2,3,4-tetrahydroisoquinoline hydrochloride (IV). Reduction of IV in 6 *N* HCl with palladium-on-charcoal as the catalyst yielded anhalonidine hydrochloride (VI). Alternatively, III was mixed with 6 *N* HCl and palladium-on-charcoal and reduced to give VI directly. Yields by both methods were approximately equal.

Pellotine (VII) was synthesized by adding sodium borohydride to a mixture of IV and formaldehyde in methanol to give 4,8-dihydroxy-6,7-dimethoxy-1,2-dimethyl-1,2,3,4-tetrahydroisoquinoline (V). Reduction of V in 6 *N* HCl with palladium-on-charcoal as the catalyst yielded VII as the hydrochloride. Alternatively, VII was prepared by methylation of VI using formaldehyde in methanol in the presence of sodium borohydride.

In addition to presenting new methods for the synthesis of VI and VII in better yields than previously reported, III, IV, and V represent new compounds not previously reported in the literature. Proof of structure of these compounds is based upon elemental analyses, IR and NMR spectral data, and analogy with similar types of compounds synthesized by Bobbitt and Sih (7).

EXPERIMENTAL

***N*-[2-(3',4'-dimethoxy-2'-hydroxyphenyl)ethyl]aminoacetaldehyde Diethylacetal (III)**—A solution of I (3.96 g.) and aminoacetaldehyde (2.66 g.) in 80 ml. of absolute ethanol was allowed to stand at

room temperature for 24 hr. The solution was stirred at room temperature and sodium borohydride (1.0 g.) was added in small portions over a period of 0.5 hr. The solution was then added to 80 ml. of water and extracted with ether (3 \times 200 ml.). The ether solution was concentrated and extracted with 1 *N* HCl. The acid extract was basified with 2 *N* Na₂CO₃ solution and extracted with ether. The ether was removed and the oil (4.5 g., 71%) was purified by distillation, b.p. 116–117°/0.03 mm. $\nu_{\text{max}}^{\text{film}}$: 3275 cm⁻¹ (—NH—); 3125 cm⁻¹ (—OH). NMR¹ (CDCl₃), p.p.m.: 6.46 d [1], *J* = 8 c.p.s. (ar. H); 6.13 d [1], *J* = 8 c.p.s. (ar. H); 4.45 tr [1], *J* = 5 c.p.s. Anal.—Calcd. for C₁₆H₂₇NO₅: C, 61.32; H, 8.68. Found: C, 61.74; H, 8.48.

4,8-Dihydroxy-6,7-dimethoxy-1-methyl-1,2,3,4-tetrahydroisoquinoline (IV) Hydrochloride (4-Hydroxyanhalonidine Hydrochloride)—Compound III (3.0 g.) was dissolved in 75 ml. 8 *N* HCl and the solution was permitted to stand for 10 hr. at room temperature. The acid solution was then adjusted to pH 6.5 with aqueous NaOH and washed with chloroform. The aqueous solution was filtered, freeze-dried, and the solid residue extracted with chloroform-methanol (9:1). The extract was evaporated to dryness *in vacuo* at <40° and the residue crystallized from methanol-ethylacetate as colorless plates, m.p. 217–218° (yield, 2.5 g., 87%). IR (KBr): 3420 cm⁻¹ (—NH—); 3100 cm⁻¹ (—OH); 1178 cm⁻¹ (phenolic —OH); 1070 cm⁻¹ (sec. alcohol —OH).

Anal.—Calcd. for C₁₂H₁₃ClNO₄: C, 52.27; H, 6.58; Cl, 12.86; N, 5.08. Found: C, 52.10; H, 6.70; Cl, 12.84; N, 5.03.

The base, prepared from the hydrochloride, crystallized from benzene-ethylacetate as colorless plates, m.p. 195–196° (dec.). IR (KBr): 3510 cm⁻¹ (—NH—); 3070 cm⁻¹ (—OH); 1190 cm⁻¹ (phenolic —OH); 1060 cm⁻¹ (sec. alcohol —OH). NMR (DMSO),

p.p.m.: 6.49 s [1], (ar. H); 4.17, 4.05, 3.95 complex [2], [CH₃—CH—NH—, —CH(OH)—CH₂—]; 3.77 s [3], (—OCH₃); 3.68 s [3], (—OCH₃); 2.91 q [2], *J* = 2.5 c.p.s. [—CH(OH)—CH₂—]; 1.26 d [3], *J* = 6.5 c.p.s. (CH₃—CH—NH—).

The picrate, prepared from the hydrochloride, recrystallized from benzene-ethanol as yellow plates, m.p. 206–208°.

4,8-Dihydroxy-6,7-dimethoxy-1,2-dimethyl-1,2,3,4-tetrahydroisoquinoline (V) (4-Hydroxypellotine)—Compound IV (200 mg.) and formaldehyde (120 mg., 37%) were dissolved in methanol (10 ml.). Sodium borohydride (80 mg.) was added to the stirred solution in small portions over a period of 0.5 hr. The solution was then added to water (10 ml.) and extracted with chloroform (3 \times 20 ml.). The chloroform extract was evaporated to dryness and the residue washed with ether. The crystalline solid remaining was crystallized from benzene to give colorless needles, m.p. 177–178° (yield 180 mg., 86%). IR (KBr): 3130 cm⁻¹ (—OH); 1185 cm⁻¹ (phenolic —OH); 1080 cm⁻¹ (sec. alcohol —OH). NMR (CDCl₃), p.p.m.: 6.54 s [1], (ar. H); 4.40 s, 4.09 s, 3.98 complex [2], [—CH(OH)—CH₂—, —NH—CH—CH₃]; 3.88 s [3], (—OCH₃); 3.86 s [3], (—OCH₃); 2.90 d [2], *J* = 13 c.p.s. [—CH(OH)—CH₂—]; 2.50 s [3], (>N—CH₃); 2.17 s [1], [—CH(OH)—CH₂—]; 1.17 d [3], *J* = 6.5 c.p.s. [—CH—(CH₃)—N—].

Anal.—Calcd. for C₁₃H₁₉NO₄: C, 61.64; H, 7.56; N, 5.53. Found: C, 61.84; H, 7.66; N, 5.44.

Anhalonidine (VI) Hydrochloride—Method A—Compound III (1.2 g.) was dissolved in 8 *N* HCl (25 ml.) and the solution was permitted to stand at room temperature for 9 hr. The solution was then adjusted to approximately 6 *N* by the addition of water (10 ml.) and additional 6 *N* HCl (10 ml.) added. Palladium-on-charcoal (1.0 g., 5%) was added and the mixture was reduced at atmospheric pressure and room temperature for approximately 24 hr. The mixture was filtered and the filtrate concentrated *in vacuo* at <50° using a film-flash evaporator. Ethanol-benzene was added from time to time to azeotrope the water. The solid residue obtained was crystallized from methanol-ether to give colorless needles (yield 0.75 g., 73%).

Method B—Compound IV (100 mg.) was dissolved in 6 *N* HCl (20 ml.), palladium-on-charcoal (0.2 g., 5%) added, and the mixture

¹ s = singlet; d = doublet; tr = triplet; q = quartet; m = multiplet; ar. = aromatic.

was reduced and treated as described above (yield, 70 mg., 74%).

The free base, m.p. 160° [lit. m.p. (1) 160°], and the salicylate, m.p. 223–225° [lit. m.p. (4) 223.5–224.5°], prepared from VI hydrochloride showed no melting point depression when mixed with authentic samples. The IR spectra of the hydrochloride and the salicylate were identical with authentic samples.

Pellotine (VII) Hydrochloride—*Method A*—Sodium borohydride (20 mg.) was added in small portions over a period of 0.5 hr. to a stirred solution containing VI (38 mg.) and formaldehyde (2 drops, 37%) in methanol (5 ml.) at room temperature. The solution was then added to water (5 ml.) and extracted with chloroform (3 × 10 ml.). The chloroform extract was dried over anhydrous sodium sulfate and then evaporated to dryness. The residue was dissolved in a small quantity of methanol–chloroform–ether, and dry HCl gas was passed through the solution. Colorless needles crystallized (yield 35 mg., 75%).

Method B—A mixture of V (90 mg.), 6 N HCl (20 ml.), and palladium-on-charcoal (200 mg., 5%) was reduced at atmospheric pressure and room temperature for approximately 24 hr. The mixture was filtered and the filtrate concentrated *in vacuo* at <50° using a film-flash evaporator. Ethanol–benzene was added from time to time to azeotrope the water. The solid residue was crystallized from methanol–ether (yield 87 mg., 89%).

The free base, m.p. 116° [lit. m.p. (1) 111–112°], showed no melting point depression when mixed with authentic pellotine. The IR spectra of the base and hydrochloride were identical with that of authentic samples.

Pentaerythritol Tetranitrate Sustained-Release Tablets: Relation of *In Vitro* Release of the Drug to Blood Pressure Changes after Administration to Anesthetized Cats

SACHCHIDANANDA BANERJEE, ARUN KUMAR MUKHERJEE, and ARUP KUMAR HALDER

Abstract □ The *in vitro* release of pentaerythritol tetranitrate (PET) from a sustained-action PET tablet was determined using USP tablet disintegration apparatus with the modification that 100-mesh stainless steel wire cloth replaced the usual 10-mesh. The immersion medium was simulated gastric fluid for the first 2 hr. and simulated intestinal fluid for the subsequent 10 hr. There was a gradual release of the drug and 80 to 100% of the drug was dissolved at the end of 12 hr. The tablet when administered by mouth to anesthetized cats produced a 28 to 30% fall in arterial blood pressure which persisted for 12 hr. A good correlation between the rate of release of the drug *in vitro* and the *in vivo* effect in sustained lowering of the blood pressure was obtained. The *in vitro* method described is proposed for the quality control of sustained-action PET tablets.

Keyphrases □ Pentaerythritol tetranitrate sustained-release tablets—drug release □ Blood pressure changes—pentaerythritol tetranitrate release □ Dissolution rates—pentaerythritol tetranitrate tablets □ *In vivo-in vitro* release rates correlation—pentaerythritol tetranitrate tablets

Difficulties were experienced in testing the quality of sustained-release tablets of pentaerythritol tetranitrate using procedures usually adopted for the quality control of sustained-release preparations. In the dissolution test the concentration of the drug released in the bath fluid from the tubes containing tablets is esti-

mated at various intervals. In the assay of pentaerythritol tetranitrate such a procedure could not be adopted as the analysis is based on the estimation of nitrates. To estimate nitrates in the bath fluid, large volumes of the solution had to be evaporated to dryness before extraction with glacial acetic acid (1). In the *in vivo* test the determination of the rate of absorption of the drug would involve the collection of large volumes of blood at frequent intervals and estimation of the drug in these blood samples. Both procedures were impractical.

In the dissolution test, if the remnants of the tablets in the disintegration apparatus and not the bath fluid were collected at different intervals, the estimation of pentaerythritol tetranitrate would be possible and the *in vitro* rate of release of the drug from the tablet could be calculated. The drug lowered blood pressure and a sustained fall in blood pressure could be observed when the sustained-release tablet was administered to cats. A study, therefore, was undertaken to establish a relation, if any, between the *in vitro* release of the drug and the lowering of blood pressure in cats after administration of sustained-release pentaerythritol tetranitrate tablets. A good correlation was observed between the *in vitro* release of the drug and the fall in

was reduced and treated as described above (yield, 70 mg., 74%).

The free base, m.p. 160° [lit. m.p. (1) 160°], and the salicylate, m.p. 223–225° [lit. m.p. (4) 223.5–224.5°], prepared from VI hydrochloride showed no melting point depression when mixed with authentic samples. The IR spectra of the hydrochloride and the salicylate were identical with authentic samples.

Pellotine (VII) Hydrochloride—*Method A*—Sodium borohydride (20 mg.) was added in small portions over a period of 0.5 hr. to a stirred solution containing VI (38 mg.) and formaldehyde (2 drops, 37%) in methanol (5 ml.) at room temperature. blood pressure which indicates that the *in vitro* procedure described in this communication can be used for the quality control of the sustained-release dosage form of pentaerythritol tetranitrate.

EXPERIMENTAL

Dissolution Rate Determination—The sustained-action pentaerythritol tetranitrate (PET) tablets under study were two-layered compressed tablets of which one layer contained 10 mg. PET for immediate release and the second layer contained 70 mg. of the drug for sustained release.

For the determination of the dissolution rate, the tablet disintegration apparatus as described in USP XVII (2) was used with the modification that 100-mesh stainless steel wire cloth was attached to the under surface of the lower end of the disintegration tubes in place of 10-mesh usually used for determination of disintegration of tablets. One tablet was placed in each of the tubes and the machine was switched on using simulated gastric fluid with a pH of 1.2 (3). After 2 hr. the machine was switched off. One of the tubes used for disintegration was withdrawn and the remnant of the tablet transferred into a 150-ml. conical flask. The simulated gastric fluid was replaced by simulated intestinal fluid (4) adjusted to pH 7.5. The machine was switched on again and operated for another 10 hr. At intervals of 1 hr., one of the disintegration tubes was withdrawn and the remnant of the tablet was transferred into a 150-ml. flask. The remnants of the tablets were extracted with glacial acetic acid on a boiling water bath, suitably diluted with the acid to bring to a definite volume, and PET content was estimated (1). Twenty of the tablets were crushed to powder and PET content was estimated in an aliquot to obtain the contents in one tablet before disintegration. From the contents of PET in the remnants of tablets after various hours of dissolution, the rate of release of the drug from a tablet was calculated. The results are given in Table I.

Blood Pressure Studies—Cats weighing 2.5–3 kg. were anesthetized by intramuscular injection of sodium phenobarbital, 150 mg./kg., dissolved in 4 ml. of water for injection. After the animal was under the anesthesia the left common carotid artery was cannulated in the usual way to record the arterial blood pressure on a kymograph. The trachea was connected to a recording tambour for the recording of respiration. When the initial blood pressure and respiration were recorded the sustained-release PET tablet, 15 mg./kg., was fed to the animal through a stomach tube, 10 ml. water was

injected through the tube so as to push the tablet into the stomach, and blood pressures were recorded at intervals. Fifteen milligrams PET per kilogram body weight was found to produce a marked fall in blood pressure without showing any undesirable effect. The relation of percent fall of blood pressure to *in vitro* release of PET with statistical analysis is shown in Table II.

When quick-release PET was administered in the same dose, there was a 40% fall in blood pressure which came to the initial level within 6 hr. The anesthesia itself did not produce any marked change in the blood pressure.

RESULTS AND DISCUSSION

The results in Table I indicate that the *in vitro* release of PET was gradual and 90% of the drug was released in the course of 12 hr. The results were found reproducible, within the limits of the assay methods, from lot to lot of the same batch and in different batches. Table II shows that the percent fall in blood pressure, after administration of PET, at different hours had a good correlation with the release of PET in the *in vitro* experiment.

With regards to PET, controlled studies in humans based on the blood concentration of the drug or its degradation product are not possible as the rate of release of the drug is only 5 to 7 mg./hr. and concentration of the drug in the blood is too low to be analyzed. The *in vitro* test, therefore, may be used as a quality control procedure for the evaluation of a sustained-release preparation of pentaerythritol tetranitrate tablets.

Mannich Bases from 1,2-Diphenylindolizine: Ephedrine and Methamphetamine as Amine Components

WILLIAM B. HARRELL

Abstract □ Two unique Mannich bases derived from 1,2-diphenylindolizine have been synthesized. Ephedrine and methamphetamine were employed as the secondary amine components in the syntheses. Both products showed an initial marked CNS depression. The activity of the methamphetamine derivative was reversed after 1.5 hr. to a pronounced CNS stimulation.

Keyphrases □ Mannich bases—synthesis □ 1,2-Diphenylindolizine—Mannich bases, synthesis □ Ephedrine, methamphetamine—amine components, Mannich reaction □ CNS activity—1,2-diphenylindolizine derivatives

It has been established in these laboratories, as a result of a continuing search for indolizines with useful biological activity, that certain 3-dialkylaminomethyl derivatives of 1,2-diphenylindolizine were potent CNS depressants (1). It was a natural curiosity that prompted the consideration of compounds with established CNS stimulant activity as secondary amine components in the synthesis of Mannich bases of this type. 1,2-Diphenyl-3-[*N*-(2-hydroxy-1-methyl-2-phenylethyl)-*N*-methylaminomethyl]indolizine (I) and 1,2-diphenyl-3-[*N*-(1-methyl-2-phenylethyl)-*N*-methylaminomethyl]indolizine (II) were synthesized from 1,2-diphenylindolizine using ephedrine and methamphetamine, respectively, as the secondary amine components in the Mannich reaction (2) (Scheme I).

Scheme I

EXPERIMENTAL

Melting points were taken on a Thomas-Hoover capillary melting point apparatus and are uncorrected. Elemental analysis of I was provided by Weiler and Strauss Microanalytical Laboratory, Oxford, England. The analysis of II was performed by Galbraith Laboratories, Knoxville, Tenn. The parent indolizine employed in the synthesis of the Mannich bases was 1,2-diphenylindolizine (3, 4).

Spontaneous Motor Activity—A preliminary evaluation of the activity of these compounds on the CNS was carried out in the

following manner. The compounds were dissolved in one part *N,N*-dimethylacetamide, diluted with nine parts water, and injected intraperitoneally in mice (Swiss white, random bred, 20–30 g.) in dosages of 5 mg./kg. body weight. Spontaneous motor activity was measured in a photoelectric cell activity cage and run against controls injected with solvent only. Both I and II showed strong CNS depressant activity. However, the animals were easily aroused and did not lose their righting reflex during this period. After approximately 1.5 hr., II showed a marked reversal of activity. The spontaneous motor activity increased significantly above that of the controls. This stimulation is presumably due to the metabolic release of the methamphetamine moiety. No significant stimulation was observed with I after 4 hr. A more extensive pharmacological study of these compounds will be carried out and the results will be reported.

1,2-Diphenyl-3-[*N*-(2-hydroxy-1-methyl-2-phenylethyl)-*N*-methylaminomethyl]indolizine (I)—To a 125-ml. conical flask was added 0.75 ml. of 40% aqueous formaldehyde (0.01 mole), 2.48 g. of *L*-ephedrine (0.015 mole), and 30 ml. of *N,N*-dimethylformamide. The mixture was allowed to stand at -5° for 48 hr. At this point 1.35 g. of 1,2-diphenylindolizine (0.005 mole) was added to the flask and the mixture stirred at room temperature for 72 hr. The reaction solution was nearly saturated with water and stirring was continued for 24 hr., during which the product crystallized out. The yield was 1.7 g. (76%). On recrystallization from acetone-water the compound gave m.p. $157-158^\circ$. The compound gave a negative color test with *p*-dimethylaminobenzaldehyde indicating that substitution had occurred at the C-3 position (5).

Anal.—Calcd. for $\text{C}_{31}\text{H}_{30}\text{N}_2\text{O}$: C, 83.37; H, 6.77; N, 6.27. Found: C, 83.29; H, 6.61; N, 6.15.

1,2-Diphenyl-3-[*N*-(1-methyl-2-phenylethyl)-*N*-methylaminomethyl]indolizine (II)—Methamphetamine hydrochloride, 6.2 g. (0.033 mole), was converted to the free base and transferred to a 250-ml. conical flask. To the flask was added 1.5 ml. of 40% aqueous formaldehyde (0.02 mole) and 70 ml. of *N,N*-dimethylformamide. The flask was stoppered and allowed to stand at -5° for 48 hr. To the mixture was added 2.7 g. of 1,2-diphenylindolizine (0.01 mole). The reaction mixture was refrigerated for 96 hr. with occasional agitation. The product crystallized out on saturation with water. The yield was 3.6 g. (83%) of fluorescent yellow crystals. Upon recrystallization from acetone-water the product gave m.p. $141-142^\circ$. The compound gave a negative color test with *p*-dimethylaminobenzaldehyde.

Anal.—Calcd. for $\text{C}_{31}\text{H}_{30}\text{N}_2$: C, 86.47; H, 7.02; N, 6.51. Found: C, 86.20; H, 7.02; N, 6.49.

4-Thiazolylmethoxyureas as Potential Anticancer Agents

GLENN H. HAMOR and ANDON HUDAUERDI*

Abstract □ Preparation of a series of substituted 4-thiazolylmethoxyureas and 4-thiazolylmethoxythioureas is described. These compounds, which are structurally related to the antitumor agent hydroxyurea, were essentially inactive when screened against the L-1210 lymphoid leukemia test system. One compound, 4-thiazolylmethoxyurea, showed moderate anti-inflammatory activity in the carrageenin-induced rat paw edema test.

Keyphrases □ Anticancer agents, potential—synthesis □ 4-Thiazolylmethoxyureas—synthesis □ Pharmacological screening—4-thiazolylmethoxyureas □ IR spectrophotometry—identity

Recent studies have demonstrated the antineoplastic activity of hydroxyurea (I) (1, 2) and hydroxyurethan (II) (3). Hydroxyurea has been shown to inhibit several mouse tumors and has been used clinically in the treatment of cancer (4–6).

The aim of the present work is the synthesis of some 4-thiazolylmethoxyurea derivatives (III) for evaluation as possible antineoplastic agents. These 4-thiazolylmethoxyureas are structurally related to hydroxyurea, and also are related to 4-thiazolylmethoxyamine (IV) which is a potent histidine decarboxylase inhibitor (7). Histamine biosynthesis and histidine decarboxylase activity have been reported to increase in tumor tissue (8–11).

The five 4-thiazolylmethoxyureas synthesized are listed and their analytical data and melting points given in Table I and have the formula shown above (III). These ureas were prepared as shown in Scheme I.

The synthesis of the starting 4-thiazolylmethoxyamine dihydrochloride (IV) is described in another publication (7). The desired 4-thiazolylmethoxyurea was prepared by the reaction of potassium cyanate and 4-thiazolylmethoxyamine dihydrochloride by the method used by Bauer and Dalalian for the synthesis of aryloxyureas (12). By a modification of this method, the reaction of IV with phenyl isocyanate, with 1-naphthyl isocyanate, and with cyclohexyl isocyanate gave, respectively, 1-phenyl-3-(4-thiazolylmethoxy)urea, 1-(1-naphthyl)-3-(4-

Scheme I

thiazolylmethoxy)urea, and 1-cyclohexyl-3-(4-thiazolylmethoxy)urea. The use of the alkyl isocyanates, methyl, ethyl, and *n*-butyl isocyanate, with IV by the above method gave no desired compounds.

The reaction of phenyl isothiocyanate and IV yielded the expected 1-phenyl-3-(4-thiazolylmethoxy)thiourea. This thiourea showed apparent decomposition upon standing at room temperature for 2 months. The synthesis of 4-thiazolylmethoxythiourea by the method used in the preparation of 4-thiazolylmethoxyurea was attempted. However, the isolation and purification of the desired 4-thiazolylmethoxythiourea could not be accomplished, because the compound was very unstable, apparently decomposing in 1–2 hr.

BIOLOGICAL RESULTS

Anticancer Screening—Four of the compounds, namely 4-thiazolylmethoxyurea (Compound No. 1, Table I) (NSC 116197), 1-phenyl-3-(4-thiazolylmethoxy)urea (No. 2) (NSC 116723), 1-cyclohexyl-3-(4-thiazolylmethoxy)urea (No. 4) (NSC 119183), and 1-phenyl-3-(4-thiazolylmethoxy)thiourea (No. 5) (NSC 119182), were submitted to the Cancer Chemotherapy National Service Center, National Cancer Institute, for screening against the L-1210 lymphoid leukemia test system (13). None of the compounds possessed any significant antitumor activity. The cyclohexyl derivative (No. 4) was considerably more toxic than the other alkoxyureas, being lethal to 5/6 mice at a dose of 75 mg./kg., injected intraperitoneally. The other three compounds tested showed no lethality at 400 mg./kg.

Antimalarial Screening—Two compounds (Nos. 1 and 3) were tested for antimalarial activity against *Plasmodium berghei* in mice under the auspices of Walter Reed Army Institute of Research and were found to be inactive.

Preliminary Pharmacological Screening—Preliminary pharmacological results¹ are available for 4-thiazolylmethoxyurea (No. 1) and 1-phenyl-3-(4-thiazolylmethoxy)urea (No. 2). Compound No. 1 has no cardiovascular effect in the dog on i.v. injection. Tests performed in the rat (oral administration) showed that No. 1 has slight antipyretic and moderate anti-inflammatory (carrageenin-induced edema in the rat paw) effects, has a slight antidiuretic effect, and causes considerable anorexia. Tests in mice (i.p. injection) showed that the compound has no analgesic, antielectroshock,

¹ The authors thank Riker Laboratories, Northridge, CA 91324, for performing the pharmacological testing.

antiamphetamine, nor antireserpine activity and no effect on conditioned avoidance response. It decreases considerably the locomotor activity of the animal (i.p. or p.o.). At very high doses it causes hyperactivity. The LD₅₀ of the compound in mice (i.p.) is greater than 800 mg./kg. (0/10 mice dead).

Compound No. 2 has no cardiovascular effects in the dog. In contrast to the results on No. 1, slight increases in the amount of urine and in the body temperature of the rat (p.o.) were seen. There was no effect on conditioned avoidance response. Anorexic activity was present. Tests in mice (i.p.) showed a slight antielectroshock, a slight analgesic, and no antiamphetamine nor antireserpine effect. The compound (i.p., mice) slightly increased locomotor activity, and at high doses caused ataxia. The LD₅₀ of the compound is greater than 800 mg./kg., i.p. (3/10 mice dead).

EXPERIMENTAL

The syntheses of the compounds reported in Table I are described here. All melting points were taken on a Fisher-Johns melting point apparatus and are uncorrected. Elemental microanalyses were performed by Elek Microanalytical Laboratories, Torrance, Calif. The IR spectra of all compounds were determined on a Perkin-Elmer Infracord apparatus in mineral oil mulls, and were in agreement with the assigned structures.

4-Thiazolylmethoxyurea (No. 1)—To 20.31 g. (0.1 mole) of 4-thiazolylmethoxyamine dihydrochloride (7) dissolved in 150 ml. H₂O was added 8.9 g. (10% excess) of potassium cyanate. The solution was stirred at 60° for 1 hr. and then left overnight at 60° to evaporate to dryness. Extraction of the residue with 50 ml. boiling acetone, followed by concentration of the solution and cooling gave 6.2 g. (33.8% yield), m.p. 124–125°. An analytical sample was obtained by three recrystallizations from acetone.

1-Phenyl-3-(4-thiazolylmethoxy)urea (No. 2)—To a solution of 0.6 g. (0.003 mole) of 4-thiazolylmethoxyamine dihydrochloride in 10 ml. of water was added 100 ml. of benzene. Sufficient anhydrous K₂CO₃ (approximately 30 g.) was added not only to form the free base but also to remove all water. The mixture was filtered through a folded filter paper and the water layer (if any) discarded. To the benzene layer containing the free 4-thiazolylmethoxyamine was added 0.325 ml. (0.003 mole) phenyl isocyanate; the mixture was stirred for 30 min. at room temperature and then let evaporate to dryness overnight at room temperature to yield 0.48 g. (63%), m.p. 100°.

1-(1-Naphthyl)-3-(4-thiazolylmethoxy)urea (No. 3)—The naphthyl compound was synthesized by the same procedure used for the phenyl derivative above. From 1.02 g. (0.005 mole) 4-thiazolylmethoxyamine dihydrochloride and 0.85 g. (0.72 ml., 0.005 mole) 1-naphthyl isocyanate was obtained a white, crystalline product, which after three recrystallizations from benzene weighed 0.7 g. (49%), m.p. 132°.

1-Cyclohexyl-3-(4-thiazolylmethoxy)urea (No. 4)—The cyclohexyl derivative was prepared similarly. From 1.34 g. (0.0066 mole) 4-

thiazolylmethoxyamine dihydrochloride and 0.83 g. (0.0066 mole) cyclohexyl isocyanate were obtained 0.67 g. (39%) of product, m.p. 76°. An analytical sample was obtained by three recrystallizations from anhydrous ether.

1-Phenyl-3-(4-thiazolylmethoxy)thiourea (No. 5)—In a similar manner, 1.02 g. (0.005 mole) of 4-thiazolylmethoxyamine dihydrochloride and 1.08 g. (0.6 ml., 0.005 mole) phenyl isothiocyanate gave, after recrystallization from benzene, 0.6 g. (45%) of cream-colored solid, m.p. 119°.

Effect of Charge Shielding by Nonpolar Groups on the Partitioning of Quaternized Amines

HOWARD L. JOHNSON, PANAYOTIS TSAKOTELLIS, and JOSEPH I. DeGRAW

Abstract □ The methiodide salts of a number of tertiary organic bases were examined for their distribution properties between chloroform and water. An attempt was made to demonstrate whether the screening of ionic charge by nonpolar groups would substantially increase the lipid solubility of the methiodides. Comparison of a series of 2,6- versus 3,5-methyl-substituted *N*-methylpiperidine methiodides revealed little difference in their partition coefficients. Syntheses are described for some previously unreported substituted piperidines.

Keyphrases □ Amines, quaternized—partitioning □ Charge shielding, nonpolar groups, effect—quaternized amine partitioning □ Partition coefficients—quaternized amines □ Tertiary bases—synthesis

In recent years considerable effort has been directed toward the development and study of drugs which affect the central nervous system (CNS). Both qualitative and quantitative aspects of central *versus* peripheral activity depend not only upon the “intrinsic activity” and “receptor affinity” of a given drug, but also upon its rate and extent of distribution to specific sites within the CNS. Although knowledge is still incomplete, numerous studies have served to emphasize the lipid nature of the blood-brain barrier membrane. Two physicochemical parameters become of prime importance in determining rate and degree of penetration of this barrier by a drug (1). These are the lipid/water partition coefficient (*K*) and the degree of ionization at physiological pH with rate of penetration being directly related to the former and inversely to the latter. Therefore it is generally assumed that there is little or no penetration by charged quaternary ammonium compounds. This is supported by pharmacological experience in that such compounds generally do not elicit effects attributable to central actions.

In the initial phase of a program designed to evaluate the membrane permeability of quaternary ammonium compounds, the effect of structural variations in some quaternized bases have been investigated with regard to the partition coefficient in chloroform–water. Specifically, an attempt has been made to assess the importance of the steric relationship of hydrophobic, charge-insulating moieties to the locus of positive coulombic charge in a series of methyl-substituted piperidine methiodides. In addition, a few other quaternary salts of similar hydrocarbon content, but of a caged nature, were evaluated. The physical data and partition coefficients for all of the methiodides are listed in Table I.

It can be seen from the data in Table I that the major factor which determined the ability of the quaternary compounds to partition more favorably into the organic phase was the amount of hydrocarbon residue. If one allows that a change of about tenfold in the *K* value is significant, then the compounds of similar hydrocarbon content are not sufficiently different from one another

to construct a case for enhancement of partitioning due to charge shielding. Indeed, the results seem to be to the contrary when one compares the 2,6-dimethyl *versus* 3,5-dimethylpiperidines (6 *versus* 7; 10 *versus* 11) and the 2,2,6,6-tetramethyl *versus* 3,3,5,5-tetramethylpiperidines (8 *versus* 9; 12 *versus* 13). These comparisons are between compounds of equal hydrocarbon content, but with differences in proximity of the methyls to the coulombic charge. In each case the more distant 3,5-substituted methiodides have a *K* about equal to or greater than the corresponding 2,6-substituted compounds. The authors had originally intended to study only the acetoxy amine methiodides but were suspicious that the acetoxy groups were somehow distorting the results. However, comparison of the simple piperidine methiodides (10–13) did not alter their conclusions based on the acetoxy compounds.

It would be premature to say that these results concerning partition coefficient could be extrapolated to a biological situation involving membrane permeability. However, the speculation of Friess *et al.* (2) to explain the similarity in functional acceptance of a quaternary and tertiary amine in the tropine series would seem to be affected by the authors' data. Their hypothesis that the “tropine ring structure may obscure the classic differentiation between quaternary and tertiary amine structure in terms of preferential penetration to and adsorption at certain peripheral and central chemoreceptor surfaces” does not seem to be tenable when based on the concept of charge shielding. Such shielding, as expressed in partition coefficients, is similar in most of the compounds and is certainly not uniquely enhanced for the tropine esters. Again, one must be cautious in this interpretation when comparing chemical *versus* biological systems. The authors hope to report on the degree and rate of penetration of the quaternary compounds through the blood-brain barrier as the second phase of this work.

CHEMISTRY

With the exception of the 1,3,3,5,5-pentamethylpiperidine compounds, synthesis of the various tertiary bases proceeded in a straightforward manner. All of the bases were liquids and characterization was achieved *via* methiodide or picrate salts. The Reformatsky reaction of ethyl formate, amalgamated zinc, and two equivalents of ethyl 2-bromoisobutyrate afforded diethyl 3-hydroxy-2,2,4,4-tetramethylglutarate in a 75% yield. Acid hydrolysis yielded the glutaric acid (3) which was converted to the *N*-methyl-4-acetoxy-3,3,5,5-tetramethylglutarimide by the general procedure of Hall (4). Reduction of the acetoxy imide with diborane in tetrahydrofuran afforded 1,3,3,5,5-pentamethyl-4-piperidinol. 1,3,3,5,5-Pentamethylpiperidine was also prepared by Hall's procedure.

EXPERIMENTAL

Melting points are uncorrected and were taken in evacuated capillaries in the case of the methiodide salts.

Table I—Physical Data for Tertiary Amines and Methiodides

No.	Amines			Methiodides			
	Structure	B.p., °C. /mm.Hg	M.p., °C.	Formula	Calcd.	Found	$K \times 10^4$ (CHCl ₃ /H ₂ O)
1		64/0.65	279–280	C ₁₁ H ₂₀ INO ₂	C, 40.6 H, 6.20 N, 4.31	C, 40.8 H, 6.28 N, 4.31	2.3, 1.8

1,3,5-Trimethyl-4-piperidinol—A mixture of 0.30 g. of lithium aluminum hydride, 1.0 g. of 1,3,5-trimethyl-4-piperidone hydrochloride (8) and 20 ml. of dioxane was stirred at reflux for 5 hr. The solvent was removed *in vacuo* and the residue was suspended in ether and decomposed with ice water. The ether was decanted from the aqueous sludge and three additional ether extractions were made. The ether was dried over magnesium sulfate and evaporated

to leave 0.60 g. (74%) of syrup; $\lambda_{\text{film}}^{\text{OH}}$ 3.0 μ (OH), no ketone remained at 5.8 μ . Vapor-phase chromatography showed a single peak. The oil was characterized as the methiodide salt, m.p. 226–230°.

Anal.—Calcd. for C₉H₂₀INO: C, 37.9; H, 7.08; N, 4.91. Found: C, 38.0; H, 6.99; N, 5.01.

1,2,2,6,6-Pentamethyl-4-piperidinol—To a solution of 9.2 g. (0.059 mole) of 2,2,6,6-tetramethyl-4-piperidone (free base) in 55

ml. of toluene was added 3.0 ml. (0.025 mole) of methyl chloroformate and the mixture was stirred at reflux for 45 hr. The toluene solution was washed with dilute acid, dried over magnesium sulfate, and evaporated *in vacuo* to leave 3.15 g. (59%) of the *N*-carbo-methoxy compound as a syrup; $\lambda_{\text{film}}^{25}$ 5.80 μ (ketone, C=O), 5.92 (urethan, C=O).

A mixture of 3.1 g. of the crude urethan, 3.1 g. of lithium aluminum hydride, and 50 ml. of dioxane was stirred at reflux for 30 hr. The mixture was cooled in ice and cautiously decomposed with ice water. The dioxane was removed *in vacuo* and the white, pasty residue was extracted with several portions of ether. The ether was dried over magnesium sulfate and evaporated to leave 2.1 g. (84%) of the pentamethyl alcohol as a viscous syrup; $\lambda_{\text{film}}^{25}$ 3.0 μ (OH), no carbonyl remained. Picrate, m.p. 244–246° (from ethanol).

Anal.—Calcd. for $\text{C}_{16}\text{H}_{24}\text{N}_4\text{O}_8$: C, 48.0; H, 6.04; N, 14.0. Found: C, 48.0; H, 5.95; N, 14.0.

3-Hydroxy-2,2,4,4-tetramethylglutaric Acid—A stirred mixture of 13.3 ml. (0.165 mole) of ethyl formate, 39 g. (0.60 g. atom) of 20-mesh zinc amalgam, 30 g. of ethyl 2-bromoisobutyrate, and a catalytic amount of iodine was heated to boiling. Reaction commenced immediately and an additional 64.7 g. (total of 0.49 mole) of bromo ester was added dropwise over 15 min. The mixture was refluxed for 4 hr., cooled in ice, and decomposed by the addition of 250 ml. of 3 *N* hydrochloric acid. The benzene layer was separated and the aqueous portion extracted twice with 150-ml. portions of benzene. The combined benzene extracts were washed with water, dried over magnesium sulfate, and evaporated *in vacuo*. Distillation of the residual liquid through a short Vigreux condenser afforded 31.5 g. (75%) of diethyl 3-hydroxy-2,2,4,4-tetramethylglutarate at b.p. 86–93° (0.35 mm.).

Hydrolysis of the ester (30.4 g.) was accomplished by refluxing with 620 ml. of 6 *N* hydrochloric acid for 6 hr. The solution was chilled to afford 14.1 g. (60%) of white crystals, m.p. 170–171°; lit. (3) m.p. 169–170°.

***N*-Methyl-4-hydroxy-3,3,5,5-tetramethylglutarimide**—The hydroxy diacid above (14.1 g.) was refluxed for 16 hr. with 113 ml. of acetyl chloride, followed by evaporation of the reagent and distillation of the residue under vacuum (100° at 0.2 mm.) to afford 15.6 g. (98%) of 4-acetoxy-3,3,5,5-tetramethylglutaric anhydride. This material was immediately added to an ice-cold mixture of 60 ml. of 40% methylamine and 100 ml. of 75% acetone (4). After 20 min. the acetone was removed and the aqueous residue was acidified and extracted with chloroform to give 17.0 g. of a syrup regarded as the 4-acetoxy-3,3,5,5-tetramethylglutaric acid mono *N*-methylamide. The amino acid (16 g.) was treated with 25 ml. of acetic anhydride and 75 ml. of pyridine at reflux for 5 min. followed by standing at room temperature for 40 hr. The solvent was removed *in vacuo* and the residue treated with ice water and concentrated hydrochloric acid to precipitate *N*-methyl-4-acetoxy-3,3,5,5-tetramethylglutarimide (12.6 g., 85%). Recrystallization of a portion from water afforded white crystals, m.p. 53–55°.

Anal.—Calcd. for $\text{C}_{12}\text{H}_{19}\text{NO}_4$: C, 59.7; H, 7.94; N, 5.81. Found: C, 59.7; H, 7.82; N, 5.58.

1,3,3,5,5-Pentamethyl-4-piperidinol—A mixture of 5.0 g. of the imide, 40 ml. of tetrahydrofuran, and 60 ml. of 1 *M* diborane in tetrahydrofuran was refluxed for 3 hr. An equal charge of diborane solution was added and refluxing was continued for another 3 hr. The solution was cooled in ice and treated with 1 ml. of water and a few drops of 6 *N* hydrochloric acid. A violent reaction caused the loss of approximately one-half of the contents of the flask. The remainder was evaporated *in vacuo* and the residue was treated with 40 ml. of water and 6 *N* hydrochloric acid until strongly acidic. The resulting precipitate was extracted into chloroform, which was dried and evaporated to leave a white crystalline residue which possessed strong B-H bands in the IR at 4.2–4.4 μ . The complex was decomposed by heating with 50 ml. of 2 *N* hydrochloric acid for 15 hr. The resulting solution was made strongly alkaline with 10% sodium hydroxide and extracted with dichloromethane. The extract was dried over magnesium sulfate and evaporated *in vacuo* to leave 1.1 g. of liquid which was directly acetylated and characterized as the methiodide salt.

1,3,5-Trimethylpiperidine—A solution of 9.1 g. of 1,3,5-trimethyl-pyridinium iodide (9) in 100 ml. of 80% methanol was

passed through a column of 90 g. of ion-exchange resin [Dowex 2 (chloride)]. The column was further eluted with 80% methanol and the solvent then evaporated *in vacuo* to leave 5.2 g. (91%) of the methochloride salt. The material (4.7 g.) was hydrogenated over 1.0 g. of platinum oxide in glacial acetic acid at 3 atm. After 20 hr. the calculated amount of gas was consumed. The catalyst was removed and the solvent evaporated *in vacuo*. The residue was alkalinized with 10% sodium hydroxide and the base was extracted into dichloromethane. Since the amine tended to form a carbonate salt rapidly, it was directly converted to the methiodide salt.

Acetate Esters—The appropriate alcohol, as the free base, was mixed with excess acetic anhydride and the solution was heated 3–5 hr. on the steam bath. Pyridine was added in the case of hydrochloride salts. Excess reagent was removed *in vacuo* and the residue was partitioned between chloroform and 10% potassium carbonate. The chloroform extract was dried over magnesium sulfate, evaporated, and the residual liquid distilled *in vacuo* through a short path apparatus; yields were 50–70%. The boiling points of the bases are listed in Table I. Tropinol, pseudo-tropinol, 3-hydroxyquinuclidine hydrochloride, and 1-methyl-4-piperidinol were obtained from commercial sources; 1,2,6-trimethyl-4-piperidinol hydrochloride (β -epimer, m.p. 266°) was prepared by the hydrogenation of 1,2,6-trimethyl-4-pyridone (10).

Methiodide Salts—An ethereal or acetone solution of the appropriate tertiary base was treated with excess methyl iodide and allowed to stand for 24 hr. For the hindered bases, no cosolvent was used and reaction times were extended to 2 days in the case of 1,2,6-trimethyl-4-acetoxy piperidine and 7 days for 1,2,2,6,6-pentamethyl-4-acetoxypiperidine; 1,2,2,6,6-pentamethylpiperidine was refluxed 20 hr. in methyl iodide solution. The salts were recrystallized from absolute ethanol for analysis. Physical data are listed in Table I. 1,2,2,6,6-Pentamethylpiperidine was prepared by the method of Laboratorios Bonaplata, S.A. (11) and 1,3,3,5,5-pentamethylpiperidine by the procedure of Hall (4).

Determination of Partition Coefficients—Values of *K* were estimated from the distribution of quaternary salts between chloroform and water (10:1 volume ratio). Compounds were dissolved in the aqueous phase (2.0 mg./ml.) and partitioned with shaking over a period of 0.5 hr. The material in the chloroform phase was extracted into water and the quantity determined colorimetrically by the bromophenol blue method of Mitchell and Clark (12). A standard curve was determined for each compound.

Hydrophobic Self-Association of *d*-Propoxyphene Hydrochloride and the Effect of Urea: A Nuclear Magnetic Resonance Study

Keyphrases ☐ *d*-Propoxyphene HCl—hydrophobic self-association
☐ Urea effect—*d*-propoxyphene HCl self-association ☐ NMR spectroscopy—molecular interaction

Sir:

d-Propoxyphene is an important nonnarcotic analgesic agent. In a previous study from our laboratories, Conine has reported that aqueous solutions of *d*-propoxyphene hydrochloride¹ possess the ability to solubilize sparingly water-soluble organic acids (1). Conine's data have strong parallels to the phenomenon of micellar solubilization; he observed an apparent solute critical micelle concentration (SCMC). The amount of organic acid solubilized per mole of *d*-propoxyphene hydrochloride increased appreciably once the SCMC had been exceeded. Formation of aggregates of some type by propoxyphene ions was suggested but no direct evidence for this phenomenon was presented. Other reports (2, 3) in the literature also show that pharmacologically active amines form aggregates in aqueous solutions of their salts. It was of interest to us to develop a more definitive understanding of the aggregation phenomenon in aqueous *d*-propoxyphene hydrochloride solutions.

Nuclear magnetic resonance (NMR) spectroscopy can provide much detailed information about molecular interactions. In recent years NMR has been utilized for this purpose in such diverse areas as micelle formation (4), micellar solubilization (5), drug-protein interactions (6), and enzyme-substrate interactions (7). Applications of this versatile tool to research problems in physical pharmacy are not well documented in the literature. In this communication we wish to describe the findings of a preliminary NMR spectroscopic study of the self-association of *d*-propoxyphene hydrochloride in aqueous solutions.

The effect of concentration on the high resolution NMR spectrum of *d*-propoxyphene hydrochloride in D₂O is illustrated in Fig. 1. Assignments of the various signals, based on a first-order analysis, are also indicated in the figure.² As the concentration is increased, the signals of the aromatic and C-1 methylene protons are the most strongly affected. The fine structure in the aromatic region, apparent at low concentrations, is gradually lost as the solute concentration is increased.

¹ Marketed as Darvon by Eli Lilly and Co.

² The C-3 proton multiplet coincides with the *N*-methyl singlet and therefore it cannot be observed directly.

Figure 1—Effect of concentration on 100-Mc.p.s. NMR spectrum of *d*-propoxyphene hydrochloride in D₂O at 30°. The scale is referred to external TMS which was used as the source of a lock signal. Key: A, 0.1 M; B, 0.2 M; C, 0.3 M; D, 0.5 M; and E, 1.0 M.

In a 1 M solution, two rather broad singlets appear for the aromatic protons. The signal at 4.22 p.p.m. due to the C-1 methylene group is also appreciably broadened as indicated by its linewidth at half-height. The width of the sharp singlet due to the dimethylamino protons appears to be the least affected.

In addition to line broadening, all the signals move upfield as the concentration is increased; however, those due to the aromatic and the C-1 methylene protons undergo the most pronounced upfield shifts. It thus appears that aggregation in aqueous *d*-propoxyphene

Figure 2—Effect of urea on 100-Mc.p.s. NMR spectrum of 0.3 M *d*-propoxyphene hydrochloride in D_2O at 30° . The scale is referred to external TMS which was used as the source of a lock signal. The peaks symmetrically placed on either side of the HOD peak are spinning sidebands. The rather broad peak at 6.16 p.p.m. is due to the unexchanged amide protons of urea. Key: A, 0.0 M urea; B, 0.5 M urea; C, 1.0 M urea; D, 2.0 M urea; E, 3.0 M urea; F, 4.0 M urea.

hydrochloride solution takes place primarily through hydrophobic interactions of the aromatic systems. Further evidence supporting the proposed hydrophobic nature of this self-association comes from the fact that the concentration effects are absent in acetone and methanol solutions. It has been shown before that hydrophobic aggregation does not take place in these solvents (8, 9).

One of the factors causing such hydrophobic bonding would be the highly ordered water structure around the nonpolar moieties of the solute molecule. This ordered, cooperative, or iceberg-like structure of water may be altered by the addition of urea which has a strong

potential to interact with water. There appears to be some controversy about the effect of urea on water structure as to whether it acts as a structure breaker or as a structure maker (10); however, the hydrophobic bond-weakening effect of urea is generally recognized.

Increasing the addition of urea to *d*-propoxyphene hydrochloride solutions (at a given concentration) should weaken the hydrophobic interactions of the aromatic moieties. This predicted effect was observed when the NMR spectra of a 0.3 M *d*-propoxyphene hydrochloride solution were examined (Fig. 2). This particular concentration was chosen to demonstrate the effect of urea since it appeared, from chemical shift *versus* concentration plots, to be just above the concentration at which aggregation is complete. Weakening of hydrophobic bonding can be seen by the progressive reappearance of the fine structure of aromatic multiplets and by the increasing sharpness of C-1 methylene proton singlet as the urea concentration is increased from 0.5–4 M. The protons which are responsible for the intermolecular hydrophobic interactions also show the most significant downfield shifts indicating that as hydrophobic bonds are weakened, solute structure becomes less ordered. To our knowledge this is the first direct NMR demonstration of the hydrophobic bond-weakening effect of urea.

We are, at present, studying in detail the effect of hydrophobic self-association on chemical shifts and spin-spin relaxation rates. We are also examining, by NMR spectroscopy, aqueous *d*-propoxyphene hydrochloride solutions containing solubilized aromatic molecules. Results of these studies will be reported in future, more complete papers.

Plasmalogens are a naturally occurring group of aldehydogenic phosphoglycerolipids widely distributed in plants, animals, and microorganisms but detected in highest concentration in the heart, skeletal muscle, and the myelin of the brain and nerve. Low concentrations of nonphosphatide or "neutral plasmalogens" have also been detected in mammalian tissue as well as in the tissues of different fish. A number of reviews are available on the biochemistry (1-5) and the chemistry and analyses (6-8) of plasmalogens and other ether-linked lipids, and the general reactivity of *O*-alk-1-enyl groupings in organic compounds has just recently been summarized (8).

The presence of plasmalogens in tissues was first noted in 1924 by Feulgen and Rossenbeck (9) in their histochemical studies on the cell nucleus with fuchsin-sulfurous acid. This dye was found to produce a violet stain on both the nuclear and cytoplasmic portions of the cell after mild acid hydrolysis. Because these workers were able to extract the violet color with lipid solvents, they believed that the positive reaction produced in the cytoplasm was due to the presence of lipids rather than sugar aldehydes. Further, when the staining compound was subjected to treatment with acids or mercuric chloride, it liberated a long-chain fatty aldehyde. The cytoplasmic staining was referred to as the plasmal reaction. Feulgen and Voit (10) coined the name "plasmalogen" for the lipoid precursor compound and "plasmal" for the product liberated. The

plasmals appeared to be a mixture of hexadecanal and octadecanal, although other aldehydes might have been present. To demonstrate the presence of plasmals during histochemical studies on tissues, the tissues had to be hydrolyzed in the presence of either HCl or mercuric chloride. Without hydrolysis, Feulgen found that Schiff's test for aldehydes with sulfurous acid and fuchsin dye gave a slow positive reaction with the cytoplasmic lipid-like precursor.

In 1939, Feulgen and Bersin (11) were able to isolate a pure aldehydogenic phospholipid from horse muscle after vigorous alkaline hydrolysis of the ester phosphatides. Apparently, the aliphatic aldehyde formed a cyclic acetal bond with the glycerol skeleton, and the phosphorus and nitrogen base (ethanolamine) was attached by ester bonding to the third hydroxyl group in glycerol. This crystalline ethanolamine plasmalogen (I) was designated "acetal phospholipide." In 1951,

R = long-chain alkyl group

Thannhauser *et al.* (12) published a series of papers on the isolation of a crystalline ethanolamine plasmalogen from brain tissue. They used a more prolonged but more gentle alkaline hydrolysis than Feulgen and Bersin (11) had described earlier. The catalytic hydrolysis of their acetal phospholipid was carried out with mercuric chloride with the formation of long-chain fatty aldehydes (hexadecanal and octadecanal) and glycerylphosphorylethanolamine. By periodate titration they demonstrated that the glycerylphosphorylethanolamine derived from the brain acetal phospholipid belonged to the L- α structure.

The acetal structure served as a prototype for this class of lipids in earlier years, but its chemical structure was questioned and several alternatives were proposed. Doubt was cast on the correctness of Structure I when it failed to explain the great differences in the reaction rates between synthetically prepared glyceryl acetals and lipid extracts with fuchsin-sulfurous acid. Anchel and Waelsch in 1944 (13) observed that at low temperatures their lipid extracts gave a full color development while the synthetic acetals failed to produce a color; this observation suggested that the aldehyde linkage in the native compound may be more labile than that represented by Structure I. The observations of Schmidt *et al.* (14) also suggested that the native plasmalogens probably contained an alkali-labile residue, because upon hydrolysis of crude brain lipid extracts by the fuchsin-sulfurous acid reagent, no acid-soluble phosphate (glycerylphosphorylethanolamine) was obtained as one would expect from Structure I. However, prior treatment of the crude brain lipid extract with base and then subsequent acid hydrolysis did result in the correct amount of acid-soluble glycerylphosphorylethanolamine. On the basis of these experiments, they assumed that the lipid acetals were derived from other

lipid groups during analyses. It was suggested that plasmalogens normally obtained may be artifacts and that rupture of the alkali-labile linkages by which the original compound is bound to other lipid groups occurs during the isolation procedure. Assuming that the native plasmalogens were represented by Structure I, Baer and Stancer (15) proposed Structure II to explain the observations of Schmidt *et al.* (14).

The removal of a fatty acid by alkali from Structure II should yield the hemiacetal structure that then could undergo ring closure to form the cyclic acetal (I), and consequently only after pretreatment with alkali would Structure I be expected to give rise to glycerylphosphorylethanolamine when subjected to mild acid hydrolysis.

Further studies have provided strong evidence that the aldehydogenic residue in the native plasmalogens is an alk-1-enyl ether that is not altered by mild alkaline hydrolysis. In 1954, Rapport *et al.* (16) fractionated "acetal" phosphatides from bovine muscle by chromatographic separation on silicic acid. Upon analysis, they showed the presence of two fatty chains per atom of phosphorus, one of which was a fatty acid and the other a fatty aldehyde. Klenk and Debuch (17) found that catalytic reduction of the ethanolamine-plasmalogen led to a complete disappearance of an aldehydic reaction. Subsequent treatment of the reduced compound with base resulted in the isolation of a mixture of *O*-hexadecyl and *O*-octadecyl analogs of phosphatidic acid (III).

(a) Hexadecyl analog of phosphatidic acid

(b) Octadecyl analog of phosphatidic acid

III

Klenk and Debuch (17) did not investigate the linkage between the aldehyde and glycerol moieties, but they did propose three possible formulas (I, IV, and V) for the plasmalogens. Rapport *et al.* (18) firmly established the *O*-alk-1-enyl linkage in plasmalogens (IV).

CHEMISTRY

Proof of the Alk-1-enyl Structure—It is now known that the naturally occurring plasmalogens occur as glycerol derivatives of phosphorylcholine, phosphoryl-ethanolamine, or phosphorylserine containing a fatty acid residue and an alk-1-enyl linkage (IV). The terms saturated or unsaturated (19a) have been used to refer to the presence or absence of an alk-1-enyl group adjacent to the *O*-ether linkage of the hydrocarbon chain attached to the 1-position of glycerol (1). The α,β -unsaturated glyceryl ethers (enol ethers and vinyl ethers) are alk-1-enyl glyceryl ethers, which are the structural components of plasmalogens; in the earlier literature, the alk-1-enyl types are often referred to as plasmalogens. "Phosphatidal" has been proposed to differentiate alk-1-enyl phosphoglycerides from the "phosphatidyl" diacyl analogs (19b).

The first definitive clue to the α,β -unsaturation of the aldehydogenic linkage in plasmalogens was provided by Rapport *et al.* (18) from their studies on lysophosphatidal ethanolamine. Alkaline hydrolysis of the ethanolamine-plasmalogen fraction in bovine muscle was used to form the "lyso" compound. The "lyso" derivative exhibited a loss of aldehyde reaction upon hydrogenation, generated one molecule of a long-chain fatty aldehyde, and contained an alk-1-enyl ether group adjacent to the oxygen. Further evidence confirming the structural analogy between α,β -unsaturated ethers and plasmalogens was obtained by Rapport and Franzl (20) on their lyso compound in 1957 by using a modification reported in 1948 by Siggia and Edsberg (21) for the quantitative determination of alk-1-enyl ethers. This method is based on the addition of iodine to alk-1-enyl ether bonds and it is specific for the α,β -unsaturated ethers in the presence of ordinary olefinic unsaturation, alcohols, aldehydes, acetals, or acetylene. An iodo acetal forms during the reaction between methanolic iodine and alk-1-enyl ethers. Other workers (22, 23) have confirmed the specificity of this iodometric procedure. The iodometric reaction was utilized by Rapport and Lerner (24) in conjunction with the procedure of

Wittenberg *et al.* (25) based on the formation of a *p*-nitrophenyl hydrazine to measure the plasmalogen content of several normal and neoplastic tissues. Further proof of the alk-1-enyl ether linkage was supplied by Blietz (26), who studied the effect of acid hydrolysis on tissue plasmalogens synthesized in the presence of tritium-labeled water; these experiments demonstrated

that the original hemiacetal structure could be formed by the hydrolysis procedure itself (26). Furthermore, tritium-labeled aldehydes were isolated as the semicarbazone (26), which is not in accord with the proposed hemiacetal structure (V) but does support Structure IV.

Position of the Aldehydogenic Residue—The aldehydogenic chain in Structure IV is depicted in the α -position. The other possibility would be for the unsaturated ether chain to be attached to the β -position of the glycerol moiety. Opinions among the early investigators varied considerably with reference to the position of the aldehydogenic chain on the glycerol moiety. Initial studies determining the correct position of the aldehydogenic chain were carried out by Marinetti *et al.* (27, 28) on pig heart lipids. After catalytic reduction and alkali hydrolysis of total pig heart phosphatides, batyl alcohol (VI) (*O*-alkylglycerol) was isolated and indicated that the potential aldehyde group in the pig heart plasmalogens had to be attached to the α -carbon of glycerol. Debuch (29, 30) presented further

chemical evidence confirming that the aldehydogenic chain is attached to the α -position in the glycerol moiety. This evidence was based on results of hydrogenation studies on brain ethanolamine plasmalogens. The mixture of batyl (VI) and chimyl alcohol (VII), isolated, provided further evidence that the chemical structure of the plasmalogen was a 1-(alk-1-enyl) ether of a 2-acyl-3-glyceryl phosphate (IV).

A number of workers (31, 32) have studied the variations in the aldehydogenic chain by means of gas-liquid chromatography (GLC). A number of branched and unsaturated compounds were isolated in addition to normal C_{12} – C_{18} hydrocarbons. The aldehydogenic chain in Structure IV consists predominantly of 16:0, 18:0, and 18:1 alk-1-enyl chains; the fatty acids are almost completely unsaturated and the alk-1-enyl ether linkage possesses the *cis* configuration (29, 33–36). Norton *et al.* (35), working with pure choline plasmalogen from beef heart, and Warner and Lands (36), working with pig heart lecithin, obtained IR spectra that clearly indicated the configuration of the $-\text{OCH}=\text{CH}-$ grouping in natural plasmalogens to be wholly *cis*. Enzymatic treatment of phosphorylcholine with phospholipase C and hydrolysis of the acyl groups with base resulted in alk-1-enyl glyceryl ether (VIII). There was no absorption in the 930 cm^{-1} region, which is characteristic of substituted alk-1-enyl ethers possessing a *trans* configuration (37, 38), but the IR spectrum

showed a maximum at 738 cm^{-1} that is characteristic of the *cis* configuration. Hydrogenation caused complete loss of absorption and resulted in the isolation of an *O*-alkylglycerol. Cymerman-Craig *et al.* (39), by means of optical rotatory dispersion, determined the absolute stereochemical configuration of *cis*-1-(alkenyl-1-enyloxy)-2,3-diacetate obtained from pig heart plasmalogen. The natural plasmalogen had the same configuration as natural chimyl (VII) and batyl alcohols (VI). These data supported the earlier experiments of Thannhauser *et al.* (12) which had established the L- α -structure for plasmalogens by the isolation of L- α -glycerylphosphorylethanolamine from their lyso compound.

Chemical Properties—Little information is available on the chemistry of long-chain α,β -unsaturated ethers, but the $-\text{OCH}=\text{CH}-$ moiety occurs in other organic compounds on which there are more data available (8). The juxtaposition of the $-\text{OCH}=\text{CH}-$ moiety relative to the polar glyceryl residue would probably create some chemical differences between the alk-1-enyl linkage as found in plasmalogens and other ethers. Alk-1-enyl ethers are more reactive than other olefinic compounds; they are known to undergo a number of addition reactions as is illustrated in Scheme I. Few of these reactions have been investigated with the native plasmalogens (2). It is known that plasmalogens are stable in an alkaline or neutral medium but very quickly decompose in the presence of trace amounts of acid to form long-chain fatty aldehydes and glycerol derivatives.

The double bond of alk-1-enyl ethers may add halogens, acids of halogens, halides, organic acids (40), alcohols, phenols, and naphthols, and thus gives rise to simple or mixed acetals (41). The addition of alcohols and carboxylic acids is catalyzed by anhydrous acids, such as hydrogen halides, and also by boron fluoride (42, 43). Catalytic amounts of basic compounds cause hydrogen sulfide and mercaptans to add to alk-1-enyl ethers; the addition of water produces a hemiacetal intermediate that forms the aldehyde. An alk-1-enyl transesterification, catalyzed by mercuric sulfate and reported to occur at a temperature range between -70 and -10° (44), illustrates the reactivity of this ether linkage. The addition of iodine to alk-1-enyl ethers produces violent polymerization reactions as do heat and UV light (45). However, methanolic iodine produces a product that has been identified as unsymmetrical methylacetal (21) and which has been used as a sensitive and specific method for estimating plasmalogens and other alk-1-enyl ethers (2, 22). Alk-1-enyl ethers also have a characteristic absorption band in the IR at $8.3\text{ }\mu$ (1200 cm^{-1}) which does not appear in native plasmalogens (3, 46). The characteristic absorption band in the infrared of naturally occurring α,β -unsaturated ethers appears at $6.0\text{ }\mu$ (1650 cm^{-1}). The plasmalogens with their α,β -unsaturation behave in a manner similar to other alk-1-enyl ethers with reference

Scheme I
Reactivity of the O-Alk-1-enyl Linkage in
Organic Compounds (also see Reference 8).

to their alkaline stability, hydrolysis with acids and mercuric ions, reaction with fuchsin-sulfurous acid, addition of hydrogen and methanolic iodine, ozonolysis, and reactions with aldehyde reagents (2, 3, 20).

Related Plasmalogen Structures—Klenk and Böhn (47) and Ansell and Norman (48) have described the isolation and characterization of alk-1-enyl serine phosphatides (IX) in brain tissue. The existence of an alk-1-enyl inositol phosphatide (X) has also been demonstrated (49). Marinetti *et al.* (28) have obtained evidence for the presence of small amounts of diether phosphatides in beef heart, and Marinetti has described reactions involving mild alkaline and acidic hydrolysis (50) of Structures XI, XII, and XIII.

As has been pointed out in this review, the cyclic acetal phospholipid (I) isolated by Feulgen and Bersin (11) and Thannhauser *et al.* (12) from the alkaline hydrolysis of muscle and brain phospholipids is considered an artifact formed by acid hydrolysis of ethanolamine lysoplasmalogen; subsequent studies have proved that the cyclic compounds are mainly *cis*-1-(alk-1-enyl)-2-acylglycerolphosphoryl nitrogenous bases. Further evidence that the cyclic acetal is an artifact of isolation has been presented by Davenport and Dawson (51, 52), who studied the formation of cyclic acetals during the acid hydrolysis of lysoplasmalogens. Evidence was presented to indicate that the mild acid hydrolysis of alk-1-enyl ethers of glycerylphosphorylethanolamine, obtained from alkali treatment of natural plasmalogen, will cause cyclization. The IR spectra were identical with those of a synthetic 2-aminoethyl-2,3-*O*-hexadecylidene-1-glycerophosphate. Mercuric ions prevented this cyclization and liberated the fatty aldehyde. Pietruszko and Gray (53) reported similar results. Pianadosi *et al.* (54) synthesized alk-1-enyl glycerols and studied their conversion to the corresponding cyclic glycerol acetals. The conditions necessary for their

cyclization were studied and no cleavage of the alk-1-enyl linkage was observed. The compounds isolated from the cyclization reaction were identical to the synthetic cyclic glycerol acetals prepared by a different route.

Landowne and Bergmann (55) reported the isolation of a choline plasmalogen (XIV) (1,2-alkylidene glyceryl-3-phosphorylcholine) from the total lipids of the sea anemone, *Anthopleura elegantissima*. Identification of this compound was based on IR data and on the isolation of a long-chain fatty aldehyde on acid hydrolysis. The chemical synthesis of this type of compound (XIV) ($\text{R} = \text{C}_{15}$, i.e., 1,2-*O*-hexadecylidene glyceryl-3-phosphorylcholine) has been reported (56). Cyclic acetals of the ethanolamine type (I) have also been established by synthesis (57–59a). Recently, Frosolono *et al.* (59b) reported a convenient method for the preparation of

crystalline lysophosphatidyl choline (XV) in good yields from beef heart lecithin. The plasmalogen was physically

characterized and its chemical properties were compared with other α,β -unsaturated ethers of glycerol. Their (59b) evidence indicated that the choline plasmalogens (XIV) isolated from sea anemones were in reality Structure XV, and not a cyclic acetal of glycerol as originally proposed (55). All the evidence available indicates that the cyclic acetal structures probably do not make any significant contribution to the alk-1-enyl glyceryl ethers.

Neutral plasmalogens of nonphosphatide aldehydogenic lipids (XVI) have also been reported (60–62) and have been characterized as alk-1-enyl diacyl glycerols; this subject has been reviewed (5). Bergelson (63) has also presented an extensive review of neutral diol lipids and related compounds.

Chemical Synthesis—The synthesis of a *cis*-1-(alk-1-enyl) 2-acyl-3-glycerylphosphate constitutes a chemical problem beset with considerable practical difficulties. In 1961, Piantadosi and Hirsch (64, 65) began the first studies toward the chemical synthesis of plasmalogen. The initial step involved the synthesis of α -bromo cyclic acetal of glycerol, i.e., 2-(1-bromodecyl)-4-hydroxymethyl-1,3-dioxolane (XVII) and its subsequent reaction with sodium ($\text{R} = \text{C}_6\text{--C}_{11}$). The method used in

preparing XVII was a transacetalation reaction (66) between glycerol and various 2-bromo-1,1-dimethoxyalkanes derived from long-chain aldehydes. The first step in the transacetalation reaction is acid-catalyzed and pictured as proceeding through a carbonium ion mechanism leading to the formation of the mixed acetal. The second step is characterized by a slow, temperature-dependent inductometric effect that leads to ring closure (67). The dehalogenation of XVII was accomplished with sodium in ether (68, 69) and produced alk-1-enyl ethers with *trans* configuration. The alk-1-enyl ethers were hydrogenated to yield the corresponding saturated ethers. Diol plasmalogens (XVIII and XIX) were prepared in an analogous manner; acylation furnished the neutral-

type plasmalogens (64). This synthesis resulted in isomeric products that were about 92% pure, but it was often necessary to fractionate very carefully.

Using a modification of the same reactions, Cymerman-Craig *et al.* (70) reported that the debromination of XVII by lithium in dimethoxyethane formed a mixture of four isomers. They later reported a synthesis that yielded solely the 1-(alk-1-enyl) glycerol (71, 72). To avoid the formation of the 2-alk-1-enyl glycerol, 2-benzoyloxyglycerol was used in the transacetalation reaction with 2-bromo-1,1-dimethoxyhexadecane. Finally, catalytic debenzoylation and debromination afforded a mixture of (\pm) *cis* and *trans* 3-(*n*-hexadec-1-enyloxy)-1,2-propanediols, whose diacetates could be separated by preparative GLC.

Cunningham and Gigg (73) used heptanal di(glycerol-1,2-carbonate) acetal (XX) as starting material for the synthesis of *cis* and *trans* isomers of \pm 1-(hept-1-enyl) glycerol (XXI), which was obtained by thermal decomposition of XX followed by alkali hydrolysis ($n = 4$). The acetal (XX) when treated with acetyl chloride

was readily converted into a chloro ether, *i.e.*, 1-chloroheptyl-glycerol-2,3-carbonate, which underwent dehalogenation by the action of triethylamine to yield 1-(hept-1-enyl) glycerol-2,3-carbonate; alkaline hydrolysis formed XXI. The base-catalyzed rearrangement of allyl ethers (74, 75) used earlier by Cunningham *et al.* (76) to prepare 1-(prop-1-enyl) glycerol did not occur with allyl ethers containing a long hydrocarbon chain.

Berezovskaya *et al.* (77, 78) proposed an interesting route leading to the formation of alk-1-enyl ethers of glycerol by the corresponding acetylenic intermediates. These workers reported the synthesis of 1-(alk-1-enyl)-2,3-isopropylideneglycerol (XXII) ($n = 3, 11$) by reaction of the sodium derivative of 1,2-isopropylidene-glycerol with bromo alk-1-ynes. Partial reduction of XXII in the presence of Lindar catalyst yielded the *cis*-1-(alk-1-enyl)-2,3-isopropylideneglycerol (XXIII); however, doubts have been expressed (79) on the validity of this reaction sequence. The results of studies

using the same method (77, 78) led Chacko *et al.* (79) to suggest that the final product in condensation to form XXII was predominantly an allenic ether rather than the expected acetylenic ether. Oswald *et al.* (80), using the same conditions (77), were unable to obtain the reported alk-1-enyl glyceryl ether. Russian workers (81-83) have further described the synthesis of various derivatives of racemic 1-(alk-1-enyl) glycerols by the elimination of a tosyloxy group from XXIV by potassium *tert*-butoxide (where $n = 11, 13$). Compound XXIV was prepared by reacting 1,2-epoxyhexadecane with

isopropylidene to form 1-(2-hydroxyalkyl)-isopropylidene (82). This alcohol was treated with *p*-toluenesulfonyl chloride to give the tosylate. The original ketal group in the isopropylidene was hydrolyzed and subsequently replaced with trimethylsilyl groups. Finally, dehydrotosylation with potassium *tert*-butoxide produced a mixture of *cis* and *trans* isomers of 1-(alk-1-enyl) glycerol (XXI) which was acylated with various long-chain acid chlorides to give a "neutral plasmalogen," 1-(alk-1-enyl) 2,3-diacylglycerol (XXV). The authors did not indicate the presence of any alk-2-enyl ethers, as one might expect. However, under the reaction conditions, the alk-2-enyl ether would decompose, whereas the alk-1-enyl ether would not (73, 85) be affected.

A similar procedure (82) was investigated for the synthesis of octadecyl alk-1-enyl glyceryl ethers, but results indicated that the desired compound was present in small amounts only (80). A slightly less polar impurity, the major product of the reaction, was difficult to eliminate. Analysis of the fractions obtained after resolution of the total aldehydogenic material on silicic acid columns revealed that 15% of the alk-1-enyl glyceryl ether was present. Other modifications of the dehydrotosylation route have been used to improve the preparation of XXV (85). The application of the transacetalation reaction (66, 67) has been explored and proposed as a possible route to neutral plasmalogens (86-88). The method proposed is based on pyrolytic cleavage of di(α,β -diglyceryl) acetals of long-chain fatty aldehydes, *i.e.*, reactions of diethylacetal of stearaldehyde with the appropriate α,β -diglycerides to form di(α,β -diglyceryl) acetal of stearaldehyde (XXVI) (88). Since an acid is used in the reaction, the possibility of migration of acyl groups in the starting α,β -diglycerates exists, as well as formation of other isomeric products.

A similar method describes the pyrolysis of di-(glycerol-1,2-carbonate) acetal of heptaldehyde (73) as a route to 1-(alk-1-enyl) ethers of glycerol, but this reaction produces a mixture of *cis* and *trans* isomers. The elimination of alcohol from 1-(1-ethoxyalkyl)-2,3-diacylglycerol (XXVII) to form plasmalogens and XXV (87) has also been proposed by other workers (84).

Recently, Slotboom *et al.* (89) have described partial chemical synthesis of racemic *trans*-1-(hexadec-1-enyl-oxy)-2-oleoyl glycerol-3-phosphorylcholine (XXVIII). The synthesis of XXVIII required 1-(1-ethoxyhexa-

decyl)-2,3-dipalmitoyl glycerol (XXVII) as the intermediate; this was prepared by a modification of the method of Zvonkova *et al.* (87), using ethyl-1-hexadecyl ether and racemic 1,2-dipalmitoyl glycerol. Ethanol was eliminated from XXVII by heating it to 180° in the presence of sulfanilic acids *in vacuo*; this produced Compound XXV, *i.e.*, racemic *trans*-1-(hexadec-1-enyl)-2,3-dipalmitoyl glycerol. This compound was subjected to hydrolysis under alkaline conditions (90) and then reacylated with oleoyl chloride to yield racemic *trans*-1-(hexadec-1-enyl)-2,3-dioleoyl glycerol (XXV) (where R = C₁₅H₃₁ and R' = R'' = C₁₇H₃₃). Conversion of Structure XXVII to the monoacyl analog (XXIX) was accomplished enzymatically with pancreatic lipase,

which shows specificity for hydrolyzing fatty acyl bonds attached to the primary hydroxyl groups of glycerol. The method of Hirt and Berchtold (91) was used for the synthesis of Structure XXVIII from XXIX.

Recently, Gigg and Gigg (92), in an extension of their earlier work on plasmalogens (73), described a chloro-

ether route for the synthesis of racemic and optically active alk-1-enyl glyceryl ethers (neutral plasmalogens) in which the *cis* isomer was the major product. Their use of the pyrolysis method (73) had given a preponderance of the *trans* isomer. Finally, the *cis* and *trans* isomers in the form of their diacetates and dipalmitates were separated by thin-layer chromatography (TLC) on silica gel layers containing silver nitrate. Other workers have also used the dehydrohalogenation reaction to prepare alk-1-enyl ethers of glycerol (93-96).

As shown in Scheme II, Gigg and Gigg (92) used a trans-acetalation reaction between octadecanal dimethyl acetal [A] and D-(glycerol-1,2-carbonate) [B]. The lengthy sequence required for the synthesis of [B] by degradation (97) has recently been simplified by using a stereoselective route (98). The initial reaction between [A] and [B] produced octadecanal di-D-(glycerol-1,2-carbonate) acetal [C], which was then treated with acetyl chloride to give the chloroether, 3-(1-chlorooctadecyl)-D-glycerol-1,2-carbonate (XXX). The dehydrohalogenation reaction with triethylamine produced a mixture of *cis-trans* isomers of 3-(octadec-1-enyl)-D-glycerol-1,2-carbonate (XXXI); the *cis* isomer was the major product. Alkaline hydrolysis of Structure XXXI gave a mixture of *cis-trans* isomers of 1-(octadec-1-enyl)-L-glycerol (XXXII) that was converted to the diacyl analog by means of palmitoyl chloride and acetic anhydride. The earlier pyrolysis method for preparing the alk-1-enyl ethers (84) produced mainly the *trans* isomer, and the preparation of Slotboom *et al.* (89) contained only the *trans* isomer. At the present time, the most promising route for the synthesis of possible phosphorylated and other derivatives of the naturally occurring *cis* alk-1-enyl glyceryl ethers seems to be the method described by Gigg and Gigg (92). The reaction sequences are illustrated in Scheme II.

METABOLISM

Occurrence—The occurrence of ether bonds in biological compounds is limited in comparison to that of the acetal linkage of sugars, amides of proteins, and acyl groupings of lipids. In nature, ether linkages are found in guaiacol, vanillin, methyl phenyl ethers, enolpyruvylskimate-5-*P*, muramic acid, thyroxine, diphenyl ethers, and lipids. Lipids are known to contain alkyl and alk-1-enyl hydrocarbon moieties in ether linkage with glycerol or glycol. In general, the more prevalent ether-linked lipids are the alk-1-enyl phospholipids (plasmalogens), but phosphorus-free lipids that contain *O*-alk-1-enyl bonds have also been reported. The ether-linked lipids are found in most living cells, although most commonly in those of animal origin.

In mammals, the highest concentrations of *O*-alk-1-enyl lipids are found in brain and heart tissues, and plasmalogens appear to be an important constituent of biomembranes. The reader is referred to earlier reviews (1, 2, 5) on the occurrence of plasmalogens, but for convenience a summary of known biological sources of ether-linked lipids is provided in Table I. The table is not meant to be all inclusive but should serve to demonstrate the widespread distribution of lipids with

Scheme II

ether bonds in living cells. Although the close structural and metabolic relationships of the alkyl and alk-1-enyl ether bonds of lipids cannot be ignored (5), the discussion of their biochemistry in this paper will emphasize only the glycerolipids that contain *O*-alk-1-enyl bonds.

Methods of Detection—Methodology currently available for analyses of alk-1-enyl and alkyl ether-linked lipids has recently been reviewed (6, 7, 99). In general, plasmalogens are easily analyzed if the acyl, phosphorus, or phosphorylbase moieties are removed. Alkaline hydrolysis (100–102), enzymatic (103), or LiAlH_4 reduction (104–106) of these groups has been successfully used for this purpose. The *O*-alk-1-enyl glycerols formed can be measured quantitatively by photodensitometry or colorimetric reactions. During thin-layer chromatography, the *O*-alk-1-enyl glycerols migrate ahead of the *O*-alkylglycerols on silica gel G layers in solvent systems such as diethyl ether–water (100:0.5, v/v) or chloroform–methanol (98:2, v/v). This R_f behavior is probably explained by differences in the configuration of the alkyl and alk-1-enyl link-

ages, since the latter has a *cis* bond in the α,β -position (106).

Renkonen (107) has successfully isolated intact plasmalogens from the corresponding diacyl-, alkyl-, or acyl-ethanolamine lipids by TLC after masking the polar base groups as their methylated dinitrophenyl derivatives. However, the resolution of these intact derivatives requires multiple solvent developments. The advantage of this technique is that it permits labeling of all functional groupings in the intact subclasses of *P*-ethanolamine lipids and *P*-choline lipids to be followed in tracer experiments.

The nature of the *O*-alk-1-enyl side chains is best determined by GLC after releasing the long-chain fatty aldehydes by acid treatment (108) or by forming the dimethylacetals (109). Gas-liquid chromatography of long-chain fatty aldehydes and their derivatives has recently been reviewed by Gray (110). The fatty aldehydes can also be converted to fatty alcohols by LiAlH_4 reduction (109) or to acids by oxidation (109). The acetate derivatives of the alcohols and the methyl esters of the fatty acids are then analyzed by GLC to determine the lengths of the carbon chains and their degree of unsaturation. Oxidation of aldehydes to acids is only practical with saturated aldehydes, since degradation of unsaturated aldehydes occurs (109).

The variety of techniques used by biological investigators to investigate the quantities and nature of plasmalogens might account for some of the discrepancies that appear in the literature. Furthermore, it is likely that the vulnerability of the *O*-alk-1-enyl linkage to oxidative and acidic alterations would further complicate the meaning of some of the quantitative findings that have been published. Nevertheless, the chemical nature of plasmalogens and their distribution in various lipid classes have been well established by numerous independent investigators.

Nature of Plasmalogens in Biological Materials—The *O*-alk-1-enyl linkage is found almost entirely in phospholipids, mostly associated with the ethanolamine-containing phosphatides (Table I). In contrast, the *O*-alkyl bonds tend to be associated with the choline-containing phosphatides which have only small quantities of the *O*-alk-1-enyl linkages (99). However, in recent years, trace quantities of *O*-alk-1-enyl glycerolipids have been detected in the neutral lipid fractions of cells (Table I), primarily as 2,3-diacyl-1-*O*-alk-1-enyl

glycerols; such compounds are often referred to as "neutral plasmalogens." The location of the *O*-alk-1-enyl linkage in the 1-position glycerolipids and its *cis* configuration have been firmly established (27-30, 36, 39, 111-114).

The *O*-alk-1-enyl moieties in all glycerolipid classes are primarily 16:0, 18:0, and 18:1 carbon chains (5). Although significant differences in the quantitative distribution of these predominant *O*-alk-1-enyl chains exist, they clearly resemble the *O*-alkyl moieties of various lipid classes. The similarities of *O*-alk-1-enyl and *O*-alkyl moieties in glycerolipids suggest that interconversions might occur. However, no enzymes have yet been found that can catalyze these interconversions.

Biological Effects, Properties, and Function of Plasmalogens—Glycerolipids containing alkyl ether bonds have been thought to possess many biologically active properties, such as stimulation of growth, neurogenic activity, and hemopoiesis or inhibition of hemolysis. Bacteriostatic properties have also been associated with the ether-linked lipids. Furthermore, they have been proclaimed as therapeutic agents for radioprotection, wound healing, and bracken poisoning in cattle. These biological effects of alkyl glyceryl ethers have been thoroughly reviewed recently (5). Although many of these studies have been questioned, primarily because of the purity of the preparations or poor statistical comparisons, the fact remains that the listing of beneficial activities associated with *O*-alkyl lipids is overwhelming.

In contrast, no reports have dealt with similar type experiments carried out with plasmalogens. It is, perhaps, important to stress that the *O*-alk-1-enyl grouping in glycerolipids imparts a lower surface potential than that of the corresponding acyl analog (115). This is borne out in a biological system by the significant decrease in the hemolytic activity of lysophosphatidylethanolamine when alk-1-enyl (or alkyl) chains are substituted for an acyl chain (116).

The function of plasmalogens in living cells is not yet known. Their occurrence in biomembranes [organelles (117) and plasma membranes (118, 119)] and especially their high content in nervous tissue (120), suggest that their role is an important one in the structure and function of membranes. The orientation of protein and lipids in biomembranes could probably be a consequence of the ratio of ether- and ester-linked lipids in such residues; this proposition has been made on the basis of experimental data (117, 118). Further speculation on the function of plasmalogens is difficult since their biosynthetic pathway still remains to be elucidated.

Possible Biochemical Mechanisms for the Biosynthesis of Plasmalogens—Recent experimental work has finally provided an enzymatic system that can synthesize ether-linked glycerolipids (121a-121f). However, only the alkyl linkage is formed readily in this microsomal system isolated from a number of cells. So far, the biosynthesis of *O*-alk-1-enyl bonds is unknown. In this section, a number of possible mechanisms for the biosynthesis of plasmalogens is summarized; some of these have been discussed previously (3, 5, 122-128).

A. Reduction of Acyl Groups to *O*-Alk-1-enyl Groups—

The reductive step would presumably require a hydrogen donor, such as NADH, NADPH, or FADH.

B. Reaction of a Fatty Aldehyde with a Primary Hydroxyl Group of a Derivative of Glycerol—

The glycerol precursor could be one of many glycolytic products, such as dihydroxyacetone-*P* or even a hexose-*P* that later could be split into a 3-carbon unit.

C. Direct Formation of an Alk-1-enyl Linkage by a Transfer Reaction—

Table I—The Biological Occurrence of Plasmalogens in Phospholipids and Neutral Lipids

Biological Source	O-Alk-1-enyl Phospholipids References ^a	O-Alk-1-enyl Neutral Lipids References ^a
Mammals		
Normal tissues	25, 106, 200	61, 62, 106, 200, 204, 205
Neoplastic tissues	25, 140, 200	149, 200
Fishes	139, 201	63, 139, 201
Invertebrates	61, 202	61
Bacteria	149, 203	149
Insects	206	

^a Not a complete listing of references available.

D. Reaction of an Alkane-1,2-diol with Glyceraldehyde-3-P—

E. Reaction of an α -Hydroxy Fatty Acid and a Primary Hydroxyl Group of a Derivative of Glycerol—

This reaction would require an esterification and a reduction step before the final splitting out of hydrogen peroxide.

F. Conversion of an O-Alkyl Linkage to an O-Alk-1-enyl Linkage—

A hydrogen acceptor such as NAD, NADP, or FAD would be an essential cofactor.

Substituted groups such as $-\text{NH}_2$, $-\text{OCH}_3$, or $-\text{OCH}_2\text{CH}_3$ on the α - or β -carbons of the alkyl chain of glyceryl ethers could also produce alk-1-enyl ethers by splitting out ammonia, methanol, or ethanol, respectively.

G. Hydroxylation of an O-Alkyl Lipid—

H. Involvement of Cofactors—It is presumed that the reaction of functional groups listed in the preceding section would probably be facilitated through CoA or analogous intermediates, since the biosynthesis of the alkyl glyceryl ethers (121a) and acyl-substituted lipids (129) have an absolute requirement of coenzyme A, ATP, and Mg^{++} . Possible complexes that can be envisioned for such cofactors are shown below. All are hypothetical, since such complexes have never been isolated from biological materials.

Experimental Studies on the Biosynthesis of Plasmalogens—The reader is referred to an extensive review of this subject recently published (5).

A. Formation of the O-Alk-1-enyl Linkage—Cell-free systems that can form O-alk-1-enyl linkages in lipids have still not been isolated. Therefore, all data on the biosynthesis of these compounds available at the present time are largely circumstantial. *In vivo* studies have demonstrated that fatty acids (130–144), fatty alcohols (136, 140, 145–147a and b), fatty aldehydes (130–132, 148–150), and acetate (132, 134, 137, 138, 149, 151–155) can be incorporated into the alk-1-enyl moiety of glyceryl ethers. Experiments with doubly labeled fatty moieties have demonstrated that fatty aldehydes (132, 150) are much better precursors of the alk-1-enyl ethers than fatty acids. Some of the data obtained with fatty alde-

hydes have suggested that they are first oxidized and then incorporated into acyl linkages and that then the ester linkage is reduced (148). Nevertheless, experiments with the doubly labeled aldehydes strongly indicate that they are incorporated into the *O*-alk-1-enyl linkage directly instead of *via* the acyl-reductive mechanism.

Data indicating that alkyl glyceryl ethers can be desaturated in the α,β -position of the alkyl chain to form alk-1-enyl glyceryl ethers in the terrestrial slug, *Arion ater*, have been obtained by Thompson (141–143, 156a). Although the early evidence (141–143) for this conversion was based solely on the time course of specific activities, recent experiments with 1-¹⁴C-hexadecyl-2-³H-glyceryl ether (156b) have demonstrated that the ratio of ³H/¹⁴C in plasmalogens is identical to that of the alkyl glyceryl ether precursor. Experiments with the doubly labeled alkyl glyceryl ethers in Ehrlich ascites cells (156b) agree with the results obtained in slugs. Others (146, 147a, 157) have arrived at the same conclusion as Thompson (156a) by measuring specific activities of acyl, alkyl, and alk-1-enyl moieties in tracer experiments with glyceryl ether precursors. Some experiments in mammals (158–160) have not confirmed Thompson's thesis on the direct incorporation of ¹⁴C-labeled alkyl glyceryl ethers into plasmalogens; radioactivity has been found in the alk-1-enyl chains of brain lipids (160), but this was attributed to the products of ether cleavage. Interconversions between neutral lipid and phospholipid classes that contain ether bonds have not been investigated; ideas about possible relationships have been based on structural studies of lipid classes (161).

B. Phosphorylase and Acyl Transferase Reactions Involving Alk-1-enyl Lipids as Substrates—Kiyasu and Kennedy (162) found that a particulate fraction of rat liver could catalyze the transfer of cytidine diphosphate choline or cytidine diphosphate ethanolamine to 1-*O*-alk-1-enyl-2-acyl-glycerols. The formation of the choline and ethanolamine plasmalogens by this reaction indicated that the transferases involved cannot distinguish between acyl and alk-1-enyl substituents on the substrates. Others have confirmed this reaction in homogenates (163–165) or particulate fractions (166) of brain and in a particulate fraction from ox heart (167). However, the importance of these cytidine-catalyzed reactions, at least in the brain, has been questioned by *in vivo* experiments with ¹⁴C-ethanolamine (157) that involved the subsequent tracing of acyl, alkyl, and alk-1-enyl groupings in the various phospholipid classes at various times after their administration. Experiments with ³²P have also revealed considerable differences in the labeling of alk-1-enyl-acyl and diacyl phosphatides (130, 164, 168–172).

The acylation of alkyl glyceryl ethers occurs *in vivo* (158, 173–177) and *in vitro* (178–181). Cell-free systems isolated from numerous tissues have been shown to acylate 1-*O*-alkyl glycerols only in the 3-position (181). Presumably, acylation of the 2-position on the 1-isomer of alkyl glyceryl ethers requires the phosphorylated alkyl glyceryl ether as a substrate. Limited information on acylation reactions is available for the *O*-alk-1-enyl-linked lipids. Although rat liver microsomes (182) were unable to utilize 1-*O*-alk-1-enyl glycerol-3-phosphoryl-

choline as a substrate for acyl-CoA-phospholipid transferase, this acylation reaction did occur in erythrocytes from humans and in sarcoplasmic reticulum from rabbits (183). Endogenous phospholipids have been shown to be important factors in the reactivation of alk-1-enyl-GPC hydrolase (184).

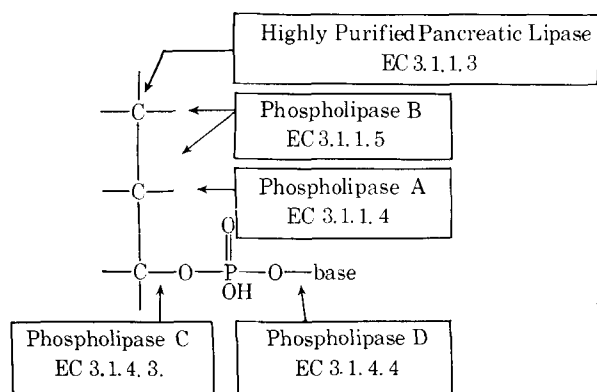

Experimental Studies on the Enzymatic Degradation of Plasmalogens—**A. Enzymatic Cleavage of the *O*-Alk-1-enyl Linkage**—Enzymes from liver (185) and brain (186) have been described that can catalyze the cleavage of the *O*-alk-1-enyl bond in plasmalogens. The liver enzyme, located in microsomes, can only utilize 1-*O*-alk-1-enyl glycerylphosphorylcholine as a substrate. The enzyme is specific for the lysocholine compound and no other cofactors are required.

The enzyme isolated from acetone powders of brain yields products similar to those found with the liver preparation, but it preferentially hydrolyzes the *O*-alk-1-enyl bond of 1-*O*-alk-1-enyl-2-acyl-glycerylphosphoryl-ethanolamine, and Mg⁺⁺ was required as a cofactor. The enzyme was also capable of cleaving the ether linkage of the lyso derivative, but the cleavage did not equal that obtained with the native plasmalogen substrate.

Other nonspecific reactions involving the enzymatic cleavage of the *O*-alk-1-enyl moieties of plasmalogens have been documented (187–190), but cleavage reactions of this type have not been reported for *O*-alk-1-enyl bonds found in neutral lipids. Considerable efforts have centered on the enzymatic cleavage of *O*-alkyl bonds in neutral lipids (191, 192). Enzymes for the cleavage of *O*-alkylglycerols have been found in rat liver that require tetrahydropteridine and NADPH as cofactors; the initial products formed during this cleavage are fatty aldehydes and glycerol. Similar systems have been found in other cells (192).

B. Removal of Acyl and Phosphorylbase Moieties from Plasmalogens by Phospholipases—Phospholipases are defined as A, B, C, or D, depending on the enzymatic specificity for the groups attached to the three positions of glycerol in phosphatides (103, 193). None of the lipase or phospholipase enzymes attacks ether bonds in lipids. Phospholipase A catalyzes the hydrolysis of fatty acids from the 2-position of phospholipids, whereas phospholipase B is thought to catalyze the hydrolysis of fatty acids from positions 1 and 2 or only position 1. Phospholipase B activity is the least understood since it is unknown whether its dual specificity is due merely to contamination with phospholipase A. Phospholipase C catalyzes the hydrolysis of the entire phosphorylbase moiety and phospholipase D catalyzes the hydrolysis of the base (choline or ethanolamine) portion only. It has also been shown that electrophoretically purified pancreatic lipase will catalyze the hydrolysis of acyl moieties in the 1-position of glycerophosphatides (194).

All of the phospholipases are capable of utilizing *O*-alk-1-enyl phosphatides as substrates under certain conditions, but generally the reaction rates are somewhat slower than with the diacyl analogs. Marinetti *et al.* (195) found that phospholipase A required several days to remove the acyl moiety from alk-1-enyl-acylcholine phosphatides in yields equivalent to those obtained with phosphatidyl choline. The sluggishness of this reaction was successfully applied to the purification of native plasmalogens (removal of contaminating phosphatidyl choline) by Gottfried and Rapport (33). However, the source of the enzyme is thought to be important, since Hartree and Mann (196) found essentially the opposite results in similar studies of phosphatides isolated from the sperm of rams. Phospholipase C from *Clostridium welchii* has also been found to hydrolyze *O*-alk-1-enyl-acylcholine phosphatides more slowly than the diacyl analog (197); *O*-alk-1-enyl ethanolamine phosphatides are also hydrolyzed by phospholipase C obtained from *Bacillus cereus* (198). In contrast, phospholipase D isolated from cabbage was unable to hydrolyze the choline moiety from the *O*-alk-1-enyl-acylcholine phosphatides (182). Investigations of lipases that catalyze the removal of acyl groups in neutral lipid classes containing *O*-alk-1-enyl linkages has recently been reported by Slotboom (199).

CONCLUSIONS

Even after 40-odd years of research, the biosynthesis and function of the alk-1-enyl linkage in plasmalogens

remain obscure although the structures, chemistry, and occurrence of plasmalogens in living cells are now firmly established. The striking similarities of chain lengths and degree of unsaturation between *O*-alkyl and *O*-alk-1-enyl moieties in glycerolipids suggest a close metabolic relationship and that they might perhaps originate from identical precursors. The requirements for the biosynthesis of alkyl ether bonds are known, and a clear understanding of the mechanism of this new pathway could elucidate fresh approaches to solving the riddle of plasmalogen biosynthesis. The biosynthetic problem is mirrored by the poor yields of plasmalogens synthesized in the organic laboratory. Certainly, the presence of *O*-alk-1-enyl bonds in biomembranes hints at their significance in the structural orientation of the lipid and protein in these structures. It is hoped that this review will serve to acquaint other chemists with both the past and present scope of research involving the *O*-alk-1-enyl linkages of plasmalogens.

RESEARCH ARTICLES

Effect of Certain Additives on the Photochemistry of Riboflavin

CHUNG TECK SHIN*, B. J. SCIARRONE, and C. A. DISCHER

Abstract □ The quantum efficiency of riboflavin under aerobic conditions was determined by using a microirradiation method. It was found that the initial quantum efficiency was constant and independent of intensity of light, wavelength of light, and concentrations employed. The quantum efficiency of riboflavin in the presence of phenols and other compounds was also determined. Only in the presence of phenols was the quantum efficiency decreased yielding a linear relationship between the Hammett's sigma values and the rate of photodecomposition. Benzyl alcohol and benzoic acid were found to be relatively ineffective as photochemical stabilizers compared to phenols. Cinnamyl alcohol, as an electron donor, enhanced the photodecomposition of riboflavin. It appears, from the compounds tested, that the hydroxyl group should be either attached to the benzene ring or be in conjugation with the benzene ring in order to be an effective photochemical stabilizer. The effects of temperature and pH on the system were also determined. Kinetic studies were made to elucidate the reaction mechanism.

Keyphrases □ Riboflavin, photochemistry—additives, temperature, pH effects □ Microirradiation—riboflavin, quantum efficiency □ Kinetic studies—riboflavin degradation □ Quantum riboflavin, efficiency—equations derived □ Spectrophotometry—analysis

The photosensitivity of riboflavin was first observed in 1932 by Warburg and Christian (1). Since then its photochemistry has been the subject of extensive investigation, and can be followed by recent reviews (2, 3). Although the fact that riboflavin will undergo photoreduction in the absence of an electron donor has been generally accepted, there have been conflicting views concerning the

actual mechanism of the reaction. However, the presently accepted theory for the photodecomposition of riboflavin proposes that the reaction proceeds from the lowest triplet state of the flavin and involves intramolecular hydrogen-transfer from the ribityl sidechain with the subsequent formation of lumichrome and/or lumiflavin depending on basicity of the solution (4-6). The photolysis of riboflavin and several other flavins in acid or neutral solution is subject to general acid and base catalysis (6).

The formation of molecular complexes between riboflavin and various compounds has also been observed (7-11). Particularly, studies of the charge-transfer complexes between riboflavin and phenol derivatives have received considerable attention, because interactions of donor-acceptor type may be quite common in biological systems (12). Thus, an understanding of the correlation of these properties with the photochemical behavior of riboflavin might provide an insight into some of the energy transfer and storage mechanisms of living organisms.

Stabilization of riboflavin to light in the presence of additives is pharmaceutically important, since certain additives were observed to have considerable influence on the light stability of the system (13-22). Despite this importance, very few photochemical kinetic studies have been published for riboflavin in the presence of complexing agents. Therefore, the present study was undertaken

RESEARCH ARTICLES

Effect of Certain Additives on the Photochemistry of Riboflavin

CHUNG TECK SHIN*, B. J. SCIARRONE, and C. A. DISCHER

Abstract □ The quantum efficiency of riboflavin under aerobic conditions was determined by using a microirradiation method. It was found that the initial quantum efficiency was constant and independent of intensity of light, wavelength of light, and concentrations employed. The quantum efficiency of riboflavin in the presence of phenols and other compounds was also determined. Only in the presence of phenols was the quantum efficiency decreased yielding a linear relationship between the Hammett's sigma values and the rate of photodecomposition. Benzyl alcohol and benzoic acid were found to be relatively ineffective as photochemical stabilizers compared to phenols. Cinnamyl alcohol, as an electron donor, enhanced the photodecomposition of riboflavin. It appears, from the compounds tested, that the hydroxyl group should be either attached to the benzene ring or be in conjugation with the benzene ring in order to be an effective photochemical stabilizer. The effects of temperature and pH on the system were also determined. Kinetic studies were made to elucidate the reaction mechanism.

Keyphrases □ Riboflavin, photochemistry—additives, temperature, pH effects □ Microirradiation—riboflavin, quantum efficiency □ Kinetic studies—riboflavin degradation □ Quantum riboflavin, efficiency—equations derived □ Spectrophotometry—analysis

The photosensitivity of riboflavin was first observed in 1932 by Warburg and Christian (1). Since then its photochemistry has been the subject of extensive investigation, and can be followed by recent reviews (2, 3). Although the fact that riboflavin will undergo photoreduction in the absence of an electron donor has been generally accepted, there have been conflicting views concerning the

actual mechanism of the reaction. However, the presently accepted theory for the photodecomposition of riboflavin proposes that the reaction proceeds from the lowest triplet state of the flavin and involves intramolecular hydrogen-transfer from the ribityl sidechain with the subsequent formation of lumichrome and/or lumiflavin depending on basicity of the solution (4-6). The photolysis of riboflavin and several other flavins in acid or neutral solution is subject to general acid and base catalysis (6).

The formation of molecular complexes between riboflavin and various compounds has also been observed (7-11). Particularly, studies of the charge-transfer complexes between riboflavin and phenol derivatives have received considerable attention, because interactions of donor-acceptor type may be quite common in biological systems (12). Thus, an understanding of the correlation of these properties with the photochemical behavior of riboflavin might provide an insight into some of the energy transfer and storage mechanisms of living organisms.

Stabilization of riboflavin to light in the presence of additives is pharmaceutically important, since certain additives were observed to have considerable influence on the light stability of the system (13-22). Despite this importance, very few photochemical kinetic studies have been published for riboflavin in the presence of complexing agents. Therefore, the present study was undertaken

Figure 1—The effect of light intensity (wavelength = 363 $m\mu$) on the photodecomposition of riboflavin at 30°. Riboflavin concentration = 5.0×10^{-5} M. Key: Light intensity (photons/sec. $\times 10^{-14}$) A = 7.63; B = 10.46; C = 12.62; D = 13.66.

to investigate the effect of certain additives, particularly, phenol derivatives and other compounds on the quantum efficiency of riboflavin. The phenol derivatives employed were phenol, *p*-chlorophenol, *p*-methoxyphenol, resorcinol, and hydroquinone. Benzyl alcohol, cinnamyl alcohol, and benzoic acid were also included to note the effect of the hydroxyl group conjugated with the benzene ring. Kinetic studies were also made to elucidate the mechanism of photodecomposition of riboflavin in the presence of additives. Temperature, pH, wavelength, and concentration were varied during these studies.

There is considerable information on the photodecomposition products and other compounds related to riboflavin using high intensity light sources. Under such conditions the photodecomposed products of riboflavin complicate the kinetic pattern and the calculation of quantum efficiency. Thus a microirradiation method developed by Discher *et al.* (23–25) was chosen for this study.

EXPERIMENTAL

Instrumentation and Equipment—The irradiation instrumentation employed was basically that developed by Discher *et al.* (23–25). Since the photodecomposition study was carried out at an elevated temperature, slight modifications were necessary on the reaction chamber; it was insulated with urethan foam and covered with aluminum foil to better maintain temperature at $30 \pm 0.1^\circ$. Irradiation studies were performed only after 1-hr. temperature equilibration.

All solutions were analyzed in the visible region using a Beckman DU spectrophotometer, and the absorption spectra of the solutions were obtained with the Beckman DK-2 recording spectrometer.

Materials—Riboflavin¹ was used without further purification. Other materials employed were phenol, *p*-chlorophenol, *p*-methoxyphenol, resorcinol, hydroquinone, benzyl alcohol, cinnamyl alcohol, and benzoic acid. All phenol derivatives and aromatic alcohols were purified by recrystallization or distillation.

Photodecomposition Studies—These were conducted under aerobic conditions since most pharmaceutical products including

riboflavin are stored in this manner. Few photochemical kinetic studies have been reported for these conditions.

Fresh solutions of riboflavin with and without additives were prepared in 0.05 M phosphate buffer, pH = 6.8. A 3-ml. sample of solution was pipeted into a Teflon-stoppered 1-cm. cell. The irradiation sample was analyzed by measuring its absorbance at 445 $m\mu$ on the Beckman DU spectrometer immediately before and after irradiation.

The mercury lamp employed showed two intense and sharp emission spectral lines at 363 and 433 $m\mu$. Since these lines are close to the maximum absorbance of riboflavin, photodecomposition studies were undertaken at these wavelengths. The intensity of the light falling on the reaction cell was determined by measuring the galvanometer response as described by Discher *et al.* (23–25). Since the intensity of the mercury lamp changed over a period of about 5 hr. by only 1.4% of the initial intensity, it was considered essentially constant for the period of irradiation. The quantum efficiency of riboflavin was calculated as described also by Discher *et al.* (23–25). The initial rate of photodecomposition of riboflavin was determined from the linear portion of a zero-order plot of concentration *versus* time. All irradiation measurements were made two or three times.

Figure 2—Kinetic studies for the photodecomposition of riboflavin at various concentrations at 363 $m\mu$. Key: Concentration (molarity $\times 10^5$) A = 7.5; B = 5.0; C = 3.0; D = 2.5.

RESULTS AND DISCUSSION

Kinetic Studies—The results of the kinetic studies at 363 $m\mu$ in the presence and absence of additives all fit the zero-order kinetic pattern rather than a pseudo first-order process. This is illustrated in Figs. 1 and 2. However, a linear zero-order relationship deviated after 5 hr. of irradiation, *i.e.*, when riboflavin was decomposed by more than 35% of initial concentration. This is illustrated in Fig. 1. Therefore, the length of exposure time was limited to 5 hr. so that the rate of decomposition of riboflavin was calculated from only the linear portion of the zero-order plot. When the 433 $m\mu$ wavelength of irradiating light was used a similar zero-order kinetic pattern was obtained.

Basic Quantum Efficiency Studies—The effect of the light intensity on the quantum efficiency of riboflavin was studied. The results of these studies are summarized in Table I (see Fig. 1). According to these data the quantum efficiency of riboflavin is independent of intensity of light. The number of molecules decomposed per unit time is directly proportional to the number of photons absorbed per unit time at each wavelength.

The effect of concentration of riboflavin on its quantum efficiency was also investigated. The data are summarized in Table II (see Fig. 2). These data indicate that quantum efficiency of riboflavin is constant within the concentration range tested. As shown in Table II, the higher the concentration of riboflavin solution the more photons were absorbed and subsequently more riboflavin decomposed. According to the above two series of studies the quantum efficiency of riboflavin was found to be constant at each wavelength employed.

It was deemed important to note the influence of irradiating time on the quantum efficiency of riboflavin. It was found that

Benzoic acid	1.82	1.77	1.73

quantum efficiency of riboflavin initially varied slightly in each study, but decreased after 5 hr. of irradiation. Such a result might be expected if a photodecomposition product or an intermediate quenches excited molecules or if a product of the reaction or an intermediate absorbs incident light.

The quantum efficiency of riboflavin can be evaluated from the slope of the plot of the molecules decomposed per unit time as a function of photons absorbed per unit time. All data in Tables I and II are plotted in Fig. 3. A linear relationship was observed between molecules decomposed and photons absorbed. This indicates that the riboflavin photodecomposition, under conditions used in this experiment, obeys the first law of photochemistry. The slope of the straight line was found to be 2.04×10^{-3} . Standard deviation for the measurement of quantum efficiency was 0.04×10^{-3} in this study. Theoretical and experimental rates of decomposition were compared as functions of the number of photons absorbed resulting in a superimposition of the straight line plots (not shown). Slopes of both lines were 6.76×10^{-23} .

Effect of Additives on the Quantum Efficiency—The quantum efficiency of riboflavin in the presence of various additives at

Figure 4—Plot of difference in quantum efficiency of riboflavin in the presence and absence of additives as a function of the ratio of additive concentration to riboflavin concentration at 30°. Figure 5—A plot of rate of photodecomposition of riboflavin in the presence of phenols as a function of Hammett's sigma value for each phenol. Concentration of riboflavin = 2.5×10^{-5} M; concentration of phenols = 1.0×10^{-4} M. Key: A = *p*-methoxyphenol; B = phenol; C = *p*-chlorophenol.

different concentrations are summarized in Table III. As shown in this table the quantum efficiency of riboflavin was either decreased or increased or remained constant depending on the physical and/or chemical properties of the additives. Any decrease in quantum efficiency in the presence of additives would be indicative of a photochemical stabilization process. A plot of the difference in quantum efficiencies of riboflavin in the presence and absence of additives as a function of the ratio of additive concentration to riboflavin concentration is shown in Fig. 4. The quantum efficiency of riboflavin in the presence of each phenol decreased gradually in the same fashion as the concentration of the given phenol was increased. This is probably due to the formation of the same type of complex between riboflavin and the different phenols. Therefore, the mechanism involved in the photodecomposition of riboflavin in the presence of monophenols may be considered to be similar.

The *p*-chlorophenol, which has an electron attracting chlorine atom (Hammett's sigma value = +0.227), lowered the quantum

efficiency more than *p*-methoxyphenol, which has an electron donating methoxy group (Hammett's sigma value = -0.268). This indicates that the inductive and conjugative effects of substituents may influence both the stability of the complexes and the rate of photodecomposition of riboflavin. The rate of decomposition of riboflavin in the presence of phenols are plotted in Fig. 5 as a function of their respective sigma values. A linear relationship is observed in this plot and can be expressed as:

$$K_1 = 7.11 \times 10^{-9} \sigma + 1.83 \times 10^{-8} \quad (\text{Eq. 1})$$

where K_1 = the rate of decomposition of riboflavin in the presence of 1.0×10^{-4} M phenol (per min.) and σ = Hammett's substituent constant for phenols.

A linear relationship was observed between the pK values of phenols in the ground state and the quantum efficiency of riboflavin in the presence of the phenol. However, this linear relationship was not observed when pK* for the excited phenols was similarly plotted. In both the ground and excited states phenols which have lower pK and pK* values were found to be more effective in lowering the quantum efficiency of riboflavin. This appears to be due to the electron attracting chlorine atom in the *p*-chlorophenol which causes the molecule to be a better proton donor and subsequently giving it a greater tendency to form a stable hydrogen bond-type complex than *p*-methoxyphenol. It has been known that the excited molecules in many cases have a greater tendency to form hydrogen bonds and that a new equilibrium is reached during the life time of the excited states (26). However, none of the phenols showed absorbance at the wavelength of irradiating light used.

The quantum efficiency of riboflavin in the presence of resorcinol was significantly decreased as the concentration of resorcinol was increased. A possible explanation for this observation would be that if the excited molecules have a greater tendency to form a hydrogen bond-type complex (26) resorcinol would have a better chance to form complexes than a monohydroxyphenol since it has two hydroxyl groups. Resorcinol would then be much more effective in lowering the quantum efficiency of riboflavin. However, in the case of hydroquinone the quantum efficiency of riboflavin first increased and then decreased gradually at higher concentrations. These phenomena indicate that two different reaction mechanisms are involved depending upon the concentration of hydroquinone—*viz.*, redox-reaction as well as complexation. In the presence of lower concentration of hydroquinone the redox-reaction mechanism is favored, *i.e.*, hydroquinone reduced the riboflavin, which was more easily decomposed through a triplet state. Therefore, the quantum efficiency of riboflavin was increased in the presence of lower concentration of hydroquinone. However, as the concentration of hydroquinone was increased, more of the complex(es) form(s), thereby stabilizing riboflavin.

It is interesting to note that when a riboflavin (2.5×10^{-5} M) solution was irradiated in the presence of a higher concentration (5.0×10^{-4} M) of resorcinol a red-brown colored solution resulted. The irradiation of a resorcinol solution (5.0×10^{-4} M) alone did not produce the colored product under the same conditions. Furthermore, in the ground state the colored products did not appear. Thus it is considered that the reaction involves interaction of riboflavin with resorcinol under irradiation. The colored solution had a maximum absorbance at 477 mμ. It was found that the photodecomposition product of resorcinol (1.0×10^{-3} M) formed after 78 hr. of irradiation also had this absorbance maximum. It is concluded, therefore, that the photooxidation of resorcinol was sensitized tremendously by the presence of riboflavin.

On the basis of these experiments it is clear that the photodynamic behavior of riboflavin in the presence of phenols is complicated and several other explanations are possible for the reduction of the quantum efficiency of riboflavin in addition to the complexation mechanism. It may be speculated that there might exist a direct transfer of the excitation energy from riboflavin to phenols, probably a triplet-triplet transfer may be an acceptable explanation of the phenomena observed.

The quantum efficiency of riboflavin in the presence of 2.5×10^{-5} M concentration of cinnamyl alcohol was found to decrease but it then increased as the concentration of cinnamyl alcohol was increased. In the case of benzyl alcohol the quantum efficiency of riboflavin was very slightly decreased initially and remained essentially constant as the concentration of benzyl alcohol was increased. When in the presence of benzoic acid the quantum efficiency of

Figure 6—A plot of rate of decomposition of riboflavin in the presence of benzoic acid, phenol, and resorcinol as a function of quenching efficiency (from Reference 2) of fluorescence of riboflavin. Key: A = benzoic acid; B = phenol; C = resorcinol.

riboflavin was found to be slightly lower than that of riboflavin in the presence of benzyl alcohol and also remained essentially constant as the concentration of benzoic acid was increased. All three compounds were found to be less effective than the phenols in lowering the quantum efficiency. Therefore, it is considered that the hydroxyl group attached to the benzene ring must be conjugated with the benzene ring in order to be an effective stabilizer for the photodecomposition of riboflavin.

The cinnamyl alcohol, which has a conjugated double bond with the benzene ring, behaves entirely differently from benzyl alcohol and phenol in these irradiation studies. It is considered that cinnamyl alcohol is photochemically interacting with riboflavin as an electron donor. It is well known that alcohols are good electron donors and are photooxidized in the presence of riboflavin (21). However, in the case of benzyl alcohol there was no photochemical interaction between riboflavin and benzyl alcohol except possibly hydrogen bonding or a solvent effect. It has been reported that benzyl alcohol does not form complexes and does not quench the fluorescence of riboflavin (2, 9). However, benzoic acid does quench the fluorescence of riboflavin slightly (2). Therefore, it is obvious that the addition of benzoic acid can affect the excited state of riboflavin and lower its quantum efficiency more effectively than benzyl alcohol.

The rate of photodecomposition of riboflavin in the presence of resorcinol, phenol, and benzoic acid are plotted in Fig. 6 as a function of their quenching efficiency (2) of the fluorescence of riboflavin. There appears to be a direct correlation between the rate of decomposition and quenching efficiency, *i.e.*, the rate of decomposition of the riboflavin is decreased in the presence of a substance which has a higher quenching efficiency. Mataga (26) and El-Bayoumi (27) ascribed this quenching effect to the formation of the hydrogen bond type of complex.

The Effect of Temperature—The quantum efficiency of riboflavin in the absence and presence of phenol as a function of temperature is shown in Fig. 7. Separately an Arrhenius plot was constructed over the temperature range of 20 to 30°, which showed that the reaction had a greater temperature dependence in the absence of phenol. The activation energies, calculated from the slope of the Arrhenius plots, were 8.94 kcal. in the absence of phenol and 6.25 kcal. in the presence of phenol (1.0×10^{-4} M).

The Effect of pH—Since phosphate buffer also affects the rate of decomposition of riboflavin all samples were prepared in water by adjusting pH with hydrochloric acid and sodium hydroxide. Figure 8 presents the pH effect on the quantum efficiency of riboflavin first in the absence and then the presence of phenol as an additive. When phenol was added to a riboflavin solution at constant pH it was found that the quantum efficiency decreased. These phenomena indicate that the reduction of the quantum efficiency is not merely due to a pH effect but that the phenol itself is hindering the excitation process of riboflavin and thereby stabilizes it. Since the protonated riboflavin is essentially stable to light and does not fluoresce, the riboflavin becomes quite stable toward photodecomposition below pH 3.

Kinetic Analysis—Oster *et al.* (18) proposed a kinetic scheme for the photoreduction of riboflavin illustrating the role of the triplet state in the reaction. Such a scheme can be applied to the present study with certain modifications. On the basis of the present investigation the following reaction mechanism is proposed.

Riboflavin absorbs light to give the first electronically excited species, Rf^* ,

This excited Rf^* may fall to the ground state with the emission of fluorescence and the production of heat,

Equations 3a and 3b indicate deactivation of the first excited singlet state by fluorescence (k_{2a}) and a radiationless process (k_{2b}), respectively. For the purpose of simplification of the kinetic mechanism, these two processes can be expressed as follows:

Figure 7—Quantum efficiency as a function of temperature. Key: A = quantum efficiency of riboflavin in the absence of phenol; B = quantum efficiency in the presence of phenol (1.0×10^{-4} M).

where $k_2 = k_{2a} + k_{2b}$

Alternatively the singlet excited species, Rf^* , undergoes transition to a long-lived (triplet) state, Rf' , through electronic vibration.

This long-lived species may fall to the ground state, with the evolution of heat, and possibly phosphoresce,

Equation 5b indicates deactivation of the triplet state by a radiationless transition (k_{4b}). Again in order to simplify the kinetic mechanism the two above processes can be expressed as follows:

where $k_4 = k_{4a} + k_{4b}$

The long-lived species may undergo transition to a more reactive species or may react directly to form various photodecomposed products. The kinetic mechanisms are simplified at this point to include all possible reactions with the triplet state in one rate constant, k_5 ,

The addition of quencher, Q , reduces the rate of decomposition of riboflavin by affecting the singlet and triplet excited states. It

Figure 8—The effect of pH on the quantum efficiency of riboflavin in the presence and absence of phenol. Key: A = riboflavin only (2.5×10^{-5} M); B = riboflavin with phenol (5.0×10^{-4} M).

will probably quench the fluorescence and phosphorescence of the riboflavin and the excited species may fall to the ground state. During these processes there might exist a direct transfer of the excitation energy from the riboflavin to the quencher with the resulting formation of an excited complex. These new species may then dissociate to riboflavin and the excited quencher. The conjugative and inductive effects of substituents of a quencher (phenol) might show an influence on the stability of the excited complex. The excited quencher may finally be decomposed. The photosensitization of resorcinol in the presence of riboflavin can be explained by this mechanism.

If the excited complex is assumed to be short-lived the overall reactions can be simplified as follows:

Using steady state assumptions regarding the transient species Rf^* and Rf' , the overall rate of photodecomposition of riboflavin can be expressed as follows:

$$\frac{d(\text{Rf})}{dt} = \frac{-k_1 k_3 k_5 (I)}{[k_2 + k_3 + k_6(Q)][k_4 + k_5 + k_7(Q)]} \quad (\text{Eq. 8})$$

where I = intensity of irradiating light.

The quantum efficiency of the reaction, ϕ , is equal to the overall rate divided by the initial rate. Therefore, the quantum efficiency can be expressed in terms of the rate constants:

$$\phi = \frac{k_3 k_5}{[k_2 + k_3 + k_6(Q)][k_4 + k_5 + k_7(Q)]} \quad (\text{Eq. 9})$$

This equation indicates that the quantum efficiency of riboflavin is proportional to k_3 and k_5 , i.e., the mechanism of the photodecomposition of riboflavin involves mainly the long-lived (triplet) state. This equation also expresses the quantum efficiency of riboflavin to be inversely proportional to the concentration of quencher. This relationship is well demonstrated experimentally in Fig. 4.

N-Aralkyl-piperidyl Carbanilates as Hypocholesteremic Agents

DARRELL E. O'BRIEN* and WILLIAM J. ROST

Abstract □ A number of *N*-aralkyl-*N*-methylaminoethyl carbanilates have been described in the literature as possessing hypocholesteremic activity. This series of compounds now has been extended to include 12 new *o*-[1-(substituted benzyl)-4-piperidyl]-*N*-(substituted phenyl) urethans and six new *o*-[1-(substituted benzyl)-4-piperidylideneimino]-*N*-(substituted phenyl) urethans. Two new derivatives of *N*′-[1-(substituted benzyl)-4-piperidyl]-*N*′-(*p*-chlorophenyl)urea have been prepared. Eleven intermediate piperidine derivatives, that have not been previously described in the literature, have been prepared and characterized. Fifteen of these new compounds have been studied for their ability to inhibit the incorporation of mevalonate-2-¹⁴C into cholesterol by homogenates of rat liver. Six of the compounds exhibited greater than 50% inhibition when tested at a concentration of 2×10^{-6} M. Appreciable incorporation of radioactivity into 7-dehydrocholesterol was observed with these six compounds. No significant reduction in serum cholesterol levels could be found in rats dosed at a level of 40 mg./kg. of body weight over a period of 7 days.

Keyphrases □ *N*-Aralkyl-piperidyl carbanilates, ureas—synthesis □ *N*-Aralkyl-piperidylideneimino urethans—synthesis □ Mevalonate-2-¹⁴C incorporation—cholesterol □ Hypocholesteremic activity—*N*-aralkyl-piperidyl carbanilates

N-Aralkyl-*N*-methylaminoethyl carbanilates have been reported to possess hypocholesteremic activity (1). The potential value of compounds possessing this pharmacological activity prompted the study of this type of compound in greater detail (see Structure I).

Structure I

The benzyl, phenethyl, and phenpropylaminoalkyl carbanilates all showed significant activity. Other variations of the aralkyl group studied were detrimental to the hypocholesteremic activity. Increasing ester functions as in compounds of the dicarbanilate type did not yield useful agents. The analogous urea derivatives did not exhibit patterns similar to the carbanilate series. However, substitution in the carbanilate ring markedly affected the activity of this series. *Meta* and *para* substitutions produced compounds with a greater activity than *ortho*-substituted products. To study the effects of greater bulk in the ester portion of these carbanilates, a series of *o*-(1-aralkyl-4-piperidyl)-*N*-(substituted phenyl) urethans and related compounds have been prepared. The synthesis of compounds related to Classes I, II, and III would provide new structural modifications of this type of hypocholesteremic agent.

The various derivatives of piperidine could be studied in order to ascertain if the basic amino function of the parent compounds could be incorporated into a cyclic structure. By studying compounds of Class I, one would be able to obtain more information on the effects brought about by substitutions on the aralkyl moiety

Classes of Compounds

and the effects brought about by changing the parent compounds' primary carbinol function to a secondary carbinol function.

The compounds of Class II are the corresponding urea derivatives. The compounds of Class III are the urethane derivatives of the oximes of 1-(substituted benzyl)-4-piperidones. The pharmacological evaluation of these compounds would provide new information concerning the structure-activity relationships of this new class of hypocholesteremic agents.

Examples of the piperidine starting materials appear in the literature (2, 3). These known synthetic procedures were expanded where necessary to yield the required starting materials. Reaction of these materials with the appropriate isocyanate yielded the desired products.

It had been shown earlier that the *m*- and *p*-methyl and *m*- and *p*-chloro carbanilates were among the most active in the series. For this reason, these carbanilates of *N*-benzyl, *N*-*p*-chlorobenzyl, and *N*-*p*-methylbenzyl piperidinols were prepared. The *p*-chlorocarbanilates of *N*-benzyl and *N*-*p*-methylbenzyl piperidylamines were also synthesized. The *p*-methyl- and *p*-chlorocarbanilates of the oximes of the *N*-benzyl, *N*-*p*-methylbenzyl, and *N*-*p*-chlorobenzyl piperidones have also been synthesized.

See Tables I, II, and III for the specific compounds prepared.

EXPERIMENTAL

Chemical—Preparation of 1-Benzyl Piperidones—These compounds were prepared as described in the literature by Thayer and McElvain (2).

Preparation of 1-Benzyl-4-piperidinols—1-Benzyl-4-piperidinols were prepared by the reduction of 1-benzyl-4-piperidones with diisobutyl aluminum hydride according to the method of Miller *et al.* (4).

Preparation of 1-Benzyl-4-piperidone Oximes—These compounds were prepared from the corresponding 1-benzyl-4-piperidones and

hydroxylamine as described in the literature by Brookes *et al.* (3).

Preparation of *o*-[1-(Substituted benzyl)-4-piperidyl]-*N*-(substituted phenyl) Urethans—The compounds listed in Table I were prepared by reacting 0.02 mole of the appropriate alcohol with 0.022 mole of the isocyanate in 60 ml. of dry toluene at reflux temperature for 2 hr. On cooling, a white precipitate formed which was crystallized from toluene, ethanol, or hexane.

Preparation of *o*-(1-Substituted benzyl-4-piperidylideneimino)-*N*-(substituted phenyl) Urethans—A solution of the appropriate oxime (0.02 mole) and isocyanate (0.022 mole) in 50 ml. of anhydrous toluene was refluxed for 2 hr. At the end of this time, the clear yellow solution was allowed to cool slowly. The white crystalline product which deposited from the cooled solution was filtered, washed with toluene, and air dried. The product was recrystallized from toluene.

Preparation of 4-Amino-1-benzyl Piperidines—These compounds

were prepared from the corresponding oximes by sodium metal reduction as described in the literature by Brookes *et al.* (3).

Preparation of *N*¹-[1-(Substituted benzyl)-4-piperidyl]-*N*²-(substituted phenyl) Ureas—A solution of 4-amino-1-substituted benzyl piperidine dihydrochloride monohydrate (0.025 mole) in 50 ml. of water was treated with anhydrous potassium carbonate until pH 8–9 was obtained. The mixture was extracted three times with ether (25 ml.), and the combined ethereal extracts were washed two times with water (25 ml.). The ether solution was dried over anhydrous sodium sulfate and evaporated to dryness. The residue was dissolved in 100 ml. of hot anhydrous toluene, and this solution was evaporated to 50 ml. The isocyanate (0.0275 mole) was added to the hot toluene solution, and the resultant solution was refluxed for 2 hr. At the end of this time, the light yellow solution was allowed to cool slowly. The white crystalline product which deposited from the cooled solution was separated by filtration, washed with

cold toluene, and air dried. The product was recrystallized from aqueous ethanol.

Pharmacological Evaluation—A number of these compounds have been evaluated for their ability to inhibit the biosynthesis of cholesterol.¹ The compounds have been evaluated by *in vitro* and *in vivo* procedures.

DISCUSSION

The hypocholesteremic activity of *N*-aralkyl-piperidyl carbanilates has been demonstrated in certain cases. Six compounds exhibited greater than 50% inhibition when tested at a concentration of 2×10^{-6} M. These compounds were: *o*-(1-benzyl-4-piperidyl)-*N*-(*p*-chlorophenyl) urethan I, *o*-[1-(*p*-methylbenzyl)-4-piperidyl]-*N*-(*p*-chlorophenyl) urethan V, *o*-[1-(*p*-methylbenzyl)-4-piperidyl]-*N*-(*p*-tolyl) urethan VI, *o*-[1-(*p*-methylbenzyl)-4-piperidyl]-*N*-(*m*-chlorophenyl) urethan VII, *o*-[1-(*p*-methylbenzyl)-4-piperidyl]-*N*-(*m*-

tolyl) urethan VIII, and *N*-[1-(*p*-methylbenzyl)-4-piperidyl]-*N*-(*p*-chlorophenyl)urea XIV. With each of these compounds there is appreciable incorporation of radioactivity in 7-dehydrocholesterol. These compounds have also been evaluated (McNeil Laboratories) for their hypocholesteremic activity in rats. In rats receiving 40 mg./kg. of body weight for a 7-day period, it was found there was no significant reduction in serum cholesterol levels.

Some activity was seen in the urea series, but no appreciable hypocholesteremic activity was found among the piperidylideneimino urethan derivatives.

The hypocholesteremic activity of the *N*-aralkyl-piperidyl carbanilates was not superior to that activity found for the *N*-aralkyl-aminoethyl carbanilates. Hence, it was concluded that there was no advantage in the cyclic series of carbanilates.

In the previously reported series, substitution in the aralkyl group did not produce hypocholesteremic compounds. The *N*-*o*-chlorobenzylaminoethyl carbanilates had an unfavorable effect on cholesterol levels. However, in the present series, substitution in the aralkyl group was advantageous in certain cases. The *N*-*p*-methylbenzyl piperidyl carbanilates were among the most active in inhibiting cholesterol synthesis *in vitro*. This fact points out the need for further investigation of various substitutions on the *N*-benzyl group in this hypocholesteremic series.

Blood Levels of Chlorphentermine in Man

HUNG WON JUN and EDWARD J. TRIGGS

Abstract □ Blood level determinations of chlorphentermine (*p*-chloro- α,α -dimethylphenethylamine) in man following oral administration of the drug in solution, as a prolonged-release formulation, and as an intravenous injection have been carried out by gas-liquid chromatography (GLC). The drug had a long apparent elimination half-life in the body, and the therapeutic need for a prolonged-release formulation of a drug of this type therefore may be doubtful. The significance of blood level studies in evaluating therapeutic dosage levels was emphasized with respect to dosage form evaluation and pharmacokinetics, even though such studies may not represent pharmacological efficacy in cases of extensive drug localization.

Keyphrases □ Chlorphentermine blood levels—determination □ Pharmacokinetic parameters—chlorphentermine distribution, elimination □ Half-life, apparent—chlorphentermine □ GLC—analysis

Urinary excretion studies of amphetamine analogs have been carried out by a number of workers as a method for evaluating biopharmaceutical drug parameters in man (1, 2). This technique, however, is not completely satisfactory as a number of assumptions are implicit in the method (3, 4). To overcome some of these shortcomings, blood level studies have been developed for a number of these compounds (5, 6). Such studies require the use of specific and sensitive analytical procedures since these drugs are extensively concentrated extravascularly in the body (7). Both the use of radioisotopically labeled drugs (8) and electron-capture GLC (9) have been found satisfactory in such analysis.

A method to determine chlorphentermine blood levels in man was developed using flame ionization GLC, and a study made of the drug following oral administration of solution and prolonged-release formulations together with intravenous administration.

EXPERIMENTAL

Extraction Procedure and Analytical Method—The extraction procedure from blood was based on that used by Reynolds and Beckett (10) for a series of local anesthetics. A 3–5-ml. blood sample was diluted with an equal volume of water in a 15-ml. glass centrifuge tube, and 1 ml. of 20% w/v NaOH was added. Four milliliters of redistilled reagent grade diethyl ether was then added. The tube was stoppered tightly and shaken for 10 min., followed by centrifugation at 2000 r.p.m. for 5 min. The upper ethereal layer was transferred to a second centrifuge tube, and the procedure was repeated for two further ether extractions. The combined ethereal extracts were shaken twice for 10 min with 3 ml. 0.1 *N* HCl. The aqueous layer containing the extracted drug was transferred to a third centrifuge tube and adjusted to approximately pH 11 with 20% w/v NaOH (about 1 ml.) and extracted 3 times with 3 ml. diethyl ether as for blood. The ethereal layers were transferred to a 12-ml. glass sedimentation tube containing 1 ml. of a 2 mcg./ml. solution of azobenzene in diethyl ether (internal marker).

The sedimentation tube was placed in a water bath at 40° and the contents evaporated to near dryness. The tube was then stoppered and placed in an ice bath to produce a final volume of about 5 μ l. A 2–3- μ l. sample of this concentrate was then injected onto the gas chromatographic column.

The apparatus and conditions for GLC were as reported by Jun and Triggs (11) with the following modifications: (a) the gas chro-

matographic column was packed with 1% silicon gum rubber¹ on 80–100-mesh general-purpose solid support², and (b) helium flow rate 40 ml./min.

Blood Level Studies—Oral Administration—Chlorphentermine hydrochloride was administered in 20 ml. aqueous solution as a 100-mg. dose (5 mg. HCl/ml.) to four healthy male subjects (aged 25–30 years), approximately 30 min. after a light breakfast of coffee and toast. Blood samples (7 ml.) were taken intravenously using Vacutainer tubes³ at 30-min. intervals for 3 hr. and then at 7, 11, 13, 25, 35, and 48 hr. after drug administration. Urine samples were also collected irregularly over the 48-hr. time period, and in some cases for a further 8 days.

The drug was also administered as a 78-mg. dose in the form of prolonged-release Preparation A⁴ to three of the four subjects who had received the drug in solution. Blood samples were taken as previously at 60-min. intervals for 4 hr.; 120-min. intervals for a further 8 hr.; and at 24, 28, 32, 36, and 48 hr. after drug administration. Urine samples were taken as previously described.

Intravenous Administration—Chlorphentermine hydrochloride injections were prepared in the laboratory and sterilized by passing the solution through a bacterial filter⁵ under aseptic conditions followed by autoclaving. The solution for injection contained 25 mg./ml. of the drug as the hydrochloride salt. The ampuls were tested for sterility⁶ and for drug content by GLC.

The drug was infused intravenously over a 2-min. period as a 50-mg. dose to two of the four subjects. Blood samples were taken at 2, 5, 10, 20, 40, 60, and 120 min. and at 4, 7, 10, 24, 36, and 48 hr. after drug administration. Urine samples were taken as previously described.

RESULTS

Extraction Procedure and Analytical Method—Figure 1 shows a typical chromatogram of a blood extract containing chlorphentermine. Good symmetrical peaks were obtained for both chlorphentermine and the internal marker, azobenzene. Analysis of blank samples of blood from the subjects used in the studies showed no interfering peaks with the same retention times as chlorphentermine or azobenzene.

Figure 2 illustrates a calibration curve obtained for chlorphentermine in blood; the ratio peak height of chlorphentermine to peak height of azobenzene was plotted against the concentration of chlorphentermine per 5 ml. of blood. The calibration curve was a straight line passing through the origin.

Ten duplicate analyses of a blood sample containing 0.5 mcg. chlorphentermine/5 ml. were performed, and the results showed a standard deviation of $\pm 4.92\%$.

The percentage recovery of chlorphentermine from blood was found to be $95 \pm 5\%$.

Blood Level Studies—Oral Administration—Average blood levels for chlorphentermine following oral administration of the 100-mg. solution dose to four subjects are shown in Fig. 3. The pharmacokinetic parameters, apparent elimination half-life, apparent volume of distribution, and area under the blood level curve were estimated and appear together with the cumulative urine data in Table I.

Subjects experienced no stimulant effect from the drug at this dosage level. The only effects noticed were pupil dilation and marked anorexia.

Average blood levels for chlorphentermine following oral administration of the 78-mg. prolonged-release formulation to three subjects are shown in Fig. 4. Areas under the blood level curves and urine data are shown in Table I. No subjective effects were noted.

Figure 2—Calibration curve for chlorphentermine in blood.

Figure 3—Average blood level-time curves for chlorphentermine following drug administration in solution (100 mg.) and intravenous injection (50 mg.). Key: ○, solution; and ●, intravenous injection.

Intravenous Administration—Average blood levels of chlorphentermine following intravenous administration of the drug to two subjects as a 50-mg. dose are shown in Fig. 3. The pharmacokinetic parameters and urine data appear in Table I.

Effects noted were lightheadedness and marked anorexia.

DISCUSSION

In most chromatograms the drug peak occurred on the solvent slope at the low attentuations used in these studies; however, reasonably accurate peak height measurements could be made as indicated by the size of the standard deviation. Drug concentrations as low as 125 ng./5 ml. of blood could be detected. The average blood levels for chlorphentermine (see Fig. 3) were well within the range of sensitivity of the method.

Peak blood levels for chlorphentermine in all subjects occurred at 1.5–2.5 hr. following oral administration of the drug in solution, and blood levels after the peak showed a slow exponential decline. The apparent elimination half-life for the drug ranged from 35 to 45 hr. (average 41 hr.) and was in close agreement with that obtained from predicted blood levels determined by analog computation (3). The apparent volume of distribution (average 213 l.), together with the long apparent elimination half-life, suggested extensive tissue

Figure 4—Average blood level-time curve for chlorphentermine following drug administration as prolonged-release formulation A (78 mg.).

distribution of the drug. These findings suggested that the drug may be localized to a large extent in the body. Previous reports (12, 13) have shown chlorphentermine to be localized in various body organs of rats and mice, notably brain and lung tissue.

Peak blood levels for chlorphentermine occurred at 6–8 hr. following oral administration of prolonged-release Preparation A, suggesting delayed release and subsequent slow absorption of the drug. The areas under the blood level curves were compared following intravenous and prolonged-release drug administrations, and an average of 62% (maximum 87%) of the drug was found to be available from the prolonged-release dosage form. However, it is possible that this average result may be an underestimate since comparisons were made only over the 48-hr. time period and ideally should be compared from zero to infinite time (22). Subject variation, which did occur (see Table I), probably also contributed to the spread of the value of the availability term.

Urinary excretion studies of chlorphentermine in this and previous studies (3) suggested almost complete drug availability from this prolonged-release preparation. Thus, the determination of drug availability from urinary excretion studies may lead to a discrepancy as the assumption is made that urine drug levels reflect tissue levels of the drug which might not be the case where some degree of localization occurs in the body.

The observations that the apparent elimination half-life of the drug was, on the average, in excess of 40 hr. and that the cumulative amount of drug in the urine in 48 hr. was less than 25% of the administered dose suggested doubts as to whether a prolonged-release drug formulation was indeed clinically necessary. It could, however, be argued that tissue levels resulting from administration of a prolonged-release formulation would perhaps follow a more clinically acceptable pattern than those levels following administration of the drug in solution. This possibility and the determination of pharmacokinetic data are the subject of further study. It has been shown previously that this particular prolonged-release formulation gives a good *in vivo/in vitro* correlation of drug availability (3).

A dose of 50 mg. of drug was chosen for the intravenous drug administration studies since it was felt that there would be less subjective effects at this dosage level. The initial phase of the blood level curve following intravenous drug administration was indicative of the extensive extravascular distribution of the drug (see Fig. 3). However, it was not possible with the blood sampling times used to extrapolate accurately this initial drug distribution phase to time zero. Reference to the area under the blood level curves (see Table I) following oral and intravenous drug administration showed that the drug was completely available when administered in solution. This confirmed results in an earlier study in which the cumulative amount of drug excreted in acid pH controlled urine over an extended period of time following drug administration in solution was about 90% (14). Also, previous reports have shown the drug to be almost completely excreted unchanged (15, 16).

It is difficult to determine the required therapeutic dose levels of a drug which is largely localized in the tissues by means of blood level studies. Ideally the concentration of drug at its site of action should be measured or a pharmacological response of the drug monitored. However, blood level studies are of importance as they enable the

determination of drug pharmacokinetic parameters (17) and comparison between performance of different dosage forms to be made (18, 19).

SUMMARY

1. Blood level determinations of chlorphentermine in man following administration of the drug in solution, prolonged-release formulation, and as an intravenous injection have been carried out by GLC.

2. The apparent elimination half-life of the drug in man was on the average 41 hr.

3. Comparison of areas under the blood level-time curves for intravenous and oral solution drug administration indicated complete availability of the drug from solution. However, the area under the curve resulting from administration of the prolonged-release formulation was lower possibly due to the limited experimental time period and subject variation.

4. The shape of the blood level-time curves suggested that the drug undergoes some degree of body localization.

5. Therapeutically, prolonged-release formulations of chlorphentermine may be doubtful.

Pharmacokinetic Profile of Coumermycin A₁

STANLEY A. KAPLAN

Abstract □ The pharmacokinetic profile of coumermycin A₁ has been determined in man following intravenous and oral administration. The antibiotic is eliminated slowly from the bloodstream and appears to be highly biotransformed. The plasma level *versus* time curve after intravenous injection is consistent with a two-compartment open system containing a primary compartment with a volume equivalent to the volume of plasma water. The design of a pharmacokinetic model is discussed.

Keyphrases □ Coumermycin A₁—pharmacokinetic profile □ Absorption, elimination—coumermycin A₁ □ Model, two-compartment open—coumermycin A₁ □ Kinetic equations—coumermycin A₁ absorption, elimination

Coumermycin A₁ is an antibiotic isolated from *Streptomyces hazeliensis* var. *hazeliensis* nov. sp. which exhibits antistaphylococcal activity *in vitro* and *in vivo* (1). The compound, a monosodium salt, has a molecular weight of 1132. Coumermycin A₁ is a bis-hydroxy coumarin with two weakly acidic groups which are widely separated spatially in the molecule and therefore ionize simultaneously with an approximate pK_a of 6. The three pyrrole groups are weakly acidic, pK_a > 11, and may decrease the solubility of the compound due to hydrogen bonding. The compound is only very slightly soluble in water at 25°. The structure is given as I (2):

The pharmacokinetic profile of coumermycin A₁ was determined in four human subjects based on the serum level data obtained from the report of a clinical study on file (3, 4).

EXPERIMENTAL

Protocol—Four healthy human adults fasted overnight, received single intravenous and oral doses of coumermycin A₁ at the Special Treatment Unit of Martland Hospital. Subjects A and B each received single 50-mg. doses intravenously and orally, 3 weeks apart. Subjects C and D each received single 100-mg. doses intravenously and orally, 2 weeks apart. The drug was administered in the dosage forms presently used in clinical trials. Blood and urine specimens were collected periodically and the serum separated and frozen for subsequent analysis.

Microbiological Assay—Coumermycin A₁ was analyzed by the cup plate assay employing *Staphylococcus aureus* HLR No. 82. The sensitivity of the method is 0.08 mcg./ml. of biological fluid (4).

RESULTS AND DISCUSSION

The serum level data following both intravenous and oral administration of the drug are presented in Figs. 1–4. Following the intravenous injection of coumermycin A₁, a biexponential serum level curve is obtained with all four subjects. The consideration of the disposition of coumermycin A₁ in terms of a two-compartment open system model is therefore a minimal requirement in order to describe adequately the distribution of the drug into the body. The

Pharmacokinetic Profile of Coumermycin A₁

STANLEY A. KAPLAN

Abstract □ The pharmacokinetic profile of coumermycin A₁ has been determined in man following intravenous and oral administration. The antibiotic is eliminated slowly from the bloodstream and appears to be highly biotransformed. The plasma level *versus* time curve after intravenous injection is consistent with a two-compartment open system containing a primary compartment with a volume equivalent to the volume of plasma water. The design of a pharmacokinetic model is discussed.

Keyphrases □ Coumermycin A₁—pharmacokinetic profile □ Absorption, elimination—coumermycin A₁ □ Model, two-compartment open—coumermycin A₁ □ Kinetic equations—coumermycin A₁ absorption, elimination

Coumermycin A₁ is an antibiotic isolated from *Streptomyces hazeliensis* var. *hazeliensis* nov. sp. which exhibits antistaphylococcal activity *in vitro* and *in vivo* (1). The compound, a monosodium salt, has a molecular weight of 1132. Coumermycin A₁ is a bis-hydroxy coumarin with two weakly acidic groups which are widely separated spatially in the molecule and therefore ionize simultaneously with an approximate pK_a of 6. The three pyrrole groups are weakly acidic, pK_a > 11, and may decrease the solubility of the compound due to hydrogen bonding. The compound is only very slightly soluble in water at 25°. The structure is given as I (2):

I

The pharmacokinetic profile of coumermycin A₁ was determined in four human subjects based on the serum level data obtained from the report of a clinical study on file (3, 4).

EXPERIMENTAL

Protocol—Four healthy human adults fasted overnight, received single intravenous and oral doses of coumermycin A₁ at the Special Treatment Unit of Martland Hospital. Subjects A and B each received single 50-mg. doses intravenously and orally, 3 weeks apart. Subjects C and D each received single 100-mg. doses intravenously and orally, 2 weeks apart. The drug was administered in the dosage forms presently used in clinical trials. Blood and urine specimens were collected periodically and the serum separated and frozen for subsequent analysis.

Microbiological Assay—Coumermycin A₁ was analyzed by the cup plate assay employing *Staphylococcus aureus* HLR No. 82. The sensitivity of the method is 0.08 mcg./ml. of biological fluid (4).

RESULTS AND DISCUSSION

The serum level data following both intravenous and oral administration of the drug are presented in Figs. 1–4. Following the intravenous injection of coumermycin A₁, a biexponential serum level curve is obtained with all four subjects. The consideration of the disposition of coumermycin A₁ in terms of a two-compartment open system model is therefore a minimal requirement in order to describe adequately the distribution of the drug into the body. The

Figure 1—Coumermycin A_1 serum levels in Subject A following the i.v. and oral administration of a single 50-mg. dose. Key: ●, i.v. (data point); X---, oral (data point); and —, i.v. (calculated curve).

Figure 2—Coumermycin A_1 serum levels in Subject B following the i.v. and oral administration of a single 50-mg. dose. Key: ●, i.v. (data point); X---, oral (data point); and —, i.v. (calculated curve).

basic equations of the two-compartment open system model have been described by Riegelman *et al.* (5).

Solution of the differential equations resulting from a two-compartment open system model yields the following integrated solution describing the blood level-time curve after a single intravenous injection:

$$C_p = Ae^{-\alpha t} + Be^{-\beta t}$$

where C_p is the concentration of the drug in the plasma, A and B are the zero-hour ordinate axis intercepts, and α and β are both hybrid rate constants reflecting all the individual rate processes. The term $-\beta/2.303$ is the slope of the linear portion of the curve and B is its extrapolated zero-hour intercept. Resolving the curve into its two components by the method of residuals yields a second linear segment with a slope of $-\alpha/2.303$ and an extrapolated zero-hour intercept of A .

The disposition data of coumermycin A_1 were evaluated in terms of the two-compartment open system model as described by Riegelman *et al.* (5) Model I, as shown below:

where k_{12} and k_{21} are the first-order rate constants of distribution, and k_{13} is the sum of the simultaneous processes of biotransformation and excretion, all assumed to be first-order processes. The constants, A , B , α , and β , were obtained graphically. They were then used with the appropriate equations to evaluate the rate constants of the two-compartment open model shown above. In addition, the volume of the central compartment (V_p) was determined and found to range in the four subjects studied from 2.6–3.5 l. It is interesting to note that this volume corresponds almost exactly with the volume of the plasma water.

Usually when a single dose of a drug of small molecular size is injected intravenously the blood plasma does not behave as a discernible compartment. Mixing in the plasma is not instantaneous since a few recirculations of blood may be required before mixing is complete. Moreover with small molecules, filtration and diffusion out of the capillary beds is extremely rapid so that by the time the

drug is uniformly distributed in the plasma, the drug has already penetrated into a much larger volume. It would be this larger volume, which includes the blood plasma, that constitutes the apparent initial volume of distribution for small drug molecules.

In contrast, coumermycin A_1 is a rather large molecule with a molecular weight of 1132 and is highly bound to plasma albumin (3). In cases where a large molecule is administered, and/or if the molecule is firmly bound, one may be able to identify a separate plasma compartment by analyzing the early part of the curve of serum level *versus* time. In fact, the V_p values of coumermycin A_1 in the four subjects studied bear this out in that the V_p range of 2.6–3.5 l. corresponds directly to the plasma water compartment *per se*. Therefore, the usual concept of a central compartment as defined by Riegelman (5) may be inappropriate for the disposition of coumermycin A_1 . In the model for the disposition of coumermycin A_1 the first compartment apparently reflects solely the plasma water, while the second compartment comprises the remaining body distribution space. It is interesting to note that only one other report (6) was found with an example of a defined plasma water compartment, and this too was for a highly bound drug.

In designing a model for the disposition of coumermycin A_1 the following additional factors should be considered. The drug is not eliminated from the central or plasma compartment inasmuch as intact drug is not excreted, and biotransformation can be assumed not to occur in the plasma since the drug is not hydrolyzed or de-

Figure 3—Coumermycin A_1 serum levels in Subject C following the i.v. and oral administration of a single 100-mg. dose. Key: ●, i.v. (data points); X---, oral (data points); and —, i.v. (calculated curve).

graded in the plasma. Therefore biotransformation is occurring elsewhere in the body.

The above factors indicate that the appropriate model for the disposition of coumermycin A₁ may then be as follows (Model II):

As with the previously described model the concentration of drug in the plasma, C_p , as a function of time is given by the equation:

$$C_p = Ae^{-\alpha t} + Be^{-\beta t}$$

α and β are both hybrid rate constants reflecting all the individual rate processes, while k_{12} , k_{21} , and k_{23} are individual rate constants calculable from this equation, as described in Appendix I.

By assigning k_{23} as the elimination rate constant in Model II we make the assumption that Compartment 2 is homogeneous, i.e., the total amount of drug in the compartment is immediately accessible to the elimination mechanism. This assumption would be meaningful if the drug were distributed essentially into the liver. However, Compartment 2 in Model II represents the entire available body space minus the plasma and until such time that tissue level studies are completed the utility of Model II is governed by the accuracy of this assumption.

The rate constants associated with each of the models were calculated and are presented in Table I. In evaluating both models in terms of the disposition of coumermycin A₁, it should be noted that the elimination rate constant, k_{13} as defined in Model I, may be an overestimate of the elimination rate since the model design indicates that only the relatively small fraction of drug in the plasma compartment, Compartment No. 1, is immediately available for elimination. On the other hand the elimination rate constant, k_{23} , in Model II may be an underestimate of the elimination rate for the author is assuming that Compartment 2 is homogeneous with all the drug contained therein immediately available for elimination. The elimination rate constant, therefore could be some value other than k_{13} or k_{23} . It should also be noted that since individual compartments are not detected, the corresponding rate constants into and out of compartments are not specific in that they do not apply to any real compartments.

Although the value of the elimination rate constant is interesting from a purely pharmacokinetic point of view it is not as meaningful physiologically, in terms of the disposition of the drug as is β , the apparent elimination rate of the drug. Therefore, the inability to define the value of the elimination rate constant at this time will not alter the validity of the pharmacokinetic profile of coumermycin A₁ presented herein. In fact, one might wonder in this particular case as to the relevance of the elimination rate constant in defining the physiological disposition of a drug.

Figure 4—Coumermycin A₁ serum levels in Subject D following the i.v. and oral administration of a single 100-mg. dose. Key: ●, i.v. (data points); ×, oral (data points); and —, i.v. (calculated curve).

Physiological Disposition Characteristics of Coumermycin A₁—In describing the physiological disposition of coumermycin A₁ many of the calculated parameters are independent of Models I and II. This model independence results from the fact that certain constants such as A , B , α , and β are the same for both models. It is these model independent parameters, therefore, which will now be discussed in terms of the pharmacokinetic profile of coumermycin A₁. They are presented in Table II. It should be noted that the simulated intravenous blood level curves in Figs. 1–4 obtained using A , B , α , and β coincide quite well with the experimentally determined data points.

Elimination Characteristics—The results in Table II indicate that coumermycin A₁ has a fast disposition rate constant, α , which ranged from 25.7–41.2%/hr., corresponding to a half-life of 2.7–1.7 hr. The slow disposition rate constant, β , derived from the slope of the linear segment of the serum level curve reflects the apparent elimination rate of the drug from the body. The slow disposition rate constant, β , ranged from 1.5–4.7%/hr., corresponding to a half-life of 46.3–14.8 hr.

It should be noted that in the four subjects studied there seems to be a trend toward a decreased elimination rate with increase of dose. However, there were too few subjects studied to make any definitive statement at this time. As seen in Table II, as the dose was increased the apparent half-life increased as follows:

Subject	Dose, mg./kg.	Half-Life of Elimination, hr.
B	0.61	14.8
A	0.78	20.6
C	1.02	28.6
D	1.85	46.3

This might be a result of saturation of plasma- or tissue-binding sites and/or saturation of the metabolizing enzymes.

Another parameter, the fraction of drug in the body in the central compartment (f_c) during the β -phase (7) was found to be very close when calculated with the elimination rate constant from either

of the models in that: Model I, $fc = \beta/k_{13}$ (7) or Model II, $fc = 1 - \beta/k_{23}$.

The values reported in Table II indicated that f_c ranged from 0.19–0.39 (Model I) and 0.11–0.28 (Model II).

Absorption Characteristics—Orally administered coumermycin A₁ resulted in clinically effective blood levels. Fourteen percent of the administered dose was absorbed in three of the subjects and 28% in the fourth.

The extent of absorption was determined by two different procedures. In one, the areas under the oral and intravenous serum level curves were compared to yield a measure of availability. This method would be model independent. In the other, the kinetic constants and volume of Compartment I, V_d , were used for the calculation of the percent absorbed by utilizing the equation presented by Loo *et al.* (8) for Model I, and by modifying the equation of Loo *et al.* (8) for Model II. The derivation of the modified equation is presented in *Appendix II*. The data in Table II indicate that the estimates of oral availability were practically the same when calculated with either of the models resulting in an additional model independent parameter.

The percent available drug absorbed with time has been calculated for each subject and is also reported in Table II. The mean values indicate that approximately 8% of the absorbed dose was absorbed in 1 hr., 28% in 2 hr., 53% in 3 hr. and 89% in 6 hr. In each case the serum level peaks following oral administration of the drug appear to plateau during the 3-6-hr. interval.

SUMMARY

The pharmacokinetic profile of coumermycin A₁ has been determined for four subjects following intravenous and oral administration of the drug. The apparent elimination rate from the bloodstream is slow with a half-life range of 15–46 hr. In addition, there appears to be a tendency toward a decrease in elimination rate with an increase in mg./kg. dose. The slow elimination may result in a potential for prolonged therapeutic effectiveness. The distribution characteristics are such that the drug is initially confined to the small plasma water compartment following intravenous injection. The drug appears to be highly biotransformed inasmuch as no intact drug is detectable in the urine. However, alternate routes of excretion remain to be explored.

Following the oral administration of coumermycin A₁, 14% of the administered dose was absorbed in three of the subjects and 28% was absorbed in the fourth, with a mean percent of absorbed dose

absorbed with time calculated to be 8% in 1 hr., 28% in 2 hr., 53% in 3 hr., and 89% in 6 hr.

The design of a pharmacokinetic model for coumestrol is discussed with emphasis on the meaning of the elimination rate constant, as defined by each of the models.

APPENDIX I: DETERMINATION OF KINETIC CONSTANTS

where the amount in Compartment 1 = X_p and the amount in Compartment 2 = X_t , and k_{12} , k_{21} , and k_{23} are first-order rate constants.

The differential equations for the model are:

$$\frac{dX_p}{dt} = -k_{12}X_p + k_{21}X_t \quad (\text{Eq. 1})$$

$$\frac{dX_t}{dt} = k_{12}X_p - (k_{21} + k_{23})X_t \quad (\text{Eq. 2})$$

if $X_p = X^0$ (administered dose) and $X_t = 0$ at time = 0, Eq. 1 and 2 can be solved by Laplace transforms so that

$$\frac{X_p}{X^0} = \left[\frac{k - \alpha}{\beta - \alpha} \right] e^{-\alpha t} + \left[\frac{k - \beta}{\alpha - \beta} \right] e^{-\beta t} \quad (\text{Eq. 3})$$

where

$$k = k_{21} + k_{23} \quad (\text{Eq. 4})$$

$$\alpha\beta = k_{12}k_{23} \quad (\text{Eq. 5})$$

$$(\alpha + \beta) = k_{12} + k_{21} + k_{23} \quad (\text{Eq. 6})$$

$$C_p = Ae^{-\alpha t} + Be^{-\beta t} \quad (\text{Eq. 7})$$

so that

$$A = \frac{C_p \circ (k - \alpha)}{\beta - \alpha} \quad (\text{Eq. 8})$$

and

$$B = \frac{C_p^{\circ}(k - \beta)}{\alpha - \beta} \quad (\text{Eq. 9})$$

where

$$C_n^{\circ} = A + B \quad (\text{Eq. 10})$$

Therefore, $k = \frac{A\beta + B\alpha}{A + B} = k_{21} + k_{23}$ (Eq. 11)

from Eq. 6, $k_{12} = \alpha + \beta - k = \alpha + \beta - \frac{A\beta + B\alpha}{A + B}$ (Eq. 12)

from Eq. 5, $k_{23} = \frac{\alpha \cdot \beta}{k_{12}}$ (Eq. 13)

and therefore from Eq. 6,

$$k_{21} = \alpha + \beta - k_{12} - k_{23} \quad (\text{Eq. 14})$$

APPENDIX II: INTRINSIC ABSORPTION RATE CALCULATION

where the mass balance equation indicates that the amount of drug absorbed at any time, in concentration units, is defined as:

$$\left(\frac{A}{V_p}\right)_{t_n} = (C_p)_{t_n} + (C_t)_{t_n} + (C_{me})_{t_n} \quad (\text{Eq. 1})$$

The concentration in Compartment 1 = C_p , and the concentration in Compartment 2 = C_t , and k_{12} , k_{21} and k_{23} are the first-order rate constants.

The differential equation to express the rate of change of the tissue compartment with time is

$$\frac{d(C_t)_{t_n}}{dt} = -k_{21}(C_t)_{t_n} + k_{12}(C_p)_{t_n} - k_{23}(C_t)_{t_n} \quad (\text{Eq. 2})$$

Since the blood level data between times t_{n-1} and t_n can be approximated by a straight line segment, we write

$$(C_p)_{t_n} = (C_p)_{t_{n-1}} + M\tau \quad (\text{Eq. 3})$$

where $\tau = t_n - t_{n-1}$; $\Delta C_p = (C_p)_{t_n} - (C_p)_{t_{n-1}}$ and $M = \Delta C_p / \tau$. If we take t_{n-1} as an initial time, the Eq. 2 can be written as

$$\frac{d(C_t)_{t_n}}{d\tau} = -k_{21}(C_t)_{t_n} + k_{12}[(C_p)_{t_{n-1}} + M\tau] - k_{23}(C_t)_{t_n} \quad (\text{Eq. 4})$$

Let $K = k_{21} + k_{23}$.

Equation 4 can be solved by Laplace transformation with initial conditions $C_t(0) = (C_t)_{t_{n-1}}$. Rewriting Eq. 4 as

$$\frac{d(C_t)_{t_n}}{dt} + K(C_t)_{t_n} = k_{12}[(C_p)_{t_{n-1}} + M\tau] \quad (\text{Eq. 5})$$

and taking the Laplace transform of both sides, we obtain

$$\begin{aligned} S(\bar{C}_t)_{t_n} - (C_t)_{t_{n-1}} + K(\bar{C}_t)_{t_n} &= k_{12} \left(\frac{(C_p)_{t_{n-1}}}{S} + \frac{M}{S^2} \right) \\ (S + K)(\bar{C}_t)_{t_n} &= (C_t)_{t_{n-1}} + k_{12} \left(\frac{(C_p)_{t_{n-1}}}{S} + \frac{M}{S^2} \right) \\ (\bar{C}_t)_{t_n} &= \frac{(C_t)_{t_{n-1}}}{(S + K)} + \frac{k_{12}(C_p)_{t_{n-1}}}{S(S + K)} + \frac{k_{12}M}{S^2(S + K)} \\ &= \frac{(C_t)_{t_{n-1}}}{(S + K)} + \frac{k_{12}(C_p)_{t_{n-1}}}{K} \left(\frac{1}{S} - \frac{1}{S + K} \right) \\ &\quad + k_{12}M \left(\frac{1/K}{S^2} - \frac{1/(K)^2}{S} + \frac{1/(K)^2}{(S + K)} \right) \quad (\text{Eq. 6}) \end{aligned}$$

taking inverse Laplace transforms on both sides of equation

$$\begin{aligned} (C_t)_{t_n} &= L^{-1}[(C_t)_{t_n}] \\ &= (C_t)_{t_{n-1}}e^{-K\tau} + \frac{k_{12}(C_p)_{t_{n-1}}}{K} (1 - e^{-K\tau}) \\ &\quad + \frac{k_{12}M}{(K)^2} [\tau(K) - 1 + e^{-K\tau}] \quad (\text{Eq. 7}) \end{aligned}$$

or

$$\begin{aligned} (C_t)_{t_n} &= (C_t)_{t_{n-1}}e^{-K\tau} + \frac{k_{12}(C_p)_{t_{n-1}}}{K} (1 - e^{-K\tau}) \\ &\quad + \frac{k_{12}M}{K^2} (K\tau + e^{-K\tau} - 1) \quad (\text{Eq. 8}) \end{aligned}$$

The third term of Eq. 8 can be expanded in terms of a two term Taylor series:

$$\begin{aligned} \frac{k_{12}}{K^2} \left(\frac{C_p}{\tau} \right) \left[1 - K\tau - \left(1 - K\tau + \frac{K^2\tau^2}{2} \right) \right] \\ = \frac{k_{12}}{K^2} \frac{\Delta C_p}{\tau} \frac{K^2\tau^2}{2} = -\frac{k_{12}\tau\Delta C_p}{2} \end{aligned}$$

Then Eq. 8 becomes

$$(C_t)_{t_n} = (C_t)_{t_{n-1}}e^{-K\tau} + \frac{k_{12}(C_p)_{t_{n-1}}}{K} (1 - e^{-K\tau}) + \frac{k_{12}\Delta C_p\tau}{2}$$

i.e.,

$$(C_t)_{t_n} = (C_t)_{t_{n-1}}e^{-K\tau} + \frac{k_{12}(C_p)_{t_{n-1}}}{K} (1 - e^{-K\tau}) + \frac{k_{12}\Delta C_p\tau}{2} \quad (\text{Eq. 9})$$

Using Eq. 9, we can calculate the amount metabolized C_{me} and excreted up to time t_n in concentration units:

$$(C_{me})_{t_n} = k_{23} \int_{t_0}^{t_n} (C_t)_{t_n} dt \quad (\text{Eq. 10})$$

Therefore, the amount of drug absorbed at any time in concentration units results when Eqs. 9 and 10 are substituted into Eq. 1.

$$\begin{aligned} \left(\frac{A}{V_p}\right)_{t_n} &= (C_p)_{t_n} + (C_t)_{t_n}e^{-(K\tau)} + \frac{k_{12}(C_p)_{t_{n-1}}}{K} (1 - e^{-K\tau}) \\ &\quad + \frac{k_{12}\Delta C_p\tau}{2} + k_{23} \int_{t_0}^{t_n} (C_t)_{t_n} dt \quad (\text{Eq. 11}) \end{aligned}$$

Eq. 11 has been programmed for computation on the GE 265 time sharing system. The slope of the percent remaining to be absorbed versus time plot provides the absorption rate constant of the drug.

Effect of Lipid Polarity and Cell Design on the *In Vitro* Transport of Salicylic Acid

MATTHEW A. AUGUSTINE and JAMES SWARBRICK

Abstract □ The transport kinetics of salicylic acid have been studied in a Schulman-type *in vitro* model cell containing two aqueous phases (*A* and *C*) separated by a third liquid lipid phase (*B*) simulating the biomembrane. Prime consideration was given to evaluating the effect of increasing the polarity of the lipid phase on the two forward rate constants, K_1 and K_2 . While K_1 ($A \rightarrow B$) always increased with increasing polarity of the lipid phase, K_2 ($B \rightarrow C$) was found to increase or decrease depending on the stirring conditions employed in the two aqueous phases. The surface-to-volume ratio of the immiscible phases was significant in determining the magnitude of the rate constant K_1 .

Keyphrases □ Salicylic acid—*in vitro* transport kinetics □ Lipid phase polarity effect—salicylic acid transport □ Surface-to-volume ratio, stirring—salicylic acid transport □ Schulman cell, evaluation —transport studies □ Partition coefficients, salicylic acid—oil-water phases

With model *in vitro* systems that employ liquid lipids to simulate the biomembrane, there is the possibility that drug concentration may build up in the lipid phase. Such an effect is in contrast to the *in vivo* situation and reduces the validity of the *in vitro* model.

The retention of drug in the lipid phase will be, in part, a function of the polarity of the lipid and this, in turn, will affect the rate constants which describe the transport of the drug through the model system. Such an effect was demonstrated by Khalil and Martin (1) who used the inverted Y-tube as an *in vitro* model. Using various single-component lipid materials as the "membrane" phase, these workers obtained forward and reverse rate constants for the transport of salicylic acid: (a) from an aqueous pH 2.0 phase to the lipid phase (K_1 and K_{-1} , respectively), and (b) from the lipid phase to a second aqueous phase buffered to pH 7.4 (K_2 and K_{-2} , respectively). It was observed, predictably, that as the polarity of the lipid phase, expressed in terms of the δ -value (2), increased, the forward rate constant K_1 increased while the forward rate constant K_2 decreased.

The *in vitro* model cell designed by Schulman (3) has been claimed to possess certain advantages over the inverted Y-tube (4). Thus, long-chain alcohols can be used as the lipid phase with less chance of emulsification; phospholipid material can also be placed at the oil-water interfaces which do not continuously expand and contract in area, as is the case with the inverted Y-tube. Accordingly, the Schulman-type cell was chosen for these *in vitro* transport studies.

As a preliminary study, the effect of polarity of the lipid phase on the transport kinetics of salicylic acid was investigated. The polarity of the oil phase was increased by the addition of isoamyl alcohol to cyclohexane, with the expectation of finding at least a qualitative correlation between these data and that of Khalil and Martin. The results obtained demonstrate, however, that the magnitude and rank order of the rate constants are

Figure 1—Schulman-type *in vitro* model cell. See text for explanation of symbols.

dependent to a significant degree on the design of the cell and the agitation conditions used.

EXPERIMENTAL

***In Vitro* Model Cells**—Three Schulman-type cells, designated I, II, and III, similar to that shown in Fig. 1 were used in these preliminary studies. These model cells, constructed of Plexiglas (I, II) or glass (III), physically simulate the two membrane interfaces found *in vivo*, one between the gastrointestinal fluid (*A*) and the membrane (*B*) and one between the membrane and blood plasma (*C*). Either gastric or intestinal absorption can be studied by choosing the appropriate pH conditions for Compartment *A*, while keeping the pH of Compartment *C* constant at 7.4.

The two aqueous compartments were stirred using Teflon-coated magnetic stirring bars, and the oil phase was stirred using an overhead constant-speed motor equipped with shaft and propeller (see Tables I and II). The cells were maintained at $25 \pm 0.1^\circ$ in all the studies performed.

The volumes of liquid used for each of the three phases in the various cells are shown in Tables I and II. Also included in these tables are the surface-to-volume ratios of the cells, which are based on the volume of either aqueous phase and the surface area in contact with the lipid phase, *B*, in the absence of any agitation. Only slight rippling of the interfaces was noted with the various agitation conditions employed.

Materials—Salicylic acid, cyclohexane, isoamyl alcohol, and the buffer ingredients were all reagent grade. Clark and Lubs buffer solutions at pH 2.0 and pH 7.4 were prepared and their pH values checked prior to use.¹

Procedure—In all studies, Compartment *A* was maintained at pH 2.0 while the receiving compartment, *C*, was buffered to pH 7.4.

The two aqueous phases were preequilibrated with respect to the lipid phase prior to the transport studies. At various time intervals following the addition of salicylic acid into Compartment A, samples were removed from the aqueous and lipid phases by pipet and assayed for salicylic acid by means of previously prepared calibration curves. In all studies, Beer's law was found to be obeyed over the concentration range examined. The volume of each of the sampled phases was kept constant by replacing a quantity of either buffer or oil equal to that removed for assay. Calculations were based on the percent of salicylic acid remaining in each of the phases with corrections made for the quantity of salicylic acid removed with each sample.

Analysis of Data—The kinetics governing *in vitro* drug transport in a three-phase system have been described elsewhere (1). The solution of the differential equations involved in a consecutive reversible first-order system requires the calculation of four rate constants. These are the two forward rate constants, K_1 and K_2 , which govern the transport of drug between Compartments A and B and B and C, respectively, and their corresponding reverse rate constants, K_{-1} and K_{-2} . To facilitate their determination, an analog computer² was employed whose output was displayed on an X-Y recorder. The analog program and the differential equations are shown in Fig. 2. The volume terms associated with the solution of these equations are absent since the volumes of all three phases were kept equal. Once goodness-of-fit of the experimental and theoretical curves was achieved with the analog computer, the resultant rate constants were then verified using a digital computer³ programmed for the integrated forms of the differential equations (5).

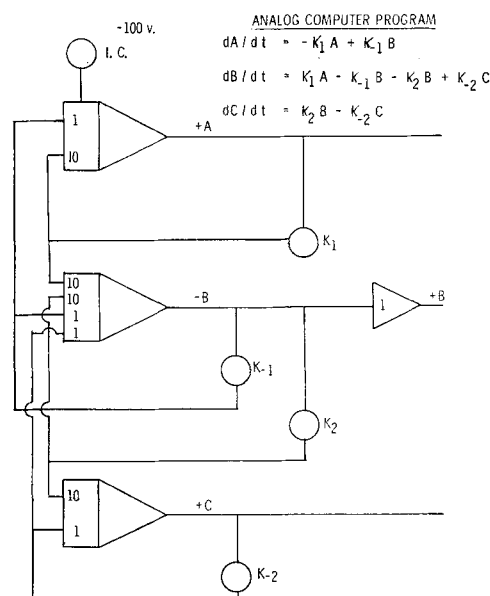

Solubility of Salicylic Acid—An excess of salicylic acid was placed in 100 ml. of each of the various lipid phases contained in 125-ml. ground-glass-stoppered flasks. The flasks were shaken in a constant-temperature shaker bath for 2 weeks at 25°. Filtered, diluted samples were assayed spectrophotometrically⁴ for salicylic acid, using previously determined Beer's law plots.

Determination of Partition Coefficients—Twenty milliliters of either pH 2.0 or pH 7.4 aqueous buffers containing a known amount of salicylic acid was shaken in a 60-ml. separator with an equal volume of the various lipid phases used in the transport studies.

The separators were placed in a constant-temperature bath at 25° and shaken manually until equilibrium was attained. Both phases were assayed spectrophotometrically for salicylic acid and the apparent partition coefficients calculated.

RESULTS AND DISCUSSION

The percents of salicylic acid in each of the three phases at various time intervals and isoamyl alcohol concentrations are shown in Figs. 3–5 for Cell I. The disappearance of salicylic acid from the compartment buffered at pH 2.0 is plotted against time in Fig. 3. As the polarity of the lipid phase is increased by the addition of isoamyl alcohol in cyclohexane, the rate of disappearance of salicylic acid increases. Consequently, the initial rate of appearance of

Figure 3—Rate of disappearance of salicylic acid from Compartment A, buffered at pH 2.0, to Compartment B, composed of increasing amounts of isoamyl alcohol in cyclohexane.

salicylic acid in the oil phase increases with increasing polarity of this phase (Fig. 4). However, while the time for the peak concentration of drug to appear in the oil phase was progressively reduced as this phase became more polar, the concentration of salicylic acid at the peak was not directly related to the polarity. The appearance of salicylic acid in the pH 7.4 buffer is shown in Fig. 5. As the polarity of the oil phase increases, so does the rate of appearance of salicylic acid into this phase.

In contrast to the results of Khalil and Martin (1), both forward rate constants, K_1 and K_2 , for salicylic acid in Cell I were found to increase as the polarity of the oil phase increased. These data are presented in Table I and Fig. 6. The rank order of the K_1 values obtained with Cell I was in agreement with those previously reported. However, the reverse was apparently true in the case of the K_2 values, which increased with increased polarity of the oil phase.

In an attempt to rationalize these results, the solubility of salicylic acid in each of the various lipid phases was determined to see if saturation of this phase was occurring. While it was found that the solubility of salicylic acid increased linearly with increasing concentrations of isoamyl alcohol in cyclohexane (Table I), the concentration of salicylic acid employed in the transport studies (3.63 mg./100 ml.) was far below that needed to saturate the oil phase.

Figure 4—Initial rate of appearance of salicylic acid in Compartment B as a function of the amount of isoamyl alcohol in cyclohexane.

Figure 5—Rate of appearance of salicylic acid in Compartment C, buffered at pH 7.4, as a function of the composition of the lipid phase.

The next parameter investigated was the equilibrium partitioning of salicylic acid between the two aqueous phases and the various oil phases. The apparent partition coefficients were calculated based on the concentration of drug in each of the two phases at equilibrium. The possibility of dimerization of salicylic acid in the oil phase was also investigated by using initial concentrations of 20, 40, and 50 mg. of salicylic acid per 20 ml. of buffer solution. However, the data presented in Table I did not indicate the presence of a dimer in the lipid phase. As would be expected, both partition coefficients vary in a manner that is proportional to the concentration of isoamyl alcohol in the lipid phase. The relatively high standard deviations obtained for the pH 7.4/oil systems are due to the very low concentrations of salicylic acid remaining in the oil phase at equilibrium.

Although the ratio of the partition coefficient (oil/pH 2.0) to K_1 does not remain constant as the concentration of isoamyl alcohol is increased, K_1 does increase with increasing partition coefficient, as would be expected.

Predictably, the apparent partition coefficients based on the concentration of salicylic acid in the pH 7.4 buffer over that in the various lipid phases (pH 7.4/oil) were found to decrease as the polarity of the lipid phase increased. However, when these apparent partition coefficients were compared to K_2 , the reverse of what would be expected, based on the partition data, occurred (Table I). Thus, the forward rate constant K_2 would be expected to decrease with increasing polarity of the lipid phase. As noted earlier, the values obtained for K_2 with Cell I increased with polarity.

Further transport studies were then carried out at 300 r.p.m. with 2.54-cm. (1-in.) magnetic stirring bars in the aqueous phases using two other model cells having surface-to-volume ratios different from that of Cell I (Tables I and II). Within any one cell, the rank order of

Figure 6—The effect of increasing lipid polarity of the oil phase on the two forward rate constants, K_1 and K_2 , for salicylic acid.

K_1 with increasing polarity of the lipid phase was not changed. However, the data demonstrate a relationship between the surface-to-volume ratio and K_1 . Thus, with one exception (Cell II, 10% isoamyl alcohol), the value of K_1 increased as did the surface-to-volume ratio for any one lipid phase employed. Under the same stirring conditions of the aqueous phases [namely, 300 r.p.m. with 2.54-cm. (1-in.) stirring bars] in any one cell, K_2 still showed increasing values with increasing lipid polarity. There was no rank order correlation between the value of K_2 for a particular lipid phase and the surface-to-volume ratio.

The effect of stirring conditions in the aqueous phases was then investigated. While keeping the surface-to-volume ratio constant at 0.148, the stirring conditions of the aqueous compartments were arbitrarily changed from 300 r.p.m. using 2.54-cm. (1-in.) oblong magnetic stirring bars to 400 r.p.m. using 1.27-cm. (0.5-in.) circular magnetic stirring bars. The lipid phase was stirred at the same rate of 60 r.p.m. The data, which were obtained using Cell II, are presented in Table II. It is readily apparent that the size and revolutions per minute of the stirrer did not change the order of the K_1 values, although the magnitude of this rate constant was affected. What is relevant is that, under the second set of stirring conditions, the order of K_2 now is reversed, with K_2 tending to decrease with increasing lipid polarity, as found by Khalil and Martin (1).

In light of these preliminary results, it would appear that the use of the Schulman model cell to correlate *in vitro* with *in vivo* absorption data could produce misleading results if factors such as the size and shape of the stirring bars and the rate of stirring in the various compartments are not closely monitored. The authors have also found further discrepancies between the Schulman cell and the inverted Y-tube apparatus. For example, benzene, when used as the

lipid phase by Khalil and Martin, appeared to be ideal, because there was negligible retention of salicylic acid in this phase over a 24-hr. period. However, when benzene was used as the lipid phase in Cell II, appreciable retention of salicylic acid by this phase was observed over the same time period.

Effect of pH of Precipitation on Antacid Properties of Hydrous Aluminum Oxide

STANLEY L. HEM*, EMANUEL J. RUSSO, SURENDRA M. BAHAL, and RALPH S. LEVI

Abstract □ The effect of the pH of precipitation on the physical and chemical properties of hydrous aluminum oxide prepared by the reaction of aluminum chloride and strong ammonia solution NF; aluminum sulfate USP, and strong ammonia solution NF; and aluminum chloride, sodium bicarbonate USP, and sodium carbonate USP, was studied. During aging, changes may occur in the hydrous aluminum oxide structure which result in a loss in acid reactivity. This loss followed apparent first-order kinetics. The rate of loss was directly dependent on the pH of precipitation and continued until a constant end-point was reached. The percentage of theoretical reactivity remaining at the end-point was inversely related to the pH of precipitation. X-ray diffraction showed no differences in form, either initially or during aging. Gel stability appears to depend on the presence of anions in the gel structure. The concentration of these anions is related to the pH of precipitation. Data are presented which demonstrate that a stable, completely acid-reactive gel would be obtained if 1 mole of a monovalent anion such as chloride or bicarbonate or 0.5 mole of a bivalent anion such as sulfate is incorporated in the gel structure per mole of aluminum.

Keyphrases □ Hydrous aluminum oxide—antacid properties, preparation □ pH precipitation effect—hydrous aluminum oxide, chemical and physical properties □ Gel stability—anion concentration data, acid reactivity kinetics □ X-ray diffraction—analysis

Alumina gel, which can be described chemically as hydrous aluminum oxide, is widely used in the management of peptic ulcer and gastric hyperacidity. Several

factors, such as the precipitation temperature (1, 2), the order of addition of the reactants (2), and the concentration of the reactants (2, 3), have been shown to affect the properties of the precipitated gel. Although previous authors (4–6) have suggested that the pH of precipitation influences the crystallinity of the precipitated gel, no workers have directly examined the effect of the pH of precipitation on the acid reactivity of the gel. Therefore, the purpose of the present study was to examine the effect of the pH of precipitation on the antacid properties of hydrous aluminum oxide prepared from several reactant systems.

EXPERIMENTAL

Materials—All chemicals used were either official or reagent grade.

Method of Preparation of Hydrous Aluminum Oxide—A series of hydrous aluminum oxides, to be referred to as chloride-containing gels, were prepared at 25° by the addition of a 13% solution of strong ammonia solution NF to an aqueous 8.5% aluminum chloride heptahydrate solution. The method of Papée *et al.* (4) and the conditions described by Lewis and Taylor (2) were followed to ensure reproducible precipitations. Sufficient ammonia solution was added to control the pH of precipitation. Alumina gels were precipitated at pH 4.8, 6.1, 7.7, and 9.2 and washed with deionized water until the concentration of the chloride ion in the filtrate, as determined by the Volhard method (7), was less than 0.1%. The

K_1 with increasing polarity of the lipid phase was not changed. However, the data demonstrate a relationship between the surface-to-volume ratio and K_1 . Thus, with one exception (Cell II, 10% isoamyl alcohol), the value of K_1 increased as did the surface-to-volume ratio for any one lipid phase employed. Under the same stirring conditions of the aqueous phases [namely, 300 r.p.m. with 2.54-cm. (1-in.) stirring bars] in any one cell, K_2 still showed increasing values with increasing lipid polarity. There was no rank order correlation between the value of K_2 for a particular lipid phase and the surface-to-volume ratio.

The effect of stirring conditions in the aqueous phases was then investigated. While keeping the surface-to-volume ratio constant at 0.148, the stirring conditions of the aqueous compartments were arbitrarily changed from 300 r.p.m. using 2.54-cm. (1-in.) oblong magnetic stirring bars to 400 r.p.m. using 1.27-cm. (0.5-in.) circular magnetic stirring bars. The lipid phase was stirred at the same rate of 60 r.p.m. The data, which were obtained using Cell II, are presented in Table II. It is readily apparent that the size and revolutions per minute of the stirrer did not change the order of the K_1 values, although the magnitude of this rate constant was affected. What is relevant is that, under the second set of stirring conditions, the order of K_2 now is reversed, with K_2 tending to decrease with increasing lipid polarity, as found by Khalil and Martin (1).

In light of these preliminary results, it would appear that the use of the Schulman model cell to correlate *in vitro* with *in vivo* absorption data could produce misleading results if factors such as the size and shape of the stirring bars and the rate of stirring in the various compartments are not closely monitored. The authors have also found further discrepancies between the Schulman cell and the inverted Y-tube apparatus. For example, benzene, when used as the

lipid phase by Khalil and Martin, appeared to be ideal, because there was negligible retention of salicylic acid in this phase over a 24-hr. period. However, when benzene was used as the lipid phase in Cell II, appreciable retention of salicylic acid by this phase was observed over the same time period.

Effect of pH of Precipitation on Antacid Properties of Hydrous Aluminum Oxide

STANLEY L. HEM*, EMANUEL J. RUSSO, SURENDRA M. BAHAL, and RALPH S. LEVI

Abstract □ The effect of the pH of precipitation on the physical and chemical properties of hydrous aluminum oxide prepared by the reaction of aluminum chloride and strong ammonia solution NF; aluminum sulfate USP, and strong ammonia solution NF; and aluminum chloride, sodium bicarbonate USP, and sodium carbonate USP, was studied. During aging, changes may occur in the hydrous aluminum oxide structure which result in a loss in acid reactivity. This loss followed apparent first-order kinetics. The rate of loss was directly dependent on the pH of precipitation and continued until a constant end-point was reached. The percentage of theoretical reactivity remaining at the end-point was inversely related to the pH of precipitation. X-ray diffraction showed no differences in form, either initially or during aging. Gel stability appears to depend on the presence of anions in the gel structure. The concentration of these anions is related to the pH of precipitation. Data are presented which demonstrate that a stable, completely acid-reactive gel would be obtained if 1 mole of a monovalent anion such as chloride or bicarbonate or 0.5 mole of a bivalent anion such as sulfate is incorporated in the gel structure per mole of aluminum.

Keyphrases □ Hydrous aluminum oxide—antacid properties, preparation □ pH precipitation effect—hydrous aluminum oxide, chemical and physical properties □ Gel stability—anion concentration data, acid reactivity kinetics □ X-ray diffraction—analysis

Alumina gel, which can be described chemically as hydrous aluminum oxide, is widely used in the management of peptic ulcer and gastric hyperacidity. Several

factors, such as the precipitation temperature (1, 2), the order of addition of the reactants (2), and the concentration of the reactants (2, 3), have been shown to affect the properties of the precipitated gel. Although previous authors (4–6) have suggested that the pH of precipitation influences the crystallinity of the precipitated gel, no workers have directly examined the effect of the pH of precipitation on the acid reactivity of the gel. Therefore, the purpose of the present study was to examine the effect of the pH of precipitation on the antacid properties of hydrous aluminum oxide prepared from several reactant systems.

EXPERIMENTAL

Materials—All chemicals used were either official or reagent grade.

Method of Preparation of Hydrous Aluminum Oxide—A series of hydrous aluminum oxides, to be referred to as chloride-containing gels, were prepared at 25° by the addition of a 13% solution of strong ammonia solution NF to an aqueous 8.5% aluminum chloride heptahydrate solution. The method of Papée *et al.* (4) and the conditions described by Lewis and Taylor (2) were followed to ensure reproducible precipitations. Sufficient ammonia solution was added to control the pH of precipitation. Alumina gels were precipitated at pH 4.8, 6.1, 7.7, and 9.2 and washed with deionized water until the concentration of the chloride ion in the filtrate, as determined by the Volhard method (7), was less than 0.1%. The

concentrations of the reactants required for 1 l. of washed gel and the resultant Al_2O_3 concentration for each alumina gel are listed in Table I.

A series of hydrous aluminum oxides, to be referred to as sulfate-containing gels, were prepared by the reaction of aluminum sulfate USP and strong ammonia solution NF. To ensure reproducible precipitations, the conditions described by Lewis and Taylor (2) were followed. Alumina gels were precipitated at 25° by the addition of a 13% solution of strong ammonia solution NF to an aqueous 12% aluminum sulfate USP solution. Sufficient ammonia solution was added to control the pH of precipitation. Alumina gels were precipitated at pH 4.9, 6.2, 7.9, and 9.2 and washed with deionized water until the concentration of sulfate ion in the filtrate, as determined by the USP gravimetric method (8), was less than 0.1%. The concentrations of reactants required for 1 l. of washed gel and the resultant Al_2O_3 concentration for each alumina gel are listed in Table II.

A series of hydrous aluminum oxides, to be referred to as bicarbonate-containing gels, were prepared by the reaction of aluminum chloride, sodium carbonate USP, and sodium bicarbonate USP. The alumina gels were precipitated at 25° following the conditions of Lewis and Taylor (2). An aqueous 11.4% solution of aluminum chloride heptahydrate was added to an aqueous solution containing 2.8% sodium carbonate USP and 4.5% sodium bicarbonate USP. Sufficient aluminum chloride solution or sodium carbonate USP, and sodium bicarbonate USP, solution was added to control the pH of precipitation. Alumina gels were precipitated at pH 4.8, 6.5, and 8.0 and washed with deionized water until the concentration of chloride ion in the filtrate, as determined by the Volhard method (7), was less than 0.1%. The concentrations of reactants required for 1 l. of washed gel and the resultant Al_2O_3 concentration for each alumina gel in this series are listed in Table III.

Methods of Studying Various Properties of Alumina Gels—The antacid property of each alumina gel was determined by its acid-consuming capacity. The precision of the USP acid-consuming

capacity test (9) was improved by titrating to pH 3.5 rather than using bromophenol blue T.S., as given in the USP.

The theoretical acid-consuming capacity of each alumina gel is based on the stoichiometric reaction of the aluminum oxide in the alumina gel and 0.1 N HCl. The antacid property of the aged alumina gel is given as a percentage of the theoretical acid-consuming capacity.

The X-ray diffraction pattern of each alumina gel was determined in the colloidal state by irradiating a sample in dialyzer tubing.

The Al_2O_3 content of each washed alumina gel was determined by the ethylenediaminetetraacetic acid titration (10).

The concentration of chloride ion was determined by the Volhard method (7). Total chloride was determined by dissolving the gel in nitric acid and assaying for the chloride ion as described. The amount found in the filtrate and the amount which could be eluted with deionized distilled water from an equal quantity of untreated gel were determined. The difference was regarded as representing the chloride content of the gel structure.

The concentration of sulfate ion in the gel structure was determined by the USP gravimetric method (8). The total sulfate in the alumina gel was determined by dissolving the alumina gel in nitric acid prior to sulfate assay. The amount found in the filtrate and the amount which could be eluted with deionized distilled water from an equal quantity of alumina gel was also determined. The

9.2	27.5	24.3	20	10	—	10	9	10

difference was regarded as representing the sulfate content of the gel structure.

The amount of CO₂ which was evolved from the gel structure was determined by the gasometric determination of carbon dioxide (11). A volume of gel was filtered and washed with previously boiled deionized distilled water. The CO₂ which resulted from the addition of hydrochloric acid USP to the retained solids was taken as the CO₂ evolved from the gel structure.

RESULTS AND DISCUSSION

Chloride-Containing Alumina Gels—When initially precipitated, all the chloride-containing alumina gels were colloidal when examined by optical microscope and amorphous when examined by X-ray diffraction. Figure 1 shows a typical X-ray diffraction pattern. The broad, diffuse band is typical of scattering by amorphous material. The other gels in this series had similar diffraction patterns, indicating that form is independent of the pH of precipitation.

All the alumina gels studied showed a decrease in acid reactivity upon aging at 25° until they reached a constant end-point acid reactivity (Table IV). The data of Table IV were used to construct linear plots from which rate constants were calculated. Figure 2 shows the plot for the gel precipitated at pH 6.1. Each plotted point represents the logarithm of the difference between the reactivity observed at some point in aging (R_{observed}) and that observed at the end-point ($R_{\text{end-point}}$). The plots for all gels were linear, indicating that the loss of acid reactivity follows apparent first-order kinetics.

The rate of loss of acid reactivity is directly dependent upon the pH of precipitation (Fig. 3). Alumina gels which were precipitated at a relatively high pH showed high rates of loss of reactivity. For example, the alumina gel precipitated at pH 9.2 lost reactivity 20 times faster at 25° than the one precipitated at pH 4.8.

The end-point acid reactivity is inversely related to the pH of precipitation (Fig. 4). For example, the gel precipitated at pH 9.2 had an end-point reactivity of only 10% of theory, while the gel precipitated at pH 4.8 was 70% reactive at its end-point.

The end-point acid reactivity does not appear to be a function of the aging temperature, although the rate of loss of activity increases with increasing temperature. The alumina gel precipitated at pH 4.8 reached the same end-point reactivity of 70% of theory

whether aged at 25 or 35°, but it reached it sooner at 35° than at 25°.

The losses in acid reactivity observed in these studies appear irreversible. Samples of an alumina gel, which had been precipitated at pH 7.7 and had reached its end-point reactivity of 25% of theory, did not regain any reactivity when adjusted to pH 5.5 or 4.5 with 0.1 *N* HCl and aged for 1 month at 25°.

The changes in acid reactivity on aging do not appear to be due to crystallization, since all the end point alumina gels were found to be colloidal by optical microscopy and amorphous by X-ray diffraction.

A probable explanation for the effect of pH on the acid reactivity of these gels lies in the effect of chloride ion in stabilizing the gel

Figure 4—Effect of pH of precipitation of chloride-containing alumina gels on the end-point acid reactivity.

Figure 3—Effect of pH of precipitation of chloride-containing alumina gels on the rate of change of acid reactivity at 25°.

Figure 5—Effect of pH of precipitation on the concentration of chloride ions in the chloride-containing alumina gels.

Figure 6—Effect of chloride ion concentration on the end-point acid reactivity.

structure. A varying concentration of chloride ion was found in the gel structure depending on the pH of precipitation (Fig. 5). The concentration did not change during the aging of these gels. A high chloride ion concentration appears to favor stability (Fig. 6). For example, the gel precipitated at pH 4.8, which retained 70% of its theoretical acid-consuming capacity at its end-point, had a high chloride ion concentration, while the alumina gel precipitated at pH 9.2, which lost virtually all its acid reactivity after 1 month at 25°, had little chloride ion in its gel structure. Figure 6 also indicates by extrapolation that a stable 100% acid-reactive gel would be obtained if 1 mole of chloride ion were present in the gel structure for every mole of aluminum. Unfortunately, this ideal gel cannot be produced from this system due to the solubility of the gel at a low pH.

Sulfate-Containing Alumina Gels—This series of alumina gels when initially precipitated were colloidal when examined by optical microscope and amorphous when examined by X-ray diffraction. The X-ray diffraction pattern was similar to that obtained for the chloride-containing gels (Fig. 1).

All the sulfate-containing gels studied showed a decrease in acid reactivity upon aging at 25° until a constant reactivity was reached. This behavior is similar to that observed for the series of chloride-containing gels. The rate of loss of acid reactivity is directly dependent on the pH of precipitation (Fig. 7).

The end-point reactivity is related to the pH of precipitation through an inverse linear relationship (Fig. 8). The changes in

Figure 7—Effect of pH of precipitation of sulfate-containing alumina gels on the rate of change of acid reactivity at 25°.

Figure 8—Effect of pH of precipitation of sulfate-containing alumina gels on the end-point acid reactivity.

acid reactivity on aging do not appear to be due to crystallization, since all the sulfate-containing gels at their end point were found to be colloidal when observed by optical microscope and amorphous by X-ray diffraction.

A varying concentration of sulfate ion was found in the gel structure, depending on the pH of precipitation (Fig. 9). As was noted for the chloride-containing gels, a high concentration of sulfate ion in the gel structure favors gel stability (Fig. 10). It is predicted from Fig. 10 that a stable, 100% acid-reactive gel would be obtained if 0.5 mole of sulfate ion was present per mole of aluminum.

Bicarbonate-Containing Alumina Gels—The alumina gels precipitated at pH 4.8, 6.5, and 8.0 by the reaction of aluminum chloride, sodium carbonate USP, and sodium bicarbonate USP, were colloidal and amorphous, similar to Fig. 1, when initially precipitated.

The bicarbonate-containing gels precipitated at pH 6.5 and 8.0 retained complete acid reactivity when stored for 2 years at 25° (Table V). The gel precipitated at pH 4.8 reached an end-point reactivity of 85% of theory. All the gels remained colloidal and amorphous during aging. Less than 0.03 mole of chloride ion per mole of aluminum was found in these gels. However, 1.01 and 1.07 moles of CO₂ per mole of aluminum were evolved when the gels precipitated at pH 8.0 and 6.5 were dissolved in hydrochloric acid USP. The gel precipitated at pH 4.8 evolved 0.72 mole of CO₂ per mole of aluminum. In the pH range of 4.8 to 8.0, bicarbonate ion would be the source of the evolved CO₂. Thus a stable, 100% acid-reactive gel was obtained when 1 mole of bicarbonate ion was present in the gel structure for every mole of aluminum. In this

Figure 9—Effect of pH of precipitation on the concentration of sulfate ions in the sulfate-containing alumina gels.

Figure 10—Effect of sulfate ion concentration on the end-point acid reactivity.

system the optimum concentration of bicarbonate ion was incorporated into the gel structure when the pH of the reaction mixture was 6.5 to 8.0. Effervescence occurred when the pH of the reaction mixture was below pH 5.5. Thus CO_2 was driven from the reaction mixture of the gel precipitated at pH 4.8, which resulted in a lower bicarbonate concentration in the gel structure.

It is concluded that the chloride-, sulfate-, and bicarbonate-containing gels studied may be in a highly unstable form when initially precipitated. The degree of instability is a function of the pH of precipitation. During aging, changes may occur in the gel structure which result in a loss in acid reactivity. Anions such as chloride, sulfate, and bicarbonate present in the reaction mixture are incorporated into the gel structure and act to stabilize the gel. A stable, completely reactive gel is expected if 1 mole of a monovalent anion such as chloride or bicarbonate or 0.5 mole of a bivalent anion such as sulfate is present in the gel structure per mole of aluminum.

SUMMARY

Hydrous aluminum oxide prepared by the reaction of aluminum chloride and strong ammonia solution NF; aluminum sulfate USP and strong ammonia solution NF; and aluminum chloride, sodium bicarbonate USP, and sodium carbonate USP, may exhibit an apparent first-order decrease in acid reactivity upon aging until a constant end-point is reached. The rate of loss of reactivity and the end-point reactivity are related to the pH of precipitation. The end-point reactivity is independent of storage temperature and was found to be irreversible. According to X-ray diffraction, these

Table V—Effect of Aging at 25° on the Acid Reactivity of Bicarbonate-Containing Alumina Gels Precipitated at Various pH Conditions

pH of Precipitation	Moles CO_2 Evolved/ Mole Al^{+++}	% of Theoretical Acid-Consuming Capacity after Storage at 25° for		
		Initial	30 Days	2 Years
4.8	0.72	100	85	85
6.5	1.07	100	100	100
8.0	1.01	100	100	100

changes are not related to changes in form. It is concluded that anions present in the reaction mixture are incorporated into the gel structure, depending on the pH of precipitation, and act to stabilize the gel. A stable, completely acid-reactive gel is obtained if 1 mole of a monovalent anion such as chloride or bicarbonate or 0.5 mole of a bivalent anion such as sulfate is incorporated in the gel structure per mole of aluminum.

Prazepam Metabolites in Dog Urine

FREDERICK J. DiCARLO and JEAN-PAUL VIAU

Abstract □ Within 24 hr. after receiving a single oral dose (10 mg./kg.) of ^{14}C -labeled prazepam, two dogs excreted small quantities (4.6 and 1.8%) of the radioactivity into the urine. Thin-layer chromatograms showed the presence of at least eight radioactive compounds in these urine collections. Six of the labeled compounds were identified, and accounted for 86% of the ^{14}C in the urine from Dog 1 and 95% of the ^{14}C in the urine from Dog 2. These compounds and their contributions to the urinary radioactivity were: prazepam (1%, Dog 1; 0.2%, Dog 2); desalkylprazepam (2%, Dog 1; 0.4%, Dog 2); 3-hydroxyprazepam glucuronide (9%, Dog 1; 11%, Dog 2); oxazepam (14%, Dog 1; 3%, Dog 2); oxazepam glucuronide (52%, Dog 1; 72%, Dog 2), and 4'-hydroxyoxazepam glucuronide (8%, Dogs 1 and 2).

Keyphrases □ Prazepam- ^{14}C metabolites—urinary excretion, dog □ Metabolites, prazepam—isolation, identification □ TLC—separation, identification □ Scintillometry—analysis

The identification of prazepam metabolites was of interest because it appeared that the drug might serve as the precursor to a series of tranquilizers. A previous study (1) demonstrated that prazepam is converted into one established tranquilizer, oxazepam, by the dog. Dealkylation and hydroxylation are involved in transforming prazepam into oxazepam and it was interesting to learn whether one or both oxidative sequences actually occur *in vivo*. Also in question was whether the dog hydroxylates the 5-phenyl group of benzodiazepines as does the rabbit (2). These points were investigated both qualitatively and quantitatively with the aid of ring-labeled prazepam.

EXPERIMENTAL

Reference Compounds—*N*-Phthalimidoacetyl-5-chloro-2-cyclopropylmethylamino-benzophenone-(carbonyl- ^{14}C) was treated with hydrazine to form *N*-glycyl-5-chloro-2-cyclopropylmethylamino-benzophenone-(carbonyl- ^{14}C) which cyclized spontaneously to yield 7-chloro-1-(cyclopropylmethyl)-5-phenyl-1*H*-1,4-benzodiazepin-2(3*H*)-one-5- ^{14}C (3). The product, better known as prazepam, showed chemical and radiochemical purity in excess of 99%. Its specific activity was 1.31 mc./g.

^{14}C -2-Cyclopropylmethylamino-5-chlorobenzophenone (CACB) was prepared by hydrolyzing 1 mg. of ^{14}C -prazepam in 0.5 ml. of 6 *N* HCl for 1 hr. in a boiling water bath (4). For chromatography, 5 ml. of water was added to the reaction mixture, the solution was neutralized partially with NaOH, and the product was extracted with ethyl acetate. Upon chromatography in a variety of solvents, the reaction product yielded a single radioactive spot which was yellow and did not react as a primary aromatic amine (5).

Other available reference compounds were desalkylprazepam, 3-hydroxyprazepam, oxazepam, 2-amino-5-chlorobenzophenone (ACB), and 4'-hydroxy-2-amino-5-chlorobenzophenone (4'-hydroxy ACB). The chemical purity of these preparations was >95%.

Protocol—Two male mongrel dogs of beagle conformity were used. Their weights were 8.6 and 10.5 kg. Each animal was fed a capsule containing ^{14}C -prazepam equivalent to 10 mg./kg. body weight and placed into a separate metabolic cage. Urine was collected at 24-hr. intervals for 3 days and counted by scintillation spectrometry.

The 0-24-hr. urine collections were used to identify drug metabolites as outlined in Fig. 1. The plan was based upon: (a)

Figure 1—Plan for identifying prazepam metabolites in dog urine. The urine, unconjugated metabolite fraction, aglycone fraction, and hydrolysate were submitted to TLC in four solvents.

hydrolysis of the urinary drug metabolites to ACB and its derivatives, (b) extraction of unconjugated urinary metabolites, and (c) enzymatic hydrolysis of the conjugated metabolites followed by extraction of the aglycones.

Hydrolysis of Drug Metabolites—Walkenstein *et al.* (4) described a method of quantitatively hydrolyzing diazepam, oxazepam and their analogs to their corresponding 2-amino-5-chlorobenzophenones. This procedure was used for the identification of prazepam metabolites. A 10-ml. portion of the dog urine was hydrolyzed by heating with an equal volume of concentrated HCl for 1 hr. at 100°. The hydrolysate was kept ice cold during partial neutralization by the addition of 4.4 g. of NaOH (4.8 g. required for neutralization). The acidic solution was extracted with three 5-ml. portions of ethyl acetate. All of the urinary ^{14}C was recovered in the ethyl acetate. The extracts were combined and concentrated to about 1 ml. for chromatography.

Extraction of Unconjugated Metabolites—A 50-ml. portion of the urine was adjusted to pH 7.0 and extracted with five 20-ml. portions of ethyl acetate. The combined ethyl acetate extracts were evaporated to about 1.5 ml.

Extraction of Aglycones of Conjugated Metabolites—After extracting the unconjugated metabolites, the urine was brought to pH 5.0-5.5 and incubated overnight at 37° with 50,000 units of β -glucuronidase. Then the pH was adjusted to 7.0 and the solution was extracted five times with 20-ml. portions of ethyl acetate. The combined organic phase was evaporated to about 2 ml.

Thin-Layer Chromatography—Submitted to chromatography were the reference compounds; untreated urines; hydrolyzed urines; extracts of unconjugated metabolites; extracts of the aglycones of conjugated metabolites; hydrolysates of authentic prazepam, oxazepam, 3-hydroxyprazepam, and desalkylprazepam; and hydrolysates of fractions eluted from chromatograms. All of the chromatograms were developed on glass plates coated with silica gel G. The solvent systems employed were 206: benzene-ethyl acetate (5:1), 304: chloroform-acetic acid-methanol (15:1:4), 306: chloroform-ethanol-acetone (8:1:1), and 307: chloroform-acetone (9:1).

Rechromatography—Rechromatography was conducted in order to confirm R_f data, to obtain R_f values in other solvents, and to check the purity of fractions. The technique for collecting a given radioactive fraction from TLC plates simply involved scraping the area from several plates, eluting the fraction with ethyl acetate, and concentrating the eluate.

Cochromatography—Cochromatography refers to spotting a mixture of an unknown and a reference compound and developing

Table I—TLC of Reference Compounds

the chromatogram. This procedure was employed to detect any minor difference between the migration of the unknown and known compounds.

Detection Methods Applied to Chromatograms—The radioactive bands on the chromatograms were scanned with a Packard model 7201 radiochromatogram scanner to determine their *R_f* values. Chromatograms of the hydrolysis products, with the benzophenones (ACB or CACB) as the major components, showed distinct yellow spots for these compounds. ACB, a primary aromatic amine, was detected at low levels by running the Bratton-Marshall assay (5) directly on chromatograms. This was done by spraying chromatograms successively with 4 *N* HCl, 0.5% sodium nitrite, 0.5% ammonium sulfamate, and finally 0.1% *N*-(1-naphthyl)-ethylenediamine dihydrochloride. Prazepam, desalkylprazepam, and 3-hydroxyprazepam were sometimes located on chromatograms by enclosing the plates in a cylinder with crystalline iodine. The iodine vapor caused the compounds to become yellow. Some plates were sprayed with a phenol reagent to detect 4'-hydroxy ACB. The reagent was freshly prepared by dissolving 1.0 g. of ferric chloride and 50 mg. of potassium ferricyanide in 10 ml. of water (6).

Quantitative Methods—Scintillation spectrometry was used to determine the absolute levels of radioactivity in the various fractions. For this purpose, a dioxane cocktail was employed in conjunction with a Packard Tri-Carb model 3324 liquid scintillation spectrometer equipped with automatic external standardization. The relative quantities of the compounds resolved chromatographically were determined by using a planimeter to measure the areas under the peaks of radioscan.

RESULTS

In 24 hr., Dog 1 excreted 4.6% of the administered radioactivity into the urine and Dog 2 excreted only 1.8%. The urinary recovery values for 72 hr. were 9.2% from Dog 1 and 8.3% from Dog 2. Figure 1 shows that the distribution of radioactivity between unconjugated and conjugated metabolites also differed considerably for the 24-hr. urine collections from the two dogs. Nevertheless, there was a preponderance of conjugated labeled compounds (77 and 96%) in these specimens.

All of the benzodiazepin and benzophenone reference compounds were separable from one another by TLC (Table I). Table II illustrates the resolutions obtained by applying the same technique to the urine from Dog 1, to the same urine after hydrolysis, to extracts of the unconjugated metabolites, and to extracts of the aglycones of the labeled glucuronides. Table III shows the translation of these data into terms of specific compounds based upon the identifications described below.

Identification of Prazepam—It was known that prazepam, if present, would be in the unconjugated fraction. This fraction was submitted to chromatography in three solvents. Chromatograms developed in Solvents 206 and 307 showed 5 to 6% of the unconjugated radioactivity to be located at *R_f* values corresponding to prazepam (Table II). Chromatograms produced in Solvent 306 gave a higher ¹⁴C value (13%) for the prazepam area and suggested that desalkylprazepam might also be present. After extracting the suspected prazepam from thin-layer chromatograms, rechromatography in different solvents yielded single radioactive bands at *R_f* values corresponding to prazepam. In addition, exposure of the chromatograms to iodine vapor produced yellow bands only where there was radioactivity. When the eluates of the suspected prazepam were hydrolyzed and chromatographed in four solvents, a single radioactive product was formed. This product corresponded to 2-cyclopropylmethylamino-5-chlorobenzophenone (CACB) upon chromatography in all solvents and was so identified. The identification of prazepam was based upon all of these facts (radioactivity, quantitative agreement between the quantities estimated to be present on different chromatograms, reaction with iodine, *R_f* values in four solvents, and conversion to tagged CACB).

Identification of Desalkylprazepam—This compound was also sought in the unconjugated fraction. Again, there was a problem with one of the solvents, this time because 72% of all of the ¹⁴C in this fraction centered at *R_f* 0.05 and obscured the metabolite with an *R_f* of 0.11 (Solvent 206). However, well-resolved spots were observed at appropriate places on chromatograms developed in the other two solvents and the quantities of ¹⁴C corresponded satisfactorily: 13 and 10% of the ¹⁴C of the unconjugated fraction in Solvents 306 and 307, respectively (Table II). Eluates of the spots showed single radioactive bands upon rechromatography in the various solvents, and the *R_f* values corresponded to desalkylprazepam. Cochromatography of the metabolite with synthetic desalkylprazepam showed the presence of ¹⁴C and of the iodine-reacting material at the same *R_f* in each solvent. Further confirmation of the identity of the metabolite came from its hydrolysis to ACB. The hydrolysis product was radioactive, yielded the same *R_f* values as ACB, and was inseparable from authentic ACB by cochromatography.

Identification of Oxazepam—The presence of free oxazepam was indicated by chromatography of the urine in Solvents 304 and 306 and by chromatography of the unconjugated fraction in Solvents 206, 306, and 307 (Table II). In addition, the quantities of the metabolite agreed fairly well, considering that five different experimental situations were involved. The methods used to identify oxazepam unequivocally were described earlier in detail (1).

Table II—TLC of Urine of Dog 1 and Its Major Fractions

Sample	Solvent	<i>R_f</i> and Amount
Urine	206	0.0 (100%)
Urine	304	0.12 (75%), 0.30 (13%), 0.89 (12%)
Urine	306	0.0 (86.5%), 0.40 (13.5%)
Urine	307	0.05 (100%)
Hydrolysate	206	0.0 (19%), 0.22 (5%), 0.35 (8%), 0.78 (62%), 0.95 (5%)

Unconjugated	307	0.10 (38%), 0.20 (47%), 0.35 (10%), 0.67 (5%), 0.88 (10%)
Aglycones	206	0.07 (100%)
Aglycones	304	0.89 (100%)
Aglycones	306	0.0 (9%), 0.22 (10%), 0.50 (68%), 0.75 (13%)
Aglycones	307	0.10 (91%), 0.25 (9%)

^a Sample hydrolyzed for 18 hr. rather than the usual 1 hr.

Table III—Identification and Estimation of Metabolites in Urine of Dog 1

Compound	Urine or Fraction	Solvent	Urine, %
Prazepam	Unconjugated	206	1
Prazepam	Unconjugated	307	1
Oxazepam	Urine	304	12
Oxazepam	Urine	306	14
Oxazepam	Unconjugated	206	15
Oxazepam	Unconjugated	306	13
Oxazepam	Unconjugated	307	10
Desalkylprazepam	Unconjugated	306	3
Desalkylprazepam	Unconjugated	307	2
Oxazepam glucuronide	Aglycone	206	77
Oxazepam glucuronide	Aglycone	304	77
Oxazepam glucuronide	Aglycone	306	52 ^c
Oxazepam glucuronide	Aglycone	307	70
3-Hydroxyprazepam glucuronide ^a	Aglycone	306	10
3-Hydroxyprazepam glucuronide ^a	Aglycone	307	7
4'-Hydroxyoxazepam ^b	Hydrolysate	307	13 ^d

^a N₁-Cyclopropylmethyloxazepam glucuronide. Confirmed by 4% CACB in hydrolysate, Solvent 206. ^b No model compound available; based upon detection of hydrolysis product. 4'-Hydroxyoxazepam may be the *R_f* 0.22 spot in Solvent 306, aglycone fraction; 8% of urinary ¹⁴C. ^c Most probable value because sample was resolved into four radioactive areas whereas Solvents 206 and 304 gave one spot and Solvent 307 gave two. ^d Further chromatography in Solvents 307, 206, and 306 showed about 60% of this material to be 4'-hydroxyoxazepam.

Identification of Oxazepam Glucuronide—After treating the ethyl acetate-extracted urine with β -glucuronidase, it was possible to extract practically all of the remaining labeled material from the urine of Dog 1 into ethyl acetate (Fig. 1). Chromatograms de-

Scheme I—Oxidative metabolism of prazepam in dogs. (The sequences involving 4'-oxidation of prazepam and of N₁-cyclopropylmethyloxazepam were omitted for clarity.)

Table IV—Prazepam and Its Metabolites in Dog Urine

Compound	¹⁴ C in Urine, % Dog 1	¹⁴ C in Urine, % Dog 2
Prazepam	1	0.2
Desalkylprazepam	2	0.4
3-Hydroxyprazepam glucuronide	9	11
Oxazepam	14	3
Oxazepam glucuronide	52	72
4'-Hydroxyoxazepam glucuronide	8	8
Total	86	95

veloped in four solvents showed spots corresponding to oxazepam. The oxazepam contribution to the conjugated fraction was 68% as indicated by chromatography in Solvent 306 (Table II). The higher estimates (91 to 100%) obtained from the other solvents obviously included other aglycones.

Identification of 3-Hydroxyprazepam Glucuronide—Chromatography following treatment with β -glucuronidase also suggested the presence of 3-hydroxyprazepam. The material separated from oxazepam by Solvent 306 was identified as 3-hydroxyprazepam on the basis of rechromatography data, cochromatography experiments with authentic material, and conversion to CACB by acid hydrolysis.

Identification of 4'-Hydroxyoxazepam Glucuronide—As expected from the results presented above, the direct hydrolysis of the dog urine yielded radioactive bands corresponding to ACB and CACB (Table II). Other radioactive compounds were also present. The application of spray reagents to the chromatograms showed that the radioactive band at *R_f* 0.58 in Solvent 307 gave positive tests for a primary aromatic amino group and for a phenolic group. Therefore, it was considered possible that the compound was 4'-hydroxy ACB which could be formed by the hydrolysis of 4'-hydroxyoxazepam or its glucuronide. Since the aglycone, 4'-hydroxyoxazepam, was not available, the authors tried to identify this metabolite through its possible hydrolysis product, 4'-hydroxy ACB, by a chromatographic application of the isotope dilution technique. To this end, radioactive material eluted from *R_f* 0.58 of TLC plates developed in Solvent 307 was mixed with authentic 4'-hydroxy ACB and submitted to chromatography in Solvent 307. Three radioactive bands showed up in the radioscan. The major band (*R_f* 0.55) corresponded exactly to the yellow area occupied by 4'-hydroxy ACB. This band was collected and eluted for chromatography in Solvent 206. The radioscan showed a single peak at the same *R_f* (0.49) as the yellow color. The collection and elution process was repeated for chromatography in Solvent 306. Again, a single radioactive band coincided with the yellow 4'-hydroxy ACB (*R_f* 0.80).

The urine of both dogs contained the same six compounds and they accounted for 86 to 95% of the radioactivity (Table IV). Although oxazepam glucuronide was the main component of both specimens, its contribution to the total radioactivity varied considerably in the two urine collections. The sums of free and conjugated oxazepam were in closer agreement. The data for the glucuronides of 3-hydroxyprazepam and 4'-hydroxyoxazepam corresponded closely. In both instances, the smallest contributions were made by prazepam and desalkylprazepam.

DISCUSSION

Three oxidative reactions characterize prazepam metabolism in the dog. They are the Phase 1 reactions: (a) dealkylation, probably releasing cyclopropylformaldehyde, (b) oxidation of the methylene at C-3 to a secondary alcohol function, and (c) oxidation of the phenyl group at C-5 to a phenol. Reactions 1 and 2 occur directly with prazepam, as is evident from the identification of 3-hydroxyprazepam and desalkylprazepam (Scheme I). Which of the reactions proceeds faster remains a moot question for prazepam, although the evidence indicates that diazepam is dealkylated more rapidly than it is hydroxylated *in vivo* (7-9) and *in vitro* (10). Reactions 1 and 2 are also involved in the subsequent metabolism. Thus, there are two independent but competitive routes from prazepam to oxazepam. At this time, there is no evidence for the direct hydroxylation of prazepam in the 4'-position; i.e., it is not known whether prazepam simultaneously undergoes Reactions 1, 2,

and 3. Nevertheless, the authors consider that Reaction 3 is properly classified as a Phase 1 conversion (11). Although 4'-hydroxy-desalkylprazepam has not been identified, this compound, as well as oxazepam, may be a precursor to 4'-hydroxyoxazepam. Other routes to 4'-hydroxyoxazepam are also possible as stated in the legend of Scheme I.

Another of the unidentified metabolites may be 2'-hydroxyoxazepam. It seems that aromatic hydroxylation in the *ortho* and *para* positions is catalyzed by different enzymes (12) and that the dog generally produces more of the *ortho* isomer (13, 14). The authors' identification of the *para* hydroxy compound (4'-hydroxyoxazepam) in dog urine implies steric hindrance of the *ortho* (2') position. On the other hand, it is quite possible that some 2'-hydroxy ACB was present with the 4'-hydroxy ACB. Since the 2'-hydroxy compound is not available for study, the possibility cannot be excluded that the four solvent systems did not resolve 2'- and 4'-hydroxy ACB.

In the dog, a single Phase 2 reaction was observed, namely, conjugation with glucuronic acid. As far as could be determined, all of the 3-hydroxyprazepam was conjugated. Thus, a competitive situation would exist if 3-hydroxyprazepam were also converted to oxazepam, as seems likely. The data show that most of the oxazepam was conjugated. The presence of some free oxazepam is interesting and suggests intermediate ranking of the dog among species capable of forming *O*-glucuronides. Although conclusive evidence is lacking, it is surmised that 4'-hydroxyoxazepam was also excreted mainly as a glucuronide.

Unlike diazepam (7, 8) and oxazepam (4), some unaltered prazepam was excreted into the urine by dogs. Thus, dogs treated with prazepam circulate at least three compounds with tranquilizer activity, namely prazepam (15-18), oxazepam, and desalkylprazepam (19).

CONCLUSIONS

The radioactivity from ^{14}C -prazepam administered to dogs was excreted slowly into the urine. Most of the drug was transformed, apparently by oxidative enzymes of the liver microsomes. The major drug metabolite was oxazepam glucuronide. Other glucuronides were formed from 3-hydroxyprazepam and 4'-hydroxyoxazepam. The urine collections also contained unaltered prazepam, desalkylprazepam, and unconjugated oxazepam. Prazepam is considered to serve as the precursor to a series of metabolites with tranquilizer activity.

Gastric Absorption and Distribution of Acetylsalicylic Acid and Other Acidic Compounds in the Rat

CLARENCE H. MORRIS, JOHN E. CHRISTIAN, TOM S. MIYA, and WARREN G. HANSEN

Abstract □ A comparison was made of the gastric absorption and distribution of sodium acetylsalicylate-7- ^{14}C with the absorption and distribution of sodium salts of other weakly acidic compounds. Each of the other compounds observed had an absorption pattern which was characteristic for the compound. Only sodium acetylsalicylate caused gastric lesions in the rat. The observations do not rule out the possibility that absorption characteristics of acetyl-

salicylic acid and its salts may be associated with their ability to cause gastric ulcers.

Keyphrases □ Acetylsalicylate-7- ^{14}C , Na—absorption, distribution □ Acidic compounds—acetylsalicylate-7- ^{14}C , Na—absorption, distribution comparison □ Gastric lesion production—acetylsalicylate-7- ^{14}C , Na, acidic compounds □ TLC—analysis □ Autoradiography—analysis

It has been known for more than 50 years that oral administration of acetylsalicylic acid is followed by erosion of the gastric mucosa and bleeding from the site of the lesion (1). These aspirin-induced lesions have been observed in humans (1), dogs (2), cats (3), guinea

pigs (4), and albino rats (5). A number of hypotheses have been suggested to explain the occurrence of these lesions. Davenport (6) and Martin (7) have suggested chemical models based upon the interaction of the compound with cellular constituents following its absorption

and 3. Nevertheless, the authors consider that Reaction 3 is properly classified as a Phase 1 conversion (11). Although 4'-hydroxy-desalkylprazepam has not been identified, this compound, as well as oxazepam, may be a precursor to 4'-hydroxyoxazepam. Other routes to 4'-hydroxyoxazepam are also possible as stated in the legend of Scheme I.

Another of the unidentified metabolites may be 2'-hydroxyoxazepam. It seems that aromatic hydroxylation in the *ortho* and *para* positions is catalyzed by different enzymes (12) and that the dog generally produces more of the *ortho* isomer (13, 14). The authors' identification of the *para* hydroxy compound (4'-hydroxyoxazepam) in dog urine implies steric hindrance of the *ortho* (2') position. On the other hand, it is quite possible that some 2'-hydroxy ACB was present with the 4'-hydroxy ACB. Since the 2'-hydroxy compound is not available for study, the possibility cannot be excluded that the four solvent systems did not resolve 2'- and 4'-hydroxy ACB.

In the dog, a single Phase 2 reaction was observed, namely, conjugation with glucuronic acid. As far as could be determined, all of the 3-hydroxyprazepam was conjugated. Gastric Absorption and Distribution of Acetylsalicylic Acid and Other Acidic Compounds in the Rat

CLARENCE H. MORRIS, JOHN E. CHRISTIAN, TOM S. MIYA, and WARREN G. HANSEN

Abstract □ A comparison was made of the gastric absorption and distribution of sodium acetylsalicylate-7-¹⁴C with the absorption and distribution of sodium salts of other weakly acidic compounds. Each of the other compounds observed had an absorption pattern which was characteristic for the compound. Only sodium acetylsalicylate caused gastric lesions in the rat. The observations do not rule out the possibility that absorption characteristics of acetyl-

salicylic acid and its salts may be associated with their ability to cause gastric ulcers.

Keyphrases □ Acetylsalicylate-7-¹⁴C, Na—absorption, distribution □ Acidic compounds—acetylsalicylate-7-¹⁴C, Na—absorption, distribution comparison □ Gastric lesion production—acetylsalicylate-7-¹⁴C, Na, acidic compounds □ TLC—analysis □ Autoradiography—analysis

It has been known for more than 50 years that oral administration of acetylsalicylic acid is followed by erosion of the gastric mucosa and bleeding from the site of the lesion (1). These aspirin-induced lesions have been observed in humans (1), dogs (2), cats (3), guinea

pigs (4), and albino rats (5). A number of hypotheses have been suggested to explain the occurrence of these lesions. Davenport (6) and Martin (7) have suggested chemical models based upon the interaction of the compound with cellular constituents following its absorption

Figure 1—Corpus mucosal surface showing lesions and areas of hemorrhage.

into the cell. It became of interest to compare the absorption of aspirin, which causes ulceration and bleeding in the corpus portion of the rat stomach, with the absorption of other weakly acidic compounds which do not cause ulceration and bleeding.

MATERIALS AND METHODS

The radiochemical purity of sodium acetylsalicylate-7- ^{14}C , sodium benzoate-7- ^{14}C , sodium acetate-1- ^{14}C , and sodium barbital-2- ^{14}C (Tracer Labs, Waltham, Mass.) was established by TLC employing a stationary phase of silica gel G and a solvent system of low-boiling petroleum ether and 99% propionic acid. The location of the radioactive spots was determined by gross autoradiography.

All animals were fasted for 36 hr. prior to administration of the compound. Water was allowed *ad libitum* during the fast but was withdrawn after administration of the compound.

The compounds were administered orally to male Holtzman rats weighing between 150 and 275 g. (Holtzman Rat Co., Madison, Wis.) by means of a No. 16 curved steel oral catheter which had been dipped in mineral oil for lubrication. Each animal received a dose of 0.28 mmole of the selected compound per kg. of body

Figure 2—Average gastric lesion rating of six animals per time interval following oral administration of: Δ , sodium acetylsalicylate; \circ , sodium barbital; \bullet , sodium acetate; and \blacktriangle , sodium benzoate. All control animals had a rating of 1.

Figure 3—Disappearance of labeled compounds from the corpus portion of the rat stomach. Key: Δ , sodium acetylsalicylate; \circ , sodium barbital; \bullet , sodium acetate; and \blacktriangle , sodium benzoate. Each point represents the mean of three animals. To indicate the range of values around the averages shown in the plot, the minimum variation around any single point was 2.62×10^{-1} , 1.98×10^{-1} , and 2.24×10^{-1} (average 2.28×10^{-1}) $\mu\text{moles per gram of tissue}$. The maximum variation around any single point was 1.94×10^{-3} , 1.06×10^{-2} , and 5.13×10^{-2} (average 4.95×10^{-2}) $\mu\text{moles per gram of tissue}$.

weight. Each dose contained 30.5 μC . per kg. body weight of the ^{14}C -labeled compound diluted with the appropriate amount of carrier. The sodium acetylsalicylate was administered in 0.15 M citrate buffer, final pH 4.6. All other compounds were dissolved or suspended in a solution of 5% polyvinylpyrrolidone (PVP). Control animals received 0.5 ml. of the respective vehicle.

The rats were killed in groups of three by etherization at intervals of 5, 15, 30, 60, 90, and 120 min. following administration of each compound. The stomachs were removed, opened along the line of lesser curvature, stretched, and pinned on a large rubber stopper. The mucosal surface of each stomach was decontaminated with 0.9% NaCl, examined for the appearance of lesions, and rated on an 8-point scale developed by Morris *et al.* (5).

After being rated with respect to the severity of lesions, the stomachs were frozen in the stretched position with dry ice. Whole frozen stomachs were covered with plastic wrap (Saran), placed between two sheets of X-ray film (No Screen Medical, Eastman Kodak Co., Rochester, N. Y.), and stored in light, tight cassettes at -20° for 60 days for gross autoradiography.

Following exposure of the film, samples of frozen rumen (non-glandular portion of the rat stomach) and corpus (glandular portion of the rat stomach) were prepared for liquid scintillation counting (Tri-Carb liquid scintillation counter model 3003, Packard Instrument Co., La Grange, Ill.) as described by Morris *et al.* (5). The amount of compound present per gram of tissue was calculated for each sample according to the following expression:

$$\mu\text{moles of compound/g. of tissue} = \frac{\text{observed d.p.m.}}{(W)(SA)(L)}$$

where: W = wet weight of the tissue in grams; SA = specific activity, d.p.m./mcg. of compound; and L = mcg. of compound/ μmole .

RESULTS

Appearance of Lesions—Typical lesions as they appeared in the corpus portion of the rat stomach are shown in Fig. 1. It is of interest to note that the lesions appear in rows or furrows roughly paral-

Figure 4—Disappearance of labeled compounds from the rumen portion of the rat stomach. Key: Δ , sodium acetylsalicylate; \circ , sodium barbitol; \bullet , sodium acetate; and \blacktriangle , sodium benzoate. Each point represents the mean of three animals. To indicate the range of values around the averages shown in the plot, the minimum variation around any single point was 4.27×10^{-2} , 3.94×10^{-2} , and 3.94×10^{-2} (average 4.95×10^{-2}) μ moles per gram of tissue. The maximum variation around any single point was 1.12×10^{-2} , 2.04×10^{-2} , and 4.6×10^{-3} (average 1.2×10^{-2}) μ moles per gram of tissue.

lel to the longitudinal axis of the stomach. Under the conditions employed in these experiments, such lesions occurred only in the corpus portion of the rat gastric mucosa.

Figure 5—Gross autoradiograph of mucosal surface of rat stomach 120 min. following oral administration of ^{14}C -sodium acetylsalicylate.

Figure 6—Gross autoradiograph of mucosal surface of rat stomach 120 min. following oral administration of ^{14}C -sodium benzoate.

It may be seen in Fig. 2 that, of the compounds studied, only sodium acetylsalicylate caused gastric lesions in the rat. A mild erythema, rated as 2 on the scale, occurred in some cases after the administration of the other compounds. Formation of lesions was essentially maximal 60 min. after administration of sodium acetylsalicylate.

Concentration Study—The concentration in micromoles per gram of tissue of each ^{14}C -labeled compound in gastric tissue was determined at each time interval. It is seen in Fig. 3 that the concentration of each compound in the corpus tissue diminishes rapidly with time.

The levels of these compounds in the rumen are remarkably different from the levels in the corpus (see Fig. 4). The concentration of sodium barbitol in rumen tissue increases with time during the first 30 min. after its administration. Its concentration then drops

Figure 7—Gross autoradiograph of mucosal surface of rat stomach 120 min. following oral administration of ^{14}C -sodium barbitol.

Figure 8—Gross autoradiograph of mucosal surface of rat stomach 5 min. following oral administration of ^{14}C -sodium acetate.

for the remaining time intervals. The concentration of sodium acetylsalicylate diminishes very slowly throughout the entire period of observation. The concentration of sodium acetate in rumen tissue remains essentially constant for the first 30 min. after its administration and then drops rapidly in a manner similar to that of sodium barbital. Sodium benzoate levels decrease rapidly with time.

Distribution Study—Figures 5 through 10 show selected autoradiographs of the mucosal surfaces. All stomachs are positioned such that the rumen is at the top of the figure. The compounds are localized in the rumen of all stomachs up to 120 min. following administration with the exception of sodium acetate. Sodium acetate disappears from both the rumen and the corpus within 60 min. following administration (Figs. 8–10). Sodium acetylsalicylate, sodium benzoate, and sodium barbital demonstrate gastric distribution patterns similar to the pattern of acetylsalicylic acid reported by Morris *et al.* (5).

Figure 9—Gross autoradiograph of mucosal surface of rat stomach 60 min. following oral administration of ^{14}C -sodium acetate.

Figure 10—Gross autoradiograph of mucosal surface of rat stomach 120 min. following oral administration of ^{14}C -sodium acetate.

SUMMARY AND CONCLUSIONS

The data presented in Fig. 2 indicate a high incidence of lesions following the administration of sodium acetylsalicylate. These findings are in agreement with those reported by Morris *et al.* (5) who used acetylsalicylic acid. Sodium acetylsalicylate, sodium benzoate, and sodium barbital showed similar localization patterns. It is obvious from both the quantitative data and the gross autoradiographs that these three compounds disappear with time from the corpus but remain in relatively high concentrations at all observed time intervals in the rumen portion. By contrast, the results of the autoradiographic localization and the tissue analysis of sodium acetate indicate a relatively rapid disappearance from both the rumen and corpus.

It should be emphasized that the concentration values reported represent a specific concentration at the designated time following administration, and that this value is a function of the penetration of the compound from the lumen into the tissue, possible metabolism, binding, absorption into the bloodstream, reabsorption from the blood into the stomach tissue, and possible loss of activity from the tissue into the lumen following tissue damage. Although this study does not provide an explanation of gastric ulceration by aspirin, the observations do not rule out the possibility that absorption characteristics of acetylsalicylic acid and its salts may be associated with their ability to cause gastric ulcers. Since sodium acetylsalicylate administration results in lesion formation and administration of the other compounds studied did not result in lesion formation, it becomes difficult to escape the conclusion that absorbed sodium acetylsalicylate interacts with the corpus tissue or its secretions in some manner which is different from the interaction of the other weak acids. In addition, since lesions appeared only in the corpus, through which sodium acetylsalicylate penetrates and is absorbed, and not in the rumen, where the compound remains localized, it appears that the processes involved in penetration and absorption play a role in the mechanism of lesion formation. Investigations into the nature of the interactions between sodium acetylsalicylate and corpus and rumen tissue are presently in progress.

Quantification of the Binding Tendencies of Cholestyramine II: Mechanism of Interaction with Bile Salt and Fatty Acid Salt Anions

WILLIAM H. JOHNS and THEODORE R. BATES

Abstract □ The binding of a series of conjugated bile salt and fatty acid salt anions to cholestyramine from aqueous media was investigated and the data were plotted according to the Langmuir adsorption equation. Increases in affinity constants were noted as the number of hydroxy substituents on the bile salt-ring structure decreased. An increase in the chain length of the fatty acid salt caused a corresponding increase in the affinity constant, whereas an increase in the extent of unsaturation in the fatty acid chain produced a reduction in the affinity constants for the fatty acid-cholestyramine interaction. Apparent surface tension-lowering properties of the adsorbate molecules were found to parallel the affinities obtained for both classes of adsorbate molecules, with the exception of the fatty acid anion, linoleate. Based on the results of these studies, it is suggested that the binding mechanism involves a primary electrostatic component reinforced by a secondary nonelectrostatic interaction, the strength of the latter force being dependent on the degree of hydrophobicity of the adsorbate molecule.

Keyphrases □ Cholestyramine binding—quantification □ Bile salts, fatty acid salt anions—cholestyramine interaction mechanism □ Surface tension values—affinity constants, correlation—bile salts □ Hydrophobic character relationship, adsorbate—cholestyramine binding □ UV spectrophotometry—analysis

In previous work with the anionic exchange resin cholestyramine (1), the authors studied the effect of the physiologic electrolytes, sodium chloride and bicarbonate, on the binding process of bile salt anions to cholestyramine. The dihydroxy bile salt anions studied were noted to be insignificantly affected in their extent of interaction with the resin, while the trihydroxy bile salt anion-cholestyramine interactions were markedly reduced in the presence of an added electrolyte. These results suggested that a secondary, nonelectrostatic, type of interaction was taking place at the adsorption site.

The observation that structurally different bile salt anions exhibit varying types, as well as extents, of binding to cholestyramine is of biologic significance in that an appreciation of the possible modes of interaction could ultimately contribute to an enhancement in

the efficiency of this pharmacologically important resin.

The purpose of this study was to elucidate the nature of this secondary binding mechanism and the effect of adsorbate structure thereon. In order to accomplish this, the binding tendencies of a selected series of glycine-conjugated bile salts and various physiologic fatty acid salts to cholestyramine were investigated.

EXPERIMENTAL

Materials—The sodium salts of glycocholic acid,¹ glycodeoxycholic acid,¹ glycodehydrocholic acid,¹ glycolithocholic acid,¹ lauric acid,² and oleic acid³ were dried *in vacuo* for at least 48 hr. prior to use. The sodium salt of linoleic acid³ was prepared by reacting equimolar quantities of the acid with sodium ethylate in absolute alcohol. The resulting salt was washed several times with absolute alcohol, dried at room temperature, and subjected to vacuum desiccation. The cholestyramine⁴ employed in this study was of pharmaceutical grade (1). Reagent grade concentrated sulfuric acid, glacial acetic acid, hydrochloric acid, chloroform, sodium hydroxide, copper nitrate, *n*-butanol, and diethyldithiocarbamate were used as received.

Procedure for Adsorption Studies—A series of aqueous solutions of each bile salt and fatty acid salt was prepared over the concentration range of 0.75–5.0 millimolar (mM).⁵ Twenty-five-milligram samples of cholestyramine were accurately weighed and placed into 50-ml. glass-stoppered conical flasks, together with a 25.0-ml. portion of the adsorbate solution. At each concentration, a control flask was prepared containing a similar quantity of the solution under study but no cholestyramine. These latter control solutions, which were assayed concomitantly with the solutions exposed to cholestyramine, were used to prepare the required Beer's law plots.

⁵ All systems exhibited complete solution over the concentration range studied, with the exception of the higher concentrations of glycolithocholate, which showed slight turbidity. Adsorption, being a dynamic process, would tend to increase the apparent solubility of a relatively insoluble material by removing molecules from solution and thereby promoting solution of any undissolved material.

Figure 1—Adsorption isotherms for the binding of glycine-conjugated bile salt anions to cholestyramine at 25°. Key: glycolithocholate (●), glycodeoxycholate (□), glycocholate (○), and glycodehydrocholate (■).

All containers were closed securely and mechanically shaken⁶ at 25° until equilibrium was established; this normally occurred within 24 to 48 hr. The equilibrated samples were subjected to Millipore filtration (0.45- μ pore size), the filtrates suitably diluted or concentrated, and the equilibrium bile salt or fatty acid salt concentration determined (see *Assay Procedures*).

Procedure for Desorption Studies—In order to determine the desorption characteristics of the bound adsorbate molecules, 25.0-ml. quantities of each bile salt or fatty acid salt solution were prepared and shaken with 25.0 mg. of cholestyramine in 125-ml. glass-stoppered conical flasks. After attainment of equilibrium, the samples were diluted with 50.0-ml. portions of distilled water and agitated until equilibrium was again established. After filtration and appropriate dilution or concentration, the filtrates were assayed for free adsorbate concentration.

Surface Tension Determinations—The surface tension-lowering properties of the adsorbate molecules were studied at concentrations well below their respective critical micelle concentrations (CMC). All surface tension measurements were conducted at 25° using a Fisher ring tensiometer. At least eight determinations were performed for each solution and the pure solvent. Apparent surface tension-lowering (π) values were calculated from the difference between the mean surface tension value obtained for distilled water and the adsorbate solutions.

Assay Procedures—The equilibrium concentration of unbound or free adsorbate was determined by one of the following methods.

Bile Salts—Sodium glycocholate and glycodeoxycholate were determined spectrophotometrically in 65% sulfuric acid as described previously (1).

The spectrophotometric method of Minibeck (2) was modified for the determination of sodium glycolithocholate. The residue from an evaporated filtrate sample was dissolved in a 9:1 mixture of concentrated sulfuric and glacial acetic acids and the resultant solution heated at 60° for 30 min. A quantity of 9:1 acid mixture, treated in the same manner, served as a blank.

For the determination of sodium glycodehydrocholate, an aliquot of the equilibrated, filtered sample was evaporated to dryness and the residue dissolved in 0.1 *N* sodium hydroxide. Spectrophotometric determinations were made using the base as a blank.

Absorbance readings were determined using a Beckman model DB-G recording spectrophotometer. All of the adsorbates were

Figure 2—Adsorption isotherms for the binding of several physiologic fatty acid salt anions to cholestyramine at 25°. Key: oleate (●), linoleate (○), and laurate (■).

found to obey the Beer-Lambert law relationship at their respective wavelengths of maximum absorbance (i.e., glycodeoxycholate, 385 $m\mu$; glycocholate, 320 $m\mu$; glycolithocholate, 316 $m\mu$; glycodehydrocholate, 282 $m\mu$).

Fatty Acid Salts—The fatty acid salts were assayed by a modification of the method proposed by Duncombe (3). An aliquot of the equilibrated, filtered sample was acidified with 1.0 *N* HCl and the free fatty acid extracted with 15.0-ml. quantities of chloroform. A 5-ml. portion of the chloroform phase, diluted when necessary, was shaken with 2.5 ml. of a copper nitrate reagent for a period of not less than 2 min. The aqueous phase was removed by means of aspiration, and a 3-ml. aliquot of the chloroform solution was reacted with 0.5 ml. of a 0.1% w/v solution of diethyldithiocarbamate in *n*-butanol. The blue color which developed was read on a Bausch and Lomb Spectronic-20 colorimeter at 437 $m\mu$ using chloroform, treated in an identical manner, as the blank. All fatty acid salts under investigation followed the Beer-Lambert relationship.

The amount of bile salt or fatty acid salt bound to cholestyramine was calculated from the difference between the initial concentration of adsorbate introduced into the system and the concentration present free in solution at equilibrium.

RESULTS AND DISCUSSION

All adsorption experiments were conducted in aqueous solution. Under these conditions, the pH of the systems after equilibration with cholestyramine was essentially independent of initial adsorbate concentration. Based on reported pKa values (4) for the bile acids employed in this study,⁷ at concentrations below their respective critical micelle concentrations, it was previously determined (1) that the bile salts were present essentially in the ionized form.

There is scanty information in the literature pertaining to the pKa values of long-chain fatty acids. Ralston (5) reports that small decreases in dissociation constants of fatty acids are noted with increasing molecular weight. Using a method for apparent pKa determination described by Guntow (6), the apparent pKa's for

⁷ Ekwall *et al.* (4) report pKa values of 4.99 for lithocholic acid and 4.91 for dehydrocholic acid. Using the equilibrium pH's of 6.66 for the glycolithocholate system and 6.30 for that of the glycodehydrocholate system, percentages ionized were calculated to be 97.9 and 96.1%, respectively. Since the pKa values of glycine conjugates are normally lower than those of the unconjugated bile salts (9), the use of the reported lithocholic and dehydrocholic acid pKa's is a justifiable approximation.

⁶ Precision Constant Temperature Shaker Bath, Precision Scientific Co., Chicago, Ill.

Figure 3—Langmuir adsorption isotherm for the binding of the glycodehydrocholate anion to cholestyramine at 25°.

lauric, oleic, and linoleic acids were found to be 4.92, 5.35, and 5.10, respectively. The value obtained for oleic acid is similar to that reported for stearic acid (7) ($pK_a = 5.75$ at 35°), while that of lauric acid is in close agreement with the 4.96 value reported by Markley (8) for nonanoic acid. These experimental values, together with equilibrium pH's (laurate, 6.90; oleate, 6.30; linoleate, 6.10), were used in the Henderson-Hasselbach equation to obtain values of 98.9, 91.3, and 91.0% ionized, respectively. Using this

Figure 4—Langmuir adsorption isotherms for the binding of glycine-conjugated, hydroxy-substituted bile salt anions to cholestyramine at 25°. Key: glycocholate (○), glycodeoxycholate (□), and glycolithocholate (●).

Figure 5—Langmuir adsorption isotherms for the binding of fatty acid salt anions to cholestyramine at 25°. Key: laurate (□), oleate (●), and linoleate (○).

as a first approximation, the fatty acids under study were considered to be completely ionized.

Adsorption Studies—The adsorption isotherms describing the binding of the investigated bile salt and fatty acid salt anions to cholestyramine were plotted according to the following Langmuir equation (10) and are shown in Figs. 1 and 2.

$$x/m = \frac{k_1 k_2 (C_{eq.})}{1 + k_1 (C_{eq.})} \quad (\text{Eq. 1})$$

where $C_{eq.}$ = the concentration of adsorbate molecules remaining in solution at equilibrium, x/m = the number of moles of adsorbate bound per gram of adsorbent, k_1 = the association or affinity constant, and k_2 = the capacity constant. The general shape of the x/m versus $C_{eq.}$ plots is representative of only monolayer adsorption (11). The curves show a tendency to plateau at high $C_{eq.}$ values, indicating that the system is approaching the limiting monomolecular-exchange capacity of cholestyramine for the particular adsorbate molecule.

Figures 3–5 represent the data plotted according to a rearranged form of Eq. 1:

$$\frac{(C_{eq.})}{x/m} = \frac{1}{k_1 k_2} + \frac{(C_{eq.})}{k_2} \quad (\text{Eq. 2})$$

The linearity observed with all adsorbate anions under study demonstrates the adherence of the binding process to the Langmuir-type adsorption isotherm (Eq. 2). The adsorption constants, k_1 and k_2 , were obtained from the least-squares intercept and slope values of a regression line drawn through the data points and are reported in Table I.

Except for the glycodehydrocholate anion, the capacity constants, k_2 (expressed as the number of moles of anion adsorbed per mole equivalent of cholestyramine), all demonstrate a tendency toward unity. As a possible explanation of glycodehydrocholate's behavior, it is suggested that hydration, expected of the polar substituents on the phenanthrene ring system, would be more extensive with this bile salt due to the greater polarity induced by the presence of the three keto substituents (12). This could lead to enhanced steric hindrance and possible occlusion of neighboring binding positions, thus resulting in the reduced capacity observed.

An examination of the affinity constants, k_1 , for the bile salt series shows an increase in the following order: glycodehydrocholate (triketo) < glycocholate (trihydroxy salt) < glycodeoxycholate (dihydroxy salt) < glycolithocholate (monohydroxy salt). Since all of the bile salt anions are glycine conjugates, the observed differences cannot be related to changes in the structure of the side chain. Reduction in steric hindrance in the ring structure when going from tri- to monohydroxy salts cannot, in and of itself, be responsible for the observed affinity differences, nor is it reasonable to assume that substitution of hydroxy groups by keto functions can cause any appreciable effects on the anionic charge strength.

Table I—Langmuir Adsorption Constants for the Binding of Conjugated Bile Salt and Fatty Acid Salt Anions to Cholestyramine at 25°

Anion	k_1 (l./mole of Adsorbate, $\times 10^{-4}$)	$(k_2)^a$ (Moles of Adsorbate Bound per Mole Equivalent of Resin)	Apparent Surface Tension Lowering (dynes/cm.)
Bile salt			
Glycodehydrocholate	0.163	0.593	7.9 ^b
Glycocholate	0.891	0.863	12.0
Glycodeoxycholate	4.25	0.941	23.7
Glycolithocholate	5.70	1.12	36.6
Fatty acid salt			
Laurate	5.23	0.892	10.8 ^c
Oleate	7.39	1.01	38.0
Linoleate	1.92	1.03	31.8

^a Based on a monomer equivalent weight for cholestyramine of 230.

^b Based on surface tension determinations of 2.0 mM bile salt solutions.

^c Based on surface tension determinations of 0.25 mM fatty acid salt solutions.

As stated earlier, the presence of three keto groups in the glycodehydrocholate system confers a greater hydrophilic character to this anion (12). This increased hydrophilicity would lead to a more extensive association of glycodehydrocholate with water molecules, thus producing an anion possessing larger molecular dimensions than the less hydrated hydroxy derivatives. The increased bulkiness of the glycodehydrocholate molecule could effectively prevent the close proximity of this adsorbate to the binding positions on cholestyramine and hence reduce the possibility for a significant degree of interaction. This results from the fact that the strength of the forces involved in the adsorbate-adsorbent interaction would tend to decrease with increasing separation of the two reactants. The results obtained in the present investigation are consistent with ion-exchange phenomenon in general, in that ion-exchange resin selectivity, which is related directly to the strength of adsorbate-adsorbent interaction (13), decreases as the extent of hydration of the adsorbate increases (14). In addition, the fact that the triketosubstituted bile salts exhibit negligible tendencies to undergo micelle formation as compared with hydroxy-substituted derivatives (15) would seem to indicate that their participation in nonpolar interactions, in general, is rather limited. The interrelated effects of an increase in the molecular dimensions due to the increased hydration of this adsorbate molecule and a decrease in its capability of significant nonpolar interactions with the resin matrix are probably responsible for the diminution in the affinity observed with the glycodehydrocholate-cholestyramine interaction.

The data clearly suggest that the primary electrostatic interaction (*i.e.*, between the anionic carboxyl group of the bile salt and the cationic quaternary ammonium group of cholestyramine) is being reinforced by secondary, nonelectrostatic binding forces existing between the hydrophobic portions of the bile salt and resin molecules. As the degree of polarity of the ring system, and hence the degree of hydration, increase (glycolithocholate < glycodeoxycholate < glycocholate < glycodehydrocholate), the hydrophobicity, and hence the strength of the nonelectrostatic component of the interaction, diminish. These results parallel those obtained by Rudman and Kendall (16) who investigated the interaction of a series of bile salts with the protein, albumin. This phenomenon was also qualitatively alluded to in the work of Gordon *et al.* (17), in which the hydroalcoholic, chromatographic elution sequence of conjugated bile acids from a column composed of the acetate form of an anion-exchange resin (Dowex 1-X2) was studied.

The adsorption characteristics of a series of physiologic, long-chain fatty acid salts were examined to establish whether or not a similar secondary, nonelectrostatic binding mechanism was operable. The k_1 values for the laurate and oleate anions, listed in Table I, show an increase in affinity with increasing chain length. Consistent with these results, the studies of Boyer *et al.* (18) and Ballou *et al.* (19) demonstrated an intensification of fatty acid interaction with albumin as the chain length of the adsorbate molecule increased. In connection with fatty acid-albumin binding, Goldstein

(20) states that "... the primary bond is presumably electrostatic, but the resulting complex is probably stabilized by van der Waals' forces through the close approximation of the nonpolar residue to similar portions of adjacent protein surfaces." The increase of six carbons, in the case of the oleate anion over that of the laurate anion, confers to the former anion a higher degree of hydrophobic character (even in the presence of the hydrophilic double bond) which results in a magnification of the strength of interaction.

The introduction of a second double bond into the adsorbate molecule, as in the linoleate system (9,12-diene), produced a marked decrease in the affinity constant relative to the oleate anion. The increase in the hydrophilicity of the carbon chain, and thus a weakening of the strength of the nonelectrostatic component of the interaction, could account for the observed reduction in the affinity. In addition, the presence of a second alkene linkage might contribute to this reduction by placing steric restrictions on the mobility of the linoleate molecule; the *cis-cis* configuration of the molecule prohibiting the proximity of adsorbate and adsorbent molecules required for significant nonionic interaction.

Desorption Studies—Under the experimental conditions employed, the studies designed to determine the dissociation or desorption characteristics of the adsorbent-adsorbate complexes showed the binding process to be essentially nonreversible.

Surface Tension Studies—The bile salt and fatty acid anions employed in this investigation all possess surface-active properties in aqueous solution and, as a result, have some facility to concentrate at interfaces. In general, the degree of surface activity elicited is dependent on the existence of a proper balance between the hydrophilic and hydrophobic regions of the molecule, normally increasing with increasing hydrophobicity (21). Since it was the objective of this investigation to establish the role of a secondary, nonelectrostatic type of interaction in the binding process, it was of interest to determine the air-water surface adsorption tendencies of the various bile salt and fatty acid anions. The purpose, therefore, of these surface tension studies was to ascertain whether a parallelism existed among the degree of hydrophobicity of the adsorbate molecules, their binding affinity, and their surface tension-lowering properties.⁸

In Table I are listed the apparent surface tension-lowering (π) values obtained for the various salts under investigation. A comparison of the bile salt values with their respective affinity constants shows that an excellent rank order correlation exists between the two parameters. Likewise, the surface activity of the laurate and oleate systems compares well with their respective k_1 values.

The deviation of the linoleate system from the parallelism found to exist with the other fatty acid salts is thought to be due to the molecular structure of that fatty acid salt. The adsorption process, being heavily dependent on proper steric alignment for maximum nonelectrostatic interaction, would be seriously hindered by the *cis-cis* configuration offered by the linoleate anion. However, the surface tension properties of this anion would not be as drastically affected, since the nonpolar portions of the molecule would be capable of assuming any packing arrangement at the air-water interface commensurate with maximum thermodynamic stability. In addition, it is possible that a minor quantity of contamination was present in the linoleate system. Such an occurrence could produce a significant change in the surface tension-lowering capabilities of the salt below the CMC (22), while at the same time having only negligible effects on the binding characteristics of the anion.

The results of this investigation indicate that the affinity with which fatty acid and bile salt anions bind to cholestyramine is, in part, dependent on the extent of hydrophobic character of the adsorbate anion. A relationship was found to exist between the surface activity of adsorbate molecules, with the exception of linoleate, and the strength of the adsorbate-cholestyramine interactions as reflected by the magnitudes of the association constants for the respective complexes.

Apparently a similar interaction mechanism is functioning in both the bile salt and fatty acid salt series. It would not be unrealistic, therefore, to imagine an *in vivo* situation where a competition existed between endogenous bile salts and exogenous fatty

⁸ It should be pointed out that the authors do not intend to imply that possession of surface activity is a necessary prerequisite for significant interaction with cholestyramine.

acids, the latter being present either in food or generated in the small intestine by the action of digestive enzymes on dietary triglycerides. Such a competition, depending on the nature and relative concentration of the fatty acid, could cause a reduction in the therapeutic efficiency of cholestyramine to sequester certain bile salt anions. Studies to determine the nature and extent of any competition which may exist between bile salt anions and other physiologic substances for the binding positions on cholestyramine are in progress and will be the subject of subsequent communications.

Flexible Nonisothermal Stability Studies

H. V. MAULDING and M. A. ZOGLIO

Abstract □ A method is described which allows *ad libitum* temperature adjustment during the course of a nonisothermal kinetic study. The data obtained are compared to theoretical degradation patterns to obtain from a single experiment activation energy, reaction rates, and stability predictions at any desired temperature. The inversion of sucrose and the hydrolysis of ethyl acetate are studied to demonstrate the validity of the theory and the advantages of the method.

Keyphrases □ Stability studies—flexible, nonisothermal □ Kinetic equations—flexible nonisothermal stability studies □ Sucrose inversion—nonisothermal stability methodology □ Ethyl acetate hydrolysis—nonisothermal stability methodology □ Polarimetry—analysis

The field of nonisothermal kinetics has grown considerably in popularity since the classic treatment by Rogers (1) was published in 1963. Since then numerous publications have appeared in the literature utilizing nonisothermal techniques (2, 3). Others have introduced new ideas and techniques to the field (4, 5). The objective of this study is to eliminate the need for a fixed time-temperature profile during the course of a nonisothermal study. The advantages of such an approach lie in the

freedom to change temperature at a rate consistent with analytical findings and also in minimizing experimental requirements. The method involves the subjection of a solution of the substance for study to changing temperature to provide sufficient breakdown for calculation of activation energy, reaction rates, and stability predictions. The degradation is controlled by adjusting the rate of change of temperature according to analytical findings during the experiment. The time-temperature data are fitted to a polynomial expression of sufficient degree to describe the changes. This relationship and the experimental data are then combined and utilized to synthesize a series of degradation pathways corresponding to different levels of activation energy. The curves are compared to the experimental analytical data to obtain the correct energy of activation for the reaction. Utilizing this activation energy and the analytical data, reaction rate and stability calculations can be made.

THEORETICAL

Consider a drug in solution degrading according to some unchanging reaction order as in Fig. 1. Drug concentration can then

acids, the latter being present either in food or generated in the small intestine by the action of digestive enzymes on dietary triglycerides. Such a competition, depending on the nature and relative concentration of the fatty acid, could cause a reduction in the therapeutic efficiency of cholestyramine to sequester certain bile salt anions. Studies to determine the nature and extent of any competition which may exist between bile salt anions and other physiologic substances for the binding positions on cholestyramine are in progress and will be the subject of subsequent communications.

Flexible Nonisothermal Stability Studies

H. V. MAULDING and M. A. ZOGLIO

Abstract □ A method is described which allows *ad libitum* temperature adjustment during the course of a nonisothermal kinetic study. The data obtained are compared to theoretical degradation patterns to obtain from a single experiment activation energy, reaction rates, and stability predictions at any desired temperature. The inversion of sucrose and the hydrolysis of ethyl acetate are studied to demonstrate the validity of the theory and the advantages of the method.

Keyphrases □ Stability studies—flexible, nonisothermal □ Kinetic equations—flexible nonisothermal stability studies □ Sucrose inversion—nonisothermal stability methodology □ Ethyl acetate hydrolysis—nonisothermal stability methodology □ Polarimetry—analysis

The field of nonisothermal kinetics has grown considerably in popularity since the classic treatment by Rogers (1) was published in 1963. Since then numerous publications have appeared in the literature utilizing nonisothermal techniques (2, 3). Others have introduced new ideas and techniques to the field (4, 5). The objective of this study is to eliminate the need for a fixed time-temperature profile during the course of a nonisothermal study. The advantages of such an approach lie in the

freedom to change temperature at a rate consistent with analytical findings and also in minimizing experimental requirements. The method involves the subjection of a solution of the substance for study to changing temperature to provide sufficient breakdown for calculation of activation energy, reaction rates, and stability predictions. The degradation is controlled by adjusting the rate of change of temperature according to analytical findings during the experiment. The time-temperature data are fitted to a polynomial expression of sufficient degree to describe the changes. This relationship and the experimental data are then combined and utilized to synthesize a series of degradation pathways corresponding to different levels of activation energy. The curves are compared to the experimental analytical data to obtain the correct energy of activation for the reaction. Utilizing this activation energy and the analytical data, reaction rate and stability calculations can be made.

THEORETICAL

Consider a drug in solution degrading according to some unchanging reaction order as in Fig. 1. Drug concentration can then

Figure 1—Hypothetical drug degradation in solution during a flexible nonisothermal experiment.

be considered to be a time-dependent function, where the instantaneous rate of change of drug concentration is related to the total loss in drug concentration by the following expression:

$$f(b) - f(c) = \int_c^b f'(t) dt \quad (\text{Eq. 1})$$

where $f'(t)$ represents drug concentration as a function of time. Dividing both sides of Eq. 1 by $(b - c)$ yields

$$\frac{f(b) - f(c)}{b - c} = \frac{\int_c^b f'(t) dt}{b - c} \quad (\text{Eq. 2})$$

If t_c to t_b is divided into two equal increments,

$$\frac{f(b) - f(c)}{b - c} = \frac{[f(b) - f(f)/(b - c)/2] + [f(f) - f(c)/(b - c)/2]}{2} \quad (\text{Eq. 3})$$

which is equivalent to saying that the tangent of triangle abc is equal to the arithmetic average of the tangents of triangles aed and ebf . If this concept is extended to include more triangles of equal base, the tangents of these triangles will approach slopes on the curve aeb as the number of triangles is increased. This is a somewhat intuitive way of looking at the following expression:

$$\frac{f(b) - f(c)}{b - c} = \frac{k_1 + k_2 + k_3 + \dots + k_i + \dots + k_n}{n} \quad (\text{Eq. 4})$$

where k_i represents the slope of the i th triangle and n equals the number of triangles being considered. Since each triangle describes some equal and individual interval Δt , the question is raised as to how large a value of n is needed for the tangent of each triangle to approach the slope on the curve aeb for each interval Δt .

Consider the zero-order case where

$$-k_i = \frac{C_{(i+1)} - C_i}{t_{(i+1)} - t_i} \quad (\text{Eq. 5})$$

C here representing concentration. If Δt is very small the slope over this interval could approximate the rate over an isothermal interval. The rate constant corresponding to k_i of Eq. 4 may be represented by the following expression,

$$k_1 = a^* e^{-E/RT_1} \quad (\text{Eq. 6})$$

where E is activation energy, R is the universal gas constant, and T is temperature.

The concentration at the end of the first interval would be

$$C_1 = C_0 - a^* \Delta t e^{-E/RT_1} \quad (\text{Eq. 7})$$

If the temperature is changed to T_2 for the same increment of time and then to T_3 and so on, then after n increments the concentration would be

$$C_n = C_0 + \sum_{i=1}^n -\Delta t a^* e^{-E/RT_i} \quad (\text{Eq. 8})$$

Therefore,

$$\frac{C_n - C_0}{n \Delta t} = \frac{a^*}{n} \sum_{i=1}^n -e^{-E/RT_i} = \bar{k}_n \quad (\text{Eq. 9})$$

where k_n represents the average rate constant for n discrete values. For the time interval t_c to t_b of Fig. 1, temperature will most likely be related to time in a manner which can be described mathematically. The assumption is thus made that

$$T_i = G(t_i) \quad (\text{Eq. 10})$$

where the relationship can be obtained perhaps by some polynomial-fitting technique. Consider the function

$$-\left(\frac{a^*}{t_b - t_c}\right) e^{-E/RG(t_i)} \quad (\text{Eq. 11})$$

An upper Rieman sum for the interval t_c to t_b would be

$$\sum_{i=1}^n -\frac{(t_b - t_c)}{n} \left(\frac{a^*}{t_b - t_c}\right) e^{-E/RG(t_i)} = \frac{a^*}{n} \sum_{i=1}^n -e^{-E/RG(t_i)} \quad (\text{Eq. 12})$$

As the value of n approaches infinity, this sum will approach

$$-\frac{1}{t_b - t_c} \int_{t_c}^{t_b} a^* e^{-E/RG(t)} dt = \bar{k} \quad (\text{Eq. 13})$$

which implies through Eqs. 2 and 4 that for very large n a discrete curve over the interval t_c to t_b should approach the smooth curve, and the average value of k should not differ significantly from the quantity

$$\frac{f(b) - f(c)}{b - c}$$

Figure 2—Time-temperature relationship for nonisothermal acid-catalyzed inversion of sucrose (a). Key: ●, mathematical fit; and ○, experimental points.

Table I—Convergence for the Acid-Catalyzed Inversion of Sucrose (Experiment a) for the Expression

$$\left\{ 1 + \sum_{i=2}^n \exp E/R[(T_i - T_1)/(T_i T_1)] \right\} / n$$

Value of n	Value of Expression for				
	$E = 10$ kcal.	$E = 15$ kcal.	$E = 20$ kcal.	$E = 25$ kcal.	$E = 30$ kcal.
100	1.228	1.360	1.512	1.684	1.883
200	1.222	1.355	1.504	1.676	1.874

In order to utilize Eq. 4, the magnitude of n needed for the equation to be of use must be determined. If all rates in Eq. 4 are expressed in terms of one rate (k_1), then

$$\frac{f(b) - f(c)}{b - c} = \{k_1 + k_1 \exp E/R[(T_2 - T_1)/(T_1 T_2)] + \cdots \times k_1 \exp E/R[(T_i - T_1)/(T_i T_1)] + \cdots k_1 \exp E/R[(T_n - T_1)/(T_n T_1)]\} / n \quad (\text{Eq. 14})$$

which may be expressed as

$$\frac{f(b) - f(c)}{b - c} = k_1 \left\{ 1 + \sum_{i=2}^n \exp E/R[(T_i - T_1)/(T_i T_1)] \right\} / n \quad (\text{Eq. 15})$$

The convergence of the expression

$$\left\{ 1 + \sum_{i=2}^n \exp E/R[(T_i - T_1)/(T_i T_1)] \right\} / n$$

for various values of E at increasing levels of n can be used to find a value for n . Upon obtaining n , Eq. 15 can be used to calculate k_1 for a particular activation energy. The remaining rates necessary to synthesize a model degradation pathway for this energy of activation are calculated through the Arrhenius equation. The calculations are repeated for a series of activation energy values to obtain a family of degradation pathways. The experimental degradation pathway is then compared to the theoretical pathways to obtain the energy of activation for the reaction. Rates can be calculated using Eq. 15 and the Arrhenius equation. Stability predictions can then be made by integration of the proper rate equations. The arguments presented in the theory are applicable to reaction orders other than zero and can be realized through the same type of reasoning.

EXPERIMENTAL

Sucrose—A 40% w/v sucrose solution in distilled water was prepared and 400 ml. of this solution thoroughly mixed with 200 ml. 0.05 N HCl. Aliquots (30 ml.) of this stock solution were pipeted into 50-ml. ampuls which were flame sealed and immersed in a water bath. The water bath was fitted with a thermoregulator¹ and thermometer (0.1° graduations). The thermometer was immersed in an unsealed ampul containing the reaction mixture for determination of the temperature inside the reaction solution. Sufficient time was allowed for equilibration of the temperature in the reaction solution before the nonisothermal run was begun. Following temperature equilibration an initial sample was taken and the water bath temperature was increased by manual manipulation of the thermoregulator at an appropriate rate, with samples being removed for analysis at convenient intervals and the temperature continuously recorded.

For analysis the ampuls were cooled and opened, and the solution was diluted with 50 ml. 0.1 N NaOH. This solution was read on a polarimeter² using the sodium D line. Sucrose concentration is directly proportional to $(\alpha_t - \alpha_\infty)$ where α is the optical rotation. The rotation at time infinity, α_∞ , is determined by heating a sample at 90° for 2–3 hr., diluting with 0.1 N NaOH, and reading in the usual manner.

² Model 70 polarimeter, O. C. Rudolph and Sons Inc., Caldwell, N. J.

Figure 3—Model degradation curves for nonisothermal acid-catalyzed inversion of sucrose (a). Key: ---, experimental data.

Ethyl Acetate—A solution of 25 ml. (22.45 g., 0.255 mole) of ethyl acetate in 500 ml. 0.1 N HCl was prepared (0.5096 mole/l.) and 25-ml. aliquots pipeted into 50-ml. ampuls which were heat sealed. These ampuls were immersed in a water bath fitted with a thermoregulator and thermometer (0.1° graduations). The thermometer was immersed in one of the unsealed ampuls containing the ethyl acetate solution, and the temperature of this solution was allowed to become constant. An initial sample was taken and the nonisothermal run was begun by hand manipulation of the thermoregulator at an appropriate rate of temperature increase. Samples were taken for analysis at convenient times and the temperatures continuously recorded.

The ampuls were quickly cooled under ice water. Five milliliters of solution was pipeted into a 250-ml. conical flask containing 50 ml. ice water and the flask immersed in ice water. A titration with 0.05 N NaOH was then performed using phenolphthalein as the indicator. Correction was made for the initial HCl content of the solution, with the remainder of NaOH consumed being proportional to the amount

of acetic acid present. The average value of three titrations per sample was taken and the moles of acetic acid present calculated and subtracted from the ethyl acetate initially in solution for use in the first-order calculations.

RESULTS AND DISCUSSION

The time-temperature relationship for the acid-catalyzed inversion of sucrose is illustrated in Fig. 2. This relationship is described by the following polynomial expression,

$$\text{temp.} = 311.66 + 1.7482t + 0.086257t^2 - 0.013662t^3$$

When the expression was utilized to calculate the number of rates necessary to describe a degradation curve adequately for the experiment, 200 rates were found necessary. The criterion used to determine convergence was a change of less than 1% with an increase in *n* of 100 in the value of that portion of Eq. 15 used to test convergence. The convergence for this experiment is shown in Table I.

The model degradation pathways for the five activation energies considered in Table I were calculated and are represented in Fig. 3. Hours 1–3 of the experiment are represented. The model curves tend to lie very close to each other for the early and final stages of the experiment and do not contribute to an accurate activation energy determination. The experimental points are averages of results from six separate samples and yield an activation energy of about 28 kcal. This is slightly higher than the reported values of 25–27 kcal. (6).

The time-temperature relationship for the acid-catalyzed hydrolysis of ethyl acetate is shown in Fig. 4. The relationship can be de-

Figure 5—Model degradation curves for nonisothermal acid-catalyzed hydrolysis of ethyl acetate. Key: ▼, experimental curve; and ○, model curves.

Table III—Convergence for the Acid-Catalyzed Inversion of Sucrose (Experiment b) for the Expression

$$\left\{ 1 + \sum_{i=2}^n \exp E/R[(T_i - T_1)/(T_i T_1)] \right\} / n$$

Value of <i>n</i>	Value of the Expression for—				
	<i>E</i> = 10 kcal.	<i>E</i> = 15 kcal.	<i>E</i> = 20 kcal.	<i>E</i> = 25 kcal.	<i>E</i> = 30 kcal.
100	1.454	1.755	2.126	2.587	3.158
200	1.448	1.749	2.119	2.579	3.150

scribed by the following polynomial expression,

$$\text{temp.} = 305.26 + 4.4450t + 1.6114t^2 - 2.2298t^3 + 0.98356t^4 - 0.070209t^5 + 0.011573t^6 - 0.034019t^7 + 0.0076531t^8$$

The convergence testing for this experiment is shown in Table II and resulted in a value of 200 rates to describe adequately the model degradation curves.

The model curves for this experiment are shown in Fig. 5 for hours 0.45–2.55 of the 3-hr. experiment. Segments of the model curves were eliminated for the reasons given for the sucrose experiment. Since the analytical points in this experiment were scattered, they were averaged and fitted to a second-degree polynomial to yield the smooth experimental curve shown in Fig. 5. The activation energy is approximately 17 kcal., which is in good agreement with the values of 16.5–17.3 kcal. reported in the literature (7).

The time-temperature profile of a second sucrose inversion experiment is given in Fig. 6. This experiment was essentially a test of the limits of flexibility of this method. A fair mathematical fit to this time-temperature relationship is given by the following equation,

$$\text{temp.} = 311.23 + 54.445t - 20.70t^2 - 350.95t^3 + 406.57t^4 + 187.83t^5 + 50.62t^6 - 899.25t^7 + 776.93t^8 - 193.08t^9$$

The convergence testing for this experiment showed a requirement of 200 rates to describe degradation. The results are given in Table III.

The rapid convergence is probably due to the brevity of the experiment. The model curves for the experiment are shown in Fig. 7. The experimental curve is not as smooth as in the first sucrose experiment, but the activation energy of about 27 kcal. is in good agreement with the sucrose experiment. The model curves for this experiment are drawn for hours 0.45–0.9 of the experiment. The tendency of the curves to group very closely together at the beginning and second half of the experiment was the reason for their elimination. In the three experiments the assumption of first order was made. Reaction orders other than first are handled by choosing the proper concen-

tration function for calculation of model degradation pathways. The calculations in the study were performed utilizing a quiktran terminal.³

SUMMARY

A method which eliminates the disadvantages of fixed time-temperature relationships in nonisothermal kinetic studies has been developed. The investigator utilizing this method may change temperature during the experiment to fit analytical findings. The

data obtained from the single experiment allow calculation of activation energy, reaction rate, and shelf-life prediction. To obtain this information a series of theoretical degradation pathways are synthesized by utilizing the experimental time-temperature relationship and initial and final analytical points. The concentration-time plot for degradation is then compared to the model curves to obtain the energy of activation for the reaction. Calculations using analytical data and the activation energy are then used to determine reaction rates and stability predictions at desired temperatures. In addition to the flexibility of temperature adjustment introduced, the advantages of the method lie in the use of a single experimental unit, the analysis of one set of samples, the shorter time required for completion of the experiment, and the use of readily available laboratory equipment. Disadvantages (8) lie in the need for a separate experiment to determine the order of the reaction, the nonapplicability of the technique in situations where equations cannot be made linear (as in equilibria), the need to compensate for ionic strength effect with change in temperature, and the sometimes difficult task of fitting an equation to the experimental time-temperature data. The approach is also limited by assay precision, constancy of activation energy, and applicability of the Arrhenius equation.

Preparation and Evaluation of the Prolonged Release Properties of Nylon Microcapsules

L. A. LUZZI, M. A. ZOGLIO*, and H. V. MAULDING*

Abstract □ A method for *in situ* preparation of nylon encapsulated sodium pentobarbital by emulsion polymerization is reported. This was followed by work-up of the microcapsules by one of two processes: (a) spray drying and (b) vacuum drying. However, somewhat different properties were noted when the free-flowing spray-dried substance was compared to that which had been vacuum dried. Nylon capsules produced in these manners containing sodium pentobarbital exhibited a considerable reduction in dissolution rates relative to the instantaneously soluble barbiturates when examined in distilled water, 0.1 M phosphate buffer, pH = 6.75, and 0.1 N HCl. When the microcapsular material was tableted, the release rate of the sodium pentobarbital was seen to be inversely proportional to tablet hardness.

Keyphrases □ Nylon microcapsules—release rate, preparation □ Sodium pentobarbital—microcapsule preparation, polymerization □ Release rate—sodium pentobarbital nylon microcapsules □ UV spectrophotometry—analysis

As a method of protecting or prolonging the release of drugs, microencapsulation has intrigued pharmaceutical scientists (1–3) for several years. The first patented use of microcapsules was made by Green and Schleicher (4, 5) to prepare “carbonless carbonpaper.” They made use of a gelatin–acacia coacervate system (6) to entrap emulsified oil droplets containing dissolved dyes. In 1967, Luzzi and Gerraughty (2, 7) developed a method for the evaluation of drug-containing capsules prepared *via* complex coacervation.

Miller and Anderson (8) were granted a U. S. patent for the manufacture of microcapsules using “hydrophobic film-forming polymeric wall materials dispersed in a liquid manufacturing vehicle.” This patent claims as “an unsuspected virtue . . . the encapsulation of aspirin” in ethylcellulose microcapsules. The authors state that aspirin was encapsulatable since it was wettable by cyclohexane. A further, and most interesting, statement made in this patent is that the thickness of the microcapsule wall can be controlled by changing the relative quantity of shell-forming material.

Chang *et al.* (9) prepared semipermeable nylon-shell microcapsules containing an erythrocyte hemolysate and, later (10), published information concerning the use of this type of microcapsule in an extracorporeal shunt system. In this system, the authors assert that capsules prepared in such a manner will allow passage of plasma through the capsule wall, thus allowing contact with the encapsulated material.

The findings, by the above authors, indicate that encapsulation is possible by several systems. There is, however, little indication of work done on encapsulation and evaluation of pharmaceuticals, especially with nylon as the encapsulating medium. In this respect, then, this investigation was designed to encapsulate a drug in a nylon membrane and to evaluate the

resultant capsular material as it may pertain to pharmaceutical dosage forms.

EXPERIMENTAL

Preparation of Nylon Microcapsules—The method of Chang *et al.* (9), with certain modifications, was used to prepare nylon microcapsules containing sodium pentobarbital. The basic solutions included: (a) mixed solvent system consisting of 1 part by volume chloroform (reagent grade) and 4 parts by volume cyclohexane (reagent grade); (b) 0.16% sebacyl chloride (Eastman Organic Chemicals) in part of the above mixed solvent system; (c) 1% commercial emulsifier¹ also in part of the mixed solvent; (d) an aqueous solution of 2% methylcellulose² (50 cps.), and (e) an aqueous solution consisting of 2% sodium pentobarbital and 6.75% of 1,6-hexamethylenediamine (Eastman Organic Chemicals).

The procedure for the preparation of the product consisted of slowly adding at low speed³ a mixture of equal volumes (25 ml.) of the methylcellulose and sodium pentobarbital–hexamethylenediamine solutions, then adding 165 ml. of the mixed solvent–surfactant solution, and blending for approximately 30 sec. at low speed. Sebacyl chloride solution (165 ml.) was added and blended at high speed for 10 sec. and then for 1 min. at low speed to complete the nylon-producing reaction. The capsules were allowed to settle and the supernatant was removed.

Spray-Drying Process—A Nerco-Niro portable spray dryer equipped with a special nozzle adapter atomizing assembly (Nichols Engineering and Research Corp.), a Zero-Max Sigma-motor assembly, and a vacuum exhaust system attached to the dryer were used to effect drying.

In order to prepare the mixture for the spray-drying process, approximately 15 ml. of chloroform was added to the slurry remaining after decantation. The resultant dilution was constantly agitated while liquid remained in the feed flask in order to maintain a uni-

form flow of solids to the spray dryer. The internal temperature of the dryer was maintained at 125° throughout the drying process.

The collected powder was placed in a vacuum oven at 35° for 10–12 hr. to remove residual solvent and moisture. The resultant free-flowing powder containing 7.6% sodium pentobarbital was divided into several lots. One portion was examined as the free-flowing powder and the other portions were tableted so as to yield a range of tablet hardnesses prior to examination. Tablets were prepared by power compression on a single punch tableting machine (Stokes model E). Five hundred to one thousand tablets of each hardness were prepared with care taken to maintain a hardness variation of approximately ± 0.5 . Hardness was measured on a model B, Strong Cobb Arner tablet hardness tester.

Flash Evaporation Process—The wet slurry consisting of the microcapsule material and the vehicle which remained after decantation (along with the chloroform) was placed into a flash evaporator at 35° for 24 hr. The resultant dry material containing 7.6% sodium pentobarbital was held together loosely and was not dense.

Assay Methods—A Cary model 14 recording spectrophotometer was used to determine the concentration of sodium pentobarbital in each case. The wavelength of maximum absorption was found at $240\text{ m}\mu$, and all measurements were made at this wavelength while employing appropriate blanks. The same basic procedure was used to detect solubilized sodium pentobarbital regardless of the form of the drug being tested.

The following is the assay procedure used to study dissolution. A 200-mg. sample of free-flowing microcapsular powder or a 200-

Figure 4—Release rate of sodium pentobarbital from microcapsules prepared via evaporation and suspended in various aqueous media. Key: \circ , in 0.1 N HCl; \square , in H_2O ; \triangle , in 0.1 M PO_4 ; and \circ , nonencapsulated sodium pentobarbital.

mg. tablet was placed in a 150-ml. beaker and 100 ml. of liquid (0.1 N HCl, 0.1 M KH_2PO_4 -KOH buffer, pH 6.75, ionic strength 0.2, or distilled water) was added and the mixture stirred at a constant rate of 6 r.p.m., using a Bodine electric speed reducing motor (Bodine Electric Co.). The temperature was maintained at 37° and the beaker covered with aluminum foil. One-milliliter filtered samples were removed at the time intervals indicated in the various figures and appropriate dilutions were made employing 0.1 N NH_4OH .

Table I—Rates^a (*K*) of Dissolution for Tablets of Various Hardness in Three Liquid Media

Tablet Hardness	Liquid Medium	<i>K</i> hr. ⁻¹	Time Measured, hr.
8	0.1 <i>M</i> HCl	5.01	9.0
8	0.1 <i>M</i> PO ₄	4.12	9.0
8	H ₂ O	3.81	9.0
5	0.1 <i>M</i> HCl	7.13	8.0
5	0.1 <i>M</i> PO ₄	4.28	8.0
5	H ₂ O	5.54	9.0
2	0.1 <i>M</i> HCl	14.37	1.5
2	0.1 <i>M</i> PO ₄	15.22	3.0

^a First-order rates are used for comparative analysis of results. The order of release cannot be established by the data presented in this study although there appears to be a trend toward first order.

Total Concentration—In order to be able to make a comparison of the amount of active ingredient released to that contained, 100 mg. of the microcapsular powder was placed in a blender and 500 ml. of 0.1 *N* NH₄OH was added. The blender was run for 5 min. at high speed and a clear liquid collected through a 0.45- μ filter. The absorbance was taken and compared to a standard.

Analysis of Data—An IBM 360 model 50 computer was used. The equations were standard and readily available (11).

Particle Size—Determination of particle distribution was carried out by using a Coulter Counter model B equipped with a model M volume converter. A 30- μ aperture tube, 2% sodium chloride, and a ragweed pollen standard (19.5 μ mean diameter) were used in this determination. No attempt was made to separate particles into definite ranges nor were other particle size distributions employed.

RESULTS AND DISCUSSION

Only one particle size range of spray-dried microcapsular material was used in this experiment. Figure 1 is a log-probability plot of the particles which shows that a statistically normal distribution was found. The geometric mean diameter was 10 μ with an arithmetic mean diameter of 12.08 μ . The vacuum-dried material did not, however, show a normal particle distribution, but contained particles as estimated microscopically ranging from about 1.0 to about 100.0 μ with 90% greater than 25.0 μ .

Figure 2 is a photomicrograph⁴ of a typical grouping of spray-dried nylon-membraned microcapsules. It can be seen that the particles are not spherical and that, in most cases, several particles are clumped together. Figure 3 is a photograph of nylon-membraned

microcapsules before drying. The particles here are generally spherical and clumping is minimal; no coalescence of particles was noted.
