The iodometric assay (1–3) is the official designated potency method for penicillin V benzathine drug substance and formulations (4). Normally in this method, a sample and reference standard of the same chemical species are analyzed under identical conditions. With the benzathine salt of penicillin V, however, the drug is assayed against a penicillin V acid standard. Moreover, the inactivated and blank solutions are titrated at a different pH. Under these conditions, benzathine was reported to react with iodine in the sample blank solution (5), resulting in reduced thiosulfate titers and values for the penicillin V content that are 5–10% low.

An absorptivity test is also specified in the "Code of Federal Regulations" (4) for the penicillin V benzathine bulk drug. This method is nonspecific since a known impurity, *p*-hydroxyphenoxymethylpenicillin, interferes (6).

Because of these problems, a new analytical approach was needed. High-performance liquid chromatography (HPLC) has been used for the analysis of other penicillins (7–11), and its application as a specific, rapid, and accurate assay for penicillin V benzathine products was examined.

EXPERIMENTAL

Apparatus—The liquid chromatograph was equipped with two constant-flow pumps[1], a solvent programer[2], a septumless injector[3], and a commercial 4.6-mm × 25-cm prepacked reversed-phase column[4]. A variable-wavelength spectrophotometer[5] operating at 274 nm and 0.20 aufs was used for detection. Peak areas and calculations were computed using a chromatographic data system[6].

Reagents—A low UV cutoff, distilled-in-glass grade of methanol[7] was employed. All other chemicals were reagent grade.

Chromatographic Parameters—The mobile phase, 53% methanol in phosphate buffer (v/v), was prepared by adding 53% solution of methanol in 0.05 *M* aqueous phosphoric acid to 53% methanol in 0.05 *M* sodium dihydrogen phosphate until pH 3.5 was obtained. A flow rate of 1.0 ml/min (600 psi) was employed, and injection volumes were 5 μl.

Internal Standard Solution—A stock solution of 1,3,5-trimethoxybenzene[8] (45 mg/ml) was prepared in methanol.

Standard Preparation—European Pharmacopoeia[9] (EP) reference standard phenoxymethylpenicillin CRS (labeled 100% potency) and USP phenoxymethylpenicillin reference standard[10] (labeled 98.06% potency) were dried as required before use. Penicillin V USP bulk drug powder[11] was employed as a working standard and used as received. Solutions were

Table I—Retention Times of Various Common Excipients and Penicillin V Impurities

Compound	Retention Time, min
FD&C Red No. 2	2.7
FD&C Yellow No. 6	3.0
p-Hydroxyphenoxymethylpenicillin	4.9
Phenoxyacetic acid	5.6
Benzathine	6.0
Penicillin V penicilloic acid	6.4
Penicillin V penilloic acid	7.2
Sodium benzoate	7.7
Methylparaben	8.1
Penicillin G	8.3
Penicillin V	12.3
Propylparaben	16.0
Penicillin V penicillenic acid	18.2

prepared in methanol to contain 9 mg/ml of the internal standard and either 3 or 6 mg/ml of penicillin V.

Sample Preparation—*Penicillin V Benzathine Bulk Drug*—Solutions (6 mg/ml) were prepared in the same way as for the standards.

Penicillin V Benzathine Oral Suspension—Approximately 2.5 ml of suspension was weighed accurately into a 25-ml volumetric flask. Internal standard solution, 5.0 ml, and about 15 ml of methanol were added. The flasks were swirled to disperse the suspension, methanol was added to volume, and insoluble materials were allowed to settle.

RESULTS AND DISCUSSION

The EP phenoxymethylpenicillin standard, with a labeled potency of 100%, chromatographed as a single peak in this HPLC system and was used as a reference standard. Penicillin V benzathine chromatographed as two separate entities. A typical chromatogram of a commercial formulation is shown in Fig. 1. The concentration of methanol in the mobile phase was critical to achieve baseline separation between penicillin V (peak 2) and the internal standard (peak 3). The benzathine portion of the molecule was eluted prior to peak 1 but was not detected at the wavelength used. With a conventional fixed-wavelength detector (254 nm), the benzathine was visible as a broad peak eluting with a retention time of about 6 min. This type of detector may also be used.

Figure 1 shows that common formulation excipients such as methylparaben and propylparaben, sodium benzoate, and coloring agents did not interfere. Methylparaben and sodium benzoate had nearly identical retention times (peak 1). Common degradation products such as the penicillenic, penicilloic, and penilloic acids, the congener penicillin G, and the precursor phenoxyacetic acid were resolved from the penicillin V peak. Table I lists the retention times obtained for these compounds in the system described.

Both the USP and working standard penicillin V contained a small amount of an impurity with a retention time of 4.9 min. Relative to the penicillin V peak and based on relative peak areas, 1 and 3% of this product were found in the USP and working standard, respectively. This impurity was collected from HPLC using 50% methanol–water as the mobile phase, and rechromatography indicated its integrity. This material had an absorbance maximum at 287 nm, which underwent a phenolic shift in base to 303 nm, suggesting that the product was *p*-hydroxyphenoxymethylpenicillin, an impurity known to be occasionally present in penicillin V (6, 12, 13). PMR spectrometry[12] confirmed this structure.

With six solutions (2–8 mg/ml), a linear calibration curve ($r = 0.9995$) was obtained over the range tested (10–40 μg injected) with a linear regression of $y = 0.0303x + 0.005$.

The precision of the method was determined by analysis of 10 aliquots of a commercial sample of a 150-mg/5 ml penicillin V benzathine suspension. A mean assay of 24.89 mg/g of suspension and a relative standard deviation of 0.94% was obtained (Table II).

There was good agreement between the HPLC and iodometric values for both the USP and working standard penicillin V (Table III). Similarly, excellent agreement between the HPLC and official (4) absorptivity assays for penicillin V content of the penicillin V benzathine bulk drug was obtained. The iodometric assay of this product exhibited the interference previously mentioned (5).

Table III—Analysis of Penicillin V and Penicillin V Benzathine Bulk Drug and Oral Suspension

Product	Penicillin V, %	
	HPLC	Official[a]
USP penicillin V reference standard (98.06% label claim)	98.7	97.6
Penicillin V working standard	95.9	97.8
Penicillin V benzathine bulk drug	66.0	65.9
Oral Suspension A (300 mg/5 ml)	54.7, 54.0[b]	49.0, 49.2[b]
Oral Suspension B (300 mg/5 ml)	54.2, 54.7[b]	49.8, 50.3[b]

[a] Iodometric assay except for penicillin V benzathine bulk drug which is the UV absorptivity method. [b] Results are expressed as milligrams of penicillin V per gram of suspension.

Table III also shows a comparison of the assay results using the two methods for two commercial formulations of penicillin V benzathine (300 mg/5 ml) from different manufacturers. The values listed are expressed as milligrams of penicillin V per gram of suspension. For potency determination, conversion to milligrams per dose is required and is effected by determination of the specific gravity of the suspension, because problems are encountered when pipetting such viscous preparations. The difference between the HPLC and iodometric assay values for these oral suspensions is due to the interference by the benzathine in the iodometric method (5).

The HPLC procedure can be used for the analysis of other penicillin V products and as a combined identity and purity test to control the quality of these antibiotics.

Simple and Specific Electron-Capture GLC Assay for Plasma and Urine Ephedrine Concentrations following Single Doses

K. K. MIDHA ˣ, J. K. COOPER, and I. J. McGILVERAY

Received June 13, 1978, from the *Drug Research Laboratories, Health Protection Branch, Health & Welfare Canada, Ottawa, Ontario, Canada.* Accepted for publication October 18, 1978.

Abstract □ An electron-capture GLC procedure for determination of plasma ephedrine concentrations is described. The procedure is capable of determining 2 ng/ml of ephedrine and is adequate for following profiles after 25-mg single doses. Pentane extraction of the drug and the internal standard and formation of the *N*-pentafluorobenzoyl derivatives were followed by GLC. Plasma ephedrine concentrations following a 24-mg dose of ephedrine hydrochloride to a human volunteer are presented. Formation of *N*-trifluoroacetyl, *N*-pentafluoropropionyl, *N*-heptafluorobutryl, and *N*-pentafluorobenzoyl derivatives and their GLC–mass spectrometric identification are discussed together with comparative electron-capture sensitivities of these derivatives toward a nickel-63 detector. The detection of the *N*-pentafluorobenzoyl derivative of ephedrine is at least 100-fold greater in sensitivity than detection of the *N*-trifluoroacetyl derivative.

Keyphrases □ Ephedrine—electron-capture GLC analysis in human plasma and urine □ Electron-capture GLC—comparison of various fluoroacyl derivatives of ephedrine □ GLC, electron capture—analysis, ephedrine in plasma and urine

Ephedrine (I) is widely used in the treatment of asthma, either alone or in combination with theophylline and a barbiturate. Several GLC methods (1–4) are adequate for determining plasma and urine ephedrine concentrations following therapeutic doses but are not sensitive enough for single-dose pharmacokinetic and bioavailability studies.

GLC with flame ionization has been used to estimate ephedrine and its congeners in urine (1). Heptafluorobutyryl ephedrine derivatives following benzene extraction of basified serum were used for electron-capture analysis of blood levels at therapeutic dosages (2). Previously reported procedures have been insufficiently sensitive for clinical use (3, 4).

No details are available on a modification of an electron-capture GLC assay for pseudoephedrine and norpseudoephedrine, which may have the sensitivity required for single-dose bioavailability studies (5).

A simple and specific electron-capture GLC assay of ephedrine and norephedrine is described. This procedure has a 2-ng/ml sensitivity and is used routinely for assay of ephedrine bioavailability following a single dose of the drug either alone or in combination with theophylline and a barbiturate.

EXPERIMENTAL

Reagents—Glass-distilled *n*-pentane[1] and analytical grade amyl acetate[2] were employed. Pentafluorobenzoyl chloride[3], trifluoroacetic anhydride[3], heptafluorobutyric anhydride[3], pentafluoropropionic anhydride[3], and pyridine[3] were all GLC grade. *d,l*-Ephedrine hydrochloride[4], *d,l*-norephedrine hydrochloride[4], and 3,4-dimethoxyamphetamine hydrochloride[4] were donated. *d,l*-Ephedrine[5] free base, *p*-hydroxyephedrine[5], and *p*-hydroxynorephedrine[5] were purchased. All other chemicals were analytical reagent grade.

Stock solutions of I (100 μg/ml) and the internal standard 3,4-dimethoxyamphetamine (II) (100 μg/ml) were prepared weekly by dissolving their hydrochloride salts in water. Appropriate dilutions were made daily as required.

Plasma Level Study—Ephedrine hydrochloride (24 mg) was administered in a combination tablet[6], which also contained theophylline (130 mg) and phenobarbital (8 mg), to a healthy 67.6-kg male volunteer. Blood samples, 10 ml, were withdrawn from the cubital vein into heparinized tubes[7] at 10 appropriate time intervals. The blood samples were centrifuged, and the plasma was transferred to another tube before storage at −10°.

Extraction of Ephedrine—To 1 ml of plasma or 0.1 ml of urine diluted to 1 ml with distilled water, in a 15-ml glass round-bottom tube[8], were added 1 ml of aqueous solution of II (100 ng/ml) and 0.5 ml of 10 *N* NaOH. The sample was mixed[9] for 30 sec, and 7.0 ml of glass-distilled pentane[1] was added before mixing[10] for 10 min followed by centrifugation[11] (5 min at 0° at 6000 rpm). The clear organic extract was transferred by Pasteur pipet to an 8-ml polytef[12]-lined, screw-capped, round-bottom tube[13].

Pentafluorobenzoyl chloride[3], 0.1% in pentane (200 μl), was added to the extract. The tube was tightly stoppered and incubated[14] at 65° for 90 min. Then the tube was allowed to reach room temperature, and a small antibumping granule[2] was added. The sample was evaporated[14] at 65° without nitrogen until just dry.

To the dried reaction mixture, 0.5 ml of 0.1 *N* NH_4OH was added and the sample was mixed[9] for 30 sec. Amyl acetate[2] (50 μl) was added, and the sample was mixed[9] for 30 sec and centrifuged[15] for 2 min at 2500 rpm. Approximately 25 μl of the amyl acetate solution was transferred to a 1-ml disposable screw-capped vial[13]. About 2–3 μl of the sample was injected into the gas chromatograph.

GLC—The gas chromatograph[16] was equipped with a ^{63}Ni electron-capture detector. The column was a spiral glass tube[17], 0.9 m long × 2.0 mm i.d., packed with 3% phenyl cyanopropyl methyl silicone[18] coated by fluidization on acid-washed, dimethylchlorosilane-treated, 100–120-mesh, high-performance, flux-calcined diatomite support[19].

The column was conditioned at 245° for 48 hr with low nitrogen flow. For plasma analysis, the injection port, outlet, and oven temperatures were 250, 260, and 235°, respectively. Argon–methane (95:5) as a carrier gas was maintained at 93 ml/min. The ^{63}Ni detector was operated at 325° with a standing current of 3.0 namp.

For determination of the response of various ephedrine derivatives, the column was operated from 170 to 230°. The detector was operated at a standing current of 2.0 namp.

Calculations—Peak height ratios were calculated by dividing the peak height from the *N*-pentafluorobenzoyl derivative of I (1.40 min) by that of the *N*-pentafluorobenzoyl derivative of II (3.82 min). Calibration

Table I—Electron-Capture Sensitivity and Retention Times of Ephedrine Derivatives

Derivative	Response, coulombs × 10^3/mole	Retention Time, min	Column[a] Temperature
Pentafluorobenzoyl	14.303	1.42	230°
Heptafluorobutyryl	0.971	1.04	170°
Pentafluoropropionyl	0.812	1.28	170°
Trifluoroacetyl	0.013	1.46	170°

[a] Chromatographed on OV-225.

curves were constructed by plotting the spiked control plasma peak height ratios against the concentrations of I (nanograms per milliliter of plasma).

Electron-Capture Response of Various Ephedrine Derivatives—*Stock Solution of* d,l-*Ephedrine*—A solution of *d,l*-ephedrine free base (1000 μg/ml) in glass-distilled pentane was prepared.

N-*Trifluoroacetyl,* N-*Heptafluorobutyryl, and* N-*Pentafluoropropionyl Derivatives*—To 1 ml of I stock solution (1000 μg) in an 8-ml polytef-lined, screw-capped, round-bottom tube[13] were added either 0.5 ml of trifluoroacetic anhydride[3] or 200 μl of heptafluorobutyric[3] or pentafluoropropionic anhydride[3] and 20 μl of pyridine[3]. The tubes were tightly stoppered and incubated for 60 min at 45° for trifluoroacylation or for 90 min at 65° for other derivatives. The tubes were cooled to room temperature, a small antibumping granule was added to each, and excess anhydride was removed by evaporation without nitrogen until just dry at 45° for trifluoroacetic anhydride and at 65° for other anhydrides. Then 1 ml of 1 *N* NaOH and 0.5 ml of amyl acetate[2] were added, and the contents of the tube were mixed for 5 min and centrifuged for 2 min at 2500 rpm. Appropriate dilutions of each derivative were made with amyl acetate to yield final concentrations of 13.33 ng/μl for the *N*-trifluoroacetyl derivative and 6.66 ng/μl for the other two derivatives.

N-*Pentafluorobenzoyl Derivative*—The reaction was the same as described for the other *N*-acyl derivatives. In this case, dilution of 10 μl of pentyl acetate to 15 ml yielded a final concentration of 0.67 ng/μl. Flame-ionization GLC analysis of the three undiluted reaction mixtures described previously showed that at least 95% of I was present as the corresponding *N*-monoacyl derivative.

Di-Derivatives of Ephedrine with Trifluoroacetic Anhydride, Heptafluorobutyric Anhydride, and Pentafluoropropionic Anhydride—The reactions for the di-derivatives of I were the same as described for each reagent, except that the derivative was back-extracted following the addition of 1 ml of 0.1 *N* NH_4OH instead of 1 ml of 1 *N* NaOH.

Measurement of Electron-Capture Response—The electron-capture response of the ephedrine amide derivatives was determined by mixing the pentafluorobenzoyl derivative with each derivative separately at a ratio of exactly 1:1 (v/v). This step was necessary because the former three derivatives did not separate completely under the chromatographic conditions employed. No change in the response of the *N*-pentafluorobenzoyl derivative was observed when it was chromatographed separately or as a mixture with any of the three derivatives. The response of the other three derivatives was calculated using the *N*-pentafluorobenzoyl derivative as a reference.

Each fluoroacyl derivative gave a sharp symmetrical peak when chromatographed under the conditions described. The response of each derivative was expressed in 10^3 coulombs/mole and was calculated for each derivative from its peak area (width of the peak at half height × peak height) by converting the area to coulombs from the chart speed and the current for full-scale deflection.

RESULTS AND DISCUSSION

N-Pentafluorobenzoyl derivatives of I, norephedrine, and the internal standard (II) gave sharp peaks (a, b, and c, Fig. 1B) with retention times of 1.40, 2.38, and 3.82 min, respectively. The presence of these *N*-pentafluorobenzoyl derivatives was established by GLC–mass spectrometry[20].

The GLC–mass spectra of the *N*-pentafluorobenzoyl derivative of I and norephedrine did not give molecular ions, but diagnostic ions for the derivative of I were at *m/e* 252, 253, 234, 195, 167, 107, 105, 79, and 77. For the derivative of norephedrine, they were at *m/e* 238, 239, 195, 167, 107, 105, 79, and 77. The GLC–mass spectrum of the *N*-pentafluorobenzoyl derivative of II gave a molecular ion at *m/e* 389 and other characteristic ions at *m/e* 238, 178, 151, 121, 195, 167, 91, and 77. These mass spectra indicate that peaks a, b, and c (Fig. 1) were due to *N*-monoacyl derivatives.

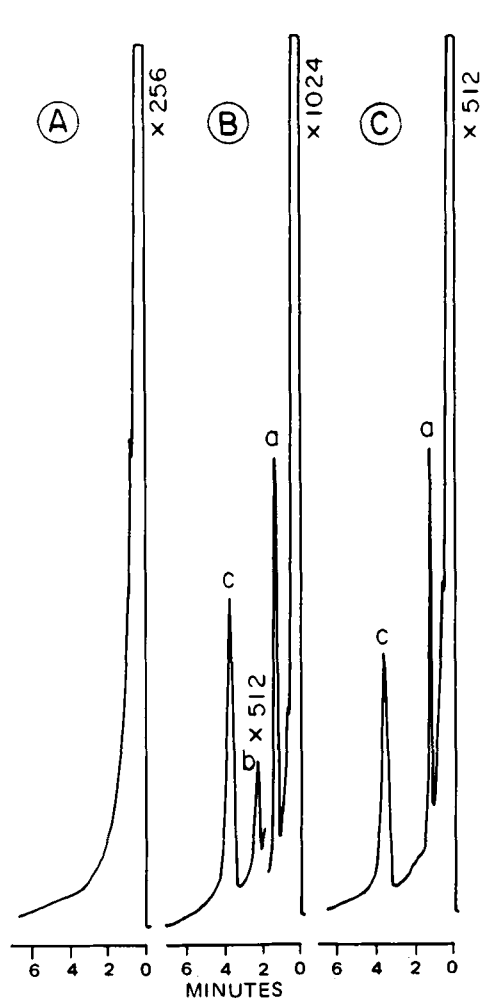

Figure 1—*Typical chromatograms of human plasma. Key: A, blank control plasma; B, spiked plasma containing 100 ng of ephedrine, 100 ng of norephedrine, and 100 ng of 3,4-dimethoxyamphetamine; C, plasma (0.5-hr sample) from a dosed volunteer who received a combination tablet (containing 24 mg of ephedrine hydrochloride) containing 57.14 ng of ephedrine and 100 ng of 3,4-dimethoxyamphetamine; peak a,* N-*pentafluorobenzamide of ephedrine; peak b,* N-*pentafluorobenzamide of norephedrine; and peak c,* N-*pentafluorobenzamide of 3,4-dimethoxyamphetamine.*

Derivatization of I and norephedrine with pentafluorobenzoyl chloride followed by GLC did not give any peaks other than for *N*-monoacyl derivatives, which suggested that the β-hydroxy group did not undergo acylation. However, on increasing the reaction time to 7 hr with subsequent GLC examination, a small peak (5% by peak area) eluted (retention time of 0.5 min) just before peak a. The GLC–mass spectrum of this peak gave a base peak at *m/e* 195 and other diagnostic ions at *m/e* 342, 341, 252, 238, 208, 168, 167, 105, and 77. The absence of ions at *m/e* 253 and 107 is diagnostic for the formation of the *O*-pentafluorobenzoyl derivative[21].

Similarly, reactions of I and norephedrine with heptafluorobutyric anhydride, pentafluoropropionic anhydride, and trifluoroacetic anhydride as checked by GLC–mass spectrometry yielded *N,O*-diacyl derivatives as the main products equal to 95% peak area compared to *N*-monoacyl derivatives. *N,O*-Diacyl derivatives of I were not hydrolyzed with 0.1 *N* NH_4OH. Shaking of diacyl derivatives with 1 *N* NaOH gave *N*-monoacyl derivatives, showing that the *O*-acyl, and not the *N*-acyl, functions of these derivatives are hydrolyzed with 1 *N* NaOH.

N-Pentafluorobenzoyl derivatives of phenylalkylamines have great

[20] GC–MS-data system model HP5985, Hewlett-Packard Corp., Ottawa, Ontario, Canada.

[21] K. K. Midha, J. W. Hubbard, J. K. Cooper, and D. Gagné, to be published.

electron-capturing affinity (1, 6). In the present study, the electron-capturing affinity of the *N*-pentafluorobenzoyl derivative of I was nearly 15 times that of the *N*-heptafluorobutyryl derivative, 18 times that of the *N*-pentafluoropropionyl derivative, and 1100 that of the *N*-trifluoroacetyl derivative of I (Table I).

Figure 1 shows a typical chromatogram obtained by processing control blank plasma without the internal standard. No extraneous peaks are observed. Similar chromatograms of urine extracts were as clean as those from plasma. A chromatogram obtained when the method was applied to spiked human plasma containing 100 ng each of I, norephedrine, and II is also shown in Fig. 1.

Figure 1 also shows a chromatogram of the plasma sample (1 ml) from blood withdrawn from a male volunteer (67.6 kg) at 0.5 hr after administration of 24 mg of I in a combination tablet[6] containing theophylline and phenobarbital. Analysis time was 6 min, and a 57.14-ng/ml level of I was found in this 0.5-hr sample.

Ether was the solvent of choice for the extraction of ephedrines from biological fluids in several studies (3, 4, 7, 8). Recently, degradation of I during extraction with ether was observed (9, 10). In the present study, ether was tried as a solvent for the extraction of I and II from plasma at different pH values. The extraction from plasma with ether at pH 12 and subsequent derivatization of I and II with pentafluorobenzoyl chloride yielded chromatograms with many endogenous interfering peaks and irreproducible peak height ratios (I to II). Back-extracting the ethereal extract of plasma containing I and II into aqueous acid, basifying the aqueous layer to pH 12, extracting with ether, and derivatizing with pentafluorobenzoyl chloride did not eliminate all interfering peaks. Raising the pH to 14 and extracting with pentane eliminated all interfering peaks, which may have been from phenolic substances that would not be extracted into a nonpolar solvent such as pentane at pH 14.

When two known phenolic metabolites of I, *p*-hydroxyephedrine and *p*-hydroxynorephedrine, were carried through the extraction and derivatization procedures, neither was observed by GLC. However, peaks for the *N*-pentafluorobenzoyl derivatives of these metabolites were observed when they were not carried through the extraction but were derivatized directly[22].

After extraction and derivatization of I and II with pentafluorobenzoyl chloride, the excess reagent was hydrolyzed with 0.1 *N* NH_4OH, and the derivatives of I and II were extracted with amyl acetate. The pentyl acetate extract had to be removed from contact with the ammonium hydroxide within 20 min or slow hydrolysis of the derivatives occurred, as shown by a decrease in peak heights. Once the amyl acetate was removed from contact with the ammonia layer, these derivatives were stable for several months.

Nitrogen evaporation of pentane extracts of derivatized or underivatized drug caused perceptible loss of derivative and even greater loss of free drug. Even after reaction and evaporation to dryness without nitrogen, the derivative was lost if the samples were left too long in the bath. Thus, the samples were evaporated without the use of nitrogen and removed immediately when dry.

Different GLC stationary phases such as phenyl methyl dimethyl silicone[23] and phenyl methyl (50:50) silicone[24] were tried but were not suitable for quantitation. The drug and internal standard were poorly resolved with the former, and broad peaks were obtained with the latter. A column of methyl phenyl silicone containing about 75% phenyl silicone[25] gave sharp peaks for I and the internal standard. However, norephedrine, the major metabolite of I (which was extracted in the procedure) could not be separated from I. A liquid phase of phenyl cyanopropyl and methyl silicone[17], however, separated the *N*-pentafluorobenzamide derivatives of I and norephedrine.

After repeated injections into the gas chromatograph, a noisy baseline was occasionally observed, and the ratios of I to II became irreproducible. This result was initially considered to be due to detector contamination. However, baking the detector at 350° over 24 hr did not remedy the problem. When the glass liner in the injection port of the gas chromatograph was examined, a white coating of small particles was observed on the inside. After cleaning the glass liner by soaking it in a chromic acid solution in an ultrasonic bath overnight, reproducible ratios of I to II were obtained. The irreproducible ratios may have been caused by buildup of endogenous materials contained in derivatized plasma extracts and/or by septum particles. By changing the glass liner in the injection port either weekly or after approximately 500 injections, the problem of irreproducible ratios was overcome.

Table II—Calibration Curve of Ephedrine Extracted from Plasma [a]

Nanograms per Milliliter	*n*	Mean	±*SD*	±*CV*, %
5	8	0.113	0.0046	4.09
10	7	0.216	0.0089	4.13
20	8	0.445	0.0169	3.77
30	9	0.659	0.0190	2.89
50	11	1.092	0.0436	3.98
100	9	2.128	0.0755	3.55

[a] Mean *CV* = 3.74%, slope = 0.0215 ± 0.0002, and correlation = 0.9986.

Table III—Recovery of Ephedrine and 3,4-Dimethoxyamphetamine from Plasma

Nanograms Added to 1 ml of Plasma	*n*	Mean Nanograms Recovered	Percent Recovery, mean ± *SD*
	Recovery of Ephedrine		
20	4	19.51	97.56 ± 1.16
100	4	96.94	96.94 ± 1.18
Mean			97.25 ± 1.13
	Recovery of 3,4-Dimethoxyamphetamine		
100	4	51.74	51.74 ± 0.85

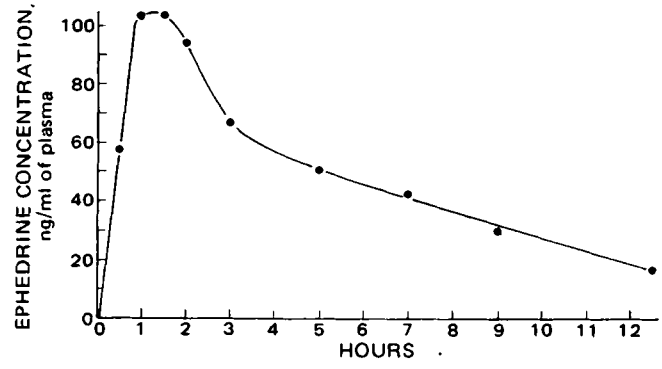

Figure 2—*Ephedrine concentrations in the plasma of a human volunteer (67.6 kg) following a single 24-mg dose of ephedrine hydrochloride in a combination tablet.*

The accuracy and precision of the GLC assay are demonstrated in Table II. Results are based on at least seven determinations of each concentration of I, ranging from 5.0 to 100.0 ng/ml. The overall coefficient of variation was 3.98%. The calibration curve obtained by plotting the peak height ratio of the *N*-pentafluorobenzoyl derivatives of I:II *versus* the I concentration was linear ($y = mx$) over the 5.0–100.0-ng of I/ml of plasma range. A mean slope value of 0.0215 ± 0.0002 ($r^2 = 0.999$) was obtained.

The overall recoveries of I and II from plasma were 97.25 ± 1.13 and 51.74 ± 0.85%, respectively (Table III). The procedure described has been applied to numerous plasma sample analyses. However, since II is a restricted drug in Canada, an alternative internal standard may be desirable. 3,4-Dimethoxyphenethylamine[5], a commercially available chemical, was suitable, and its *N*-pentafluorobenzoyl derivative gave a sharp symmetrical peak at 4.3 min, well separated from the peak due to the derivative of I. Recovery under the extraction conditions and the sensitivity of the procedure using this alternative internal standard were approximately equivalent to those with II.

The application of the present method to the determination of plasma I concentrations is shown in Fig. 2. A combination tablet[6] containing ephedrine hydrochloride (24 mg), theophylline, and phenobarbital was given as outlined in the *Experimental* section, and aliquots of the sampled plasma were assayed for I by GLC. Plasma concentrations over 24 hr in the subject fit a one-compartment model from which the elimination half-life was calculated (4.8 hr).

Abstract □ The dissolution profiles of prednisone, digoxin, and griseofulvin in simulated GI fluids were determined after solvent deposition or ball milling with three commercially available grades of amorphous silicon dioxide. The former procedure resulted in adsorbates showing evidence of drug entrapment by the two grades with larger average pore diameters. Ball milling the drugs with the grade possessing the largest average particle diameter produced triturations with the slowest dissolution rates. A relationship between drug dissolution and extent of dilution with the amorphous silicon dioxides was shown. Particle-size measurements revealed that the ball milling procedure was more apt to broaden the size distribution as compared with the solvent-deposition method of drug incorporation.

Keyphrases □ Dissolution rate—effects of amorphous silicon dioxides on prednisone, digoxin, griseofulvin, simulated GI fluids, solvent deposition compared to ball milling □ Silicon dioxide, amorphous—effect on dissolution rates of prednisone, digoxin, griseofulvin in simulated GI fluids, solvent deposition compared to ball milling □ Dispersions, solid—effect of amorphous silicon dioxides on prednisone, digoxin, griseofulvin, simulated GI fluids, solvent deposition compared to ball milling

Various water-insoluble drugs, solvent deposited on fumed silicon dioxide, have been reported to have more rapid dissolution rates than the pure micronized drugs. Surface area of the acidified and basified silica gel adsorbents was a controlling factor for the increased dissolution rate of these adsorbate samples (1).

This study evaluated the effects of three commercial grades of amorphous silicon dioxide on the dissolution rates of digoxin, griseofulvin, and prednisone. The micrometer-sized, synthetic, amorphous silicon dioxides possess a unique combination of properties. Purity, nontoxicity, uniformity, chemical inertness, large surface area and porosity, controlled particle size, and a high adsorptive capacity for both oil and water characterize these versatile products. The three grades selected differ from one another in surface pH, particle size, surface area, and pore volume and diameter (Table I).

In addition to the customary procedure of solvent deposition, ball milling was used to spread each drug on the amorphous silicon dioxide surfaces. Earlier studies had shown that ball milling was superior to solvent deposition for preparing drug–lactose triturations (2, 3). Besides comparison of these two methods, the effect of pore diameter on the dissolution rate of entrapped drug molecules was studied.

EXPERIMENTAL

Materials—The following were obtained from commercial sources: amorphous silicon dioxides[1], digoxin[2] USP, griseofulvin[3] USP, prednisone[4] USP, sodium hydroxide[5] USP, monobasic sodium phosphate[6] USP, sodium chloride[7] USP, reagent grade hydrochloric acid[5], and absolute ethanol[8].

Equipment—The following were used: the USP XIX dissolution test basket assembly[9]; a constant-temperature shaker bath[10]; a grating spectrophotometer with digital display[11]; a jar mill, 10.16-cm (4-in.) diameter with 1.27-cm (0.5-in.) diameter porcelain balls[12]; a pH meter[11]; a particle-size counter[13]; a U.S. standard sieve, 60 mesh[14]; a Swinny adapter[15], 13 mm; and filter paper, 0.45-μm porosity[15].

Preparation of Drug–Amorphous Silicon Dioxide Triturations—The drug–amorphous silicon dioxide triturations were prepared in a weight ratio of 1:20. Simple blends were prepared by manual bottle tumbling for 15 min. Ball milled triturations were prepared from homogeneous simple blends. Ball milling was carried out for 48 hr in a jar mill half-filled with porcelain balls.

Solvent deposition consisted of dissolving prednisone or griseofulvin in sufficient absolute ethanol (80% ethanol was used for digoxin) and uniformly wetting the various silicas contained in a beaker. The mixture was stirred with a magnetic stirrer while the solvent was evaporated in an air stream. The residues were dried at 37° for 24 hr and passed through a 60-mesh screen to break up any agglomerates. The sieved material was bottle blended to ensure homogeneity.

Table II—Wavelengths of UV Light Used in Development of Calibration Curves for the Three Drugs in Various Solvents

Solvent	Wavelength of Light, nm		
	Digoxin	Griseofulvin	Prednisone
Simulated gastric fluid (without pepsin)	222	296	242
Simulated intestinal fluid (without pancreatin)	222	296	245
Absolute ethanol	—	290	240
80% Ethanol	220	—	—

Triturations were assayed spectrophotometrically for content uniformity. Only samples containing 100 ± 5% of the required amount of drug were used in the dissolution studies.

Spectrophotometric Absorption and Calibration Curves—Stock solutions were prepared by dissolving 100 mg of each drug in 50 ml of absolute ethanol or 80% ethanol (digoxin). Aliquots were diluted with appropriate solvents to develop absorption spectral and calibration curves. The following solution concentrations were employed: prednisone, 20 μg/ml; griseofulvin, 10 μg/ml; and digoxin, 40 μg/ml.

To blank out interference of colloidal silica particles on the UV measurements, stock suspensions of the silicas were prepared. Aliquots were added 20:1 (w/w) to the drug solutions. The suspensions were filtered through a 0.45-μm membrane filter before determination of the absorption spectral and calibration curves. Only in the case of digoxin was an interference found. An absorption spectral curve of one amorphous silicon dioxide (silica 63) in 80% ethanol showed a maximum absorbance at 228 nm. The maximum absorbance values for digoxin ranged from 220 to 222 nm. Thus, the blanks used for the spectrophotometric measurements of digoxin solutions were the corresponding solvents plus the appropriate silica. For the measurements of prednisone and griseofulvin, the appropriate solvent without silica addition was adequate.

All calibration curves determined at the wavelength of maximum absorbance obeyed Beer's law. The wavelengths employed for calibration curves are summarized in Table II.

Assay of the Drug–Silica Triturations—The various drug-silica triturations were extracted with absolute or 80% ethanol. The extracts were passed through a 0.45-μm membrane filter. After dilution with solvent, the absorbance was determined spectrophotometrically and the concentration was ascertained from the calibration curves.

Dissolution Studies—The dissolution studies were conducted in simulated gastric fluid (without pepsin) and simulated intestinal fluid (without pancreatin) (4). The stability of the three drugs was satisfactory in these dissolution media after 2 hr of exposure at 37°. An insignificant change in absorbance occurred after addition of 20-fold excesses of either silica 63 or 266. On the basis of these observations, the possibility of drug adsorption by the silicas during the dissolution rate determinations was discounted (Fig. 1).

A modification of the procedure of Monkhouse and Lach (1) was used to determine the dissolution rates of the three drugs and the various triturations. Simulated gastric fluid, 200 ml, was brought to 37° in a constant-temperature bath. The dissolution medium was stirred with the basket used in the USP dissolution test. The stirrer was vertically centered at a depth 2 cm from the beaker bottom and was maintained at 60 rpm.

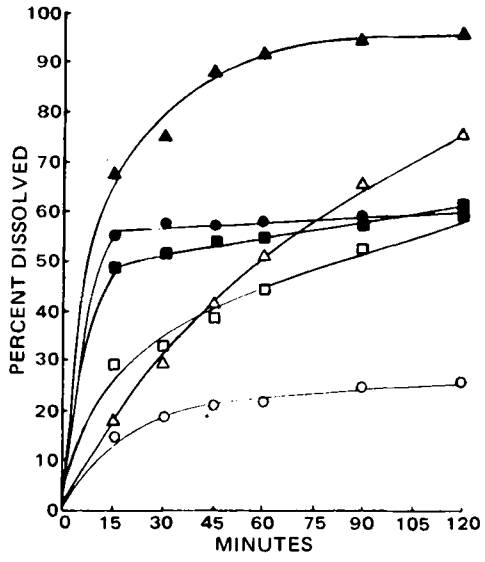

Figure 1—*Dissolution rate in simulated gastric fluids of selected samples of griseofulvin, digoxin, and prednisone solvent deposited on amorphous silicon dioxide (drug–silica 63 ratio, 1:20) compared with the pure drugs. Key: ○, griseofulvin (simulated intestinal fluid); ●, griseofulvin–silica 63 (simulated intestinal fluid); □, digoxin (simulated gastric fluid); ■, digoxin–silica 63 (simulated gastric fluid); △, prednisone (simulated gastric fluid); and ▲, prednisone–silica 63 (simulated gastric fluid).*

Accurately weighed samples, equivalent to a quantity of drug to ensure sink conditions, were spread over the medium surface (digoxin, 9.44 mg; grisofulvin, 1.45 mg; and prednisone, 8 mg). Any large aggregates that formed at this stage were lightly broken up within 10 sec after sample addition. Aliquots of the dissolution medium were withdrawn periodically and passed through a 0.45-μm membrane filter. After appropriate dilution, the absorbance was determined spectrophotometrically.

Immediately after withdrawing an aliquot, an equal quantity of dissolution medium was added to the beaker to maintain a constant volume. Cumulative corrections were made for the previously withdrawn aliquots in calculating the total amount of drug dissolved. Each point on the dissolution curves represents at least two determinations.

In another series of experiments, 500 ml of dissolution medium was used. The quantity of sample added was 2.5-fold greater than that used in the experiments with 200 ml. The dissolution rate data are summarized in Tables III and IV.

Initial screening experiments showed that the dissolution rates were not significantly altered when 0.02% polysorbate 80 was present in the media, so it was not used.

Particle-Size Measurement—Pure drug, each of the three silica grades, and the drug–silica triturations were ultrasonically dispersed in an aqueous medium buffered at pH 2. The concentrations of the resulting aqueous dispersions were less than 0.01%. Aperture diameters ranged from 30 to 280 μm, and two apertures were routinely used. Each particle-size determination was completed in less than 10 min. The particle-size data are summarized in Table V.

RESULTS AND DISCUSSION

A significant drop in digoxin potency resulted from 48-hr ball milling, making dissolution rate determination impossible. This potency drop was unexpected, since such ball milling operations were conducted at room temperature with ingredients previously dried at 37°[16].

Digoxin (4.8%), solvent deposited on the three grades of silica, did not show a significant improvement in dissolution rate in simulated gastric fluids (Samples 4–6 and 10–12) compared with the pure drug. However, the best of the three proved to be silica 63 (Samples 4 and 10) due to its larger surface area (Table I). Indications of digoxin instability were encountered with the digoxin–silica 63 trituration but not with either of the other two[17].

The data in Table IV clearly show that the dissolution rate of digoxin in simulated gastric fluid increased as the quantity of silica 63 increased

[16] Details of these observations will be presented in a future publication.
[17] The stability studies will be described in a future publication.

[a] Each drug was dissolved in absolute or 80% ethanol (digoxin). The solvent was evaporated in the absence of silica in an air stream and then dried at 37° for 24 hr. The crystalline residue was passed through a 60-mesh screen.

(Samples 49–56). Minimal improvement in the dissolution rates of drugs with the addition of fumed silicon dioxide above 10% was reported (1). The dissolution profiles in Table IV reveal that increased dilutions of the amorphous silicon dioxides favor a more rapid digoxin dissolution rate. The increased dissolution rate became apparent only in the 120-min study, which is why it was missed by previous researchers using a 14-min experimental design (1). The 120-min dissolution study clearly shows the advantage of adding additional adsorbent.

Significant portions of the total drug went into solution within the first 15 min (Table III). Thus, while 55.5% (Sample 55) of the digoxin had dissolved within the first 15 min, only 12.4% more dissolved after an additional 105 min. The dissolution profiles reported previously (1) also are indicative of a reduction in rate after 14 min. Increased dissolution of solvent-deposited phenylbutazone with increased silicon dioxide concentration has been reported (5). In agreement with our findings, these authors also showed that incomplete recovery of the solvent-deposited phenylbutazone occurred with the more concentrated triturations.

Whereas the simple blend was not of value for digoxin (Sample 3), it enhanced the griseofulvin dissolution rate in simulated gastric fluid (Sample 15). Solvent deposition of 4.8% griseofulvin on each of the three silicas produced equally inefficient triturations as measured in simulated gastric fluid (Samples 16–18). In simulated intestinal fluid, the dissolution rate of pure griseofulvin was much slower (Samples 22 and 23). In this dissolution medium, the simple blend (Sample 24) and the three silica triturations prepared by solvent deposition (Samples 25–27) all showed significant improvement over micronized griseofulvin (Sample 22).

Solvent deposition of 4.8% griseofulvin on silica 63 showed the expected rapid dissolution rate in simulated intestinal fluid (Sample 25).

Griseofulvin, 4.8%, with silica 266 unexpectedly yielded the best dissolution rate after 48 hr of ball milling (Sample 30), followed by silica 72 (Sample 29). This order is exactly the rank order in average particle size (Tables I and V). Thus, silica 266, with the finest particle size (2.05 μm) significantly increased in particle size when ball milled (15.3 μm) or when treated with solvent (22.4 μm). Such increases probably result from an aggregation of particles with little further reduction in size of individual silica 266 particles.

Silica 63 has the largest particle size (9.2 μm), and one would expect the generation of more fines from its ball milling. Ball milling silica 63[18] with griseofulvin yielded a trituration with smaller particle size and a very broad cumulative particle-size distribution (7.8 μm; $V = 2.6$). Thus, an increase in the production of fines and a decrease in particle size might possibly favor the trapping of drug particles beneath and between the fine particles of silica 63. With silica 266, the large increase in average particle size may be due primarily to the buildup of large, softer agglomerates from which the drug particles can be expected to dissolve more readily. Silica 72[19] had an intermediate average particle size (3.4 μm). It yielded an intermediate particle-size increase on ball milling with griseofulvin (10.3 μm). Solvent treatment of silica 63[20] led to an insig-

[a] The parameter V is a measure of the width of a particle-size distribution. Mathematically such width corresponds to dispersion around a central measure such as the average, mean, median, or mode. V is dimensionless and is calculated from the 84% (D_1) and 16% (D_2) points of the cumulative curve: $V = \sqrt{D_2/D_1} - 1$. For a true log normal distribution, $V = \sigma_g - 1$, where σ_g is the geometric standard deviation. In practice, most distributions are skewed, and $V + 1$ is then only an approximation to σ_g. Since relative, rather than absolute, measures of width of nonsymmetrical distributions were of interest, the tedious calculations associated with σ_g were avoided by using V as a basis for comparison. For disperse systems, the range of V is as follows: $V = 0$, monosize particles; $V = 0.5$, narrow distribution; $V = 1.5$, broad distribution; and $V \geq 2.0$, very broad distribution. The Coulter reproducibility of V is ±0.05% at $V = 1$ and ±10% at V above 1.5. [b] The pure silica was wet with ethanol. The solvent was evaporated in the absence of drug in an air stream and then dried at 37° for 24 hr. The residue was passed through a 60-mesh screen. Alternatively, the drug was dissolved in ethanol and the solution was evaporated to dryness in an air stream and then dried at 37° for 24 hr. The crystalline residue was passed through a 60-mesh screen. [c] Full distribution could not be determined because of the failure of agglomerates to pass through the 50-μm aperture.

Table VI—Dissolution Rates of Selected Samples in Simulated Gastric Fluids at 37° Plotted in First-Order Fashion (Ratio of Drug to Amorphous Silicon Dioxide, 1:20)

Number and Description of Sample	Simulated Gastric Fluid			Simulated Intestinal Fluid		
	K_1, min^{-1} (×0.0001)	K_2, min^{-1} (×0.0001)	t_{50}[a], min	K_1, min^{-1} (×0.0001)	K_2, min^{-1} (×0.0001)	t_{50}, min
1 and 7. Digoxin	—	54.4	127	—	14.9	465
4 and 10. Digoxin (solvent deposited on silica 63)	—	25.3	274	—	2.0	3500
13 and 22. Griseofulvin	—	50.5	137	—	12.9	537
16 and 25. Griseofulvin (solvent deposited on silica 63)	—	7.7	902	—	12.2	568
19 and 28. Griseofulvin (ball milled with silica 63)	—	9.8	704	—	39.7	175
31 and 40. Prednisone	118	115	60	140	134	52
34 and 43. Prednisone (solvent deposited on silica 63)	139	138	50	66	42	165
37 and 46. Prednisone (ball milled with silica 63)	14.1	2.3	3000	38	20	347
39 and 48. Prednisone (ball milled with silica 266)	80.8	15.7	441	31.8	10.7	648

[a] Some first-order plots exhibited steeper slopes from 15 to 60 min (Figs. 4 and 5). The t_{50} values were calculated from the less steep slopes generated from the dissolution data beyond 60 min.

nificant increase in particle size, whereas silica 72[19] and 266 increased particle size significantly.

The dissolution profiles (Table IV) demonstrated that griseofulvin solvent deposited on silica 63 in concentrations greater than 50% inefficiently dissolved in simulated gastric fluid (Samples 59 and 60). Micronized griseofulvin attained the highest percentage in solution after 120 min (Sample 57). Solvent deposition of griseofulvin in the absence of silica 63 exhibited a poor dissolution rate (Sample 58). This difference can be explained on the basis of particle size. Thus, the average particle size of the solvent-deposited griseofulvin was fourfold greater than the micronized material (Table V).

Solvent deposition of 4.8% prednisone on silica 63 showed the fastest dissolution rate in simulated gastric fluid (Table III, Sample 34). Solvent deposition of a similar quantity on silica 72 produced a trituration with the fastest dissolution rate in simulated intestinal fluid (Sample 45). On the other hand, ball milled triturations containing 4.8% drug showed silica 266 to give the best dissolution in both simulated gastric media (Fig. 2, Samples 39 and 48).

Solvent deposition of prednisone on silica 63 at various drug concentrations produced triturations exhibiting unusual dissolution profiles in simulated gastric fluid (Table IV, Samples 65–72). Triturations with drug concentrations of 50% exhibit dissolution rates faster than 80 or 90% triturations. After 120 min, the three triturations achieved virtually the same extent of dissolution. However, further dilution with silica 63 resulted in less efficiently dissolving triturations (Samples 70–72).

During the dissolution experiments, the three grades of amorphous silicon dioxides did not tend to adsorb dissolved drug under the sink conditions employed. However, there was an indication of drug entrapment within the pores of silicas 72 and 266 in samples prepared by solvent deposition. Thus, silica 63, which has the smallest average pore diameter (20 Å), usually showed the most rapid drug release when compared with silicas 72 (150 Å) and 266 (210 Å). Digoxin (Table III, Sample 4) dissolved most rapidly in simulated gastric fluid after solvent deposition on silica 63. Griseofulvin (Sample 25) dissolved most rapidly in simulated intestinal fluid after solvent deposition on silica 63, whereas prednisone, after solvent deposition on silica 63, showed the most rapid dissolution in simulated gastric fluid (Sample 34).

The selected samples exhibited in Figs. 1 and 2 highlight some key points. The significance of the data presented in Table V may be more quickly grasped by inspection of Fig. 3. Ball milling silica 63, which had the largest average particle size of the three amorphous silicon dioxides used, significantly broadened the particle-size distribution. Solvent

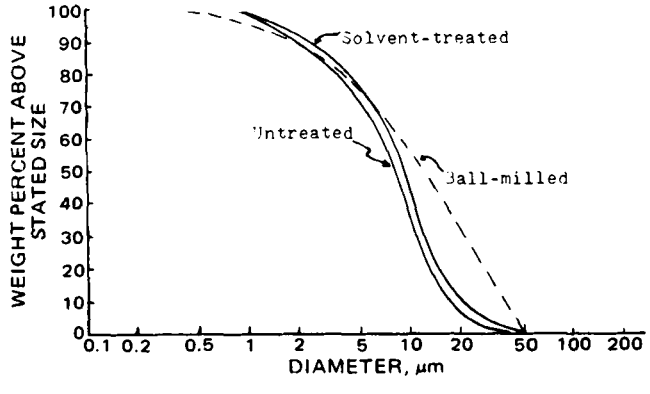

Figure 3—*Particle-size analysis (dual aperture, 50 and 140 μm) of amorphous silicon dioxide (silica 63, lot 22288) in pH 2 buffer before and after treatment with solvent or ball milled for 48 hr.*

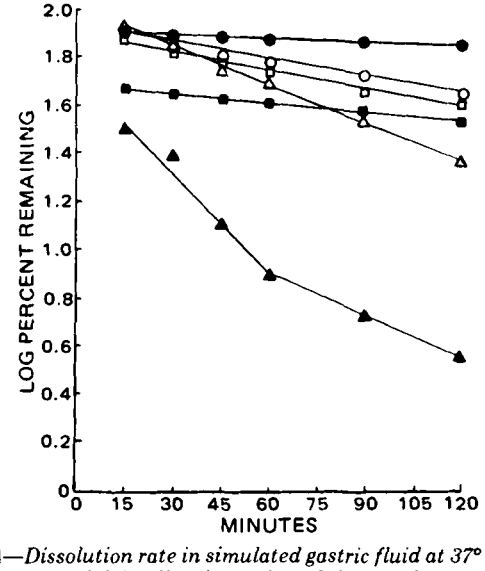

Figure 4—*Dissolution rate in simulated gastric fluid at 37° of selected samples of griseofulvin, digoxin, and prednisone solvent deposited or ball milled with amorphous silicon dioxide (drug–silica 63 ratio, 1:20). Key: △, prednisone; ▲, prednisone–silica 63 (solvent deposited); ○, griseofulvin; ●, griseofulvin–silica 63 (ball milled); □, digoxin; and ■, digoxin–silica 63 (solvent deposited).*

treatment of silica 63, however, resulted in an insignificant change in the particle-size distribution.

In Table VI and Fig. 4, the data gathered on selected samples are plotted in first-order fashion. The values for K_1 and K_2 were determined from the slopes of the lines, and the dissolution half-lives were calculated from the K_2 values. Where two first-order processes were evident, K_2 represented the slower process that occurred 60 min after dissolution had commenced (Fig. 4, prednisone–silica 63, solvent deposited). The data in Table VI clearly show that a significant change in dissolution half-life can be affected by solvent deposition on, or ball milling with, the amorphous silicon dioxides.

Fusion of Disubstituted Benzenes

ERIC MARTIN, SAMUEL H. YALKOWSKY ˣ, and JOHN E. WELLS

Received June 9, 1978, from the *Pharmacy Research Unit, The Upjohn Company, Kalamazoo, MI 49001.* Accepted for publication October 3, 1978.

Abstract □ The entropy of fusion of 84 disubstituted benzenes was essentially constant and independent of the participation of the compounds in intramolecular or intermolecular hydrogen bonding. It was also independent of the shapes, sizes, and dipole moments of the rigid molecules studied. While the entropy of fusion was independent of these parameters, the melting point and the heat of fusion showed a direct dependence on molecular properties.

Keyphrases □ Entropy of fusion—disubstituted benzenes, independent of hydrogen bonding, shape, size, dipole moment of rigid molecules, structure-activity relationships □ Melting point—analysis, disubstituted benzenes, structure-activity relationships □ Benzenes, disubstituted—entropy of fusion, melting point, heat of fusion, structure-activity relationships

The ability to predict the melting point, entropy of fusion, and heat of fusion from chemical structure would make possible the design of compounds having a specified physical state or even a specified melting range. The aqueous solubility of many organic compounds can be predicted from their melting points, entropies of fusion, and octanol–water partition coefficients (1). Since partition coefficients can be predicted by several group contribution methods (2, 3), the estimation of fusion properties makes possible the estimation of aqueous solubility. This possibility has direct implications for drug delivery.

BACKGROUND

In 1908, Walden (4) proposed that entropy of fusion is constant for many classes of compounds. Most elements have entropies of fusion of 2–3 entropy units (eu = cal/deg/mole); salts and small organic molecules usually have entropies of fusion of 5–7 eu; most organic molecules have entropies around 13 eu.

The entropy of fusion rule for organic compounds was later refined to account for molecular geometry (5). If heat of fusion is plotted *versus* melting point, molecules fall into groups according to molecular shape. The data for the chain-like, disk-like, and spherical molecules fall into regions (6) characterized by:

$$\frac{\Delta H_f}{T_m - a} = K \qquad \text{(Eq. 1)}$$

where ΔH_f is the heat of fusion, T_m is the melting point, and the constants K and a are characteristic of the spatial form of the molecules. Since at the melting point:

$$\Delta S_f = \frac{\Delta H_f}{T_m} \qquad \text{(Eq. 2)}$$

the entropy of fusion is dependent on the melting point for each class of compounds:

$$\Delta S_f = K - \frac{Ka}{T_m} \qquad \text{(Eq. 3)}$$

The entropy of fusion of flexible chain-like molecules increases as R ln 3 for the addition of each CH_2 group to a chain because there are three potential minima for rotation about a carbon–carbon bond (7). This theory explains the apparent dependencies of ΔS_f on area and volume (8, 9).

The entropy of fusion of rigid molecules does not vary directly with surface area (10, 11) or with molecular volume. The entropy of fusion of rigid hydrocarbons varies according to their moments of inertia and symmetry. Strong dipoles and hydrogen bonding have also been assumed to lower the entropy of fusion by hindering rotation in the liquid.

The purposes of this report are to determine the effect of molecular shape, hydrogen bonding, and dipole moment on ΔS_f for rigid nonspherical organic molecules and to consider the effects of these parameters on heat of fusion and melting point.

EXPERIMENTAL

Data Set—The compounds studied were all disubstituted benzene molecules. They included all 84 combinations of the substituents CH_3, Cl, Br, NO_2, OH, NH_2, and COOH in the *ortho*, *meta*, and *para* positions. The entropy of fusion was either determined experimentally or found in the literature for all compounds solid at room temperature as well as for many that are liquid. These compounds were chosen because of their similar size, shape and symmetry, but the substituents cover a wide range of dipole strengths and hydrogen bonding sites. Entropy of fusion differences due to symmetry and shape should have been minimal, while those due to dipole interactions and hydrogen bonding should have been readily apparent.

Determination of Entropy of Fusion—All entropies of fusion were calculated from the heats of fusion and melting points. These quantities were either obtained from the literature (12) or determined experimentally on a differential thermal analyzer[1] with a high-pressure differential scanning calorimeter cell. The literature values were obtained at atmospheric pressure. The experimental values were obtained at 500 psi to inhibit sublimation of the more volatile compounds. This pressure had little or no effect on the entropy of fusion of nonvolatile compounds and was assumed to have no effect on the entropy of fusion of the volatile crystals.

Reliable values for the entropy of fusion of three solids could not be determined experimentally. *p*-Aminophenol decomposed before melting, even under 1000 psi of nitrogen. Phthalic acid dehydrated to phthalic anhydride upon melting. Terephthalic acid sublimed, even under 1000 psi of nitrogen, as shown by a coating of compound around the inside of the calorimeter cell. This coating was insoluble in dilute sodium hydroxide and had the texture of a polymer, suggesting that some chemical

treatment of silica 63, however, resulted in an insignificant change in the particle-size distribution.

In Table VI and Fig. 4, the data gathered on selected samples are plotted in first-order fashion. The values for K_1 and K_2 were determined from the slopes of the lines, and the dissolution half-lives were calculated from the K_2 values. Where two first-order processes were evident, K_2 represented the slower process that occurred 60 min after dissolution had commenced (Fig. 4, prednisone–silica 63, solvent deposited). The data in Table VI clearly show that a significant change in dissolution half-life can be affected by solvent deposition on, or ball milling with, the amorphous silicon dioxides.

Fusion of Disubstituted Benzenes

ERIC MARTIN, SAMUEL H. YALKOWSKY ˣ, and JOHN E. WELLS

Received June 9, 1978, from the *Pharmacy Research Unit, The Upjohn Company, Kalamazoo, MI 49001.* Accepted for publication October 3, 1978.

Abstract □ The entropy of fusion of 84 disubstituted benzenes was essentially constant and independent of the participation of the compounds in intramolecular or intermolecular hydrogen bonding. It was also independent of the shapes, sizes, and dipole moments of the rigid molecules studied. While the entropy of fusion was independent of these parameters, the melting point and the heat of fusion showed a direct dependence on molecular properties.

Keyphrases □ Entropy of fusion—disubstituted benzenes, independent of hydrogen bonding, shape, size, dipole moment of rigid molecules, structure-activity relationships □ Melting point—analysis, disubstituted benzenes, structure-activity relationships □ Benzenes, disubstituted—entropy of fusion, melting point, heat of fusion, structure-activity relationships

The ability to predict the melting point, entropy of fusion, and heat of fusion from chemical structure would make possible the design of compounds having a specified physical state or even a specified melting range. The aqueous solubility of many organic compounds can be predicted from their melting points, entropies of fusion, and octanol–water partition coefficients (1). Since partition coefficients can be predicted by several group contribution methods (2, 3), the estimation of fusion properties makes possible the estimation of aqueous solubility. This possibility has direct implications for drug delivery.

BACKGROUND

In 1908, Walden (4) proposed that entropy of fusion is constant for many classes of compounds. Most elements have entropies of fusion of 2–3 entropy units (eu = cal/deg/mole); salts and small organic molecules usually have entropies of fusion of 5–7 eu; most organic molecules have entropies around 13 eu.

The entropy of fusion rule for organic compounds was later refined to account for molecular geometry (5). If heat of fusion is plotted *versus* melting point, molecules fall into groups according to molecular shape. The data for the chain-like, disk-like, and spherical molecules fall into regions (6) characterized by:

$$\frac{\Delta H_f}{T_m - a} = K \qquad \text{(Eq. 1)}$$

where ΔH_f is the heat of fusion, T_m is the melting point, and the constants K and a are characteristic of the spatial form of the molecules. Since at the melting point:

$$\Delta S_f = \frac{\Delta H_f}{T_m} \qquad \text{(Eq. 2)}$$

the entropy of fusion is dependent on the melting point for each class of compounds:

$$\Delta S_f = K - \frac{Ka}{T_m} \qquad \text{(Eq. 3)}$$

The entropy of fusion of flexible chain-like molecules increases as R ln 3 for the addition of each CH_2 group to a chain because there are three potential minima for rotation about a carbon–carbon bond (7). This theory explains the apparent dependencies of ΔS_f on area and volume (8, 9).

The entropy of fusion of rigid molecules does not vary directly with surface area (10, 11) or with molecular volume. The entropy of fusion of rigid hydrocarbons varies according to their moments of inertia and symmetry. Strong dipoles and hydrogen bonding have also been assumed to lower the entropy of fusion by hindering rotation in the liquid.

The purposes of this report are to determine the effect of molecular shape, hydrogen bonding, and dipole moment on ΔS_f for rigid nonspherical organic molecules and to consider the effects of these parameters on heat of fusion and melting point.

EXPERIMENTAL

Data Set—The compounds studied were all disubstituted benzene molecules. They included all 84 combinations of the substituents CH_3, Cl, Br, NO_2, OH, NH_2, and COOH in the *ortho*, *meta*, and *para* positions. The entropy of fusion was either determined experimentally or found in the literature for all compounds solid at room temperature as well as for many that are liquid. These compounds were chosen because of their similar size, shape and symmetry, but the substituents cover a wide range of dipole strengths and hydrogen bonding sites. Entropy of fusion differences due to symmetry and shape should have been minimal, while those due to dipole interactions and hydrogen bonding should have been readily apparent.

Determination of Entropy of Fusion—All entropies of fusion were calculated from the heats of fusion and melting points. These quantities were either obtained from the literature (12) or determined experimentally on a differential thermal analyzer[1] with a high-pressure differential scanning calorimeter cell. The literature values were obtained at atmospheric pressure. The experimental values were obtained at 500 psi to inhibit sublimation of the more volatile compounds. This pressure had little or no effect on the entropy of fusion of nonvolatile compounds and was assumed to have no effect on the entropy of fusion of the volatile crystals.

Reliable values for the entropy of fusion of three solids could not be determined experimentally. *p*-Aminophenol decomposed before melting, even under 1000 psi of nitrogen. Phthalic acid dehydrated to phthalic anhydride upon melting. Terephthalic acid sublimed, even under 1000 psi of nitrogen, as shown by a coating of compound around the inside of the calorimeter cell. This coating was insoluble in dilute sodium hydroxide and had the texture of a polymer, suggesting that some chemical

change (possibly to a linear anhydride) occurred as well. These data were excluded from the analysis.

Variables—One purpose of this study was to determine whether the thermodynamic properties of melting point, MP, heat of fusion, ΔH_f, and entropy of fusion, ΔS_f, are dependent on other, easily predicted properties. Molecular properties rather than bulk properties were chosen as parameters for two reasons. First, they can be estimated from the molecular structure so they can be used for predictions about little-studied compounds and about compounds that have not yet been synthesized. Second, the effects of molecular properties are more easily interpreted and are more valuable in explaining and understanding any discovered relationship.

Because these three thermodynamic properties are directly related [$\Delta H_f = (\Delta S_f) \times T_m$, where T_m is the Kelvin melting point], only two of them need be determined to obtain all three. Melting point is among the most difficult properties to predict. Fortunately, it is easily determined and frequently reported, so it is usually known. The entropy of fusion is largely predictable from previous work. The effects of certain electronic factors have not yet been determined and were the focus of this study.

The maximum possible number of hydrogen bonds (HNO) and the dipole moment (DM) were selected because they are known to affect the degree of disorder in the liquid state. They also affect the entropy of fusion. The simulated quadrapole moment (QM) accounted for electronic effects that are strong in the closely packed crystal but weak at the greater intermolecular distances in the liquid. The parameters (HNO, DM, and QM) can be predicted accurately from molecular structure alone (3), although experimental literature values were used in most cases.

The orientational symmetry number, σ, accounted for the statistical likelihood of finding a molecule properly oriented for incorporation into the crystal. Sigma is defined as the orientational degeneracy of a molecule, *i.e.*, the number of orientations of the molecule that will appear identical when viewed from a given point. The *ortho*-, *meta*-, and *para*-dichlorobenzenes have sigma values of 2, 2, and 4, respectively; *ortho*-, *meta*-, and *para*-bromochlorobenzenes have values of 1, 1, and 2, respectively. In this report, polyatomic groups such as CH_3, NH_2, NO_2, OH, and COOH are treated as monoatomic substituents which are coplanar with the benzene ring.

The polarizability, α, reflected the ability of the compound to interact with dipoles or induced dipoles. Polarizabilities were calculated from the following group incremental values: C_6H_4, 10.0; CH_3, 2.2; Cl, 2.3; Br, 3.3; NO_2, 2.6; NH_2, 1.7; OH, 1.0; and COOH, 2.8.

The dipole moments (DM) for all compounds were found in Ref. 13 except for *m*-bromophenol, terephthalic acid, and *p*-hydroxyaniline. The bromo compound was assigned the same value as the corresponding chloro compound because their group contributions were similar. *p*-Hydroxyaniline was estimated as being in the same ratio to *p*-dihydroxybenzene and *p*-diaminobenzene as the corresponding *ortho* and *meta* values. Terephthalic acid was assumed to be zero by its planarity and symmetry.

The simulated quadrapole moment is an artificial variable. It is the sum of the squares of the group dipole contributions from the two substituents:

$$QM = \mu_1^2 + \mu_2^2 \qquad \text{(Eq. 4)}$$

The squares were used because quadrapole moment is defined by $q = \Sigma er^2$, where e is the charge and r is the distance between the charges, whereas dipole moment is simply proportional to the distance:

$$\mu = \Sigma er \qquad \text{(Eq. 5)}$$

The maximum number of possible hydrogen bonds touching each molecule was the smaller of:

$$HNO = 2 \times H_a \qquad \text{(Eq. 6}a\text{)}$$

or:

$$HNO = 2 \times H_d \qquad \text{(Eq. 6}b\text{)}$$

where H_a is the number of hydrogen bond acceptor sites (electron pairs on oxygen or nitrogen) and H_d is the number of hydrogen bond donor sites (hydrogen attached to oxygen or nitrogen). The smaller of the two values was used instead of the number of protons because repeating networks of association in the liquid must have an acceptor for each donor.

The IHB variable indicated the ability of a molecule to form intramolecular hydrogen bonds. Internal hydrogen bonding competes with external (intermolecular) hydrogen bonding and thus would be expected to decrease melting point. The IHB is unity if the compound is capable of forming a hydrogen bond in a six- or seven-membered ring and zero if it is not. Thus, for resorcinol and related compounds, IHB = 0.0.

The data were analyzed by multiple linear regression using the Statistical Analysis System. The r^2 value was used as a measure of correlation for each set tested. Values above 0.9 were considered quantitatively useful; values above 0.7 were considered a qualitative correlation, indicative of a trend but not good enough for accurate predictions; values below 0.7 were considered random. The T values were used to determine the significance of each independent variable's contribution to the whole equation in multiple regressions. Values above 3 were considered to be borderline correlations, and values above 4 were considered to be significant contributions. The results of these tests are given in Tables I and II.

RESULTS AND DISCUSSION

The data consisted of ΔS_f, MP, σ, α, DM, QM, HNO, and IHB values for all 84 compounds (Table I). The ΔH_f and ΔS_f have been determined for only 69 compounds. If any of the variables were missing for a compound in a given analysis, that compound was not included in that run. The number of common values determined the size of the data set for each regression.

The results of the more interesting regression analyses for ΔS_f, ΔH_f, and MP are given in Table II.

Inspection of Table II shows that ΔS_f does not depend on any of the parameters against which it was measured ($r^2 < 0.40$). It is independent of the number of hydrogen bonds, of dipole moment, and of other measures of attractive electronic factors. It is approximately constant, with a value of 12.7 ± 2 eu (mean ± SD) for all 69 data points. Constancy is also shown by the low estimated coefficients,which indicate an approximately horizontal slope. The low T value for σ (Table II) indicates that the effect of molecular geometry is also insignificant. Symmetry, moment of inertia, and other structurally related properties do not affect the entropy of fusion for these compounds. However, because this set of compounds was chosen to minimize these geometrical effects, this result cannot be generalized.

The fact that the entropy of fusion is independent of the electronic attractive factors (Table III) contradicts previous reports (10). For the 24 compounds in the upper left quadrant (Table III), neither substituent has a hydrogen bond-forming hydrogen. The average value of ΔS_f for this group is 13.0 ± 1.48 eu. The upper right quadrant is occupied by the 30 compounds with one hydrogen bond-forming substituent. The mean ΔS_f for these compounds is 12.7 ± 2.20 eu. (Two compounds with questionable values were excluded.) The average for all three groups is between 12.5 and 13 eu, with no systematic decrease apparent.

Bondi (10) stated that any factors that interfere with free rotation in the liquid would decrease the entropy. Hydrogen bonds and strong di-

poles restrict free rotation and decrease the disorder in the liquid state. The lack of effect of these phenomena on the entropy of fusion can be explained on the basis of the effect of hydrogen bonding in the crystal.

Entropy is related to disorder by a logarithmic function:

$$\Delta S_{or} = R \ln \frac{\Omega_r}{\Omega_{tor}} \qquad \text{(Eq. 7)}$$

The orientational contribution to the entropy is determined by the ratio of the number of complexions available in the liquid to the number of complexions available in the crystal. If the magnitude of the torsional oscillations were restricted in the crystal by the same percentage as the rotations are restricted in the liquid, there would be no change in entropy. The effect of hydrogen bonding on bulk crystalline properties such as packing density and melting point shows that factors that lead to association in the liquid also hold the molecules more tightly in the solid. The smaller A-B intermolecular distances and the appearance of A-H···B vibrational modes in the IR regions provide evidence that hydrogen bonds might restrict these torsional oscillations in the crystal (14).

The lack of a consistent effect of hydrogen bonding can be demonstrated by comparing the entropy of fusion of hydroxyl compounds with that of their methyl homomorphs (Table IV).

The heat of fusion equals the product of the entropy and the melting point. If the entropy is a constant, ΔH_f should depend only on MP. Therefore, the value of the correlation coefficient of the regression ΔH_f *versus* MP indicates how well 12.7 approximates the entropy of the set of compounds tested. Table II shows that ΔH_f does indeed depend only on MP. The r^2 value of 0.78 shows that a strong correlation exists but accurate values must be determined experimentally.

The regression analysis of melting point is also given in Table II. Four parameters were necessary to obtain a definite trend. These results were difficult to interpret because of the low r^2 value for the number of parameters and the large contribution of the sigma parameter, which probably includes a large variety of unspecified factors. The most interesting results is the much larger contribution of QM than DM as a result of the proximity of the molecules in the crystal. In the tightly packed, highly ordered crystal lattice, the molecules arrange themselves so that the negative parts of one molecule are closest to the positive portions of neighboring molecules. At these distances, a negative group is strongly attracted to the positive charge adjacent to it, but it is largely unaffected by the repulsive forces at the other end of the molecule since quadrapole fields fall off so rapidly with distance (much more rapidly than dipoles). Although no definite conclusions can be drawn from the melting-point correlations, they provide some encouragement for the eventual ability to understand and predict melting point.

Use of a Nitrogen-Specific Detector for GLC Determination of Plasma Bucainide

HERSCHEL H. C. LI ˣ, WILLIAM P. FEENEY, and MARTHA M. JOHNSTON

Received April 12, 1978, from the *Department of Biochemistry and Drug Disposition, USV Pharmaceutical Corp., Tuckahoe, NY 10707.* Accepted for publication October 18, 1978.

Abstract □ A sensitive and specific GLC determination of plasma bucainide was developed using a nitrogen-specific detector. The method permits the determination of bucainide as low as 5.0 ng/ml of plasma and provides sufficient sensitivity and reproducibility for clinical use.

Keyphrases □ GLC—bucainide, analysis in plasma □ Bucainide—GLC analysis in plasma □ Antiarrhythmic—bucainide, GLC analysis in plasma

Bucainide maleate[1] (I), 1-(*N*-isobutyl)benzimidoyl-4-(*N*-hexyl)piperazine dimaleate, is a novel, potent antiarrhythmic agent. The antiarrhythmic effect was demonstrated in the following animal models: mouse chloroform-induced ventricular arrhythmias, refractory period prolongation in guinea pig isolated atria, aconitine-induced atrial arrhythmias in the dog, ventricular arrhythmias following coronary artery ligation in the dog, and ouabain-induced ventricular tachyarrhythmias in the dog (1). The drug also possesses local anesthetic effects and is a weak central nervous system depressant[2].

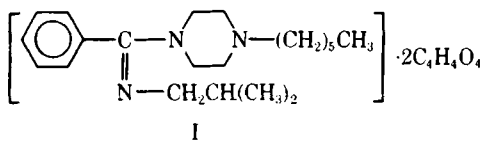
The development of a reliable, specific, and sensitive determination of bucainide in plasma was initiated to support clinical and related studies. Recent advances in GLC detector technology indicated that a nitrogen-specific detector would be feasible. The use of a nitrogen-specific detector for the determination of imipramine and desipramine (2), cocaine (3), and theophylline (4) in biological fluids was reported. Bucainide, due to the three nitrogen atoms on the molecule, appeared to be a promising candidate for this mode of detection.

EXPERIMENTAL

GLC—The gas chromatograph[3] was equipped with a nitrogen-phosphorus detector (NPD). A 1.8-m × 0.2-cm i.d. glass column was packed with 3% phenyl methyl silicone fluid coated on acid-washed, dimethylchlorosilane-treated (80–100-mesh) diatomite support[4]. Retention times and peak areas were measured by a single-channel computing integrator[5].

The gas chromatograph was run in the isothermal mode at a column temperature of 240°. The flow rate of the carrier gas (helium) was 40 ml/min, while the detector gases were set at 100 ml/min for air and 3 ml/min for hydrogen.

The standing current of the detector was calibrated daily by adjustment of the potentiometer so that a 50% full-scale response was obtained on the recorder at an attenuation setting of 64 on the integrator.



I

Reagents and Materials—Hexane, acetone, *n*-butyl chloride, and 2-propanol were "distilled-in-glass" grade[6]. The aqueous solution of saturated sodium bicarbonate was filtered[7] before use.

N^1-Hexyl-N^4-benzoylpiperazine maleate[1] (II) was selected as the internal standard. Oxalated dog plasma[8], which was kept frozen in polypropylene containers, was employed for standard curves.

All glassware was kept in chromic acid overnight. After cleaning, the glassware was rinsed with acetone prior to use.

Procedure—Aliquots of 7.5, 15, 30, 60, 90, 120, and 150 μl of bucainide maleate aqueous stock solution (equivalent to 14.8 ng/10 μl as base) were added to 2.0 ml of control dog plasma samples in 15-ml polytef-lined screw-capped tubes. In addition, an aliquot of 50 μl of the internal standard aqueous stock solution (equivalent to 14.1 ng/10 μl as base) was added to each tube. These samples were used to generate a standard curve. An equal aliquot of the internal standard solution was added to all unknown samples.

After an addition of 2.0 ml of saturated sodium bicarbonate solution to each plasma sample, bucainide was extracted with 5.0 ml of *n*-butyl chloride–2-propanol (90:10 v/v) by shaking at 120 oscillations/min for 15 min on a reciprocating shaker[9]. The organic phase was transferred to a second extraction tube containing 5.0 ml of hexane. Bucainide was then extracted with 1 ml of 0.1 *M* H_2SO_4. The addition of hexane to lower the solvent polarity of the organic phase enhanced the extraction of bucainide into acid.

After the solution was alkalinized with 3.0 ml of saturated sodium bicarbonate solution, the drug was back-extracted into 5.0 ml of *n*-butyl chloride–2-propanol (90:10 v/v). The organic extract was evaporated[10] to dryness under nitrogen at 30°, and the residue was redissolved with 25 μl of acetone by vigorous vortexing. To avoid evaporation, the sample was kept on ice prior to GLC analysis, which used an aliquot of 5.0 μl.

RESULTS AND DISCUSSION

Solvent Extraction—The extractibility of bucainide and II as a function of pH was studied in separate experiments with *n*-butyl chloride–2-propanol (90:10 v/v) as the solvent. Bucainide, together with *n*-dososane[11] as an internal standard, was spiked into pH 6, 7, 8, 9, 10, 11, and 12 buffers. The organic extracts were evaporated to dryness and redissolved in acetone before detection by flame ionization. The results showed that after an initial increase from pH 6 to 7, no significant increase in bucainide extraction was observed between pH 7 and 12. Similarly, II was found equally extractible over the pH 6–12 range.

The extraction efficiency of bucainide with II as the internal standard was studied by comparing the relative areas of the extracted spiked plasma samples with those of the unextracted reference standards. An average of 98.5% recovery was observed for the range of 7.5–111.8 ng/ml of plasma.

Plasma Standard Curves—Figure 1 is a typical chromatogram of a spiked plasma sample used for the standard curve. The peak at 150 sec represents 66.6 ng/ml of bucainide, whereas the peak at 210 sec represents 35.3 ng/ml of the internal standard.

Four plasma standard curves for the range of 5.6–111.0 ng/ml were analyzed over 3 weeks (Table I). The standard error was 9.1% for 5.6 ng/ml and 1.8% for 111.0 ng/ml. The composite standard curve was determined by regression analysis, the equation of which was: $y = 0.01445x + 0.05788$, where y represents the relative areas of bucainide to II and x is the bucainide concentration in nanograms per milliliter.

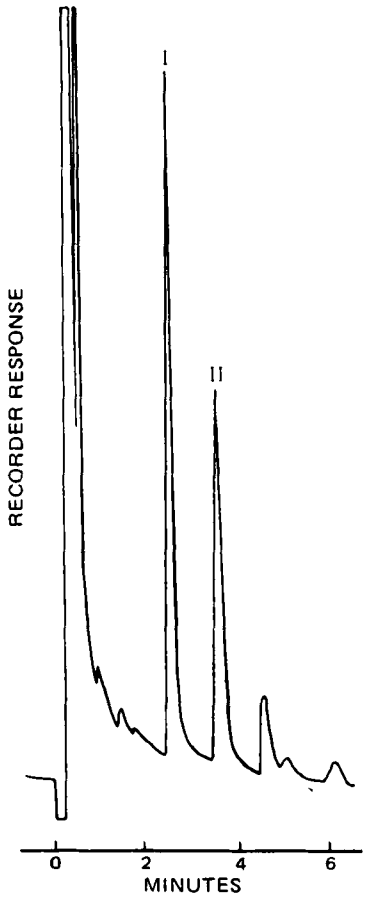

Figure 1—*Chromatogram of a control dog plasma sample, which was spiked with the bucainide reference standard and the internal standard. The peaks at 150 and 210 sec represent 66.6 ng of bucainide and 35.3 ng of II/ml of plasma, respectively.*

The standard curve was linear for the range studied (r = 0.986).

Specificity—To study the possible interference due to endogenous materials in the plasma, plasma samples of four different subjects from a clinical study were extracted as already described and analyzed without addition of the internal standard under the established GLC conditions. The samples represent either predose plasma blanks or samples at various time intervals from subjects receiving a placebo. No interference peaks at the retention times of bucainide or II were observed.

Similarly, another set of plasma samples from a multiple-dose clinical study was analyzed by the same procedure without the internal standard. These samples were obtained after the fourth intravenous dose of 50 mg at 10 min and 1, 3, and 6 hr. None of these samples showed any interference peaks at the II retention time.

Subsequently, GLC–mass spectrometry[12] was employed to substantiate further the absence of interference due to either unidentified metabolites or plasma endogenous materials coextracted and cochromatographed with bucainide or II. A set of plasma samples from the same subject at 0 and 15 min and 1, 2, and 3 hr after the fourth intravenous dose was spiked with the internal standard and extracted as described. The pooled extract was analyzed using chemical ionization with isobutane as the reactant gas.

For each fraction, the chemical-ionization mass spectra showed a base peak at m/e 330 and 275, corresponding to the expected protonated molecular ions, MH^+, of bucainide and the internal standard. Minor peaks at m/e 202 for bucainide and m/e 140 for the internal standard also were observed. These minor peaks were the breakdown products of the corresponding MH^+ ions. These assignments were supported by the identical spectra of the respective unextracted reference standards. Based on these studies, the present method was specific for the determination of bucainide in plasma samples from controlled clinical studies when the subjects were free from other medication.

Clinical Samples—A complete profile of the plasma bucainide levels of one subject from a multiple-dose clinical study is shown in Table II. The subject received four intravenous doses of 50 mg at a dose interval of 4 hr. The predose levels of bucainide at Doses 2 and 3 were approximately 5 ng/ml. The levels of the samples taken immediately after Doses 1, 2, 3, and 4 were about 500–1000 ng/ml.

[12] Chemical-ionization mass spectra were obtained using a Varian MAT 112 GLC-mass spectrometer interfaced to a Varian MAT SS-100C data processing system, Varian MAT, Florham Park, NJ 07832.

Table I—Composite Plasma Standard Curve [a]

Plasma Concentration, ng/ml	Mean Relative Area ± *SE*	*SE*, %
5.6	0.11 ± 0.01	9.1
11.1	0.23 ± 0.02	8.7
22.2	0.42 ± 0.03	7.1
44.4	0.65 ± 0.01	1.5
66.6	1.03 ± 0.04	3.9
88.8	1.28 ± 0.07	5.5
111.0	1.70 ± 0.03	1.8

[a] Composite of four standard curves, and each concentration point was determined in duplicate; $y = 0.01445x + 0.05788$ (r = 0.986).

Table II—Plasma Bucainide Levels for One Subject [a]

Sample Time	Dose 1	Dose 2	Dose 3	Dose 4
Predose[b]	0.0	5.2	5.6	—
"Zero"[c]	940.2	497.0	533.9	482.8

Rotating-Disk Method for Determining Cutaneous Metabolism

L. C. LEUNG and H. Y. ANDO ˣ

Received September 13, 1978, from the *Department of Pharmacy, Philadelphia College of Pharmacy and Science, Philadelphia, PA 19104.* Accepted for publication October 19, 1978.

Abstract □ Since design and evaluation of topical dosage forms should account for both skin permeation and cutaneous metabolism, an *in vitro* system was formulated to determine the metabolic component of viable guinea pig skin utilizing the diffusion layer property of the rotating disk. The drug investigated was vidarabine, an antiviral agent, which was rapidly metabolized to 9-β-D-arabinofuranosylhypoxanthine. The aqueous diffusion coefficient of the drug was determined by the capillary cell method. The rotating-disk system was standardized using benzoic acid. The dorsal skin of a guinea pig was removed after shaving, and the epidermal section was excised by a keratome. After the section was mounted on the stainless steel disk with a tissue adhesive, the preparation was immersed in a 10-ml beaker containing 5 ml of drug solution at 37°. At suitable intervals, samples were withdrawn, separated by TLC, and assayed by liquid scintillation. The enzyme rate constant was 1.54×10^{-1} sec^{-1}.

Keyphrases □ Rotating disk—analysis, cutaneous metabolism of vidarabine, guinea pig, *in vitro* study □ Skin—metabolism of vidarabine, rotating-disk method, guinea pig, *in vitro* study □ Antiviral agents—vidarabine, cutaneous metabolism, rotating-disk method, guinea pig, *in vitro* study □ Vidarabine—cutaneous metabolism, analysis by rotating-disk method, guinea pig, *in vitro* study

Recently (1, 2), an *in vitro* model was proposed for determining the simultaneous transport and metabolism of vidarabine (I) into 9-β-D-arabinofuranosylhypoxanthine (II) in hairless mouse skin. However, some experimental parameters required for the metabolic rate constant calculation were not determined, namely, the aqueous diffusion coefficient of I, D_{aqA}, and the diffusion layer thickness, h.

The objectives of the present investigation were to assess these parameters and to determine the enzyme metabolic rate constant. A capillary cell method (3) was used for the determination of D_{aqA}. By using the rotating-disk theory (4) and benzoic acid standardization (5), h was calculated. These parameters were then used for the calculation of the cutaneous metabolic enzyme rate constant.

EXPERIMENTAL

Apparatus—A constant-speed synchronized motor[1], a 50-μl syringe[2], a liquid scintillation counter[3], a laboratory press[4], two variable-speed synchronized motors[5], a light tachometer[6], 10-ml micropipets[7], a membrane filter[8], an electric shaver[9], a keratome[10], and silica GF plates[11] were used.

Reagents and Materials—The following were used: vidarabine[12], ^{3}H-vidarabine[13], 9-β-D-arabinofuranosylhypoxanthine[12], benzoic acid (primary standard)[14], ^{14}C-benzoic acid, a commercially prepared liquid scintillation cocktail[15], 0.01 *N* HCl[14], female albino guinea pigs (500–600 g), and pentobarbital sodium.

Aqueous Diffusion Coefficient, D_{aqA}, Determination—The upper reservoir of the diffusion cell (3) was nylon, and the capillary portion was a 50-μl gas-tight syringe[2] ground flat to the zero calibration mark. The value of D_{aqA} was determined by Saraf's method (3) using ^{3}H-vidarabine and liquid scintillation.

Estimation of Aqueous Diffusion Layer, h—The stainless steel rotating disk consisted of an outer cone-shaped manifold and an inner cylindrical disk (Fig. 1). Experimental deviations from the Levich (4) theory due to geometry and hydrodynamics were assessed using a benzoic acid standardization (5, 6).

By recrystallizing 0.1 mCi (0.9 mg) of ^{14}C-labeled and 9 g of primary standard benzoic acid from alcohol, radioactive benzoic acid crystals were obtained. Pellets of this material were prepared on a laboratory press by directly compressing about 500 mg of the crystals in a flat surface die (1.27 cm i.d.) with an average force of 4086 kg (9000 lb).

For each dissolution run, 5 ml of 0.01 *N* HCl, preequilibrated at 37°, was pipetted into a 10-ml beaker in a 37° controlled bath. The benzoic acid pellet was firmly seated in the outer cone-shaped manifold, which was connected to a synchronized motor. The rotation speed was determined with a light tachometer and adjusted to 300 rpm. After the disk was immersed in the hydrochloric acid solution, 10-μl samples were withdrawn with a micropipet at 5-min intervals and were assayed by liquid scintillation counting.

Metabolism Study of Vidarabine (I)—*Preparation of Radioactive Solution*—A 600 μ*M* I solution was prepared by dissolving 16.0 mg of I in 100 ml of Delbecco buffer (7) and filtering the solution through a 0.22-μm filter. By successive serial dilutions, stock solutions of 0.25, 0.5, 0.75, 1.0, and 6.0 μ*M* were obtained. Five-milliliter samples of these solutions were spiked with 10 μCi of ^{3}H-vidarabine (I) prior to each experiment.

Preparation of Skin—A female albino guinea pig, 500–600 g, was anesthetized with pentobarbital sodium (100 mg/kg ip). The dorsal skin was shaved first with an animal shaver and then with a manual razor. The area was washed with distilled water and dried with a stream of warm air. After removal from the animal, the dorsal skin was stapled onto a wooden board. The animal was then sacrificed with pentobarbital sodium.

A keratome set at 0.2 mm removed a thin layer of the epidermis plus some underlying dermis from the skin. The inner disk was removed from the outer manifold and placed over the shaved surface; tissue adhesive[16] was used to secure the skin to the side of the disk. To expose a constant surface area of the skin, polytef tape was wrapped around the skin on the cylindrical surface and secured with tissue adhesive. The outer cone-shaped manifold was then replaced on the inner disk (Fig. 1). This preparation was connected to a synchronized motor and immediately immersed in the 5 ml of radioactive I solution prepared prior to each experiment and maintained at 37°.

Five microliters of this solution was spotted with 1.5 μg of nonradioactive I and II onto prescored silica GF plates under a nitrogen stream. The plates were immediately developed in the solvent system described previously (8). After separation, I and II were scraped into vials and assayed by liquid scintillation. As a control, the experiment was duplicated twice without the skin.

RESULTS AND DISCUSSION

Aqueous Diffusion Coefficient Determination—The aqueous diffusion coefficient for Compound *A*, D_{aqA}, can be determined from (9):

$$D_{aqA} = \frac{4L^2}{\pi^2 T} \ln\left(\frac{8C_0}{\pi^2 C_a}\right) \qquad \text{(Eq. 1)}$$

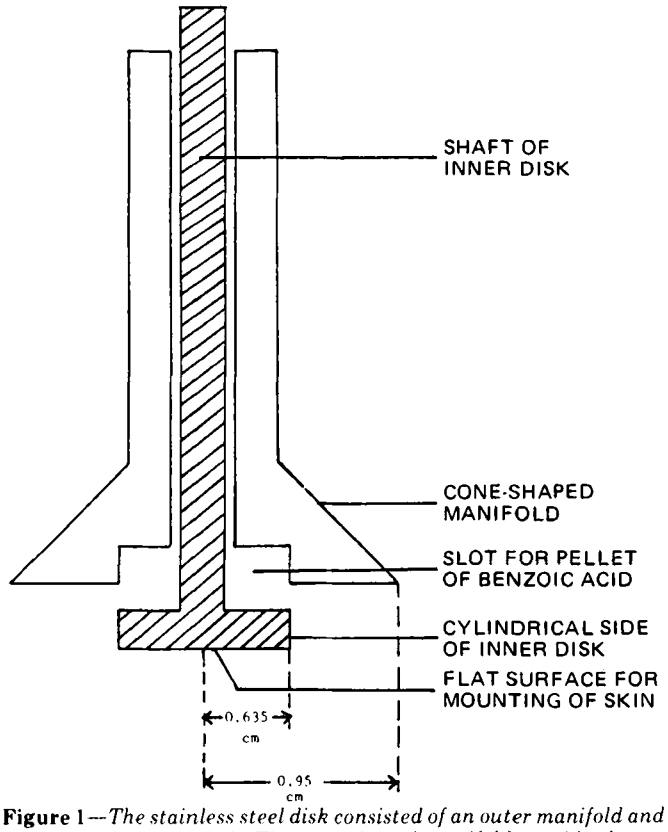

Figure 1—*The stainless steel disk consisted of an outer manifold and an inner cylindrical disk. The cone-shaped manifold provides better hydrodynamic conditions and serves as a slot for the benzoic acid pellet. The inner cylindrical disk is for the anchorage of skin in the metabolism experiments.*

where C_a and C_0 are the solute concentrations of A at time T and time zero, respectively, and L is the capillary length in centimeters. Compound I was found to have an average D_{aqA} of $(1.05 \pm 0.01) \times 10^{-5}$ cm^2/sec at 37° (Table I).

This value appears to be a little high compared with that of cyclic adenosine monophosphate (III), which was reported as 4.44×10^{-6} cm^2/sec at 20° (10). This difference may be due to the difficulty in the measurement and in the accurate reproduction of the capillary length. However, this higher value may be justified partly by the Stoke-Einstein equation (10). First, I was at a higher temperature, so the viscosity of the solvent was lower. Second, I has a smaller molecular weight and a lesser degree of solvation than III due to the absence of the phosphate group.

Estimation of Aqueous Diffusion Layer Thickness—When Compound A diffuses out of a rotating disk into an aqueous liquid, a theoretical diffusion layer thickness, h_{th}, which retards the loss of A, is described by the Levich (4) relationship:

$$h_{th} = (1.612)(D_{aqA}^{1/3})(\nu^{1/6})(\omega^{-1/2}) \qquad \text{(Eq. 2)}$$

where D_{aqA} is the aqueous diffusion coefficient (square centimeters per second), ν is the kinematic viscosity (centimeters per second), and ω is the angular velocity (radians per second). This equation requires that the disk have an infinite diameter and that it rotate with a constant velocity in a liquid of infinite volume. Therefore, the finite size and shape

Table I—Parameters in Determination of Aqueous Diffusion Coefficient of I by Capillary Cell Method [a]

Time[b], sec	L, cm	C_0, cpm	C_a, cpm	D_{aqA}, (cm^2/sec) $\times 10^5$

[a] The average value of the coefficient is $(1.05 \pm 0.01) \times 10^{-5}$ cm^2/sec. [b] About 24 hr.

Table II—Dissolution Profile of Benzoic Acid Pellets (A = 1.27 cm^2) in 0.01 N HCl at 300 rpm

Minutes	Concentration, mg/ml	ΔC[a], mg/ml
5	1.21	0.87
10	2.08	0.62
15	2.70	0.46
20	3.16	0.34
25	3.50	0.25
30	3.75	

[a] Concentration differential between successive time periods.

of the disk and the hydrodynamic condition within a real system may cause h to be considerably different from h_{th}. If h is the effective diffusion layer thickness in the experimental system, then let:

$$R = \frac{h}{h_{th}} \qquad \text{(Eq. 3)}$$

To determine R, consider the Levich relationship for the flux from the disk (4), assuming sink conditions:

$$J_{th} = (0.62)(D_{aqA}^{2/3})(\nu^{-1/6})(\omega^{1/2})(C_s) \qquad \text{(Eq. 4)}$$

where C_s is the saturation concentration of A.

Combining Eqs. 2 and 4 gives:

$$J_{th} = \left(\frac{D_{aqA}}{h_{th}}\right)(C_s) \qquad \text{(Eq. 5)}$$

which is Fick's first law. Since this law must hold for the experimental system as well:

$$J = \left(\frac{D_{aqA}}{h}\right)(C_s) \qquad \text{(Eq. 6)}$$

Then R can be determined by combining Eqs. 5 and 6 to give:

$$R = \frac{J_{th}}{J} \qquad \text{(Eq. 7)}$$

The dissolution of benzoic acid was used to standardize the disk for the determination of J_{th} since its aqueous diffusion coefficient is well known.

Data Treatment—Three dissolution experiments of benzoic acid pellets rotating at 300 rpm in 0.01 N HCl (Table II) showed the relation between the concentration and the successive concentration differential and time. The dissolution rate constant, K, was determined from these data (11) (Fig. 2) assuming a first-order equation. This constant was 6.17 $\pm$ 1.19 min^{-1}. The experimental flux was determined from:

$$J_{exp} = (K)(C_s)\left(\frac{V}{A}\right) \qquad \text{(Eq. 8)}$$

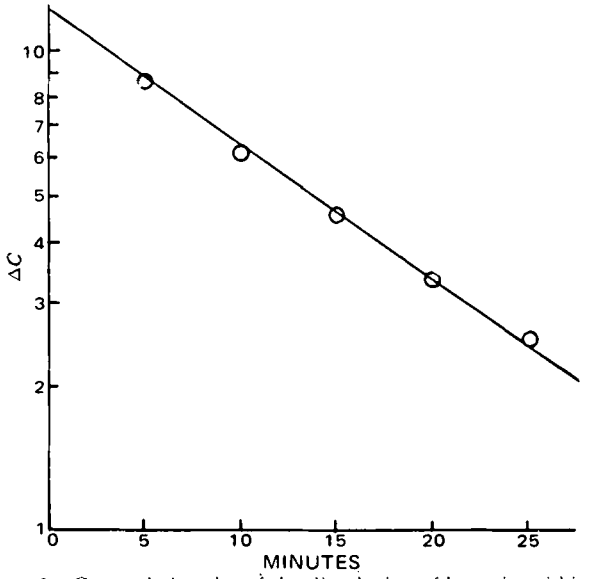

Figure 2—*Guggenheim plot of the dissolution of benzoic acid in 0.01 N HCl;* $C_t = C_{(t+i)} - C_t$, *where* i *is the sampling interval (5 min).*

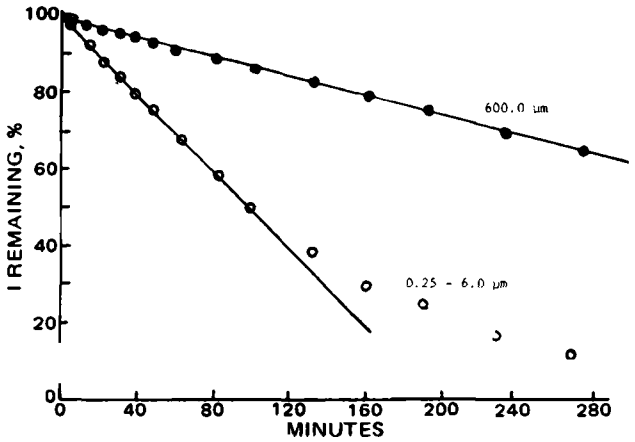

Figure 3—*Metabolism of I by guinea pig skin rotating at 300 rpm and 37°. Plots for concentrations of 0.25–6.0 μM were similar.*

where (V/A) is the volume to surface area ratio (3.95 cm in this system). The flux J_{exp} was 0.244 ± 0.047 C_s.

By using reported values of the aqueous diffusion coefficient of benzoic acid (1.40×10^{-5} cm²/sec) (12) and the aqueous kinematic viscosity (0.00699 cm²/sec) (13), the theoretical flux and the diffusion layer thickness, under the same experimental conditions, were computed to be 0.277 C_s and 27.57 μm, respectively. From Eq. 3, R was estimated to be 1.135. This value of R predicts an experimental aqueous diffusion layer thickness, h, of 31.3 μm, which differs from h_{th} by 13.5%.

This high discrepancy came as a surprise since the cone-shaped design is accepted as the best configuration for a rotating-disk system (14). However, this deviation can be explained by the fact that within the rotating system, the solvent does not have an infinite volume, nor does the disk have an infinite diameter, as required by the Levich (4) equation. Also, as benzoic acid dissolution continued, surface erosion occurred, disturbing the flow pattern. All of these nonideal hydrodynamic conditions, as well as the continual solvent evaporation, contributed to the 13.5% deviation, which is similar to that previously reported (5).

Metabolism Study of Vidarabine—Vidarabine (I) was metabolized to 9-β-D-arabinofuranosylhypoxanthine by the cutaneous enzyme system (Fig. 3). The initial slope was derived from the regression analysis, which included all data points up to 100 min. These regression coefficients were all greater than 0.995.

The flux of I, F_A, was then calculated from:

$$F_A = \left(\frac{V}{A}\right)\left(\frac{dC}{dt}\right) \qquad \text{(Eq. 9)}$$

where V is the solution volume in milliliters, A is the area of the exposed skin (square centimeters), and (dC/dt) is the initial slope of metabolism (percent per minute) (Table III). Statistical analysis of the fluxes showed a significant difference between 600.0 μM and the other concentrations. The mean flux was 1.75 ± 0.09%/min.

Determination of Cutaneous Metabolic Rate Constant—As shown in Eq. 10, the enzyme metabolic rate constant, k_m, can be expressed in terms of the initial substrate concentration, $C_A(h)$; the flux of the substrate in the system, F_A; the aqueous diffusion coefficient, D_{aqA}; the epidermal layer thickness, M; and the diffusion layer thickness, h:

$$k_m = \left(1 \Big/ \left[\frac{C_A(h)}{-F_A} - \frac{h}{D_{aqA}}\right]\right)(M) \qquad \text{(Eq. 10)}$$

This equation is derived by using Eq. 25 of previous work (2) and taking the limit of $\theta \to 0$, such that $\tanh \theta \to 0$. By substituting into Eq. 10 the reported epidermal thickness of 20.85 μm (15) and the other experimentally determined parameters, the enzyme metabolic rate constant was found to be 1.56×10^{-1} sec^{-1}.

In the controlled metabolism study, I remained unchanged at the initial concentration of 98.1% over 6 hr in the presence of the stainless steel rotating disk. The stability of I during the storage period was also investigated. The stock solution had been sterilized by being passed through a 0.22-μm filter and was then stored in an enclosed sterile vial and refrigerated. There was no apparent adsorption of I onto the filter. At the end of the 40th day, when all of the stock solutions were used up, the I purity was determined to be 97.9%. These findings show that the degradation of I into II was the sole result of the enzyme system existing in the viable guinea pig epidermal slice.

Table III—Fluxes of I at Different Concentrations

The enzyme that converts I into II is adenosine deaminase, which metabolizes adenosine and various adenine nucleoside drug analogs, rendering them pharmacologically inactive. Calf intestinal mucosa adenosine deaminase has a metabolic rate constant of 0.8×10^{-1} sec^{-1} mg^{-1} (16). Although no direct comparison can be drawn, it can be concluded that adenosine deaminase is present in abundance in guinea pig skin.

In the final calculation of the enzyme rate constant from Eq. 10, the I flux and the epidermal thickness were the two most important parameters.

Since the flux depends on the concentration data of I and II, the assumption of mass balance used in their determination was evaluated. The criterion for mass balance is that the sum of the activities of I and II on the TLC plate is equal to the total activities of the sample. This assumption holds if II is the only major metabolite of I and if I and II bind identically to the tissue.

Several 6th-hr samples of the metabolism experiments were examined. The entire plate was scraped into scintillation vials in strips of 2 cm. It was found that I and II accounted for over 98% of the total activities.

Possible binding of I and II to the tissue was investigated statistically. From the raw data from five experiments at 0.5 μM, the corresponding activities of I and II were plotted *versus* time. The slope for the disappearance of I was 31.44 cpm/min, while the appearance rate of II was 31.48 cpm/min. Since the appearance rate of II was accompanied by an equivalent amount of disappearance of I, and since I and II accounted for over 98% of all activities, the assumption of mass balance was valid.

The average flux was obtained from the results of all concentrations except those of 600.0 and 0.5 μM. The former was rejected because it was significantly different from the others. The latter was excluded on the ground that two of the values were obtained from animals that did not meet the protocol.

The epidermal thickness is another important parameter in the determination of the rate constant. The model calls for the use of only the epidermal thickness on the assumption that the dermis is less active enzymatically than the epidermis. However, the dermis does contribute to the overall metabolism (17). Variation of hand pressure and speed of dermatoming caused variation in skin thickness, which was usually about 0.3 mm microscopically. Future studies may investigate the possibility of preparing epidermal slices of reproducible thickness using a motor-driven constant-pressure dermatome device. A method for accurate measurement of skin thickness must be developed also.

Future studies may determine the epidermal diffusion coefficient of the drug. With this parameter and the present data, one can estimate how metabolism and, possibly, formulation adjuvants can modify the bioavailability of the drug as it is administered in a topical dosage form.

GLC Assay of Verapamil in Plasma: Identification of Fluorescent Metabolites after Oral Drug Administration

R. G. McALLISTER, Jr. *, T. G. TAN *, and D. W. A. BOURNE ‡x

Received August 21, 1978, from the **Department of Medicine, Veterans Administration Hospital, and the School of Medicine and the* ‡*College of Pharmacy, University of Kentucky, Lexington, KY 40506.* Accepted for publication October 20, 1978.

Abstract □ The fluorometric assay for verapamil in plasma is not useful after oral drug administration because of interference by inactive, but fluorescent, metabolites extracted along with the parent drug. A GLC method using a flame-ionization detector after silylation allows the separation of unchanged active verapamil from the metabolites and quantitation to a sensitivity of 0.025 μg/ml. After a single oral dose of drug in dogs, up to 80% of "fluorescent verapamil" represented inactive metabolites.

Keyphrases □ Verapamil—GLC analysis, plasma fluorometric analysis, metabolite interference □ GLC—analysis, verapamil in plasma □ Vasodilators—verapamil, GLC analysis in plasma

Verapamil, 5-[(3,4-dimethoxyphenethyl)methylamino]-2-(3,4-dimethoxyphenyl)-2-isopropylvaleronitrile (I), is an experimental antiarrhythmic and antianginal agent (1–5) and is currently undergoing clinical evaluation in the United States. Its pharmacological activity is related to suppression of transmembrane calcium fluxes in cardiac and other tissues (6, 7). These "slow" calcium currents may be involved in the genesis of fatal arrhythmias during myocardial ischemia and associated with sudden cardiac death (8).

BACKGROUND

A fluorometric assay for verapamil in plasma (9) has been used to determine its elimination kinetics in dogs after intravenous injection (10) and to demonstrate a linear correlation between plasma drug concentrations and both electrophysiologic and hemodynamic effects in dogs following systemic dosing (11). However, after oral administration of verapamil to dogs, no relationship between plasma level and effect was found (12), raising the possibility that metabolites generated during the first passage through the liver interfere with the fluorometric assay.

Verapamil is known to be metabolized extensively in rats and dogs, primarily to *O*- and *N*-dealkylated derivatives through loss of the 3,4-dimethoxyphenylethyl moiety (13). Schomerus *et al.* (14) used mass fragmentography to confirm the extensive metabolism of the drug in three normal human subjects after a single oral dose but did not identify the specific metabolites produced.

Since verapamil may become an important addition to the drugs available for treatment of cardiovascular disorders, the assay validity must be defined before further kinetic and pharmacological studies can be carried out. Two major metabolites of verapamil, 5-amino-2-(3,4-dimethoxyphenyl)-2-isopropylvaleronitrile (D620) (II) and 5-methylamino-2-(3,4-dimethoxyphenyl)-2-isopropylvaleronitrile (D617) (III)[1], were studied to determine possible interference with the fluorometric assay for parent verapamil. Furthermore, a GLC procedure specific for unchanged verapamil in the presence of II or III was developed and is described.

EXPERIMENTAL

Fluorometric Assay—The fluorometric assay for verapamil in plasma (9) involves extraction of drug from alkaline plasma with heptane and back-extraction into acid. Fresh plasma from normal drug-free human subjects was pooled. To one group of aliquots, verapamil was added to achieve concentrations of 0.1, 0.5, and 1.0 μg/ml; to two other aliquots, II or III were added similarly. All samples were prepared in triplicate.

The fluorometric assay was performed on each sample by an experienced technician under blind conditions, and the resulting fluorescence at an excitation/emission spectra of 275/310 nm was recorded[2]. The calculated recovery from these standards ranged from 85 to 94%.

To additional aliquots of plasma from the same pool, combinations of verapamil and II and III were added, each in a concentration of 0.5 μg/ml. The assay was carried out as previously described, and total fluorescence was determined[2].

GLC Assay—All reagents and solvents were of analytical grade, and glassware was cleaned by superheating after a distilled water rinse (15). Fresh plasma was collected from normal human volunteers as well as from drug-free mongrel dogs; no differences were found between the two for the work described here, and the term "plasma" used here may apply equally to either species.

Known amounts of verapamil and/or II and III were added to 2-ml plasma samples. After addition of 1.0 ml of 1 *N* NaOH and 5.0 ml of heptane, the mixture was shaken for 15 min and centrifuged at 1800 rpm for 10 min. Four milliliters of the heptane layer was transferred to a 15-ml centrifuge tube containing 2.0 ml of 0.1 *N* HCl; each tube was shaken and centrifuged as before. The heptane layer was aspirated and discarded, and the aqueous phase was washed twice with 2.0 ml of heptane. One milliliter of 1.0 *N* NaOH was added, and the acid layer was extracted with 4.0 ml of heptane, with agitation and centrifugation as before.

Three milliliters of the heptane layer was then transferred to another tube and evaporated under a nitrogen stream during heating to 60° on

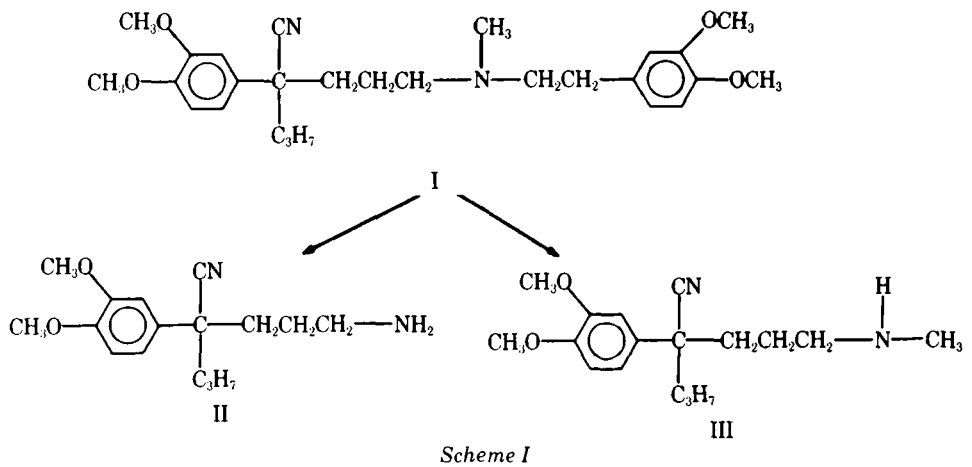

Scheme I

a waterbath. To the residue was added 100 μl of *N*-methyl-*N*-trimethylsilyltrifluoroacetamide (IV)[3], with heating for 1 hr at 65–70°. After cooling, evaporation was again effected under a nitrogen stream; the sample was then reconstituted with 25 μl of methanol, and 5-μl amounts were injected into the gas chromatograph.

The gas chromatograph[4] was equipped with a glass column (1.8 m × 2 mm i.d.) packed with 3% Dexsil-300[3] on 100–200-mesh WHP[3]. The column was silanized and conditioned at 325° for 72 hr prior to use. The conditions were as follows: carrier gas (nitrogen) flow rate, 30 ml/min; inlet temperature, 310°; column temperature, 270°; and detector temperature, 350°. The flame-ionization unit was supplied with hydrogen at 30 ml/min and with air at 300 ml/min. Detector responses were recorded[5], and peak areas were integrated electronically[6].

Animal Study—Verapamil (3 mg/kg in 30 ml of water) was administered by nasogastric tube to a healthy 20-kg mongrel dog which had been fasted overnight. Serial blood samples were collected over the following 4 hr. Plasma was analyzed for verapamil by the fluorometric method (9) and the GLC technique described here.

RESULTS AND DISCUSSION

Fluorometric Assay—The fluorescence of verapamil, II, and III is shown in Fig. 1. Both metabolites fluoresced maximally at the same excitation/emission wavelength combination as the parent drug, and both were extracted with high recoveries (80–90%) in the plasma–heptane–acid procedure used for verapamil. The potential for interference by these metabolites with the fluorometric verapamil assay is illustrated in Fig. 2; various combinations of the compounds were extracted from plasma, and total fluorescence was determined. Both II and III showed a concentration–fluorescence intensity relationship similar to that for unchanged verapamil; addition of one or both metabolites to plasma containing the parent drug resulted in a proportionate increase in total fluorescence.

The pharmacological activity of these fluorescent metabolites has not

Figure 4—*Chromatograms of plasma to which II or III was added, using a column temperature of 220°. Both compounds were added in a concentration of 0.100 μg/ml.*

been specifically determined. However, since the concentration of plasma verapamil determined fluorometrically is linearly related to the drug's effects after intravenous administration (10, 11) but not after oral administration (12), these (and possibly other) fluorescent metabolites probably are generated during the first passage through the liver and are either inactive or have little pharmacological effect. In any event, the fluorometric assay for verapamil in plasma is not a valid reflection of the concentration of active drug in the presence of drug metabolites after oral dosing.

GLC Assay—Under the conditions described, verapamil could be extracted from plasma with good recoveries (range of 89–96%) in a concentration range of 0.025–1.000 μg/ml. Figure 3 shows chromatograms of blank plasma and of plasma containing 0.100 μg of added verapamil/ml. The retention time for verapamil was 7.3 min. Table I gives data on the reproducibility and sensitivity of the GLC procedure. The assay was linear over the concentration range studied ($r = 0.9995$; $p < 0.001$), which reflects the plasma drug concentrations likely to be of clinical interest (10, 11).

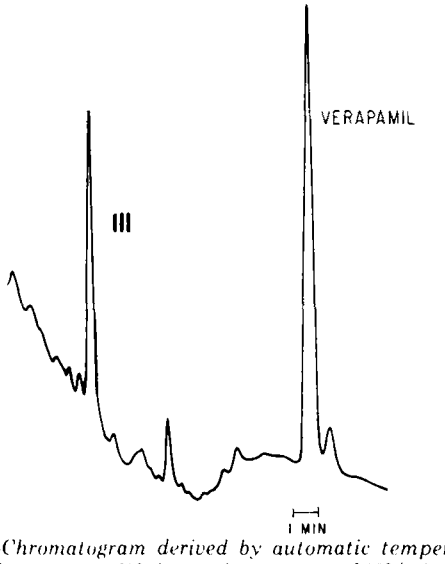

Figure 5—*Chromatogram derived by automatic temperature programming, from 190 to 270°, increasing at a rate of 10°/min. Compound III eluted at a column temperature of approximately 220°, while verapamil emerged at 270°.*

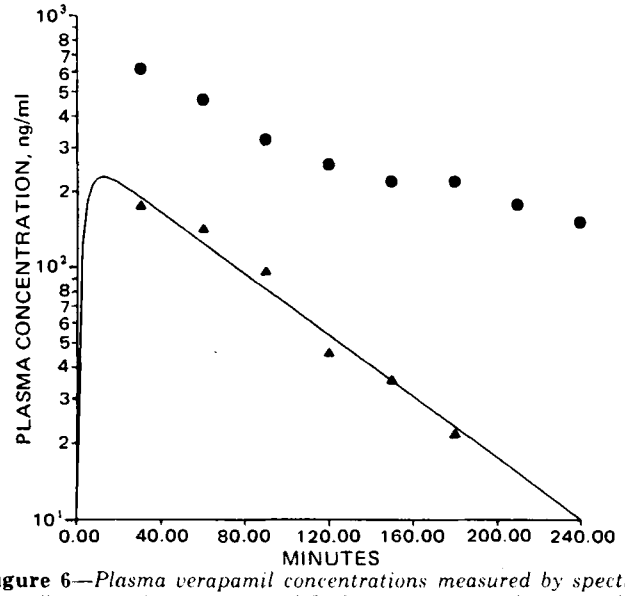

Figure 6—*Plasma verapamil concentrations measured by spectrophotofluorometric assay (●) and GLC (▲); serial samples were taken from a 20-kg mongrel dog given 3 mg of verapamil/kg at time zero.*

Of the two metabolites studied, II did not appear to form a silyl derivative and could not be detected under the GLC conditions used. Compound III, however, was easily and quantitatively detected at a column temperature of 220° (Fig. 4). Automatic temperature programming, beginning at a column temperature of 190° and increasing at 10°/min, could be used to detect both III and parent verapamil in the same plasma sample (Fig. 5). At the column temperature of 270° used to measure parent verapamil concentrations, III emerged with the solvent front.

Since this assay is specific for unchanged verapamil, it will be particularly useful in pharmacokinetic and pharmacodynamic studies of the drug after oral dosing. For example, when both spectrophotofluorometric and GLC techniques were used to measure serial drug plasma levels in a dog given a single oral dose of verapamil, fluorometric analysis gave results four- to fivefold higher than those measured by GLC, indicating the presence of metabolites interfering with the fluorometric procedure (Fig. 6).

On the basis of these and prior studies (10–12), it appears that the fluorometric assay for plasma verapamil is a valid reflection of the concentration of unchanged, active drug only after intravenous verapamil administration. After oral doses, a more specific assay, such as the described GLC procedure, must be used to quantitate the parent compound.

Stability-Indicating High-Performance Liquid Chromatographic Determination of Chlorpropamide, Tolbutamide, and Their Respective Sulfonamide Degradates

D. L. ROBERTSON, A. G. BUTTERFIELD, H. KOLASINSKI, E. G. LOVERING, and F. F. MATSUI ˣ

Received October 19, 1977, from the *Drug Research Laboratories, Health Protection Branch, Health and Welfare Canada, Ottawa, Canada K1A 0L2.* Accepted for publication October 19, 1978.

Abstract □ A quantitative high-performance liquid chromatographic method for the determination of chlorpropamide, tolbutamide, and their respective hydrolysis products, *p*-chlorobenzenesulfonamide and *p*-toluenesulfonamide, in solid dosage forms was developed. The method is stability indicating and can be used to determine the sulfonamide hydrolysis product and the intact drug in the presence of minor degradates. Method reproducibility, demonstrated by repeated injections of a calibration standard, was 1.21%. The lower limit of quantitation of the hydrolysis products, *p*-chlorobenzenesulfonamide and *p*-toluenesulfonamide, was 0.2 μg/5-μl injection. The accuracy of the method for intact drugs was determined by comparison of the HPLC results to those obtained by the appropriate USP or BP assays. The mean of the results obtained by the two methods differed by 0.7% for chlorpropamide and 0.3% for tolbutamide. Pure drug samples were spiked with amounts of the hydrolysis products ranging from 20 to 120% of the intact drug content. The mean percent recovery for *p*-chlorobenzenesulfonamide was 98.6%; for *p*-toluenesulfonamide, it was 100.6%. A qualitative TLC procedure for the detection of chlorpropamide, *p*-chlorobenzenesulfonamide, dipropylurea, propylurea, *n*-propylamine, tolbutamide, *p*-toluenesulfonamide, dibutylurea, butylurea, and *n*-butylamine is also described.

Keyphrases □ High-performance liquid chromatography—analysis of chlorpropamide, tolbutamide, *p*-chlorobenzenesulfonamide, *p*-toluenesulfonamide, stability in solid pharmaceutical dosage forms □ Chlorpropamide—high-performance liquid chromatographic analysis of stability in solid pharmaceutical dosage forms, sulfonamide degradates □ Tolbutamide—high-performance liquid chromatographic analysis of stability in solid pharmaceutical dosage forms, sulfonamide degradates □ Sulfonamides—degradation products of chlorpropamide and tolbutamide, high-performance liquid chromatographic analysis □ Antidiabetic agents—chlorpropamide, tolbutamide, high-performance liquid chromatographic analysis of stability and sulfonamide degradation products

The antidiabetic agents chlorpropamide and tolbutamide decompose under various experimental conditions. The major degradation route is hydrolysis (1, 2), mainly to *p*-chlorobenzenesulfonamide or *p*-toluenesulfonamide, but thermal dissociation in various solvents has been reported also (3, 4).

The USP XIX (5) spectrophotometric assay for tablets containing these drugs lacks specificity since the sulfonamide degradates retain the UV chromophore of the intact drug. The BP 1973 (6) titrimetric procedures are selective because the sulfonamide degradates are weak acids that are not neutralized by the aqueous solution of sodium hydroxide. However, the method cannot be used to assay highly discolored samples due to interference in the visual detection of the end-point.

Colorimetric procedures have been reported (2, 7, 8), but these methods require prior separation of the degradates before the intact drug can be quantitated. A high-performance liquid chromatographic (HPLC) method for the quantitation of sulfonylureas in pharmaceuticals has been reported (9), but separation and quantitation of the hydrolysis products were not demonstrated. An HPLC procedure for the determination of chlorpropamide in tablet formulations was described (10) but was not suitable for resolution of the sulfonamide from the main drug.

This paper describes a TLC technique for the detection of the major degradates of chlorpropamide and tolbutamide and an HPLC assay of intact chlorpropamide, tolbutamide, and their sulfonamide impurities, *p*-chlorobenzenesulfonamide and *p*-toluenesulfonamide, in solid dosage formulations.

EXPERIMENTAL

Materials—Chlorpropamide[1] and tolbutamide[2] were recrystallized from acetone and found to meet USP XIX (5) specifications. *p*-Chlorobenzenesulfonamide[3], *p*-toluenesulfonamide[4], *n*-propylurea[3], *n*-butylurea[4], *n*-dipropylurea[5], *n*-dibutylurea[6], *n*-propylamine[7], *n*-butylamine[3], micronized prednisone[8], acetic acid[9], hydrochloric acid[9], chlo-

n-Butylamine	0	0	0	0

[a] Development and visualization details given in the text. [b] Relative to chlorpropamide or tolbutamide.

roform[9], absolute ethanol[9], ethyl acetate[10], *n*-hexane[10], tetrahydrofuran[10], toluene[9], sodium hypochlorite solution[11], and phenothiazine[12] were used as received.

TLC Procedures—For chlorpropamide, 0.25-mm Sil G-25 UV 254[13] or silica gel G/MH[14] plates were used. For tolbutamide, 0.25-mm silica gel 60 F-254[15] or silica gel G/HL[14] plates were used.

The solvent system was toluene–ethyl acetate–chloroform–acetic acid (80:15:5:10). The detection agents were: A, 0.2% ninhydrin aerosol[7]; B, 0.6% (v/v) aqueous sodium hypochlorite; C, 1% (w/v) phenothiazine in chloroform (prepared fresh each week); and D, 20% (v/v) acetic acid in ethanol.

Sample Preparation—An accurately weighed amount of powdered tablet was tumbled[16] for 30 min in a screw-capped test tube with sufficient acetone to yield a 25-mg/ml final solution. The sample was centrifuged, 10 μl of the supernate was applied to the appropriate TLC plate, and the plate was developed 15 cm in a filter paper-lined chromatographic chamber, which had been equilibrated with the solvent system for 1 hr prior to use.

Visualization—The plate was air dried, and the origin was sprayed with Detection Agent A to disclose *n*-propylamine in chlorpropamide or *n*-butylamine in tolbutamide. Detection Agent B was then applied. The plate was dried with a warm air stream until free of chlorine odor and then sprayed consecutively with Detection Agents C and D. The main component and the potential degradates appeared as green spots on a white background. The R_f values are given in Table I.

HPLC Procedure—*Apparatus*—A liquid chromatograph[17] equipped with a fixed wavelength UV detector (254 nm)[17], a septumless injector port[17], and a computing integrator[18] were used. The detector was operated at an attenuation of 0.02 absorbance unit full scale (aufs), and the integrator output to the recorder was attenuated ×16 throughout. Integrator malfunction would necessitate peak height quantitation of the degradates. If peak height is to be utilized for the degradate determination, the signal from the chromatograph electrometer to the recorder would be 0.02 aufs. At this signal level, 2% impurity levels were seen and measured easily.

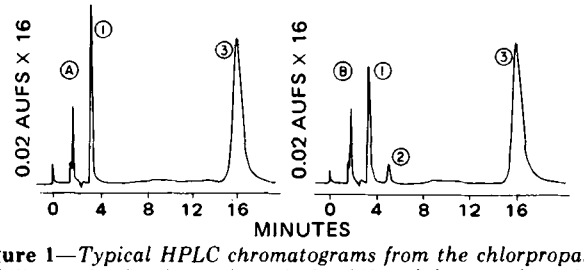

Figure 1—*Typical HPLC chromatograms from the chlorpropamide stability study of an intact formulation (A) and the same formulation exposed to 60° and 70% RH for 6 weeks (B). Key: 1, chlorpropamide; 2, p-chlorobenzenesulfonamide; and 3, prednisone.*

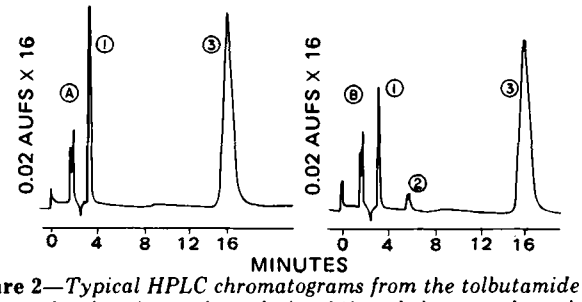

Figure 2—*Typical HPLC chromatograms from the tolbutamide stability study of an intact formulation (A) and the same formulation exposed to 60° and 70% RH for 6 weeks (B). Key: 1, tolbutamide; 2, p-toluenesulfonamide; and 3, prednisone.*

Column—A 250 × 3.2-mm i.d. column was packed with 10-μm diameter silica gel[19], using a balanced density slurry technique (11). All chromatographic operations were performed at ambient temperature and at a flow rate of 60 ml/hr (35 bar).

Mobile Phase—A mixture of 4% absolute ethanol, 8% tetrahydrofuran, and 0.06% acetic acid in *n*-hexane was prepared as required, degassed (reflux, 5 min), and stored in the solvent reservoir of the instrument.

Internal Standard Solution—A solution of micronized prednisone in ethyl acetate (0.70 mg/ml) was used.

Linearity—Solutions containing 0.3–3.0 mg/ml of chlorpropamide and tolbutamide (15–150% of label claim) were assayed; 2 mg/ml of drug substance was chosen as the 100% level. Solutions containing 0.04–1.2 mg/ml of *p*-chlorobenzenesulfonamide and *p*-toluenesulfonamide (2–60% of label claim) were prepared and analyzed.

Calibration Standards—A calibration standard was prepared in a 50-ml glass tube to contain accurately weighed amounts (about 50 mg) of chlorpropamide or tolbutamide and about 10 mg of the respective impurity.

System Check Sample—Powdered, well-mixed composites were prepared from a minimum of 20 tablets of chlorpropamide or tolbutamide previously shown by TLC to contain a sulfonamide impurity. The tablet composites were analyzed repeatedly for intact drug and impurity content. An aliquot of this powdered tablet substance, equivalent to ~50 mg of intact drug, was accurately weighed into a 50-ml glass tube.

Chromatography—To the calibration standard tube and the system check sample tube were added 4.0 ml of 10% (v/v) aqueous hydrochloric acid and 25.0 ml of the internal standard solution. Both tubes were agitated for 30 min on a shaker[20] and centrifuged[21] for 5 min. Duplicate 5-μl aliquots of the organic phases of both tubes were chromatographed.

If the check sample assay fell within the limits of experimental error (Table II), the system was established as functioning satisfactorily and tablet formulations were sampled. The system check sample was injected periodically to detect any changes within the chromatographic system.

Tablet Analysis—Powdered tablet substance aliquots, equivalent to ~50 mg of drug, were accurately weighed into separate 50-ml glass tubes and treated as previously described.

Calculations—Peak area ratio was determined by electronic integration of the sample and the internal standard.

RESULTS AND DISCUSSION

The ideal stability assay would measure the undegraded drug and all possible degradates without prior separation. A chromatographic technique such as HPLC generally comes closest to meeting this criterion. Preliminary TLC stability studies showed that the main degradation products of chlorpropamide and tolbutamide are the respective sulfonamides and alkylamines. The alkylamines, propyl and dipropylurea, and butyl and dibutylurea did not interfere with the HPLC assay because these compounds give no absorbance at 254 nm. Prior separation of these

[a] Five points were subjected to regression analysis with each compound. [b] The slope was obtained by dividing the count ratio of the compound to the internal standard by the weight ratio of the compound to the internal standard. [c] The y-coordinate for a value of $x = 0$.

compounds from the intact drug and the sulfonamide impurity was not necessary.

An important prerequisite for an HPLC stability study is separation reproducibility over time. The forward-phase technique on microparticulate silica gel fulfills this need. The chromatograms in Figs. 1 and 2 are typical of the separation achieved.

Chlorpropamide and tolbutamide exhibited linear responses between 0.3 and 3.0 mg/ml (1.5 and 15 μg/injection). The respective sulfonamide impurities exhibited linear responses between 0.04 and 1.2 mg/ml (0.2 and 6.0 μg/injection) (Table II).

The precision of the quantitation of the main drugs and the respective sulfonamide impurities was determined by analyzing a degraded formulation on different days (Table III). The reproducibility of the chromatographic system over a single day was shown by injecting 12, 5-μl aliquots of the ethyl acetate layer of a calibration standard (2.90 mg/ml of

[a] Expressed as equivalent weight of intact drug.

chlorpropamide and 0.697 mg/ml of the internal standard). The relative standard deviation of the peak area ratios was 1.21%. The lower limit of quantitation[22] of *p*-chlorobenzenesulfonamide or *p*-toluenesulfonamide was 0.2 μg/5-μl injection. This impurity level is ~2% of the label claim of chlorpropamide or tolbutamide.

Several injections at the low impurity level were made to analyze the error involved in quantitating the sulfonamide impurity. For *p*-toluenesulfonamide at the 1.95% level, the relative standard deviation of the count ratio of the substance to the internal standard was 3.77%, an estimate of the error expected at the lower limit of quantitation.

The accuracy of the intact drug quantitation was established by analysis of individual tablet composites of chlorpropamide and tolbutamide, shown to be free of impurities by TLC. The samples were analyzed by the official method and also by HPLC. Additional weighings of these samples were spiked with known amounts of the respective sulfonamide impurity and reanalyzed by the HPLC method (Table IV).

To establish that quantitative partitioning of the intact drug and the related sulfonamide impurity was obtained, accurately weighed tablet composite samples, equivalent to 50 mg of the intact drug, were partitioned between 10, 20, and 30 ml of ethyl acetate and 4 ml of 10% (v/v) aqueous hydrochloric acid. Duplicate 5-μl aliquots of the organic layer were chromatographed. The assay values obtained after partition with 20 and 30 ml of ethyl acetate were not significantly different. The partitioning experiment was repeated with tablets that had been partially degraded by exposure to 60° and 70% relative humidity (RH). The total amount of intact drug and impurity obtained after partition with 20 and 30 ml of ethyl acetate was not significantly different. These data indicated that 25 ml of ethyl acetate was sufficient to extract completely the intact drug and impurities from degraded formulations.

The time required for complete extraction was determined by shaking replicate samples for 15, 30, and 45 min with 4.0 ml of 10% aqueous hydrochloric acid solution and 25.0 ml of the internal standard solution. There was no difference in assay value after 30 min of shaking. The aqueous layers of a calibration standard and of a decomposed formulation extracted with ethyl acetate for 30 min were chromatographed. No peaks were detected in these layers, indicating that complete extraction had taken place.

The system check sample in combination with the calibration standard indicated the status of the total system. Reproducible check sample values showed that the calibration standard factors were correct and that the sampling procedure had been carried out properly. For chlorpropamide and *p*-chlorobenzenesulfonamide, the relative standard deviations of these calibration factors were 1.42 and 3.11%, respectively, over ~8 weeks. For tolbutamide and *p*-toluenesulfonamide, the relative standard deviations of the calibration factors were 1.39 and 2.37%, respectively. These values indicate that the method is reproducible over an extended time.

[22] Defined as the level of impurity that, on repeated analysis, gives a relative standard deviation of ~4%.

Tablet formulations of chlorpropamide and tolbutamide stored for 3 months at ambient temperature (range of 21–23°) and ambient relative humidity and replicate samples stored at 60° and 70% RH (12) were analyzed by HPLC for the intact drug and the sulfonamide degradates. The samples were also analyzed by the appropriate compendial method.

Chlorpropamide samples were analyzed by the USP XIX (5) spectrophotometric technique. From the known absorptivity of *p*-chlorobenzenesulfonamide and its HPLC-determined level in the formulation, the contribution to the measured total absorbance was estimated, and the absorbance due to the intact drug was calculated. The percent recoveries of the undegraded drug determined by the two methods are given in Table V.

Similarly, the BP 1973 (6) titrimetric procedure was utilized for the tolbutamide formulations (Table VI). Because the degradate, *p*-toluenesulfonamide, is not titratable, this method allowed for a direct determination of the intact drug. The method was not applicable to some decomposed samples because discoloration in the tablets interfered with the end-point.

Comparison of the data in Tables V and VI indicates that the HPLC method is equivalent or superior to existing techniques with respect to accuracy. The HPLC method could be used to determine levels of the sulfonamide impurities in amounts less than 2% by increasing the amount of sample injected onto the column; however, the levels of chlorpropamide and tolbutamide might exceed the linear range of the system. The TLC method can be used to follow the stability profile of formulations in a stability study and to estimate semiquantitatively the concentration of impurities.

Enthalpy of Bile Salt–Lecithin Mixed Micelle Formation

RUPERT O. ZIMMERER, Jr. *, and SIEGFRIED LINDENBAUM ˣ

Received July 17, 1978, from the *Department of Pharmaceutical Chemistry, McCollum Laboratories, University of Kansas, Lawrence, KS 66044.* Accepted for publication October 20, 1978. *Present address: Analytical Research Department, Endo Laboratories Inc., Garden City, NY 11530.

Abstract □ The enthalpies for the dissolution of lecithin by sodium salts of cholic, deoxycholic, and chenodeoxycholic acids and their glycine and taurine conjugates are reported. Exothermic enthalpies were found in each case. It is suggested that heat evolution is due to a bile salt–lecithin interaction other than hydrophobic interactions. These results provide strong support for the "mixed disk" model for the complex lecithin–bile salt micelle, which requires that a substantial fraction of the bile salt molecules be incorporated within a lecithin bilayer where hydrogen-bonded pair formation can occur. Calorimetric studies of the interaction between sodium cholate and nonionic, cationic, and anionic detergents yielded exothermic heats. These results suggest that these bile salt molecules partition into the detergent micelle interior as hydrogen-bonded pairs.

Keyphrases □ Enthalpy—dissolution of lecithin in aqueous bile salt solutions, micelle formation, hydrogen bonding □ Lecithin—dissolution in aqueous bile salt solutions, micelle formation, enthalpy, hydrogen bonding □ Bile salts, solutions—dissolution of lecithin, micelle formation, enthalpy, hydrogen bonding

Recent clinical success in dissolving cholesterol gallstones by chenodeoxycholic acid administration has renewed interest in the role of bile salts in the dissolution of cholesterol and other lipids (1, 2).

Whereas bile salts are essential for cholesterol solubilization, bile salts alone in aqueous solution increase cholesterol solubility only slightly: 30–100 bile salt molecules are required to solubilize one cholesterol molecule (3). Therefore, bile salts by themselves cannot account for lipid solubilization and transport in digestion or for maintenance of cholesterol in solution in the gallbladder. Lecithin (phosphatidylcholine) is an essential component of bile; in fact, the bile salt–lecithin combination is required for the solubilization of cholesterol and other lipids (5). Bile

Taurodeoxycholic acid	OH	H	OH	$NHCH_2CH_2SO_3H$

salts have been shown to solubilize lecithin efficiently, forming a micellar solution (3, 5).

On the basis of phase equilibrium and X-ray diffraction studies, a model for the bile salt–lecithin mixed micelle was proposed (6, 7). According to this model (Fig. 1), a disk-shaped micelle is formed on the association of lecithin with bile salt. The disk core consists of the hydrocarbon alkyl chains of the lecithin molecules surrounded by a ring of bile salt molecules. Thus, the disk-shaped micelle exterior presents to the aqueous solvent only the hydrophilic end groups of the phosphatidylcholine and the hydrophilic sides of the bile salt.

Recently, a modified model was proposed on the basis of quasielastic light-scattering data (8). The revised model allowed for the presence of both lecithin and bile salt molecules within the micelle interior (Fig. 1). The bile salt molecules within the micelle interior are presumed to exist as hydrogen-bonded dimers. Recently, other researchers suggested that hydrogen-bonded dimer formation also occurs in dilute aqueous bile salt solutions (9).

The purposes of this study were to measure the enthalpy accompanying the formation of the lecithin–bile salt mixed micellar solution and to correlate the results with the proposed models for these complex micelles.

EXPERIMENTAL

Materials—L-α-Lecithin (egg phosphatidylcholine), obtained commercially[1], had been purified by chromatography over alumina and silica gel. The lecithin yielded a milky white suspension when mixed with water on a vortex mixer[2]. TLC showed one spot after visualization with iodine vapor. The bile salts used (Table I) were the highest purity available commercially[3]. They were purchased as the sodium salts, with the exception of glycocholic acid, which was obtained as the free acid. The free acid in 25% ethanol was titrated to pH 9 with sodium hydroxide and lyophilized.

Each bile salt was tested by TLC to estimate the number and approximate concentration of the impurities present. Quantitative TLC was performed using a densitometer[4] in the diffuse reflectance mode. The only major impurities were other bile acids, and in no case did the impurity represent greater than 1% of the total bile salt. Some salts were titrated with percholic acid in acetic acid as a further check on purity. Sodium taurocholate was recrystallized from ethanol–ether before use.

Deuterium oxide, 99.8 atom %D, was used as received[5].

Sodium lauryl sulfate[6] was recrystallized from ethanol. Cetrimonium bromide[3] was recrystallized from water–ethanol. "Scintillation grade" polyoxyethylated *tert*-octylphenol[7] was used without further purification. All other chemicals were reagent grade and were used as received. Aqueous solutions were prepared with deionized water.

pensions were measured in a batch microcalorimeter[8] described previously (10). The normal calorimeter strip-chart recorder with an integrator was replaced with a digital output device. The potential from the calorimeter thermopile was amplified[9], and the output was fed sequentially to a voltage-to-frequency converter[10] and to a counter[11].

Heats of mixing of aqueous sodium cholate solutions with aqueous solutions of nonionic, cationic, and anionic detergents were measured with a titration calorimeter[12] interfaced with a minicomputer[13]. The computer counted and recorded the number of pulses representing the calorimeter heat output. It also controlled the on–off timing of the buret and calibration heater[14].

Methods—The techniques and methods of calibration of the batch microcalorimeter were described previously (11). Heats of dissolving aqueous suspensions of egg lecithin with bile salt solutions were obtained by mixing 1–4 ml of 0.1 molal solutions of sodium bile salt with 0.25–2 ml of 0.01–0.05 molal suspensions of lecithin in the batch microcalorimeter. Solutions and suspensions were prepared by weight and injected into the calorimeter cell with syringes, which were weighed before and after delivery of solution.

Enthalpies for the dissolution of lecithin by sodium cholate in the presence of sodium chloride were measured in the same way, except that aqueous sodium chloride solutions were substituted for distilled water in the preparation of lecithin suspensions and sodium cholate solutions.

Likewise, the enthalpy measurements in deuterium oxide were performed with deuterium oxide substituted for distilled water in the solutions and suspensions.

Heats of mixing aqueous solutions of sodium cholate with aqueous surfactant solutions were measured by placing 20 ml of 0.03 molal sodium cholate in the isothermal reaction vessel and titrating with 0.05 molal surfactant with the motor-driven syringe buret. Detailed procedures for the operation and calibration of the titration calorimeter were published (12, 13). The batch and titration calorimeter gave results in good agreement with literature values for the heat of dilution and heats of mixing for standard reactions.

RESULTS

Heats of dissolution of suspended lecithin by aqueous bile salt solutions are given in Table II and Fig. 2 as calories per mole of lecithin as a function of the final system composition expressed as moles of lecithin per mole of bile salt. For the dissolution of lecithin by sodium cholate solutions, these experiments were repeated in deuterium oxide (Table III and Fig. 3) and in 0.1 and 0.2 M NaCl (Table IV and Fig. 4). In all cases, the initially cloudy lecithin suspension formed a clear solution after mixing in the calorimeter with the bile salt solution. Over the concentration range studied, the measured heats were a function only of the lecithin to bile salt ratio and not of the total lipid concentration.

Enthalpy values for the mixing of surfactant solutions with aqueous sodium cholate solutions are given in Table V and Fig. 5 as calories per mole of surfactant as a function of moles of surfactant per mole of sodium cholate.

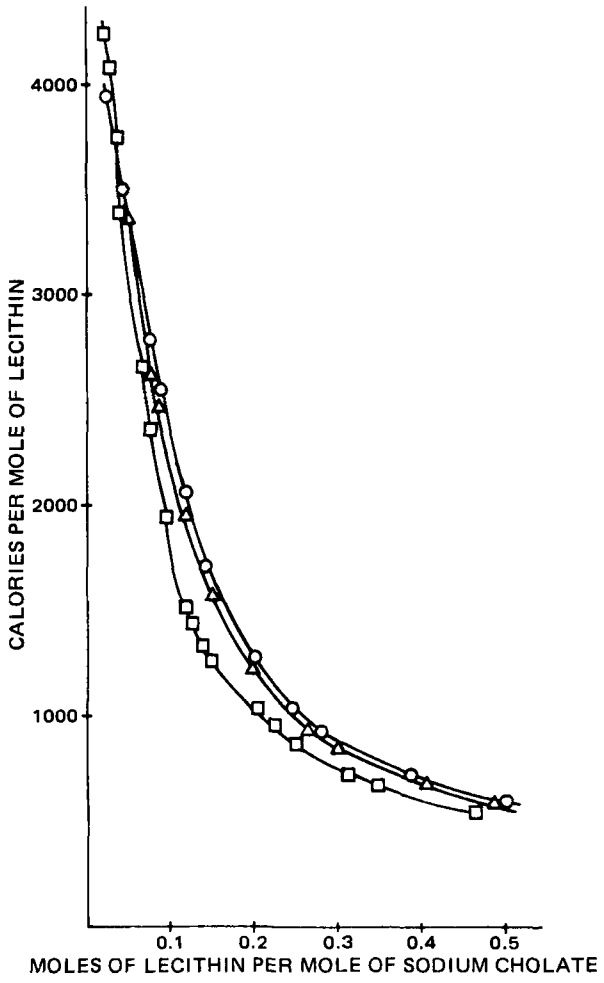

Figure 4—*Enthalpy of dissolution of lecithin by sodium cholate in the presence of added sodium chloride at 25°. Key: □, water; △, 0.1 M NaCl; and ○, 0.2 M NaCl.*

DISCUSSION

The dissolution of suspended hydrated lecithin by bile salt solutions was accompanied in every case by the evolution (negative ΔH) of large amounts of heat (Fig. 2). Previous observations of heats of micelle formation generally yielded small and positive values for the enthalpy (14–18). It has generally been assumed, therefore, that the driving force for micelle formation is the positive entropy change associated with a hydrophobic species leaving the aqueous environment to form a micelle (17). Micelle formation of surfactants is attributed to the hydrophobic effect phenomenon, similar to the stabilization of proteins in their native configuration in an aqueous environment (17, 19).

The large exothermic heats obtained in these studies suggest that the process is not simply "hydrophobic" micelle formation. The process investigated here is shown in Scheme I:

$$x\mathrm{L}(\mathrm{H_2O}) + y(\mathrm{BS})_{\mathrm{sol}} \rightarrow \mathrm{L}_x(\mathrm{BS})_y$$

Scheme I

in which x moles of hydrated lecithin (L) interact with y moles of bile salts (BS) in aqueous solution to form a complex micellar solution. In an aqueous dispersion, lecithin is presumably in the form of liposomes (20–22) consisting of concentric envelopes of lipid bilayers. The milky-white lipid bilayer dispersions are solubilized in the presence of bile salt solutions to form optically clear micellar solutions. Under the experimental conditions, the heat measured may be seen as the sum of the heat of simple bile salt micelle dissociation and the heat of mixed micelle formation with lecithin.

Dilution heat studies on sodium cholate solutions showed that the enthalpy of simple micelle dissociation is negligible compared to the total heat observed for the dissolution of lecithin by bile salt solution. The observed heat is, therefore, virtually entirely the heat of mixed micelle formation. Heat evolution during this process is difficult to understand

in terms of the Small–Dervichian model (Fig. 1) since no new chemical bonds are formed in the mixed micelle. In the mixed disk model, however, a substantial fraction of the bile salt molecules are partitioned into the bilayer interior as hydrogen-bonded pairs. It may be assumed that in the low dielectric micelle interior, the bile salt molecules are hydrogen bonded to each other to a much greater extent than in the aqueous phase. The partition of bile salt molecules from the aqueous phase to the micelle interior would be accompanied by increased hydrogen bonding and heat evolution.

Recently, Oakenfull and Fisher (9) suggested that bile salts are associated by hydrogen bonding in aqueous solution. This finding, based on conductance and volume studies, is in conflict with earlier models for bile salt association. It has generally been assumed that premicellar association of bile salts occurs by hydrophobic interaction between the nonpolar flat surfaces of the bile salt molecules. This hydrophobic association model was suggested on the basis of NMR studies of aqueous bile salt solutions (23). This conflict remains to be resolved. It seems reasonable to assume that any hydrogen-bonded association in the aqueous phase will be enhanced in a less polar medium. Hydrogen bonding between bile salt molecules in a lecithin bilayer also would be consistent with spectroscopic evidence for hydrogen-bonded association of di- and trihydroxy methylcholanoates in carbon tetrachloride (24).

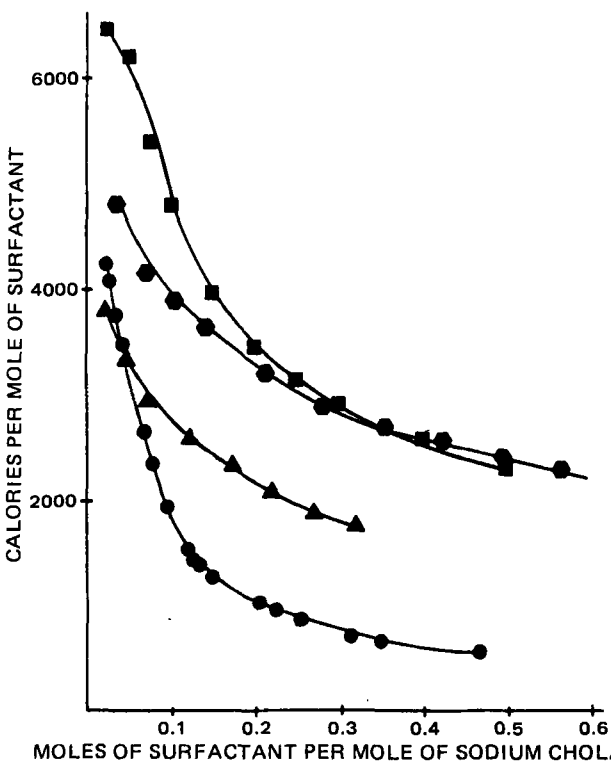

Figure 5—*Enthalpy of mixing surfactant solutions with sodium cholate solution at 25°. Key: ●, lecithin; ■, polyoxyethylated* tert*-octylphenol; ▲, cetrimonium bromide; and ●, sodium lauryl sulfate.*

According to the mixed disk model (8), the ratio of lecithin to cholate within the micelle interior is 2:1, not including the cholate molecules that make up the circumference of the disk.

This 2:1 ratio is also the proportion observed at the phase limit (7, 25, 26). Therefore, for each mole of lecithin solubilized, there is 0.5 mole of bile salt within the micelle. If each pair of bile salt molecules is attached by two hydrogen bonds, then one-half of a hydrogen bond is formed for each lecithin molecule solubilized. The enthalpy for hydrogen bond formation in alcohols varies from −3 to −10 kcal/mole (27, 28). If a value of −6 kcal/mole is assumed, then the heat accompanying the dissolution of 1 mole of lecithin would be −3 kcal/mole. This crude estimate of the enthalpy change expected assumes that hydrogen bonding is the most important contribution. Since other processes such as hydrophobic effects and changes in hydration also contribute, the expected enthalpy value cannot be estimated more accurately.

Comparison of the dissolution heat of lecithin by sodium cholate in water and deuterium oxide (Fig. 3) shows that the results are indistinguishable. These results also suggest that the extent of interaction of the bile salt in the micellar interior determines the enthalpy observed and that hydrophobic forces in the aqueous phase play only a minor role.

In several cases (Fig. 2), the enthalpy per mole of lecithin dissolved increased sharply as the lecithin to bile salt ratio decreased. This result suggests that as this ratio decreases, more bile salt partitions into the micelle phase, with a concomitant increase in hydrogen bonding. An increase in bile salt partition into the micellar phase as the aqueous bile salt concentration increases would be expected to occur if the distribution of bile salt between the micelle interior and the aqueous phase is seen as a mass action phenomenon. For taurocholate and taurochenodeoxycholate, equilibrium dialysis studies have shown that the micellar concentration of bile salt increases with the aqueous bile salt concentration (29).

The effect of added electrolyte on the enthalpy of dissolution of lecithin by sodium cholate is shown in Fig. 4. The enthalpy values become more negative as the concentration of added sodium chloride increases. This enhancement may be caused by increased partition of bile salt into the micelle due to "salting out" of the bile salt from the aqueous phase. The increased penetration of bile salt into the micellar phase is expected to lead to increased hydrogen-bonded association and, therefore, to more heat evolution.

Bile salts form complex micellar solutions with ampiphilic substances other than lecithin (3). It was hoped that an examination of the thermodynamic properties of the interaction between bile salts and other ampiphiles would shed further light on the bile salt–lecithin association.

Enthalpies of mixing sodium cholate solutions with solutions of a nonionic detergent (polyoxyethylated *tert*-octylphenol), a cationic detergent (cetrimonium bromide), and an anionic detergent (sodium lauryl sulfate) were measured. The results (Fig. 5) were compared with the lecithin data. In each case, even larger, more exothermic values for the complex micelle formation heat were obtained.

A detailed discussion of the differences in enthalpies between the different detergents would be highly speculative on the basis of the limited information available. However, these results are consistent with the suggestion that, in each case, the heat evolution is due to enhanced hydrogen-bonded association of the bile salt molecules in the micellar interior.

Decreased Tetracycline Bioavailability Caused by a Bismuth Subsalicylate Antidiarrheal Mixture

K. S. ALBERT ˣ, R. D. WELCH, K. A. DeSANTE, and A. R. DiSANTO

Received April 3, 1978, from *The Upjohn Company, Kalamazoo, MI 49001.* Accepted for publication August 3, 1978.

Abstract □ Oral coadministration of a single 250-mg tetracycline capsule and 60 ml of a bismuth subsalicylate antidiarrheal mixture reduced tetracycline absorption by 34% without appearing to perturb its absorption or disposition rate. A pronounced increase in intersubject tetracycline absorption variability also was noted. Apparently, the reduction in tetracycline bioavailability previously reported with a kaolin–pectin suspension is not peculiar to kaolin–pectin but can be expected with almost any antidiarrheal whose mechanism of action is adsorptive in nature.

Keyphrases □ Tetracycline—bioavailability, decreased by coadministered bismuth subsalicylate antidiarrheal □ Bismuth subsalicylate—antidiarrheal mixture, interference with bioavailability of coadministered tetracycline □ Antibiotics—tetracycline, bioavailability decreased by coadministered bismuth subsalicylate □ Antidiarrheals—bismuth subsalicylate, interference with bioavailability of coadministered tetracycline □ Drug-antibiotic interactions—bismuth subsalicylate interference with tetracycline bioavailability

Several studies (1–8) demonstrated that kaolin–pectin-containing antidiarrheal mixtures[1] interfere with the absorption of some concomitantly administered oral drugs. Retrospective *in vitro* experiments[2] suggested that drugs that can exist as cations in solution (*e.g.*, clindamycin, lincomycin, and tetracycline) are most susceptible to irreversible adsorption by negatively charged components of the antidiarrheal, but neutral molecules that can hydrogen bond (*e.g.*, digoxin, which contains a large sugar molecule) also may interact in an untoward way.

This paper describes the effect of a bismuth subsalicylate antidiarrheal mixture[3] on the bioavailability of the cationic drug tetracycline. Concomitant administration of both products markedly decreased the antibiotic bioavailability, suggesting that, in general, any antidiarrheal whose mechanism of action is adsorptive may interfere with the absorption of coadministered cationic and hydrogen-bonded drugs.

EXPERIMENTAL

The 16 normal, nonobese adult volunteers, whose average age was 26 years (range of 20–37 years) and whose average weight was 79 kg (range of 69–90 kg), exhibited normal vital signs and selected laboratory parameters and were without evidence of cardiac, renal, or GI abnormalities. These subjects did not receive any antibacterial medication for 30 days before initiation of the protocol. During the study, volunteers received only the medication prescribed, with 7 days separating each administered treatment.

Subjects were fasted (food and beverage) from 10:00 pm the night before their allocated treatment until 4 hr after drug administration. To ensure adequate urine output, subjects were required to drink at least 360 ml of water with their noon meal. Smoking was permitted if it was the usual custom of a subject. Volunteers did not engage in strenuous or athletic activities during the days the drug was given.

Each subject received a 250-mg tetracycline capsule[4] with and without bismuth subsalicylate suspension in crossover fashion (Table I). Serum samples were obtained at 0, 0.5, 1.0, 2.0, 2.5, 3.0, 4.0, 5.0, 6.0, 8.0, 10.0, 12.0, 16.0, and 24.0 hr. Urine specimens were collected at the following time intervals during each treatment period: predose (to serve as a urine blank), 0–12, 12–24, 24–48, and 48–72 hr. All samples were kept frozen until assayed microbiologically for tetracycline-like activity (9).

RESULTS

The bismuth subsalicylate antidiarrheal preparation effect on average tetracycline serum levels and urinary excretion for the 15 subjects who completed the study is summarized in Tables II and III, respectively; Fig. 1 shows the serum tetracycline time course through 24 hr. It is evident from Table II and the figure that, at every sampling, significantly lower serum antibiotic levels were found following coadministration with the antidiarrheal mixture. With the exception of the 24–48-hr interval, Table III shows that the urinary tetracycline excretion was reduced as well.

The average times of individual peak serum levels were comparable for the two treatments, which suggests that absorption rates were similar (Table II). In contrast, Table II shows that, following the bismuth subsalicylate treatment, the individual peak average concentration was decreased by 27% and the average 24-hr area under the antibiotic curve

Table I—Dosage Schedule and Treatments

Group	Subjects in Group	Treatment for Phase Number[a] I	II
I	1, 3, 6, 9, 10, 12, 14, 16	A	B
II	2, 4, 5, 7, 8, 11, 13, 15	B	A

[a] Treatment A was 60 ml of Pepto-Bismol (lot 830547, Norwich Products) followed immediately by one Panmycin H.F.C., 250 mg (lot 532EK, Upjohn), administered orally with 90 ml of water. Treatment B was one Panmycin H.F.C., 250 mg (lot 532EK, Upjohn), administered orally with 90 ml of water.

0–72	105	159	<0.001

[a] See Table I. [b] NS = not significant.

(*AUC*) was reduced 33%, while Table III shows that the 72-hr urinary tetracycline recovery was reduced by 33%. These results indicated that the antidiarrheal disturbed either the absorption or the disposition of the antibiotic. All 15 subjects showed lower 24-hr serum antibiotic *AUC* values in the presence of the antidiarrheal, while 14 of 15 subjects showed the same trend in 72-hr urinary recoveries (Table III).

Two parameters free from absorption influences, renal clearance and half-life, also were evaluated to ascertain whether the bismuth subsalicylate product altered tetracycline disposition. Mean renal clearances were virtually identical while treatment half-lives differed by only 8% (Table II). Apparently, the interaction between the antidiarrheal and the antibiotic affected only absorption, not disposition.

An estimate of the antidiarrheal influence on absorption can be made utilizing a model-independent method described previously (10). This technique bases bioavailability assessment on total urinary recovery (U_∞) and renal clearance ($\dot{V}_{cl,r}$) and assumes that changes in serum clearance ($\dot{V}_{cl,s}$) would be manifested as observed differences in renal clearance among treatments.

Individual relative bioavailability estimates utilizing this approach are summarized in Table IV. Even though average treatment renal clearances were virtually equal, individual subject values did vary between study days. To compensate for these observed differences, adjustments in serum clearance were made on the assumption that individual nonrenal elimination components did not change. With the exception of Subject 8, bioavailability ratios were less than unity, indicating that the antidiarrheal had an adverse effect on absorption. On the average, tetracycline bioavailability when coadministered with bismuth subsalicylate was only 66% ($F^A/F^B = 0.66$, $p < 0.001$).

The effect of the bismuth subsalicylate antidiarrheal mixture on intersubject tetracycline variability is summarized in Table V. Except for time to peak, the data show that the variabilities exhibited by the parameters peak maximum, area under the curve, and urinary recovery were greater for the bismuth subsalicylate treatment. Since the two disposition parameters (renal clearance and half-life) exhibited similar ranges and percent standard deviations between treatments, the greater variation

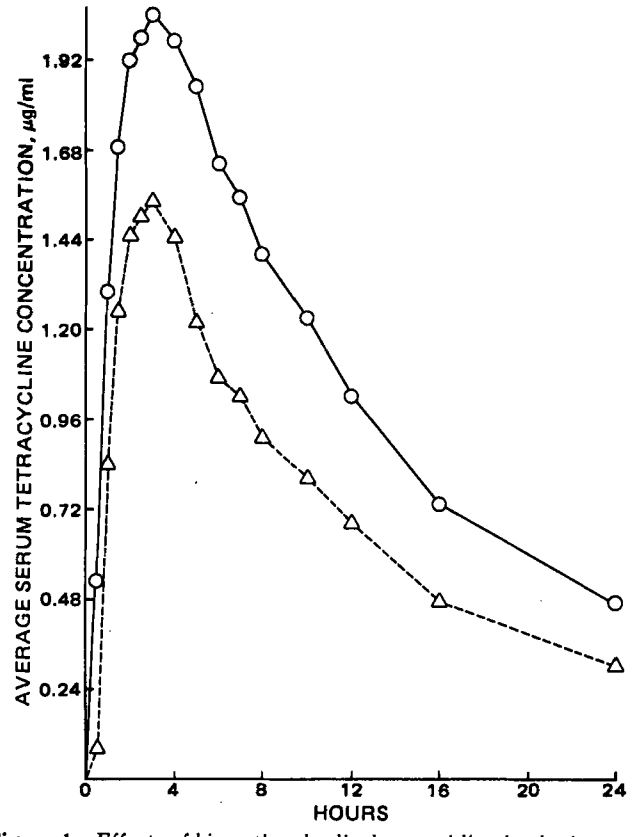

Figure 1—*Effects of bismuth subsalicylate antidiarrheal mixture on serum tetracycline levels following concomitant administration of both drugs. Key: ○, tetracycline alone; and △, tetracycline plus bismuth subsalicylate.*

associated with antidiarrheal coadministration can be attributed predominantly to a perturbation in tetracycline absorption. These results parallel the findings on absorption efficiency already described.

DISCUSSION

The only previous studies of antidiarrheal effect on coadministered oral drug absorption involved kaolin–pectin products (1–8). These studies

[a] Calculated according to the method of Kwan and Till (10) where:

$$(\dot{V}^B_{cl,s})_{ex} = \frac{(\dot{V}^B_{cl,r})(D^B)}{U^B_\infty}$$

$$(\dot{V}^A_{cl,s})'_{ex} = \dot{V}^A_{cl,r} + (\dot{V}^B_{cl,s})_{ex} - \dot{V}^B_{cl,r}$$

$$F^A/F^B = \frac{U^A_\infty (\dot{V}^A_{cl,s})'_{ex}}{(D^A)(\dot{V}^A_{cl,r})}$$

[b] Subject 3 did not complete the study. [c] Statistically significantly different from unity using t test ($p < 0.001$).

Table V—Bismuth Subsalicylate Antidiarrheal Mixture Effect on Tetracycline Product Variability

Parameter	Range A	Range B	SD, % A	SD, % B
Peak serum level, μg/ml	0.69–2.29	1.79–2.52	24.4	9.34
Peak time, hr	2.50–4.0	2.50–5.0	18.9	37.6
AUC through 24 hr, μg/ml × hr	7.13–27.9	21.1–30.5	28.9	11.0
Urinary recovery through 72 hr, mg	42.2–173	108–216	32.8	18.8
Half-life, hr	7.09–10.8	7.58–11.8	11.4	15.1
Renal clearance, ml/min	53.3–151	25.8–126	29.7	27.3

suggested that the antidiarrheal influence on antibiotic absorption is dose dependent.

In the present study, 60 ml of a bismuth subsalicylate antidiarrheal product was administered concomitantly with a 250-mg tetracycline hydrochloride capsule. Since the "active" bismuth subsalicylate concentration was not given on the package, molar comparisons of "active" bismuth subsalicylate antidiarrheal to "active" kaolin–pectin products were impossible. Nonetheless, the 34% decrease in relative tetracycline bioavailability was consistent with the kaolin–pectin with tetracycline data and indicated that similar drug interactions are likely with any antidiarrheal whose mechanism of action is adsorptive.

Molecular Weight Determination of Commercial Heparin Sodium USP and Its Sterile Solutions

H. J. RODRIGUEZ * and A. J. VANDERWIELEN ˣ

Received June 19, 1978, from *Control Analytical Research and Development, The Upjohn Company, Kalamazoo, MI 49001.* Accepted for publication September 8, 1978. *Present address: Waters Associates, Milford, MA 01757.

Abstract □ A liquid chromatographic assay for the characterization of heparin sodium USP and heparin sterile solutions was developed. The method employs size exclusion chromatography and computer-based data collection and manipulation. An examination of commercially available heparin showed only minor differences between the heparins extracted from beef lung and porcine intestinal mucosa. The molecular weight averages of the material and its sterile solutions were 9000–12,000 daltons. A correlation was observed between average molecular weight and anticoagulant activity for the heparin sodium samples examined.

Keyphrases □ Heparin sodium—molecular weight determination of commercial products and sterile solutions using liquid chromatography □ Molecular weight determination—commercial heparin sodium USP and its sterile solutions, liquid chromatography □ Liquid chromatography—molecular weight determination of commercial heparin sodium USP and its sterile solutions □ Anticoagulants—heparin sodium, molecular weight determination, liquid chromatography

Several methods for the molecular weight fractionation of heparin sodium have been reported (1–3), gel filtration being most commonly used (4). In most cases, analysis requires several hours per sample and complicated detection procedures. Recently, a fast and reliable method was developed (5, 6) using high-performance liquid chromatography (HPLC) with refractive index detection for the determination of molecular weight averages of heparin sodium USP and injectable heparin sodium solutions (6).

The literature contains conflicting reports regarding the relationship of molecular weight and anticoagulant activity (7–9). There are also significant differences in the reported molecular weights of commercially available heparin (5, 6, 10). This paper presents the results of an examination of sterile injectable heparin sodium from commercial sources. The liquid chromatographic method recently developed (5) was modified and used to determine if any relationship exists between molecular weight and anticoagulant activity.

EXPERIMENTAL

A liquid chromatograph[1] was equipped with a refractive index detector and a syringe loop injector. A minicomputer[2] was used to monitor the refractive index detector signals and to run the molecular weight calculation programs. The detector–computer interface is shown in Fig. 1.

Chromatographic Conditions—Two sets of columns were used. The hand-packed set was used initially to compare molecular weight fractions for their relationship to anticoagulant activity. Commercially available columns were used for the comparative study on heparin sterile solutions.

A set of three columns was tap packed with various pore sizes of 5–10-μm glycophase-controlled porous glass. These columns were packed

suggested that the antidiarrheal influence on antibiotic absorption is dose dependent.

In the present study, 60 ml of a bismuth subsalicylate antidiarrheal product was administered concomitantly with a 250-mg tetracycline hydrochloride capsule. Since the "active" bismuth subsalicylate concentration was not given on the package, molar comparisons of "active" bismuth subsalicylate antidiarrheal to "active" kaolin–pectin products were impossible. Nonetheless, the 34% decrease in relative tetracycline bioavailability was consistent with the kaolin–pectin with tetracycline data and indicated that similar drug interactions are likely with any antidiarrheal whose mechanism of action is adsorptive.

Molecular Weight Determination of Commercial Heparin Sodium USP and Its Sterile Solutions

H. J. RODRIGUEZ * and A. J. VANDERWIELEN ˣ

Received June 19, 1978, from *Control Analytical Research and Development, The Upjohn Company, Kalamazoo, MI 49001.* Accepted for publication September 8, 1978. *Present address: Waters Associates, Milford, MA 01757.

Abstract □ A liquid chromatographic assay for the characterization of heparin sodium USP and heparin sterile solutions was developed. The method employs size exclusion chromatography and computer-based data collection and manipulation. An examination of commercially available heparin showed only minor differences between the heparins extracted from beef lung and porcine intestinal mucosa. The molecular weight averages of the material and its sterile solutions were 9000–12,000 daltons. A correlation was observed between average molecular weight and anticoagulant activity for the heparin sodium samples examined.

Keyphrases □ Heparin sodium—molecular weight determination of commercial products and sterile solutions using liquid chromatography □ Molecular weight determination—commercial heparin sodium USP and its sterile solutions, liquid chromatography □ Liquid chromatography—molecular weight determination of commercial heparin sodium USP and its sterile solutions □ Anticoagulants—heparin sodium, molecular weight determination, liquid chromatography

Several methods for the molecular weight fractionation of heparin sodium have been reported (1–3), gel filtration being most commonly used (4). In most cases, analysis requires several hours per sample and complicated detection procedures. Recently, a fast and reliable method was developed (5, 6) using high-performance liquid chromatography (HPLC) with refractive index detection for the determination of molecular weight averages of heparin sodium USP and injectable heparin sodium solutions (6).

The literature contains conflicting reports regarding the relationship of molecular weight and anticoagulant activity (7–9). There are also significant differences in the reported molecular weights of commercially available heparin (5, 6, 10). This paper presents the results of an examination of sterile injectable heparin sodium from commercial sources. The liquid chromatographic method recently developed (5) was modified and used to determine if any relationship exists between molecular weight and anticoagulant activity.

EXPERIMENTAL

A liquid chromatograph[1] was equipped with a refractive index detector and a syringe loop injector. A minicomputer[2] was used to monitor the refractive index detector signals and to run the molecular weight calculation programs. The detector–computer interface is shown in Fig. 1.

Chromatographic Conditions—Two sets of columns were used. The hand-packed set was used initially to compare molecular weight fractions for their relationship to anticoagulant activity. Commercially available columns were used for the comparative study on heparin sterile solutions.

A set of three columns was tap packed with various pore sizes of 5–10-μm glycophase-controlled porous glass. These columns were packed

by adding very small quantities (25–30 mg) of material and tapping the column 50–100 times. This procedure was repeated until the column appeared full. The column was then pressurized at 3500 psi, and any void observed was repacked. This procedure was repeated until no void was observed after pressurizing.

This column set consisted of three different lengths of 2.3-mm i.d. tubing packed as follows: 10 cm of 40-Å pore size, 25 cm of 100-Å pore size, and 60 cm of 250-Å pore size. The mobile phase used was 0.1 *M* sodium acetate (0.01% in sodium azide to inhibit bacterial growth) in double-distilled water at a flow of 0.1 ml/min (2500 psi).

All columns were calibrated using heparin sodium samples[3] of varied molecular weights. Retention times of these standards were plotted against molecular weight(s).

Efficient molecular sizing columns that can be used for molecular weight determinations are commercially available. These columns[4] consisted of 30-cm × 3.9-mm i.d. stainless steel tubing packed with microparticles (10 μm) of a fully porous silica–ether [$Si(RO)_xCH_3$].

After examination of various combinations of the available columns,

a set consisting of one column of 125-Å pore size packing and two columns that were a blend of 125-, 300-, 500-, and 1000-Å pore size packing gave adequate resolution, reproducible measurements, and fast analyses (about 12 min/sample). A chromatogram showing the typical resolution obtained is shown in Fig. 2. This figure also shows the peaks due to methanol and an injection artifact resulting from changes in the refractive index due to inorganic salts (5, 6). Methanol (eluting at the total permeation volume) was used as an internal standard.

The columns were calibrated using seven samples of heparin sodium of known molecular weight. Three of these samples (14K, 8.0K, and 5.5K) were characterized previously using ultracentrifugation. The remaining samples were fractions collected on the original hand-packed columns, and their average molecular weights were determined on these columns (calibrated using four standards). The calibration was performed by a linear least-squares analysis on the relative retention time of heparin (relative to methanol) *versus* the weight average molecular weight. A well-characterized sample of sodium heparin was run with each set of analyses to monitor the performance of the columns and to correct the data for the comparative study (eliminate column and preparation variations).

Samples and Analysis—The samples consisted of commercially available material[5]. The powdered heparin sodium was dissolved (~12 mg/ml) in mobile phase containing 4% by volume methanol. Approximately 9 μl of this solution was injected. All sterile solutions were diluted accurately to a final concentration of 1000 USP units/ml by adding an appropriate amount of the mobile phase–methanol solution.

Molecular Weight Calculations—Molecular weight averages were calculated by literature methods (5, 11) using a FORTRAN program. The data were collected on-line by the system depicted in Fig. 1. The programs to collect the data and to perform the calculations were developed for this project to save time and calculation errors.

Anticoagulant Activity Determination—The samples were tested for potency (anticoagulant activity) using the USP assay (12).

RESULTS AND DISCUSSION

The results of a typical calibration are shown in Table I. Statistical treatment showed that molecular weight averages could be determined accurately to about ±500 daltons (*SD*) when the columns were calibrated properly. Figure 3 shows chromatograms of beef lung and intestinal porcine mucosal heparin. The chromatograms also indicate a difference that was noted previously (5): beef lung heparin sodium gave a fairly

symmetrical peak about the maxima whereas most porcine intestinal mucosal heparin gave a peak that was skewed toward low molecular weights.

Eight heparin fractions were collected using the hand-packed columns. When enough of each fraction had been collected, the heparin sodium was precipitated out of the mobile phase by adding methanol. In all cases, the heparin sodium precipitated at approximately a 1:2 ratio of methanol to mobile phase. After centrifuging and drying, the fractions were characterized accurately. The molecular weight was determined by the HPLC method, and the anticoagulant activities were determined by the USP method (Table II and Fig. 4).

These results show that there was a relationship between molecular weight and anticoagulant activity; however, this relationship was linear only over a narrow range of molecular weights (8000–12,000 daltons). Johnson and Mulloy (10), using intrinsic viscosity to measure molecular weight, observed this same relationship. In addition, they noted that the

[a] Results obtained by Chromatrix, Sunnyvale, Calif., using a low-angle laser light-scattering technique.

anticoagulant activity decreased for molecular weights above 20,000 daltons.

The molecular weight and anticoagulant activity were determined on 32 different lots[6] of heparin sodium USP (24 of beef lung origin and eight of porcine intestinal mucosal origin). The results (Table III) show that the relationship observed for the heparin fractions also held true for the samples of commercial grade heparin. A linear regression analysis showed good correlation (0.93) and an estimated error of about 9 USP units (2 *SD*) for the anticoagulant activity. Although there was considerable overlap, these results indicate that one can expect differences in anticoagulants when the molecular weights differ by 1000 daltons or more.

In contrast to previously reported results (6), these results (Table III) show that beef lung heparin cannot be distinguished from porcine mucosal heparin on the basis of molecular weight analyses.

Twelve lots of sterile solution from the different manufacturers were analyzed by the HPLC method on the commercial columns. The results (Table IV) show a molecular weight range from 11,200 to 10,100 daltons. As noted previously (5), some lots of beef lung heparin had a distribution that was wider than porcine intestinal mucosal heparin (*e.g.*, compare Sample D-1 to D-2).

Sugisaka and Petracek recently (6) stated that porcine mucosal heparin has an average molecular weight somewhere between 21,000 and 24,000 daltons and that beef lung heparin has an average molecular weight between 16,000 and 19,000 daltons. This study shows that there is very little difference between commercial heparin extracted from beef lung and porcine intestinal mucosa and that the average molecular weight is 9000–12,000 daltons. The major difference between the results on the average molecular weight of sterile solutions is the calibration method. In this study, standardized heparin sodium was used to calibrate the liquid chromatographic column whereas Sugisaka and Petracek (6) used dextrans of various molecular weights.

The difference observed is not unexpected since molecular size is the property responsible for the separation observed by HPLC. Differences in molecular shape can appear as differences in molecular weight in size exclusion chromatography. The higher results obtained when the columns are calibrated with dextrans (6) are to be expected if the dextran molecules are smaller than molecules of heparin of equivalent weight. Accurate calibration, therefore, requires that the standards have the same molecular shape as the samples.

To check the accuracy of these results, the molecular weights of three samples were determined using a low-angle laser light-scattering tech-

[6] Manufactured by Upjohn, Abbott, and Inolex.

nique. This technique requires no reference to external standards since the molecular weight is obtained from a simple linear extrapolation to zero concentration of the light-scattering data obtained at a single angle from two or more solutions of different solute concentrations (13–16). The results (Table V) show that the HPLC molecular weight determinations were in fair agreement with those of the light-scattering technique. The average of the three samples agreed within 100 daltons, although there was considerable sample-to-sample variation. Both the HPLC and spectroscopic results showed a good correlation between molecular weight and anticoagulant activity.

Heterocyclic Analogs of Amphetamine: Thioureas, Dithiocarbamates, and Negatively Substituted Amides

WILLIAM O. FOYE ˣ and SUCHINTA TOVIVICH

Received September 1, 1978, from the *Samuel M. Best Research Laboratory, Massachusetts College of Pharmacy, Boston, MA 02115.* Accepted for publication October 20, 1978.

Abstract □ A series of heterocyclic analogs of amphetamine was synthesized. The heterocycles employed included the 2-furyl, 2-thienyl, 3-methyl-2-thienyl, 3-pyridyl, and 6-methyl-2-pyridyl rings. The aliphatic amine group was converted to the *N*-methylthiourea, dithiocarbamate, methanesulfonyl, trifluoromethanesulfonyl, and trifluoroacetyl functions since similar conversions of the β-phenethylamine structure had shown blood pressure-lowering effects and some loss of behavioral effects. *p*-Chlorophenyl and 1-naphthyl analogs were also converted to these derivatives. Behavioral and other biological effects, including antiarthritic, passive cutaneous anaphylactic, and antimicrobial, were observed. The 3-methyl-2-thienyl analog of amphetamine significantly increased papillary muscle contractile force without producing arrhythmias.

Keyphrases □ Amphetamine analogs—thioureas, dithiocarbamates, negatively substituted amides, synthesis, behavioral effects, antiarthritis effects, cutaneous anaphylaxis, antimicrobial effects, blood pressure, rats □ Structure–activity relationships—amphetamine analogs, thioureas, dithiocarbamates, negatively substituted amides, synthesis, behavioral and biological effects, rats □ Motor activity—effects of amphetamine analogs, rats □ Antiarthritis agents—amphetamine analogs, rats □ Blood pressure—effects of amphetamine analogs, rats

Formation of negatively substituted amides on the aliphatic nitrogen of amphetamine and related structures has produced compounds with blood pressure-lowering effects (1). This result occurred also with negatively substituted amides of the β-phenethylamine structure as well as dithiocarbamate and thiourea derivatives (2, 3). Conversion of the aliphatic nitrogen to a neutral or acidic function thus led to a depressor response from a basic structure having motor stimulant activity. Previously, inclusion of the alkanesulfonamide group in the aromatic ring of phenethanolamines conferred either adrenergic stimulant or blocking activity (the latter generally appearing with an isopropyl or larger group on the aliphatic nitrogen) (4, 5).

DISCUSSION

A number of dithiocarbamates of the β-phenethylamine structure showed varying degrees of amphetamine-like behavioral effects (6). The presence of heterocyclic rings, in place of the phenyl, generally resulted in a loss of amphetamine behavioral effects. Diethyldithiocarbamate had previously been shown to deplete brain norepinephrine and to maintain the conditioned avoidance response of the rat (7). The dithiocarbamates of the heterocyclic ethylamines failed to alter this response (6). Antiobesity manifestations were observed in rats with some negatively substituted amides, dithiocarbamates, and thioureas of the β-phenethylamines and amphetamine derivatives. The possibility existed, therefore, of removing many or all of the behavioral attributes of the basic amphetamine structure while retaining depressor and antiobesity effects by appropriate substitutions on the nitrogen and inclusion of heterocyclic rings.

A series of heterocyclic analogs of amphetamine, including neutral or negatively substituted functions on the aliphatic nitrogen, was synthesized to determine if behavioral activity could be diminished and other useful effects retained. Corresponding derivatives of *p*-chloroamphetamine and the 1-naphthyl analog were prepared for similar observations. Negatively substituted amides prepared included the methanesulfonamide, trifluoromethanesulfonamide, and trifluoroacetyl as well as dithiocarbamates and methylthioureas. Both thioureas and dithiocarbamates have shown inhibitory activity against dopamine-β-hydroxylase (8, 9), so these derivatives were expected to produce depressor effects.

Previously, the furyl and thienyl analogs of amphetamine were obtained, and their motor effects were compared to those of amphetamine (10). Amphetamine and its thienyl analog were more active motor stimulants than the furyl analog, but both the heterocyclic analogs were less toxic than amphetamine.

Previously, the furyl and thienyl analogs of amphetamine were obtained, and their motor effects were compared to those of amphetamine (10). Amphetamine and its thienyl analog were more active motor stimulants than the furyl analog, but both the heterocyclic analogs were less toxic than amphetamine.

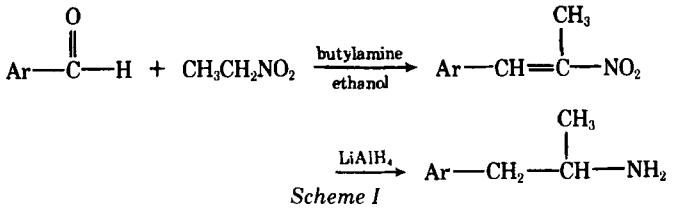
The heterocyclic analogs of amphetamine were synthesized by reduction of the intermediate nitropropenes. The nitropropenes were obtained by a base-catalyzed condensation of aromatic aldehyde and nitroethane (11). Physical constants of the nitropropenes are listed in Table I. The nitropropenes were reduced to amphetamines with lithium aluminum hydride (12) (Scheme I). The amines were generally isolated as the hydrochlorides. Physical constants of the amines are listed in Table II.

The methanesulfonamides were prepared from reaction of the respective amines with methanesulfonyl chloride and triethylamine, giving up to 97% yields. The trifluoroacetamides were obtained from reaction with trifluoroacetic anhydride, with yields up to 90%. The trifluoromethanesulfonamides were obtained from reaction with trifluoromethanesulfonyl chloride and triethylamine. Dark, sticky liquids were usually obtained, and they could not be purified by distillation; prolonged refrigeration generally produced semisolids that could be recrystallized.

The methylthioureas were prepared by reaction of the amine with



Scheme I

methyl isothiocyanate. The resulting liquids could not be distilled without decomposition. Therefore, the crude products were washed with petroleum ether and thoroughly dried, giving yields of analytically acceptable products of about 70%.

The dithiocarbamates were prepared as the triethylammonium salts on reaction of the amines with carbon disulfide and triethylamine. Generally, yellow liquids were obtained, and they gave hygroscopic solids on washing with anhydrous ether. The compounds were isolated as hydrates, as verified by the IR spectra (Table III).

EXPERIMENTAL[1]

Melting points were determined in capillaries with a melting-point block[2] and are uncorrected. IR absorption spectra were obtained with a grating spectrophotometer[3]. Silica gel TLC was carried out, and products were detected by exposure to iodine vapor.

The aldehydes and nitroethane were commercially prepared[4]. Methanesulfonyl chloride[5], trifluoromethanesulfonyl chloride[5], trifluoroacetic anhydride[5], methyl isothiocyanate[5], carbon disulfide[5], and lithium aluminum hydride in ether[6] (1 *M*) were used as received.

The following procedures are representative.

1-(2-Thienyl)-2-nitropropene—A mixture of 56.0 g (0.5 mole) of 2-thiophenecarboxaldehyde, 37.5 g (0.5 mole) of nitroethane, 90 ml of absolute ethanol, and 10 ml of *n*-butylamine was stirred in the dark at room temperature for 5 days. The resulting yellow crystalline mass was filtered and recrystallized from absolute ethanol, giving 37.5 g (44.4% yield) of yellow needles, mp 67–68°; IR (KBr): 1640 (C=C), 1510 (NO_2), and 1300 (NO_2) cm^{-1}.

1-(2-Thienyl)-2-aminopropane Hydrochloride—To 300 ml of anhydrous ether was added 7.6 g (0.2 mole) of lithium aluminum hydride, and the mixture was stirred until the hydride dissolved. A solution of 16.8 g (0.1 mole) of 1-(2-thienyl)-2-nitropropene in 100 ml of anhydrous ether was added dropwise at such a rate that the capacity of the condenser was not exceeded, requiring 30–60 min. The mixture was stirred for 3 hr after the addition, the reaction flask was placed in an ice bath, and water was added dropwise until hydrogen evolution ceased.

The ether layer was separated, the solvent was removed by flash evaporation, and the product was distilled at 146–150° (20 mm), giving 5.5 g (39% yield) of amber liquid. Addition of dry hydrogen chloride to an ethereal solution of the amine produced the hydrochloride, mp 149–152°; IR (KBr): 2900–3000 (NH_3^+) and 720 (ring CH) cm^{-1}.

***N*-Methanesulfonyl-1-(2-thienyl)-2-aminopropane**—To a cooled solution of 2.8 g (0.02 mole) of 1-(2-thienyl)-2-aminopropane in 25 ml of benzene were added dropwise, with stirring, 1.67 ml (0.022 mole) of methanesulfonyl chloride in 20 ml of methylene chloride and 3 ml (0.022 mole) of triethylamine in 20 ml of methylene chloride. The mixture was stirred at 25° for 15 hr, and the resulting solution was washed with dilute hydrochloric acid and water and distilled *in vacuo*. The residue was recrystallized from ethanol, giving 3.1 g (70.5% yield) of colorless needles, mp 63–64°; IR (KBr): 3320 (NH), 1310 (SO_2), and 1125 (SO_2) cm^{-1}.

***N*-Trifluoroacetyl-1-(2-thienyl)-2-aminopropane**—To a cooled solution of 4.2 g (0.03 mole) of 1-(2-thienyl)-2-aminopropane in 50 ml of benzene was added dropwise, with stirring, 6.7 g (0.03 mole) of trifluoroacetic anhydride. The mixture was stirred for 3 hr and refrigerated overnight. The solvent was removed under reduced pressure, and the resulting semisolid was refrigerated. The solid obtained was washed with dilute hydrochloric acid and water and recrystallized from dilute ethanol, giving 1.1 g (16.4% yield) of colorless needles, mp 59–61°; IR (KBr): 3310 (NH), 1690 (C=O), and 1160–1180 (CF_3) cm^{-1}.

***N*-Trifluoromethanesulfonyl-1-(2-thienyl)-2-aminopropane**—To a cooled solution of 2.2 g (0.02 mole) of 1-(2-thienyl)-2-aminopropane in 25 ml of methylene chloride were added, with stirring, 3.36 g (0.02 mole) of trifluoromethanesulfonyl chloride in 20 ml of methylene chloride and 3 ml (0.022 mole) of triethylamine in 20 ml of methylene chloride. The mixture was stirred at room temperature for 12 hr, and the resulting solution was washed with dilute hydrochloric acid and water.

The solvent was removed under reduced pressure, and the residue was dissolved in anhydrous ether and decolorized with charcoal. The solvent was removed in a rotary evaporator, and the residue was refrigerated for 1 week. The resulting semisolid was recrystallized from petroleum ether, giving 1.2 g (22% yield) of colorless crystals, mp 35–37°; IR (KBr): 3300 (NH), 1375 (SO_2), 1190 (CF_3), and 1145 (SO_2) cm^{-1}.

[a] Determined in brain heart infusion broth after 24–48 hr at 37°. [b] Determined in Sabouraud broth after 48–78 hr at 25°. [c] Reference 15.

1-Methyl-3-[1-methyl-2-(2-thienyl)-ethyl]thiourea—A solution of 1.125 g (0.025 mole) of methyl isothiocyanate in 10 ml of absolute ethanol was added dropwise, with stirring, to a cooled solution of 2.8 g (0.02 mole) of 1-(2-thienyl)-2-aminopropane in 25 ml of absolute ethanol. The mixture was refluxed for 12 hr and allowed to cool. The solvent was removed in a rotary evaporator under reduced pressure, and the residue was washed several times with petroleum ether and dried *in vacuo*. A yield of 3.23 g (75.5%) of viscous oil was obtained; IR (film): 3260 (NH) and 1340 (C=S) cm^{-1}.

Triethylammonium 1-Methyl-2-(2-thienyl)-ethyldithiocarbamate—Triethylamine (3.03 g, 0.03 mole) was added, with stirring, to a cooled solution of 2.2 g (0.02 mole) of 1-(2-thienyl)-2-aminopropane in 25 ml of absolute ethanol. To this mixture was added dropwise 2.28 g (0.03 mole) of carbon disulfide, and stirring was continued for 24 hr. The solvent was removed in a rotary evaporator, and the yellow residue was washed with anhydrous ether and dried *in vacuo*, giving 4.1 g (64.5% yield); IR (film): 2960–2990 (NH^+), 1290 (C=S), and 965 (C=S) cm^{-1}.

RESULTS[7]

Rats were observed continuously for 6 hr and daily for 7 days after dosing (Table IV). The 2-thienyl analog of amphetamine (II) produced a behavior pattern similar to that of amphetamine. The dithiocarbamate of the 6-methyl-2-pyridyl analog (XXIV) showed few behavioral effects. The methylthiourea of the *p*-chloro analog (XXVII) also showed many behavioral effects of amphetamine, whereas the methanesulfonamide (XXV) and the dithiocarbamate (XXVIII) showed fewer of these effects.

Passive cutaneous anaphylaxis tests were conducted for XIV, XVII, XXII, and XXV. No inhibition was seen except for XVII, which gave 31% inhibition at a 5.0-mg/kg dose. Antiarthritic activity of X, XV, XVIII, and XXVI was observed *via* the adjuvant-induced arthritis test. A significant decrease in the inflamed hindleg volume of the treated rat was found for XXVI at a 50-mg/kg dose.

Blood pressure effects have not been determined yet for these compounds, but III gave a significant increase (42%) in papillary muscle contractile force *in vitro* at a 1.10-μg/ml dose. No arrhythmia was produced.

Tests for antimicrobial activity were also carried out by both the agar plate method and *in vitro* serial dilution (Table V). Results are expressed in terms of the minimum inhibitory concentration (1/*M*) of compound for inhibition of 24-hr broth cultures of Gram-positive and Gram-negative bacteria, a mold, and a yeast. Appreciable activity was observed against *Candida albicans* for most of the compounds tested and against *Aspergillus niger* for the dithiocarbamates. Previously, thiourea and dithiocarbamate derivatives of β-phenethylamine and 4-substituted β-phenethylamines showed significant antimicrobial activity against these organisms (2).

[7] Behavioral observations, antiarthritic tests, passive cutaneous anaphylaxis tests, and papillary muscle contractile force measurements were carried out at Smith Kline and French Laboratories through the courtesy of Dr. Blaine Sutton.

Percutaneous Absorption of Butylparaben through Guinea Pig Skin *In Vitro*

HIDEO KOMATSU ˣ **and MASAMI SUZUKI**

Received July 10, 1978, from *Pola Laboratories, 27-1, Takashimadai, Kanagawa-ku, Yokohama, Japan.* Accepted for publication October 20, 1978.

Abstract □ Percutaneous absorption of aqueous butylparaben through guinea pig dorsal skin was studied using a diffusion chamber. Polysorbate 80 increased the solubilized concentration but decreased penetration of the preservative. Polyethylene glycol 400 also reduced the amount of penetration. Propylene glycol was less effective than polyethylene glycol 400. Preservative activities of these systems on several microorganisms were evaluated on agar plates. The relationship between the butylparaben penetration and preservative activity is discussed.

Keyphrases □ Percutaneous absorption—butylparaben, guinea pig, *in vitro*, effect of surfactants, relation to preservative activities □ Butylparaben—percutaneous absorption, effect of surfactants, guinea pig, *in vitro*, relation of absorption and preservative activities □ Surfactants—effect on percutaneous absorption of butylparaben, guinea pig, *in vitro* □ Preservatives—butylparaben, percutaneous absorption, effect of surfactants, relation of absorption and preservative activities, guinea pig, *in vitro*

The preservative activity of a system is dependent on the aqueous concentration of the preservative (1–3). This fact suggests that organic compounds employed as preservatives will be somewhat solubilized in the aqueous phase in systems such as foods, ointments, and cosmetics. Such organic preservatives have affinities to both water and oil and are expected to penetrate into the skin easily (4, 5).

Many studies have concerned the percutaneous absorption of preservatives, especially hexachlorophene (6–9), and their preservative activities in various systems (3, 10). However, few reports concerning butylparaben (I) have been published, despite its wide use as a preservative, and there are few reports on the relationship between preservative activity and percutaneous preservative absorption.

Although recent reports stated that esters of *p*-hydroxybenzoic acid did not pass through a natural membrane 15 hr after application (11), these substances must penetrate into the skin since they induce allergic reactions (12, 13). A whole body autoradiography study of hairless mice (14) showed that I was percutaneously absorbed from several ointments.

In this paper, percutaneous absorption *in vitro* and preservative activity of I in an aqueous system were measured; the relationship between the preservative activity and the percutaneous preservative absorption is discussed.

EXPERIMENTAL

^{14}C-Butylparaben[1] was obtained with a specific activity of 1.65 mCi/mmole. Propylene glycol, polyethylene glycol 400, and polysorbate 80 were reagent grade[2].

Vehicle compositions are listed in Table I. A 2-ml aliquot of each system was used for the diffusion study.

Male guinea pigs (Hartley strain), ~320 g, were used. The dorsal hair was removed with a hair clipper immediately prior to the experiment. The residual hair was 0.5 mm long. The adipose tissue was removed after the dorsal skin was excised from the sacrificed animal. The skin sample was then punched into a 3-cm diameter disk.

The disk was placed in a modified diffusion chamber (15). The area of the donor side was 3.14 cm^2, and the volume of the receptor space was 4.4 ml. The dermal side receptor fluid was saline and flowed through the chamber continuously at ~8 ml/hr. The eluted solution was fractionally collected in test tubes. The chamber was placed in a controlled 37° water bath throughout the experiment.

Aliquots (1 ml) of eluted I were pipetted from each test tube into a vial containing 10 ml of Bray's scintillation fluid (16). The radioactivity was measured by a liquid scintillation counter[3].

Preservative activities were studied according to a modified method of Ishizeki (17). The test sample was mixed with each solution of *Escherichia coli* (IFO[4] 3043) plus *Staphylococcus aureus* (IFO 3061), *Bacillus subtilis* (IFO 3024), *Pseudomonas aeruginosa* (IFO 3445), *Aerobacter aerogenes* (IFO 3320), *Aspergillus niger* (IAM[5] 3001) plus *Penicillium citrinum* (IAM 7316), and *Candida albicans* (IFO 0583). After several intervals of up to 7 days at 32°, each mixture was transferred onto an agar plate[6]. For *P. aeruginosa* and *A. aerogenes*, glucose was added to the agar; for *A. niger* plus *P. citrinum* and *C. albicans*, Sabouraud medium[6] was employed.

Colonies were counted after 24 hr of incubation at 37° for bacteria and after 48 hr of incubation at 30° for fungi and yeasts. Preservative activities were evaluated by counting the days before all colonies disappeared. The score was 8 when no colonies were found on the plate zero day after addition of the test sample. The score decreased with time; when colonies were still observed after 7 days, the score was 0.

RESULTS AND DISCUSSION

The penetration flux, J, of a solute through the skin is expressed as:

$$J = \frac{Q}{At} = \frac{(D)(PC)(C_v)}{l} \qquad \text{(Eq. 1)}$$

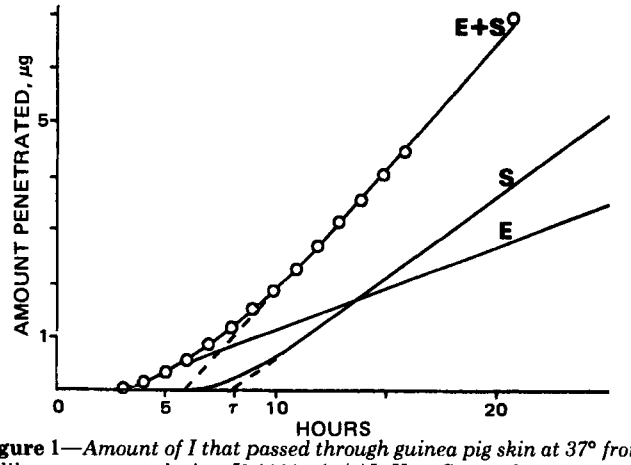

Figure 1—*Amount of I that passed through guinea pig skin at 37° from a dilute aqueous solution [0.002% (w/v)]. Key:* S, *steady-state penetration through epidermis;* E, *early penetration through appendages;* S + E, *observed amount of penetration; and* τ, *lag time.*

where Q is the amount of solute that diffuses across the area, A, in time, t; PC is the skin–vehicle partition coefficient of the solute; D is the solute diffusion constant in the skin of thickness l; and C_v is the solute concentration in the vehicle (18, 19). The permeability constant, k_p, which represents a penetration rate, is given by J/C_v.

Figure 1 shows the total amount of I absorbed from an aqueous vehicle through the skin as a function of time. Transient penetration through appendages becomes less important than the steady-state penetration through an unbroken membrane over time (18). In Fig. 1, however, the amount of early penetration, E, was comparable to the steady-state penetration, S. In the present study, therefore, the observed penetration was explained as the sum of two diffusion processes ($E + S$) (20).

A lag time, τ, was given by the intercept of the line S on the t-axis. The lag time is the time required for the solute to pass transepidermally through skin of thickness l with the diffusion constant D (20):

$$\tau = \frac{l^2}{6 \times D} \qquad \text{(Eq. 2)}$$

The penetration of I increased with time from Systems A–K (Tables I and II and Figs. 2 and 3). The average thickness of the skin samples from 22 animals without subcutaneous fat was 0.134 cm (SD 0.017 cm). This value was used for the diffusion constant calculations.

Percutaneous solute absorption is reportedly enhanced by solvents such as dimethyl sulfoxide and chloroform–methanol (21–24) because, perhaps, of stratum corneum changes (23, 24). Although there was a small D value deviation in the 11 systems in the present study ($D = 3.63 \pm 0.47 \times 10^{-4}$ cm^2/hr), no correlation was found between the system compositions and D values. The I partition coefficient varied markedly with the systems. Propylene glycol reduced the value significantly, but the effect was much less than that of polyethylene glycol 400. The effect of polysorbate 80 on the decrease of the partition coefficient was much more drastic. When polyethylene glycol 400 was coexistent with the surfactant, further reduction of the partition coefficient occurred. Propylene glycol addition had no effect.

The percentage of the solute passing through the skin from the system correlated well with the partition coefficient, indicating that the system–skin partition coefficient determined the penetration flux.

Preservative activities were evaluated qualitatively. Since the solubility of I in water is 0.015% (w/v), the I concentration in System A was slightly less than that in Systems B–E. The System E score was relatively high, but the preservative levels of these five systems were comparable (Table III). This finding suggested that there were no interactions between the solubilizers and I that would deactivate the preservative.

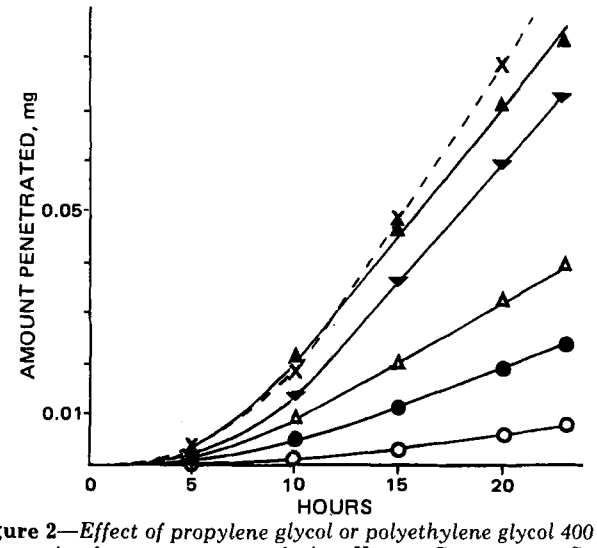

Figure 2—*Effect of propylene glycol or polyethylene glycol 400 on I penetration from an aqueous solution. Key: ▼, System A; ▲, System B; ●, System C; △, System D; ○, System E; and ×, supposed amount of penetration from 0.02% aqueous I solution.*

The increase in I concentration with polysorbate 80 did not improve preservative activity. On the contrary, the activity was reduced (Table III). Since the preservative activity is dependent on the effective aqueous I concentration (1), these results indicate that the surfactant increased the amount of I trapped in micelles and reduced the I concentration in the outer phase (3, 25).

Since the partition coefficient is also regarded as an index of mutual affinity between the preservative and vehicle (26), a low partition coefficient reflects the tendency of the preservative to remain in the vehicle. Therefore, the addition of propylene glycol or polyethylene glycol 400 to water, which increased the I solubility, decreased the partition coefficient. If the aqueous solubility were 0.02% (w/v) and the concentration were not increased by the solubilizers, the penetrated amount would be reduced in Systems B–E (Fig. 2). System A contained only 0.015% I, so the addition of solubilizers decreased the partition coefficient and increased I concentration. The latter was larger than the former in System B (Fig. 2), whereas the decrease in the partition coefficient was much more effective in Systems C–E. Polyethylene glycol 400 induced a greater decrease in the penetrated amount (or partition coefficient) than propylene glycol, as shown by a preliminary experiment. The saturated I concentration in 10% aqueous polyethylene glycol 400 was 0.050% (w/v) while that in 10% aqueous propylene glycol was 0.032% (w/v). These values were obtained by spectrophotometry[7] at 256 nm. An increase in

J	0	0	7	0	0	0	7
K	0	0	7	6	0	0	13

solubility means an increase in affinity to the system, which results in a decrease in the partition coefficient.

The preservative activity increased following addition of polyethylene glycol 400 to the surfactant solution (Table III), indicating that the I concentration in the outer phase increased due to alteration of the aqueous phase–micelle partition coefficient. The increase in I concentration in the outer phase (Table III) and the decrease in the amount passing through the skin (Fig. 2) caused by polyethylene glycol 400 help explain the percutaneous absorption results for Systems F–K.

The effect of the polyethylene glycol 400 addition in Fig. 3 was not so great as that in Fig. 2, where the surfactant was not present. Although the value of the skin–vehicle partition coefficient was reduced by the addition of polyethylene glycol 400, the effective concentration in the outer phase, which can contribute to penetration (19), was increased. Thus, the product of the effective outer phase concentration and the partition coefficient showed only a slight decrease in the penetrated amount.

The effect of propylene glycol was not so great as that of polyethylene glycol 400 on either permeability or preservative activity. Propylene glycol induced only a small increase in I concentration in the outer phase, which was counteracted by a small decrease in the partition coefficient, resulting in a smaller permeability change.

Some other factors also affected penetration from a surfactant solution since the amount of penetration from System F was similar to that from System A, although the preservative activities of these two were significantly different. Malik *et al.* (27) suggested that a surfactant increased the drug–skin affinity but that the excess addition of a surfactant decreased drug absorption, an effect also seen in Systems F and I in this study. Ostrenga *et al.* (28) suggested that the whole vehicle was absorbed or that the vehicle was separated on the skin after application. These reports reflect the difficulty of comparing the amount of penetration from systems with and without surfactant on the basis of the concentration and partition coefficient only. It was possible, however, to evaluate the effect of propylene glycol and polyethylene glycol 400 in each system on the basis of these two factors.

Although the addition of excess surfactant is an effective way to prevent a preservative from penetrating into the skin, such a system was inactive on microorganisms. Moreover, it is very dangerous to apply a large amount of a preservative on living skin since the compositions of the system change with time due to water evaporation and the secretion of sebum and sweat. The results in this study suggest that both the increase in preservative activity and the reduction of percutaneous preservative absorption can occur following the addition of a solubilizer, *i.e.*, polyethylene glycol 400, to the system.

High-Performance Liquid Chromatographic Assay for the Antiprotozoal Agent, Tinidazole, in Human Plasma

K. B. ALTON ˣ and J. E. PATRICK

Received August 7, 1978, from *Ortho Pharmaceutical Corporation, Raritan, NJ 08869.* Accepted for publication October 20, 1978.

Abstract □ A rapid and specific high-performance liquid chromatographic (HPLC) assay for the quantitative determination of tinidazole in human plasma is described. After a simple extraction procedure, the compound is analyzed by HPLC using a reversed-phase column and a UV detector. Quantitation is accomplished using an external standard, and peak areas are determined with an integrating computer. The average recovery of tinidazole over a concentration range of 0.20–20.0 μg/ml was 86.9 ± 2.8% *SD*. The maximum sensitivity of the assay is approximately 0.10 μg/ml; it is suitable for use in pharmacokinetic studies following administration of therapeutic levels of tinidazole to humans.

Keyphrases □ Tinidazole—high-performance liquid chromatographic assay, human plasma □ High-performance liquid chromatography—analysis, tinidazole in human plasma □ Antiprotozoal agents—high-performance liquid chromatographic analysis in human plasma □ High-performance liquid chromatography—analysis, tinidazole in human plasma

The antitrichomonal agent tinidazole, ethyl-2-(2-methyl-5-nitro-1-imidazolyl ethyl) sulfone (I), is one of the most active compounds in a series of nitroimidazole derivatives (1) active against *Trichomonas vaginalis* (2–5). Attempts to measure tinidazole or other *N*-1-substituted nitroimidazoles in plasma samples have included polarography (6–8), absorptiometry (9, 10), GLC (10), TLC (10, 11), *in vitro* agar diffusion (12), and high-performance liquid chromatography (HPLC) (13).

Quantitation of both tinidazole and metronidazole (7, 8) based on the polarographic assay described by Kane (6) lacks specificity since all drug-related species possessing the nitroimidazole nucleus are similarly detected. The *in vitro* agar diffusion assay (12), the absorptiometry method (9, 10), and the HPLC procedure (13) have maximum sensitivities of 0.5–1.0 μg/ml for the *N*-1-substituted 5-nitroimidazoles. This sensitivity limitation may diminish their usefulness in describing the initial phase of drug absorption or the terminal portion of the elimination phase in humans.

The absorptiometric method and the pulsed polarographic and electron-capture GLC procedures (10) require time-consuming isolation of the intact, parent *N*-substituted nitroimidazole by TLC before quantitation. In a modified TLC–densitometry method (11), direct quantitation of tinidazole and metronidazole was achieved, but this method is not as rapid as conventional HPLC or GLC, which can be automated to handle a large number of clinical samples.

This report describes a simple and specific HPLC method for the rapid estimation of tinidazole in human plasma at concentrations suitable for pharmacokinetic studies. No interference from two known urinary metabolites (II and III) (14, 15) of tinidazole was encountered.

III

EXPERIMENTAL

Apparatus—Analyses were performed on a liquid chromatograph[1] operated at ambient temperature and equipped with a differential UV (313 nm) detector[2]. Separations were accomplished on a 30-cm × 3.9-mm i.d. reversed-phase column[3]. Samples were introduced onto the column through a septumless injector[4] with a 25-μl syringe[5]. Chromatograms were traced on a strip-chart recorder[6], and peak area integrations were performed by an integrating computer[7] interfaced with the detector by an analog–digital converter[8].

Reagents and Solvents—Tinidazole (I) and two known metabolites of tinidazole, ethyl[2-(2-hydroxymethyl-5-nitro-1-imidazolyl)-ethyl] sulfone (II) and the *O*-glucuronide conjugate of II (III), were used as received[9]. All chemicals and reagents except methanol[10] were reagent grade. Both 2-butanone and water were distilled before use.

Chromatographic Conditions—The mobile phase was 0.05 *M* pH 7.0 KH_2PO_4–NaOH buffer–methanol (86:14 v/v) with the flow rate adjusted to 2.0 ml/min (~2000 psi). The solvent mixture was prepared daily and degassed under reduced pressure before use.

Extraction Procedure—An aliquot (1.0 ml) of plasma was transferred to a 15-ml vial (16 × 125 mm) fitted with a polytef-lined screw cap and diluted with 2.0 ml of 0.05 *M* pH 7.0 KH_2PO_4–NaOH buffer. This aqueous portion was extracted by vigorous shaking with 7.0 ml of petroleum ether (bp 30–60°). The mixture was centrifuged (2 min at 1500×*g*) to obtain a clear supernate, and the organic (upper) layer was discarded. The aqueous layer was extracted twice with ethyl acetate (7.0 ml) by manual shaking for 1 min, and the phases were separated by centrifugation at 1500×*g* for 3 min.

The organic layers were removed with a Pasteur pipet, pooled, taken to dryness under a nitrogen stream in a water bath (55°), and then transferred to a 2.5-ml conical centrifuge tube using ethyl acetate. The ethyl acetate was concentrated as described, the residue was dissolved in 2-butanone (0.1–0.5 ml), and aliquots (5–20 μl) were injected onto the HPLC column.

Extraction Efficiency—Blood from several untreated volunteers was drawn into heparinized containers[11] and centrifuged to generate a plasma pool from which an extraction efficiency was established. Known amounts of tinidazole dissolved in methanol were added to each of six 11.0-ml drug-free plasma pool samples to obtain concentrations of 0.20, 0.39, 1.93, 4.82, 9.82, and 20.0 μg/ml. The plasma pools were thoroughly mixed on a tube rotator for 30 min. Aliquots (1.0 ml) of plasma from each pool were transferred to 15-ml screw-capped vials and stored frozen (−20°) until extracted as described.

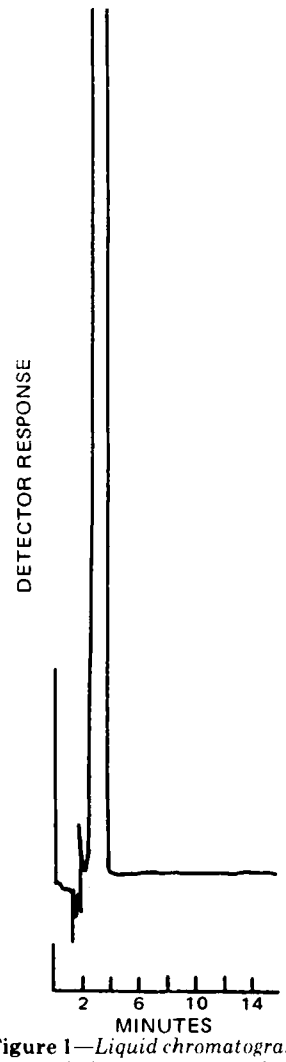

Figure 1—*Liquid chromatogram of an ethyl acetate extract from drug-free plasma. The mobile phase consisted of 0.05* M *KH_2PO_4–NaOH buffer–methanol (86:14 v/v) with the flow rate adjusted to 2.0 ml/min.*

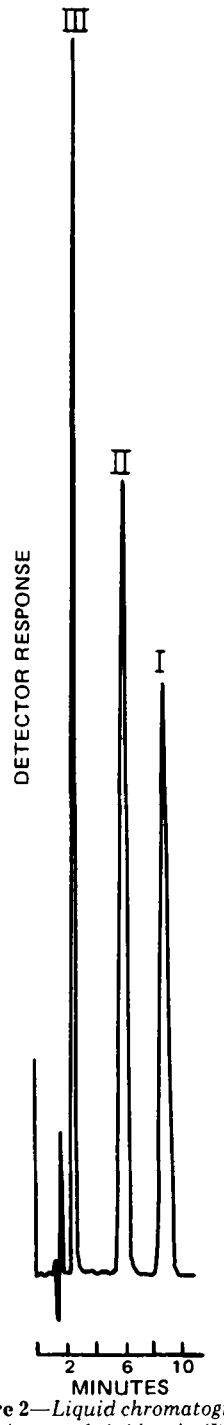

Figure 2—*Liquid chromatogram of a mixture of tinidazole (I), II, and III. Approximately 0.2 μg of each standard was injected for analysis.*

Since the prepared drug concentrations ranged over two orders of magnitude (0.20–20.0 μg/ml), varying volumes of the final 2-butanone dilutions were injected for analysis by HPLC. Typically, when the drug concentration approached 0.2 μg/ml, one-fifth (20 μl/100 μl) of the final dissolved residue volume was analyzed; at a concentration of 20 μg/ml, only one-one hundreth (5 μl/500 μl) of the final dissolved residue was injected. All samples were analyzed in duplicate. After chromatography, quantitation of tinidazole was accomplished by use of the external standard method.

Calibration and Standard Preparation—Tinidazole (10.0 mg) was dissolved in 2-butanone and diluted in a 10.0-ml volumetric flask to 1.0 μg/μl. Two additional stock solutions were prepared containing 0.10 and 0.01 μg/μl of tinidazole by serial dilution of the 1.0-μg/μl stock solution with 2-butanone. Since the external standard method prepared from the software section of the computer assumes a linear relationship between micrograms injected and peak area (microvolt-seconds as reported by the integrating computer), this relationship was initially evaluated by repeated ($n \geq 5$) injections of 0.25, 0.20, 0.15, 0.10, 0.05, and 0.025 μg of tinidazole from the 2-butanone stock solutions. Thereafter, an average calibration response factor was established by the computer following triplicate injections equivalent to 0.15 μg of tinidazole.

Specificity—Assay specificity was determined by analyzing a methanolic solution containing a mixture (0.2 μg) of tinidazole and two of its known urinary metabolites (II and III). A portion of an extract (20 μg/100 μl) from a drug-free plasma sample was evaluated chromato-

graphically for the presence of any extractable ethyl acetate UV-absorbing (313 nm) material that might interfere with tinidazole measurement.

RESULTS AND DISCUSSION

A successful chromatographic assay for drug levels in the large number of plasma samples generated from a clinical study would provide highly reproducible drug recovery, specificity, sensitivity, precise measurement, and rapid throughput of samples.

The average recovery of drug from plasma samples to which tinidazole had been added was 86.9 ± 2.8% *SD* (Table I). Linear regression analysis of percent recovery *versus* plasma concentration revealed no statistically significant slope (β) ($p = 0.7431$). These data, therefore, suggest that there is no concentration dependence on extraction efficiencies over the range of expected plasma drug levels (10–12).

Tinidazole was monitored at 313 nm since its λ_{max} was observed in methanol at 310 nm ($\epsilon = 9070$). Ethyl acetate extracts from drug-free plasma were free of interfering UV- (313 nm) absorbing peaks (Fig. 1). Preextraction with petroleum ether eliminated nonpolar material that would otherwise be highly retained on this reversed-phase system. Little or no loss of tinidazole was encountered in this step.

Baseline resolution among tinidazole, II, and III was achieved under the chromatographic conditions described (Fig. 2). The observed retention times (t_r) for III, II, and I were 2.73, 6.12, and 8.96 min, respectively. Representative chromatograms of plasma extracts containing 0.20 and 20.0 μg/ml of tinidazole are shown in Fig. 3.

Linear regression analysis of the curve described by plotting microvolt-seconds (area) *versus* micrograms injected indicated a linear fit of the data ($r^2 = 0.9994$) from 0.025 to 0.25 μg. The slope was 474.75 μv-sec/ng; the intercept, which was not significantly different from zero ($p < 0.05$), was 1512 μv-sec. Over 2 months, the slope of this line demonstrated little change, with a coefficient of variation equal to 3.83% ($n = 16$).

Thermal Characterization of Citric Acid Solid Dispersions with Benzoic Acid and Phenobarbital

ROBERT J. TIMKO and NICHOLAS G. LORDI ×

Received April 24, 1978, from the *College of Pharmacy, Rutgers—The State University, Busch Campus, Piscataway, NJ 08854.* Accepted for publication October 25, 1978.

Abstract □ The glass transition temperatures of citric acid glass were determined by differential scanning calorimetry to be 10.2 and 13.5° for *in situ* and bulk-prepared samples, respectively. Mechanical stress on citric acid glass induced foci for crystallization. Benzoic acid addition to citric acid glass decreased its glass transition temperature while phenobarbital addition increased its glass transition temperature, the latter forming a glass solution.

Keyphrases □ Glass transition temperature—citric acid glass, benzoic acid, mechanical stress, phenobarbital □ Citric acid—glass formation, glass transition temperature, benzoic acid, phenobarbital □ Glass formation—citric acid, benzoic acid, phenobarbital □ Phenobarbital—glass formation with citric acid

A glass is generally defined as a noncrystalline solid formed by continuous hardening or solidification of a liquid (1, 2). The use of organic compounds capable of glass formation to reduce the particle size of a drug and to increase its dissolution and absorption rates was first suggested by Chiou and Riegelman (3). They proposed the formation of a glass dispersion of a poorly water-soluble drug and a physiologically inert carrier such as citric acid. The concepts involved in glass solution and glass suspension formation were discussed previously (4).

Glass dispersions are metastable and, as a result, exhibit rapid dissolution. In a study with griseofulvin (3), the citric acid–griseofulvin glass solution had the fastest dissolution rate of the solid dispersion systems examined. However, griseofulvin decomposition occurred in the presence of citric acid during manufacturing. Citric acid was also an unacceptable sulfabenzamide carrier (5). As with griseofulvin, thermal drug degradation occurred during sample preparation.

Summers and Enever (6–8) studied citric acid–primidone glass dispersions and found the glass solutions formed to be unstable and rapidly devitrified. The devitrified dispersion systems, however, still exhibited more rapid dissolution than the pure drug or drug and carrier mixtures. The citric acid glass transition temperature increased with increasing primidone concentration (8). The

increased primidone dissolution rate was a result of its reduced particle size and increased wettability in the systems.

Most glass dispersion studies concentrate on the drug. Little information is available on carrier stability or the effect of additives on stability. This article reports some observations on citric acid glass stability; the effect of two additives, benzoic acid and phenobarbital, on its glass transition temperature; and the nature of the dispersion systems these materials form. Benzoic acid, a crystalline material, has not been reported capable of glass formation. Phenobarbital has been suggested to be capable of glass formation by rapid melt cooling (9) and has been reported to form a glass solution with citric acid (3).

EXPERIMENTAL

Materials—Citric acid[1] (mp 152–156°), benzoic acid[2] (mp 121–124°), and phenobarbital[3] (mp 174–178°) were used as received.

Thermal Analysis—A differential scanning calorimeter[4] was used to determine the glass transition temperatures and stabilities. Observed temperature values were corrected for chromel alumel thermocouples from −60 to 200° using indium metal as the standard. All determinations were made at least in duplicate.

A 10–15-mg sample size was necessary to obtain reproducible and distinct transition temperatures. Samples were scanned at 10°/min in a static air atmosphere using an empty aluminum pan as the reference.

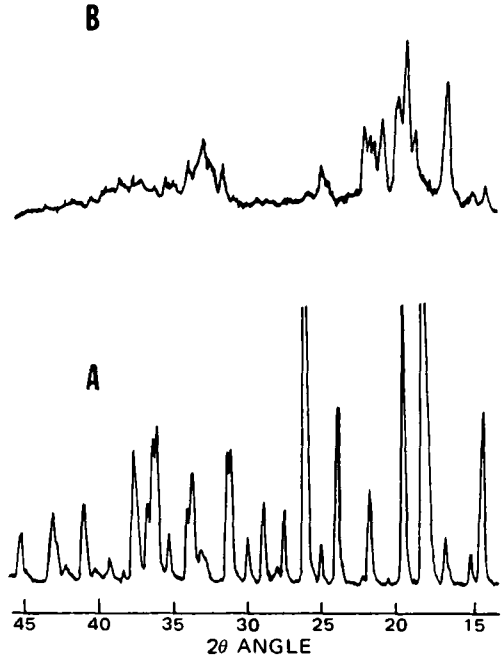

Figure 2—*X-ray diffraction pattern of anhydrous citric acid (A) and bulk-prepared citric acid solidified melt (B).*

The sensitivities were 1.0°/in. for pure materials and physical mixtures and 0.2°/in. for solidified melts and glass systems. A 20°/in. temperature scale was used.

Two procedures were used for sample preparation, an *in situ* method and a bulk procedure. In the *in situ* procedure, citric acid or mixtures of citric acid and benzoic acid or phenobarbital in the desired ratio were weighed accurately directly into an aluminum sample pan. An aluminum cover was placed on the sample, and the pan was transferred to the sample holder of the differential scanning calorimeter. After the sample was heated to melting, the melt was rapidly cooled to −60° by purging the sample holder of the instrument with liquid nitrogen. The solidified melt was reheated, and the thermogram was recorded.

Bulk glass system preparation involved melting 50 g of citric acid or mixtures of citric acid and benzoic acid or phenobarbital in the desired ratio in an electric frying pan[5] heated to 170°. Samples were stirred continually until melting was complete. The melt was rapidly solidified by transferring it to an aluminum foil boat located on a dry ice block hollowed out to fit the boat dimensions. After solidification, the melt was removed from the dry ice and placed in a desiccator over silica gel at 23° for 24 hr. The solidified melt was pulverized in a rotary granulator[6].

Samples of the solidified melts, prepared by both the *in situ* method (removed from the sample holder after cooling to −60°) and the bulk procedure, were placed in desiccators at 4, 23, and 37°. Thermograms were run periodically to examine the effects of aging on physical stability.

The melting temperatures of the physical mixtures were determined by differential scanning calorimetry and a conventional capillary tube melting-point apparatus[7]. Both the onset of melting temperature and the complete fusion temperature are reported. When using the differential scanning calorimetry, melting onset was defined as the temperature at which there was an initial endothermic deviation in the thermogram baseline. Its value was the curve extrapolation crossing point on each side of the baseline deviation. The complete fusion temperature was the endothermic peak temperature. If a sharp peak was not obtained, the sides of the peak were extrapolated and the crossing point was used as the value of the endothermic peak. With the capillary tube method, the melting onset and the complete fusion temperatures were visually estimated with a magnifying glass. The heating rate was ~10°/min.

The area under the exothermic peak in the bulk-prepared citric acid melts was determined by a cut and weigh method. Areas were calculated according to the standard area weight. Results are reported as area under the peak in square centimeters per milligram of sample weight.

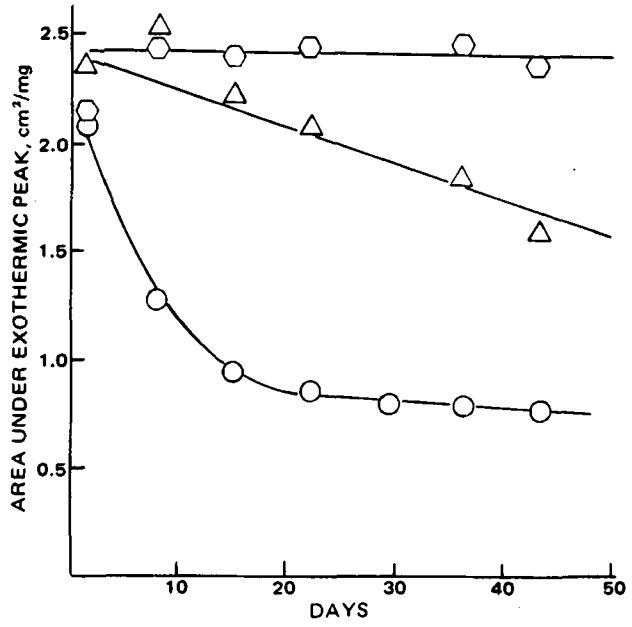

Figure 3—*Storage temperature effect on the area under the exothermic peak of bulk-prepared citric acid solidified melt. Key:* ○, *4°;* △, *23°; and* ○, *37°.*

X-Ray Diffraction—An X-ray diffractiometer[8] was used to determine the bulk-prepared solidified citric acid melt. Powdered mixed particle-size samples were mounted on a screen sample holder, and the X-ray diffraction pattern was determined using Cu K_α radiation. A powdered citric acid sample was run for comparison.

NMR Studies—Citric acid stability during sample preparation was examined by NMR[9]. The fused sample citric acid spectra, prepared by both the *in situ* and bulk methods, were compared with those of unfused citric acid and aconitic acid[10], a possible dehydration decomposition product of citric acid. The solvent was deuterium oxide, and tetramethylsilane was the internal standard.

RESULTS AND DISCUSSION

Glass is a fourth state of matter, distinct from both the crystalline and liquid states, yet exhibiting characteristics of both. Like a crystal, a glass exhibits ridigity; like a liquid, it has random molecular arrangement (1, 10, 11).

The crystalline and liquid states are delineated from each other by a definite temperature: the melting point of the crystalline material. The transition between a glass and a liquid is more ambiguous (12). In differential scanning calorimetry, it is indicated by a marked shift in the thermogram baseline due to an increase in the material's specific heat. The glass transition temperature (T_g) is the upper boundary of this transitional temperature range (10), and it is this temperature that is reported as the T_g of the glass system studied. Experimentally, it was determined by extrapolating the curve on each side of the onset of the baseline shift; the crossing point of the extrapolated lines was used as the T_g value.

Crystalline citric acid is highly hydrogen bonded (13). Citric acid glass formation has been attributed to this hydrogen bonding capacity, which may prevent its crystallization (14). Citric acid glass formation may be due also to its partial decomposition by dehydration into aconitic acid during melting (4).

Citric acid stability during sample preparation was examined by NMR. No changes were observed in the fused citric acid spectra when compared to the spectrum of unfused citric acid. A molten citric acid sample held isothermally at 175° for 5 min and then cooled rapidly also showed no spectral changes. The thermogram of this material was identical to that of citric acid melt prepared in the normal manner.

Thermal citric acid studies indicate possible anhydride formation on continuous heating at ~185° (15). Decomposition does not occur until about 200° (15, 16), where citric acid begins to decompose to a mixture of itaconic and citraconic acid anhydrides.

The thermograms of bulk-prepared citric acid melt and *in situ* prepared citric acid glass are shown in Fig. 1. The bulk and *in situ* glass transitions were 13.5 and 10.2°, respectively. These results are in conflict with a previously reported T_g of −23° for bulk-prepared citric acid glass (8). In preliminary studies with bulk-prepared citric acid melts, a small baseline shift was observed at −23°, in addition to the transition at 13.5°, when the heating rate was 2°/min. Since this shift was not observed at

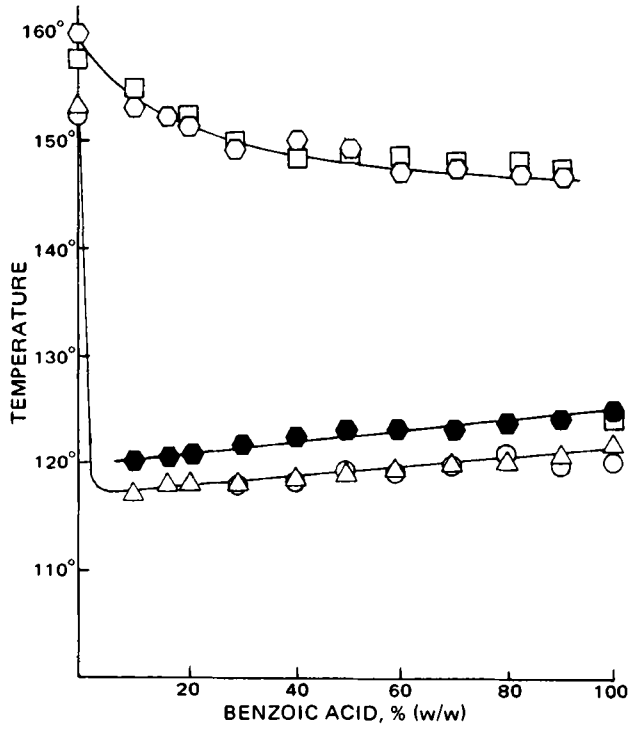

Figure 6—*Melting temperatures of the benzoic acid–citric acid binary system determined from physical mixtures. heating rates of 5, 10, and 20°/min, it was not considered to be the true citric acid glass T_g but rather an artifact or a secondary transition in the sample as a result of molecular relaxation within the solidified melt (17).

The thermogram of the bulk-prepared melt exhibited a broad exothermic transition, onset at ~80°, followed by an endotherm. The exotherm was present in all samples but varied in size and shape. The *in situ* samples did not exhibit an exotherm. No changes were observed in their thermograms after 4 weeks of storage under the test conditions. When the *in situ* sample surface was scratched with a metal probe and the scan was recorded, an exotherm similar to the one observed in the bulk samples was noted. X-ray diffraction data (Fig. 2) indicated that the bulk-prepared citric acid melt consisted of an amorphous and crystalline citric acid mixture. Mechanical manipulation of the citric acid melt during processing induced crystallization foci, and the exotherm in the bulk-prepared citric acid melt thermograms was due to crystallization. The endotherm was crystallized solid melting.

The bulk-prepared citric acid melt crystallization rate can be studied by monitoring the rate of change in area under the exothermic peak. The smaller the area, the more crystalline is the material. Although the areas under the peak differed among batches of bulk citric acid melt because of stress variability, similar trends were observed (Fig. 3). Little area change was observed in melt samples stored at 4°. At 23°, the area gradually decreased with time. At 37°, there was a rapid initial decrease followed by a slower rate of change. The abrupt change in slope corresponded to the disappearance of the glass transition. An initial rapid crystallization was followed by a slower secondary crystallization. Possibly, crystallites formed in the primary process were regrouped and a more perfect crystalline state was formed.

The benzoic acid effect on the citric acid glass T_g is shown in Fig. 4. Benzoic acid up to 20% (w/w) decreased the T_g. Above this concentration, the limit of benzoic acid incorporation into citric acid glass was reached, and no further T_g reduction was observed. Excess benzoic acid crystallized upon cooling of the melt, forming a macrocrystal dispersion in the citric acid–benzoic acid glass matrix and disrupting the glass system. Figure 5 shows thermograms of a benzoic acid–citric acid (1:4) mixture and its rapidly cooled melt. The glass system was thermally unstable; the components crystallized and then melted as the temperature was increased.

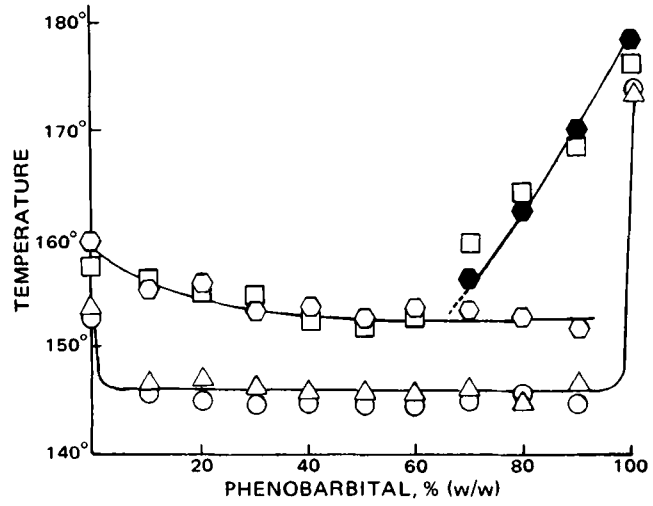

Figure 7—*Phenobarbital–citric acid binary system melting temperatures determined from physical mixtures. Key (differential scanning calorimetry): △, initial endothermic temperature deviation in the thermogram baseline; ○, citric acid endothermic peak temperature; and ●, phenobarbital endothermic peak temperature. Key (capillary tube method): ○, melting onset temperature; and □, complete physical mixture fusion temperature.*

The use of the melting characteristics of pharmaceutical mixtures to detect possible interactions between materials has been demonstrated (18, 19). Figure 6 shows the melting data for the benzoic acid–citric acid system. The results obtained by the capillary tube method were in good agreement with the melting onset and the complete fusion temperatures determined with the differential scanning calorimeter. Little interaction between benzoic acid and citric acid was indicated since the physical mixture melting temperatures showed little change when compared to the melting temperatures of the pure materials. The slight depression of the citric acid melting temperature in the mixtures was probably due to the presence of molten benzoic acid.

Phenobarbital also formed a glass on rapid cooling of its melt with a T_g of 41.9°. The thermograms (Fig. 1) showed an exotherm, onset at 90°, on continued heating above the T_g followed by an endotherm. The exotherm was attributed to crystallization, and the endotherm was attributed to crystallized phenobarbital melting. The phenobarbital crystallized into either of two polymorphic forms. A previous study of phenobarbital polymorphism showed similar results (9).

In polymeric systems, the mixture T_g of two miscible glasses can be estimated by (20):

$$\frac{1}{T_g} = \frac{W_a}{T_{ga}} + \frac{W_b}{T_{gb}} \qquad \text{(Eq. 1)}$$

where T_{ga} and T_{gb} are the glass transition temperatures of the two components of the mixture in degrees Kelvin, and W_a and W_b are their respective weight fractions. For the phenobarbital–citric acid glass system, the observed T_g values were lower than those predicted (Fig. 4), probably because the bonding between citric acid and phenobarbital molecules is less than that between either citric acid or phenobarbital molecules alone.

A thermogram of 1:1 bulk-prepared phenobarbital–citric acid melt (Fig. 5) resembled that for bulk-prepared citric acid melt (Fig. 1). As in that case, the exotherm was attributed to crystallization, and the endotherm was attributed to melting of the crystallized solid. No difference from the *in situ* T_g was observed.

The phenobarbital–citric acid mixture melting temperatures are shown in Fig. 7. As with the benzoic acid–citric acid system, the results obtained by the capillary tube method were in good agreement with those obtained using the differential scanning calorimeter. At compositions below 70% (w/w) phenobarbital, a single sharp endotherm was observed by differential scanning calorimetry. At 70% (w/w) phenobarbital and above, two endothermic peaks were observed in the thermogram. This finding indicates that the phenobarbital was dissolving in the molten citric acid. A second endothermic peak became visible in the thermogram only when the phenobarbital reached its solubility limit in the molten citric acid. The appearance of the second endothermic peak corresponded with the instability of the ≥70% (w/w) phenobarbital glass systems to tempera-

tures above the T_g. Thermograms of these systems showed an exotherm followed by an endotherm, indicating crystallization followed by melting.

Citric acid and phenobarbital seem to form glass solutions rather than dispersions as in the case of citric acid and benzoic acid. Visual examination of the melts of citric acid and phenobarbital mixtures in a capillary tube, under a hot-stage microscope[11], and during bulk preparation showed them to be a single homogeneous phase.

The *in situ* procedure is useful for screening potential glass-forming materials and glass-forming drug–carrier combinations. Physical mixture and solidified melt thermograms and the T_g data indicate whether a drug–carrier mixture will form a glass solution or suspension and what optimum drug–carrier combination can be obtained. In systems that exhibit mechanical and/or thermal instability or that have a T_g below or only slightly above room temperature, the material would not be rigid enough to withstand normal handling operations and could be eliminated from further investigation.

Of particular interest would be the preparation of glass systems containing large quantities of drugs. For example, it might be possible to stabilize the glassy state of a glass-forming drug by mixing it with a small amount of a compatible inert glassy carrier. This procedure would permit the use of less carrier, thereby reducing bulk volume, and aid in the formulation of glass dispersion systems into solid dosage forms.

Paired-Ion Reversed-Phase High-Pressure Liquid Chromatographic Assay of Pentobarbital–Pyrilamine Suppositories

JOHN H. BLOCK ˣ, HOWARD L. LEVINE, and JAMES W. AYRES

Received July 17, 1978, from the *School of Pharmacy, Oregon State University, Corvallis, OR 97331.* Accepted for publication October 23, 1978.

Abstract □ The assay of suppositories containing pentobarbital and/or pyrilamine in a water-soluble polyethylene glycol base by high-pressure liquid chromatography is described. No extraction is required. The suppository is dissolved in the mobile phase. This solution is diluted with an internal standard stock solution containing phenobarbital. Chromatographic conditions include a C_{18} bonded microporous silica column and a mobile phase of 65% 4×10^{-3} *M* *n*-butyl sodium sulfonate in 1% acetic acid and 35% acetonitrile. The procedure using commercial products gave results comparable to those obtained by GLC.

Keyphrases □ Pentobarbital–pyrilamine suppositories—analysis, paired-ion reversed-phase high-pressure liquid chromatography, compared to GLC □ Suppositories, pentobarbital–pyrilamine—analysis, paired-ion reversed-phase high-pressure liquid chromatography, compared to GLC □ High-pressure liquid chromatography—analysis, pentobarbital–pyrilamine suppositories, compared to GLC

A pharmacokinetic study involving suppositories containing pentobarbital and/or pyrilamine maleate required in-house manufacturing. This need led to the development of an assay for accurately determining the drug content and uniformity in each lot of suppositories. The rapid high-pressure liquid chromatographic (HPLC) procedure was verified by GLC using commercial products.

Several GLC assays for barbiturates (1–3) and antihistamines (4–7) have been published. In each, appropriate extraction procedures must be carried out to separate the acidic barbiturate from the basic antihistamine. Because the suppositories were made using a water-soluble polyethylene glycol base, reversed-phase HPLC seemed to be the logical approach.

tures above the T_g. Thermograms of these systems showed an exotherm followed by an endotherm, indicating crystallization followed by melting.

Citric acid and phenobarbital seem to form glass solutions rather than dispersions as in the case of citric acid and benzoic acid. Visual examination of the melts of citric acid and phenobarbital mixtures in a capillary tube, under a hot-stage microscope[11], and during bulk preparation showed them to be a single homogeneous phase.

The *in situ* procedure is useful for screening potential glass-forming materials and glass-forming drug–carrier combinations. Physical mixture and solidified melt thermograms and the T_g data indicate whether a drug–carrier mixture will form a glass solution or suspension and what optimum drug–carrier combination can be obtained. In systems that exhibit mechanical and/or thermal instability or that have a T_g below or only slightly above room temperature, the material would not be rigid enough to withstand normal handling operations and could be eliminated from further investigation.

Of particular interest would be the preparation of glass systems containing large quantities of drugs. For example, it might be possible to stabilize the glassy state of a glass-forming drug by mixing it with a small amount of a compatible inert glassy carrier. This procedure would permit the use of less carrier, thereby reducing bulk volume, and aid in the formulation of glass dispersion systems into solid dosage forms.

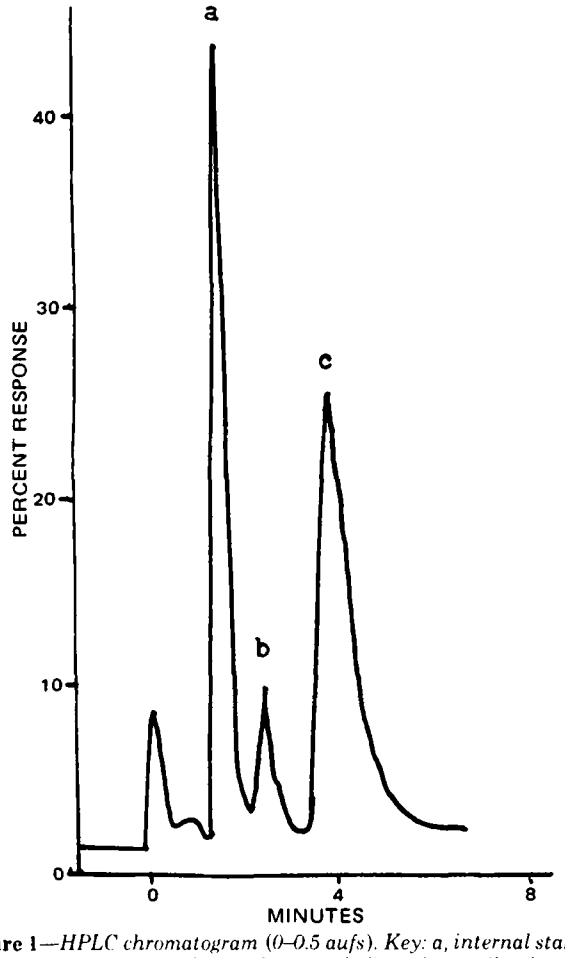

Figure 1—*HPLC chromatogram (0–0.5 aufs). Key: a, internal standard (phenobarbital); b, pentobarbital (3.5 mg/ml); and c, pyrilamine (0.972 mg/ml).*

chlorpheniramine maleate[3] were used. Reagent grade solvents were used as received. *n*-Butyl sodium sulfonate[4] was used as the anion that paired with pyrilamine. Commercial suppositories containing pentobarbital and pyrilamine maleate were purchased from local pharmacies.

HPLC Conditions—The mobile phase consisted of two parts. Solution A consisted of 1% (v/v) acetic acid and 4×10^{-3} *M* *n*-butyl sodium sulfonate (640 mg/liter). Solution B was acetonitrile. Each solution was degassed by stirring under a vacuum. They were then mixed in the ratio of 65A:35B by a solvent-flow programmer[5].

A liquid chromatograph was equipped with two constant-flow pumps[6], an on-stream injector[7], a variable-wavelength spectrophotometer[8], a 254-nm dual-pen recorder[9], and a 25-cm column packed with 10-μm porous silica chemically bonded with octadecylsilane[10]. The flow rate was 2.0 ml/min. Phenobarbital was the internal standard. An injection volume of 10 μl was used for all assays.

Each product was analyzed three times, and each analysis was done in triplicate. The spectrophotometer was set at 254 nm.

GLC Conditions—A gas chromatograph was equipped with a flame-ionization detector[11] and a 180-cm, 2-mm i.d., 6-mm o.d. U-shaped column packed with 3% phenylmethyl silicone on a silane-treated 100–120-mesh support[12]. The oven temperatures were 175 and 220° for pentobarbital and pyrilamine, respectively. For both drugs, the settings were: flash heater, 280°; detector, 310°; nitrogen carrier gas, 35 ml/min; hydrogen, 60 ml/min; and air, 400 ml/min.

[11] Hewlett-Packard model 402B.
[12] Commercially coated OV-17 on Gas Chrom Q, Applied Science Laboratories.

A 5-μl injection volume was used for all assays. All injections were made in triplicate. Each product was analyzed three times.

HPLC Stock Solutions—*Phenobarbital Internal Standard Solution*—Phenobarbital (2.200 g) was dissolved in 500 ml of warmed mobile phase. The solute remained in solution at room temperature.

Pyrilamine Stock Solution—Pyrilamine maleate, 205 mg, was dissolved in 100 ml of the mobile phase.

Pentobarbital Stock Solution—Pentobarbital sodium was dissolved in distilled water, acidified with 10% (v/v) HCl, extracted two or three times with chloroform, evaporated to dryness, and recrystallized from hot water. Then 0.700 g was dissolved in 100 ml of mobile phase.

GLC Stock Solution—Propylparaben, 400 mg, and chlorpheniramine maleate, 160 mg, were dissolved in 40 ml of ethanol and brought to 100 ml with distilled water. This stock solution was diluted 1:10 with distilled water.

GLC Standard Solutions—A separate standard solution was prepared for each suppository strength by dissolving the appropriate amount of each drug in ~10 ml of ethanol and bringing to 50 ml with distilled water. Each standard solution contained both pentobarbital and pyrilamine maleate in amounts equivalent to labeled amounts.

HPLC Procedure—*Standard Curve*—The stock solutions for each drug were diluted in the following manner. Solution 1 was prepared by diluting each stock solution 1:1 with the internal standard solution to yield a 1:2 dilution. For Solution 2, each stock solution was diluted 1:1 with mobile phase and then this new solution was diluted 1:1 with the internal standard to yield a 1:4 dilution. Solution 3 was made by diluting each stock solution 1:4 with mobile phase and then diluting this solution 1:1 with the internal standard, yielding a 1:8 dilution.

Each of the three standard solutions was prepared in triplicate, and 10 μl of each solution was injected on the column.

Suppositories—Commercially available suppositories containing 50 mg of pyrilamine maleate and 100 mg of pentobarbital were dissolved by shaking a suppository and about 30 ml of mobile phase in a 50-ml volumetric flask for 30 min. The suppositories containing lesser amounts of pentobarbital were dissolved by shaking a suppository and about 15 ml of mobile phase in a 25-ml volumetric flask for 30 min. Both solutions were brought to volume with additional mobile phase. Each resulting

Table I—GLC and HPLC Analyses of Commercial Samples

Suppository	Label, mg	Found by GLC[a], mg	Found by HPLC[a], mg	CV[b], %
Pentobarbital	30	29.21 (28.28–30.28)	28.96 (27.66–30.75)	3.04
Pyrilamine	25	24.05 (23.01–25.04)	24.10 (23.12–24.96)	2.25
Pentobarbital	45	43.79 (42.56–43.35)	44.21 (42.99–45.24)	1.81
Pyrilamine	50	48.32 (47.44–49.44)	48.38 (47.24–49.69)	1.65
Pentobarbital	100	99.47 (97.80–101.26)	96.22 (94.43–98.35)	1.64
Pyrilamine	50	47.20 (46.09–48.06)	47.48 (46.41–48.70)	1.73

[a] Average of nine injections (range). [b] Percent coefficient of variation = (*SD*/mean) × 100.

suppository stock solution was diluted 1:1 with internal standard stock solution and injected.

GLC Procedure—A suppository was placed in a 50-ml volumetric flask and dissolved in distilled water by shaking. The assay preparation for pentobarbital consisted of 2.0 ml of the suppository solution and 2.0 ml of the internal standard solution, both of which were placed in a 10-ml screw-capped vial. The pentobarbital and its propylparaben internal standard were extracted by adding 2 drops of concentrated hydrochloric acid and 2 ml of ether and shaking for 5 min. After the layers separated, 5 μl of the ether layer was injected.

The assay preparation for pyrilamine was prepared by placing a fresh 2.0-ml aliquot of the solution containing the suppository and 2.0 ml of the internal standard solution into a 10-ml screw-capped vial. A drop of phenolphthalein test solution was added, and the solution was made basic by the dropwise addition of 10 *N* NaOH. Ether, 2 ml, was added, and the mixture was shaken for 5 min. After the layers separated, 5 μl of the ether layer was injected.

These extraction procedures were repeated using 2.0-ml quantities of the stock solution corresponding to the labeled content of the suppository to be analyzed.

HPLC Calculations—A standard curve was constructed for each drug.

GLC Calculations—The following formula was used:

$$\text{mg of drug/suppository} = (0.05C)\left(\frac{b}{a}\right)\left(\frac{A}{B}\right) \qquad \text{(Eq. 1)}$$

where C = concentration (micrograms per milliliter) of drug in the standard preparation, A = peak height of the internal standard in the standard preparation, B = peak height of the drug in the standard preparation, a = peak height of the internal standard in the assay preparation, and b = peak height of the drug in the assay preparation.

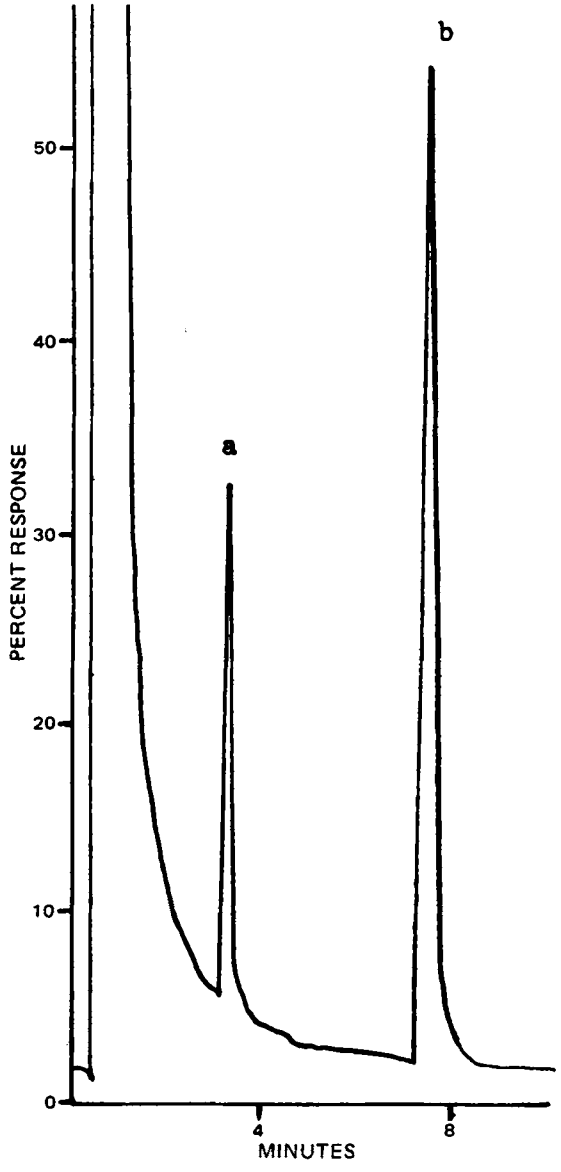

Figure 3—*GLC chromatogram (2.5 × 10⁻¹⁰ amps full scale). Key: a, internal standard (chlorpheniramine maleate); and b, pyrilamine maleate.*

RESULTS AND DISCUSSION

The objective of this study was to develop a rapid procedure for the quantitative analysis of suppositories containing pentobarbital and/or pyrilamine maleate. The described HPLC procedure eliminates the extraction steps required for GLC. The water-soluble suppository base and dyes are eluted from the reversed-phase column with the solvent front and, therefore, do not interfere with the assay. In the concentration range studied, the standard curves are straight lines: r = 1.000 for both drugs; coefficient of variation = 2.76% for pyrilamine maleate and 3.64% for pentobarbital.

Figure 1 shows a typical HPLC tracing, and Figs. 2 and 3 show GLC tracings. Table I contains a comparison of GLC and HPLC results. The only significant difference is ease of sample handling. With this particular type of suppository base, HPLC is superior since no extractions are required.

The use of the paired-ion technique produced the best separation. Initially, an acid-buffered mobile phase was tried. Good retention times were obtained for phenobarbital, but the protonated pyrilamine was eluted with the solvent front. The results were worse with a basic mobile phase. The charged barbiturate was eluted with the solvent front and pyrilamine, while having an acceptable retention time, showed considerable tailing. This procedure does not appear to affect the column since this same column was used for several months after completion of this project.

It is obvious from the chromatogram shown in Fig. 1 that pentobarbital has low sensitivity relative to the antihistamine. At the same time, pyrilamine has a very good UV-sensitive chromophore. Although a variable-wavelength detector was utilized, the 254-nm wavelength common to most fixed-wavelength detectors was selected to see if the procedure could be adapted to most instruments. Nevertheless, a wavelength closer to the end absorption of unionized pentobarbital (230 nm and lower) or perhaps a refractive index detector would produce a more esthetically satisfying chromatogram (8). An alternative procedure for obtaining a more sensitive response from pentobarbital would be to utilize the recently described postionization technique whereby pH 10 borate buffer is added to the column effluent before it enters the detector (9).

Percutaneous Nitroglycerin Absorption in Rats

S. T. HORHOTA * and HO-LEUNG FUNG ×

Received June 16, 1978, from the *Department of Pharmaceutics, State University of New York at Buffalo, Amherst, NY 14260.* Accepted for publication October 24, 1978. *Present address: Pharmacy Research and Development Department, Ayerst Laboratories, Rouses Point, NY 12979.

Abstract □ Percutaneous nitroglycerin absorption was studied in shaved rats by monitoring unchanged plasma drug concentrations for up to 4 hr. Drug absorption from the neat liquid state or from an alcoholic solution was considerably poorer than that from a commercial ointment. This observation was unanticipated since the driving force for percutaneous drug absorption was assumed to be drug thermodynamics. Potential artifacts such as drug volatilization from the skin, reduction of surface area through droplet formation, and vehicle occlusion were investigated, but they did not appear to be responsible for the observed results. Two experimental aqueous nitroglycerin gels were prepared with polyethylene glycol 400. One gel contained just sufficient polyethylene glycol to solubilize the nitroglycerin; the other had excess polyethylene glycol to solubilize nitroglycerin far below saturation. Both gels gave extremely low plasma nitroglycerin levels. The composite data suggested that percutaneous nitroglycerin absorption is highly vehicle dependent and that this dependency cannot be explained by simple consideration of drug thermodynamic activity.

Keyphrases □ Absorption, percutaneous—nitroglycerin, various topical dosage forms, rats □ Nitroglycerin—percutaneous absorption, various topical dosage forms, rats □ Dosage forms, topical—nitroglycerin, percutaneous absorption, rats

Topical nitroglycerin ointments produce sustained and clinically beneficial hemodynamic responses in patients with various cardiovascular ailments. Application of a 2% nitroglycerin preparation on 150–230 cm^2 of skin surface reduced the frequency and severity of exercise-induced angina attacks (1, 2) and decreased heart workload and myocardial oxygen consumption (3).

Systemic availability is the primary goal of topical nitroglycerin application. However, there is little information about the physical and physiological factors influencing its percutaneous absorption. The relatively large clinical nitroglycerin ointment doses and the extensive surface area needed for therapeutic effect suggest that transdermal delivery of nitroglycerin, at present, is inefficient and that attempts to increase percutaneous nitroglycerin absorption may be worthwhile.

The purpose of this investigation was to examine various factors that may affect the rate and extent of topical nitroglycerin absorption. *In vivo* and *in vitro* models were used to gather data to form a rational basis for improving transdermal drug delivery. The relationship between thermodynamic activity and *in vivo* nitroglycerin absorption was examined.

BACKGROUND

The skin is one of the most impermeable tissues of the body. It functions as a barrier against attack by microorganisms, viruses, and many toxic chemicals. At the same time, it limits the loss of physiologically essential components, such as water. The extensive skin barrier properties have caused it to be regarded as a poor route for systemic drug administration. Recently, serious attempts have been made to fabricate devices for controlled, sustained delivery through the dermal route. A tape capable of delivering a constant rate of transdermal scopolamine for up to 3 days was described (4).

Several factors influence percutaneous drug absorption (5, 6) including drug permeability through the stratum corneum, the drug's physical–chemical properties, the vehicle in which the drug is incorporated, the drug's ionization state, the skin's hydration state, the skin's lipid content, and regional variations in skin properties. The quantitative relationship between drug transfer and several of these factors is (7):

$$dQ/dt = KC_vDA/T \qquad \text{(Eq. 1)}$$

where dQ/dt is the steady-state drug transfer rate across a skin barrier, K is the effective skin–vehicle drug partition coefficient, C_v is the drug concentration dissolved in the vehicle, D is the drug diffusivity through the barrier, A is the surface area of application of the vehicle, and T is the effective barrier thickness.

The model assumes that the skin represents a simple diffusional barrier to drug transfer. When the surface area of application, drug diffusivity through the skin, and barrier thickness are constant, the equation addresses the role of thermodynamics in determining percutaneous absorption rates. Specifically, absorption will be enhanced from vehicles with a low affinity for the drug and in which the drug concentration approaches saturated solubility. Therefore, approaches toward optimizing drug delivery should maximize the drug's thermodynamic activity in the vehicle, as represented by the product term KC_v in Eq. 1. The validity of the thermodynamic relationship has been confirmed qualitatively (8, 9), and Eq. 1 has provided valuable guidance in the development of improved vehicles for topical application of new drug entities.

While the thermodynamic approach does include skin characteristics—*viz.*, D and T, in determining absorption rate, these parameters are usually difficult to measure as functions of vehicle changes. Therefore, they are often assumed to be independent of vehicle effects. This assumption is not always valid since topical formulations are known to affect these parameters (5, 6, 10). Vehicle-induced changes in these variables may be of sufficient magnitude to override the contribution of the thermodynamic term, KC_v. In such cases, thermodynamic considerations alone, although predictive for *in vitro* drug release, may not explain absorption differences in animals or humans.

Topical nitroglycerin ointments produce sustained and clinically beneficial hemodynamic responses in patients with various cardiovascular ailments. Application of a 2% nitroglycerin preparation on 150–230 cm^2 of skin surface reduced the frequency and severity of exercise-induced angina attacks (1, 2) and decreased heart workload and myocardial oxygen consumption (3).

Systemic availability is the primary goal of topical nitroglycerin application. However, there is little information about the physical and physiological factors influencing its percutaneous absorption. The relatively large clinical nitroglycerin ointment doses and the extensive surface area needed for therapeutic effect suggest that transdermal delivery of nitroglycerin, at present, is inefficient and that attempts to increase percutaneous nitroglycerin absorption may be worthwhile.

The purpose of this investigation was to examine various factors that may affect the rate and extent of topical nitroglycerin absorption. *In vivo* and *in vitro* models were used to gather data to form a rational basis for improving transdermal drug delivery. The relationship between thermodynamic activity and *in vivo* nitroglycerin absorption was examined.

BACKGROUND

The skin is one of the most impermeable tissues of the body. It functions as a barrier against attack by microorganisms, viruses, and many toxic chemicals. At the same time, it limits the loss of physiologically essential components, such as water. The extensive skin barrier properties have caused it to be regarded as a poor route for systemic drug administration. Recently, serious attempts have been made to fabricate devices for controlled, sustained delivery through the dermal route. A tape capable of delivering a constant rate of transdermal scopolamine for up to 3 days was described (4).

Several factors influence percutaneous drug absorption (5, 6) including drug permeability through the stratum corneum, the drug's physical–chemical properties, the vehicle in which the drug is incorporated, the drug's ionization state, the skin's hydration state, the skin's lipid content, and regional variations in skin properties. The quantitative relationship between drug transfer and several of these factors is (7):

$$dQ/dt = KC_vDA/T \qquad \text{(Eq. 1)}$$

where dQ/dt is the steady-state drug transfer rate across a skin barrier, K is the effective skin–vehicle drug partition coefficient, C_v is the drug concentration dissolved in the vehicle, D is the drug diffusivity through the barrier, A is the surface area of application of the vehicle, and T is the effective barrier thickness.

The model assumes that the skin represents a simple diffusional barrier to drug transfer. When the surface area of application, drug diffusivity through the skin, and barrier thickness are constant, the equation addresses the role of thermodynamics in determining percutaneous absorption rates. Specifically, absorption will be enhanced from vehicles with a low affinity for the drug and in which the drug concentration approaches saturated solubility. Therefore, approaches toward optimizing drug delivery should maximize the drug's thermodynamic activity in the vehicle, as represented by the product term KC_v in Eq. 1. The validity of the thermodynamic relationship has been confirmed qualitatively (8, 9), and Eq. 1 has provided valuable guidance in the development of improved vehicles for topical application of new drug entities.

While the thermodynamic approach does include skin characteristics—*viz.*, D and T, in determining absorption rate, these parameters are usually difficult to measure as functions of vehicle changes. Therefore, they are often assumed to be independent of vehicle effects. This assumption is not always valid since topical formulations are known to affect these parameters (5, 6, 10). Vehicle-induced changes in these variables may be of sufficient magnitude to override the contribution of the thermodynamic term, KC_v. In such cases, thermodynamic considerations alone, although predictive for *in vitro* drug release, may not explain absorption differences in animals or humans.

Nitroglycerin is a liquid at room temperature. Absorption of pure drug applied to the skin would be uncomplicated by vehicle and/or particle dissolution effects. Unless a positive deviation from Raoult's law results when nitroglycerin is formulated in topical vehicles, the neat liquid state should give the maximal thermodynamic activity for drug penetration. This mode of application could serve as a convenient thermodynamic reference point for trials of experimental formulations.

In this study, *in vivo* nitroglycerin absorption from the neat liquid was compared to that from a clinical ointment[1]. The latter contains 2% nitroglycerin formulated in an oleaginous vehicle. Because of the favorable solubility of nitroglycerin in nonpolar solvents, a strict interpretation of Eq. 1 would suggest reduced nitroglycerin absorption from the ointment when compared to the neat state. This hypothesis was tested.

Followup experiments explored other factors, *e.g.*, evaporative loss and occlusion, that may influence nitroglycerin absorption. Aqueous polymer gels reflecting widely divergent thermodynamic activities of nitroglycerin, as estimated from partitioning and solubility data, were also prepared. The *in vitro* release and *in vivo* absorption of nitroglycerin from these formulations were compared to those of the ointment. The importance of thermodynamic considerations in optimizing transdermal nitroglycerin delivery was evaluated.

EXPERIMENTAL

Materials—All reagents were analytical grade unless otherwise noted.

Isolation and Assay of Nitroglycerin Raw Material—Nitroglycerin lactose triturate[2] (10% w/w) was packed as a column and eluted with anhydrous ether[3]. The solvent was evaporated from the eluate under a stream of dry compressed air for 6–8 hr. Nitroglycerin was recovered as a liquid, and its purity was determined by the USP XIX (11) procedure or by GLC (12).

Partitioning of Nitroglycerin between Isooctane and Polyethylene Glycol 400–Water—Solutions containing varying concentrations of polyethylene glycol 400 in distilled water were equilibrated with an equal volume of isooctane[4] containing 2.60 μg of nitroglycerin/ml. The mixtures were rotated end-over-end for 24 hr in a 20 ± 0.5° water bath. Duplicate samples were prepared for each composition. After centrifugation, aliquots of the two phases were diluted with absolute methanol and assayed by the kinetic procedure (13, 14).

In the concentrations used, polyethylene glycol did not affect the calibration curve in this kinetic assay. With 100% polyethylene glycol 400, nitroglycerin was overwhelmingly distributed into the polyethylene glycol phase. Therefore, assay of the organic nitrate in the isooctane phase was conducted by GLC.

***In Vitro* Nitroglycerin Release from Topical Preparations**—Aqueous polymer gels containing 2% nitroglycerin were prepared by dissolving raw nitroglycerin (96% purity) into polyethylene glycol–water solutions with stirring. Microcrystalline cellulose[5] (~29% w/w) was added to gel these solutions. All blends were assayed and used within 24 hr of preparation.

A modification of the *in vitro* release model described by Poulsen *et al.* (8) was used. The formulation was introduced into a tared 60-mm diameter × 15-mm petri dish cover[6], leveled to the top edge with a microscope slide, and weighed accurately. The cover was lowered into a 250-ml beaker, which was then placed in a 20 ± 0.5° water bath. A three-blade propeller-stirrer, 27 mm in radius, was positioned 1.5 cm above the test material surface. A variable-speed motor drive[7] was set for 10 rpm. Isopropyl myristate[8] (100.0 ml) previously equilibrated at 20° was added with care over the formulation. Samples of isopropyl myristate (1.0 ml) were taken at specified intervals, and the volume was replaced by fresh solvent equilibrated at the same temperature.

The nitroglycerin concentration in the isopropyl myristate receptor phase was determined by GLC after appropriate dilution with hexane. The total amount of drug released into the medium at each point was corrected for sampling. The area under the percent nitroglycerin released *versus* time curve (0–60 min) was calculated by the trapezoidal rule.

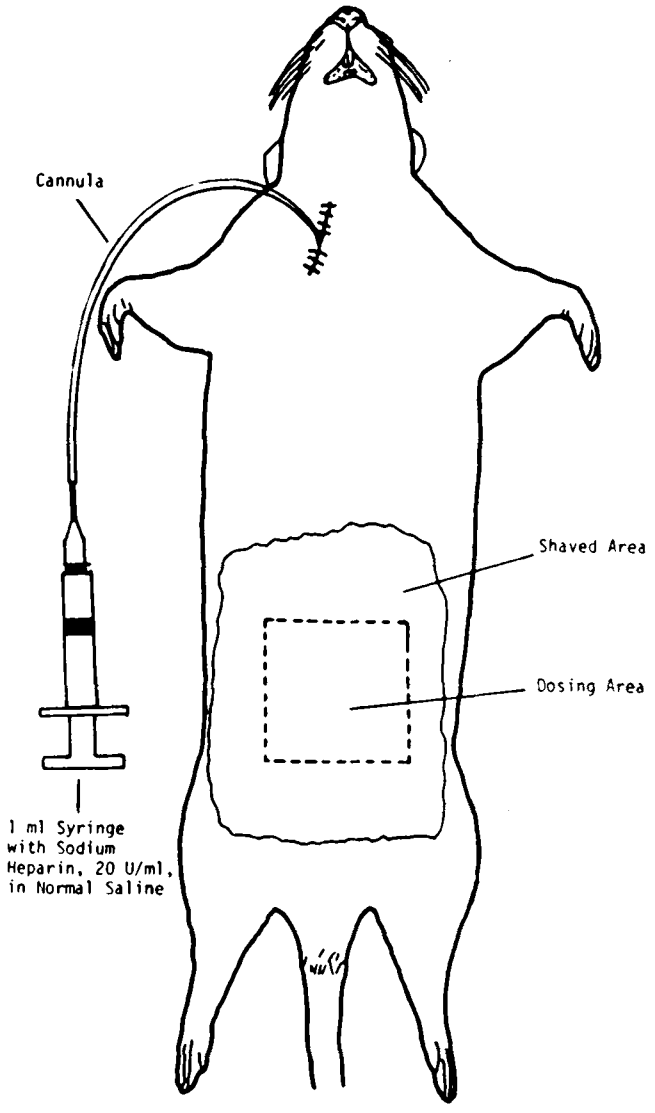

Figure 1—*Schematic representation of animal preparation and abdominal dosing area used in topical absorption studies.*

***In Vivo* Absorption Studies**—An abdominal dosing site (Fig. 1) on male Sprague–Dawley rats[9], 280–390 g, was prepared as described previously (15). The following dosage forms were investigated at 20 mg/kg: A, 2% nitroglycerin ointment[1]; B, 6.9% nitroglycerin solution in alcohol; C, neat nitroglycerin, isolated by evaporating a known volume of the alcoholic solution on a microscope slide and uniformly transferring the material to the dosing area; D, occlusion of the dosing site with polytef tape[10] 1 hr after application of the alcoholic solution; and E, 2% nitroglycerin experimental formulations, described previously. The area under the plasma concentration–time curve was evaluated from 0 to 4 hr after dosing (AUC_{0-4}) using the trapezoidal rule.

Nitroglycerin Recovery from Tissue Sections—Rat abdominal tissue sections from Treatments B and C were excised at the end of the experiments and minced. These tissue preparations were shaken with 25.0 ml of isomeric hexanes for 1 hr and allowed to sit overnight at room temperature. Appropriate dilutions with hexanes produced concentrations of 50–150 ng of nitroglycerin/ml. The internal standard was added to a final concentration of 250 ng/ml, and nitroglycerin was assayed by GLC. The extraction efficiency for this procedure was determined by excising and treating skin sections immediately after nitroglycerin application. In two experiments, a mean recovery of 75.8% was obtained.

RESULTS AND DISCUSSION

Results from trials involving abdominal dosing of 18 animals, allocated

randomly to three treatment groups, are shown in Fig. 2. The clinically used nitroglycerin ointment yielded average 30–40-ng/ml plasma levels within 1 hr, while neat and alcohol applications gave mean concentrations below 10 ng/ml. The wide standard error ranges (Fig. 2) indicate that there was a large degree of individual variability in percutaneous nitroglycerin absorption. Comparison of AUC_{0-4} is presented in Table I. Despite the observed variability, analyses of variance [Kruskall–Wallis rank method (16)] with multiple comparisons indicated the ointment treatment to be significantly different from both the neat ($p < 0.02$) and the alcohol ($p < 0.01$) administrations. The latter cases were statistically indistinguishable, suggesting that they represent equivalent topical dosing modes.

Both neat and alcohol solution treatments were studied because neat nitroglycerin represented a small volume of drug, which may have been subjected to significant transfer errors, while the alcohol solution represented a more manageable volume for uniform dosing, but the effect of the solvent on the skin could not be predetermined. The results show that the application appeared adequate in both cases and that the alcohol solvent did not significantly alter skin characteristics *vis-à-vis* nitroglycerin absorption.

The finding of reduced absorption from neat nitroglycerin was unanticipated from thermodynamic considerations of Eq. 1. Possible explanations include: (*a*) evaporative loss of neat drug from the absorption site, (*b*) alteration in skin permeability by an occlusion effect caused by the ointment, (*c*) artifactual reductions in total surface contact in the case of neat nitroglycerin, (*d*) positive deviations from Raoult's law (*i.e.*, increases in thermodynamic activity) due to a specific interaction between the drug and some vehicle component, and (*e*) nonspecific effects produced by certain components of the ointment vehicle that increase nitroglycerin penetration.

Experiments were carried out to assess each of these possible factors.

Nitroglycerin Loss from Absorption Site—The volatility of nitroglycerin sublingual tablets has been documented extensively (17–19). While the thermodynamic activity of nitroglycerin and, hence, its potential for absorption were expected to be maximized in the neat state,

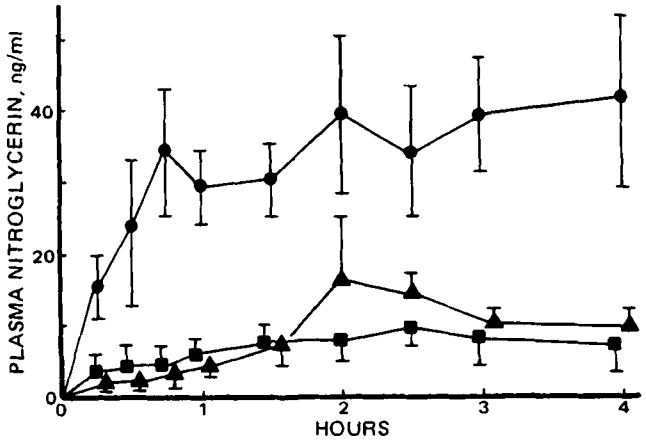

Figure 2—In vivo *absorption of nitroglycerin after topical application (20 mg/kg) to the abdominal skin surface of rats. the energy balance would simultaneously favor nitroglycerin escape to the atmosphere. This phenomenon might lead to reduced absorption because of volatilization of drug from the dosing site.

To investigate this possibility, tissue sections representing the entire dosing area were excised after the 4-hr absorption experiments and the amount of nitroglycerin remaining was determined. An average of nearly 60% of the applied drug could be recovered from the surface skin sections (Table II). The unrecovered 40% of the dose might have been in the systemic circulation or still moving through the epidermal layers. Nevertheless, the evidence suggests that there was no extensive evaporative loss of drug at the absorption site after application of neat nitroglycerin or the alcoholic solution. Significant quantities of drug were still available for absorption at the dosing site, even at the end of the experimental period. This conclusion is supported by results from the occlusion experiment.

Effect of Skin Occlusion—Skin hydration is often considered to be the most crucial parameter affecting percutaneous absorption of chemical compounds (5). Increasing the water content of the stratum corneum has been shown to alter the rate and extent of transdermal drug passage (20). Oleaginous vehicles and occlusive dressings offer certain advantages by inhibiting transepidermal water loss. Thus, the petrolatum–lanolin ointment base possibly increased percutaneous nitroglycerin absorption primarily through an occlusive effect.

To test this hypothesis, an alcoholic solution of nitroglycerin was applied to the shaved abdominal surfaces of three rats. The dosing site remained exposed for the 1st hr during which blood samples were collected to establish control values for plasma nitroglycerin concentrations. At 1 hr, the area was covered with polytef tape and sampling was continued. Enhanced nitroglycerin absorption after this time point would suggest a positive influence of an occlusive effect. The results showed, however, that the plasma concentrations were unaffected by occlusion (Fig. 3). Thus, it is unlikely that occlusion was responsible for the greater absorption of nitroglycerin from the ointment preparation.

Polytef tape presents a barrier to water mass transfer (21), and preliminary studies demonstrated a resistance to nitroglycerin transfer. The polytef tape not only prevented water loss from the skin but should have retarded significant volatilization of nitroglycerin from the dosing site.

Table II—Percent Recovery [a] of Nitroglycerin from Rat Tissue Sections 4 hr after Abdominal Application of a 20-mg/kg Dose

Application[b]	Recovery, %
Neat	50.8
Neat	64.1
Neat	55.2
Neat	49.7
Alcohol solution	60.9
Alcohol solution	74.1
Mean	59.1

[a] Corrected for extraction. [b] Each listing represents an individual tissue section from separate animals.

Because there was no increase in plasma nitroglycerin levels after enclosure of the dosing site with polytef tape, evaporative drug loss after application of neat nitroglycerin and its alcoholic solution could not have been extensive.

Surface Area Considerations—As clearly stated in Eq. 1, the conditions required for testing the thermodynamic concept must include a constant surface area for drug application. The total abdominal dosing area was controlled at 9 cm^2 for all experiments. This region could, however, represent only an apparent dosing area if the interfacial tension between nitroglycerin and the skin was of sufficient magnitude to cause poor "wetting," reducing the actual contact area through droplet formation.

Gross examination of the skin after dosing showed nothing to suggest that uniform film formation had not taken place. Microscopic examination and photographic documentation proved difficult because of the low level of contrast between the deposited drug, a clear to slightly yellowish liquid, and the skin background. Attempts to visualize the drug on the skin using oil-soluble dyes or fluorescent markers were also inconclusive. Thus, within the visualization capability of the experiment, surface area artifacts arising from droplet formation from neat nitroglycerin appeared to be absent. This conclusion will be substantiated further by comparison of *in vivo* absorption of nitroglycerin from ointment and experimental gels.

Comparison of *In Vitro* Nitroglycerin Release between Experimental Gels and Ointment—Aqueous nitroglycerin solubility at 20° was determined to be 1.77 mg/ml, in close agreement with literature reports (22). Nitroglycerin partitioning between isooctane and polyethylene glycol 400–water combinations is shown in Fig. 4. Because of extensive nitroglycerin solubility in alcohols, the partition coefficients (oil-water) were reduced drastically in the presence of significant concentrations of polyethylene glycol 400. The observed partition coefficients and measured water solubility value were used to estimate nitroglycerin solubility in the different water-polyethylene glycol 400 mixtures (Fig. 4). This method of solubility estimation was used instead of the classical excess compound technique to avoid handling large quantities of pure nitroglycerin.

Gels were prepared using polyethylene glycol 400–water mixtures and microcrystalline cellulose. Simple mixing of components yielded pharmaceutically suitable preparations of uniform texture and acceptable viscosity. Preliminary experiments involving gels prepared with different concentrations of microcrystalline cellulose showed that this material did not inhibit nitroglycerin diffusion out of the gels. This finding suggests that drug binding or adsorption to microcrystalline cellulose is insignificant in the presence of polyethylene glycol 400.

From the calculated solubility profile, it was determined that a 2% nitroglycerin gel could be prepared near saturated solubility using 70% polyethylene glycol 400 in water (Gel A). This formulation presented nitroglycerin at a near maximal thermodynamic state when compared to similar formulations in which 2% nitroglycerin did not represent saturated solubility. In 100% polyethylene glycol 400, the estimated nitroglycerin solubility was approximately 150-fold greater than in 70% polyethylene glycol 400. Thus, a 2% nitroglycerin gel prepared with 100% polyethylene glycol 400 (with microcrystalline cellulose added for viscosity) (Gel B) presented nitroglycerin at a 150-fold reduction in thermodynamic activity compared to that produced by Gel A.

Estimation of nitroglycerin thermodynamic activity in the ointment could not be made because of solubility problems. Information on the composition of this ointment was not available, and the saturated solubility of nitroglycerin in the ointment could not be determined easily. The relative thermodynamic activity of nitroglycerin in the gels and the ointment could be determined by the relative *in vitro* release rates.

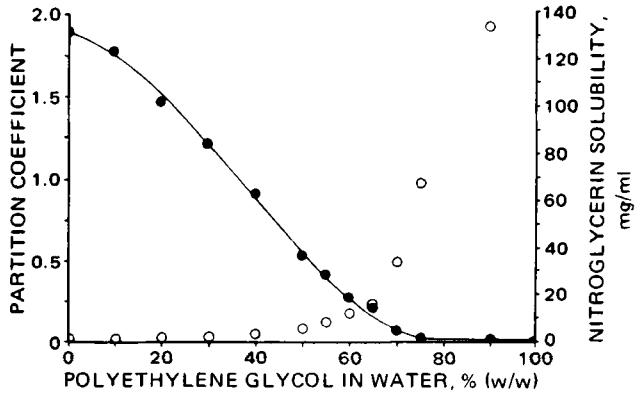

Figure 4—*Partitioning and estimated solubility of nitroglycerin at 20°. Key: ●, observed partition coefficient (isooctane–aqueous–polymer) for nitroglycerin; and ○, calculated solubility of nitroglycerin in water–polymer mixtures.*

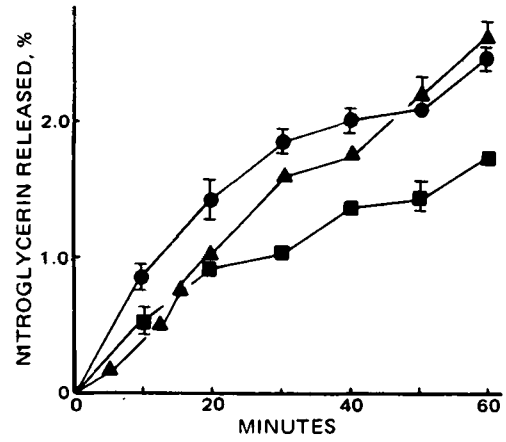

Figure 5—*In vitro release of nitroglycerin from 2% topical preparations into isopropyl myristate. Key: ●, Gel A; ■, Gel B; and ▲, commercial ointment. Each point represents the mean of two trials. Bars indicate the range of observed values. Where bars are not shown, the observed range was within the area covered by the symbols used.*

Comparative *in vitro* release rates from Gels A and B and the ointment into isopropyl myristate were evaluated. A hydrocarbon solvent such as isooctane could not be used because it caused rapid dissolution of the oleaginous vehicle. On the other hand, higher molecular weight alcohols such as octanol brought about disintegration of the polyethylene glycol-based gels. Isopropyl myristate was chosen as a compromise because both polyethylene glycol and water were immiscible with it while ointment dissolution, although present, was considerably less rapid. To avoid further artifactual results from ointment dissolution, a very slow stirring rate for the receptor phase was used. Sampling was conducted for 1 hr to compare the initial release characteristics from the three preparations (Fig. 5).

The areas under the percent release–time curves (in percent release-min) were 94.2 and 85.3 for Gel A, 55.6 and 55.1 for Gel B, and 80.2 and 75.9 for the ointment. The data suggested that Gel A released nitroglycerin about two times faster than Gel B. This result is in qualitative agreement with a prediction based on solubility arguments, but Gel A did not release nitroglycerin 150 times faster than Gel B, as would be expected if the drug solubility in the vehicle is inversely related to release. Isopropyl myristate, however, is a much better solvent for nitroglycerin than is isooctane. Thus, differences in partitioning with the latter solvent may be greatly reduced because of the solvent "leveling" effect of isopropyl myristate. At any rate, nitroglycerin release from the ointment was not statistically different from that produced by Gel A. This finding suggests that nitroglycerin is not present in the ointment at an abnormally high thermodynamic activity. Thus, a positive deviation from Raoult's law cannot be invoked for the increased nitroglycerin absorption from the ointment over the neat liquid. The absence of an enhanced "escaping tendency" of nitroglycerin in the ointment was further indicated by the following observation: when several ointment samples were placed unmixed and allowed to equilibrate with water at 20°, the resultant aqueous concentrations measured at 1 and 2 weeks did not exceed the aqueous solubility of nitroglycerin.

The lack of quantitative correlation between the *in vitro* release rate and solubility in Gels A and B might have been due to the slow stirring rate used. Release rates from topical steroid preparations using a similar *in vitro* test system were reported to be sensitive to stirring rates of less than 30 rpm (8). This degree of agitation could not be accommodated in the present study without erosion of the ointment base by the solvent. An alternative approach using a dialysis membrane[11] to separate the vehicle and isopropyl myristate was unsuccessful because polyethylene glycol 400 rapidly diffused through the artificial membrane.

***In Vivo* Nitroglycerin Absorption from Polymer Gels**—The *in vivo* study of percutaneous absorption of Gels A and B produced unan-

[11] Spectrapor membrane tubing, mol. wt. cutoff 6000–8000, Spectrum Medical Industries, Los Angeles, CA 90054.

ticipated results. In contrast to the ointment, where a plateau drug level of 30–40 ng/ml was achieved, both gels (three animals in each trial) gave negligible (<1 ng/ml) plasma nitroglycerin concentrations over 4 hr. The *in vivo* absorption data did not correlate with the *in vitro* release results.

The composite data suggest a specific skin–vehicle interaction with the ointment, which has the net effect of increasing nitroglycerin permeability or decreasing the effective skin barrier thickness. Alternatively, poor nitroglycerin absorption from the neat material, alcoholic solution, and polyethylene glycol gels may have arisen from unfavorable interactions with the skin. A recent study showed that benzocaine diffusion through human stratum corneum decreased in the presence of relatively high amounts of low molecular weight polyethylene glycol (23). These researchers also showed that polyethylene glycol significantly affected the surface structure of the stratum corneum. These effects may be tested by comparing the absorption of a marker chemical following application of neat nitroglycerin or polyethylene glycol gels on the skin to absorption through untreated skin.

The ointment may increase transdermal nitroglycerin delivery by inhibiting skin metabolism. Enzymatic process in the skin and considerations of the skin as an active metabolizing barrier were discussed recently (24, 25). Previous studies also showed a total body nitroglycerin clearance from the rat in excess of reasonable hepatic clearance (26), suggesting extensive tissue degradation of this drug. The skin may represent a first-pass metabolic site for topically applied nitroglycerin. Interference with this process can affect the amount of intact nitroglycerin reaching the systemic circulation. This aspect of nitroglycerin transdermal delivery will be investigated.

Kinetics of Dopamine Oxidation by Dialkylaminoalkylphenothiazine Cation Radicals

MARIA ROSA GASCO ˣ and MARIA EUGENIA CARLOTTI

Received March 28, 1978, from the *Istituto di Chimica Farmaceutica e Tossicologica dell'Universita' di Torino, Corso Raffaello 31, Torino, Italy.* Accepted for publication October 26, 1978.

Abstract □ The kinetics of dopamine oxidation by dialkylaminoalkylphenothiazine cation radicals (with two- or three-carbon side chains) were investigated. The two-carbon side-chain derivatives have reaction rates higher than the three-carbon ones. For chlorpromazine and promazine, extrapolation of pH 1–6 data shows that reaction rates become very fast at physiological pH.

Keyphrases □ Dopamine—oxidation by phenothiazine cation radicals, kinetics, structure–activity relationships □ Phenothiazine derivatives—oxidation of dopamine, kinetics, structure–activity relationships □ Structure–activity relationships—phenothiazine cation radicals, oxidation of dopamine, kinetics

Several reports (1–4) pointed out that transformation of chlorpromazine [2-chloro-*N*,*N*-dimethyl-10H-phenothiazine-10-propamine] (I) is necessary for some *in vitro* enzyme inhibitions. A I intermediate, the cation radical [obtained also *in vivo* (5)], was shown to inhibit (Na^+, K^+) adenosine triphosphatase (6). The cation radical also inhibited microsomal brain enzyme (7) and uridine diphosphate glucose dehydrogenase (8).

This aspect of nitroglycerin transdermal delivery will be investigated.

Kinetics of Dopamine Oxidation by Dialkylaminoalkylphenothiazine Cation Radicals

MARIA ROSA GASCO ˣ and MARIA EUGENIA CARLOTTI

Received March 28, 1978, from the *Istituto di Chimica Farmaceutica e Tossicologica dell'Universita' di Torino, Corso Raffaello 31, Torino, Italy.* Accepted for publication October 26, 1978.

Abstract □ The kinetics of dopamine oxidation by dialkylaminoalkylphenothiazine cation radicals (with two- or three-carbon side chains) were investigated. The two-carbon side-chain derivatives have reaction rates higher than the three-carbon ones. For chlorpromazine and promazine, extrapolation of pH 1–6 data shows that reaction rates become very fast at physiological pH.

Keyphrases □ Dopamine—oxidation by phenothiazine cation radicals, kinetics, structure–activity relationships □ Phenothiazine derivatives—oxidation of dopamine, kinetics, structure–activity relationships □ Structure–activity relationships—phenothiazine cation radicals, oxidation of dopamine, kinetics

Several reports (1–4) pointed out that transformation of chlorpromazine [2-chloro-*N*,*N*-dimethyl-10H-phenothiazine-10-propamine] (I) is necessary for some *in vitro* enzyme inhibitions. A I intermediate, the cation radical [obtained also *in vivo* (5)], was shown to inhibit (Na^+, K^+) adenosine triphosphatase (6). The cation radical also inhibited microsomal brain enzyme (7) and uridine diphosphate glucose dehydrogenase (8).

Barras and Coult (9) observed that phenothiazine tranquillizers accelerated enzymatic biogenic amine oxidation while phenothiazines lacking clinical tranquillizing activity had no effect. Løvstad (10, 11), investigating ceruloplasmine-catalyzed phenothiazine oxidation, found that a three-carbon side chain was essential for a rapid enzymatic oxidation to the cation radical and for further oxidation by the same cation radicals of biogenic amines.

A previous paper reported the oxidation kinetics of tricyclic amines to the corresponding radicals with Ce(IV) (12); cation radical formation rates decreased while the reduction potentials increased, passing from the drugs with antidepressant action [imipramine (5H-dibenz[*b,f*]azepine-5-propanamine, 10,11-dihydro-*N,N*-dimethyl) and 10(9H)-acridinepropanamine, *N,N*,9,9-tetramethyl (dimetacrine)] to dialkylaminoalkylphenothiazines with a two-carbon side chain and then to dialkylaminoalkylphenothiazines with a three-carbon side chain.

In the present study, the reduction kinetics of phenothiazine cation radicals with different pharmacodynamic activities (Table I) by dopamine [1,2-benzenediol-4-(2-aminoethyl)] (VII) are investigated.

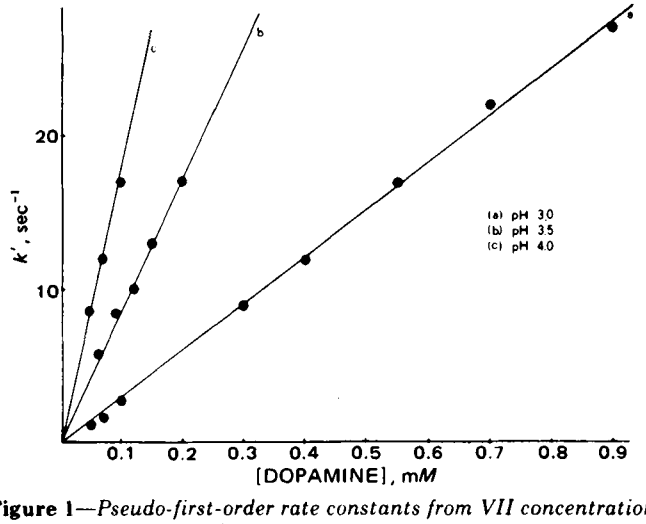

Figure 1—*Pseudo-first-order rate constants from VII concentration at different pH values (for II).*

EXPERIMENTAL

Reagents—The phenothiazine compounds (I–VI, Table I) were employed as chlorhydrates. Compound VII[1] and potassium exachloriridate were reagent grade.

Procedure—Cation radical solutions were obtained immediately before use either by adding potassium exachloriridate in slight deficiency to a solution of phenothiazine derivatives or by platinum electrode electrooxidation. Unoxidized phenothiazine had no effect on kinetics. The kinetic runs were carried out with a stopped-flow spectrophotometer[2] at the wavelength of maximum cation radical absorption (Table I). The cell path length was 2.00 cm.

Measurements were performed at different acidities: the pH ≤ 3 was obtained with perchloric acid, while the pH 3–6 range was obtained with potassium phthalate buffers. The pH measured by the potentiometer[3] was constant within 0.05 unit.

Pseudo-first-order conditions were chosen when possible; second-order conditions were adopted for the faster reactions. The cation radical concentration ranged between 5.0×10^{-6} and $5.0 \times 10^{-5}\ M$; the VII concentration ranged between 5.0×10^{-6} and $5.0 \times 10^{-4}\ M$.

The rate constants were evaluated by the least-squares method. Cation radical instability allowed a wide pH range investigation of I and II only; for other derivatives, only high acidity 0.1 *M* $HClO_4$ runs were performed. Since many radicals are unstable at high pH, the cation radical solutions were obtained at pH 3–6 with $1.0 \times 10^{-3}\ M$ $HClO_4$ and mixed with the solution of VII buffered at the desired pH. (The final pH variation was within 0.1 unit.) The cation radical decomposition rates, reported previously (13), were negligible compared to the ones in this study.

The initial cation radical concentration was estimated, when second-order conditions were used, by initial transmittance. Kinetic runs were carried out at 25° and, for I and II, at 35°.

RESULTS AND DISCUSSION

Stoichiometry—By adding successive VII aliquots to a cation radical solution in 0.1 *M* $HClO_4$, the decrease in absorbance at the proper wavelength was measured and the stoichiometric ratio was determined. The overall reaction can be depicted as:

$$2P^{+\cdot} + H_3D^+ \rightarrow 2P + DQ^+ + 2H^+$$

Scheme I

where P represents the phenothiazine derivative, $P^{+\cdot}$ is the corresponding cation radical, H_3D^+ is the fully protonated VII, and DQ^+ is the protonated dopamine quinone VIII.

Since the H_3D^+/DQ^+ reduction potential is ~0.78–0.79 v (14, 15), the reaction is shifted toward the right side with phenothiazine derivatives that exhibit higher reduction potentials or a higher pH. In the kinetic runs with less oxidizing cation radicals and excess VII, T_∞ transmittance at equilibrium came very close to 1.00. At pH 5, VIII can produce the corresponding aminochrome (16); however, the aminochrome formation rate is negligible compared to the reaction rates in this study (17).

Reaction Kinetics—In pseudo-first-order conditions, plots of $\ln(A_t - A_\infty)$ (where A_∞ and A_t represent the absorbance at equilibrium and at time t, respectively) as a function of time were linear for at least 80% of the reaction process (Table II).

The observed rate constants also exhibited a linear dependence on the VII concentration (Fig. 1). With second-order conditions, the related second-order plots were also satisfactorily linear. When the reaction rate

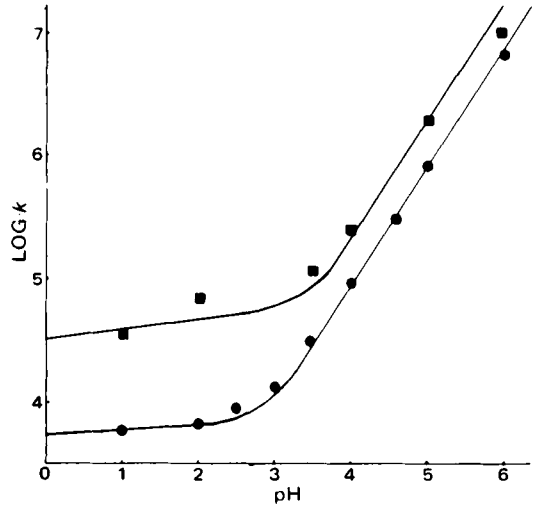

Figure 2—*The pH dependence of second-order rate constants, k, for VII oxidation with cation radicals (I and II) at 25°. The points (● for II and ■ for I) are experimental data. The curves were computed according to Eq. 2 with the values reported in Table III.*

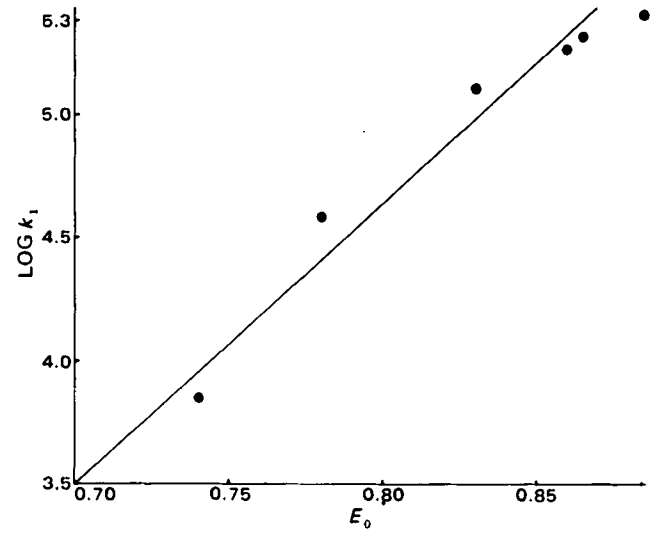

Figure 3—*Log* k_1 versus E_0 *plot of different phenothiazine cation radicals.*

was first order and dependent on each reagent concentration, the following rate law pertained:

$$-\frac{1d[P^{+\cdot}]}{2dt} = k[P^{+\cdot}][\text{dopamine}] \qquad \text{(Eq. 1)}$$

where [dopamine] represents the stoichiometric VII concentration. The observed rate constant values are reported in Table III.

pH Dependence—The data reported in Table III show that the rate constants were affected by the solution pH. This pH dependence can be explained by the different VII protonation states represented by:

$$H_3D^+ \underset{H^+}{\overset{K_1}{\rightleftharpoons}} H_2D \underset{H^+}{\overset{K_2}{\rightleftharpoons}} HD^-$$

Scheme II

where $pK_1 \cong 9$ and $pK_2 \cong 10$ (18).

Recent research (18) suggested that these dissociation constants represent competitive deprotonation and cannot be assigned to the ammonium or phenolic groups.

The acidity dependence can be ascribed to competitive paths such as:

$$P^{+\cdot} + H_3D^+ \xrightarrow{k_1} P + H_2D^{+\cdot} + H^+$$

Scheme III

Table IV—VII Oxidation Rate Constants with Different Cation Radicals at 25°

Compound	E_0	k_1, M^{-1} sec^{-1}	k_2K_1, sec^{-1}
I	0.78	$(3.7 \pm 0.4) \times 10^4$	(20 ± 8)
II	0.72	$(6.0 \pm 0.8) \times 10^3$	(7.9 ± 0.9)
III	0.83	$(1.2 \pm 0.1) \times 10^5$	—
IV	0.86	$(1.6 \pm 0.2) \times 10^5$	—
V	0.86_5	$(1.75 \pm 0.2) \times 10^5$	—
VI	0.88_5	$(2.1 \pm 0.2) \times 10^5$	—

$$P^{+\cdot} + H_2D \xrightarrow{k_2} P + H_2D^{+\cdot}$$

Scheme IV

and then follows the fast reaction:

$$P^{+\cdot} + H_2D \rightarrow P + DQ^+ + H^+$$

Scheme V

This leads to the rate law:

$$-\frac{1d[P^{+\cdot}]}{2dt} = \frac{(k_1 + k_2K_1[H^+]^{-1})[\text{dopamine}][P^{+\cdot}]}{1 + k_1[H^+]^{-1}} \qquad \text{(Eq. 2)}$$

which with $K_1[H^+]^{-1} \ll 1$ in the pH range investigated reduced to:

$$-\frac{1d[P^{+\cdot}]}{2dt} = (k_1 + k_2K_1[H^+]^{-1})[\text{dopamine}][P^{+\cdot}] \qquad \text{(Eq. 3)}$$

Figure 2 compares the experimental points and a curve calculated with Eq. 3. The parameters k_1 and, when available, k_2K_1, were collected and were $\Delta H^{\neq} = 7.3 \pm 1.1$ kcal/mol and $\Delta S^{\neq} = -17 \pm 4$ cal deg^{-1} mole^{-1} for path I and $\Delta H^{\neq} = 4.8 \pm 1.3$ kcal/mole and $\Delta S^{\neq} = -38 \pm 4$ cal deg^{-1} mole^{-1} for path II. These values are overall data, including the contribution of dissociation constant K_1 and of the diffusion-controlled term.

CONCLUSIONS

For the observed reaction between a cation radical and an organic substrate, an electron-transfer mechanism can be proposed (19–21). When this mechanism is operating, a relationship between the reaction rates and the oxidizing agent reduction potentials is expected (22, 23). This provision is fulfilled for the acid-independent path. In fact, where the phenothiazine derivative reduction potentials are reported (12), the compounds with higher reduction potential exhibit the higher reaction rates (Table IV). This can be seen in Fig. 3, where a linear relationship between log k_1 and E_0 is shown. The acid-independent path, however, although investigated for only two compounds, shows a close rate, k_2K_1. [In fact, while the ratio of k_1(II)/k_1(I) is 6.2, the ratio of k_2(II)/k_2(I) is only 2.5.]

The values of the specific rate constant k_2 could be estimated by knowing K_1, for which the value around 10^{-9} mole/liter can be suggested (19–21). This procedure leads to k_2 values of 7.9×10^9 and 2.0×10^{10} liters mole/sec for I and II, respectively, which are very close to the diffusion-controlled limit (24).

When such conditions are reached, the contribution of the activation-controlled reaction can be expressed by (25):

$$\frac{1}{k_{obs}} = \frac{1}{k_{diff}} + \frac{1}{k_{act}} \qquad \text{(Eq. 4)}$$

Consequently, it should be possible, knowing k_{diff}, to derive k_{act}, the activation-controlled electron-transfer rate. If $k_{diff} = 3.0 \times 10^{10}$ liters/mole sec (24), it follows that $k_{act} = 1.0 \times 10^{10}$ and 6.0×10^{10} liters/mole sec for I and II, respectively. The ratio $k_{2act(II)}/k_{2act(I)}$ should be approximately equal to that observed for the ratio of an independent path. This suggests that the rate of path electron transfer is also related to the oxidizing species reduction potentials. Obviously, this agreement could be fortuitous, owing to the uncertainty on k_1 and k_{diff}. The observed rate constants become very fast at physiological pH. With these conditions, VII oxidation could be a way of disappearance of I and II cation radicals.

Since dialkylaminoalkylphenothiazines with two-carbon side chains have a higher reduction potential, their cation radicals show a quicker oxidation reaction than the ones with three-carbon side chains. There is, therefore, a correlation between VII oxidation rates and the side-chain structure. The higher cation radical oxidation potential of derivatives with two-carbon side chains could explain their different behavior (11) in enzymatic oxidation of VII. This parameter might also explain the difference in their pharmacodynamic activities.

Chemical Reactions in Cephalosporin Allergy: High-Pressure Liquid Chromatographic Analysis of Cephalosporin Aminolysis Kinetics

AKIRA TSUJI, ETSUKO MIYAMOTO, and TSUKINAKA YAMANA ˣ

Received May 2, 1978, from the *Faculty of Pharmaceutical Sciences, Kanazawa University, Takara-machi, Kanazawa 920, Japan.* Accepted for publication October 30, 1978.

Abstract □ Cephalosporin reaction with protein amino groups is fundamental to cephalosporin allergy. Cephalothin and cefazolin reaction kinetics with ε-aminocaproic acid, β-alanine, and glycine in aqueous solution were investigated. All reactions were conducted at 35° and 0.5 ionic strength and were followed by ion-exchange high-pressure liquid chromatography. The aminolysis rate constants can be expressed as terms representing uncatalyzed or water-catalyzed amine reaction, self-assisted nucleophilic reaction, and hydroxide-ion-catalyzed nucleophilic amine attack on the β-lactam moiety. Cephalothin and cefazolin react with amines as readily as penicillin G. The UV spectra of several cephalothin–glycine reaction products were recorded, and their possible structures are discussed.

Keyphrases □ Cephalosporins—aminolysis kinetics, allergy, high-pressure liquid chromatography □ Aminolysis—cephalosporins, allergy, kinetic analysis, high-pressure liquid chromatography □ Kinetics—cephalosporin aminolysis, high-pressure liquid chromatography □ High-pressure liquid chromatography—analysis, cephalosporins, aminolysis kinetics, aminolysis products □ Antibacterials—cephalothin, deacetylcephalothin, and cefazolin, aminolysis kinetics, cephalosporin allergy, high-pressure liquid chromatography

Since cephalosporin reaction with free amino groups on tissue proteins to yield cephalosporoyl conjugates *in vivo* may be largely responsible for cephalosporin immunogenicity (1), a knowledge of cephalosporin aminolysis and reaction products is important. Such protein conjugates prepared *in vitro* have been strongly immunogenic in animals (2–6).

Although kinetic studies on penicillin aminolysis have been reported (7–17), little work has been performed using cephalosporins, probably due to analysis difficulties, reaction complexity, and the dearth of information on these compounds. Cephalosporin aminolysis kinetic analysis by differential UV spectrophotometry was reported recently (18, 19). Spectrophotometric analysis has been useful for following cephalosporin hydrolysis (18–23).

This paper reports the high-pressure liquid chromatographic (HPLC) analysis of cephalosporin aminolysis kinetics. This method seems to be a powerful tool for quantifying reactions, separating the hydrolysis and aminolysis products, and investigating degradation products. HPLC analysis of the kinetics and mechanism of aqueous cephalosporin hydrolysis as a function of pH was reported previously (23, 24).

EXPERIMENTAL

Materials—Cephalothin sodium[1] (944 μg/mg), deacetylcephalothin sodium[1], and cefazolin sodium[2] (966 μg/mg) were used as received.

All other chemicals were the highest grade and were used without further purification.

Kinetic Procedure—Three amino acid types, glycine, β-alanine, and ε-aminocaproic acid, were used both as buffers to maintain a constant pH and as nucleophiles. The amine buffers were prepared just before use with calculated amounts of amino acid and standard sodium hydroxide solution. The ionic strength was adjusted to 0.5 with potassium chloride. The kinetic technique was almost the same as one used previously for penicillin aminolysis (12–14).

To avoid the possible change in the kinetic solution pH[3] during the reaction, a constant pH was maintained with a pH-stat[4]. All reactions were conducted at 35.0 ± 0.1° with the total amine concentration in large excess over the reacting substrate concentration to maintain pseudo-first-order kinetics. In most cases, the initial cephalosporin concentration was 5×10^{-3} *M* and the total amine concentration was 0.04–0.60 *M*. Reaction solution aliquots (1 ml) were withdrawn at intervals, neutralized to quench the reaction by addition of 1 ml of 0.2 *M* phosphate buffer (pH 6.0) in a cooled water bath to give the final pH of 7–8, and analyzed by HPLC as described later.

Table I—Apparent First-Order Rate Constants, k_{obs}, for Cephalothin Aminolysis in Various Amine Buffers at 0.5 Ionic Strength and 35°

[a] The pH was maintained by a pH-stat.

The pseudo-first-order rate constants, k_{obs}, were usually calculated from the slope of the semilogarithmic plots of the residual concentration starting materials *versus* time by the least-squares treatment. Tables I–III summarize the amine buffer compositions and the k_{obs} values.

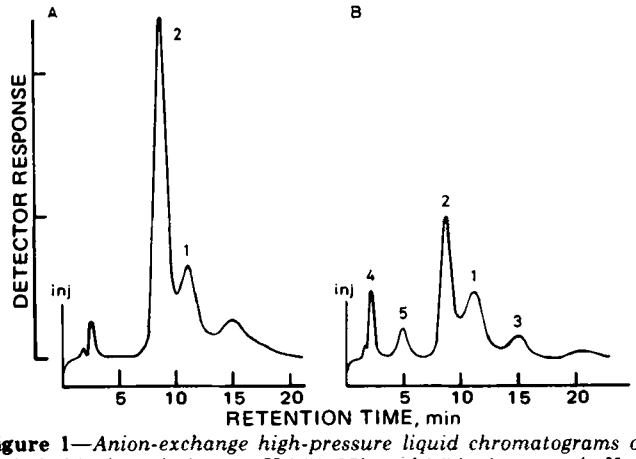

Figure 1—*Anion-exchange high-pressure liquid chromatograms of cephalothin degradation at pH 9.50, 35°, and 0.5 ionic strength. Key: A, sample after 10 hr of hydrolysis; and B, sample after 5 hr of reaction with 0.12 M glycine.*

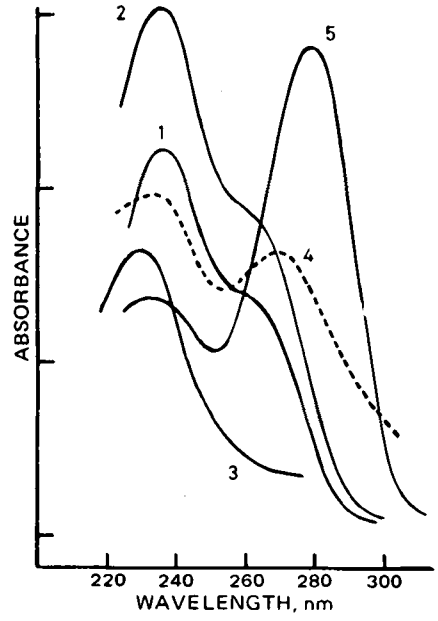

Figure 2—*UV spectra of peaks 1–5 in Fig. 1B.*

HPLC Study—The liquid chromatograph[5] was equipped with a double-beam, variable-wavelength UV detector[6] set at 254 nm. The stationary phase was strong anion-exchange resin prepacked into a stainless steel column, 2.1 mm i.d.[7]. The mobile phases were aqueous 0.02 *M* NaH_2PO_4 adjusted to pH 8.5 with sodium hydroxide for cephalothin and aqueous 0.2 *M* CH_3COONa adjusted to pH 5.0 for cefazolin. The operating parameters for the instrument were: pressure, 40–100 kg/cm^2 (changed to obtain suitable retention time for analysis); temperature, ambient; and UV attenuation, 0.16–0.32 aufs.

A 5-μl sample was injected using a 10-μl syringe and a stopped-flow mode. The cephalothin and deacetylcephalothin or cefazolin content was determined by comparing the peak heights with those of similarly chromatographed standards. Calibration curves for the substances were prepared daily.

TLC Study—TLC was employed to identify the degradation products and to verify HPLC results. Aliquots (10 μl) of the 0.01 *M* cephalothin–glycine reaction solution were applied to glass plates (5 × 20 cm) precoated with 250-μm silica gel[8]. Chromatograms were run for 15 cm in acetic acid–ethanol–chloroform (1:7:12). Spots corresponding to cephalosporins were visualized with iodine vapor. Authentic cephalothin and deacetylcephalothin samples showed R_f values of 0.39 and 0.18, respectively. The standard *N*-acetylglycine solution showed a spot at R_f 0.36, which was visualized with bromcresol green (18).

RESULTS AND DISCUSSION

Monitoring Hydrolysis and Aminolysis of Cephalothin by HPLC—Figure 1A represents the typical chromatogram of the 10-hr aged hydrolysis solution of cephalothin at 35°, μ = 0.5, and pH 9.5 maintained with a pH-stat. Several peaks appeared; two could be assigned, as demonstrated previously (23), to cephalothin itself (peak 1) and deacetylcephalothin (peak 2) resulting from 3-acetoxy moiety hydrolysis. Others were regarded as β-lactam cleavage products.

The cephalothin hydrolytic pathway in alkaline solution has been established kinetically (18, 23) as represented in Scheme I, where k_1 and k_3 represent the rate constants for cleavage of cephalothin and deacetylcephalothin β-lactam rings, and k_2 is the rate constant for cephalothin deacetylation. Simultaneous and quantitative cephalothin and deacetylcephalothin determination at pH 9.5, 35°, and μ = 0.5 was made by HPLC. Kinetic parameters (Scheme I) were computed by the nonlinear least-squares[9] method to be (in hr^{-1}): k_1 = 0.070, k_2 = 0.137, and k_3 = 0.069. Detailed kinetics (18, 23) and the mechanism (23) of cepha-

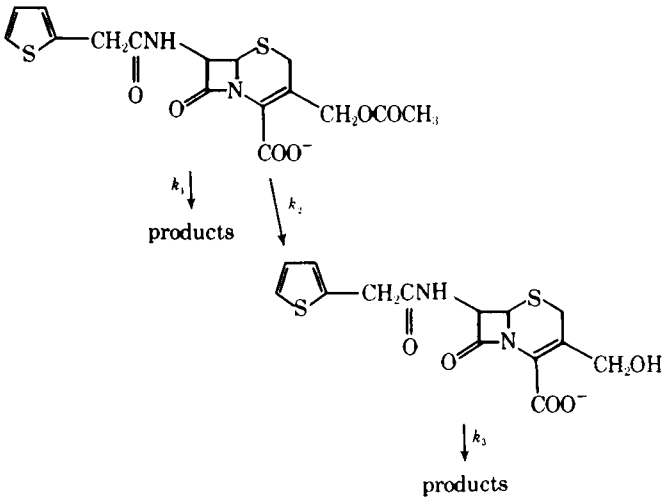

Scheme I

lothin hydrolysis were reported previously. The hydrolysis rate constants for k_1, k_2, and k_3 can be defined, in nonbuffer solutions, as $(k_1)_{pH}$, $(k_2)_{pH}$, and $(k_3)_{pH}$ and obey Eqs. 1*a*–1*c* above pH 9:

$$(k_1)_{pH} = (k_1)_{OH}a_{OH^-} \quad \text{(Eq. 1}a\text{)}$$

$$(k_2)_{pH} = (k_2)_{OH}a_{OH^-} \quad \text{(Eq. 1}b\text{)}$$

$$(k_3)_{pH} = (k_3)_{OH}a_{OH^-} \quad \text{(Eq. 1}c\text{)}$$

where $(k_i)_{OH}$ is the specific hydroxide ion-catalyzed rate constant for the respective hydrolytic reactions and a_{OH^-} is the hydroxide-ion activity and can be calculated at 35° from (25):

$$a_{H^+}a_{OH^-} = 10^{-13.68} \quad \text{(Eq. 2)}$$

The $(k_i)_{OH}$ average values (35°, μ = 0.5) for $(k_i)_{pH}$ from the data determined by HPLC and previously (23), according to Eqs. 1*a*–1*c*, were 1.06 × 10^3, 1.82 × 10^3, and 1.01 × 10^3 M^{-1} hr^{-1}, respectively.

A typical 5-hr chromatogram of cephalothin with 0.12 *M* glycine (pH 9.5, 35°, μ = 0.5) is shown in Fig. 1B. There were some differences in the product peaks between hydrolysis (Fig. 1A) and aminolysis at the same pH. UV spectra of these peaks are shown in Fig. 2. Peaks 1 and 2 had two characteristic absorption maxima at 235 and 260 nm, consistent with those of cephalothin and deacetylcephalothin (26). Peaks 3–5 were assigned to the glycinolysis products of cephalothin and/or deacetylcephalothin. These findings indicate that the cephalothin aminolysis is also represented as Scheme I.

The time course (mole percent) for cephalothin and deacetylcephalothin during cephalothin glycinolysis at pH 9.5 (Fig. 3) showed good agreement with values calculated from the nonlinear least-squares analysis[9]. The rate constants computed were (in hr^{-1}): k_1 = 0.345 ± 0.008, k_2 = 0.161 ± 0.007, and k_3 = 0.184 ± 0.018 (*SD*). No detectable *N*-

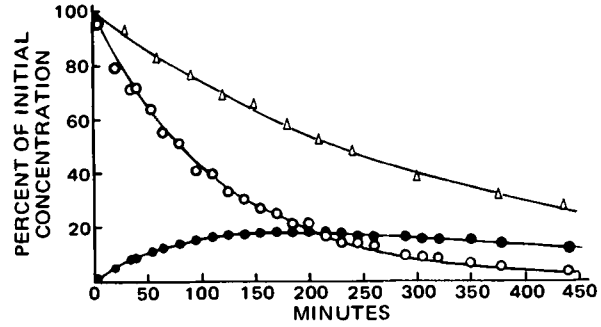

Figure 3—*Time course for cephalothin* (○) *and deacetylcephalothin* (●) *during cephalothin aminolysis and that for deacetylcephalothin aminolysis* (△), *both with 0.12* M *glycine at pH 9.50, 35°, and 0.5 ionic strength. Points for cephalothin aminolysis were from several experiments by HPLC under the same conditions. The curves were calculated according to Scheme I by the use of the following rate constants (in hours*$^{-1}$*):* k_1 = *0.345,* k_2 = *0.164, and* k_3 = *0.184.*

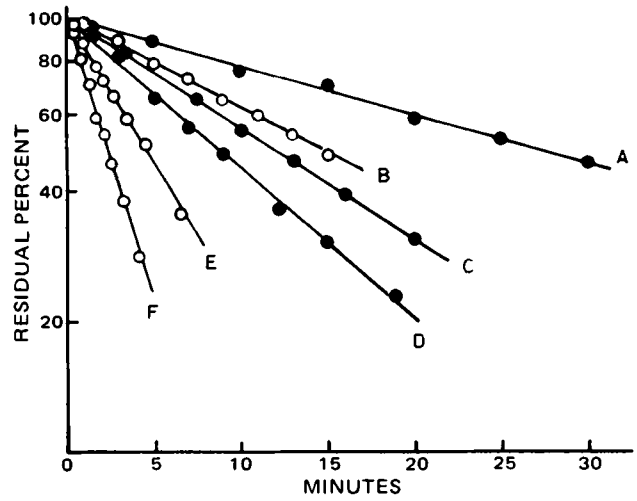

Figure 4—*Apparent first-order plots determined by HPLC for the aminolysis of cephalothin* (○) *and cefazolin* (●) *at 35° and 0.5 ionic strength. Key: A, 0.08* M *β-alanine at pH 10.30; B, 0.38* M *β-alanine at pH 9.70; C, 0.25* M *glycine at pH 10.00; D, 0.12* M *ε-aminocaproic acid at pH 10.30; E, 0.30* M *β-alanine at pH 10.30; and F, 0.094* M *ε-aminocaproic acid at pH 10.80.*

acetylglycine formation was found on TLC, as previously observed (18). These kinetic and TLC results indicate no significant ester moiety aminolysis at the cephalothin 3-position. The deacetylcephalothin reaction in 0.12 *M* glycine buffer (pH 9.5, 35°, μ = 0.5) is shown in Fig. 3. The first-order degradation rate constant was k_3 = 0.183 $hr,^{-1}$ which is in fair agreement with that computed from the cephalothin glycinolysis under the same conditions.

For other aminolysis reactions followed by HPLC, cephalothin disappearance followed first-order kinetics (Fig. 4). The pseudo-first-order rate constant, k_{obs}, can be commonly expressed for the reactions in all amine solutions as:

$$k_{obs} = k_{pH} + k_{amine} \quad \text{(Eq. 3)}$$

where k_{pH} is the cephalothin first-order hydrolysis rate constant and is equal to $(k_1)_{pH}$ + $(k_2)_{pH}$ and k_{amine} is the first-order rate constant depending on the concentration of amines.

Monitoring Cefazolin Aminolysis—Typical chromatograms of cefazolin aminolysis with ε-aminocaproic acid are shown in Fig. 5 as a function of time. Cefazolin aminolysis occurs only at the β-lactam moiety. The semilogarithmic plots of the remaining cefazolin percentage were reasonably linear (Fig. 4), indicating that the cefazolin degradation followed first-order kinetics. The pseudo-first-order rate constant, k_{obs}, obtained from the slopes is the sum of the competing rate constants, k_{pH} for hydrolysis and k_{amine} for aminolysis, and is given by Eq. 3. Cefazolin hydrolysis k_{pH} obeys Eq. 4 above pH 9, as verified previously (18, 23):

$$k_{pH} = k_{OH}a_{OH^-} \quad \text{(Eq. 4)}$$

The value of k_{OH} used for the calculation was 1.14 × 10^3 M^{-1} hr^{-1} (23).

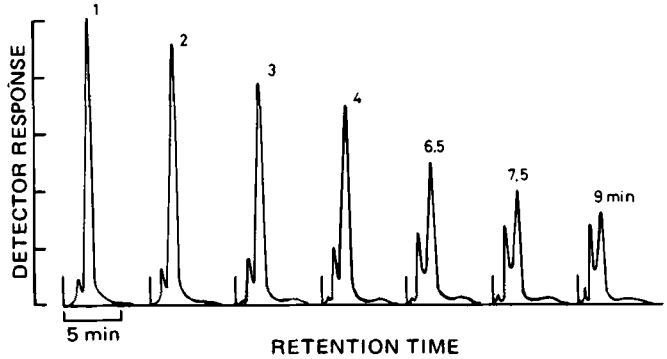

Figure 5—*HPLC changes for the cefazolin reaction with 0.10* M *ε-aminocaproic acid at pH 10.60, 35°, and 0.5 ionic strength with time in minutes (listed in graph).*

		k_{gb}	73.6	150	27.7	48	81.5	162	90.6	96.0

[a] Determined previously (13). [b] Defined in Eq. 5; k_n in M^{-1} hr^{-1} and k_{gb} and k_{gOH} in M^{-2} hr^{-1}. [c] Values reported by Bundgaard (18). [d] Undetectable. [e] Recalculated from the reported values (18) according to the definition in Eq. 5 by use of the relationship (18) $\log[OH^-] = \log a_{OH^-} + 0.12$. [f] The k_{gOH} constant could not be determined.

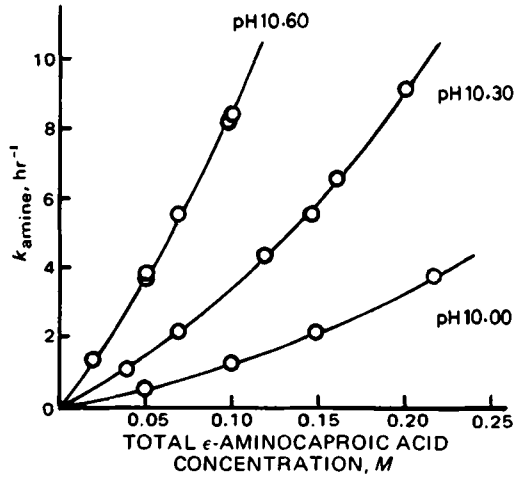

Figure 6—*Pseudo-first-order rate constants* versus *total amine concentration for cefazolin reaction with ε-aminocaproic acid at 35° and 0.5 ionic strength. Curves were calculated from Eq. 5 and rate constants in Table I.*

Aminolysis Kinetics—Typical plots of the aminolysis rate constant, k_{amine}, *versus* total amine concentration, $[amine]_T$ (Fig. 6) showed upward curvature at any pH. These pseudo-first-order rate constants apparently obey the general relationship reported previously for penicillins (7, 10, 13, 18) and cephalosporins (18):

$$k_{amine} = k_n[amine] + k_{gb}[amine]^2 + k_{gOH}[amine]a_{OH^-} \quad \text{(Eq. 5)}$$

where k_n represents the unassisted or water-catalyzed reaction of free amine on the β-lactam moiety, k_{gb} represents the general base-catalyzed and nucleophilic reaction with assistance by the amine second molecule, and k_{gOH} is the hydroxide ion-catalyzed third-order rate constant of nucleophilic displacement by the amine. The concentration of free amine can be calculated from:

$$[amine] = \frac{K_a}{K_a + a_{H^+}}[amine]_T \quad \text{(Eq. 6)}$$

where K_a is the conjugated amine acid dissociation constant. The pKa values determined previously under the same conditions (13) were used for the calculation.

Rearrangement of Eq. 5 leads to:

$$\frac{k_{amine}}{[amine]} = k_n + k_{gOH}a_{OH^-} + k_{gb}[amine] \quad \text{(Eq. 7)}$$

Equation 7 predicts that plots of $k_{amine}/[amine]$ *versus* [amine] provide k_{gb} as a slope of $k_n + k_{gb}a_{OH^-}$ as an intercept. One such plot is given in Fig. 7 for cephalothin, deacetylcephalothin, and cefazolin glycinolysis,

III

showing a single line in each case with different slopes. Another typical plot with different intercepts and the same slope is illustrated in Fig. 8, predicting significant contribution of the kinetic term of k_{gOH}.

The weighed multiple linear regression analysis according to Eq. 7 provides (with $R > 0.98$) the rate constants for the uncatalyzed (or water-assisted), general base-catalyzed, and hydroxide ion-catalyzed reactions of cephalosporins with a number of amines (Table IV). The solid lines in Figs. 6–8 were calculated from the rate law (Eq. 5) and the parameters in Table IV and show satisfactory agreement with the data.

In cephalosporin aminolysis, the rate constants of k_{gb} were 50% lower at $\mu = 0.5$ than those determined spectrophotometrically (18) for similar aminolysis at 35° and $\mu = 1.0$ (Table IV). The UV spectrophotometric analysis (18) of the present reaction solutions gave rate constants almost identical to those determined by HPLC. This significant difference may be attributed to the different ionic strength rather than to the analytical method.

This speculation was substantiated in cephalothin glycinolysis at ionic strengths of 0.5–2.0 (Table V). The aminolysis rate constants, k_{amine}, compared to the hydrolysis rate constants, k_{pH}, increased significantly with the ionic strength increase. The ionic strength effect was similar to that for phenyl acetate aminolysis in which a high concentration of potassium chloride increased the reaction rates (27, 28).

General base-catalyzed cephalosporin aminolysis was favored by ionic strength increases and presumably proceeded through activated complexes of more ionic character than the starting materials. For the cephalosporin aminolysis (Table IV), the influence of ionic strength on the uncatalyzed (or water-assisted) and hydroxide-ion-catalyzed rate constants (k_n and k_{gOH}) was small compared to that on the amine-catalyzed rate constants (k_{gb}). In contrast to cephalosporin reactivity, the marked increase of k_n compared to k_{gb} and k_{gOH} by an increase of ionic strength was noted for penicillin aminolysis.

The rate constants for penicillin G aminolysis determined at $\mu = 0.5$ in this laboratory (13) and those determined previously at $\mu = 1.0$ (18) under the same temperature condition (35°) are also listed in Table IV. The rate constants k_n of penicillin G at $\mu = 0.5$ increased significantly five to nine times at $\mu = 1.0$, while the catalyzed rate constants were almost unchanged. These different reaction rate sensitivities to the ionic strength between pencillin and cephalosporin may result from the difference in the mechanism and/or ionic nature of the transition state.

There was no significant difference in cephalosporin aminolysis rate constants as obtained by HPLC and differential UV spectrometry. The HPLC method requires no assumption on the UV absorbability of the reaction products and permits simultaneous determination of the starting materials and degradation products. The UV data for the first three to five half-lives, when treated by literature methods (29), also provide reliable rate constants (18, 19).

Mechanism of Cephalosporin Aminolysis—The amine and hydroxide-ion-catalyzed reactions of cephalosporins are likely to be catalyzed nucleophilic amine displacements on the β-lactam moiety, yielding the corresponding cephalosporoylamide, as demonstrated for penicillin aminolysis (13, 16). The uncatalyzed or water-assisted kinetic term of Eq. 5 may represent a nucleophilic displacement reaction to yield the cephalosporoylamides or a kinetically equivalent general base-catalyzed hydrolysis to yield cephalosporoic acids. For penicillin aminolysis, this reaction was nucleophilic (13, 16). Cephalosporin reaction with one amine molecule represents nucleophilic displacement (18). Since the experimental evidence strongly suggested the dominance of the nucleophilic reaction, no further experiments were performed.

Relative Reactivity, Aminolysis Products, and Chemical Aspects of Cephalosporin Allergy—There are two striking differences between the chemistry of cephalosporins and penicillins. One is the relative rate of aminolysis. Change in the acylamide side chain in penicillin molecules produces no significant change in the aminolysis rate (7, 16, 30, 31), whereas the cephalosporin aminolysis rate is markedly influenced by the nature of the cephalosporin molecules.

In comparison with the reactivity of cephalosporins containing 7-position thienyl side chains, deacetylcephalothin is less reactive than cephalothin, as seen by the glycinolysis rates (Table IV). This difference can be attributed either to the inductive effect on the 3-methylene substituent (18) or to the leavability of the 3-methylene moiety in activating the β-lactam ring toward nucleophilic attack (32). As a result, cephalosporins containing a strong electron-withdrawing or good leaving group in the 3-position, such as cephaloridine, are readily destroyed in the presence of amines (18). Cefazolin and cephalothin reaction with amino acid primary amino groups resembled that of penicillin G (Table IV). These clinically used cephalosporins may conjugate with free protein amino groups in the body as readily as does penicillin G.

Furthermore, the penicillin β-lactam ring can be opened to give a relatively stable D-α-penicilloate without further molecular degradation. The presence of a Δ^3-double bond in cephalosporins leads to more extensive cleavage on hydrolysis and aminolysis (33, 34). The initial aminolysis product (I) with λ_{max} 230 nm was followed by chromophores with λ_{max} 270 and 278 nm (attributed to molecular fragmentation) and penaldates (II) and penamaldates (III) (33, 34). These actual structures are not completely understood. UV spectra of HPLC peaks, which appeared during cephalothin glycinolysis (Fig. 1B), revealed characteristic λ_{max} absorptions at 230 and 270 nm (Fig. 2). The UV spectrum of peak 5, which increased in peak height with time at the last aminolysis stage, exhibited λ_{max} at 278 nm. On the basis of reported chemical and spectroscopic evidence (33, 34) on the cephalosporin aminolysis product, peaks 3, 4, and 5 from the cephalothin glycinolysis may correspond to I, II, and III, respectively.

Localization of Low Molecular Weight ^{99m}Tc-Labeled Dimercaptodicarboxylic Acids in Kidney Tissue

DAVID O. KUBIATOWICZ, THEODORE F. BOLLES, JAMES C. NORA, and DIONYSSIS S. ITHAKISSIOS ˣ

Received March 18, 1977, from the *Medical Products Division, 3M Co., 3M Center, St. Paul, MN 55101.* Accepted for publication October 27, 1978.

Abstract □ Kidney localization of low molecular weight ^{99m}Tc-dimercaptodicarboxylic acid complexes was examined in mice. The complexes ^{99m}Tc-dimercaptosuccinic acid, ^{99m}Tc-dimercaptoglutaric acid, and ^{99m}Tc-dimercaptoadipic acid were formed by reducing sodium ^{99m}Tc-pertechnetate with stannous chloride in the presence of 2–10-fold excess ligand at pH 2.5 or 7.5. Kidney specificity decreased as chain length between the mercapto groups increased. Optimum kidney retention occurred with complexes formed at pH 2.5. Complexes prepared at pH 7.5 were rapidly excreted through the urine and feces. Kidney localization of complexes prepared at one pH was not altered if the pH was later changed.

Keyphrases □ Technetium mercaptan complexes—localization in kidney tissue, synthesis, low molecular weight, structure–activity relationships □ Radionuclide imaging, renal—technetium mercaptan complexes, low molecular weight, localization in kidney tissue, synthesis, structure–activity relationships □ Kidney—radionuclide imaging, technetium mercaptan complexes, structure–activity relationships □ Structure–activity relationships—technetium mercaptan complexes, localization in kidney tissue

Radionuclide diagnosis of renal disease saves time in routine renal function tests and allows external kidney monitoring for clearance and morphological studies. The ^{203}Hg- and ^{197}Hg-labeled agents previously used have been replaced by ^{99m}Tc-labeled agents to decrease the high absorbed radiation dose *in vivo* (1).

Initial work on technetium mercaptan complexes as organ imaging agents led to the introduction of ^{99m}Tc-dihydrothioctic acid as a replacement for rose bengal in liver, gallbladder, and biliary tract studies (2). Other unpublished studies indicated that technetium complexes with short chain mono- and dimercaptodicarboxylic acids accumulated in kidney tissue. ^{99m}Tc-Dimercaptodicarboxylic acids were found to have better localization characteristics than their monomercapto analogs, especially ^{99m}Tc-dimercaptosuccinic acid, which has become well known as a renal imaging agent (1).

This *in vivo* study concerned organ localization of low molecular weight ^{99m}Tc-dimercaptodicarboxylic acids as affected by the number of carbon atoms between the mercapto groups and by the pH of complex formation.

III

EXPERIMENTAL

Dimercaptosuccinic acid[1] (I) was used without further purification.

Dimercaptoglutaric acid (II) was synthesized according to a literature procedure (3). Glutaric acid was brominated and esterified to form dimethyl 2,4-dibromoglutarate. The dibromide was reacted with potassium thioacetate to form the acetyl dithio ester. This derivative was subjected to alkaline hydrolysis in the presence of iodine and recrystallized from ethyl acetate to yield 1,2-dithiolane-3,5-dicarboxylic acid (the disulfide of II), mp 190–192° [lit. (3) mp 193–194°]. The structure for the disulfide was confirmed by elemental analysis, NMR, and mass spectrometry. Dimercaptoglutaric acid was generated from its disulfide, just prior to technetium complex formation, by reduction with aqueous sodium borohydride at pH 8, a technique that has been demonstrated in related compounds (4).

Dimercaptoadipic acid (III) was synthesized by incubating 2,2′-dibromoadipic acid[2] with aqueous potassium xanthogenate, followed by alkaline hydrolysis of the xanthate derivative in methanol and acidification. The solid was further purified by recrystallization from boiling water to yield pure crystalline III, mp 186–189° [lit. (5) mp 187–189°]. The structure for III was confirmed by elemental analysis and NMR.

^{99m}Tc-Dimercaptodicarboxylic Acid Complexes—These complexes were prepared in a nitrogen atmosphere by adding 0.1–2 ml of sodium pertechnetate ($Na^{99m}TcO_4$) (IV) eluate from ^{99}Mo-^{99m}Tc-generator[3] to 1–3 ml of stock tin–dimercaptodicarboxylic acid solution (pH 2.5 or 7.5), followed by 5–15 min of incubation at room temperature. [a] The complex was prepared *via* sodium hexabromotechnetate (action of hydrogen bromide on sodium pertechnetate). [b] Following injection. [c] Percent total ± *SD*. Average results from three replications.

stock solutions were made by mixing stannous chloride dissolved in oxygen-free 1 *M* HCl with 3 m*M* I, II, or III such that the ligand to tin ratio was 3:1. The stock solution pH was adjusted with 1 *M* $NaHCO_3$.

Following incubation, the complexes were analyzed for unreacted IV by TLC on silica gel 6060 paper[4] with acetone as the developing solvent; IV moved with the solvent front while reduced technetium remained at the origin. Unreacted IV was always less than 2%. If a mixture of acetone (100 parts) and 12 *M* HCl (0.5 part) was used as a developing solvent, the complexes migrated (R_f ~0.8) while IV moved with the solvent front.

To avoid accidental contamination of the complex with undesirable metal ions, all preparation steps were carried out in glass vessels and with highly pure reagents.

***In Vivo* Distribution Study**—The 84 female Swiss Webster mice[5] were from the same shipment and weighed 20–24 g. Prior to experimentation, the animals were housed in groups of six for 3 days. They were allowed free access to food and tap water.

The *in vivo* distribution of ^{99m}Tc-dimercaptodicarboxylic acids in mice *versus* time was studied by intravenous injection of 1.5 mg/kg into the tail vein. The animals were injected at random and were killed at 0.02, 0.5, 1, 2, 4, 6, and 24 hr after injection by exposure to a carbon dioxide atmosphere. Blood samples were obtained by cardiac puncture immediately after death. The organs were assayed for radioactivity, and the results were reported as percent of total injected radioactivity. The experiment was replicated four times.

RESULTS AND DISCUSSION

Preparation of ^{99m}Tc-Dimercaptodicarboxylic Acid Complexes—This paper describes the reduction of radioactive pertechnetate IV and its reaction with excess dimercaptodicarboxylic acid complexes. Dimercaptodicarboxylic acids are by themselves reducing agents. Therefore, the technetium complexes could be formed simply by heating a solution of the acid with IV at 100° for 15–30 min. The addition of trace quantities (1 μg) of cupric sulfate or ferric chloride reduced the reaction time to 5 min.

A drawback of this method was that oxidation of mercaptan groups sometimes occurred, producing incomplete labeling and formation of labeled dimercaptodicarboxylic acid fragments. This problem was eliminated by room temperature labeling in the presence of an oxidizable, lower valence metal salt such as ferrous chloride or stannous chloride under a nitrogen atmosphere and use of double-distilled water diluent. The ligand to tin ratio could vary from 2:1 to 10:1, and the labeling could be done at any pH between 2 and 9. ^{99m}Tc-Dimercaptosuccinic acid (V), ^{99m}Tc-dimercaptoglutaric acid (VI), and ^{99m}Tc-dimercaptoadipic acid (VII) prepared under these conditions were stable for at least 6 hr at room temperature.

The stannous chloride reduction was adequate for the formation of the low molecular weight ^{99m}Tc-dimercaptodicarboxylic acid complexes described in this study; however, a modified method was required for several other mercaptan derivatives that precipitated in the presence of tin. ^{99m}Tc-Mercaptan complexes were made by first reacting the sodium pertechnetate eluate with 9 *M* HBr at 100° under nitrogen to form sodium hexabromotechnetate, $Na_2{}^{99m}TcBr_6$ (VIII) (6, 7). Then the mixture was evaporated to dryness over a nitrogen stream, and a slightly red solid (VIII) residue was obtained (8). This residue was dissolved in ethanol and mixed with an equal volume of an ethanolic solution of mercaptan ligand. Afterward, the organic solvent was evaporated and the resulting ^{99m}Tc-mercaptan complex was dissolved in saline.

In all studies, the extent of reduction and the complex stability were followed by TLC and radiation monitoring since IV had a distinctly different R_f value than its complexed forms.

Kidney Localization of ^{99m}Tc-Dimercaptodicarboxylic Acids—^{99m}Tc-Dimercaptodicarboxylic acids, prepared at pH 2.4 and 7.5 and having a 3:1 ligand–tin ratio, were injected. The complexes circulated in the blood and either accumulated in kidneys and, to a lesser extent, in the liver (<10%) or were excreted.

Table I shows the distribution and excretion of the complexes formed in acidic or basic solutions in mice killed 4 hr after injection. The average

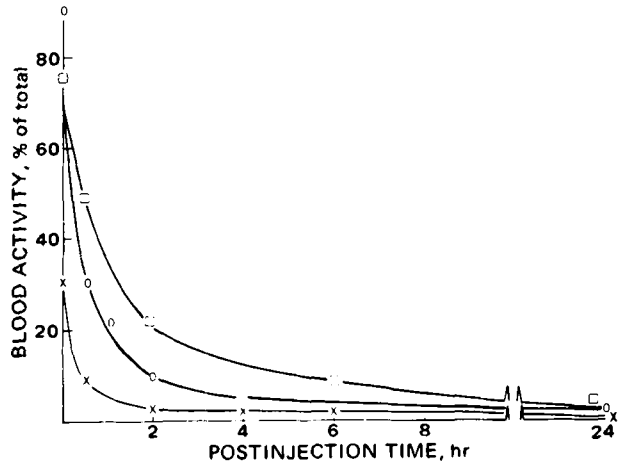

Figure 2—*Comparison of blood clearance rates of* ^{99m}*Tc-dimercaptosuccinic acid* (○), ^{99m}*Tc-dimercaptoglutaric acid* (×), *and* ^{99m}*Tc-dimercaptoadipic acid* (□) *formed at pH 2.5.*

kidney accumulation of V–VII *versus* postinjection time is shown in Fig. 1. Within a few hours after injection of the acidic complexes, V concentrated most highly in kidney tissue, plateauing at slightly above 30% of the total injected radioactivity. Five-carbon VI reached a maximum of 15%, and six-carbon VII concentrated least of all, plateauing at 8%. Paired *t* test analysis showed the curves to be significantly different ($p < 0.05$) for periods greater than 2 hr.

In contrast, the basic complexes showed an initial low kidney accumulation that radically dropped a short time after administration. Least sensitive of all to pH changes was VII, which showed very low kidney uptake of both acidic and basic preparations. In all cases, as the radioactivity in kidney tissue decreased, a marked increase in activity was found in the animal's excreta.

Figure 2 shows the average blood clearance of the three complexes formulated at pH 2.5. Slowest to clear was VII. The relative blood clearance rates were the same for complexes prepared at pH 7.5, but the individual clearance rates were faster. These complexes were excreted within 0.5 hr of injection.

Further studies indicated that low pH preparations were necessary for high kidney localization of the complexes. Complexes prepared at pH 2.5 and then raised to pH 7.5 by sodium bicarbonate addition prior to *in vivo* injection localized strongly in the kidney. However, complexes prepared at pH 7.5 and then lowered to pH 2.5 by hydrochloric acid addition still showed low kidney localization and were excreted rapidly. These observations are in agreement with those previously reported (9).

The ligand to tin ratio during complex formation and the injection time after complex preparation did not significantly affect the degree of complex localization in kidney tissue. During these studies, the ligand to tin ratio varied from 2:1 to 10:1, and the complexes were injected from 30 min to 6 hr after their preparation. If the complexes were not prepared using pure ligand and reagents and in an inert atmosphere, they rapidly decomposed into fragments that concentrated in the liver.

The nature of the technetium complexes formed is uncertain. The presence of two mercapto groups in the dicarboxylic acid molecules was necessary for good kidney uptake of the complexes. Comparative studies in this laboratory[6] using various monomercapto homologs such as ^{99m}Tc-mercaptoacetic acid and ^{99m}Tc-thiolactic acid showed that these complexes were more rapidly excreted and that their renal uptake was lower.

Reduction of pertechnetate with stannous chloride was used in this study because it was easy, rapid, and convenient. The complexes prepared by this method accumulated sufficiently in the kidney. However, reduction with hydrogen bromide, which can be used for a variety of mercaptan compounds, gave a higher deposition in the kidney with a considerable reduction in the excretion rate. Table II shows the distribution of V prepared by this method. The reason for the higher uptake is unknown. It may be due to the formation of a purer complex than that formed by tin reduction or to formation of an entirely different complex with higher specificity for kidney tissue.

Further studies are in progress to investigate the nature of complex formation as well as the chemical structure–kidney localization relationship.

Hydrocortisone Stability in Human Feces

JANIS J. MacKICHAN ˣ and WILLIAM J. JUSKO

Received July 31, 1978, from the *Clinical Pharmacokinetics Laboratory, Department of Pharmaceutics, School of Pharmacy, State University of New York at Buffalo,* and *Millard Fillmore Hospital, Buffalo, NY 14209.* Accepted for publication November 1, 1978.

Abstract □ Hydrocortisone stability in human feces was studied under various conditions to determine whether stability accounts for the variable effects of hydrocortisone enemas. Recovery from feces and assay specificity were assured using dual isotopes, TLC separation, and liquid scintillation counting. Hydrocortisone degraded slightly from 7 to 26% in 24 hr when incubated in fresh human feces at 37°. Less than 7% degradation occurred in feces stored at 10°, and negligible degradation occurred with hydrocortisone in water at 37°. Fecal bacteria may account for the observed degradation. Hydrocortisone stability in feces may contribute to local persistence and may account partly for its efficacy in ulcerative colitis treatment.

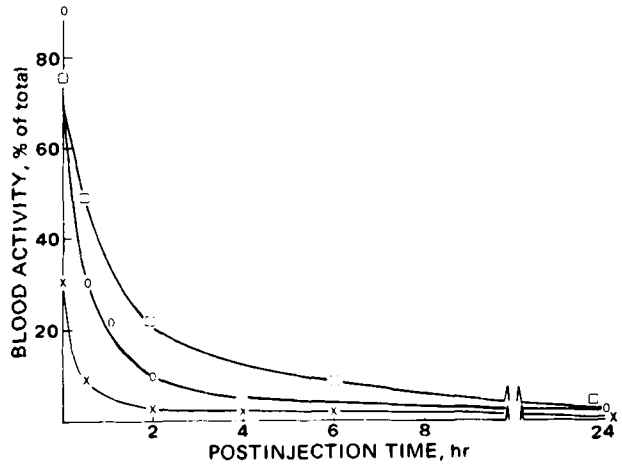

Figure 2—*Comparison of blood clearance rates of* ^{99m}*Tc-dimercaptosuccinic acid* (○), ^{99m}*Tc-dimercaptoglutaric acid* (×), *and* ^{99m}*Tc-dimercaptoadipic acid* (□) *formed at pH 2.5.*

kidney accumulation of V–VII *versus* postinjection time is shown in Fig. 1. Within a few hours after injection of the acidic complexes, V concentrated most highly in kidney tissue, plateauing at slightly above 30% of the total injected radioactivity. Five-carbon VI reached a maximum of 15%, and six-carbon VII concentrated least of all, plateauing at 8%. Paired *t* test analysis showed the curves to be significantly different ($p < 0.05$) for periods greater than 2 hr.

In contrast, the basic complexes showed an initial low kidney accumulation that radically dropped a short time after administration. Least sensitive of all to pH changes was VII, which showed very low kidney uptake of both acidic and basic preparations. In all cases, as the radioactivity in kidney tissue decreased, a marked increase in activity was found in the animal's excreta.

Figure 2 shows the average blood clearance of the three complexes formulated at pH 2.5. Slowest to clear was VII. The relative blood clearance rates were the same for complexes prepared at pH 7.5, but the individual clearance rates were faster. These complexes were excreted within 0.5 hr of injection.

Further studies indicated that low pH preparations were necessary for high kidney localization of the complexes. Complexes prepared at pH 2.5 and then raised to pH 7.5 by sodium bicarbonate addition prior to *in vivo* injection localized strongly in the kidney. However, complexes prepared at pH 7.5 and then lowered to pH 2.5 by hydrochloric acid addition still showed low kidney localization and were excreted rapidly. These observations are in agreement with those previously reported (9).

The ligand to tin ratio during complex formation and the injection time after complex preparation did not significantly affect the degree of complex localization in kidney tissue. During these studies, the ligand to tin ratio varied from 2:1 to 10:1, and the complexes were injected from 30 min to 6 hr after their preparation. If the complexes were not prepared using pure ligand and reagents and in an inert atmosphere, they rapidly decomposed into fragments that concentrated in the liver.

The nature of the technetium complexes formed is uncertain. The presence of two mercapto groups in the dicarboxylic acid molecules was necessary for good kidney uptake of the complexes. Comparative studies in this laboratory[6] using various monomercapto homologs such as ^{99m}Tc-mercaptoacetic acid and ^{99m}Tc-thiolactic acid showed that these complexes were more rapidly excreted and that their renal uptake was lower.

Reduction of pertechnetate with stannous chloride was used in this study because it was easy, rapid, and convenient. The complexes prepared by this method accumulated sufficiently in the kidney. However, reduction with hydrogen bromide, which can be used for a variety of mercaptan compounds, gave a higher deposition in the kidney with a considerable reduction in the excretion rate. Table II shows the distribution of V prepared by this method. The reason for the higher uptake is unknown. It may be due to the formation of a purer complex than that formed by tin reduction or to formation of an entirely different complex with higher specificity for kidney tissue.

Further studies are in progress to investigate the nature of complex formation as well as the chemical structure–kidney localization relationship.

Hydrocortisone Stability in Human Feces

JANIS J. MacKICHAN ˣ and WILLIAM J. JUSKO

Received July 31, 1978, from the *Clinical Pharmacokinetics Laboratory, Department of Pharmaceutics, School of Pharmacy, State University of New York at Buffalo,* and *Millard Fillmore Hospital, Buffalo, NY 14209.* Accepted for publication November 1, 1978.

Abstract □ Hydrocortisone stability in human feces was studied under various conditions to determine whether stability accounts for the variable effects of hydrocortisone enemas. Recovery from feces and assay specificity were assured using dual isotopes, TLC separation, and liquid scintillation counting. Hydrocortisone degraded slightly from 7 to 26% in 24 hr when incubated in fresh human feces at 37°. Less than 7% degradation occurred in feces stored at 10°, and negligible degradation occurred with hydrocortisone in water at 37°. Fecal bacteria may account for the observed degradation. Hydrocortisone stability in feces may contribute to local persistence and may account partly for its efficacy in ulcerative colitis treatment.

risk of side effects (1–3).

Reported systemic hydrocortisone absorption following rectal administration is 0–50% of that seen after oral administration (1, 3). The reason for incomplete rectal absorption is uncertain. In particular, hydrocortisone stability in the colo-rectal environment has never been demonstrated. Fecal bacteria are capable of 21-dehydroxylating certain corticoids (4, 5) and may degrade hydrocortisone in feces.

This paper describes the analysis and *in vitro* stability of hydrocortisone in human feces incubated at 37°.

EXPERIMENTAL

Materials—1,2-^{3}H-Hydrocortisone [250 μCi/0.002 mg in 0.25 ml of benzene–ethanol (9:1)] and 4-^{14}C-hydrocortisone [50 μCi/0.33 mg in 2.5 ml of benzene–ethanol (9:1)] were received[1] in sealed ampuls. The ^{3}H-hydrocortisone was diluted to 15 ml with benzene–ethanol (9:1).

Hydrocortisone as the free alcohol[2] and two commercial hydrocortisone rectal enema suspensions[3] were used as received. Acetone, ethanol, trichloroacetic acid, benzene, methylene chloride, sodium chloride, and sodium hydroxide were reagent grade. Reagents and standards were prepared with distilled and deionized water.

Fecal samples were collected in 1-liter polytef-lined[4] metal paint cans[5]. Hydrocortisone was extracted from fecal homogenate using 50-ml conical polyethylene tubes[6], and extracts were separated on silica gel 60 F-254 precoated TLC plates[7]. Radioactive samples and quenched standards were prepared with a universal liquid scintillation cocktail[8].

Apparatus—Hydrocortisone on TLC plates was visualized using a short wavelength (254 nm) UV visualizing cabinet[9]. Dual-labeled samples were counted with a liquid scintillation spectrometer[10].

Radiochemical Standards—Dilute stock solutions of ^{3}H- and ^{14}C-hydrocortisone were prepared. Aliquots (0.3 ml) of ^{3}H-hydrocortisone (16.7 μCi/ml) and ^{14}C-hydrocortisone (20 μCi/ml) were transferred to separate 50-ml volumetric flasks and diluted to volume with benzene–ethanol (9:1). These solutions were stored in amber, glass-stoppered bottles at 10°.

Ethanolic radioactive hydrocortisone standard solutions were prepared as needed by evaporating small volumes (3–5 ml) of the stock solutions under nitrogen and reconstituting immediately with equal volumes of pure ethanol. These solutions were used for no longer than 72 hr and were stored in darkness at 10°.

Quenched Standards—A set of quenched standards was prepared for ^{3}H- and ^{14}C-hydrocortisone to facilitate counting efficiency determination of each isotope.

To each of six scintillation vials were added 10 ml of scintillation cocktail, 3 ml of water, and 100 μl of either ^{3}H- or ^{14}C-hydrocortisone stock solution. Acetone was added as a quenching agent so that one vial in each set contained 0, 0.1, 0.3, 0.5, 0.7, or 0.9 ml.

Standard curves were prepared by plotting the external standards ratio (an index of quench) *versus* the counting efficiency of each label in two preset energy channels.

Stability Protocol—Hydrocortisone stability was tested as three different formulations in biological specimens and under various conditions:

1. Incubation in feces at 37°—hydrocortisone enema I, three subjects; hydrocortisone enema II, one subject; and hydrocortisone free alcohol, one subject.
2. Incubation in feces at 10°—hydrocortisone enema I, one subject.
3. Incubation in water at 37°—hydrocortisone enema II, one subject.

Fecal Collection—Fresh fecal samples were collected from three healthy volunteers in clean dry-weighed metal cans. The cans were weighed again, an equal weight of water was added, and the contents were shaken vigorously for 1 hr.

Incubation—Each test series consisted of 1-g aliquots of fecal homogenate or water in six 50-ml plastic tubes. To each set of tubes was added hydrocortisone enema I, II, or aqueous hydrocortisone free alcohol so that the resulting hydrocortisone concentration in each sample was 0.25 mg/g.

Freshly prepared ethanolic ^{14}C-hydrocortisone solution (150 μl, ~39,960 dpm) was added to each tube, and the contents were vortexed for 30 sec. The tubes were sealed, covered with foil, and placed in either a constant-temperature water bath at 37° or a refrigerator at 10°.

Samples from each test series were removed from incubation at 0, 3, 6, 11, 14, and 24 hr. Freshly prepared ^{3}H-hydrocortisone in ethanol (150 μl, ~33,300 dpm) was added immediately to each tube to serve as an internal recovery standard and to account for losses during extraction. Six milliliters of trichloroacetic acid (6%) was added, and the contents were vortexed for 1 min. Following centrifugation at 3000 rpm for 10 min, the supernate was transferred to a clean plastic tube and stored at 10°.

Analytical Procedure—*Extraction*—To the supernate were added 4 ml of saturated sodium chloride solution and 35 ml of methylene chloride. After shaking vigorously for 30 min, the mixture was centrifuged at 3000 rpm for 5 min. The aqueous layer was aspirated and discarded. Then 10 ml of 0.1 *N* NaOH was added, and the mixture was vortexed for 15 sec. Following centrifugation at 3000 rpm for 5 min, the aqueous layer was again aspirated and discarded. The resultant methylene chloride phase was evaporated to dryness in the same tube under nitrogen with gentle heat (55°) provided by a water bath.

TLC—The residue was reconstituted with 100 μl of methylene chloride. Approximately 20 μl of this solution was spotted on the TLC plate with a 5-μl capillary tube. A known hydrocortisone standard in methylene chloride (0.5 mg/ml) was also spotted on the plate. Plates were developed in benzene–acetone (50:50) for the entire length of the plate (18 cm). The steroid R_f was 0.4. The hydrocortisone in each sample was visualized under UV light at 254 nm and compared to the hydrocortisone standard. Degradation products were observed but were not identified.

Liquid Scintillation Spectrometry—The silica was scraped from sections of the plate corresponding to unchanged hydrocortisone and placed in a scintillation vial containing 10 ml of scintillation cocktail and 3 ml of water. Cocktails were prepared to quantitate the actual disintegrations per minute in the ethanol solutions of ^{3}H- and ^{14}C-hydrocortisone that were added to these samples.

All samples were run with the two quenched standards sets and counted for approximately 10 min or 10,000 cpm under preset dual-label counting conditions.

Calculations—Unchanged ^{14}C-hydrocortisone radioactivity (disintegrations per minute) was analyzed as a function of time in all test groups. The amount of unchanged ^{14}C-hydrocortisone in each sample before extraction was determined as follows.

The disintegrations per minute of carbon 14 in a sample was determined by:

$$^{14}\text{C dpm} = {}^{14}\text{C cpm/efficiency of } {}^{14}\text{C in } {}^{14}\text{C channel} \quad \text{(Eq. 1)}$$

The counts per minute of hydrogen 3 in each sample was corrected for its efficiency in the hydrogen 3 window as well as the efficiency of carbon 14 in the hydrogen 3 window:

$$^{3}\text{H dpm} = \frac{{}^{3}\text{H cpm} - ({}^{14}\text{C dpm} \times \text{efficiency of } {}^{14}\text{C in } {}^{3}\text{H window})}{\text{efficiency of } {}^{3}\text{H in } {}^{3}\text{H window}} \quad \text{(Eq. 2)}$$

The internal standard (^{3}H-hydrocortisone) recovery efficiency was determined by:

$$\text{recovery efficiency} = \frac{{}^{3}\text{H dpm}}{\text{known } {}^{3}\text{H dpm added to sample}} \quad \text{(Eq. 3)}$$

The unchanged ^{14}C-hydrocortisone present in the sample before extraction was then calculated:

$$\text{actual } ^{14}\text{C dpm} = \frac{^{14}\text{C dpm calculated}}{\text{recovery efficiency}} \qquad \text{(Eq. 4)}$$

Extraction Efficiency and Reproducibility—^{14}C-Hydrocortisone and ^{3}H-hydrocortisone were added to six 1-g fecal homogenate samples, and the extraction procedure was performed. Following extraction, the methylene chloride phase was transferred to an empty scintillation vial and dried under nitrogen with gentle heat. Scintillation cocktail and water were added to the vials, and they were counted using the dual-label setting. The mean recovery of each labeled compound from feces was determined as well as the variability in recovery.

Added Radioactivity Recovery—The appearance of ^{14}C-hydrocortisone degradation products with time was quantitated for one incubated fecal sample set. After the regions corresponding to unchanged hydrocortisone had been scraped from the TLC plates, the remaining silica gel for the 0-, 11-, and 24-hr samples was scraped into separate vials and counted. Added ^{14}C-hydrocortisone recovery (unchanged and degraded) was calculated for each sample.

RESULTS

Extraction Technique—The efficiency and reproducibility of the technique are shown in Table I. The similarity in recoveries of the two labeled compounds in each sample indicates that either compound may be used as an internal recovery standard for the other. The extraction procedure reproducibility was good with a variation coefficient of about 5%.

Stability Studies—Hydrocortisone degradation over time under various conditions is presented in Fig. 1. Hydrocortisone enema I degradation in the feces of three different subjects ranged from 4.4 to 12.3% in 6 hr and from 7 to 26% in 24 hr (Fig. 1A). This same formulation showed negligible degradation when incubated at 37° in water (Fig. 1B). A study comparing hydrocortisone degradation in the feces of one subject under different temperature conditions (Fig. 1C) showed only 6.5% degradation at 10° as compared to 26% at 37° in 24 hr.

The degradation of three hydrocortisone formulations in the incubated feces of one subject (Fig. 1D) ranged from 13.6 to 26%, with the least degradation occurring with hydrocortisone free alcohol.

Added Radioactivity Recovery—At 0, 11, and 24 hr, the total carbon 14 percent present on the TLC plate as degradation product was 3.5, 9.6, and 15.6%, respectively. The added carbon 14 percent recovery, as both unchanged and degraded hydrocortisone, was 102, 89.3, and 83.1 for the 0-, 11-, and 24-hr samples, respectively. Inability to extract degradation products from feces as efficiently as unchanged hydrocortisone may account for the observed decrease in total radioactivity recovery with time. These results might also be explained by increased binding of unchanged hydrocortisone to incubated feces over time.

DISCUSSION

Hydrocortisone incubation in human feces resulted in as much as 26% degradation over 24 hr. Hydrocortisone given as an enema, however, is rarely retained in the rectum and colon longer than 6 hr, and the maximum observed degradation was 12% at this time.

Fecal material itself causes hydrocortisone degradation rather than temperature and hydrolysis (Fig. 1B). Relative hydrocortisone stability in water at 65° was previously reported (6) as a degradation $t_{1/2}$ of 25 days. A lower temperature apparently confers protection against degradation in feces (Fig. 1C). This phenomenon may be consistent with bacterial hydrocortisone degradation. Other investigators (4, 5) recently isolated and characterized in human feces bacterial organisms capable of metabolizing corticosteroids.

The small amount of hydrocortisone added to feces in the study (0.25 mg/g of fecal homogenate) was chosen to provide realistic exposure of hydrocortisone to fecal material, thus maximizing any possible degradation. The usual rectal hydrocortisone dose is 100 mg. Because the fecal samples were diluted twofold, the hydrocortisone concentration was actually 0.5 mg/g of feces. This concentration was selected assuming an average of 200 g of feces in the rectum at the time of hydrocortisone administration.

Because the greatest hydrocortisone loss was 26% in 24 hr at 0.5 mg/g of feces, only 6.5% of the drug should degrade in 6 hr if the process is first order. Extrapolation of these results to the clinical situation shows that even with a large fecal content in the rectum and thorough mixing of the

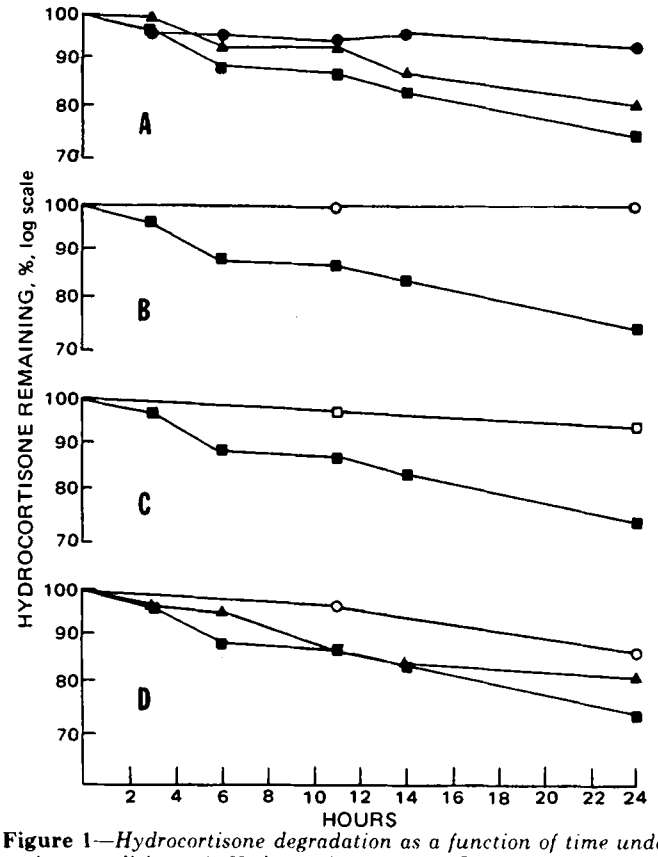

Figure 1—*Hydrocortisone degradation as a function of time under various conditions. A. Hydrocortisone enema I degradation in fecal samples from three human volunteers. Samples were incubated at 37°. administered hydrocortisone with rectal contents, little of the drug should actually be degraded during retention. For a 100-mg dose, only 6.5 mg should degrade in 6 hr.

It is widely assumed that the therapeutic benefit of hydrocortisone enemas is due in part to local action on the intestinal mucosa of ulcerative colitis patients. Previous studies (1, 3) suggested that hydrocortisone is incompletely absorbed through the intestinal mucosa and, therefore, persists in and acts upon the large intestine and rectum. A local effect could also result from lower GI tract exposure to the steroid during absorption. This demonstration of minimal hydrocortisone degradation in fecal material excludes one potential factor responsible for incomplete systemic availability of rectally administered hydrocortisone. Other factors that may account for incomplete systemic hydrocortisone availability include first-pass intestinal mucosa and/or liver metabolism and slow absorption and inadequate retention in the lower bowel.

Plasma Pentazocine Radioimmunoassay

J. E. PETERSON ˣ, M. GRAHAM, W. F. BANKS, D. BENZIGER, E. A. ROWE, S. CLEMANS, and J. EDELSON

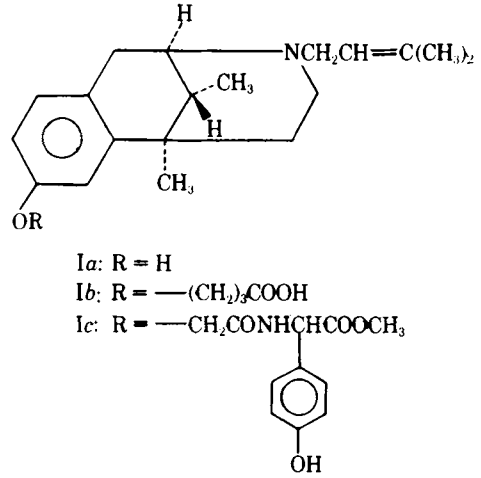
Received September 19, 1978, from the *Department of Drug Metabolism and Disposition, Sterling-Winthrop Research Institute, Rensselaer, NY 12144.* Accepted for publication October 31, 1978.

Abstract □ A sensitive and specific radioimmunoassay of dog and human plasma pentazocine is described. Rabbit antiserum and the second antibody method separated bound from free pentazocine. The radioimmunoassay employed an ^{125}I-labeled radioligand and required extraction from the sample prior to quantitation. The method had a detection limit of approximately 200 pg/assay tube (1 ng/ml). The assay was used successfully to measure pentazocine in the plasma of beagle hounds given 0.3 mg of pentazocine/kg iv. The decline in plasma levels fitted a two-compartment body model with a 100-min mean overall half-life and a 3.2-liters/hr mean plasma clearance rate.

Keyphrases □ Pentazocine—radioimmunoassay, dog and human plasma, pharmacokinetics □ Radioimmunoassay—pentazocine, dog and human plasma □ Pharmacokinetics—pentazocine, dog and human plasma, radioimmunoassay □ Analgesics—pentazocine, radioimmunoassay, dog and human plasma, pharmacokinetics

Pentazocine, (2α,6α,11R*)-(±)-1,2,3,4,5,6-hexahydro-6,11- dimethyl-3- (3-methyl-2- butenyl) -2,6- methano-3-benzazocin-8-ol[1] (Ia), is a member of the benzomorphan series of compounds (1). Pentazocine is a potent analgesic and a weak narcotic antagonist, possessing little dependence potential (2). Both oral and parenteral formulations have found widespread clinical use. To estimate the plasma pentazocine concentration accurately and conveniently, a rapid and sensitive method was needed. Previous methods include a fluorometric technique with a sensitivity of 30–50 ng/ml of plasma (3) and a GLC method with greater specificity and sensitivity (3 ng/ml) but which was more difficult to perform (4). A radioimmunoassay using ^{3}H-pentazocine (5) had no advantage in sensitivity over the GLC method.

This study reports a new radioimmunoassay, using a ^{125}I-labeled pentazocine derivative, with sensitivity in the subnanogram range. This assay has been used to measure pentazocine in both human and dog plasma. The technique permitted determination of pentazocine pharmacokinetic parameters in dogs that received a 0.3-mg/kg iv dose.



Ia: R = H
Ib: R = —$(CH_2)_3$COOH
Ic: R = —$CH_2CONHCHCOOCH_3$

EXPERIMENTAL

Solutions—Iodination buffer contained 0.5 *M* Na_2HPO_4–0.5 *M* NaH_2PO_4 (4:1), adjusted to a final pH of 7.5. Dilute iodination buffer was the same buffer diluted 1:10 with water. Phosphate-buffered saline was prepared by dissolving 24.51 g of NaCl, 1.77 g of $NaH_2PO_4 \cdot H_2O$, 3.21 g of Na_2HPO_4, and 0.285 g of thimerosal[2] in 3 liters of distilled water and adjusting the pH to 7.0. The assay buffer contained 0.1% (w/v) gelatin dissolved in phosphate-buffered saline. Nonimmune normal rabbit serum was diluted 1:400 in phosphate-buffered saline containing 0.05 *M* edetate sodium[3].

Antipentazocine Serum Preparation—A carbodiimide condensation (6) conjugated a pentazocine hapten[4] (Ib) with bovine serum albumin basic amino acid residues. Approximately 17 hapten molecules were conjugated to each albumin molecule, as shown by a trinitrobenzenesulfonic acid free amino group determination (7). The hapten-protein conjugate (2.0–3.0 mg/rabbit) was emulsified in complete Freund's adjuvant[5] and injected intradermally at several sites on the backs of seven Dutch belted rabbits (8). Conjugate (1.0 mg/rabbit) in incomplete Freund's adjuvant was administered as a booster immunization at approximately 3-week intervals for 3 months. Serum was obtained from blood collected from rabbit marginal ear veins.

Second Antibody Preparation—Rabbit γ-globulin[6] (100 μg), emulsified in complete Freund's adjuvant, was injected subcutaneously at monthly intervals into an adult female goat to obtain anti-rabbit γ-globulin. The goat was bled 2 weeks after each immunization, and serum was obtained. The appropriate second antibody dilution was determined by a progesterone assay[7]; a 1:16 dilution was used.

Radioiodination—At room temperature, a methyl tyrosinate pentazocine derivative[8] (Ic) was radiolabeled by a modified method (9). Sodium ^{125}I-iodide[9] (1.0 mCi) was added to a vial containing 50 μl of iodination buffer and 10 μl of the methyl tyrosinate derivative (1 mg/ml of methanol). The vial was stoppered, and the contents were gently agitated. Thirty micrograms of chloramine-T[10] in 15 μl of dilute iodination buffer was added, and the mixture was allowed to react for 2 min. Then 60 μg of sodium metabisulfite in 30 μl of dilute iodination buffer was added to the vial to stop the reaction.

A solution (100 μl) containing 16% (w/v) of sucrose dissolved in assay buffer was added, and the sample was transferred to a 0.5 × 20-cm gel filtration[11] column, which had been equilibrated with assay buffer. Then 70 μl of 8% (w/v) sucrose dissolved in assay buffer was used to rinse the vial, and the wash solution was added to the column. The column was eluted with assay buffer, and 1.0-ml fractions were collected and counted to determine the radioactivity.

Extraction Procedure—Duplicate samples (0.1 or 0.2 ml) of pentazocine-containing plasma were added to extraction tubes (15 × 85 mm). Pentazocine standards (1–100 ng/ml) were included. Water (0.8 or 0.9 ml) and saturated sodium bicarbonate–sodium carbonate extraction buffer (0.1 ml) were added to the plasma in each extraction tube. Ben-

zene[12] (8 ml) was added, and the tubes were shaken mechanically for 15 min. Then tubes were centrifuged for 5 min at 2200×*g*, and duplicate benzene aliquots were removed and placed in appropriately labeled tubes (12 × 75 mm) for the assay. The benzene was evaporated under a nitrogen stream, and the residue was dissolved in 0.5 ml of assay buffer. The tubes were mixed, stoppered, and left overnight at 4°.

Radioimmunoassay—The pentazocine radioimmunoassay was similar to procedures reported for steroids (10). The antipentazocine serum (200 μl), at a dilution of 1:15,000 in normal rabbit serum, was added to the assay tubes containing the plasma extracts. Radioiodinated tyrosinate pentazocine derivative (25,000–30,000 cpm/100 μl) was added. The tubes were incubated for 4–6 hr at 4°. Appropriately diluted second antibody (200 μl) was added, and the incubation was continued overnight.

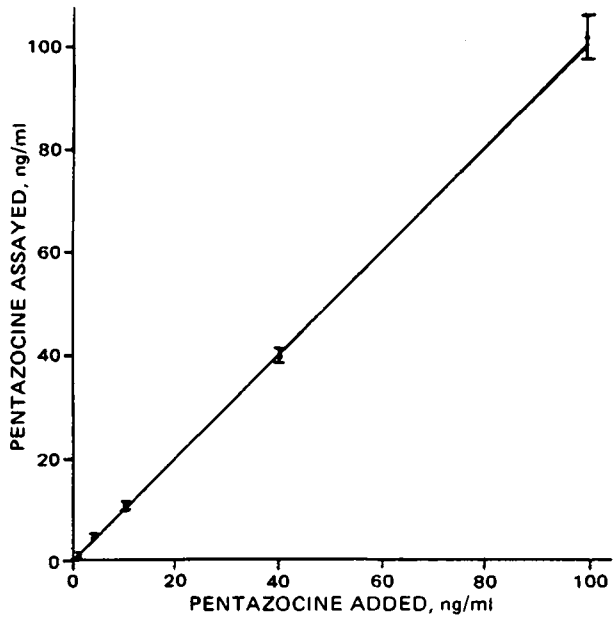

Figure 1—*Correlation of pentazocine added to human plasma with the mean values obtained by radioimmunoassay. Slope = 1.020, intercept = 0.034, and r (correlation coefficient) = 0.9705. The short vertical lines represent 2* SE (n = *8).*

[12] Analytical reagent, Mallinckrodt, St. Louis, Mo.

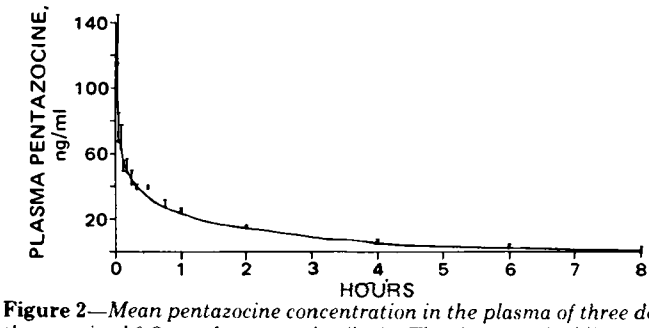

Figure 2—*Mean pentazocine concentration in the plasma of three dogs that received 0.3 mg of pentazocine/kg iv. The short vertical lines represent 1* SE.

After incubation, 2.5 ml of cold phosphate-buffered saline was added, and the tubes were centrifuged at 2500 rpm for 30 min. The supernatant solutions were discarded, and the precipitates were counted. Duplicate standards (1–100 ng/ml) were included in each assay run.

Dog Study—One male (12.6 kg) and two female (9.6 and 17.2 kg) beagle hounds were given 0.3 mg of pentazocine/kg iv (calculated as the free base), prepared as a 3-mg of pentazocine/ml of physiological saline solution.

Blood samples (3–5 ml) were collected from an indwelling venous catheter from 1.0 min to 8 hr after administration. Potassium oxalate was the anticoagulant. The samples were centrifuged, and the plasma was frozen until analyzed.

RESULTS AND DISCUSSION

All seven rabbits produced antiserum within 6 months; the antiserum titers ranged from 1:1000 to 1:20,000. The 1:15,000 antiserum dilution (~1:75,000 final dilution in the assay tube) resulted in 50–55% radioligand binding.

The antiserum specificity was assessed by three related methods. First, the ability of several related compounds, including known pentazocine metabolites, to compete with the radioiodinated pentazocine tyrosinate derivative for antibody binding was determined by comparing the amount of each compound required for 50% radioactivity binding inhibition with the pentazocine standard curves (11). Second, the percent displacement of the related compounds was evaluated (12). Third, the percent cross-reactivity of the related compounds was determined in extracted plasma.

The antiserum exhibiting the least cross-reactivity was selected for all subsequent work. The relative affinities of the related compounds for this antiserum are shown in Table I. The two compounds (II and III) that demonstrated a slight cross-reactivity with pentazocine (I) are not metabolites and posed no problem. The known metabolites (13) of pentazocine (*trans*-acid, *trans*-alcohol, and norpentazocine; X, VII, and IX, respectively) showed little affinity for this pentazocine antiserum.

The assay sensitivity or detection limit (14) is the smallest compound amount that is significantly different from zero at the 95% confidence limit. The human plasma blank gave a detection limit of 0.21 ng/assay tube. The dog plasma blanks gave a limit of 0.19 ng/tube. These values correspond to about 1 ng of compound/ml of plasma.

Precision was tested by calculating the within-assay and between-assay variances. The within-assay variance was evaluated by duplicate measurements of the same sample, and the between-assay variance was evaluated by duplicate measurements in different assays using samples with a wide range of concentrations. The variation coefficient from the mean duplicate determinations was estimated (15). The within-assay variation coefficient ranged from 7.4 to 10.1% (mean 8.2%, $n = 18$). The between-assay variation coefficient ranged from 10.5 to 13.2% (mean 11.6%, $n = 3$). These values are within the range reported for steroid radioimmunoassays (11).

Exogenous pentazocine was accurately quantitated in human plasma by the pentazocine radioimmunoassay system (Fig. 1). A similar correlation was found for canine plasma. No statistical difference was found between canine and human plasma standards.

The mean plasma pentazocine concentrations in the three dogs are shown in Fig. 2. Plasma levels declined biexponentially with time, suggesting that a two-compartment model could be applied. Pharmacokinetic parameters were computer fitted by a modified program (16) (Table II). Previous work indicated that the two-compartment model was applicable to pentazocine pharmacokinetics in dogs (17). The re-

ported pentazocine terminal elimination half-life of 150 min in dogs is in good agreement with the present estimate (102 min, Table II). The two-compartment model was used recently to describe pentazocine pharmacokinetics in healthy humans (18) where the average terminal disposition half-life was 203 min.

Drug Entrapment for Controlled Release in Radiation-Polymerized Beads

MASARU YOSHIDA, MINORU KUMAKURA, and ISAO KAETSU ×

Received June 20, 1978, from the *Takasaki Radiation Chemistry Research Establishment, Japan Atomic Energy Research Institute, Takasaki, Gunma, Japan.* Accepted for publication October 31, 1978.

Abstract □ The preparation of beads including polymer, vinyl monomer, and drug was carried out by low temperature, radiation-induced polymerization. Complete spherical particles were obtained when ethanol was the precipitation medium. Polymers such as polymethyl methacrylate and polystyrene were dissolved in various glass-forming monomers, and the drug was dispersed in the mixture. The mixture was dropped into cold precipitation media. The formed monomeric particle was irradiated at low temperatures to produce polymerization. The drug release profiles from polymerized particles were changed by varying the glass-forming monomer and the precipitation medium.

Keyphrases □ Dosage forms—controlled-release delivery devices, radiation-polymerized beads, potassium chloride □ Potassium chloride—controlled-release delivery devices, radiation-polymerized beads □ Polymers—controlled-release delivery devices, beads, potassium chloride

Controlled drug release may improve effectiveness and safety in drug use (1–3). Drug entrapment in polymerized matrixes may be an effective way to control release. Various bioactive materials, such as enzymes or microbial cells, could first be attached effectively to a carrier surface and then incorporated into a polymer by means of radiation-induced polymerization at low temperatures (4, 5). This method can be performed using monomers that form stable glass-like states when supercooled and that can be readily polymerized at low temperatures (6).

This method can be applied to entrapping low molecular weight drugs for controlled release as well as high molecular weight bioactive substances. Entrapping drugs in fine polymer particles, such as microspheres, could have practical advantages. Trapping enzymes or microbial cells on a carrier surface is desirable for the contact with the substrate (7). Immobilized enzyme or microbial cell microspheres were obtained by suspension polymerization of a hydrophobic glass-forming monomer and a buffered enzyme solution at low temperatures or by polymerization

of the salted-out hydrophilic glass-forming monomer and a buffered enzyme solution.

Drugs also can be entrapped inside the microsphere polymer matrix, because low molecular weight substances leach too rapidly from the surface-sorbed state. In this report, a new method for small solid particle preparation incorporating drugs inside the matrix by means of radiation-induced polymerization at low temperatures was investigated.

EXPERIMENTAL

Materials—Potassium chloride[1] was the drug used.

2-Hydroxyethyl methacrylate[2], diethylene glycol dimethacrylate[3], trimethylolpropane trimethacrylate[3], glycidyl methacrylate[2], and hydroxyethyl acrylate[2] were the glass-forming monomers. Methyl methacrylate[2] was the nonglass-forming monomer.

Reagent grade methanol[2], ethanol[2], n-buthanol[2], n-hexane[2], and 1,4-butanediol[2] were the precipitation media. Polymethyl methacrylate[4], polyethylene glycol 600[2], and polystyrene[5] were the polymers used.

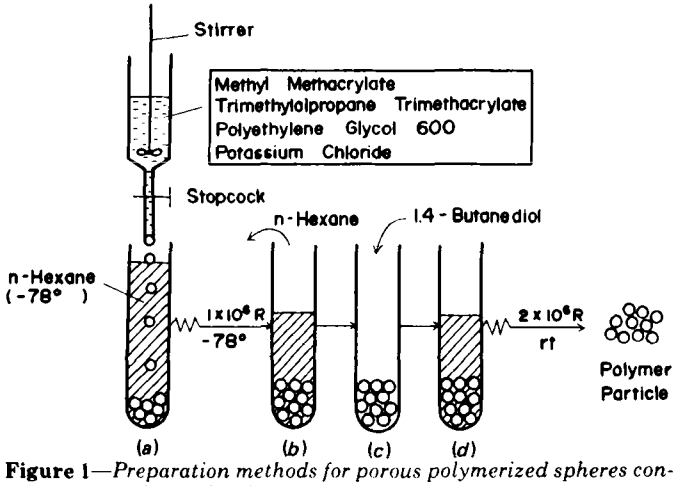

Figure 1—*Preparation methods for porous polymerized spheres containing potassium chloride.*

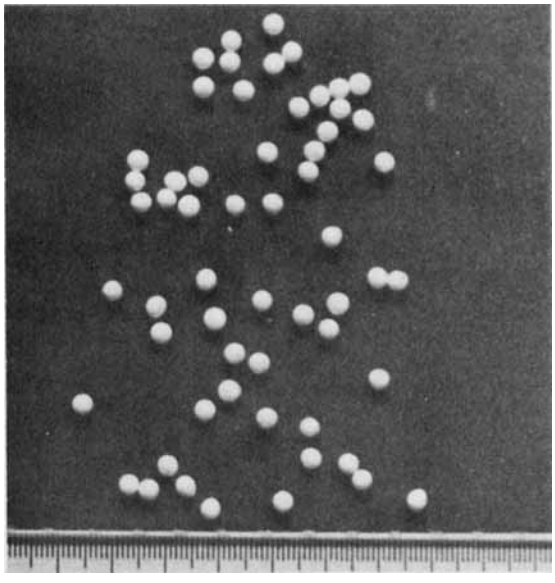

Figure 2—*Photograph of spherical particles.*

Preparation of Radiation-Polymerized Beads—Drops of polymer, monomer, and drug (potassium chloride) mixtures were allowed to fall into a cold (−78°) precipitation medium with the equipment shown in Fig. 1*a*. The solid globules were irradiated at −78° (dry ice–methanol) or −24° for 2 hr at 1×10^6 rads/hr with ^{60}Co γ-rays. After irradiation, the polymerized spheres were removed and dried. When polyethylene glycol 600 replaced the polymers polymethyl methacrylate or polystyrene, the solidified globules were irradiated for 1 hr at 1×10^6 rads/hr. Then the original n-hexane precipitation medium was replaced by cooled 1,4-butanediol, and polymerization was continued for 2 hr at room temperature at the same rate.

Properties of Spheres—The mean particle diameter, D_{av}, was measured by optical microscopic observation[6], and the mean potassium chloride amount, C_{KCl}, was estimated from the potassium chloride released from the beads. To estimate the polymer hydrophilicity, water content, W, was determined according to:

[1] About 48-mesh powder, Otsuka Pharmaceuticals Co.

[2] Tokyo Kasei Kogyo Co. Monomers were purified by distillation according to conventional methods.

[3] Shin-Nakamura Chemical Co. Monomers were purified by washing with 1% NaOH, passing over Amberlite A-27 (Rohm & Haas), and drying over molecular sieves 4A.

[4] Mitsubishi Rayon Co.

[5] Denki Kagaku Co.

[6] Model SMZ-6, Nippon Kogaku Co.

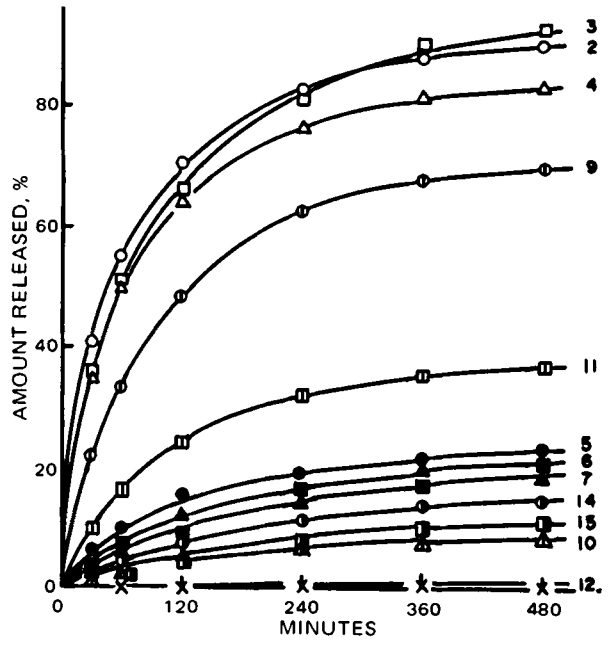

Figure 3—*Potassium chloride release profile from polymerized particles. Numbers refer to compositions (Table I).*

$$W\,(\%) = \frac{W_w}{W_p + W_w} \times 100 \qquad \text{(Eq. 1)}$$

where W_w and W_p are the weights of the water required to saturate the polymer and of the dried polymer, respectively.

Dissolution of Potassium Chloride from Polymerized Spheres—The dissolution test was carried out at 37°, 100 rpm, with the dissolution apparatus[7] based on USP XIX. The basket was immersed in the vessel containing 1000 ml of dissolution medium, usually water at pH 6.0. At selected intervals over 480 min, 5 ml of the dissolution medium was sampled and the released potassium chloride was assayed spectrophotometrically[8] (8).

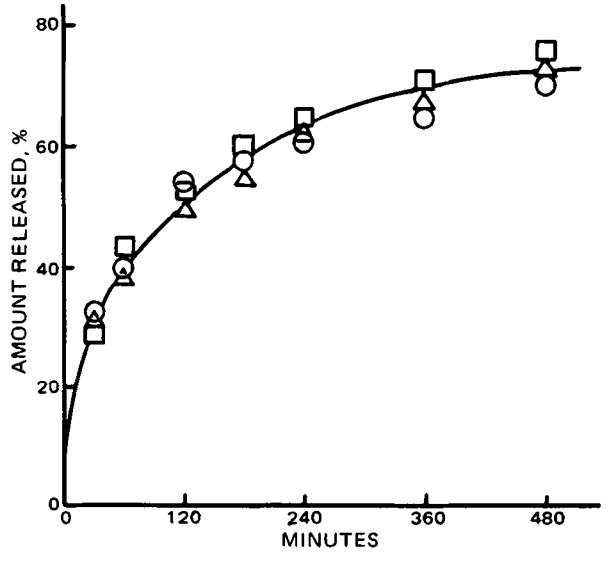

Figure 4—*Potassium chloride release from spheres as a binary monomer composition function in 30% monomers–70% polyethylene glycol 600. Key (monomer composition): ○, 70% methyl methacrylate–30% trimethylolpropane trimethacrylate; □, 50% methyl methacrylate–50% trimethylolpropane trimethacrylate; and △, 30% methyl methacrylate–70% trimethylolpropane trimethacrylate.*

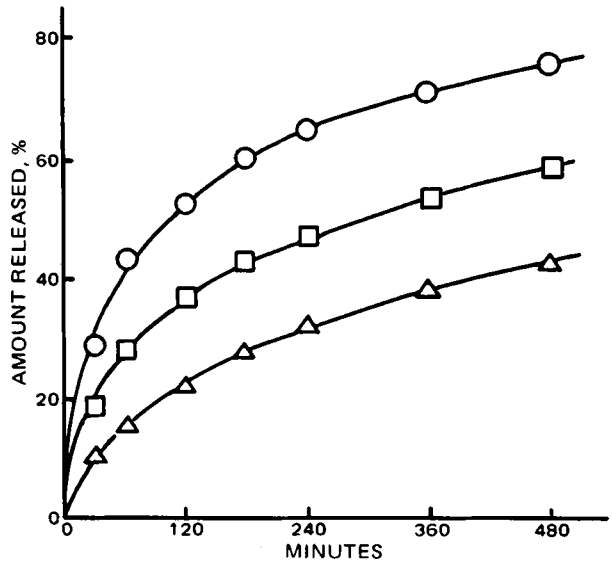

Figure 5—*Potassium chloride release from spheres as a function of polyethylene glycol 600 concentration in 50% methyl methacrylate–50% trimethylolpropane trimethacrylate monomer system. Key (polyethylene glycol 600 concentration): ○, 70%; □, 50%; and △, 30%.*

RESULTS AND DISCUSSION

Nonglass-Forming Monomers—Methyl methacrylate required at least 6% polymethyl methacrylate to form stabilized globules when dropped into cold methanol. Otherwise, the monomer-polymer-drug mixture formed threads or simply coalesced into an immiscible layer. Other precipitation media produced similar results. Methyl methacrylate polymerization did not yield solid spheres at cold temperatures and merely coalesced above 0°.

Glass-Forming Monomers—These monomers gave well-formed solid globules when mixed with polymer and potassium chloride and supercooled. They were easily polymerized by irradiation at the low temperatures used.

Globule Formation—Ethanol as the supercooled precipitation me-

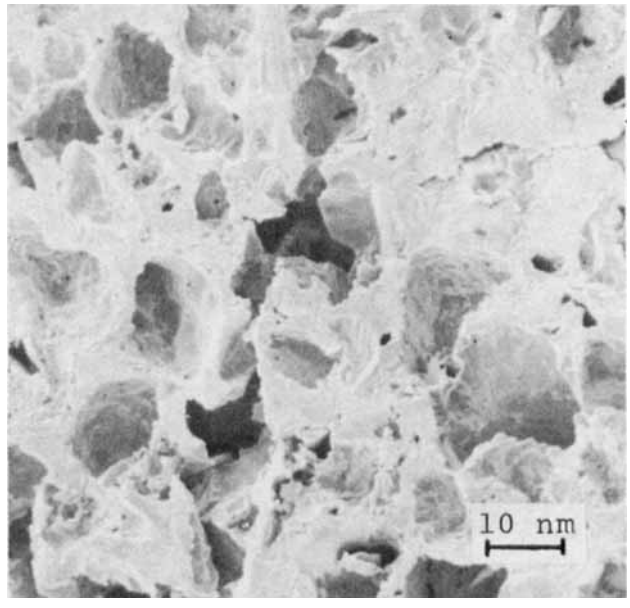

Figure 6—*Scanning electron micrograph of sphere structure. The spheres (2.4 ± 0.2 mm in diameter) were prepared with 30% (methyl methacrylate–trimethylolpropane trimethacrylate)–70% polyethylene glycol 600, a monomer composition of 50% methyl methacrylate–50% trimethylolpropane trimethacrylate, ethanol as the precipitation medium, and a precipitation temperature of −78°. Irradiation was carried out under the conditions shown in Fig. 1.*

dium yielded spherical globules (Fig. 2[9]). Methanol, *n*-butanol, and *n*-hexane formed ellipsoidal globules. Globule formation seemed dependent on the polymer present in the mixture and on a precipitation medium temperature not above −24°. When these conditions were not met, coalescence but not stabilization occurred.

Release of Potassium Chloride—In the spheres containing polymethyl methacrylate as the polymer and diethylene glycol dimethacrylate as the monomer (Samples 2–7), the methanol precipitation medium increased potassium chloride release (Fig. 3). In nonmethanol precipitation media, release from relatively strongly hydrophilic beads (Samples 9 and 11) was faster than that from less hydrophilic matrixes.

The binary monomer spheres containing polyethylene glycol 600 in place of polymer showed a release rate independent of the methyl methacrylate–trimethylolpropane trimethacrylate proportions (Fig. 4). The polyethylene glycol 600 concentration strongly affected potassium chloride release (Fig. 5). Larger polyethylene glycol 600 proportions together with 1,4-butanediol in the final polymerization step yielded spheres with a markedly porous internal structure (Fig. 6[10]).

Received August 3, 1977, from the *Department of Pharmaceutical Chemistry, College of Pharmacy, University of Baghdad, Baghdad, Republic of Iraq.* Accepted for publication October 31, 1978. *Present address: Department of Chemistry, University of Arizona, Tucson, AZ 85721.

Abstract □ Charge transfer complex formation between nucleic acid bases and isoproterenol was demonstrated from UV absorption measurements. The solvent polarity effects on equilibrium constants were investigated. The solvent systems containing 0.1 *N* HCl were 20% aqueous ethanol, water, and water containing sodium chloride. The equilibrium constants, calculated from UV absorption data by the application of the Benesi–Hildebrand equation, were small and increased with increasing ionic strength. Equilibrium constant wavelength dependence was demonstrated in some cases.

Keyphrases □ Complexes, charge transfer—nucleic acid bases with isoproterenol, various solvents, UV absorption study □ Nucleic acid bases—charge transfer complex formation with isoproterenol, various solvents, UV absorption study □ Solvents, various—charge transfer complex formation, nucleic acid bases with isoproterenol, UV absorption study

Catechol forms the catecholamine aromatic nucleus and anchors these molecules to their receptors (1). The adrenergic sites and the biogenic amine storage granules are known to contain adenosine triphosphate, phosphate, and magnesium ions (2, 3). Complex formation between these ions and catecholamines has been demonstrated (4, 5). Evidence for charge transfer complex formation between catechol, epinephrine, and nucleic acid bases has been presented (6–8).

The present study was undertaken to trace the catecholamine action mechanism, to obtain more information about adrenergic receptors, and to investigate adenosine triphosphate-like action of some other storage granule nucleoside triphosphates. UV absorption was used to study the interactions between the nucleic acid bases and isoproterenol in the following solvents containing 0.1 *N* HCl: 20% aqueous ethanol, water, and water containing sodium chloride.

EXPERIMENTAL

Isoproterenol sulfate dihydrate[1], thymine[2], cytosine[2], standard hydrochloric acid solution[2], adenine[3], uracil[3], and sodium chloride[4] (BP) were the highest commercially available purity (>99%) and were used without further purification.

Solutions containing a fixed nucleic acid base concentration (0.02 *M*, except cytosine-containing solutions in 20% alcohol, fixed at 0.01 *M*) and different isoproterenol sulfate concentrations (0.3–0.8 *M*) were prepared by dilution from concentrated standard solutions.

The solvents used were 20% aqueous ethanol containing 0.1 *N* HCl, 0.1 *N* aqueous HCl, and water solutions containing 0.1 *N* HCl and different amounts of sodium chloride.

All solutions were freshly prepared, and their spectra were recorded within 6 hr in 1-cm path length rectangular cells with stoppers. Most experimental work was carried out in subdued light to avoid isoproterenol light oxidation and at room temperature (20–25°).

The spectrophotometers[5] were checked and calibrated with an oxide film[6]. Cell holders were thermostated to maintain the temperature at 25°. The baseline was recorded before the experiments with the same solvent in the reference and in the sample compartments.

dium yielded spherical globules (Fig. 2[9]). Methanol, *n*-butanol, and *n*-hexane formed ellipsoidal globules. Globule formation seemed dependent on the polymer present in the mixture and on a precipitation medium temperature not above −24°. When these conditions were not met, coalescence but not stabilization occurred.

Release of Potassium Chloride—In the spheres containing polymethyl methacrylate as the polymer and diethylene glycol dimethacrylate as the monomer (Samples 2–7), the methanol precipitation medium increased potassium chloride release (Fig. 3). In nonmethanol precipitation media, release from relatively strongly hydrophilic beads (Samples 9 and 11) was faster than that from less hydrophilic matrixes.

The binary monomer spheres containing polyethylene glycol 600 in place of polymer showed a release rate independent of the methyl methacrylate–trimethylolpropane trimethacrylate proportions (Fig. 4). The polyethylene glycol 600 concentration strongly affected potassium chloride release (Fig. 5). Larger polyethylene glycol 600 proportions together with 1,4-butanediol in the final polymerization step yielded spheres with a markedly porous internal structure (Fig. 6[10]).

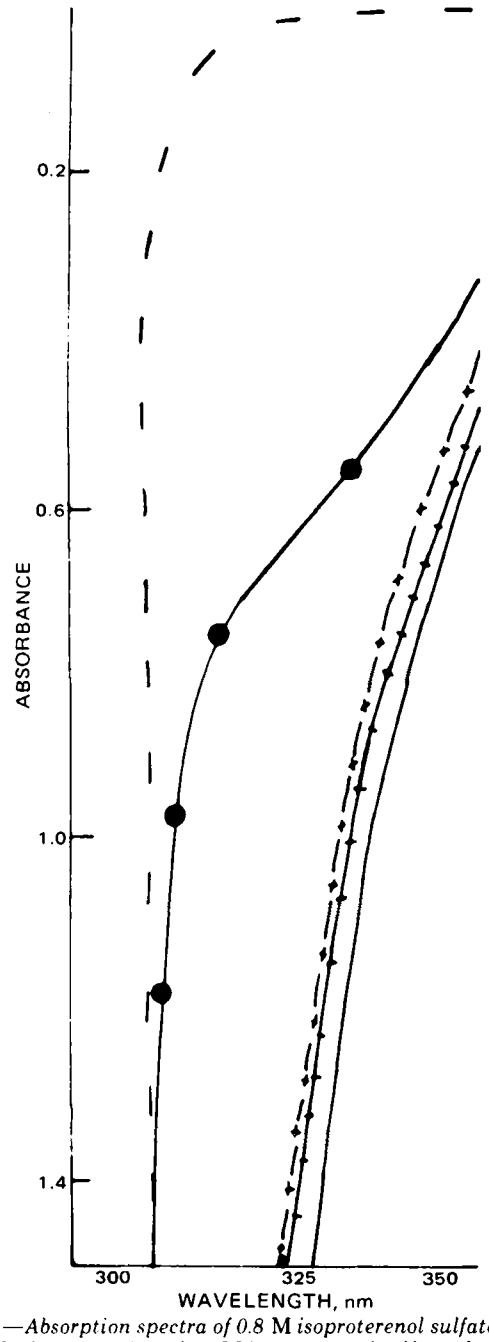

Figure 1—*Absorption spectra of 0.8 M isoproterenol sulfate (-●-), 2 × 10^{-2} M adenine (– –), and 0.8 M isoproterenol sulfate plus 2 × 10^{-2} M adenine (—) in aqueous solutions containing 0.1 N HCl at an ionic strength of 3.0; —+—+— and -×-×- represent the absorption spectra of the mixture at ionic strengths of 3.5 and 4.0, respectively. Measurements were at 25 ± 0.5°.*

RESULTS AND DISCUSSION

A representative nucleic acid base–isoproterenol UV absorption spectrum (Fig. 1) showed a shift toward longer wavelengths. The increase in absorption at longer wavelengths (Table I) was attributed to weakly bonded complex formation.

Isoproterenol and the nucleic acid base absorption at the specified wavelengths depended only on concentration. This result was to be expected if no self-association had taken place. The pH deviation (~0.8) from the initial working acidity, as well as changes in temperature and ionic strength, did not affect the pure component absorption spectra, further supporting the suggestion that the increased absorbance observed in the mixtures was due to complex formation.

Absorbances at different isoproterenol concentrations were estimated from the difference between the mixture absorbance and a sum of the absorbances of the individual substances having concentrations identical to those in the mixture. The absorbances at different wavelengths were calculated from molar absorptivities.

All UV binding interaction measurements were made at fixed wavelengths; for each mixture examined, measurements were made at several wavelengths. The complex absorbance was measured in regions where the free component absorptions were small and the complex absorption was appreciable. The accuracy of these measurements was ±0.01 unit of absorbance.

The complex equilibrium constants were calculated by assuming simple complex formation:

$$A + D = AD \qquad \text{(Eq. 1)}$$

and by application of the Benesi–Hildebrand equation:

$$\frac{[A_0]}{A_\lambda^{AD}} = \frac{1}{\epsilon_\lambda^{AD}} + \frac{1}{(K_c^{AD})(\epsilon_\lambda^{AD})[D_0]} \qquad \text{(Eq. 2)}$$

where K_c^{AD} is the equilibrium constant; $[A_0]$ and $[D_0]$ are the initial concentrations of the reactant species; and A_λ^{AD} and ϵ_λ^{AD} represent the absorbance and molar absorptivity of the complex, respectively, at the wavelength λ.

Equation 2 is based upon the assumption that $[D] \simeq [D_0]$ when designing an experiment such that $[D_0] \gg [A_0]$.

A plot of $[A_0]/A_\lambda^{AD}$ *versus* $1/[D_0]$ leads to an intercept of $1/\epsilon_\lambda^{AD}$ and a slope of $1/K_c^{AD}\epsilon_\lambda^{AD}$, whereby the molar absorptivity and the equilibrium constant can be calculated graphically.

The standard free energy changes associated with various interactions, $\Delta G°$, are calculated from the following well-known equation:

$$\Delta G° = -RT \ln K_c^{AD} \qquad \text{(Eq. 3)}$$

where R is the gas constant and T is the absolute temperature. Representative Benesi–Hildebrand plots are presented in Fig. 2; the thermo-

[a] Measurements were at 25 ± 0.5°. [b] At I = 3.0. [c] At I = 3.5. [d] At I = 4.0.

dynamic constants and molar absorptivities are summarized in Table I.

The molar absorptivities of adenine–isoproterenol and thymine–isoproterenol complexes were higher in water than in water–ethanol; the reverse was obtained with cytosine–isoproterenol. Furthermore, the adenine–isoproterenol and cytosine–isoproterenol complex molar absorptivities were ionic strength dependent.

In general, the equilibrium constants were sensitive to changes in the wavelengths at which the measurements were taken, except for thymine–isoproterenol in water. Almost all equilibrium constants were less than two, except for uracil–isoproterenol in 20% alcohol. Therefore, $\Delta G°$ values were small. The equilibrium constants of adenine–isoproterenol and thymine–isoproterenol (Table I) decreased as the solvent was changed from alcoholic to aqueous, while the cytosine–isoproterenol complex equilibrium constants increased.

Three- and fourfold increases in adenine–isoproterenol equilibrium constants at λ335 and λ330 nm, respectively, were produced by increasing the ionic strength of aqueous solutions from 3.0 to 3.5. A sixfold increase could be obtained at λ330 nm by increasing the ionic strength from 3.0 to 4.0. The same trend was observed for cytosine–isoproterenol equilibrium constants; 2.4- and threefold increases were produced by changing the ionic strength from 3.0 to 3.5 at λ345 and λ340 nm, respectively.

The increase in absorbance at longer wavelength was attributed to charge transfer complex formation where the nucleic acid bases were assumed to act as electron acceptors with catechol or epinephrine as electron donors (6–8). Similar donor and acceptor species may be hypothesized for isoproterenol–nucleic acid base complexes.

Exact complex geometry cannot be determined from UV absorption measurements, but parallel stacking interactions between nucleic acid bases and isoproterenol can be proposed. This mechanism was suggested previously for a similar system (9–12). The geometry is likely to be affected by the stoichiometry (13–17), but the present results are best interpreted by a 1:1 stoichiometry.

To account for the decrease in adenine–isoproterenol and thymine–isoproterenol equilibrium constants as the solvent polarity increases (Table I), the complex dipole moment was assumed to be larger in the excited state than in the ground state, resulting in the formation of a highly polar complex that was more solvated than the sum of the uncombined components. The reverse situation can be assumed for the cytosine–isoproterenol complex (18–20).

Little work has been done on the salt effect on the equilibrium constants. The large increase in equilibrium constants as salt concentrations were increased (Table I) can be explained by assuming ion-pair formation between the chloride ions and the protonated centers around the interacting molecules, resulting in an electrostatic repulsion decrease. Other weaker forces seem to dominate the repulsive forces. The same explanation accounted for the decrease in the equilibrium constants (21–25). Borazan (13, 17) showed that the equilibrium constants of nucleoside self-association and aqueous complex formation are similar to those obtained at higher salt concentrations.

The equilibrium constant wavelength dependence (Table I) could indicate the formation of more than one complex type; the wavelength independence was explained as due to the formation of one complex type in solution (26).

In Vitro and *In Vivo* Availability of Hydrophilized Phenytoin from Capsules

C. F. LERK ˣ, M. LAGAS, L. LIE-A-HUEN, P. BROERSMA, and K. ZUURMAN

Received July 31, 1978, from the *Laboratory for Pharmaceutical Technology, University of Groningen, Antonius Deusinglaan 2, 9713 AW Groningen, The Netherlands.* Accepted for publication November 9, 1978.

Abstract □ The effect of phenytoin hydrophilization on the liquid penetration rate into prepared plugs, on the disintegration time, on the *in vitro* release rate, and on *in vivo* absorption in humans was studied. Hydrophilization was performed by intensive mixing of the hydrophobic drug with a small amount of methylcellulose solution. Liquid penetration into the treated plugs was independent of the liquid wetting potency and extremely high compared to the pure drug plugs. Analogous results were obtained for the disintegration time and *in vitro* release rates from capsules loaded with pure and treated drug. A bioavailability study in seven healthy volunteers showed immediate absorption of the treated drug but a 1-hr absorption lag time for the pure drug.

Keyphrases □ Phenytoin, hydrophilized—*in vitro* and *in vivo* availability from capsules □ Bioavailability—hydrophilized phenytoin, capsule formulation, *in vitro* release rates □ Anticonvulsants—phenytoin, effect of hydrophilization, *in vitro* and *in vivo* availability

When a disintegratable tablet or capsule is administered orally to humans, gastric fluid must penetrate the porous mass before disintegration and absorption can occur. Any factor influencing the penetration rate may influence the absorption rate.

The liquid penetration rate into a porous mass is given by the Washburn (1) equation:

$$\frac{dl}{dt} = \frac{m\gamma \cos\theta}{2l\eta} \qquad \text{(Eq. 1)}$$

where l is the penetrated length at time t, m is the hydraulic pore radius, γ is the penetrating liquid surface tension, θ is the contact angle between solid and liquid, and η is the liquid viscosity. The penetration rate is strongly dependent on the solid contact angle.

In earlier studies on pharmaceutical powder wettability (2, 3), reported contact angles varied from 0° for dicalcium phosphate dihydrate up to 125° for chloramphenicol palmitate. Recently (4), the effect on the capsule release rate of surface hydrophilic binder distribution over a hydrophobic drug was studied. The increased hydrophilized hexobarbital release rate was independent of the dissolution medium wetting potency, in contrast to the untreated drug.

The purpose of this investigation was to examine the penetration rate effect on the *in vitro* and *in vivo* availability of poorly soluble, hydrophobic drugs from capsules. Phenytoin was selected as a prototype drug, exhibiting a contact angle of 102°. Phenytoin bioavailability is important because of the closeness of the therapeutic and toxic levels. Marked bioavailability differences between different products have been reported (5–9).

EXPERIMENTAL

Materials—Phenytoin[1] was NF grade. The mean particle size, based on air permeability measurement[2], was 5 μm. Methylcellulose[3], polysorbate[4], β-glucuronidase[5] (purified lyophilized powder, 5×10^6 units/g), 5-(*p*-methylphenyl)-5-phenylhydantoin[6], and 5-(*p*-hydroxyphenyl)-5-phenylhydantoin[6] were used as received. Trimethylanilinium hydroxide[7] was used as a 0.1 *M* solution in methanol, and tetramethylammonium hydroxide[8] was used as a 25% solution in water.

All solvents and other chemicals were analytical grade, except *n*-heptane which was spectrophotometric grade[9]. The methylene chloride used as a mobile phase component in the high-pressure liquid chromatographic (HPLC) procedure was freshly distilled and 50% saturated with water before use.

Methods—*Treatment of Drug*—Methylcellulose dispersion over the phenytoin surface was carried out in a small high-speed mixer[10]. The drug (20 g) was placed in the mixer, 6 ml of a 3% aqueous binder solution was added, and the mixer was run for 6 min at ~9000 rpm. The mixing was interrupted every 0.5 min to mix, with a spatula, material from dead spots in the mixer. The material was dried in a tray drier at 40° for 1 hr and

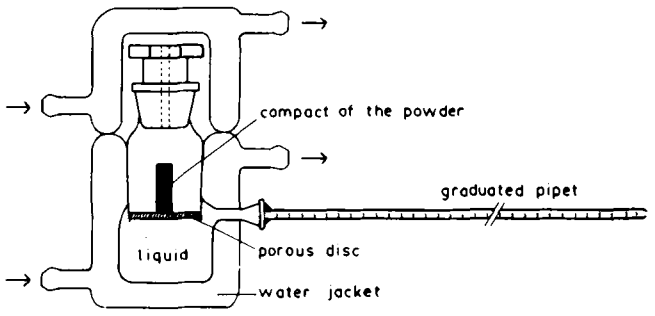

Figure 2—*Thermostated apparatus for measuring unidimensional liquid penetration into the plugs.*

screened through an 80-μm sieve. Treated drug particle-size determination (measured value of 6 μm) and electron micrographs of the untreated and treated powder showed that no milling and hardly any granulation had occurred during preparation.

Wettability—Pure and hydrophilized phenytoin wettability was characterized by contact angle determination as described previously (4).

Plug Preparation—Most commercial capsules are filled by compressing the powder and loading it into the capsule body. To reproduce this process, the pure and treated drugs were compressed with a 120 ± 5 N force to 300-mg plugs (1.8-cm length × 0.6-cm diameter) using a special die and plunger assembly (Fig. 1). The plunger was connected to a load cell for compression force registration.

Capsule Filling—Prepared plugs were manually loaded into No. 1 hard gelatin capsules[11] for the disintegration measurements, the *in vitro* release studies, and the *in vivo* availability studies.

Liquid Penetration—The unidimensional liquid penetration rate into the phenytoin plugs was measured by placing the plug on a modified thermostated apparatus glass filter plate (Fig. 2) (10). The liquid uptake rate was read from the graduated pipet. The penetrations were carried out at 37 ± 0.2° with distilled water or water to which different amounts of polysorbate had been added.

The all-side liquid penetration was measured at room temperature by registration of the phenytoin plug weight increase during penetration. The powder plug was placed in a small glass cylinder with a porous bottom and a gauze cover to prevent floating (Fig. 3). The whole was immersed in the penetrating liquid and connected to an electronic balance[12] with automatic recording. Unidimensional penetration measurements were made four times and averaged. All-side penetrations were so reproducible that they were performed in duplicate only. No significant difference in experimental results was found when the penetrating liquid was presaturated with phenytoin.

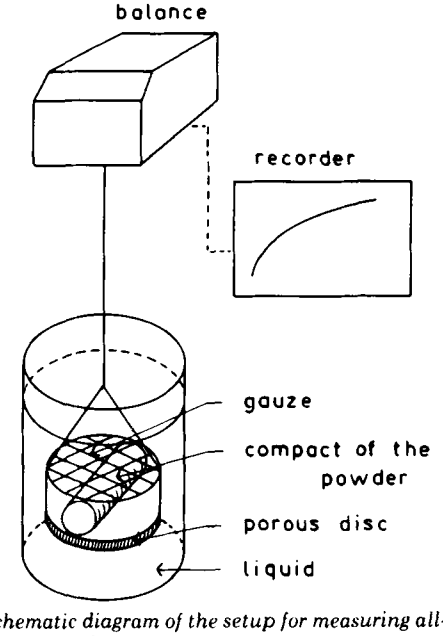

Figure 3—*Schematic diagram of the setup for measuring all-side liquid penetration into the plugs.*

[11] Snap-fit, Capsugel AG, Basel, Switzerland.

[12] PR 1200, Mettler, Greifensee-Zürich, Switzerland.

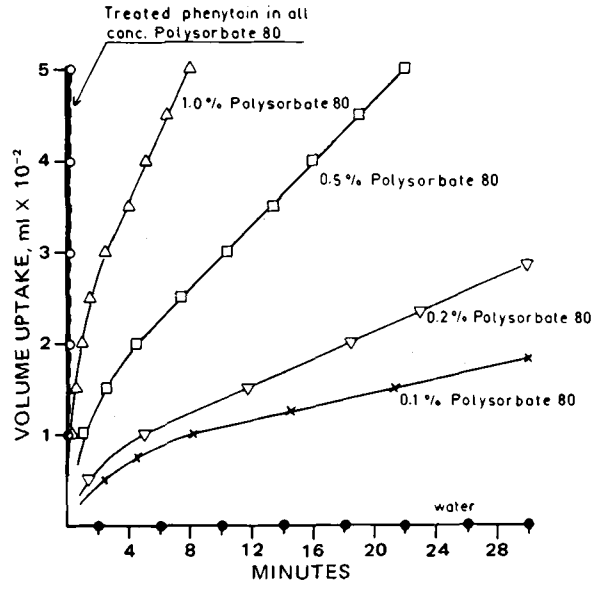

Figure 4—*Unidimensional liquid penetration profiles as a function of the polysorbate concentration. Key: ●, ×, ▽, □, and △, penetration of water and 0.1, 0.2, 0.5, and 1.0% polysorbate into plugs of untreated phenytoin, respectively; and ○, penetration of all concentrations of polysorbate into plugs of treated phenytoin.*

Disintegration—The capsule disintegration time was determined according to the BP 1973. Measurements were carried out without disks at 37 ± 0.5° in water with different polysorbate concentrations. Disintegration measurements were made eight times and averaged.

Dissolution and Solubility—A water-jacketed 1-liter beaker containing the dissolution medium (900 ml) was maintained at 37 ± 0.5°. The dissolution medium consisted of water with different polysorbate concentrations (pH < 5.5). The capsule was held in a stainless steel wire spiral located centrally 2 cm above the beaker bottom. Stirring was with a 5-cm diameter straight four-bladed impeller, rotated at 60 ± 1 rpm 3.5 cm above the capsule (11).

Samples were taken at convenient time intervals through membrane filters (0.8-μm pore diameter) and analyzed by a modified UV spectrophotometric method (12). To a 4.0-ml sample (first diluted, if necessary, with water or the test medium) in a glass-stoppered 25-ml test tube were added 0.5 g of potassium permanganate and 8 ml of 8 *N* NaOH. After

being shaken for several minutes, the tubes were immersed in an 80° water bath for 30 min. The samples were allowed to cool to room temperature, and 5.0 ml of *n*-heptane was added. The mixture was shaken for an additional 15 min; after separation of the two layers, the heptane layer absorbance was measured[13] at 247 nm against a suitable blank.

Calibration curves showed that Beer's law was obeyed with slopes of 0.017, 0.026, and 0.057 for water and 0.1 and 0.25% polysorbate, respectively. The correlation coefficients were at least 0.999. Each dissolution profile is the average of three to six determinations. The ranges are indicated in the graphs.

The saturated phenytoin solubility in the different solutions was determined by placing excess solute (about 300 mg) in glass vials filled with each test medium. The vials were closed and rotated at 25 ± 1 rpm in a water bath at 37 ± 0.5° until no increase in the amount dissolved could be measured. Samples were taken at convenient time intervals through membrane filters and analyzed as described for the dissolution study.

For the dissolution and solubility studies, all glass syringes, pipets, and the filter apparatus were prewarmed to prevent drug precipitation.

Absorption—Absorption studies were carried out with nine healthy

volunteers (66–87 kg, 21–28 years of age). Seven subjects received one capsule (300 mg) of pure phenytoin or one capsule of hydrophilized phenytoin. The two administrations were at least 2 weeks apart. The capsules were taken with 200 ml of water after an overnight fast, and no food was allowed for 4 hr after administration. Two subjects received one capsule with 300 mg of hydrophilized phenytoin; 2 weeks later, they received 300 mg of phenytoin dispersed in water.

Blood samples (8 ml) were taken from a forearm vein at 10, 40, 60, and 90 min and 2, 3, 4, 5, 6, 8, 12, 24, 30, and 48 hr. The heparinized blood samples were centrifuged, and the plasma was stored in a refrigerator until analyzed. Urine was collected at (convenient) time intervals over 48 hr. Volumes were recorded, and samples were refrigerated until assayed.

The plasma phenytoin levels were measured by HPLC[14] according to a method developed for carbamazepine (13). The column was 15 cm × 3 mm (i.d.) stainless steel, packed by a balanced-density slurry technique (14) with 5-μm porous particle silicic acid[15]. The solvent system was 5% tetrahydrofuran in methylene chloride. The flow rate was 1.2 ml/min, and the pressure required was ~10 MPa (1500 psi). Nitrazepam was the internal standard. The absorbance[16] was measured at 254 nm. The mean recovery from plasma was 95% with a relative standard deviation of ±2.5% (n = 32). The relative standard deviation of the calibration graph data down to 0.4-μg of phenytoin/ml of plasma did not exceed ±3% (n = 7).

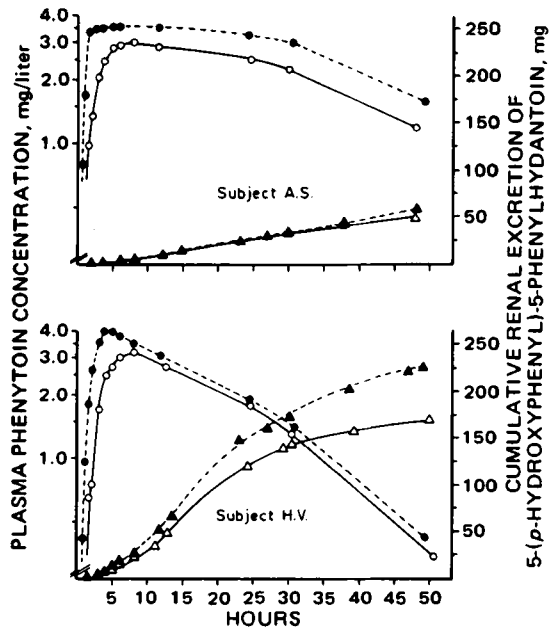

Figure 11—*Plasma phenytoin concentration–time curves and cumulative renal excretion of the total amount of 5-(p-hydroxyphenyl)-5-phenylhydantoin following oral administration of 300-mg treated and untreated phenytoin capsules. Key: ● and ▲, plasma and urine after the treated drug, respectively; and ○ and △, plasma and urine after the untreated drug, respectively.*

5-(*p*-Hydroxyphenyl)-5-phenylhydantoin and its conjugate, the main phenytoin metabolite in humans (15, 16), were assayed in the urine by a modified GLC method (17). To 1.0 ml of urine were added 0.5 ml of 0.066 *M* phosphate buffer (pH 6.9) and 250 units of β-glucuronidase. The samples were incubated for 15 hr at 37°. To the hydrolyzed samples were added 100 μl of an internal standard solution [50 μg/ml of 5-(*p*-methylphenyl)-5-phenylhydantoin in 0.01 *N* NaOH] and 1 ml of 3 *M* phosphate buffer (pH 4.5). After extraction with 8 ml of ether for 15 min and centrifugation, 7 ml of the organic phase was transferred to another test tube. Then 40 μl of 0.1 *M* trimethylanilinium hydroxide dissolved in methanol and 40 μl of 0.54 *M* tetramethylammonium hydroxide dissolved in water were added, and the tube was shaken for 10 min.

After centrifugation, 1 μl of the lower phase was injected into a gas chromatograph[17] equipped with a flame-ionization detector. The coiled glass tubing column, 1.5 m long × 2.2 mm i.d., was packed with 3% OV-17 on 80–100-mesh Chromosorb G.H.P. Operating conditions were: injection port, 300°; column oven, 240°; and detector, 275°. The nitrogen flow rate was 20 ml/min. Hydrogen and compressed air flow rates were adjusted to give maximum response. The relative standard deviation of the calibration graph data down to 15 μg of 5-(*p*-hydroxyphenyl)-5-phenylhydantoin/ml of urine did not exceed ±4% (n = 9).

All plasma and urine samples were analyzed in duplicate.

Liquid Properties—Liquid surface tensions and viscosities were determined with a tensiometer[18] and a capillary tube viscometer[19].

RESULTS AND DISCUSSION

In Fig. 4, the distilled water and polysorbate 80 solution uptakes into pure and hydrophilized phenytoin plugs are graphed against penetration time. As expected, no distilled water penetration into plugs of nontreated drug could be detected because of the strongly hydrophobic nature of the solid and the distilled water surface tension (70.1 dynes/cm at 37°). Addition of 0.1% polysorbate 80 to the penetrating liquid produced a measurable volume uptake. The penetration rate increased with increasing surfactant, decreasing the penetrating liquid surface tension to 37.7 dynes/cm at a 1% concentration.

The wetting of a powder mass by a liquid containing a surfactant is a dynamic process during which surfactant monomers are adsorbed on the substrate. The surfactant micelles are broken down to monomers, which diffuse to the liquid–solid interfaces. During the dynamic penetration process, the micelle breakdown in the capillaries may result in a micelle diffusion from the bulk of the solution into the pores of the mass. In this case, the wetting potency is not limited by the critical micelle concentration [polysorbate 80 = 0.04% (w/v) at 37°]. This is consistent with the theory (18) that micelle diffusion and breakdown will be the rate-limiting steps.

Since the penetration rate into a porous mass is, according to the Washburn equation, strongly dependent on the contact angle of the solid, the extremely hydrophobic phenytoin, exhibiting a contact angle of 102°, was hydrophilized by hydrophilic binder distribution over the solid surface. Methylcellulose treatment decreased the contact angle to 51°. The penetration rate into the hydrophilized phenytoin plugs was strongly increased (Fig. 4). The extremely fast penetration rate was independent of the penetrating liquid wetting potency.

The all-side penetration profiles are represented in Fig. 5. Again no penetration of distilled water into pure phenytoin plugs could be detected. Addition of polysorbate 80 to distilled water resulted in penetrations that increased with increasing surfactant concentrations. The steps in the recorded curves were caused by air bubbles escaping from the porous mass. The hydrophilized phenytoin plugs exhibited instant uptake, which was again independent of the penetrating liquid wetting potency.

The effect of drug hydrophilization on the disintegration of capsules loaded with 300-mg plugs of phenytoin is shown in Fig. 6. The untreated drug capsule disintegration time was 2 hr in distilled water. The disintegration time decreased with increasing surfactant concentration down to 15 min at 1% polysorbate 80. The hydrophilized phenytoin capsules all exhibited, independent of the polysorbate 80 concentration, disintegration times of 3 min, corresponding with the time in which enough of the gelatin had dissolved to open the capsule shell completely.

Analogous results were obtained for the hydrophilization effect on the *in vitro* phenytoin release rate from the different capsules (Fig. 7). The results are expressed as the percentage dissolved from saturation against time. A strong increase in the percentage dissolved for the nontreated

drug was found, along with a slight decrease for the treated drug with increasing surfactant concentrations. The slight decrease in the percentage dissolved from saturation corresponds with an absolute increase in the amount dissolved because of the increased phenytoin solubility with an increasing polysorbate 80 concentration. The latter was due to the strongly solubilizing surfactant (Fig. 8).

Comparative absorption studies were performed in humans. In Fig. 9, all of the individual and the mean plasma curves are given for two capsule preparations loaded with 300 mg of either pure or hydrophilized phenytoin. The plasma levels for all individuals were significantly higher for the treated phenytoin than for the pure drug. Moreover, phenytoin absorption from capsules with untreated drug showed an ~1-hr lag time whereas the hydrophilized drug was absorbed immediately. The area under the plasma level–time curve, evaluated by the trapezoidal rule from 0 to 8 and 0 to 48 hr, showed higher values for the hydrophilized powder than for the pure drug (Table I) ($p < 0.01$).

In two subjects, absorption profiles were compared following oral administration of a 300-mg hydrophilized drug capsule and of a 300-mg phenytoin/200 ml of water suspension (Fig. 10). Nearly identical plasma curves were obtained. The areas under the plasma concentration–time curves from 0 to 8 hr for the capsule and the suspension were 1394 and 1357 mg min/liter for one subject and 1251 and 1244 mg min/liter for the other, respectively. Differences between the areas from 0 to 48 hr after administration were similar.

The total amount of the hydroxylated phenytoin metabolite in the urine over 48 hr is shown in Fig. 11 together with the plasma drug levels in two subjects after pure and hydrophilized drug administration. The results showed remarkable intersubject variation in excretion rates and could not be used to predict relative drug absorption rates from different preparations.

These availability studies are based only on a comparison of hydrophilized drug with pure strongly hydrophobic drug without any adjuvants (*i.e.*, disintegrating agents).

Alkaline Hydrolysis of 1,3-Dimethylphenobarbital

JAMES LESLIE

Received August 31, 1978, from the *School of Pharmacy, University of Maryland, Baltimore, MD 21201.* Accepted for publication November 6, 1978.

Abstract □ The reaction of 1,3-dimethylphenobarbital (I) with 0.02–0.32 *M* KOH in aqueous methanol was studied. The barbiturate ring cleaved reversibly at the 1,6-position, forming a malonuric acid which was stable to further hydrolysis but which could readily recyclize to I. *N,N*-Dimethylethylphenylmalondiamide arose from decarboxylation of the carbamic acid formed by a 1,2-ring opening; this irreversible decarboxylation determined the diamide as the only final reaction product. The malonuric acid, which could be isolated in solid form, appeared as *N*-methyl-2-phenylbutyramide (GLC) following thermal decarboxylation and degradation of the acid. The I disappearance rate was biphasic, and the kinetics were consistent with the described reaction. The individual rate constants and the equilibrium constant for the reaction between I, the malonuric acid, and hydroxide were determined.

Keyphrases □ Dimethylphenobarbital—alkaline hydrolysis, kinetics, reaction products □ Hydrolysis, alkaline—dimethylphenobarbital, kinetics, reaction products □ Kinetics—dimethylphenobarbital alkaline hydrolysis

The 5,5-disubstituted barbituric acid alkaline hydrolysis has recently received attention (1–5). The pyrimidine ring may cleave at the 1,6-position, yielding a malonuric acid, or at the 1,2-position, forming a carbamic acid. Further hydrolysis leads to the acetic acid derivative and urea. The predominant pathway depends on the barbituric acid ionization state (2) and on the C-5 substituent size (1).

1,3-Dimethyl-5,5-disubstituted barbituric acid hydrolysis yielded only the *N,N'*-dimethylmalondiamides (6). Neither a malonuric acid nor a carbamic acid was isolated from the hydrolysis of phenobarbital, its *N*-methyl derivative (7), and 1,3-dimethylphenobarbital (6). A diamide was the main product in 1,3-dimethylbarbital alkaline hydrolysis, which also produced an acid intermediate. Acid intermediates that can recyclize to the parent barbituric acids have been reported (2, 3).

As a result of a related study (8), interest arose in the base-catalyzed degradation of 1,3-dimethylphenobarbital (I) and the alkaline hydrolysis of I in aqueous methanol was examined. Initial results were sufficiently different from those found with other barbituric acids to warrant detailed study. This paper presents a kinetic and product analysis investigation of the I reaction with potassium hydroxide.

EXPERIMENTAL

Materials—Compound I and *N*-methyl-2-phenylbutyramide (VI) were obtained as described previously (8). Compound IV was prepared by I hydrolysis in 0.7 *M* KOH in methanol–water for 24 hr. After acidification, the reaction mixture was extracted with chloroform and IV was purified by treatment with charcoal[1] in ethanol. The product, mp 106–110° [lit. (6) mp 108–109°], was characterized by mass spectrometry and yielded a single peak by GLC. Ethylphenylmalonate ethyl ester[2] was purified by distillation under reduced pressure.

The malonuric acid (II) was prepared by treating I with 0.1 *M* KOH in methanol–water for a few minutes, acidifying, and extracting with chloroform. The organic layer was shaken with pH 7 phosphate buffer, and the chloroform phase was discarded. Compound II was then obtained by chloroform extraction of the acidified aqueous phase.

All salts and solvents were reagent grade.

GLC—GLC[3] was performed on a 1.82-m × 2-mm i.d. silanized glass column packed with OV-17 on Chromosorb WHP[4]. The carrier gas was nitrogen (30 ml/min). The injection port temperature was maintained at 280°, as was the flame-ionization detector. For detailed reaction product examination, the oven temperature was programmed from 160 to 260° at 10°/min. In the kinetic studies, it was programmed from 220 to 260° at 10°/min.

TLC—TLC[5] was performed using silica gel sheets with a fluorescent indicator[6]. Petroleum ether (bp 60–110°)–ether (65:35) was used to separate reaction products. The R_f values were: I, 0.65; VI, 0.15; and IV, 0.06. In some experiments, ethanol–chloroform was used to isolate II (R_f 0.75). In this latter system, I, IV, and VI moved with the solvent front. The compounds were visualized under UV light, and the spots were scraped off the sheet and eluted with chloroform or methanol.

Kinetic Studies—Kinetic measurements were made at 25° in various potassium hydroxide concentrations with potassium chloride added to

maintain a 0.32 ionic strength. Stock I solutions were prepared by dissolving 10 mg of I in 5 ml of methanol and diluting to 10 ml with water. After thermal equilibration, 0.200 ml of the hydroxide solution in methanol–water was added rapidly to 0.200 ml of the stock I solution. The solution was mixed[7] rapidly and allowed to stand in a constant-temperature bath for the required time.

The solution was then acidified rapidly with hydrochloric acid, 0.400 ml of the internal standard solution (ethylphenylmalonate ethyl ester, 44 mg/100 ml of chloroform) was added, and the mixture was agitated vigorously for 1 min. This volume of solvent and duration of mixing were sufficient to extract the reaction products completely from the aqueous phase. Immediately after the layers had settled, 4 μl of the chloroform solution was injected into the gas chromatograph.

The I and IV peak height ratios to the internal standard were assumed to be proportional to the concentration of these compounds studied (0–0.5 μg/μl). The relative response of I to IV was determined by comparing the peak heights of I aliquots before and after completion of the reaction with potassium hydroxide. Since VI was a decomposition product in GLC and tailed on the packing used, peak height ratios were only an approximate measure of the II concentration.

IR, NMR, and Mass Spectra—IR[8] spectra were obtained in potassium bromide pellets. The NMR[9] spectrum was determined in deuterated chloroform[10] containing 1% tetramethylsilane. Mass spectra were obtained as described previously (8).

RESULTS

Compound I reacted slowly with potassium hydroxide in methanol but readily in the presence of water. The hydrolysis was studied in 50% (v/v) methanol–water.

Hydrolysis Products—When the chloroform extracts of the acidified reaction mixtures were injected into the gas chromatograph, three peaks in addition to that of the internal standard generally were observed (Fig. 1). On the basis of retention times and mass spectrometry (8), the peaks were identified as the butyramide VI, I, and the diamide IV, in order of increasing retention times. The relative peak heights depended on the reaction time and hydroxide concentration. Details are presented under *Kinetic Studies*.

TLC of the extracts using the petroleum ether–ether system showed three spots. Upon elution and GLC, two spots corresponded to I and IV, as did the R_f values. The third spot, at the origin, did not have the VI R_f value, although it yielded the butyramide by GLC. Similar behavior was observed with TLC using ethanol–acetone except that the reference I, IV, and VI moved with the solvent front, as did all of the reaction mixture components except the one that yielded VI by GLC. Since VI initially increased and then decreased to zero as hydrolysis proceeded, it must be derived from an intermediate.

Compound VI did not appear on the gas chromatograms when the reaction chloroform extract was shaken with pH 7 phosphate buffer prior to injection. This finding suggested that the VI precursor was acidic. This extraction procedure was used as the basis for VI isolation.

The IR spectrum of the intermediate was consistent with II, a malonuric acid formed by 1,6-cleavage of the pyrimidine ring (broad regions centered around 3000 cm^{-1}, 1730 cm^{-1}, —COOH; 3280, 1680, 1635, and 1530 cm^{-1}, amide functions). Solubility difficulties precluded obtaining an NMR spectrum. The intermediate melted at ~115° with effervescence. After melting, the product did not correspond on TLC to any of the previously mentioned compounds, although it yielded VI upon GLC. Its R_f value was 0.4 in petroleum ether–ether. An IR spectrum was consistent with the acetylureide V; the carboxyl group bands were no longer present, but bands at 3300, 1700, 1655, and 1530 cm^{-1} showed that the amide functions were intact. The V structure was confirmed by NMR of material purified by TLC: δ 7.29 (s, 5H, C_6H_5), 6.69 (broad peak, 1H, NH), 3.77 (t, 1H, CH), 3.22 (s, 3H, NCH_3), 2.87 [d, 3H, N-(H)CH_3], 1.87 (broad, diffuse, probably —CH_2—), and 0.88 (t, 3H, CH_3).

The possibility that the intermediate was the carbamic acid derivative was ruled out since it would have formed the diamide IV upon decarboxylation.

Samples of II gradually produced increasing I quantities on standing in methanol or chloroform or on a TLC sheet, indicating the capability of the malonuric acid to recyclize back to I. This recyclization was shown to be base catalyzed by treating the isolated intermediate with hydroxide for a short time and acidifying. Substantial I quantities were demon-

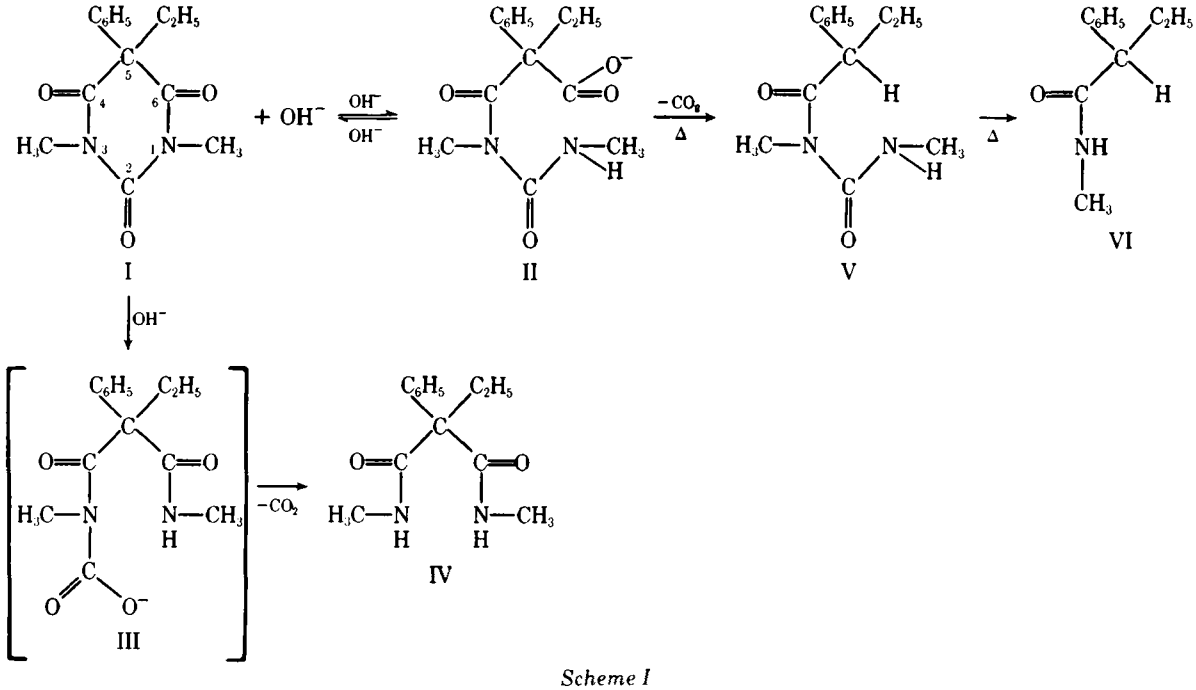


Scheme I

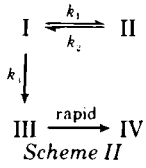
strated by GLC and TLC. Chloroform extraction of an alkaline (no acidification before extraction) II solution resulted in all of it being converted to I (except for a small amount converted to IV). This finding showed that malonurate anion recyclization occurs rapidly and that as I is formed it is removed continuously into the organic layer. When II was allowed to react to completion with potassium hydroxide, only IV could be isolated. Scheme I summarizes the previous reactions.

Kinetic Studies—At all hydroxide concentrations used, the I disappearance rate and the II change rate were biphasic; *i.e.*, a rapid change was followed by a more gradual one, the final phase being linear on a semilogarithmic plot (Fig. 2). The extent of the initial change and the terminal phase slope were strongly dependent on the hydroxide concentration. The initial phase was so fast in hydroxide concentrations greater than 0.1 *M* that it could not be followed kinetically.

The biphasic I disappearance could be fitted to:

$$[I] = Ae^{-\lambda_1 t} + Be^{-\lambda_2 t} \qquad \text{(Eq. 1)}$$

using standard curve-fitting techniques (9); A and B are constants, and λ_1 and λ_2 are rate constants (arbitrarily $\lambda_2 > \lambda_1$). This equation is consistent with the reaction sequence shown in Scheme II.



Scheme II

The constant A is the terminal line intercept at $t = 0$. From the observed A, λ_1, and λ_2 values, the rate constants k_1, k_2, and k_3 were calculated (Table I) using:

$$k_2 = \lambda_1 + A(\lambda_2 - \lambda_1)/[I]_0 \qquad \text{(Eq. 2)}$$

$$k_3 = \lambda_1\lambda_2/k_2 \qquad \text{(Eq. 3)}$$

$$k_1 = \lambda_1 + \lambda_2 - k_2 - k_3 \qquad \text{(Eq. 4)}$$

The rate constants k_1, k_2, and k_3 were plotted against various hydroxide concentration functions. The best correlations (Fig. 3) for k_1 and k_2 were:

$$k_1 = 166[OH^-]^2 + 0.0118 \qquad r = 0.996 \qquad \text{(Eq. 5)}$$

$$k_2 = 9.97[OH^-] - 0.0382 \qquad r = 0.993 \qquad \text{(Eq. 6)}$$

No hydroxide function was found that yielded a satisfactory correlation with k_3: the plots of k_3 *versus* [KOH] and [KOH]^2 (Fig. 3) show a definite curvature.

In principle, the rate constants could also be obtained from the II rate of change with time. However, at all potassium hydroxide concentrations, the terminal slope, *i.e.*, λ_1 for the II disappearance rate, measured by GLC as VI, was slightly higher than the rate for I. This finding was attributed to the nonlinearity of the peak height ratios with II concentration because of column tailing. The error is amplified in obtaining λ_2. Since II is an unstable compound, no standard response on the GLC can be obtained and the II concentration at the intercept that is needed for the rate constant calculation can only be approximated. The response factor was approximated by calculating the II concentration from the difference between the amount of I added and the amount of I unreacted and IV formed.

With the following appropriate relationships:

$$k_1 = (\text{intercept of terminal line}) \times (\lambda_2 - \lambda_1)/[I]_0 \qquad \text{(Eq. 7)}$$

$$k_2 + k_3 = \lambda_1 + \lambda_2 - k_1 \qquad \text{(Eq. 8)}$$

$$k_2k_3 = \lambda_1\lambda_2 \qquad \text{(Eq. 9)}$$

k_1, k_2, and k_3 can be estimated from the corrected peak height ratios. For example, for the reaction in 0.0606 *M* KOH, λ_1, λ_2, k_1, k_2, and k_3 were estimated to be 0.0421, 1.05, 0.558, 0.436, and 0.102 min^{-1}, respectively, compared to 0.0373, 1.33, 0.678, 0.607, and 0.0817 min^{-1}, respectively, obtained for the I rate of change. The agreement is reasonable considering the approximations made; the data are consistent with the reactions in Scheme II.

Since the III to IV conversion is rapid, the IV formation rate is proportional to the I concentration. Therefore, approximate values for k_3 can be derived using:

$$(\Delta IV/\Delta t)/[I] \simeq k_3 \qquad \text{(Eq. 10)}$$

By using increments of IV and time from [IV] *versus* t plots, approximate k_3 values were calculated (Table I). The agreement with the k_3 values obtained by the previous method is remarkable but to some extent fortuitous.

Since $d[II]/dt = k_1[I] - k_2[II] = 0$ at the maximum of the plot of [II] *versus* time, and since k_1 is proportional to [KOH]^2 and k_2 is proportional to [KOH], Eq. 11 can be derived:

$$([II]/[I])_{max}/[KOH] = (k_1/k_2)/[KOH] = K \qquad \text{(Eq. 11)}$$

where K is the equilibrium constant for the reaction between I and II and $([II]/[I])_{max}$ is the ratio of the I and II concentrations at the maximum in II. Values of K obtained in this way using the maximum obtained graphically are listed in Table I, as are values of $(k_1/k_2)/[KOH]$. Although there is a 12-fold change in hydroxide concentration, the values of K are reasonably constant.

Although λ_2 could not be obtained directly from the experimental data for the higher hydroxide concentrations, the rate and equilibrium constants were estimated as indicated in the footnotes of Table I.

DISCUSSION

Unlike 1-methylphenobarbital and phenobarbital itself (7), I alkaline hydrolysis yielded only the substituted diamide IV. Although this compound could be the result of decarboxylation of a carbamic acid intermediate formed by a 1,2-ring opening, the acid intermediate actually isolated was identified as a malonuric acid formed by a 1,6-ring opening. The formation of the diamide as the sole final reaction product is in agreement with a previous report (6), although no acid intermediates were isolated in that work, probably due to the relatively low hydroxide concentrations used and to the reaction mixture manipulation.

The malonurate (II) did not decarboxylate but recyclized to the parent barbituric acid. The overall irreversibility of IV hydrolysis was due to the decarboxylation of a carbamic acid, which was too unstable to isolate. Phenobarbital and its *N*-methyl derivative yielded acetylureides and diamides, but no malonuric acids (7), upon hydrolysis. The simplicity of I hydrolysis is due to dimethylated diamide and malonuric acid stability. A diamide is the only product of 1,3-dimethylbarbital hydrolysis (3). An acid intermediate proposed to be a carbamic acid could be a malonuric acid in rapid equilibrium with the barbituric acid.

A malonurate anion would not be expected to recyclize readily, but similar compounds form cyclic products. Diethylacetylurea cyclizes to barbital (2), 2-ureidobenzoate forms 2,4-dihydroxyquinazoline at a rate proportional to the hydroxide-ion activity (10), and 2-iodo-3-ureidopropionic acid yields 2-amino-2-oxazoline-3-carboxylic acid (11).

The observed reaction kinetics of I with hydroxide are consistent with the reaction sequence in Scheme I and agree with the qualitative observations that ring opening occurs predominantly at the 1,6-position. This is the first report of a biphasic decrease in barbiturate concentration upon alkaline hydrolysis, and its observation is due in part to the reaction mixtures being analyzed by a technique that permits separation of products. The simplicity of the reactions enabled the rate constants and equilibrium constant to be determined. The terminal disappearance of the barbituric acid is not a simple function but depends on all of the rate constants in Scheme II.

The rate of II formation is dependent on the second power of the hydroxide concentration. This result can be explained by tetrahedral complex formation between I and hydroxide ion, followed by a base-catalyzed ring opening to the malonurate. Such a sequence was proposed (12) for barbituric acid hydrolysis. The reverse reaction cyclization would have to be first order in hydroxide concentration, as was observed in this study.

The lack of a simple k_3 dependence on hydroxide concentration probably reflects the fact that the irreversible step is complex, involving ring opening and decarboxylation. Although a carbamic acid was not isolated in this work, it may be present in the reaction mixture and undergo decarboxylation during the workup. In view of carbamic acid instability, the quantity would be insignificant.

Although the reaction rate of I is biphasic, this behavior becomes modified at the lower and higher hydroxide concentrations and approaches first-order kinetics. Therefore, the complex behavior observed in the hydrolysis of barbituric acids possibly could be explained by closer examination of the experimental data.

The pyrimidine ring in 1,3-dimethylphenobarbital is preferably cleaved at the 1,6-position, as established by detailed kinetic studies, whereas final product analysis could lead to the conclusion that ring opening occurs at the 1,2-position. This system may serve as a useful model for a study of the effects of substituents at the 5 carbon without the complications of ionization or degradation to a large number of products.

Oxybutynin Influence on Autonomic Measures in Dogs

BERNARD KOROL *x **and LOWELL D. MILLER** ‡§

Received March 4, 1977, from the *Veterans Administration Medical Center, St. Louis, MO 63125, and the ‡Department of Psychiatry, St. Louis University School of Medicine, St. Louis, MO 63104. Accepted for publication November 1, 1978. §Present address: Marion Laboratories, Kansas City, MO 64137.

Abstract □ In the conscious dog, the most apparent oxybutynin effect was a dose-related tachycardia. Associated with this heart rate increase were a very slight, sometimes significant, elevation in diastolic pressure and an insignificant increase in systolic pressure. Under pentobarbital anesthesia, the systolic/diastolic arterial pressure oxybutynin responses were reversed and showed a dose-related systolic and diastolic hypotension. However, the tachycardic response to oxybutynin still appeared. The arterial pressure and heart rate responses produced by the autonomic agents were altered by the oxybutynin treatment in a pattern indicative of an anticholinergic mechanism of action. Differences in many response profiles were observed with either conscious or anesthetized dogs, but the statistically significant inhibition of the acetylcholine-induced systolic and diastolic arterial pressure and bradycardic responses were constant in both conditions. Oxybutynin is an anticholinergic agent with mild to moderate cardiovascular activity.

Keyphrases □ Oxybutynin—effect on autonomic functions in conscious and phenobarbital-anesthetized dogs □ Autonomic functions—effect of oxybutynin, conscious and phenobarbital-anesthetized dogs □ Phenobarbital—effect on oxybutynin response, autonomic functions, dogs

Previous studies indicated that the tertiary amine oxybutynin chloride (4-diethylamino-2-butynyl α-phenylcyclohexaneglycolate hydrochloride) had a weakly anticholinergic mechanism of action. In an anesthetized dog, a cumulative intravenous dose of 750 μg/kg (last dose of 400 μg/kg) completely blocked the hypotensive acetylcholine-induced response and partially (60%) inhibited the hypotensive response to vagal stimulation. Atropine, 10 μg/kg, produced a 66% reduction of the vagal blood pressure response and a 30% inhibition of the acetylcholine depressor response.

The physiological state of the experimental preparation can influence the quality and amplitude of a response profoundly. In the anesthetized dog, the alkaloid ibogaine produced a marked hypotension, which was not evident in the conscious dog (1). In anesthetized dogs, the alkaloid yohimbine lowered arterial pressure due to a peripheral α-adrenergic blocking effect (2). In these same animals, while conscious, an equivalent intravenous yohimbine dose produced a hypertension and tachycardia; both responses endured for 30 min or longer. The response from the conscious dog was an expression of the yohimbine central sympathetic nervous system stimulating effect, which was not evoked in the anesthetized (barbiturate) animal.

A recent study in chronically prepared dogs investigated anesthesia influence on cardiovascular responses to cryptenamine, an alkaloid from *Veratrum veride* (3). In

32 paired conscious and anesthetized dogs, pentobarbital anesthesia significantly lowered basal systolic/diastolic arterial pressures, raised basal heart rate, and altered responses to autonomic treatments. Pentobarbital anesthesia also significantly increased the cryptenamine dose required for inhibition of the hypotensive and/or bilateral carotid occlusion pressor response. The conscious dog systolic depressor response to cryptenamine is the most sensitive and accurate bioassay for cryptenamine potency evaluation.

Earlier studies on oxybutynin were performed only in anesthetized animals. This paper reports its effects on autonomic functions and responses to autonomimetic treatments in conscious and anesthetized matched paired dogs.

EXPERIMENTAL

Six male and female beagle dogs were surgically prepared with externalized bilateral carotid artery loops (4). Each animal was its own control and was utilized both conscious and anesthetized (~35 mg of pentobarbital sodium/kg iv). This preparation permits direct systolic and diastolic arterial pressure measurement, induction of a reflex pressure response to bilateral carotid occlusion, and measurement of other autonomic functions such as ECG, heart rate, and respiration on conscious, slightly restrained animals (5).

Direct systolic and diastolic arterial pressure (lateral) was measured from an externalized carotid artery cannula[1]. The cannula was connected to a pressure transducer[2], which supplied input into a recorder coupler[3]. Cannula patency was maintained by slow retrograde saline infusion through the pressure transducer. The infusion rate did not alter the arterial pressure measurements.

Heart rate was measured by the conversion of the R-R wave interval by a cardiotachometer coupler[4] from a bipolar electrocardiograph input obtained through biopotential electrodes positioned and affixed to the skin over the sternum. A homemade sodium chloride electrode paste (0.154 mole/kg)[5] was used to facilitate conduction.

Respiration rate and amplitude were measured indirectly through a pneumograph belt positioned around the thoracico-abdominal junction and connected to a pressure transducer[2], which was connected to a coupler[3].

Recording was on a multichannel recorder[6] at a paper speed of 5 mm/sec.

Table V—Difference in Mean Basal Level and Mean Amplitude of Cardiovascular Response to Graded Oxybutynin Doses in Six Beagle Dogs Examined in the Conscious and Anesthetized States

Treatment	Systolic, mm Hg	Diastolic, mm Hg	Heart Rate, beats/min	Respiration Rate, breaths/min
Basal level	+8	−2	−33[a]	+20[a]
Oxybutynin				
0.1 mg/kg	+5	−1	−4	+7
0.3 mg/kg	+3	+2	+20[a]	+6
1.0 mg/kg	+16[a]	+11[a]	+23[a]	+1
3.0 mg/kg	+23[a]	+29[a]	+27[a]	+1

[a] $p \leq 0.05$.

To control for order effect, the six animals were treated in a random order in both the conscious and anesthetized states.

All dogs had an indwelling venocatheter (PE-50) in the branchial-cephalic or saphenous vein for drug solution administration. They were anesthetized with pentobarbital sodium, 30–35 mg/kg. Care was taken to position the pressure transducer at the appropriate level (heart horizontal) for each dog, particularly when anesthesia was employed.

Fresh aqueous oxybutynin solutions were prepared prior to use, and the concentrations were adjusted so that equivolumes were administered at each dose level. The oxybutynin doses were 0.1, 0.3, 1.0, 3.0, and 10.0[7] mg/kg iv in equivolumes of 0.1 ml/kg. Systolic and diastolic arterial pressures, heart rate, ECG, and respiration rate were measured.

After a 10–15-min equilibration, the animal received an autonomic treatment series. The autonomic agonists and their dose levels (salt weight) were: bilateral carotid occlusion, 30 sec; tyramine hydrochloride, 0.20 mg/kg; acetylcholine chloride, 0.6 μg/kg; epinephrine hydrochloride, 2 μg/kg; histamine phosphate, 2 μg/kg; norepinephrine bitartrate, 2 μg/kg; isoproterenol hydrochloride, 2 μg/kg; and serotonin diphosphate, 10 μg/kg. The autonomic treatments were repeated after the highest oxybutynin dose. The direction and amplitude of the autonomic responses were described previously (6).

The data were analyzed for statistical significance by the matched-pair t test (7).

RESULTS AND DISCUSSION

The data are summarized in Tables I–IV.

Oxybutynin effects in the conscious dog are reviewed in Tables I and II. At a mean basal systolic arterial pressure level of 133 mm Hg, oxybutynin doses of 0.1, 0.3, 1.0, and 3.0 mg/kg iv produced statistically insignificant changes in systolic pressure (Table I). The mean basal diastolic pressure of 87 mm Hg was significantly elevated following treatment with 0.3 and 1.0 mg of oxybutynin/kg. Diastolic pressure increased insignificantly (3 mm Hg) after the 3.0-mg/kg dose. These changes in diastolic

[7] Given only if an absent or a weak response resulted from lower dose.

pressure were statistically significant but physiologically inconsequential.

Oxybutynin produced apparently dose-related tachycardia. A significant peak tachycardic response (21 beats/min) appeared after the 0.3-mg/kg dose, and a significant peak (52 beats/min) occurred after the 3.0-mg/kg iv dose. Although there was a consistent tachypnea after each oxybutynin dose, none of the respiratory changes was significant.

The effects of the cumulative 4.4-mg/kg iv oxybutynin dose on the autonomic responses in conscious dogs are summarized in Table II. Oxybutynin produced several significant autonomic responses. The tyramine-induced pressor response was significantly enhanced. The tyramine-evoked tachycardic response was significantly depressed to +3.2 beats/min. The acetylcholine-induced depressor and associated tachycardic responses were significantly inhibited. The epinephrine pressor response amplitude was significantly enhanced by oxybutynin treatment, although the associated heart rate response was inhibited by from +11 to −1 beats/min. Other significant changes included enhanced histamine tachycardia, increased norepinephrine brachycardia, and increased diastolic depressor response to isoproterenol.

When oxybutynin was administered to anesthetized dogs, the systolic and diastolic pressure responses were opposite to those observed in the conscious state (Table III). Oxybutynin (1.0, 3.0, and 10.0 mg/kg iv) produced systolic/diastolic depressor responses of −8/−5, −30/−26, and −31/−37 mm Hg, respectively. The associated significant tachycardic responses occurred only after the 1.0- and 3.0-mg/kg doses. The 10.0-mg/kg oxybutynin dose produced profound and significant depressor responses but insignificantly increased heart rate. Perhaps at this dose in the anesthetized dog the heart rate response, which appears to be compensatory to the systolic/diastolic depression, is pharmacologically antagonized by oxybutynin. The possibility of a toxicologic response to the 10.0-mg/kg dose is supported by the appearance of a marked and statistically significant tachypnea (+17 breaths/min).

Table IV describes the effects of a total cumulative 14-mg/kg iv oxybutynin dose of the autonomic treatment responses of anesthetized dogs. The acetylcholine-induced arterial pressure depressor response was inhibited. Similarly, the acetylcholine-induced tachycardia was markedly inhibited following oxybutynin. The epinephrine pressor response was enhanced, as was the heart rate response. The systolic/diastolic pressures and heart rate response to norepinephrine were also significantly altered. The respiratory rate response to norepinephrine was slightly, but significantly, increased. Only the diastolic pressure response to isoproterenol was significantly increased following oxybutynin.

Divergent responses due to the "state-of-the-animal" were reported previously (1–3). The influence of differential state on response must be considered when interpreting the experimental data, particularly from the anesthetized preparation.

The differences in systolic/diastolic arterial pressures, heart rates, and respiration rates are summarized in Table V. Basal heart rate was considerably lower in the conscious state, while basal respiratory rate was significantly greater. The amplitude of the changes indicated that the conscious animal exhibits greater oxybutynin sensitivity and response intensity. Greater oxybutynin tachycardic response in conscious animals can be explained on the basis of the Law of Initial Values (8).

In the conscious dog, the oxybutynin response was pressor; following pentobarbital anesthesia, the same oxybutynin doses evoked a systolic/diastolic arterial depressor response. These findings are inexplicable.

The consistent and significant tachycardia produced by oxybutynin in conscious and anesthetized dogs and the selective oxybutynin inhibition of the acetylcholine-induced cardiovascular responses in both conditions support the earlier pharmacological report. Oxybutynin has mild to moderate cardiovascular effects, probably through an anticholinergic mechanism of action.

Amino Acid Effect on Aspirin Stability in Propylene Glycol

PREM K. NARANG * and JAMES K. LIM *

Received July 6, 1978, from the *School of Pharmacy, West Virginia University, Morgantown, WV 26506.* Accepted for publication November 6, 1978. *Present address: School of Pharmacy, University of Maryland, Baltimore, MD 21201.

Abstract □ Temperature stability studies were conducted on 0.36 *M* (6.5% w/v) aspirin solutions including either 0.02 *M* L-methionine or 0.02 *M* histidine in propylene glycol. Aspirin was determined spectrophotofluorometrically as salicylic acid content at 412 nm. A 0.36 *M* aspirin in polyethylene glycol 400 solution was studied concurrently. Aspirin degradation rate constants, *k*, obtained from semilogarithmic plots of percent drug remaining *versus* time at 30–70 ± 0.5° were used for preparing Arrhenius plots. Good correlation was seen between predicted aspirin stability and experimental $k_{25°}$ values. L-Methionine and histidine markedly reduced aspirin stability.

Keyphrases □ Aspirin—stability in propylene glycol, effect of L-methionine and histidine, temperature □ Stability—aspirin in propylene glycol, effect of L-methionine and histidine, temperature □ Propylene glycol—stability of aspirin solutions, effect of L-methionine and histidine, temperature

Aspirin remains the most sought-after, nonprescription analgesic. It possesses a combination of anti-inflammatory, antipyretic, and analgesic properties unparalleled by other "aspirin-like" compounds. Aspirin is, however, a notoriously unstable drug and degrades to the less potent salicylic acid in the presence of moisture (1). Liquid aspirin dosage forms present a challenging pharmaceutical problem because of this instability in water and in vehicles containing traces of water.

Numerous attempts to stabilize aspirin solutions, especially in nonaqueous solvents such as polyethylene glycol 400 (2), glycerol and propylene glycol (3, 4), ethanol, (5), and esterified polyethylene glycols (6) have been reported. The objective of the present study was to measure

pressure were statistically significant but physiologically inconsequential.

Oxybutynin produced apparently dose-related tachycardia. A significant peak tachycardic response (21 beats/min) appeared after the 0.3-mg/kg dose, and a significant peak (52 beats/min) occurred after the 3.0-mg/kg iv dose. Although there was a consistent tachypnea after each oxybutynin dose, none of the respiratory changes was significant.

The effects of the cumulative 4.4-mg/kg iv oxybutynin dose on the autonomic responses in conscious dogs are summarized in Table II. Oxybutynin produced several significant autonomic responses. The tyramine-induced pressor response was significantly enhanced. The tyramine-evoked tachycardic response was significantly depressed to +3.2 beats/min. The acetylcholine-induced depressor and associated tachycardic responses were significantly inhibited. The epinephrine pressor response amplitude was significantly enhanced by oxybutynin treatment, although the associated heart rate response was inhibited by from +11 to −1 beats/min. Other significant changes included enhanced histamine tachycardia, increased norepinephrine brachycardia, and increased diastolic depressor response to isoproterenol.

When oxybutynin was administered to anesthetized dogs, the systolic and diastolic pressure responses were opposite to those observed in the conscious state (Table III). Oxybutynin (1.0, 3.0, and 10.0 mg/kg iv) produced systolic/diastolic depressor responses of −8/−5, −30/−26, and −31/−37 mm Hg, respectively. The associated significant tachycardic responses occurred only after the 1.0- and 3.0-mg/kg doses. The 10.0-mg/kg oxybutynin dose produced profound and significant depressor responses but insignificantly increased heart rate. Perhaps at this dose in the anesthetized dog the heart rate response, which appears to be compensatory to the systolic/diastolic depression, is pharmacologically antagonized by oxybutynin. The possibility of a toxicologic response to the 10.0-mg/kg dose is supported by the appearance of a marked and statistically significant tachypnea (+17 breaths/min).

Table IV describes the effects of a total cumulative 14-mg/kg iv oxybutynin dose of the autonomic treatment responses of anesthetized dogs. The acetylcholine-induced arterial pressure depressor response was inhibited. Similarly, the acetylcholine-induced tachycardia was markedly inhibited following oxybutynin. The epinephrine pressor response was enhanced, as was the heart rate response. The systolic/diastolic pressures and heart rate response to norepinephrine were also significantly altered. The respiratory rate response to norepinephrine was slightly, but significantly, increased. Only the diastolic pressure response to isoproterenol was significantly increased following oxybutynin.

Divergent responses due to the "state-of-the-animal" were reported previously (1–3). The influence of differential state on response must be considered when interpreting the experimental data, particularly from the anesthetized preparation.

The differences in systolic/diastolic arterial pressures, heart rates, and respiration rates are summarized in Table V. Basal heart rate was considerably lower in the conscious state, while basal respiratory rate was significantly greater. The amplitude of the changes indicated that the conscious animal exhibits greater oxybutynin sensitivity and response intensity. Greater oxybutynin tachycardic response in conscious animals can be explained on the basis of the Law of Initial Values (8).

In the conscious dog, the oxybutynin response was pressor; following pentobarbital anesthesia, the same oxybutynin doses evoked a systolic/diastolic arterial depressor response. These findings are inexplicable.

The consistent and significant tachycardia produced by oxybutynin in conscious and anesthetized dogs and the selective oxybutynin inhibition of the acetylcholine-induced cardiovascular responses in both conditions support the earlier pharmacological report. Oxybutynin has mild to moderate cardiovascular effects, probably through an anticholinergic mechanism of action.

tained 0.36 *M* (6.5% w/v) aspirin and 0.02 *M* of either amino acid (II or III). A 0.36 *M* aspirin in polyethylene glycol 400 (IV) solution was included for comparison (Table I).

Aspirin Content Analysis—Aspirin was assayed as salicylic acid in pH 7 phosphate buffer at 25 ± 0.1°, using a spectrophotofluorometer[6] equipped with a 150-w xenon lamp/LP 21 photomultiplier tube, at the excitation and emission wavelengths of 300 and 412 nm, respectively. A 1.3 conversion factor, representing the aspirin to salicylic acid molecular weight ratio, was used to compute aspirin concentrations from salicylic acid concentrations. Salicylic acid concentrations were determined from

Table III—Effect of Water Dilution on pH of Formulations I–III

Formulation	Percent Water (v/v) 0	10	25	50	70
I	3.1	3.1	3.1	3.0	3.0
II	3.8	3.8	3.7	3.3	3.0
III	3.9	3.9	3.8	3.5	3.1

a standard plot of salicylic acid, prepared from a fresh 0.36 *M* salicylic acid stock solution in glycol or methanol and appropriately diluted with pH 7 phosphate buffer for the fluorescence measurements.

Stability Studies—The aspirin formulations were placed in screw-capped, 30-ml, amber-colored prescription bottles and were immersed in controlled temperature water baths at 30–70 ± 0.5°. At 24-hr intervals, analytical samples were pipetted into ice-cold tubes, sealed, and stored at refrigeration temperatures until analysis. Semilogarithmic plots of percent aspirin remaining as a function of time and temperature were used to obtain the degradation rate constants, *k*. Arrhenius plots based on these rate constants were derived to predict aspirin stability at 25 and 5°. These predictions were compared with the experimental values from samples left at ambient room temperatures (25 ± 2°).

RESULTS AND DISCUSSION

Complete solubility of 6.5% (w/v) aspirin in propylene glycol or polyethylene glycol 400 was attainable within 6–8 hr of continuous agitation at 40 oscillations/min on a shaker bath maintained at 25 ± 0.1° (Fig. 1). This concentration represents the average adult dose (~325 mg/teaspoonful). Figure 2 shows the relative salicylic acid fluorescence intensity as a function of wavelength. Aspirin exerted negligible fluorescence at 412 nm.

Figures 3–6 show the semilogarithmic plots of percent aspirin remaining as a function of time and temperature for I–IV. The degradation rate constants, *k*, derived from these plots show that IV was the least stable (Fig. 7). This result may be attributed to transesterification (6) between aspirin and the polyethylene glycols. Formulation II ($k = 0.54 \times 10^{-4}$ hr^{-1}) exhibited almost twice the I degradation rate, indicating that amino acids decrease aspirin stability in propylene glycol. Table II summarizes the predicted shelflife stability at 25 and 5° for I–IV in terms of a 10% aspirin breakdown. As anticipated, the shortened shelflife of aspirin in propylene glycol due to the presence of the amino acids cor-

responded with the slight increases in pH on dilution with water (Table III).

A fair correlation was evident between the predicted and experimental degradation rate constants, $k_{25°}$ (Table IV), thus supporting the predicted stability values (Table II). Preliminary IR studies showed a carbonyl band shift from 1595 cm^{-1} of L-methionine[7], where no bonding takes place, to 1640 cm^{-1} when the amino acid was dissolved in propylene glycol, indicating weak hydrogen bonding. Similarly, weak hydrogen bonding was indicated between aspirin and propylene glycol because of a slight carbonyl band shift to a higher frequency.

Radiochemical Plasma Salicylamide Assay Using Ring-Labeled Tritiated Salicylamide

V. J. STELLA ˣ, S. A. VARIA, and M. RIEDY

Received May 4, 1978, from the *Department of Pharmaceutical Chemistry, University of Kansas, Lawrence, KS 66045.* Accepted for publication November 6, 1978.

Abstract □ A rat plasma salicylamide assay was developed using ring-labeled tritiated salicylamide, synthesized by reacting salicylamide with tritium oxide in the presence of heptafluorobutyric acid. The reaction yielded ^3H-salicylamide of specific activity up to 8.41 mCi/mmole, 60% yield. Plasma containing ^3H-salicylamide and its metabolites was extracted with a toluene-based scintillation fluid, which was subsequently counted. Specificity for free salicylamide was demonstrated by radiochemical and standard fluorescence plasma salicylamide level–time curves. Specificity resulted from nonextraction of the salicylamide sulfate and glucuronide metabolites. Sulfatase and β-glucuronidase treatment allowed the analysis of plasma sulfate and glucuronide conjugates as free salicylamide. This procedure should be effective for the analysis of salicylamide and its metabolites in the presence of similar phenolic compounds.

Keyphrases □ Salicylamide—radiochemical analysis, from plasma, compared to fluorescence assay, rats □ Radiochemistry—analysis, salicylamide in plasma, compared to fluorescence assay, rats □ Fluorometry—analysis, salicylamide in plasma, compared to radiochemical assay, rats

In a study of the effects of alternate substrates on their ability to block temporarily the first-pass metabolism (1, 2) of phenolic drugs, the oral administration of salicylamide to rats was chosen as a suitable animal model because of the similarity of salicylamide's metabolic behavior in rats (3–7) and humans (8, 9). Numerous assays for salicylamide have been proposed (9–11). The fluorometric assay of Barr and Riegelman (9) is the most extensively used procedure for the analysis of salicylamide and its metabolites in biological fluids. This sensitive and specific fluorometric assay, along with a few modifications, has been the assay of choice in numerous studies (3, 9, 12).

Since the long-term objective of this project was to screen the effects of various alternate substrates on their ability to block temporarily the sulfation–glucuronidation first-pass effect of a model phenolic compound, salicylamide, many of the alternate substrates would most likely be other phenolic compounds. Some of these phenolic alternate substrates have physical, chemical, and fluorescense properties so similar to salicylamide that they interfere with the fluorometric procedure (9). For this reason, an assay for salicylamide and its metabolites was developed using ring-labeled tritiated salicylamide. The assay selectivity was due to the separation of salicylamide from its sulfate and glucuronide metabolites by a relatively nonpolar organic solvent.

EXPERIMENTAL

Reagents and Materials—All reagents were analytical grade, and all aqueous solutions were prepared using glass-distilled, deionized water. The scintillation fluid was prepared by stirring overnight 1000 ml of toluene[1] with 0.5 g of 1,4-bis[2-(4-methyl-5-phenyloxazolyl)]benzene[2] and 4 g of 2,5-diphenyloxazole[2].

Tritiated Salicylamide Synthesis—A screw-capped Pyrex glass tube containing 300 mg of salicylamide[3], 20 μl of tritium oxide[4], and 200 μl of heptafluorobutyric acid[5] was maintained in a sealed metal container at 200–210° for 4 days. After being cooled to room temperature, the solidified contents were dissolved in a minimal amount of 0.25 *N* NaOH (~15 ml).

The solution pH was adjusted to 6 with 1 *N* HCl, and this solution was then extracted with 30 ml of ethyl acetate. The ethyl acetate layer was separated, washed twice with 30 ml of saturated sodium bicarbonate solution, and dried over anhydrous magnesium sulfate. The ethyl acetate was evaporated on a rotary evaporator[6].

The solid white material obtained was purified by vacuum sublimation at 10 mm Hg and 118–122°. The isolated salicylamide specific activity varied from 5.24 to 8.41 mCi/mmole. Labile tritium was assayed by standard methods and was negligible[7]. The radiochemical purity was determined by TLC[8]. Chemical purity, checked qualitatively by melting points and quantitatively by fluorescence spectrophotometry, was 99–99.5%. The ^{3}H-salicylamide final yield was 180–200 mg.

Animal Studies—Sixteen male Sprague–Dawley rats[9] (250–275 g) were used. The rats were fed standard rat chow and water *ad libitum*. Prior to oral salicylamide administration, the rats were fasted overnight.

The oral salicylamide dose, 500 mg/kg, was prepared by dissolving the appropriate salicylamide and ^{3}H-salicylamide amounts in 1 *N* NaOH[10] and adjusting the pH to 10 with dropwise addition of 1 *N* HCl. For example, a 250-g rat received 4.2 mg of ^{3}H-salicylamide (8.4 mCi/mmole) and 120.8 mg of salicylamide. This aqueous salicylamide solution (1.5–2 ml depending on the weight of the animal) was administered orally by intubation. After drug administration, the animals were placed in metabolism cages.

Five minutes prior to predetermined times (15, 30, 60, or 90 min postdosing), each rat was anesthetized with ether, and 5-ml blood samples were removed from the inferior vena cava (after an abdominal incision) into an edetate sodium pretreated syringe. After centrifugation, duplicate 50-μl plasma samples were assayed for free salicylamide, salicylamide sulfate, and salicylamide glucuronide by the fluorescence and radiochemical assays.

Radiochemical Assay—Free plasma salicylamide was determined by adding 100 μl of a pH 7.0 phosphate buffer (0.2 *M*) to 50 μl of plasma in a 50-ml screw-capped centrifuge tube[11] and extracting with 16 ml of the toluene-based scintillation fluid. After agitation for 2 min and centrifugation, 15 ml of the upper toluene layer was transferred by disposable pipet to a 20-ml scintillation vial[12]. The vial was stored in a dark place for 12–24 hr prior to counting.

Radioactivity was determined by liquid scintillation counting[13] using the ^{3}H optimized window. A blank was prepared from predosed tail vein plasma. Free salicylamide was determined from a previously prepared plasma standard curve. Correction for counting efficiency was not necessary because the external standard channel ratio remained essentially constant and equal for the standard curve and the measured plasma samples.

Plasma salicylamide glucuronide was determined as free salicylamide obtained after salicylamide glucuronide hydrolysis with β-glucuronidase[14]. β-Glucuronidase (25 μl, 125 units) and 0.5 ml of 0.1 *M* pH 5.0 acetate buffer were added to the 50-μl plasma sample and incubated in a constant-temperature shaking water bath[15] at 37° for 16 hr. The incubation mixture was assayed for free salicylamide as described.

Salicylamide sulfate was determined as free salicylamide after hydrolysis of a 50-μl plasma sample with sulfatase (175 units), β-glucuronidase (875 units)[16], and 100 μl of 0.1 *M* pH 5.2 acetate buffer. Salicylamide glucuronide and salicylamide sulfate concentrations were calculated as described previously (5).

Fluorometric Assay—The salicylamide fluorometric assay was described previously (5, 9, 12). The plasma salicylamide conjugates were determined as free salicylamide after sulfatase and β-glucuronidase treatment.

RESULTS AND DISCUSSION

The fluorometric salicylamide assay is selective for salicylamide in the presence of its metabolites and can detect salicylamide levels as low as 2 μg/ml from 50-μl plasma samples. However, this assay is prone to interferences from other fluorescent or fluorescence quenching phenolic compounds.

The two major metabolites of salicylamide are the highly polar and charged sulfate and glucuronide conjugates (5). Polarity differences between salicylamide and these metabolites make possible a specific radiochemical salicylamide assay. Similar assays were reported for other radiolabeled phenolic compounds (13, 14).

As stated under *Experimental*, ring-labeled tritiated salicylamide was prepared by the reaction of salicylamide with tritium oxide in the presence of heptafluorobutyric acid. The salicylamide hydroxy group is electron donating and tends to promote electrophilic substitution reactions such as the acid-catalyzed tritium–hydrogen exchange. The carboxamide group tends to be deactivating (electron withdrawing). For this reason, the conditions necessary for the acid-catalyzed tritium incorporation were severe and had to be optimized for this particular system. Heptafluorobutyric acid was more useful than trifluoroacetic acid because of its lower volatility (15). The conditions required for equilibrium tritium incorporation into salicylamide (ring substitution[17]) were worked out using deuterium incorporation, substituting deuterium oxide for tritium oxide. Deuterium incorporation was followed by mass spectral analysis of the P, P + 1, and P + 2 peaks. The high temperature and extended heating period finally used were necessary for maximum tritium incorporation with minimal product decomposition.

The white crystalline material obtained from the final sublimation showed only one spot, corresponding to salicylamide, by TLC. Spectrofluorometric analysis showed the product to be >99–99.5% pure. It was necessary, for maximum purification, to collect small fractions (~50 mg) of the sublimed material from the sublimation apparatus cold finger to prevent excess accumulation, which produced material that was only ~90% pure. This enclosed sublimation system was found to be the most efficient both in terms of the purification and recovery of ^{3}H-salicylamide. Once the synthesis procedure was standardized, ^{3}H-salicylamide of >99% purity and 5.24–8.4 mCi/mmole specific activity was consistently obtained.

The radiochemical assay for free salicylamide involved a one-step extraction. The detection limit (100 cpm above background) was 0.002 μg (0.04 μg/ml from 50-μl plasma samples)[18]. No chemiluminescence problems occurred, although routinely the samples were stored in the dark for 12–24 hr prior to counting. The overall mean ± *SD* (3.1–25 μg/ml, n = 17) toluene-based scintillation fluid ^{3}H-salicylamide extraction efficiency was 89.7 ± 0.8% (3.1 μg/ml, n = 6, 89.9 ± 0.7%; 6.25 μg/ml, n = 3, 89.5 ± 1.1%; 12.5 μg/ml, n = 4, 89.1 ± 0.5%; 25 μg/ml, n = 4, 90.1 ± 0.7%).

Salicylamide (^{3}H-salicylamide to salicylamide ratio of 1:29) was administered at 500 mg/kg to rats as an oral solution (pH ~10) to minimize problems associated with administering different crystalline forms and particle sizes. In initial studies, salicylamide in suspension in methylcellulose gave spurious results because the larger ^{3}H-salicylamide crystals dissolved more slowly than the salicylamide powder in the rat GI tract.

The fluorescent and radiochemical plasma level–time curves for salicylamide and its major metabolites are shown in Fig. 1. Each point is the mean of four animals. The areas under the curve for the fluorometric *versus* radiochemical assay (in microgram minutes per milliliter) calculated *via* the trapezoidal method for 0–90 min were 4363 and 4512 for free salicylamide, 1548 and 1570 for salicylamide sulfate, and 1405 and 1425 for salicylamide glucuronide, respectively. Plots of plasma salicylamide,

[17] Ring substitution is assumed because tritium incorporated in the hydroxyl group and carboxamide group readily exchanged. The only position for stable tritium to be incorporated into the molecule is on the phenyl ring.
[18] This limit is dependent on the specific activity of the ^{3}H-salicylamide batch.

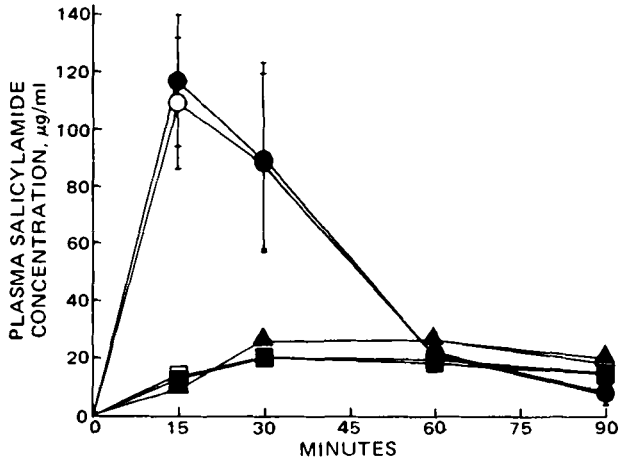

Figure 1—*Plasma concentration* ± SEM versus *time profiles for salicylamide (○, fluorescence assay; ●, radiochemical assay), salicylamide sulfate (□, fluorescence assay; ■, radiochemical assay), and salicylamide glucuronide (△, fluorescence assay; ▲, radiochemical assay) after oral administration of 500 mg of salicylamide/kg to rats. Each point is the mean of four animals. If no error bars are noted, the standard error of the mean was within the size of the symbol.*

salicylamide sulfate, and salicylamide glucuronide assayed radiochemically *versus* levels determined fluorometrically had slopes (±*SEM*) of 1.06 ± 0.02 (r = 0.99), 1.11 ± 0.14 (r = 0.81), and 0.96 ± 0.07 (r = 0.98), respectively. An overall plot combining all 48 data points gave a 1.06 ± 0.01 slope (r = 0.99). The new assay gives ~6% higher plasma salicylamide analysis than does the fluorescence assay, probably due to a slight total plasma radioactivity carryover into the extraction medium. The poorer correlation coefficients for plasma sulfate and glucuronide analyses were probably due to concentration calculation by differences (5) rather than to errors in the assay.

The radiochemical assay gave levels of salicylamide and its conjugates that were statistically equivalent ($p < 0.05$) to those determined by the fluorescence assay (Fig. 1). The large standard errors for the salicylamide levels at 15 and 30 min (Fig. 1) were due to animal differences and not to assay variations. The plasma free salicylamide levels generated in this study were considerably higher than the free salicylamide levels reported previously (3) for rats administered 500 mg of salicylamide suspension/kg. Reported glucuronide levels were larger than those generated in this study. These differences are probably attributable to the more efficient metabolism of salicylamide from the suspension compared to the solution. Similar effects were seen in a human study (12), which showed that a sodium salicylamide solution produced significantly higher free salicylamide bioavailability than salicylamide tablets. These differences were due to more efficient first-pass salicylamide metabolism from the slowly dissolving tablets. Sodium salicylamide partially saturated the enzymes responsible for the first-pass effect, which allowed more unmetabolized drug to enter the general circulation (12).

In conclusion, the advantages of the radiochemical assay just described are: (*a*) its ability to determine specifically salicylamide and its conjugates in the presence of other phenolic substances capable of exhibiting fluorescence or of quenching the fluorescence of salicylamide and (*b*) the low level of detection it can afford. This last point, of course, will be dependent on the specific activity of ^{3}H-salicylamide that can be synthesized. Another important advantage is that once the salicylamide has been extracted into the scintillant fluid, the vials can be counted at the investigator's convenience. In the fluorometric assay, the fluoresence intensity of extracted salicylamide (in 0.25 *N* NaOH) did deteriorate with time. The single-step extraction directly into the scintillant fluid used in the radiochemical assay increased its ruggedness by minimizing technical errors while speeding up the analysis. Balanced against these advantages were the problems of synthesis and handling of the ^{3}H-salicylamide.

High Steady-State Levels of Uric Acid Produced in Rats by Dietary Training and Potassium Oxonate

JEROLD NEWBURGER, TING-FENG HSU, and ALAN B. COMBS ˣ

Received August 17, 1978, from the *College of Pharmacy, University of Texas, Austin, TX 78712.* Accepted for publication October 18, 1978.

Abstract □ To reduce the inherent variability in serum uric acid levels of animals allowed *ad libitum* exposure to food containing potassium oxonate and uric acid, male Sprague–Dawley rats were trained to eat their daily food allotment in a 1.25-hr period each morning. After training, the rats were fed a food mixture containing 5% potassium oxonate and 2% uric acid (w/w each). Serum blood levels of uric acid reached a steady state within 2 hr; these levels were maintained for an additional 4 hr. It is believed that the stomach emptying rate is a zero-order process under these experimental conditions.

Keyphrases □ Uric acid—steady-state serum levels, rats, dietary training, potassium oxonate □ Hyperuricemia—animal models, rats □ Potassium oxonate—used to produce hyperuricemia in rats

Hyperuricemia can result in clinical gout (1) and can complicate the treatment of certain neoplastic diseases (2). The drugs presently used in the treatment of hyperuricemia all have distinct disadvantages and can cause adverse effects (3, 4).

A potential alternative therapy may be indicated by recent reports characterizing the *in vitro* decomposition of uric acid in the presence of light and riboflavin (5, 6). The selection of an animal model for *in vivo* testing of phototherapy is difficult, because most naturally hyperuricemic animals are typically exotic, protected, expensive, or nonmammalian (7–10). However, a murine model for hyperuricemia was reported recently. Rats given the uricase inhibitor oxonic acid can become hyperuricemic (11, 12). Moreover, these animals will develop gouty renal pathology after chronic oral feeding of oxonate and uric acid (13, 14).

We recently demonstrated that serum uric acid levels of rats fed *ad libitum* a ground laboratory ration containing potassium oxonate and uric acid are subject to a diurnal variation with higher morning levels (15). The variability produced by this method complicated the evaluation of phototherapy effects on serum uric acid. This paper reports the effects on serum uric acid levels of feeding potassium oxonate and uric acid to rats trained to eat their total daily food allotment within a short period.

EXPERIMENTAL

Male Sprague–Dawley rats[1], 150–200-g initial weights, were housed individually in hanging cages and were maintained on 12-hr light–dark cycles. They were allowed water *ad libitum* throughout the study. The animals were fed a standard pelleted laboratory ration[2] *ad libitum* for 1 week before dietary training. Following a previously reported procedure for dietary training and synchronization (16, 17), the rats were fed their laboratory ration as a ground powder given for only 1.25 hr each morning. By the end of 1 week, most animals had learned to eat their total daily ration during this brief feeding period. Animal body weights stabilized and generally began to increase again after 2 weeks. The animals were maintained on this feeding schedule for 4 weeks prior to use in the study.

On the morning of the study, animals were fed the ground laboratory ration mixed with 5% potassium oxonate[3] and 2% uric acid[4] (w/w each). The duration of feeding was the usual 1.25 hr. Animals were sacrificed for serum uric acid determinations immediately prior to drug administration and at 2, 4, 6, and 24 hr afterward. The animals were anesthetized with ether, and 3–5 ml of blood was drawn from each into heparinized syringes *via* the inferior vena cava. Analysis of serum uric acid was performed by high-pressure liquid chromatography as previously described (6). Statistical comparisons were made using analysis of variance followed by Scheffé's method of multiple contrasts (18).

RESULTS

The animal weights and the amounts of food, potassium oxonate, and uric acid ingested are listed in Table I. Serum uric acid levels as a function of time after the mixture was presented to the animals are shown in Fig. 1. The rats became hyperuricemic within 2 hr. The blood levels remained high and essentially constant for a minimum of another 4 hr. Levels returned to control values by 24 hr.

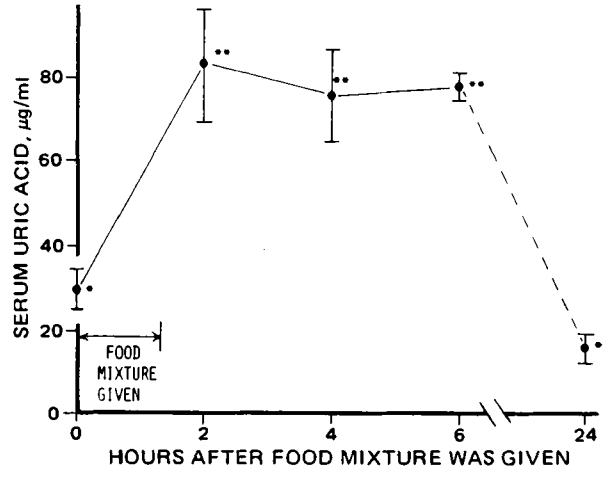

Figure 1—*Serum uric acid levels as a function of time after exposure of rats to a food mixture containing 5% potassium oxonate and 2% uric acid (w/w each). The animals were trained to eat their full daily food rations during a 1.25-hr period each morning. Each data point represents the mean ± SEM for three animals; for * versus **, $p < 0.05$ by analysis of variance followed by Scheffé's method of multiple contrasts.*

Table I—Values Observed on Day of Experiment [a]

Parameter	Value
Animal weight, g	225 ± 38
Amount of mixture eaten, g/kg[b]	57.1 ± 7.2
Potassium oxonate ingested, g/kg	2.86 ± 0.36
Uric acid ingested, g/kg	1.14 ± 0.14

[a] Values are reported as mean ± *SD*. [b] Mixture consisted of ground laboratory ration containing 5% potassium oxonate and 2% uric acid (w/w each).

Accumulation to a plateau would be expected to occur with a zero-order administration process (19). The absorption of uric acid from the rat intestine, however, has been reported to be first order (20). Therefore, gastric emptying rather than intestinal absorption may be rate limiting. Reported data (16, 17) for untreated control animals trained by this technique are consistent with a zero-order stomach emptying rate for the first 10–12 hr following the daily feeding. This animal model will be used to test the efficacy of light and riboflavin in the reduction of serum uric acid.

High-Performance Liquid Chromatographic Determination of Cephacetrile

ALBERTO MANGIA ˣ, SILVESTRO SILINGARDI, FULVIO BORTESI, GIAMPIERO GRISANTI, and MAURO DI BITETTO

Received June 6, 1978, from the *Research Laboratories, Pierrel SpA, Via Degli Artigianelli 10, 20159 Milan, Italy* Accepted for publication October 19, 1978.

Abstract □ A rapid and accurate quantitative determination of cephacetrile in finished bulk and dosage forms is reported. The high-performance liquid chromatographic method is free of interference by acetyl hydrolysis products and synthesis by-products. The assay can be performed in about 15 min, affording <0.7% coefficients of variation within and between days. The chromatographic results are in good agreement with the microbiological assay requested by the "Code of Federal Regulations" for certification of cephacetrile sodium.

Keyphrases □ High-performance liquid chromatography—analysis, cephacetrile in various dosage forms □ Cephacetrile—high-performance liquid chromatographic analysis in various dosage forms □ Antibacterials—cephacetrile, high-performance liquid chromatographic analysis in various dosage forms

Cephacetrile (I) sodium [7-cyanoacetamido-3-acetoxymethyl-3-cephem-4-carboxylic acid, sodium salt] is a new cephalosporin antibacterial for parenteral use (1). The approved methods of analysis for certification are the microbiological agar diffusion assay and the hydroxylamine colorimetric assay (2).

This report outlines a more selective, rapid, and accurate method for the quantitative determination of cephacetrile in bulk drugs and pharmaceutical formulations using high-performance liquid chromatography (HPLC). The method is free of interference by acetyl hydrolysis products and synthesis by-products. Furthermore, the desacetyl derivative (II) of cephacetrile and lactone (III) can be detected accurately up to 0.1%.

EXPERIMENTAL

Materials—Cephacetrile FDA reference standard (microbiological potency of 885 μg/mg, lot 9/72) was used as received. Desacetyl derivative (II) of cephacetrile was prepared by enzymatic hydrolysis with acetyl esterase (3), while lactone (III) was synthesized by reacting trifluoroacetic acid with cephacetrile. Cephalosporins (IV*a* and IV*b*) were obtained by reaction of V with the proper acid chloride in acetone in the presence of urea (4), while IV*c* was prepared by reaction of methanesulfonyl chloride with the silyl derivative of V in dichloroethane (Scheme I). Cefazolin was Pierrel working standard. Methanol[1], acetic acid[2], and 1 *N* NaOH[2] were analytical reagent grade.

Apparatus—A liquid chromatograph[3], equipped with a 20-μl valve

High-Performance Liquid Chromatographic Determination of Cephacetrile

ALBERTO MANGIA ˣ, SILVESTRO SILINGARDI, FULVIO BORTESI, GIAMPIERO GRISANTI, and MAURO DI BITETTO

Received June 6, 1978, from the *Research Laboratories, Pierrel SpA, Via Degli Artigianelli 10, 20159 Milan, Italy* Accepted for publication October 19, 1978.

Abstract □ A rapid and accurate quantitative determination of cephacetrile in finished bulk and dosage forms is reported. The high-performance liquid chromatographic method is free of interference by acetyl hydrolysis products and synthesis by-products. The assay can be performed in about 15 min, affording <0.7% coefficients of variation within and between days. The chromatographic results are in good agreement with the microbiological assay requested by the "Code of Federal Regulations" for certification of cephacetrile sodium.

Keyphrases □ High-performance liquid chromatography—analysis, cephacetrile in various dosage forms □ Cephacetrile—high-performance liquid chromatographic analysis in various dosage forms □ Antibacterials—cephacetrile, high-performance liquid chromatographic analysis in various dosage forms

Cephacetrile (I) sodium [7-cyanoacetamido-3-acetoxymethyl-3-cephem-4-carboxylic acid, sodium salt] is a new cephalosporin antibacterial for parenteral use (1). The approved methods of analysis for certification are the microbiological agar diffusion assay and the hydroxylamine colorimetric assay (2).

This report outlines a more selective, rapid, and accurate method for the quantitative determination of cephacetrile in bulk drugs and pharmaceutical formulations using high-performance liquid chromatography (HPLC). The method is free of interference by acetyl hydrolysis products and synthesis by-products. Furthermore, the desacetyl derivative (II) of cephacetrile and lactone (III) can be detected accurately up to 0.1%.

EXPERIMENTAL

Materials—Cephacetrile FDA reference standard (microbiological potency of 885 μg/mg, lot 9/72) was used as received. Desacetyl derivative (II) of cephacetrile was prepared by enzymatic hydrolysis with acetyl esterase (3), while lactone (III) was synthesized by reacting trifluoroacetic acid with cephacetrile. Cephalosporins (IV*a* and IV*b*) were obtained by reaction of V with the proper acid chloride in acetone in the presence of urea (4), while IV*c* was prepared by reaction of methanesulfonyl chloride with the silyl derivative of V in dichloroethane (Scheme I). Cefazolin was Pierrel working standard. Methanol[1], acetic acid[2], and 1 *N* NaOH[2] were analytical reagent grade.

Apparatus—A liquid chromatograph[3], equipped with a 20-μl valve

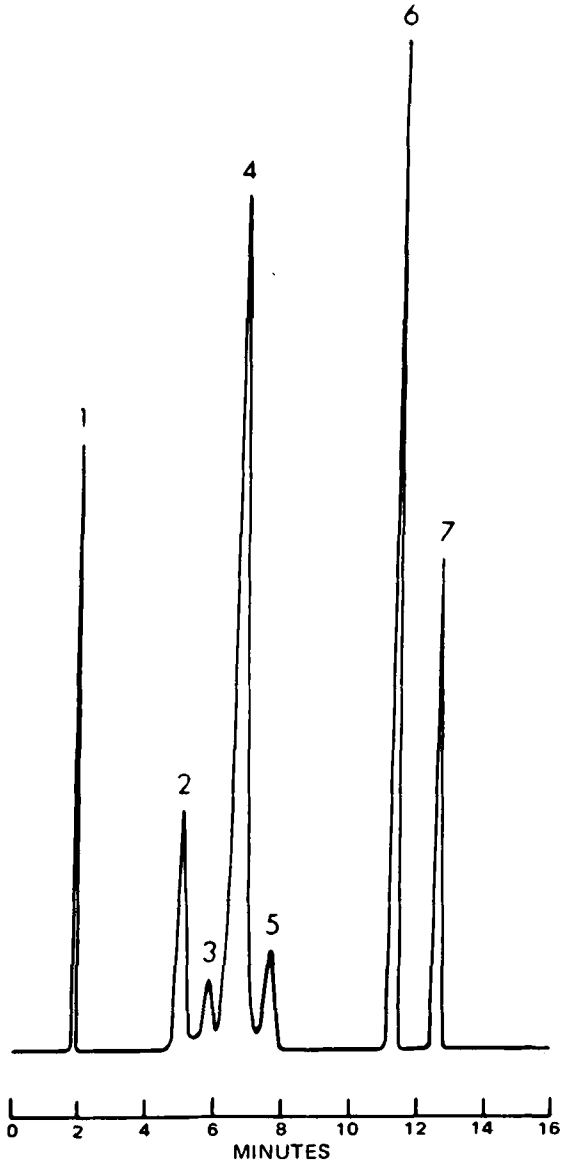

Figure 1—*High-performance liquid chromatogram of an artificial mixture of cephalosporins (I–IV). Key: 1, II; 2, III; 3, IVc; 4, I; 5, IVa; 6, cefazolin; and 7, IVb.*

and loop injector[4] and a fixed-wavelength UV detector (254 nm), was used. The prepacked[5] stainless steel column (25 × 0.45 cm i.d.) was operated at 40° at a flow rate of 2 ml/min.

Mobile Phase—An acetic acid–sodium acetate pH 4.2 buffer (0.01 ionic strength) and methanol were used as the mobile phase. The elution (5% of methanol) was isocratic for 5 min; then a linear gradient was programmed, reaching 30% of methanol in 7 min.

Standard Solutions—*Internal Standard Solution*—Approximately 25 mg of cefazolin was weighed accurately in a 50-ml volumetric flask and dissolved and diluted to volume with the pH 4.2 buffer.

Cephacetrile Standard Solution—Approximately 15 mg of the reference standard was weighed accurately in a 25-ml volumetric flask and dissolved and diluted to volume with the pH 4.2 buffer. Fresh standard solutions were prepared daily.

Standard Calibration Solution—Five standard calibration solutions were prepared daily by adding 1, 2, 3, 4, and 5 ml of cephacetrile standard solution and 3 ml of internal standard solution to five 10-ml volumetric flasks and then diluting to volume with the pH 4.2 buffer.

Sample Analyses—Approximately 15 mg of cephacetrile samples was accurately weighed in a 25-ml volumetric flask, dissolved with the pH 4.2 buffer, and diluted to volume. A 5.0-ml aliquot was pipetted into a 10-ml volumetric flask together with 3.0 ml of the internal standard solution and diluted to volume. Aliquots (20 μl) of the solution were injected onto the chromatograph.

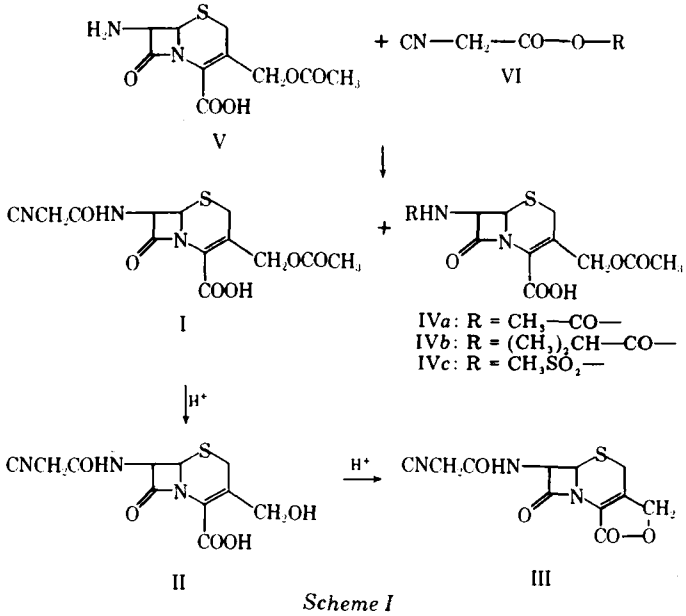
[a] Calculated as free acid (molecular weight 339.3).

RESULTS AND DISCUSSION

Synthesis—Cephacetrile is synthesized (Scheme I) by reaction of 7-amino-3-acetoxymethyl-3-cephem-4-carboxylic acid (V) with mixed anhydrides (VIa–VIc) of cyanoacetic acid, both carboxylic (3) and sulfonic[6]. Crude cephacetrile is accompanied by variable amounts of by-products (IV), as shown by TLC. Moreover, II and III, arising from I through the acid hydrolysis removal of the acetyl group, can be formed during the workup of the reaction mixture and, therefore, be present in the finished product after a long storage. The described HPLC method is a rapid and accurate tool for isolating and measuring cephacetrile.

Evaluation of Chromatographic Systems—Reversed-phase chromatography was chosen because of the stability of the resins over time and a wide pH range, easy preparation, and low cost of mobile phases. The retention times of products (I–IV) can be changed by varying the amount and type of the organic modifier and the buffer pH. With cephacetrile as the reference peak, at a constant concentration of the organic



Scheme I

[6] Unpublished data.

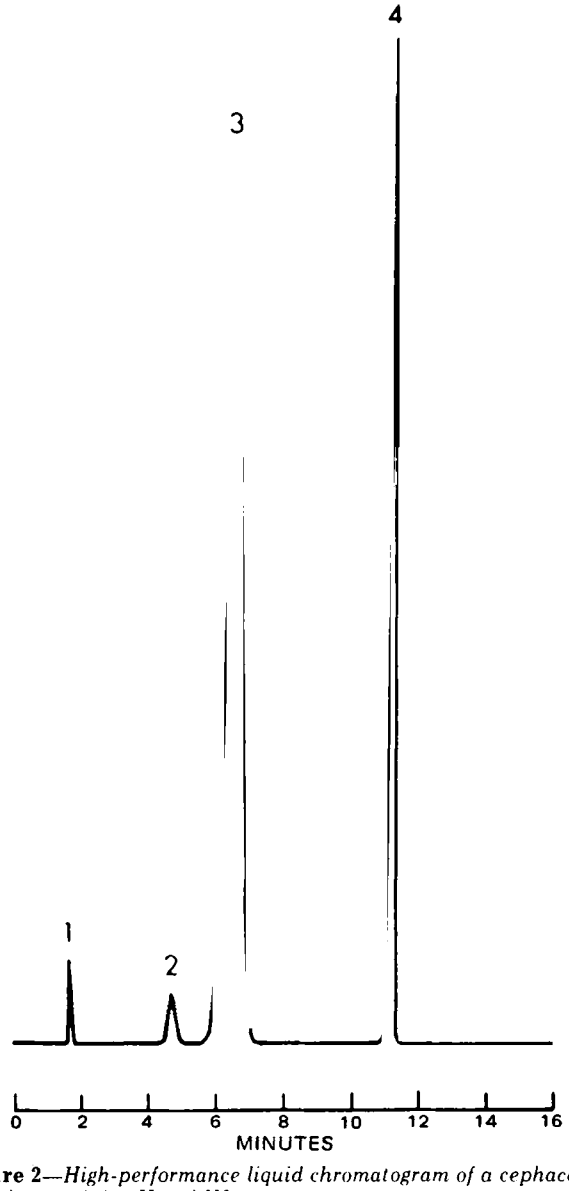


Figure 2—*High-performance liquid chromatogram of a cephacetrile sample containing II and III.*

solvent, III was rapidly eluted while the retention time of IV*a* was increased by lowering the pH from 7.2 phosphate buffer to 4.2 acetate buffer. The elution of IV*c* was not affected by changing the pH and type of the organic modifier, while IV*b* was eluted only by using a proper gradient. Methanol allowed a better partition between the components than acetonitrile. Cefazolin was selected as the internal standard because of its efficient separation from I–IV.

Figure 1 shows a chromatogram of an artificial mixture of cephalosporins I–IV and cefazolin. The peaks of the compounds were well resolved in less than 15 min. Figure 2 shows a typical chromatogram of a cephacetrile sample containing desacetyl (II) and lactone (III) impurities.

Table II—Comparison of Analysis by HPLC and Official Methods for Certification [a] of Cephacetrile Sodium

	Percent Purity (Acid)			
Sample	HPLC[b]	Microbiological[c] Method	Hydroxylamine[c] Method	Perchloric Acid[c] Method
A	85.6	82.5	91.9	89.6
B	85.3	87.3	94.7	89.6
C	87.0	85.7	92.2	91.6
D	86.3	86.1	90.8	89.1
E	78.8	77.8	88.9	90.9
F	82.7	85.3	92.7	91.3
G	79.3	81.6	88.5	90.9
H	82.3	81.6	87.4	90.3
I[d]	70.5	73	71.2	80.8
L[d]	70.9	72.5	78.2	83.5
M[d]	76.6	80.4	87.7	94.3
Average	80.48	81.3	87.6	89.3

[a] Reference 2. [b] Mean of three determinations. [c] Mean of two determinations. [d] Lyophilized salts containing 10% mannitol (w/w).

Reproducibility and Accuracy—The calibration curve was linear in the range of cephacetrile content examined [correlation coefficient (5) of 0.99993]. The within-day standard error was less than 0.4% (Table I). The pooled standard error from different days was less than 0.5%.

Specificity—As shown in Fig. 1, the hydrolysis products (II and III) and the potential impurities (IV*a*–IV*c*) cannot interfere with the quantitative HPLC determination of cephacetrile. While the desacetyl derivatives and lactones do not interfere with the *Bacillus subtilis* assay of cephalosporins, if present in a quantity lower than 15% (6), they do interfere with the colorimetric hydroxylamine assay mandated by the "Code of Federal Regulations." A comparison of the analyses of I by HPLC, the microbiological determination, the hydroxylamine colorimetric method, and the perchloric acid titration is given in Table II. Samples were selected from freshly crystallized salts (Samples A–D), aged salts (E–H), and sterile lyophilized forms (I–M) to show the dependability of the HPLC analysis. The deviation between the HPLC method and the microbiological determination was less than 1%. The other two official assays were less accurate.

Preparation of Semisynthetic (+)-Tubocurarine Chloride

JANETTE NAGHAWAY [x] **and T. O. SOINE** [†]

Received September 5, 1978, from the *Department of Medicinal Chemistry, College of Pharmacy, University of Minnesota, Minneapolis, MN 55455.* Accepted for publication October 25, 1978. [†]Deceased.

Abstract □ Semisynthetic (+)-tubocurarine chloride (II) was prepared by monoquaternization of (+)-tubocurine. The method involved treating (+)-tubocurine with a 0.5 *M* equivalent of hydrochloric acid prior to quaternization with methyl iodide, followed by neutralization and iodide–chloride ion-exchange. Column chromatography and crystallization procedures were utilized for pure semisynthetic II preparation. The neuromuscular junction blocking activities of the semisynthetic and commercial II were determined by the *in vivo* cat hypoglossal nerve–tongue muscle preparation. No detectable differences among physical constants, spectral data, and neuromuscular junction blocking activities were noted between the commercial product and the semisynthetic II. This result substantiates the chemical and biological data for the well-accepted new formula for II. The unexplained M + *n*14 mass spectral peaks shown by the curare-type bases are characteristic of the molecular species rather than a result of contaminants.

Keyphrases □ Tubocurarine chloride—chemical synthesis, comparison to naturally derived material, NMR analysis □ Neuromuscular blocking effect—tubocurarine chloride, comparison of synthesized and naturally derived materials □ NMR spectroscopy—analysis, tubocurarine chloride

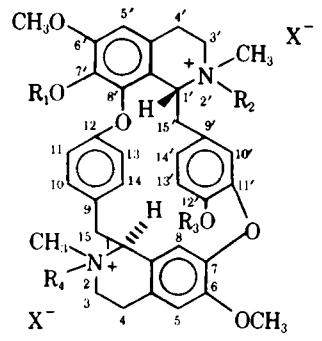
The isolation and original structural characterization of crystalline (+)-tubocurarine chloride (I) were achieved by King (1, 2), who identified I as a bisbenzyltetrahydroisoquinoline alkaloid in which both nitrogen atoms were quaternary. Subsequent structural revision (3) revealed that the bisquaternary structural assignment was erroneous and that (+)-tubocurarine chloride was actually a monoquaternary–monotertiary species (II) with the quaternary function in the tetrahydroisoquinoline ring bearing the free phenolic hydroxyl group. The new structure was soon confirmed (4) by X-ray crystallography, as was the assignment of the quaternary function to the phenolic tetrahydroisoquinoline ring system.

Although the new structure is well accepted, direct chemical synthesis or semisynthesis should be provided as confirmatory evidence. The successful synthesis of II from unequivocal sources would confirm the structure and permit comparative tests of biological activity. Pure II was also needed for determining whether the anomalous M + *n*14 mass spectral peaks observed (5, 6) in natural curare bases and similar type alkaloids were characteristic of such compounds or due to *O*-methylated contaminants.

DISCUSSION

The successful preparation of (+)-isotubocurarine chloride (III) from (+)-tubocurine (IV) (7) suggested the possiblity of preparing II by similar means. NMR spectra and TLC data obtained during the preparation of III by interaction of IV with a 0.5 *M* equivalent of methyl iodide showed that II was being formed in small yields. The small yields of II mandated a modified route for quaternization such as that employed (8) on the calabash curare alkaloids. This method involved the use of a 0.5 *M* equivalent of hydrochloric acid added prior to quaternization with methyl iodide, followed by neutralization. Treating IV sequentially with hydrochloric acid and methyl iodide, followed by neutralization, produced a multicomponent product.

TLC examination of this product on silica gel revealed four spots with R_f values corresponding to those of IV, neutralized II, neutralized III, and (+)-chondocurarine iodide (V). The presence of a higher proportion



I: $R_1 = R_3 = H$, $R_2 = R_4 = CH_3$, X = Cl
II: $R_1 = R_3 = R_4 = H$, $R_2 = CH_3$, X = Cl
III: $R_1 = R_2 = R_3 = H$, $R_4 = CH_3$, X = Cl
IV: $R_1 = R_3 = H$ (R_2, R_4, and X absent)
V: $R_1 = R_3 = H$, $R_2 = R_4 = CH_3$, X = I

of neutralized II than III was evident from the TLC plate and the NMR spectrum, which showed two NCH_3 signals: the neutralized III 2′-NCH_3 resonance (at δ 2.10) and the neutralized II 2-NCH_3 resonance (at δ 2.42) in a ratio of 1:2. The reaction mixture iodide content was ion exchanged for chloride ions, and neutralized II was isolated through column chromatography over alumina. Following treatment with hydrochloric acid to convert the product to its hydrochloride, II was crystallized from 0.1 *N* HCl by seeding with a few crystals of commercial (+)-tubocurarine chloride, followed by recrystallization from 0.1 *N* HCl to provide the pure compound.

The lesser basicity and nucleophilicity of the amine function of IV at the 2′-nitrogen center, evident by the lower magnitudes of protonation and alkylation at this position, are probably reflections of a steric factor, although solvation effects could contribute to the observed differences. A Dreiding model of IV shows that the trisubstituted aromatic ring, because of some free movement at position C-15′, could easily exert steric hindrance at the 2′-nitrogen center. On the other hand, such steric interaction cannot be invoked at the 2-nitrogen heterocyclic ring since the disubstituted aromatic ring at C-15 cannot be brought near the 2-nitrogen reaction site.

Semisynthetic II was identified by TLC, melting-point, and spectral (IR, UV, and NMR) data, which were in good agreement with those of the commercial samples. The mass spectral data indicated the base peak at *m/e* 298 and a molecular ion at *m/e* 594 with relative intensities in accord with literature values (9). The spectra[1] showed the expected *m/e* 594 major peak, resulting from the conversion of II to a ditertiary molecular ion (M), and definite M + 14 and M + 28 peaks with relative intensities of 3.7 and 0.5% of the base peak, respectively.

Previous reports (9) suggested that the formation of the ditertiary species is through loss of methyl chloride, presumably before ionization, probably in a purely thermal process similar to that observed in GLC (10) and mass spectra (11) of quaternary methiodide salts of amines. The only peaks for (+)-tubocurarine chloride cited (9) were those having an abundance greater than 5% of the base peak, although a greater significance was attached by other investigators (5) to a very low relative intensity peak (0.2%), which was assigned as the M^+ for a similar (but ditertiary) type of alkaloid.

Peaks at 14 mass units above the molecular ion in the mass spectra of bisbenzyltetrahydroisoquinoline alkaloids (5, 6) have been attributed to either contamination by a more highly methylated impurity (5) or to a thermally induced intermolecular methyl transfer (6). Thermal methyl transfer was an inadequate explanation for the II mass spectral data, since II lacks the necessary methylating group (12). Furthermore, the inten-

[1] The mass spectra of commercial II samples were determined on a Hitachi Perkin-Elmer RMU-6D spectrometer and/or an AEI-MS 30 high-resolution mass spectrometer at a 70-ev ionizing voltage and a 200° chamber temperature.

© 1979, American Pharmaceutical Association

sities of the higher peaks relative to the M^+ peak were expected to vary with changes in the vaporization temperature (12), but this was not the case with II. Since all commercial II is crystallized from natural sources, contamination by *O*-methylated congeners is possible. Small amounts of these contaminants could be detected in the mass spectrum and would not unduly distort the physical criteria of the compound but could affect the biological activity through the greater blocking potencies of the more highly *O*- and *N*-methylated congeners (13).

The M + *n*14 peaks shown by pure II indicate that this mass spectral behavior may be characteristic of the quaternary curare bases. The higher peaks may be due to preliminary thermal dequaternization, followed by generation of these peaks from the tertiary base, since pure (−)-curine and (+)-tubocurine give spectra with peaks at *m/e* 608 and 622. A thermally induced Hofmann elimination could account for the M + 14 peak from the quaternary base and coupled with radical formation from the tertiary base which could combine with generated methyl radicals to account for the higher peak(s).

EXPERIMENTAL[2]

Semisynthetic (+)-Tubocurarine Chloride (II)—A stirred solution of (+)-tubocurine[3] (1.0 g, 1.68 mmoles) in 80 ml of acetone–water (3:1) was slowly treated with 16.76 ml of 0.1 *N* HCl (1.68 mmoles). Immediate evaporation of the solvent to dryness under reduced pressure was followed by dissolution of the residue in methanol (35 ml) and the subsequent addition of methyl iodide (10 ml). The mixture was stirred for 17 min and then evaporated to dryness under reduced pressure. TLC examination of the residue on silica gel showed four spots with R_f values of 0.83, 0.43, 0.26, and 0.06. These R_f values were similar to those for (+)-tubocurine (IV), (+)-tubocurarine chloride (II) neutralized with sodium bicarbonate, neutralized (+)-isotubocurarine chloride (III), and (+)-chondocurarine iodide (V), respectively. The intensity of the R_f 0.43 spot was greater than that of R_f 0.26.

Crystallization of the residue from a methanol–chloroform mixture (15) provided V (0.38 g), which was dissolved in methanol and converted to I by passage through a column[4] (15 × 1.5 cm, chloride cycle). Methanolic solvent evaporation gave an amorphous I residue (0.28 g). Crystallization of I from absolute ethanol gave a product with a melting point of 246–247° (frothing). The methanol–chloroform mother liquor iodide content was also exchanged for chloride, and the effluent solution was evaporated to dryness. The residue (0.92 g) was suspended in water (30 ml) and extracted with chloroform (3 × 100 ml).

The aqueous layer was evaporated to dryness under reduced pressure, leaving a yellowish-white residue (0.56 g). The residue (0.37 g) was dissolved in methanol, adsorbed on a small amount of neutral alumina (grade V), and air dried. This dry powder was packed on top of a neutral alumina column (grade V, 60 g) and eluted with ethyl acetate to provide unchanged IV (0.056 g) in the early fractions. The eluting solvent was enriched with methanol, followed by enrichment with 2.5% aqueous ammonia, so that elution took place over 10–12 hr with a mixture of ethyl acetate–methanol–2.5% aqueous ammonia (8:1.5:0.5) and separated the remaining components into two yellow bands with an intermediate diffuse yellow zone.

Extrusion of the column contents enabled mechanical separation of the bands. The faster moving band was repeatedly extracted with hot methanol (300 ml). The residue left after solvent evaporation was treated with excess 1 *N* HCl, followed by evaporation of the solution to dryness under reduced pressure. The residue (0.20 g) showed trace amounts of the other components when examined by TLC. Crystallization from 0.1 *N* HCl by seeding with a few crystals of commercial II[5] provided a crop of crystals, which was used for seeding other quantities of column-separated semisynthetic II. TLC on silica gel of the crystalline product showed one spot with a higher R_f (~0.83) in addition to that at 0.43, which represents II.

Further purification was carried out by treating an aqueous solution of the foregoing crystals (0.02 g in 5 ml) with a few drops of 10% ammonium hydroxide and extracting with chloroform (6 × 30 ml). The aqueous layer was acidified with 1 *N* HCl and evaporated to dryness, affording a white solid (0.014 g), which now showed only one spot (R_f 0.43). Recrystallization from 0.1 *N* HCl provided white crystals, mp 255–257° (frothing at 263°) [lit. (16) mp 270°]; $[\alpha]_D^{25}$ +204.3° (c 0.60, methanol) [lit. (16) $[\alpha]_D$ +219° (c 0.785, methanol)]. IR and NMR spectra were similar to those of the commercial sample used for seeding; UV: λ_{max} (log ϵ) 225 (4.56) and 282 (3.90) nm; mass spectrum[6]: *m/e* (relative intensity) 622 (0.5), 609 (1.4), 608 (3.7), 595 (6.0), 594 (17.0), 593 (15.0), and 298 (100.0) [lit. (9) *m/e* (relative intensity) 595 (6.0), 594 (17.0), 593 (12.0), and 298 (100.0)].

Neuromuscular Junction Blocking Bioassay—The neuromuscular junction blocking potencies of semisynthetic and authentic II were determined by employing the *in vivo* cat hypoglossal nerve-tongue muscle preparation, which was described earlier (17). The results indicated identical blocking potencies for the two compounds.

[2] Melting points were determined on a Mel-Temp apparatus and are uncorrected. Optical rotations were measured on a Perkin-Elmer 141 polarimeter. UV spectra were taken in methanol solutions with a Cary 14 recording spectrophotometer. IR spectra were obtained in KBr pellets with a Perkin-Elmer 237 grating IR spectrophotometer. NMR spectra were measured with a Varian Associates model A-60D or XL-100 NMR spectrometer with sodium 2,2-dimethyl-2-silapentane-5-sulfonate as an internal standard. Mass spectral determinations were performed by the Mass Spectroscopy Laboratory Service, Department of Chemistry, University of Minnesota, Minneapolis, Minn., with a Hitachi Perkin-Elmer RMU-6D mass spectrometer or an AEI-MS 30 high-resolution mass spectrometer.

TLC was conducted on 0.25-mm Brinkmann silica gel HF-254 plates using 10% aqueous ammonia–methanol–ethyl acetate–isopropyl alcohol (2:2:1:1) as the developing solvent. Visualization was done with both UV lamp and iodine vapor. Activity grade V Woelm neutral alumina was employed in column chromatography. (+)-Tubocurarine chloride was obtained from Sigma Chemical Co., St. Louis, MO 63118, Abbott Laboratories, North Chicago, IL 60064, and Organon Inc., West Orange, NJ 07052.

[3] Prepared by the dequaternization of II with sodium thiophenoxide (14). It showed only one spot (R_f 0.83) when examined by TLC.

[4] Amberlite IRA-410, medium porosity, Mallinckrodt.

[5] Obtained from Abbott Laboratories, North Chicago, IL 60064. Its melting-point behavior showed collapse of the sample at 255°, followed by vigorous frothing with decomposition at 263°. It also showed $[\alpha]_D^{25}$ +214° (c 0.79, methanol). When examined by TLC, it showed only one spot (R_f 0.43).

[6] The mass spectrum of semisynthetic II was obtained using an RMU-6D Hitachi Perkin-Elmer mass spectrometer with a 70-ev ionization voltage and a 200° chamber temperature.

Differential Pulse Polarographic Determination of 2,3-Dimercaptosuccinic Acid and Tin(II) in Radiopharmaceuticals

A. J. ROSS*, H. A. MOORE‡§x, C. O. RITTER‡, and S. A. MOROS*

Received May 18, 1978, from the *Quality Control Department, Hoffmann-La Roche Inc., Nutley, NJ 07110, and the ‡Medi+Physics Inc., Emeryville, CA 94608. Accepted for publication October 30, 1978. §Present address: New England Nuclear, Billerica, Mass.

Abstract □ A differential pulse polarographic procedure was developed for the assay of dimercaptosuccinic acid and tin(II), components of a commercially available pharmaceutical kit for kidney scintigraphy. The method is quantitative and qualitative for both the chelated and unchelated forms of dimercaptosuccinic acid and tin(II) in a mixture of the two.

Keyphrases □ Dimercaptosuccinic acid—analysis, differential pulse polarography, in radiopharmaceuticals, and tin □ Tin—analysis, differential pulse polarography, in radiopharmaceuticals, and dimercaptosuccinic acid □ Polarography, differential pulse—analysis, dimercaptosuccinic acid and tin in radiopharmaceuticals □ Scintigraphy, kidney—analysis of dimercaptosuccinic acid and tin(II) in commercial preparations, differential pulse polarography

Dimercaptosuccinic acid (I) possesses clinical importance as a detoxification agent for mercury, arsenic, and other heavy metals (1) and, more recently, in conjunction with tin(II) and ^{99m}technetium as a radiopharmaceutical for kidney scintigraphy (2–4). Although the chemistry of several I chelates has been studied (5) with application to biological systems (6, 7), little work has been done to develop a specific analytical procedure.

UV procedures (8, 9) depend on the I thiol reducing properties and are inappropriate in the presence of another reducing agent. Since tin(II) is present in the kidney reagent final product (3 m*M* I + 1 m*M* $SnCl_2$), an alternative means of analysis is necessary. Krejcarek *et al.* (10) employed differential pulse polarography to analyze both tin(II) and I but gave few details of their unpublished procedure. McBride *et al.* (11) employed the same technique to quantitate tin(II) in pyrophosphate and polyphosphate radiopharmaceutical kits.

This paper expands on this recent work and presents a quantitative and qualitative technique to analyze both the chelated and unchelated forms of I and tin(II) in a mixture of the two. The method was successfully applied to ampuls of final product reagent.

EXPERIMENTAL

Reagents and Chemicals—The reagents and chemicals used were *meso*-dimercaptosuccinic acid, anhydrous stannous chloride[1], and analytical grade lithium perchlorate[2], sodium phosphate·$7H_2O$[3], and citric acid[3]. The mercury[4] used was triple distilled.

Instrumentation—A polarographic analyzer[5], equipped with a drop-time assembly[6], was used in conjunction with a three-electrode system consisting of a dropping mercury electrode, a silver–silver chloride reference electrode, and a platinum counter electrode. The mercury column height was 60 cm; the automatic drop time was 0.5 sec. At this column height, the dropping mercury electrode had an open circuit drop time of 7.36 sec and a mercury flow rate of 0.93 mg/sec in the buffer.

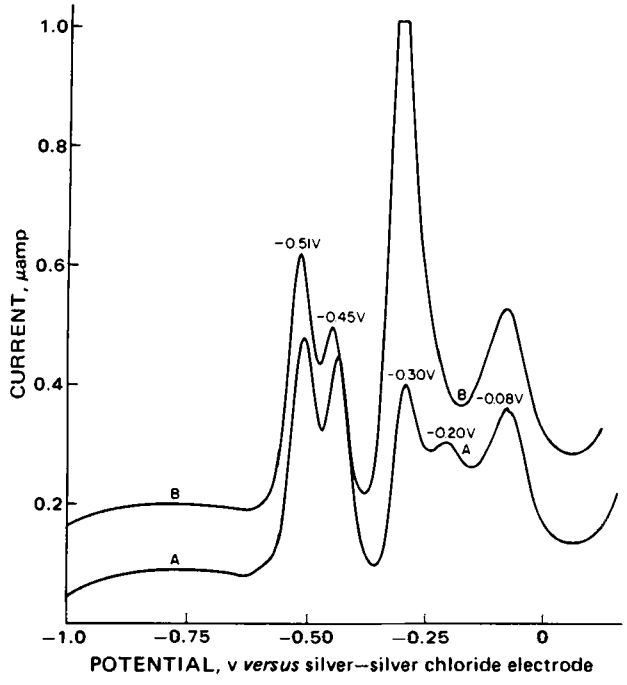

Figure 1—*Sample polarograms of ampul in supporting electrolyte (polarogram A) and with addition of excess I (polarogram B).*

A scan rate of 2 mv/sec and a pulse amplitude of 25 mv were employed. The current range was set at 1 μamp, and the scan range was 0.75 v. The samples were scanned positively from −0.70 to +0.05 v against silver–silver chloride, and the differential pulse polarograms were obtained on an *x*–*y* recorder[7].

Dissolved air was removed from solutions by bubbling prepurified nitrogen through the cell for 5 min and passing it over the solution during polarography.

Determination of I and Tin(II) in Kidney Reagent—Dilute tin(II) solutions such as those used in this procedure are susceptible to oxidation, especially when exposed to light. Consequently, it is essential to establish a technique that minimizes exposure to air and light. Dimercaptosuccinic acid slowly hydrolyzes in solution; standards and reagents containing this material should be prepared just before use.

A 150-μl aliquot of the freshly opened ampul of kidney reagent final product was diluted to 10 ml with deaerated pH 3.0, 0.1 *N* $LiClO_4$–0.1 *M* citrate–phosphate buffer supporting electrolyte, and the polarogram was recorded. The peak current at −0.30 v (due to the unchelated I) was measured and compared to a standard calibration curve for unchelated I. A second peak current at about −0.51 v (due to the reduction of chelated stannous ion) was measured also and compared to a standard curve for chelated tin(II). This second value was then normalized with respect to stoichiometry [at this pH, the chelate formula is $Sn(I)_2$] and added to the unchelated I value to arrive at the total I concentration (Fig. 1A).

Another 150-μl aliquot of the ampul contents was transferred to a

0.0580	0.0323	0.71	—	0.25	0.31

second 10-ml volumetric flask, flooded with excess deaerated I solution (1.5 ml of 1 m*M* solution) to ensure complete chelation of the tin, and diluted to volume with deaerated supporting electrolyte. The solution was analyzed polarographically and the peak current was measured at −0.51 v. Comparison to the standard curve of chelated tin gave the total stannous content (Fig. 1B).

Standard free I and chelated tin(II) curves were prepared. Five solutions, ranging in concentration from 0.012 to 0.018 m*M* of both I in the absence of tin and tin(II) flooded by an excess of I, were diluted in supporting electrolyte. The I solutions were analyzed polarographically, and the peak currents measured at −0.30 v were plotted against the respective concentrations to obtain the free I calibration curve. Similarly, for tin(II) solutions in an excess of I, the peak currents at −0.51 v were measured and plotted against concentration to obtain the chelated tin(II) calibration curve.

RESULTS AND DISCUSSION

Tin(II) in the absence of I had two distinct polarographic peaks in pH 3.0, 0.1 *N* $LiClO_4$–0.1 *M* citrate–phosphate buffer. One, at −0.20 v, was due to the tin(II) to tin(IV) oxidation. The second, at −0.45 v, was due to the reduction to tin metal. When tin(II) was chelated by I, these peaks shifted to −0.45 and −0.51 v, respectively. The standard curve was linear with concentration, demonstrating that the method can be used to determine chelated tin(II). Tin(IV) will produce a reduction peak only in the presence of high hydrogen-ion and chloride-ion concentrations (12) and does not interfere in this electrolyte.

The I wave at −0.30 v is due to the oxidation of mercury to form the mercury mercaptide salt and not to oxidation of the sulfhydryl group itself (13–16). At 0.15–0.6 m*M* levels, the peak current appeared to be independent of concentration, remaining virtually the same as the concentration was increased fourfold. A second standard curve at much lower concentrations (0.012–0.018 m*M*), however, was linear. The mercury mercaptide product apparently coats the mercury drop, preventing further oxidation. This phenomenon could also have produced the erratic baselines encountered when the scan was initiated at 0.0 v and scanned negatively. To avoid this result, all polarograms were begun at −0.70 v and scanned positively.

Adding tin(II) to I decreased the peak at −0.30 v, while a new peak at −0.08 (chelated I) grew. Further addition of tin(II) resulted in the complete elimination of the free I peak and the emergence of a second new peak at −0.20 v [unchelated tin(II)] (Table I). Since the total I concentration was known and the remaining free I and the chelated tin(II) concentrations could be evaluated, the stoichiometry of the chelate could be determined. At this pH, tin(II) was complexed to two I molecules, confirming the previous work (10) where the same ratio was determined by difference UV spectroscopy. Electrolytically reducing an aliquot of the final product at −0.75 v *versus* silver–silver chloride produced only the free I peak at −0.30 v when analyzed polarographically. These additional data provide convincing evidence of complexation.

Table II—Final Product Kidney Results

Ampul	I, m*M*	Tin(II), m*M*
First of filling operation	3.05	1.02
Middle of filling operation	3.05	1.01
Last of filling operation	3.17	1.03
Middle of filling operation	3.13, 3.10, 3.09	1.00, 0.99, 0.97
	3.11 ± σ of 0.02	0.987 ± σ of 0.015

Three ampuls taken at various stages of a production filling operation were analyzed for I and tin(II) content. A fourth ampul was analyzed in triplicate for both components. The results (Table II) are precise and show good correlation with the quantities added.

Simultaneous Determination of Isosorbide Dinitrate and Its Mononitrates in Human Plasma by Capillary Column GLC

M. T. ROSSEEL ˣ **and M. G. BOGAERT**

Received August 21, 1978, from the *J. F. & C. Heymans Institute of Pharmacology, University of Ghent, De Pintelaan 135, B-9000 Ghent, Belgium.* Accepted for publication October 25, 1978.

Abstract □ A previously described electron-capture GLC method for determination of isosorbide dinitrate in human plasma was adapted for the simultaneous determination of isosorbide dinitrate, isosorbide 2-mononitrate, and isosorbide 5-mononitrate using a capillary column. Quantitation was done with two internal standards. The lower limits of detection were approximately 0.5 ng/ml of plasma for isosorbide dinitrate, 2 ng/ml for isosorbide 2-mononitrate, and 20 ng/ml for isosorbide 5-mononitrate.

Keyphrases □ Isosorbide dinitrate—and mononitrates, simultaneous electron-capture GLC analysis, human plasma □ GLC, electron capture—analysis, isosorbide dinitrate and mononitrates, human plasma □ Isosorbide mononitrates—and dinitrate, simultaneous electron-capture GLC analysis, human plasma

The mononitrated metabolites of isosorbide dinitrate, isosorbide 2-mononitrate and isosorbide 5-mononitrate, are pharmacologically active and may contribute to the drug's therapeutic effect (1–4). Therefore, it is of interest to measure the levels of these metabolites together with the parent compound in plasma.

A method was described previously for the quantitative determination of isosorbide dinitrate in human plasma with electron-capture GLC (5), but quantitative mononitrate determination is sometimes difficult because of interfering peaks. This paper presents a modified method for simultaneous determination of isosorbide dinitrate and its two metabolites using a capillary column.

EXPERIMENTAL

Reagents and Materials—Ethyl acetate was pesticide grade[1]. Isosorbide 2-mononitrate, isosorbide 5-mononitrate, isoidide mononitrate, and isomannide dinitrate were prepared as previously described (6). Isosorbide dinitrate was available as a powder[2]. Charcoal, activated and neutralized, was washed three times with ethyl acetate[3].

Instrumental Conditions—The analysis was performed on a gas chromatograph[4] equipped with a linear ^{63}Ni-electron-capture detector[5]. The detector was operated with methane (5% v/v) in argon at a flow rate of 22.5 ml/min. The 25-m × 0.5-mm i.d. glass capillary column was deactivated and wall coated with OV-17[6]. The carrier gas was helium, prefiltered through a gas purifier[7] at a flow rate of 7.5 ml/min. Temperatures were: injector, 200°; column, 165°; and detector, 250°. Direct on-column injection without stream splitting was used. The peak areas were recorded on a recording integrator[8].

Procedure—All glassware was silanized as described previously (5).

The extraction procedure reported earlier (5) was slightly modified. To 2-ml of plasma in a glass-stoppered 10-ml centrifuge tube were added the internal standards isoidide mononitrate (25 ng) and isomannide dinitrate (200 ng). The plasma was extracted twice with 4 ml of ethyl acetate by shaking for 10 min. After separation from the aqueous phase by centrifugation (10 min, 6000 rpm), the organic phase was removed, avoiding the lipoprotein interface.

To the combined organic phase in another 10-ml tube, 55 mg of charcoal was added. The solution was shaken a few times by hand and centrifuged for 20 min at 7000 rpm. The organic phase was transferred into a 6-ml glass-stoppered conical tube and evaporated to dryness under a nitrogen flow at room temperature. The residue was immediately dissolved in 20 μl of ethyl acetate and stored at −18° until analysis. After evaporation of the ethyl acetate to approximately 5 μl under nitrogen, 0.3 μl was injected into the wide-bore glass capillary column.

Quantitation and Reproducibility—As the internal standard for the mononitrates, isoidide mononitrate was used; for isosorbide dinitrate, isomannide dinitrate was used. Human plasma samples spiked with increasing concentrations of isosorbide dinitrate (5–40 ng/2 ml), isosorbide 2-mononitrate (5–100 ng/2 ml), and isosorbide 5-mononitrate (50–1000 ng/2 ml) were carried through the whole procedure. The ratios of the test product peak areas to the internal standard peak areas were plotted *versus* the test product concentrations, and a least-squares linear regression analysis was performed. Values of unknown plasma drug concentrations were determined from this calibration graph.

RESULTS AND DISCUSSION

Typical chromatograms of a blank plasma sample and of a spiked plasma sample are shown in Fig. 1. When the ratios of the peak area of isosorbide dinitrate to that of its internal standard were calculated and plotted *versus* the isosorbide dinitrate concentrations in spiked plasma

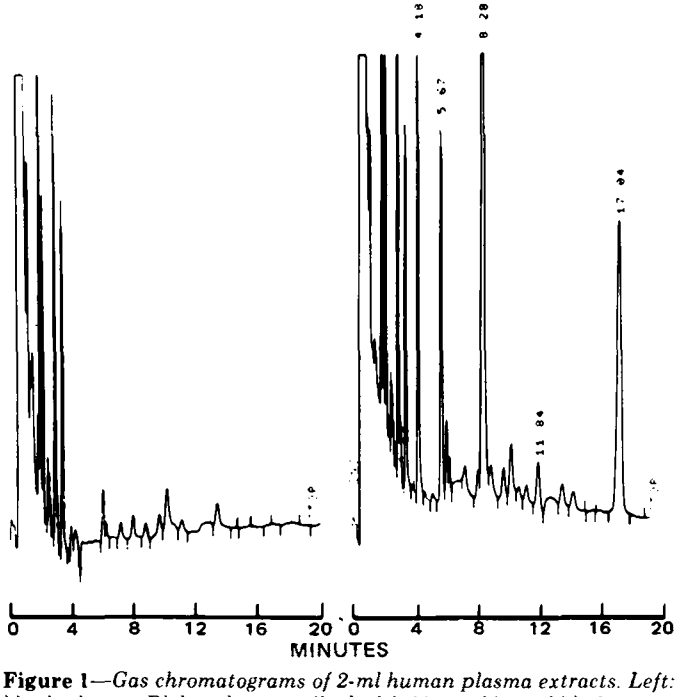

Figure 1—*Gas chromatograms of 2-ml human plasma extracts. Left: blank plasma. Right: plasma spiked with 20 ng of isosorbide 2-mononitrate (retention time of 4.18 min), 25 ng of isoidide mononitrate (5.67 min), 200 ng of isosorbide 5-mononitrate (8.28 min), 5 ng of isosorbide dinitrate (11.84 min), and 200 ng of isomannide dinitrate (17.04 min).*

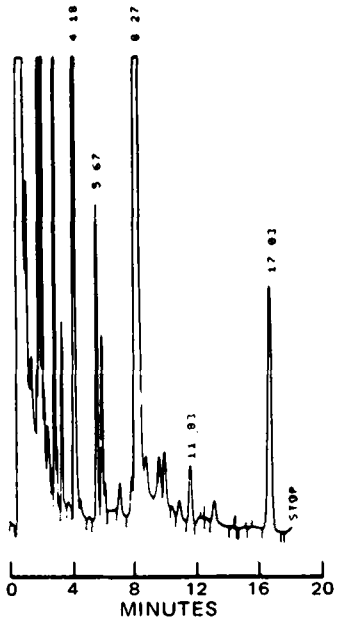

Figure 2—*Gas chromatogram of a 2-ml plasma sample extract obtained from a subject 6 hr after intake of 120 mg of isosorbide dinitrate slow-release preparation; 25 ng of isoidide mononitrate (retention time of 5.67 min) and 200 ng of isomannide dinitrate (17.03 min) were added as internal standards. Key (retention time): 4.18 min, isosorbide 2-mononitrate; 8.27 min, isosorbide 5-mononitrate; and 11.83 min, isosorbide dinitrate.*

samples, a linear relationship was found for the concentration range studied, and the intercept of the standard curve was negligible. The same was true for isosorbide 2-mononitrate and isosorbide 5-mononitrate.

As for isosorbide dinitrate (5), the recoveries of the mononitrates from plasma were quantitative. The relative standard deviations for analyses performed on different days were 7.01 for isosorbide dinitrate (11 samples, 5–20 ng), 9.13 for isosorbide 2-mononitrate (11 samples, 10–30 ng), and 10.96 for isosorbide 5-mononitrate (11 samples, 100–300 ng). The lower limits of detection were approximately 0.5 ng/ml of plasma for isosorbide dinitrate, 2 ng/ml for isosorbide 2-mononitrate, and 20 ng/ml for isosorbide 5-mononitrate.

After daily injections on the column, the glass injector adaptor was replaced weekly.

Figure 2 shows a typical plasma chromatogram 6 hr after intake of 120 mg of an isosorbide dinitrate slow-release preparation.

Several investigators reported difficulties with the quantitative mononitrate determination by conventional packed column GLC due to peak interference mainly with isosorbide 5-mononitrate (7–9). The wall-coated capillary column used here provides a suitable means of analyzing the isosorbide mononitrates with the required efficiency and specificity.

Improved Method for Morphine Extraction from Biological Samples

G. L. SPRAGUE and A. E. TAKEMORI ˣ

Received June 19, 1978, from the *Department of Pharmacology, University of Minnesota, Minneapolis, MN 55455.* Accepted for publication October 31, 1978.

Abstract □ Methadone, morphine, or naloxone extraction from brain homogenates, plasma, and urine is described. An aqueous sample was loaded on a surgical gauze support, which was washed with extracting solvents. Aqueous samples remained on the support, and nonpolar drugs partitioned into the lipophilic extracting solvent. The procedure recovered 80–100% of nanogram levels of methadone, morphine, or naloxone from biological samples. In addition, an approximate 10-fold timesaving capacity was demonstrated compared to standard liquid–liquid extraction techniques.

Keyphrases □ Methadone—analysis, liquid–liquid extraction, brain, blood, plasma, urine □ Morphine—analysis, liquid–liquid extraction, brain, blood, plasma, urine □ Naloxone—analysis, liquid–liquid extraction, brain, blood, plasma, urine □ Liquid–liquid extraction—analysis, methadone, morphine, naloxone, brain, blood, plasma, urine □ Narcotic analgesics—methadone, morphine, naloxone, liquid–liquid extraction, brain, blood, plasma, urine

Determination of tissue narcotic drug levels frequently involves radiolabeled drug administration. Following alkalinization, the lipophilic drugs are extracted from tissue preparations using standard liquid–liquid extraction techniques (1–5). These techniques typically involve partitioning the drug between two immiscible liquids by shaking, phase separation by centrifugation, and drug analysis in the nonpolar solvent phase or in the aqueous phase after back-extraction. Improved methods for morphine and related drug extraction have not altered the basic liquid–liquid extraction technique (4, 6).

A rapid, efficient extraction technique for tissue morphine and related drug determination is presented here. Extraction of tritiated methadone, morphine, and naloxone from brain, plasma, and urine samples is described. A polar support (gauze sponges) held an aqueous tissue ho-

EXPERIMENTAL

Drugs and Reagents—All solvents were reagent grade. The drugs used included morphine sulfate, methadone hydrochloride, naloxone hydrochloride, ^{3}H-methadone hydrobromide (161.0 mCi/mmole), ^{3}H-morphine (23 Ci/mmole), and ^{3}H-naloxone (4.54 mCi/mmole). All drug concentrations were expressed in terms of the base.

Extraction Columns—These columns were similar to commercially available[1] ones but were made from inexpensive, common laboratory materials. The columns consisted of 12-ml disposable syringe barrels into which one folded and tightly rolled piece of surgical gauze (10.2 × 10.2-cm, 8-ply gauze sponge) was placed. A 21-gauge needle fitted with a piece of polyethylene tubing (PE90) was attached to a three-way stopcock, which, in turn, was attached to the extraction column (syringe tip) and was used to regulate the effluent flow.

TLC—Radioactivity extracted from brain homogenates, plasma, or urine was identified as unchanged drug (*e.g.*, methadone, morphine, or naloxone) using TLC. Tritiated drug radioactive purity was verified by TLC. After extraction, excess solvent from selected samples was evaporated using nitrogen; the resulting concentrated samples were applied to individual plastic TLC plates coated with silica gel along with appropriate standards.

The solvent systems for methadone, morphine, and naloxone were ethyl acetate–butanol–ethanol–ammonium hydroxide (70:10:15:1), ethanol–acetic acid–water (60:30:10), and ethyl acetate–hexane–ethanol–ammonium hydroxide (60:25:14:1), respectively. The radioactivity in each area was determined by cutting the chromatogram into 1-cm sections and placing them in scintillation vials containing scintillation cocktail.

Biological Tissues and Fluids—Brains and blood samples were obtained from male Swiss-Webster mice killed with carbon dioxide. Blood was removed by cardiac puncture using a heparinized syringe, and plasma was obtained following centrifugation of blood samples. Brains were removed, weighed, and homogenized in four volumes of cold, distilled water using a motor-driven polytef pestle in a Potter homogenizer. Human urine was used in all cases.

Method of Extraction—The following procedure was used to extract morphine or naloxone from mouse brain homogenates. A brain homogenate aliquot (0.2 ml) was diluted with an equal volume of glycine buffer (0.5 *M*, pH 9.0) and added to the extraction column. The column capacity was 2 ml. Two minutes after the buffered homogenate was added to the column, 10 ml of solvent was added. The effluent was collected in a scintillation vial after a 2-min equilibration period. The column was washed twice with 5 ml of solvent and allowed a 2-min equilibration with each wash.

The combined effluent (20 ml) was evaporated to dryness in a water bath, and 15 ml of scintillation cocktail was added. Radioactivity was measured by liquid scintillation spectrometry, and an internal standard (^{3}H-toluene) was used to determine counting efficiency. The procedure for methadone extraction from brain homogenates was identical except that sufficient 0.1 *N* NaOH was added to the brain homogenate to adjust the pH to 10.5 prior to extraction.

[1] Jetubes, Manhattan Instruments, Santa Monica, Calif.

A similar procedure was used to extract drugs from plasma and urine samples. Aliquots (0.05 ml) of plasma or urine containing morphine or naloxone were diluted with nine volumes of glycine buffer, and the total volume added to the extraction column was 0.5 ml in each case. The upper limit of plasma or urine that was applied to the column was 1.0 ml; extraction efficiency was not reduced by applying smaller volumes. The pH of plasma or urine samples containing methadone was adjusted to 10.5 after nine volumes of glycine buffer were added. The extraction solvents were ether for methadone, ethanol–chloroform (10:90) for morphine, and chloroform for naloxone.

Determination of Percent Recovery—The specific activity of tritiated methadone, morphine, and naloxone was known. The purity was determined using TLC and appropriate standards. A measured radiolabeled drug amount was added to a sample (brain homogenate, plasma, or urine), the sample pH was adjusted, and drug was extracted. The radioactivity was measured after solvent evaporation in certain samples, and the identity of radioactivity was confirmed by TLC in others. The percent recovery was calculated, and corrections were made for the purity of added radioactivity as well as the amount of radioactivity lost in the transfer of 0.4-ml aliquots to the extraction columns.

Drug Extraction from Tissues after Subcutaneous Administration—Tritiated methadone, morphine, or naloxone was administered subcutaneously to mice to measure the extraction of metabolites and unchanged drug(s) from brain and blood. Mice were killed with carbon dioxide 20 min after drug administration, and whole brains and blood samples were obtained. Brains were homogenized, plasma was obtained, and radioactivity was extracted as already described. The percent of total radioactivity corresponding to unchanged methadone, morphine, or naloxone was determined using TLC.

RESULTS AND DISCUSSION

Table I shows the percent tritiated methadone, morphine, and naloxone recovery from brain homogenate, plasma, or urine. In each case, the extracted radioactivity was chromatographically identical to authentic methadone, morphine, or naloxone. These results demonstrate highly efficient extraction of the three drugs from mouse brain homogenates even at very low drug concentrations. The concentrations used represented values typical of pharmacological studies.

The recovery of methadone, morphine, or naloxone from brain samples in other studies using standard liquid–liquid extraction techniques was between 66.0 and 96.2% (1, 4, 6, 7). The highest recoveries required three consecutive liquid–liquid extractions. A recent study (4) reported 90% morphine recovery (0.125–0.5 μg added) from biological tissues using standard liquid–liquid extraction methods and siliconized glassware. The present extraction procedure provided efficient recovery of morphine (98.0%) from brain homogenates at low morphine concentrations (1–20 ng added) without special precautions such as siliconized glassware.

The present procedure also provided efficient methadone recovery from plasma and urine samples (91.4 and 98.0%, respectively). Extraction of morphine and naloxone from plasma samples was also efficient (94.3 and 95.6%, respectively). Morphine and naloxone recovery from urine samples (80.3 and 83.2%, respectively) was significantly lower than morphine and naloxone recovery from plasma but was acceptable. The buffered urine sample pH was not significantly lower than the buffered plasma pH, so reduced urine morphine and naloxone extraction efficiency may have been related to the procedure. Urine alkalinization (7) and extraction with a polar solvent might improve the efficiency.

Subcutaneous methadone, morphine, or naloxone was administered to mice to measure selective extraction of parent drugs and metabolites from brain and plasma. The total radioactivity extracted from brain was

chromatographically identical to methadone (80.5%), morphine (95.5%), and naloxone (100%). Total extracted plasma radioactivity represented methadone (76.9%), morphine (75.5%), or naloxone (91.8%). Parent drug extraction selectivity in each case was acceptable.

Timesaving is the greatest advantage of this method. Extraction of 20 tissue samples required 10–15 min; 1.5–2 hr was required with standard liquid–liquid extraction. Since brain and plasma drug concentrations are routinely required in pharmacological studies, the utility of the present method is obvious. Theoretically, the present procedure could be substituted for any organic base or acid solvent extraction from biological fluids and tissues.

Effect of Water-Soluble Carriers on Morphine Sulfate Release from a Silicone Polymer

JAMES W. McGINITY ˣ, LOUIS A. HUNKE, and ALAN B. COMBS

Received August 14, 1978, from the *Drug Dynamics Institute, College of Pharmacy, University of Texas, Austin, TX 78712.* Accepted for publication November 2, 1978.

Abstract □ The influence of gelatin, sodium lauryl sulfate, lactose, and sodium alginate on morphine sulfate diffusion from cylindrical silicone polymer pellets was examined in isotonic pH 7.4 phosphate buffer. These water-soluble carriers caused the pellets to swell in aqueous media. Sodium alginate exerted the greatest influence on drug release. The morphine sulfate diffusion rate from the cylindrical pellets increased as the matrix alginate content increased up to 20%. Water-soluble carrier incorporation into silicone polymeric matrixes permits controlled release of water-soluble drugs that otherwise would be released extremely slowly from the polymer. Drug diffusion from the silicone matrix containing sodium alginate followed second-order kinetics. The release mechanism probably involves the creation of pores or pathways through the matrix secondary to the swelling.

Keyphrases □ Morphine sulfate—release from silicone polymer, effect of water-soluble carriers □ Drug delivery systems—morphine sulfate, release from silicone polymer, effect of water-soluble carriers □ Silicone polymers—release of morphine sulfate, effect of water-soluble carriers □ Dosage forms, controlled release—morphine sulfate, release from silicone polymer, effect of water-soluble carriers

The drug release rate from an inert matrix is dependent on solute solubility in the matrix and diffusivity as well as on parameters independent of the particular drug (1). Previous silicone polymer work has been concerned largely with developing long acting steroidal delivery systems and investigating factors controlling drug release from silicone devices (2–9).

The divergent *in vitro* silicone polymer release patterns of four progesterone-type steroids with similar diffusion coefficients were attributed to differences in the polymer steroid solubilities (5). The release of salts and water-soluble drugs from silicone polymers has received little attention. Since polymer drug solubility is an important drug release determinant, water-soluble drug diffusion from a silicone polymer would be expected to be extremely slow.

The present study examined the influence of water-soluble carriers on the *in vitro* morphine sulfate release from a polysiloxane polymer. Recent studies (10, 11) demonstrated that polysiloxane rubber implants containing morphine sulfate and a water-soluble carrier are excellent drug delivery systems for inducing morphine dependence in rats.

EXPERIMENTAL

The following items were used: simethicone liquid[1], polydimethylsiloxane polymer and silica filler[2], stannous octoate[3], morphine sulfate, polysorbate 80[4], sodium alginate[5], sodium chloride, 0.1 *N* HCl, lactose, sodium lauryl sulfate, monobasic sodium phosphate, dibasic sodium phosphate, and microcrystalline cellulose[6].

Pellets were prepared by the addition of simethicone fluid to polydimethylsiloxane elastomer (1:1), followed by homogeneous mixing with the powders to be added. The pellets contained 25% (w/w) morphine sulfate. The drug and water-soluble carrier (lactose, sodium lauryl sulfate, gelatin, or sodium alginate) were passed through a 100-mesh screen prior to mixing with the silicone polymer. To polymerize the mixture, stannous octoate catalyst, 25 mg/g of mixture, was added and dispersed uniformly. Next, the mixture was added rapidly to a plastic tablet mold, and the pellets were allowed to cure for 24 hr.

The cylindrical pellets were 5.5 mm in diameter and 3.5 mm in thickness. The mean weights varied from 78 to 88 mg, depending on the amount of powder embedded in the pellet. Surface area measurements were made with a micrometer. Homogeneity studies were carried out by cutting individual pellets into small pieces and extracting them in 100 ml of purified water for 48 hr. Recoveries of 99 ± 2% were obtained (n = 6).

Drug release from the pellets was studied in screw-capped vials, 1.5 cm diameter × 10.5 cm length, containing 15 ml of phosphate buffer (0.13 *N*, pH 7.4). These vials were maintained at 37° and rotated end-over-end at 15 rpm. Aliquots of 5 ml were withdrawn from the vials at various times and assayed by UV spectrophotometry for morphine. To maintain sink conditions, 5-ml volumes of fresh medium were added to each vial after

sample withdrawal. The reported data represent the means of three or more runs.

RESULTS AND DISCUSSION

The influence of water-soluble carriers on morphine sulfate release from silicone pellets is shown in Fig. 1. As expected, the release of the water-soluble salt from the polymer in the absence of any carrier was very slow; after 1 week, only 9% of the drug was removed from the pellet. This result confirmed the expectation that water-soluble drugs are released slowly from lipophilic silicone matrixes.

The presence of 10% gelatin, sodium lauryl sulfate, or lactose in the silicone matrix all produced similar effects on drug release: approximately 20% of the morphine had diffused from the pellet after 1 week. This value increased to 50% when sodium alginate was incorporated into the matrix.

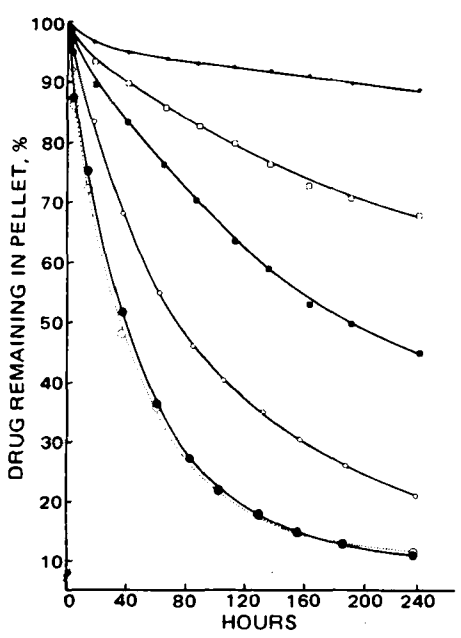

Figure 2—*Influence of sodium alginate concentration formulated within the silicone matrix on 25% morphine sulfate release. Key: •, 0%; □, 5%; ■, 10%; ○, 15%; ●, 20%; and ○, 25%.*

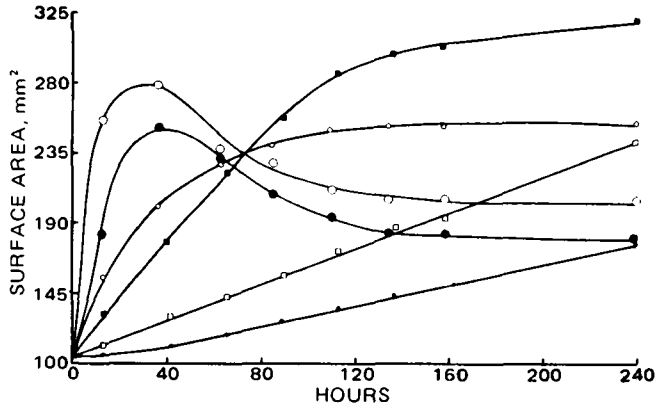

Figure 3—*Plots of Surface area as a function of time for the pellet formulations in Fig. 2.*

With all systems, an initial burst of drug from the pellet lasted for 10–15 hr.

As the sodium alginate content in the matrix was increased, so did the morphine diffusion rate from the polymer (Fig. 2). This influence appeared to be maximal at 20% alginate. One prominent action of each carrier was to swell the pellet. The influence of alginate content on silicone matrix swelling is shown in Fig. 3. Morphine sulfate dissolution from the matrix is probably facilitated by this swelling, which creates microscopic pores or channels from carrier hydration. In the absence of the swelling agent, pellets containing morphine sulfate alone increased in surface area at a uniform rate over the 10-day period studied. This increase was the smallest of the pellets studied, however.

Swelling rates increased during the first 30 hr as the level of sodium alginate in the pellet increased. Pellets containing 20 and 25% alginate achieved maximal surface area at approximately 40 and 30 hr, respectively. The matrix then began to shrink as both the drug and carrier were removed from it (Fig. 3). This phenomenon can be monitored by taking transverse sections of the pellet and measuring the core and the translucent depletion zone.

Morphine diffusion from the silicone matrix (Fig. 4) appeared to follow second-order kinetics with respect to morphine sulfate concentration. The second-order profile correlation coefficients (Fig. 4) for morphine sulfate release from silicone matrixes containing 10, 15, and 20% sodium

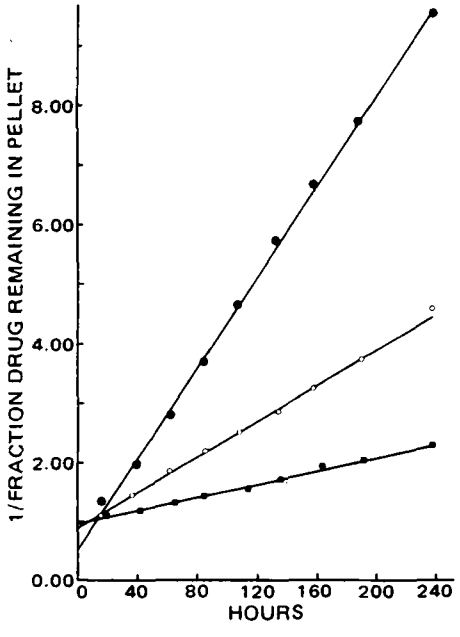

Figure 4—*Second-order profiles for silicone matrixes containing 25% morphine sulfate and three sodium alginate concentrations. Key: ■, 10% sodium alginate; ○, 15% sodium alginate; and ●, 20% sodium alginate.*

alginate were 0.9982, 0.9987, and 0.9983, respectively. The processes giving rise to the second-order elimination from the matrix are not apparent immediately since a shrinking core phenomenon with decreasing core surface area is occurring.

This technique of controlling the diffusion rate from silicone polymers was recently applied by the authors to salts of amphetamine and the barbiturates, and preliminary *in vitro* and *in vivo* results are encouraging. This simple method of drug delivery may find use also in chronic toxicity studies in small animals.

Wikstromol, Antitumor Lignan from *Wikstroemia foetida* var. *oahuensis* Gray and *Wikstroemia uva-ursi* Gray (Thymelaeaceae)

STERLING J. TORRANCE, JOSEPH J. HOFFMANN, and JACK R. COLE ×

Received September 11, 1978, from the *Department of Pharmaceutical Sciences, College of Pharmacy, University of Arizona, Tucson, AZ 85721.* Accepted for publication November 1, 1978.

Abstract □ The ethanol extracts of *Wikstroemia foetida* var. *oahuensis* and *Wikstroemia uva-ursi* showed antitumor activity against the P-388 lymphocytic leukemia (3PS) test system. One PS-active constituent of both plants was the lignan wikstromol. Several inactive compounds were identified as daphnoretin, pinoresinol, and syringaresinol.

Keyphrases □ Wikstromol—isolation from plant material, antineoplastic activity □ Antineoplastic agents—wikstromol, isolated from plant material

In the continuing search for plants having antitumor constituents, it was found that the chloroform fractions of *Wikstroemia foetida* var. *oahuensis* Gray and *Wikstroemia uva-ursi* Gray[1] (Thymelaeaceae) ethanol extracts were active against the P-388 lymphocytic leukemia (3PS) test system[2].

DISCUSSION

The lignan wikstromol (I) was isolated from both *Wikstroemia* species. This compound was isolated recently from *Wikstroemia viridiflora* (1) and *Daphne odora* (Thymelaeaceae) (2). Wikstromol is the enantiomer of nortrachelogenin (II, also called pinopalustrin), isolated from *Trachelospermum asiaticum* var. *intermedium* (Apocynaceae) (3) and *Pinus palustris* (Pinaceae) (4).

Comparison of the sample spectra (IR, PMR, and mass) with literature values (1, 3) for wikstromol and nortrachelogenin and comparison of the sample's physical constants with those of these two lignans (Table I) suggested that it was wikstromol. Confirmation was by direct comparison of authentic spectra[3] (IR and PMR) and of the sample[3] of the nortrachelogenin dimethyl ether with the study sample dimethyl ether. The spectra were identical, and TLC behaviors were indistinguishable. Unfortunately, the study sample could not be made to crystallize, and an authentic sample of wikstromol, or its dimethyl ether, was unobtainable.

In addition to the PS-active wikstromol, three inactive compounds were isolated from both *W. foetida* var. *oahuensis* and *W. uva-ursi*. These compounds were daphnoretin (III), pinoresinol (IV), and syringaresinol (V). In each case, identity was confirmed by comparison with authentic specimens[4].

Wikstromol (I) demonstrated activities of 154, 146, 137, 141, and 130% test/control (T/C) at does of 16, 10, 4, 2, and 1 mg/kg, respectively. Activity in the PS test system is defined as an increase in the survival of treated animals over that of control animals resulting in a T/C ≥ 130%[5].

EXPERIMENTAL[6]

Wikstromol was isolated similarly from *W. foetida* var. *oahuensis* and *W. uva-ursi*. The procedure for isolation from the former follows.

Whole *W. foetida* var. *oahuensis* plants were ground in a Wiley mill and stored at −10° prior to extraction. The ground material (9 kg) was exhaustively extracted in a Lloyd-type extractor with petroleum ether

[1] *W. foetida* var. *oahuensis* and *W. uva-ursi* were collected in Hawaii in September 1975 and March 1973, respectively. Identification was confirmed by Dr. Robert E. Perdue, Jr., Medicinal Plant Resources Laboratory, U.S. Department of Agriculture, Bethesda, Md. Reference specimens are maintained by the Department of Agriculture.

Wikstromol, Antitumor Lignan from *Wikstroemia foetida* var. *oahuensis* Gray and *Wikstroemia uva-ursi* Gray (Thymelaeaceae)

STERLING J. TORRANCE, JOSEPH J. HOFFMANN, and JACK R. COLE ×

Received September 11, 1978, from the *Department of Pharmaceutical Sciences, College of Pharmacy, University of Arizona, Tucson, AZ 85721.* Accepted for publication November 1, 1978.

Abstract □ The ethanol extracts of *Wikstroemia foetida* var. *oahuensis* and *Wikstroemia uva-ursi* showed antitumor activity against the P-388 lymphocytic leukemia (3PS) test system. One PS-active constituent of both plants was the lignan wikstromol. Several inactive compounds were identified as daphnoretin, pinoresinol, and syringaresinol.

Keyphrases □ Wikstromol—isolation from plant material, antineoplastic activity □ Antineoplastic agents—wikstromol, isolated from plant material

In the continuing search for plants having antitumor constituents, it was found that the chloroform fractions of *Wikstroemia foetida* var. *oahuensis* Gray and *Wikstroemia uva-ursi* Gray[1] (Thymelaeaceae) ethanol extracts were active against the P-388 lymphocytic leukemia (3PS) test system[2].

DISCUSSION

The lignan wikstromol (I) was isolated from both *Wikstroemia* species. This compound was isolated recently from *Wikstroemia viridiflora* (1) and *Daphne odora* (Thymelaeaceae) (2). Wikstromol is the enantiomer of nortrachelogenin (II, also called pinopalustrin), isolated from *Trachelospermum asiaticum* var. *intermedium* (Apocynaceae) (3) and *Pinus palustris* (Pinaceae) (4).

Comparison of the sample spectra (IR, PMR, and mass) with literature values (1, 3) for wikstromol and nortrachelogenin and comparison of the sample's physical constants with those of these two lignans (Table I) suggested that it was wikstromol. Confirmation was by direct comparison of authentic spectra[3] (IR and PMR) and of the sample[3] of the nortrachelogenin dimethyl ether with the study sample dimethyl ether. The spectra were identical, and TLC behaviors were indistinguishable. Unfortunately, the study sample could not be made to crystallize, and an authentic sample of wikstromol, or its dimethyl ether, was unobtainable.

In addition to the PS-active wikstromol, three inactive compounds were isolated from both *W. foetida* var. *oahuensis* and *W. uva-ursi*. These compounds were daphnoretin (III), pinoresinol (IV), and syringaresinol (V). In each case, identity was confirmed by comparison with authentic specimens[4].

Wikstromol (I) demonstrated activities of 154, 146, 137, 141, and 130% test/control (T/C) at does of 16, 10, 4, 2, and 1 mg/kg, respectively. Activity in the PS test system is defined as an increase in the survival of treated animals over that of control animals resulting in a T/C ≥ 130%[5].

EXPERIMENTAL[6]

Wikstromol was isolated similarly from *W. foetida* var. *oahuensis* and *W. uva-ursi*. The procedure for isolation from the former follows.

Whole *W. foetida* var. *oahuensis* plants were ground in a Wiley mill and stored at −10° prior to extraction. The ground material (9 kg) was exhaustively extracted in a Lloyd-type extractor with petroleum ether

[1] *W. foetida* var. *oahuensis* and *W. uva-ursi* were collected in Hawaii in September 1975 and March 1973, respectively. Identification was confirmed by Dr. Robert E. Perdue, Jr., Medicinal Plant Resources Laboratory, U.S. Department of Agriculture, Bethesda, Md. Reference specimens are maintained by the Department of Agriculture.

[6] Melting points were determined on a Kofler hot-stage apparatus and are uncorrected. IR and mass spectra were recorded on a Beckman IR-33 and Hewlett-Packard quadrupole spectrometer (model 4930), respectively. PMR spectra were recorded on Varian T-60 and EM-360L spectrometers, and optical rotations were taken on a Perkin-Elmer model 241 MC polarimeter.

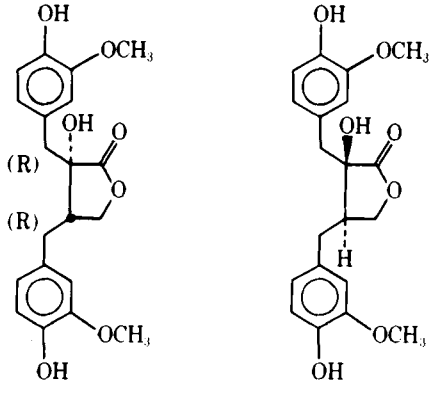
Table I—Comparison of Physical Constants

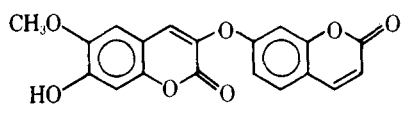
Constant	Wikstromol	Study Sample	Nortrachelogenin	Daphne Lignan	Pinopalustrin
Melting point	Amorphous	Amorphous	Amorphous	Amorphous	Amorphous
$[\alpha]_D$	+72° (chloroform)	+41° (chloroform)	−17° (ethanol)	+48°	—
		Dimethyl Ethers			
Melting point	96–97°	Amorphous	97–98.5°	—	96–97°, 127–128°
$[\alpha]_D$	+35° (chloroform)	+26° (chloroform)	−46° (ethanol)	—	−39° (chloroform)

(bp 30–60°) followed by 95% ethanol. The air-dried ethanol extract was partitioned between chloroform and water (1:1). Removal of the solvent from the chloroform phase provided a sticky, green residue (227 g). The latter was extracted with hexane (5 × 0.5 liter) and ether (4 × 0.5 liter), and the hexane-insoluble, ether-soluble material (84 g after solvent removal) was chromatographed over silica gel 60[7] (2 kg, 9.5 × 80 cm). Elution was begun with chloroform–methanol (98:2 v/v), and wikstromol (I) was eluted with chloroform–methanol (97:3 v/v). Final purification of wikstromol was by preparative TLC [chloroform–methanol–water (188:12:1 v/v/v)].

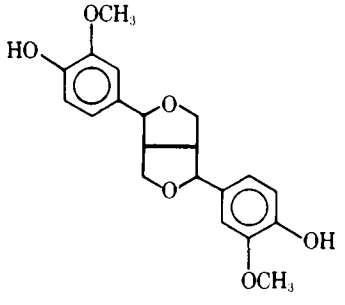


I

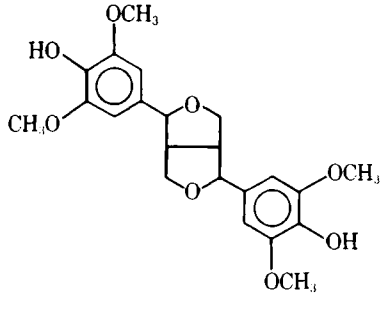
II



III



IV



V

Wikstromol was obtained as an amorphous powder, $[\alpha]_D^{25}$ +41° (c 0.93, $CHCl_3$) whose IR, PMR, and mass spectra were identical to those reported for wikstromol (1) and nortrachelogenin (3).

Wikstromol dimethyl ether, prepared in the usual way with diazomethane, was obtained as an amorphous semisolid, $[\alpha]_D^{25}$ +26.3° (c 1.09, $CHCl_3$). Its spectra (IR, PMR, and mass) were in accord with those in the literature (1, 3), and its IR and PMR spectra were identical in all respects with authentic nortrachelogenin dimethyl ether spectra[3]. In several solvent systems, TLC behaviors of our material and authentic nortrachelogenin dimethyl ether[3] were indistinguishable.

Daphnoretin (III) and syringaresinol (V) were isolated from other fractions of the preparative TLC used to obtain wikstromol. Daphnoretin was obtained as yellow needles, mp 246–248°. Recrystallization from methanol–chloroform provided colorless needles, mp 261–262°. Comparison with an authentic sample (identical IR spectra and undepressed mixed melting point) confirmed its identity. The PMR and mass spectra were in accord with Structure III. Syringaresinol was obtained as colorless cubelets from methanol, mp 178–180°. Comparison with an authentic specimen[4] (identical IR and undepressed mixed melting point) confirmed its identity.

Pinoresinol (IV) was obtained from the wikstromol-containing column fraction by preparative TLC using benzene–ethyl acetate–methanol (30:10:2 v/v/v). Recrystallization from ether gave colorless cubelets, mp 120–121°, identical (superimposable IR spectra and undepressed mixed melting point) with an authentic sample[4].

Effect of UV Irradiation and Tritiation on Hydroxyzine

Keyphrases □ Hydroxyzine—decomposition by UV irradiation, tritiation, degradation products □ Tranquilizers, minor—hydroxyzine, UV photodecomposition, tritiation, degradation products □ Chlorobenzophenone—degradation product of hydroxyzine following UV irradiation

To the Editor:

Hydroxyzine, a diphenylmethane minor tranquilizer, is commercially available as a tablet, syrup, suspension, and solution. It is an effective antianxiety agent (1) and is particularly useful in its ability to render disturbed patients more approachable and amenable to psychotherapy. Recently, it was shown to be more effective than cyproheptadine in pruritus treatment (2).

An aqueous hydroxyzine solution turned dark brown in the air (3), and hydroxyzine was photodegraded by UV light to give three spots on TLC (4). During the purification of tritiated hydroxyzine for the metabolic study (5), the tritiated hydroxyzine solution gradually turned dark brown in the air under room light. Therefore, hydroxyzine susceptibility to oxidative deterioration in the presence of light is apparent. Since the nature of the degradative products of hydroxyzine is still unknown, the effect of UV irradiation on hydroxyzine was studied. In a preliminary experiment, the aqueous hydroxyzine solution turned slightly brown in the dark and >90% of the hydroxyzine remained unchanged.

Three grams of hydroxyzine hydrochloride was dissolved in 20 ml of distilled water and irradiated under a UV lamp (3660 Å, 100 w) at a distance of 20 cm for 3 days. The reaction mixture, which was white material in the brown solution, was extracted three times with two volumes of cyclohexane. The combined extracts were dehydrated over anhydrous sodium sulfate and filtered through 10 g of activated magnesium silicate in a Büchner funnel. The solvent was evaporated *in vacuo*, and the colorless residue was sublimed at 70° at 5 mm Hg pressure to give white crystals.

The product was soluble in organic solvent and insoluble in water. It was negative to Dragendorff and iodoplatinate reagents, indicating the absence of a piperazine ring. It was positive to the 2,4-dinitrophenylhydrazine test, and its IR spectrum showed a strong peak at 6.1 μm attributable to a ketone group. It gave a positive Beilstein test, indicating the presence of a chloride atom. It fluoresced strongly under UV light, implicating a highly conjugated system in the structure. The information suggested that the product was *p*-chlorobenzophenone.

Anal.—Calc. for $C_{13}H_9ClO$: C, 72.07; H, 4.7. Found: C, 71.96; H, 4.24.

Moreover, the product had TLC behavior, UV (UV_{max} 211 and 261 in ethanol) and IR spectra, and a melting point (77–78° uncorrected) identical to those of authentic *p*-chlorobenzophenone. Therefore, the product was identified as *p*-chlorobenzophenone. The yield was ~13%. The mother liquor of the reaction mixture was yellowish brown and became darker on standing in the air at room temperature. The mixture contained at least four yellowish Dragendorff-positive compounds separable by silica gel TLC in chloroform containing 2% methanol. Characterization of the products was not attempted further.

This finding prompted us to identify the tritiation degradation products of hydroxyzine. Hydroxyzine (1 g) was tritiated[1] according to Wilzbach's method (6) by exposing it to 3 Ci of tritium gas at 250 mm Hg pressure at 26° for 2 weeks. The unpurified product gave five distinct dark spots on the fluorogram (7) of the silica gel sheet[2], developed in cyclohexane–benzene–diethylamine (75:15:10), with R_f values and percentages of radioactivity as follows: 0, 16%; 0.24, 12%; 0.46, 19%; 0.70, 8%; and 0.88, 45%.

The silica gel zones with R_f 0.46 and 0.88 were scraped off, purified, chromatographed in other solvent systems, and identified as hydroxyzine and *p*-chlorobenzophenone, respectively. The tritiated product was purified according to Wilzbach (8). The specific activities of the tritiated hydroxyzine before and after purification were 154 and 16.3 μCi/mg, respectively. The decrease in specific activity after purification indicated that contaminants with high specific activities formed during the tritiation procedure were removed.

This study indicates that hydroxyzine in aqueous solution is very unstable on UV irradiation and that hydroxyzine is also vulnerable to tritiation. In either case, *p*-chlorobenzophenone was a main decomposition product.

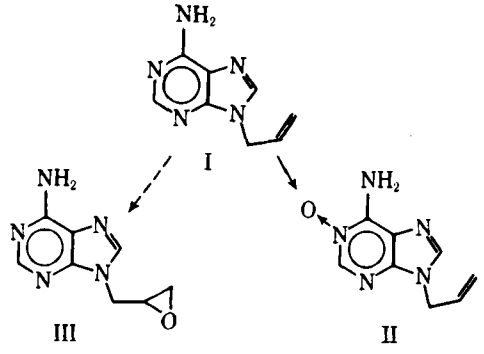
Synthesis of 9-Allyladenine N^1-Oxide

Keyphrases □ Allyl adenine N^1-oxide—chemical synthesis □ Hypolipidemic agents—allyl adenine N^1-oxide, chemical synthesis

To the Editor:

During our investigations of novel hypolipidemic agents (1), we desired to synthesize 9-(2,3-epoxypropyl)adenine (III) by the reaction of *m*-chloroperoxybenzoic acid with 9-allyladenine (I) as described previously (2). Compound III was not obtained, although the decomposition point and NMR data in trifluoroacetic acid were consistent with the literature (2). For comparison, the spectrum of I in trifluoroacetic acid was taken. No difference in the chemical shifts of the protons in the side chain between I and the oxidized material was observed (Scheme I). However, there was a difference in the ring protons.



Scheme I

A spectrum of the oxidized material in dimethyl sulfoxide-d_6 was obtained by using a Fourier transform NMR (650 scans, saturated 1.5-ml sample). This spectrum was consistent with the N^1-oxide (II). A shift downfield of the C_2 ring proton and a splitting of the nitrogen protons occurred[1]. The fact that no change in the chemical shift of the olefinic protons in dimethyl sulfoxide-d_6 was observed establishes this material as the N^1-oxide. This product also is more consistent with the literature, since peroxidation of 9-substituted adenines using hydrogen peroxide or *m*-chloroperoxybenzoic acid gives the N^1-oxide (3).

Temperature-Dependent Aqueous Solubilities of Lidocaine, Mepivacaine, and Bupivacaine

Keyphrases □ Lidocaine—aqueous solubility, effect of temperature □ Mepivacaine—aqueous solubility, effect of temperature □ Bupivacaine—aqueous solubility, effect of temperature □ Local anesthetics—aqueous solubility, effect of temperature

To the Editor:

We previously prepared 3-hydroxy-2-naphthoates of lidocaine, mepivacaine, and bupivacaine to prolong the duration of action of these local anesthetics through their sparingly soluble salt forms and studied their dissolution characteristics at 37° in 0.7 *M* phosphate buffer, pH 7.46 (1). Only the bupivacaine salt exhibited unusual dissolution characteristics. At equilibrium, the solution was saturated incongruously with respect to the base and the acid component. Further studies with the bupivacaine salt at 25° showed no such unusual behavior. The unusual behavior at 37° resulted from the fact that the concentration of the base component dissolved out of the solid salt exceeded the solubility of the base at 37° (2).

These observations prompted us to examine the temperature dependency of aqueous solubilities of bupivacaine and its structural analogs, lidocaine and mepivacaine. The only available data on the solubility of these local anesthetics at different temperatures were those of Setnikar (3), who reported lidocaine solubility in an alkaline medium to be 16 m*M* at 20° and 15 m*M* at 37°.

Lidocaine base[1] and mepivacaine base[2] were used as received. Bupivacaine hydrochloride[2] was converted to the base for solubility determination. Excess base was placed in a 20-ml glass-stoppered test tube together with a small magnetic stirring bar. Two milliliters of either 0.5 *M* phosphate buffer[3], pH 7.4[4], or 1–4 m*M* NaOH was added to it. The test tube was placed in a jacketed beaker and mounted on the platform of a magnetic stirrer, together with a magnet bar and water. The water temperature inside the jacketed beaker was maintained constant with water circulated through the jacket by a constant-temperature circulator[5].

After equilibration for 16–48 hr at different temperatures, the solid phase was separated by vacuum filtration through a glass filter. All glassware used in the filtration process and subsequent sampling was preincubated to the study temperature. The filtrate was suitably diluted for spectrophotometric assay for lidocaine and mepivacaine at 262 nm. The bupivacaine equilibrium concentration was determined, after extraction with methylene chloride, by GLC[6], using a 3% OV-17 column (4) and mepivacaine as an internal standard.

As with bupivacaine (2), lidocaine and mepivacaine showed decreases in solubility with increasing temperature

[a] Either the result of a single determination or average (two or three determinations) ± *SE*. [b] Composition at the time of preparation was 0.427 *M* Na_2HPO_4 and 0.0710 *M* NaH_2PO_4, pH 7.40 ± 0.01 at 25° and 7.38 ± 0.01 at 37°. [c] The pH varied from 10.43 (1 m*M* at 34.5°) to 11.86 (4 m*M* at 14.9°). [d] Temperature control was ±0.1°.

in the phosphate buffer (Table I). Since the pKa of these bases varied at 23° from 7.78 for mepivacaine to 8.09 for bupivacaine (5), at pH 7.4 these local anesthetics existed as a mixture of protonated and unprotonated forms. Thus, the solubilities of the unprotonated base species were determined in 1–4 m*M* NaOH. The solubilities in these high pH media were independent of hydroxyl-ion concentration and increased with decreasing temperature (Table I), although this trend was not as great as in the phosphate buffer.

The difference in temperature dependency is now being studied in our laboratories and is probably due to a measurable decrease in the pKa values of the bases with increasing temperature whereas the phosphate buffer pH remains relatively constant (Table I, footnote *b*). Our preliminary determination of lidocaine pKa values at different temperatures by the solubility method indicated that they vary from 8.2 at 15° to 7.7 at 35°. With increasing temperature, therefore, the gap between the medium pH and the pKa diminishes. Thus, the proportion of the soluble protonated base, BH^+, decreases with increasing temperature, which is reflected greatly in the total solubility, S_t, of the base at pH around 7.4; *i.e.*, S_t is given by (6):

$$S_t = [B] + [BH^+] = S_0\left(1 + \frac{[H^+]}{K_a}\right) \qquad \text{(Eq. 1)}$$

where $[B] = S_0$ is the solubility of the unprotonated species and K_a is the acid dissociation constant of BH^+. Since S_0 decreases and K_a increases as the temperature is increased (Eq. 1) at pH 7.4, both of these effects contribute to lower solubility at higher temperatures.

Since the unusual temperature-dependent solubility is likely to extend over a fairly wide pH range, including physiological pH, the following clinical problem could arise. In parenteral dosage forms of these drugs as local anesthetics, solution is effected by means of their hydrochloride salts. Therefore, the pH of these preparations can be as low as 3.0–4.5 (7). The results of the present study suggest possible precipitation of the base at the injection site from the following two points: (*a*) an increase in pH to the tissue pH after injection, as was suggested earlier for lidocaine (8); and (*b*) a lowering of free base solubility at body temperature relative to ambient temperature.

For most organic compounds, solubilities are usually assumed to increase with temperature. These local anesthetics, however, behave differently. Even if the decrease in solubility with increasing temperature at pH values of around 7.4 is mainly attributable to a decrease in the fraction of protonated species because of a shift in pKa with increasing temperature, the unprotonated species also show atypical temperature-dependent solubilities. Only a few organic medicinal compounds are known to exhibit such behavior. These include anhydrous ampicillin (9), dactinomycin (10), aminopyrine and propyphenazone (11), and colchicine (12).

Carbocyclic Analog of Cytarabine

Keyphrases □ Cytarabine, analogs—synthesis, carbocyclic analog, antileukemic activity □ Antineoplastic agents—cytarabine, carbocyclic analog, synthesis □ Antineoplastic activity—cytarabine, carbocyclic analog

To the Editor:

Cytarabine (1-β-D-arabinofuranosylcytosine, Ara-C) inhibits a variety of experimental neoplasma (1, 2), produces remissions in some patients with acute myelocytic or acute lymphocytic leukemia (3–5), and is considered the most effective single-drug treatment for acute myelogenous leukemia (6). It is also effective in suppressing the replication of certain DNA viruses (2) and is a useful agent for the clinical treatment of herpes virus infections (7). Recently, we reported (8) the synthesis and activity of the carbocyclic analog (carbodine, I) of cytidine against a murine leukemia (L-1210). Brockman *et al.* (9) showed that carbodine inhibits both DNA and RNA synthesis in

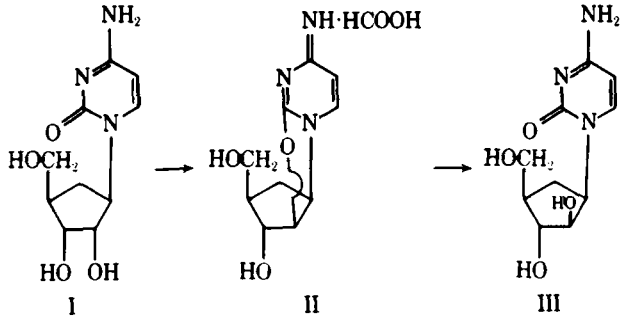

Scheme I

L-1210 cells and that it is phosphorylated to the mono-, di-, and triphosphate stages. Collectively, these facts provided the rationale for the synthesis of the carbocyclic analog (III) of cytarabine.

Carbodine served as the precursor of III (Scheme I). Treatment of I with dimethylformamide–thionyl chloride reagent in excess dimethylformamide, a method reported (10) for the conversion of cytidine to cytarabine, produced the carbocyclic analog (II) of 2,2′-anhydrocytidine (cyclocytidine). A solution of I (500 mg) in the reagent solution (0.75 ml of thionyl chloride in 5 ml of dimethylformamide stirred for 0.5 hr at room temperature prior to the addition of I) was stirred for 3 hr at room temperature, diluted with water (2.5:1), sparged with nitrogen to remove sulfur dioxide, and applied to a column of a cation-exchange resin[1] in the pyridinium salt form. Elution of the column with 0.1 *M* pyridinium formate, combination of fractions containing II[2], and concentration of the solution *in vacuo* furnished a viscous syrupy residue that contained II, as well as pyridinium formate.

A solution of this residue in 1 *N* aqueous ammonia was heated at 80° for 15 min to hydrolyze II to III. The reaction solution was concentrated *in vacuo*, and an aqueous solution of the residue was chromatographed on a strong cation-exchange resin[1] in the pyridinium salt form, as already described. Fractions containing III[2] were concentrated *in vacuo*, and an aqueous solution of the residue was applied to a column of a strongly acidic cation-exchange resin[3]. The column was washed thoroughly with water and then eluted with 2 *N* aqueous ammonia.

The portion of the eluate containing III[2] was concentrated to dryness *in vacuo*, and the white, solid residue was recrystallized from ethanol–water; 60% yield from I; mp 227–230° dec.; mass spectrum (1 m*A*, direct-inlet probe, 240°): *m/e* 242 (M + 1), 241 (M), 224 (M − OH), 223 (M − H_2O), 210 (M − CH_2OH), and 138 (cytosinyl group + C_2H_4); UV: λ_{max} 283 (ϵ 14,500) and 214 (10,100) at pH 1, 274 (10,000) and 225 (sh) at pH 7 or pH 13; PMR (dimethylsulfoxide-d_6, δ in parts per million downfield from tetramethylsilane): 1.5–2.05 (m, CH_2 and CH at positions 5 and 4 of the cyclopentane ring), 3.25–3.7 (m, CH_2OH and CH at position 3 of the cyclopentane ring), 3.7–3.9 (m, CH at position 2 of the cyclopentane ring), 4.46–4.85 (m, OH of CH_2OH), 4.85–5.14 (m, CH at position 1 and OH at positions 2 and 3 of the cyclopentane ring), 5.65 (center of doublet, CH at position 5 of the pyrimidine ring), 6.94 (broad singlet, NH_2), and 7.57 (center of doublet, CH at position 6 of the pyrimidine ring).

Compound III moved slightly faster than I on a thin-layer plate of silica gel with 2-propanol–1 *M* ammonium acetate (7:3) as developing solvent.

Anal.—Calc. for $C_{10}H_{15}N_3O_4$: C, 49.79; H, 6.27; N, 17.42. Found (after drying at 100° for 4 hr): C, 49.57; H, 6.30; N, 17.45.

The carbocyclic analog (II) of cyclocytidine was isolated from another reaction of I with dimethylformamide–thionyl chloride. The mixture of II and pyridinium formate, obtained by chromatographing the reaction product on the pyridinium cation-exchange resin[1], as already described, was stored in a high vacuum for an extended period to volatilize pyridine and formic acid. The residue was triturated several times with ether and then with cold ethanol. Ethanol evaporation, addition of a second portion of cold ethanol, and drying of the crystalline precipitate at 56° afforded II formate as a hydrate; TLC, one spot [40 or 80 μg on silica gel, 2-propanol–1 *N* ammonium acetate (7:3)[4], UV detection]; mass spectrum: *m/e* 223 (M), 192 (M − CH_2OH), and 46 (HCOOH); UV: λ_{max} 269 (ϵ 9500) and 232 (9000) at pH 1.

Anal.—Calc. for $C_{10}H_{13}N_3O_3 \cdot HCOOH \cdot \frac{3}{4}H_2O$: C, 46.39; H, 5.84; N, 14.76. Found: C, 46.29; H, 5.54; N, 15.28.

Kikugawa and Ichino (10) reported the preparation of cytarabine from cytidine through the intermediate formation of cyclocytidine with dimethylformamide–thionyl chloride reagent. The overall yield of cytarabine was about 27%. When the first procedure outlined for the preparation of III was applied to the preparation of cytarabine from cytidine, the yield of product obtained from the second ion-exchange column[1] was 41%.

Analysis of the product by high-pressure liquid chromatography showed it to be a mixture of cytarabine and cytidine (55:45) and indicated an overall yield of about 23% of cytarabine. In comparison, the yield of III free of I was 68% at the same stage.

In tests performed by standard protocols (11), the carbocyclic analog of cytarabine was active against L-1210 leukemia in mice (Table I).

Table I—Tests of Compound III against L-1210 Leukemia [a]

Dose, mg/kg/day	Weight Change[b], T − C	Average Lifespan, T/C	Increase in Lifespan, %
150	−2.2	16.6/8.1	104
100	−0.8	13.8/8.7	58
67	−1.5	11.4/8.1	40

[a] Mice were implanted intraperitoneally with 10^5 L-1210 cells on Day 0. Treatment was begun on Day 1 and continued through Day 9 (*q.d.* 1–9). T = treated mice; C = control mice. [b] The weight change is the difference on Day 5 between the average change in weight of treated mice and the average change in weight of control mice.

[1] Styrene-sulfonic acid-type resin, analytical grade (AG-50W-X4, Bio-Rad Laboratories, Richmond, Calif.).

[2] Fractions of the eluate containing II or III were located by monitoring the effluent with a UV spectrophotometric monitor.

[3] Amberlite CG-120, H^+ form.

[4] In this TLC system, II moved more slowly than I and III.

Absorption of Insulin Delivered to Rabbit Trachea Using Aerosol Dosage Form

Keyphrases □ Insulin—aerosol dosage forms, tracheal administration, absorption, rabbits □ Dosage forms, aerosol—insulin, tracheal administration, absorption, rabbits □ Proteins—aerosol dosage forms, insulin, tracheal administration, absorption, rabbits

To the Editor:

Insulin, an endogenous hormone used in treatment of diabetes mellitus, has been administered parenterally rather than orally because it readily decomposes in the GI tract. However, some effective approaches have been developed for oral (1–3), nasal (4), and rectal and aerosol (5, 6) dosage forms. The aerosol dosage form has been receiving much attention because it can be used by diabetic patients with little difficulty.

Wigley *et al.* (5) reported that insulin delivered to patients and volunteers by aerosol inhalation using a nebulizer was absorbed through the respiratory tract epithelium and was an effective therapeutic form for diabetes mellitus (5). However, little has been mentioned about the pharmaceutical factor that governs insulin absorption from aerosol dosage forms.

The present study was undertaken to investigate the bioavailability of powdered aerosol insulin when administered intratracheally to rabbits.

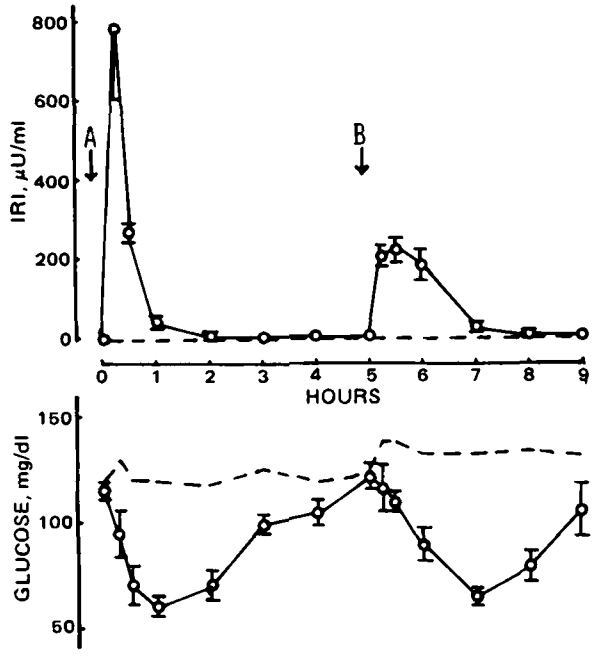

Figure 1—*Plasma concentration profiles of immunoreactive insulin (IRI) and glucose after intravenous (A, 1 U/kg) or intratracheal (B, 2.5 U/kg) insulin administration. Each point represents the mean ± SEM of three experiments. Broken lines denote immunoreactive insulin and glucose levels in sham-operated rabbits.*

White male rabbits, 2.8–3.1 kg, were anesthetized with pentobarbital sodium and maintained under anesthesia for the entire experiment. After the animal was secured in a supine position, insulin solution (1.0 U/kg) or physiological saline (as the control) was injected into the ear vein.

Blood samples were collected from the femoral vein at timed intervals to monitor immunoreactive insulin and glucose levels in plasma. Four hours after intravenous insulin injection, the rabbit trachea was exposed and polyethylene tubing was inserted through a tracheal incision. Insulin aerosol was sprayed into the trachea 1 hr after surgical treatment, and the appearance of immunoreactive insulin and the blood glucose level then were determined at timed intervals.

The insulin aerosol formulation was composed of: monocomponent porcine insulin[1], 5 mg; lactose, 75 mg; acetylglycerin monostearate, 50 mg; dichlorodifluoromethane, 3.6 g; and dichlorotetrafluoroethane, 2.4 g. A metered aerosol valve was designed to release 0.058 mg (1.5 U) of insulin/delivery. The plasma glucose level was measured by the method of Hyvärinen and Nikkilä (7), and immunoreactive insulin in plasma was determined by the method of Desbuquois and Aurbach (8).

Figure 1 shows the time courses of immunoreactive insulin and glucose concentrations in plasma after intravenous injection and after intratracheal aerosol insulin administration. After intravenous administration, there was a sharp increase in plasma immunoreactive insulin and a decrease in plasma glucose. The decline in plasma glucose continued for about 3 hr, although the plasma immuno-

However, little has been mentioned about the pharmaceutical factor that governs insulin absorption from aerosol dosage forms.

The present study was undertaken to investigate the bioavailability of powdered aerosol insulin when administered intratracheally to rabbits.

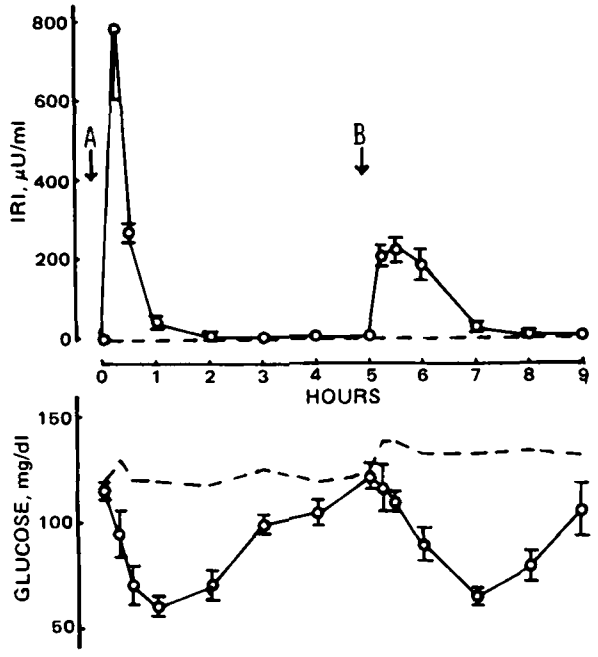

Figure 1—*Plasma concentration profiles of immunoreactive insulin (IRI) and glucose after intravenous (A, 1 U/kg) or intratracheal (B, 2.5 U/kg) insulin administration. Each point represents the mean ± SEM of three experiments. Broken lines denote immunoreactive insulin and glucose levels in sham-operated rabbits.*

White male rabbits, 2.8–3.1 kg, were anesthetized with pentobarbital sodium and maintained under anesthesia for the entire experiment. After the animal was secured in a supine position, insulin solution (1.0 U/kg) or physiological saline (as the control) was injected into the ear vein.

Blood samples were collected from the femoral vein at timed intervals to monitor immunoreactive insulin and glucose levels in plasma. Four hours after intravenous insulin injection, the rabbit trachea was exposed and polyethylene tubing was inserted through a tracheal incision. Insulin aerosol was sprayed into the trachea 1 hr after surgical treatment, and the appearance of immunoreactive insulin and the blood glucose level then were determined at timed intervals.

The insulin aerosol formulation was composed of: monocomponent porcine insulin[1], 5 mg; lactose, 75 mg; acetylglycerin monostearate, 50 mg; dichlorodifluoromethane, 3.6 g; and dichlorotetrafluoroethane, 2.4 g. A metered aerosol valve was designed to release 0.058 mg (1.5 U) of insulin/delivery. The plasma glucose level was measured by the method of Hyvärinen and Nikkilä (7), and immunoreactive insulin in plasma was determined by the method of Desbuquois and Aurbach (8).

Figure 1 shows the time courses of immunoreactive insulin and glucose concentrations in plasma after intravenous injection and after intratracheal aerosol insulin administration. After intravenous administration, there was a sharp increase in plasma immunoreactive insulin and a decrease in plasma glucose. The decline in plasma glucose continued for about 3 hr, although the plasma immuno-

[1] Crystals, lot S 837301 (biological potency 26.6 I.U./mg), Novo Industry Co., Copenhagen, Denmark.

reactive insulin was almost completely cleared within 1 hr. After intratracheal insulin administered by aerosol, the circulating plasma immunoreactive insulin showed a significant rise and there was a sustained decline in the plasma glucose level.

The bioavailability calculated from the area under the plasma immunoreactive insulin curves after intratracheal aerosol administration of about 2.5 U of insulin/kg was almost the same as that after intravenous injection of 1 U/kg. Wigley *et al.* (5) reported that the plasma immunoreactive insulin area with aerosol delivery of about 3 U/kg was 7–16% of that after intravenous injection of 0.2 U/kg. This low bioavailability might depend on many factors such as adherence to the glass nebulizer, the mouth, and the throat. Our results indicated that most of the insulin (~40%) delivered directly into the trachea in an aerosol formulation is absorbed into the bloodstream through the epithelial layer of the respiratory tract. Accordingly, if an aerosol formulation could be administered directly into the trachea, it could be an effective tool for clinical applications of proteins and peptides.

BOOKS

REVIEWS

Analysis of Drugs and Metabolites by Gas Chromatography–Mass Spectrometry. Vol. 1: Respiratory Gases, Volatile Anesthetics, Ethyl Alcohol, and Related Toxicological Materials; Vol. 2: Hypnotics, Anticonvulsants, and Sedatives; Vol. 3: Antipsychotic, Antiemetic, and Antidepressant Drugs; Vol. 4: Central Nervous System Stimulants; Vol. 5: Analgesics, Local Anesthetics, and Antibiotics. By BENJAMIN J. GUDZINOWICZ and MICHAEL J. GUDZINOWICZ. Dekker, 270 Madison Avenue, New York, NY 10016, Vol. 1: 1977, 223 pp., 15 × 23 cm, Price $23.75; Vol. 2: 1977, 493 pp., 15 × 23 cm, Price $45.00; Vol. 3: 1977, 268 pp., 15 × 23 cm, Price $29.75; Vol. 4: 1978, 458 pp., 15 × 23 cm, Price $45.00; Vol. 5: 1978, 541 pp., 15 × 23 cm, Price $55.00.

The above titles are the first five volumes in what the publisher promises to be a continuing series. Indeed, the flyleaf of Volume 5 states that Volume 6 will cover cardiovascular, antihypertensive, hypoglycemic, and thyroid-related agents. The stated purposes of this series are: to provide a chronological literature compilation of the GLC and GLC–mass spectrometry procedures for the analysis of specific drugs and their metabolites; to provide qualitative and quantitative procedures in such detail that they might be reproduced "faithfully" in the reader's laboratory; to present the results, precision, accuracy, and limits of detection achieved by a given procedure; and to indicate, wherever possible, the procedure's applicability to pharmacokinetic studies.

Each volume has a separate author and subject index. These indexes are not cumulative, but that is not necessary since each volume is self-contained. The authors assume that the reader is familiar with GLC and GLC–mass spectrometry. No pages are wasted on cursory introductory chapters, although the authors do include a few sketches of special instrument modifications such as sampling traps and injection ports. Where appropriate, the chemistry of a chemical class is described in an expanded discussion, which usually contains the structures and sometimes the biotransformations. Each chapter contains representative GLC tracings and tabulated retention data. Some mass spectra or printouts of mass fragment values are presented.

A logical question is: Does this series duplicate or overlap *Analytical Profiles*? To a limited extent, the answer is yes, only because GLC and mass spectra analyses are found in *Analytical Profiles*. Whereas the latter deals more with the pure drug, *Analysis of Drugs and Metabolites by Gas Chromatography–Mass Spectrometry* emphasizes the analysis of mixtures that include the specific drugs under discussion. The two series complement each other, and the volumes covered in this review discuss a much larger group of compounds.

Volume 1 consists of two chapters of about equal length. The first chapter discusses respiratory gases, volatile anesthetics, and related toxicological materials. The second includes sterilizing agents, common organic solvents found in blood, and riot-control aerosol irritants. The second chapter also features ethanol and volatile trace components in breath, body fluids, and body tissues. The term "volatile" may be a little misleading, because the discussion on urine includes screening of urinary steroids and acids plus other chemicals.

The topics become more pharmaceutically oriented in the remaining volumes. About half of Volume 2 is devoted to barbiturates. One-third of the volume is a chapter that includes chloral derivatives, tertiary acetylenic alcohols, cyclic ethers, carbamates and ureides, piperdinediones, quinazalones, benzodiazepines, and carbamazepine. The third and final chapter makes up about 20 percent of the book and covers the traditional anticonvulsants including hydantoins, succinimides, primidone, paramethadione and trimethadione, and some miscellaneous anticonvulsants.

Volume 3 has two chapters of about equal length. Chapter 1 covers phenothazines, butyrophenones, and thioxanthines; Chapter 2 includes a moderate discussion on monoamine oxidase inhibitors and a rather complete coverage of the tricyclic antidepressants.

Volume 4 also contains two chapters of about equal length. Most of Chapter 1 is devoted to the amphetamines and related compounds, with the remainder including the xanthines and pentylenetetrazol. Chapter 2 mainly covers the phenylethylamine-related compounds, with the balance devoted to tryptamine- and propranolol-related compounds.

reactive insulin was almost completely cleared within 1 hr. After intratracheal insulin administered by aerosol, the circulating plasma immunoreactive insulin showed a significant rise and there was a sustained decline in the plasma glucose level.

The bioavailability calculated from the area under the plasma immunoreactive insulin curves after intratracheal aerosol administration of about 2.5 U of insulin/kg was almost the same as that after intravenous injection of 1 U/kg. The above titles are the first five volumes in what the publisher promises to be a continuing series. Indeed, the flyleaf of Volume 5 states that Volume 6 will cover cardiovascular, antihypertensive, hypoglycemic, and thyroid-related agents. The stated purposes of this series are: to provide a chronological literature compilation of the GLC and GLC–mass spectrometry procedures for the analysis of specific drugs and their metabolites; to provide qualitative and quantitative procedures in such detail that they might be reproduced "faithfully" in the reader's laboratory; to present the results, precision, accuracy, and limits of detection achieved by a given procedure; and to indicate, wherever possible, the procedure's applicability to pharmacokinetic studies.

Each volume has a separate author and subject index. These indexes are not cumulative, but that is not necessary since each volume is self-contained. The authors assume that the reader is familiar with GLC and GLC–mass spectrometry. No pages are wasted on cursory introductory chapters, although the authors do include a few sketches of special instrument modifications such as sampling traps and injection ports. Where appropriate, the chemistry of a chemical class is described in an expanded discussion, which usually contains the structures and sometimes the biotransformations. Each chapter contains representative GLC tracings and tabulated retention data. Some mass spectra or printouts of mass fragment values are presented.

A logical question is: Does this series duplicate or overlap *Analytical Profiles*? To a limited extent, the answer is yes, only because GLC and mass spectra analyses are found in *Analytical Profiles*. Whereas the latter deals more with the pure drug, *Analysis of Drugs and Metabolites by Gas Chromatography–Mass Spectrometry* emphasizes the analysis of mixtures that include the specific drugs under discussion. The two series complement each other, and the volumes covered in this review discuss a much larger group of compounds.

Volume 1 consists of two chapters of about equal length. The first chapter discusses respiratory gases, volatile anesthetics, and related toxicological materials. The second includes sterilizing agents, common organic solvents found in blood, and riot-control aerosol irritants. The second chapter also features ethanol and volatile trace components in breath, body fluids, and body tissues. The term "volatile" may be a little misleading, because the discussion on urine includes screening of urinary steroids and acids plus other chemicals.

The topics become more pharmaceutically oriented in the remaining volumes. About half of Volume 2 is devoted to barbiturates. One-third of the volume is a chapter that includes chloral derivatives, tertiary acetylenic alcohols, cyclic ethers, carbamates and ureides, piperdinediones, quinazalones, benzodiazepines, and carbamazepine. The third and final chapter makes up about 20 percent of the book and covers the traditional anticonvulsants including hydantoins, succinimides, primidone, paramethadione and trimethadione, and some miscellaneous anticonvulsants.

Volume 3 has two chapters of about equal length. Chapter 1 covers phenothazines, butyrophenones, and thioxanthines; Chapter 2 includes a moderate discussion on monoamine oxidase inhibitors and a rather complete coverage of the tricyclic antidepressants.

Volume 4 also contains two chapters of about equal length. Most of Chapter 1 is devoted to the amphetamines and related compounds, with the remainder including the xanthines and pentylenetetrazol. Chapter 2 mainly covers the phenylethylamine-related compounds, with the balance devoted to tryptamine- and propranolol-related compounds.

Volume 5 covers a mixed group of drugs. Chapter 1 is about 40 percent of the book and includes natural and synthetic narcotics and narcotic antagonists. The balance of Volume 5, Chapter 2, discusses antipyretics, antiinflammatory and antihyperuricemic agents, local anesthetics, and antibiotics. Since these volumes are part of a continuing series, it would have seemed more appropriate to include antibiotics in a volume covering antiinfective and chemotherapeutic agents.

At first glance, from the authors' goals, the reader might expect a combination of an exhaustive treatise and laboratory manual for each subject. An examination of any volume will show that this was not necessary. The general format of each section is: (*a*) a general literature review including the chemistry and biochemical transformation of the drug class under discussion; (*b*) a discussion of derivatization, sensitivity, and quantitation; and (*c*) several specific examples. A limited number of actual procedures is found in the latter part of each chapter. All information is well referenced. Perhaps the best way to describe this series is to say that each chapter is a very extensive review article.

Unless an individual is an analytical laboratory director, there is little reason to purchase the entire set. On the other hand, individual volumes are highly recommended to scientists needing to be knowledgeable in the analysis of a specific drug group. The entire set should be purchased by libraries whose collections include books dealing with instrumental analysis.

Aromatic and Heteroaromatic Chemistry, Volume 6. A Review of the Literature Abstracted between 7/76 and 6/77. By H. SUSCHITZKY and O. METH-COHN. Chemical Society, Burlington House, London, W1V OBN, England. 1978. 326 pp. 14 × 22 cm. Price $47.50.

This latest volume in the series of Specialist Periodical Reports reviews the literature on aromatic and heteroaromatic chemistry abstracted between July 1976 and June 1977 and covered by Volumes 85 and 86 of *Chemical Abstracts*.

The two new senior reporters, Professors Suschitzky and Meth-Cohn, have partially reorganized the chapters of this volume in an attempt to reduce the cost and to aid the reader in locating particular topics quickly, in the absence of a subject index. The high cost and lack of a subject index were the only previous criticisms of this series. The reorganization was successful in both endeavors, although the cost of the book is still relatively high.

The senior reporters have retained all other aspects developed by their predecessors, Professors Bird and Cheeseman, and have maintained the high quality presentation of a large amount of factual information so valuable to the scientist interested in this area.

The liberal use of structures and reaction schemes and the practice of placing references as footnotes on the page cited have been retained and maintain the excellent readability and continuity of the previous volumes.

The new chapter titles include: Three and Four-Membered Ring Systems; Five-Membered Ring Systems; Six-Membered Ring Systems; Six-Membered Heterocycles; Seven-Membered Ring Systems; Medium-Sized Rings and Macrocycles; and Electrophilic Substitution Reactions. Chapter titles retained include: Nucleophilic Substitution Reactions; Aromatic Substitution by Free Radicals, Carbenes, and Nitrenes; Porphyrins and Related Compounds; Naturally Occurring Aromatic Oxygen-Ring Compounds; and Other Naturally Occurring Aromatic Compounds. Not included, due to the illness of its reporter, was the new chapter entitled Six-Membered Homocycles. The volume has a complete author index containing over 4300 names, and the 11 chapters include over 2200 literature citations.

Like the previous volumes, this one provides a systematic, critical, in-depth account of the progress in aromatic and heteroaromatic chemistry.

Analysis of Steroid Hormone Drugs. By S. GÖRÖG and GY. SZÁSZ. Akadémie Kiadó, Budapest, Hungary, and Elsevier Scientific Publishing Co., Amsterdam, The Netherlands. 1978. 426 pp. Price $59.

Every scientist interested in the analysis of steroid pharmaceuticals should acquire this book. The literature on steroid analysis has become so extensive that many review articles have degenerated into mere taxonomy, like the bienniel *Analytical Chemistry* reviews on drug analysis. In contrast, this book provides an informed and intelligent review of the subject. It is a volume one can read through as a text, browse in for intellectual stimulation, or use as a reference for a specific question.

Organization of the book could well serve as a paradigm for other monographs. The chapters are titled, "Fundamental Steroid Hormone Chemistry," "Brief Outline of the Therapeutic Use of Steroid Hormones," "Development of, and Current Trends in, Methods of Steroid Hormone Analysis," "Chromatography of Steroid Hormones," "Gas Chromatography of Steroid Hormones," "Functional Group Analysis," "Assay of Dosage Forms," and "Analysis of Raw Materials for the Semi-syntheses of Steroid Hormones." The author of each chapter or section is identified, and each chapter has references. There are author and subject indexes.

HPLC methods now are probably the most useful for assay of steroids and their pharmaceutical dosage forms. Discussion of this technique in the book is much shorter than for GC, which it has largely supplanted. Nevertheless, the text is oriented to chemical principles, so it is unlikely to be dated rapidly by the appearance of new technology.

The *Journal of Pharmaceutical Sciences* (ISSN 0022-3549) is published monthly by the American Pharmaceutical Association (APhA) at 2215 Constitution Ave., N.W., Washington, DC 20037. Second-class postage paid at Washington, D.C., and at additional mailing office.

All expressions of opinion and statements of supposed fact appearing in articles or editorials carried in this journal are published on the authority of the writer over whose name they appear and are not to be regarded as necessarily expressing the policies or views of APhA.

Offices—Editorial, Advertising, and Subscription: 2215 Constitution Ave., N.W., Washington, DC 20037. Printing: 20th & Northampton Streets, Easton, PA 18042.

Annual Subscriptions—United States and foreign, industrial and government institutions $50, educational institutions $50, individuals *for personal use only* $30; single copies $5. All foreign subscriptions add $5 for postage. Subscription rates are subject to change without notice. Members of APhA may elect to receive the *Journal of Pharmaceutical Sciences* as a part of their annual $70 (foreign $75) APhA membership dues.

Claims—Missing numbers will not be supplied if dues or subscriptions are in arrears for more than 60 days or if claims are received more than 60 days after the date of the issue, or if loss was due to failure to give notice of change of address. APhA cannot accept responsibility for foreign delivery when its records indicate shipment has been made.

Change of Address—Members and subscribers should notify at once both the Post Office and APhA of any change of address.

Photocopying—The code at the foot of the first page of an article indicates that APhA has granted permission for copying of the article beyond the limits permitted by Sections 107 and 108 of the U.S. Copyright Law provided that the copier sends the per copy fee stated in the code to the Copyright Clearance Center, Inc., P.O. Box 8891, Boston, MA 02114. Copies may be made for personal or internal use only and not for general distribution.

Microfilm—Available from University Microfilms International, 300 N. Zeeb Road, Ann Arbor, MI 48106.

TOO MANY REGULATIONS?

Out in Fairfax County, Virginia, where this writer resides, we enjoy—or are afflicted with, depending upon one's viewpoint—an apparent surfeit of dogs. Moreover, the owners of many of these pets exercise exceedingly little restraint or control over the canine population.

This situation has led to the county adopting a so-called "leash law," which requires every dog to be maintained on a leash whenever the animal is off its owner's property. After being in effect for a full year, however, we see no discernible change in behavior, simply because the police do not enforce the law and the malefactors who own the dogs are well aware of that fact. Consequently, what seemed to be a good solution in theory turned out to be an exercise in futility.

We also have certain main roads designated as "snow emergency routes," and any car getting stuck there due to ice and snow is subject to being ticketed. Well, this past February, the Washington, D.C., area was hit with its worst blizzard in 50 years. Although efforts were made to keep the main arteries open, this quickly proved hopeless due to stalled cars that were abandoned on the roadways, preventing the snow removal equipment from doing its job.

In one newspaper account, a reporter asked the traffic department why the offending cars were not being ticketed. The response offered by the police was that to do so would be "unfair because the cars were snowed in." But since no one gets stuck in snow purposely, why maintain such a law on the books if it is not to be enforced?

We are reminded of these examples because we recently heard an APhA member offer the same time-worn and simplistic solution that pharmacy often employs in an effort to solve some problem situation or behavior; namely, the "there-ought-to-be-a-law" syndrome.

A pharmaceutical company house organ publication crossed our desk a few weeks ago that carried an article, the heading of which was a direct quote from a book entitled "Spirit of the Law," written in 1748 by the French state philosopher Charles de Montesquieu. The quote read: "*Superfluous laws detract from the effectiveness of those that are necessary.*"

Increasingly, there are signs and evidence that the United States in general, and the health field in particular, are becoming the victims of over-regulation. Productivity and effectiveness are gradually being strangled by excessive regulatory requirements.

This problem has gotten to the point that the federal government itself, in the form of the Carter Administration, is initiating various reviews to assess whether this trend might be reversed. Although we may be pessimistic or even cynical about such pronouncements, it is encouraging that there is some recognition of the danger posed by unbridled policy to solve problems through imposing new regulations.

Moreover, Mary Munson Runge, quoted several months ago before assuming the APhA Presidency, expressed chagrin at the "overlegislated" state of the profession of pharmacy. Who is to blame for the mountain of mandates that is slowly taking shape throughout the country? She believes that pharmacists themselves are at fault: "*Pharmacists have brought some of these things on themselves by not doing them voluntarily. I understand fully the reasons for all the mandates that are being legislated, and I think it's the fault of the profession.*"

From our perspective, she is right on target. Most new statutes and regulations come about because something wasn't working as it should have been, and a need was perceived by someone to legislate a solution.

Requirements affecting the drug industry—and especially the Good Manufacturing Practices and Good Laboratory Practices regulations—can generally be traced to some sloppy or shoddy performance by at least a part of the industry.

Similarly, in this month's issue of APhA's professional periodical, *American Pharmacy*, there is an article titled "Kelsey's Commandos: FDA Investigates the Investigators." This article deals with all the rules that have sprung up in the past decade to regulate scientists who conduct clinical investigations on new drugs. Again, as the article reveals, these people brought it on themselves through the scandalous performance of some of their own.

But if it's any consolation, the investigators-of-the-investigators are increasingly getting rapped on their back-sides also! There have been several cases lately where FDA is being dragged into court to account for its alleged failure to perform and is being slapped with requirements to speed up certain processes, to release certain information, or to complete certain projects. A big headline in the March 9 issue of *The Washington Post* serves as a cryptic example: "Judge is Asked to Force FDA to Move on Ineffective Drugs." As the story notes, "More than 16 years and one court order" after Congress passed the provision that the government halt sales of any drug lacking substantial evidence of its efficacy, some 482 prescription products lacking such evidence remain on the market.

FDA's usual excuse is that Congress is quick to pass laws but slow to appropriate funds for their implementation.

We are not sure what the answer is to the over-regulation problem. But we suspect that much of the problem is preventable if people, organizations, and agencies all performed up to the reasonable standard expected of them by society. —EGF

Benzoyl Peroxide Analysis

In a recent paper[1] in this Journal, "High-Pressure Liquid Chromatographic Assay of Benzoyl Peroxide in Dermatological Gels and Lotions," the authors questioned the validity of a TLC system described by our laboratories in a paper[2] entitled "The Stability of a Benzoyl Peroxide Acne Cream Product." The reliance on removing and measuring spectrophotometrically an extract from the solvent front of a chromatogram was recognized, and a subsequent paper[3], "An Improved TLC Procedure for the Quantitative Determination of Benzoyl Peroxide in Acne Creams," was published. This procedure utilized acetonitrile–water (1:1) in a reversed-phase system on an acetylated support, and complete resolution was achieved with benzoyl peroxide (R_f 0.42), benzoic acid (R_f 0.9–1.0), and other isolable impurities. Excellent assay agreement was obtained between this method and an iodometric titration procedure in deliberately degraded cream formulations. The fact that the iodometric titration procedure was proven to be stability indicating suggests its use as an assay method in terms of economics and simplicity over chromatographic methods.

Drug Stability in Veterinary Dosage Forms

The January 1979 issue of this Journal contained an editorial on "Consistency in Stability Testing"[1]. This timely editorial was of great interest to the Review Chemists in the Bureau of Veterinary Medicine of the Food and Drug Administration because they are deeply involved in the review and evaluation of stability testing of drug products.

The Bureau of Veterinary Medicine is a counterpart to the Bureau of Drugs, though with a smaller contingent of Review Chemists. The public only hears about veterinary medicine on such issues as DES, nitrites, nitrofurazones, and low-level antibiotics. The Bureau, however, has a much larger responsibility in approving drugs for animal use. Such critical areas as animal safety and human safety must be considered in addition to the effectiveness of the drug. The process of approval is just as intense as that for human products. In many cases, the approval is more critical since food products are involved.

Veterinary drug products are sold as pharmaceutical dosage forms (identical in many cases to the human dosage forms except for labeling), as medicated feed preparations (premixes, supplements, and complete feeds), and as other forms such as medicated blocks.

Bureau Review Chemists are responsible for evaluating the manufacturing operations related to the production of the final products to ensure that they meet the standards they purport to possess.

Stability is an important issue for veterinary products just as it is for human products. In fact, the issue is much more complex because of the variety of products and use patterns. Because of these complexities and often questionable areas of stability testing for veterinary products, the Bureau of Veterinary Medicine developed a set of guidelines for industry and reviewer use. The Bureau issued the Guidelines in July 1976 with a *Federal Register*[2] notice of availability in November of the same year. The Guidelines were updated in February 1978.

For veterinary products, stability is probably more critical and harder to focus on. Because of obvious reasons, human drug products enjoy a much higher plateau in the various fields of research and methods development. Human products are often used under controlled situations or conditions—stored in pharmacies and used in clinics, hospitals, and households. Probably the only controlled conditions for veterinary product usage, however, are in veterinary clinics, hospitals, or offices. Use by farmers of drugs purchased by them or dispensed to them leaves much to be desired as far as stability and shelflife are concerned. Many animal drugs are subjected to higher temperatures and abuse than human drug counterparts. However, as provided under our laws, a veterinary drug is a "drug" and must meet the requirements and individual standards of strength, quality, purity, and identity as proclaimed by the Act. The drug must also be manufactured under the cGMPs as published by the FDA.

We, in the Bureau of Veterinary Medicine, feel the Guidelines we have issued are meaningful and provide the guidance needed by industry. Many companies concerned with human pharmaceuticals are currently using our Guidelines. The Guidelines represent our best scientific judgment on the topic and should be used as just that—"guidelines." Our general position is that every product is unique and must "stand on its own" as far as stability is concerned.

Copies of the drug Guidelines can be obtained by writing to the: Food and Drug Administration, Bureau of Veterinary Medicine, Industry Relations Branch, HFV-226, 5600 Fishers Lane, Rockville, MD 20857.

Unified Theory of Anesthesia

The current diversity of theories of narcosis indicates a lack of understanding of the mechanism of anesthesia at the molecular level. Ecanow and coworkers[1,2] have proposed a hypothesis that integrates the descriptive, clinical, and laboratory data concerning individuals in a state of anesthesia.

This hypothesis is based on the concept that neuronal cells, like all cells, have membranes in the coacervate state; that is, the membrane exists as an aqueous phase that is in a different thermodynamic state than that of the surrounding aqueous plasma and interstitial fluids[3]. The addition of a small increment of drug to a coacervate phase produces a change in structuring, which results in a free energy change which is chiefly entropic. Accompanying the free energy change are pharmacological changes[1–3].

The colloid theory initially proposed by Claude Bernard in 1875 and subsequently elaborated by others suggested that a reversible aggregation of cell colloids causes or accompanies anesthesia. This reversible aggregation is precisely what occurs upon the introduction of an anesthetic agent to the colloidal system known as the coacervate phase. The change in aggregation relationships is measured by changes in physicochemical properties[3]. These changes, in turn, correlate with the ranking of clinical potencies in a series of depressant drugs[2].

The lipid theory advanced by Meyer and Overton proposes a direct parallelism between the affinity for a lipid phase and its resultant central nervous system (CNS) depressant action. The affinity is

Unified Theory of Anesthesia

The current diversity of theories of narcosis indicates a lack of understanding of the mechanism of anesthesia at the molecular level. Ecanow and coworkers[1,2] have proposed a hypothesis that integrates the descriptive, clinical, and laboratory data concerning individuals in a state of anesthesia.

This hypothesis is based on the concept that neuronal cells, like all cells, have membranes in the coacervate state; that is, the membrane exists as an aqueous phase that is in a different thermodynamic state than that of the surrounding aqueous plasma and interstitial fluids[3]. The addition of a small increment of drug to a coacervate phase produces a change in structuring, which results in a free energy change which is chiefly entropic. Accompanying the free energy change are pharmacological changes[1–3].

The colloid theory initially proposed by Claude Bernard in 1875 and subsequently elaborated by others suggested that a reversible aggregation of cell colloids causes or accompanies anesthesia. This reversible aggregation is precisely what occurs upon the introduction of an anesthetic agent to the colloidal system known as the coacervate phase. The change in aggregation relationships is measured by changes in physicochemical properties[3]. These changes, in turn, correlate with the ranking of clinical potencies in a series of depressant drugs[2].

The lipid theory advanced by Meyer and Overton proposes a direct parallelism between the affinity for a lipid phase and its resultant central nervous system (CNS) depressant action. The affinity is

measured in a lipid phase, which is usually a vegetable or organic liquid. By contrast, coacervates can be prepared from true lipids as well as other surfactants. Use of a coacervate as the lipid phase is more realistic to test for affinity and confirms the above parallelism[3]. Further, coacervates with their ability to show a continuum of subtle responses to the addition of anesthetics parallel the subtle responses characteristic of biophase reactions. The coacervate with its composition of lipids, colloids, water, and electrolytes is of the same composition as the biophase. On the other hand, the oils used in oil–water partition studies are at best single-point approximations of the physical–chemical properties of the biophase[3].

The cell permeability theory advanced by Hoher and others states that anesthetics stabilize the cell membrane and thus decrease the ion exchanges that normally accompany depolarization. This stabilizing of the cell membrane has been shown to accompany the increasing matrix structuring that occurs on the addition of anesthetics to a coacervate phase. This result is reflected by the increased resistance to electrical conductivity of a coacervate phase when the depressant drugs are added to the coacervate. The conductivity, in turn, parallels the clinical potency of the anesthetics added to the coacervate phase[2,5].

The increased red cell permeability to glucose normally produced by carbon dioxide can be seen by bubbling carbon dioxide through a coacervate phase and following the increasing glucose solubility (permeability). This increased permeability is inhibited upon the addition of an anesthetic agent to the coacervate phase.

In current neurophysiologocal theory, there is no satisfactory explanation for the observation that decreased synaptic transmission can be caused by anesthetic agents while, at the same time, axonal conduction remains unimpaired. We explain this observation as follows. The aqueous matrix in a synaptic cleft is a structured aqueous medium, thermodynamically different from neuronal cytoplasm and adjacent aqueous plasma. In effect, it constitutes three different states of aqueous media. The addition of an anesthetic agent concentrates in and further increases the synaptic aqueous matrix structuring, thus impairing synaptic transmission while axonal transmission remains unimpaired[2].

The Pauling and Miller concept of the structuring of water molecules around the anesthetic agent within the CNS focuses attention on the role of water. However, by focusing on water structuring as opposed to total matrix structuring, the theory suffers from the fact that the suggested stability is not likely to occur under conditions of normal body temperatures. The water–lipid equilibrium phase known as protoplasm is a coacervate and has no such limitation. The coacervate matrix at body temperature can readily become increasingly stable. The point to be emphasized is that the coacervate phase is both an aqueous phase and a lipoidal phase. As such, it integrates the attractive features of both the water structuring theory and the lipid theory of anesthetic mechanism.

The concept that general anesthetics expand the lipid phase of a membrane[4] correlates directly with the expansion of a coacervate phase as it becomes increasingly structured by the addition of clinical amounts of the anesthetic agent. High pressures that reverse anesthetic-induced expansion of the biomembrane also reduce expanded structures of coacervates. Many artificial phospholipid membranes used to confirm the expansion concept by means of electron-spin resonance are really phospholipid aqueous matrixes that are coacervate phases.

The concept of the membrane as a coacervate phase capable of undergoing subtle changes in structuring that correspond to different degrees of anesthesia supplies a fundamental predictive and experimentally verifiable basis for a unified theory to account for cellular changes produced by anesthetics as well as other drugs and metabolites. Finally, the membrane can undergo a continuum of free energy changes from polar to nonpolar properties. The anesthetic state occupies one range on this continuum.

Mechanistic and Quantitative Evaluation of Precorneal Pilocarpine Disposition in Albino Rabbits

VINCENT HON-LEUNG LEE and JOSEPH R. ROBINSON ˣ

Received July 6, 1978, from the *School of Pharmacy, University of Wisconsin, Madison, WI 53706.* Accepted for publication December 13, 1978.

Abstract □ The low ocular bioavailability of topically applied pilocarpine is attributed to extensive precorneal drug loss in conjunction with the resistance to corneal penetration. Several elements of precorneal loss were reported earlier, but a complete mechanistic understanding has not been available. The present study was designed to gain a better understanding of the mechanisms governing pilocarpine disposition in the precorneal areas as well as the relative influence of these parameters on ocular drug bioavailability. Radioactive pilocarpine and glycerin solutions were instilled into the precorneal area of the albino rabbit eye under various experimental conditions, and the drug concentration in the lacrimal lake was monitored as a function of time. The results demonstrated that nonconjunctival loss of pilocarpine, vasodilation due to the drug, and lacrimation due to vehicle formulation are additional aspects of precorneal drug disposition. The individual influence of all precorneal loss parameters on drug bioavailability was then assessed using a mathematical model formulated from experimental findings on both precorneal and intraocular drug disposition. Drainage and vasodilation, as well as nonconjunctival pilocarpine loss, exerted major influences on drug loss at the absorption site.

Keyphrases □ Pilocarpine—precorneal disposition, mechanistic and quantitative evaluation □ Precorneal area—pilocarpine disposition, mechanistic and quantitative evaluation □ Distribution, ocular—pilocarpine, mechanistic and quantitative evaluation □ Dosage forms, topical—pilocarpine, precorneal disposition, mechanistic and quantitative evaluation □ Cholinergics, ophthalmic—pilocarpine, precorneal disposition, mechanistic and quantitative evaluation

The mechanisms by which a topically applied dose of drug disappears from the precorneal area of the eye are important from the standpoint of improving ocular drug delivery systems. Pilocarpine, an important agent in glaucoma management, was selected as the probe drug for investigating this aspect of drug action.

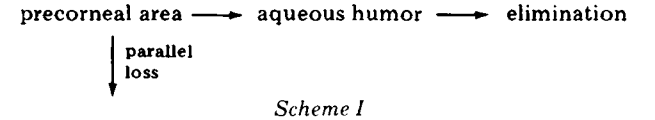
Previous studies with pilocarpine established that solution drainage (1, 2), drug protein binding (3–5), tear turnover (1, 6), and conjunctival absorption (7) compete with corneal absorption for the drug from the precorneal area. Only 1–2% or less of an instilled pilocarpine dose gains access to the internal eye structures (8, 9). While drainage removes a substantial portion of a dose within minutes of instillation, this parameter alone cannot explain the low pilocarpine bioavailability, nor can a combination of the other parameters.

In a similar manner, the large first-order rate constant, $\sim 0.6\ min^{-1}$, associated with the decline of the pilocarpine concentration in the tear film[1] for the critical first 5 min postinstillation is inconsistent with the values reported for the rate constants governing corneal absorption, tear turnover, and conjunctival absorption. Even though drainage has an associated rate constant whose value is $\sim 0.5\ min^{-1}$, it cannot be responsible for the large rate constant associated with precorneal drug loss because drainage is not expected to influence directly tear film drug concentration. In essence, this description for precorneal pilocarpine disposition implies that some as yet unidentified factors, with sizable rate constants, are present.

The purpose of the present study was to gain a better understanding of the mechanisms governing pilocarpine disposition in the precorneal area as well as of the relative influence of these parameters on ocular drug bioavailability.

MODEL

The evolution of mathematical models to describe pilocarpine disposition in the eye reflects the state of knowledge concerning the mechanisms governing its precorneal and intraocular disposition. Scheme I is an example of a commonly used model to describe the fate of pilocarpine



Scheme I

[1] The term tear film or pool is used interchangeably with lacrimal lake. It is assumed that instilled drugs are uniformly mixed with tear fluid.

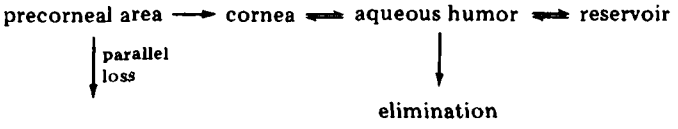


Scheme II

following topical instillation. Two deficiencies of such a model are that it considers the cornea as a single membrane with no apparent role in the disposition process and that it lumps all precorneal drug disposition constants into one large rate constant.

A more recent model (10) (Scheme II) corrects for the first deficiency by including the cornea as a component. However, it does not distinguish the specific roles exercised by the corneal epithelium and corneal stroma in the movement of pilocarpine through the cornea (11).

Both models suffer from the additional drawback of not considering the effects of instilled drop size explicitly. This important precorneal factor forms a component of a recently proposed model (12) which, for simplicity, treats the cornea as a single membrane, as in Scheme I. In summary, all of these models are incomplete descriptions of the fate of pilocarpine in the precorneal area and in the various ocular tissues.

The present study began with construction of a model that was cognizant of the deficiencies mentioned (Scheme III). The model partitions the precorneal loss rate constant into its component parts for a mechanistic understanding of the processes involved. In addition, it incorporates the findings of Sieg and Robinson (11) on pilocarpine disposition: (*a*) the corneal epithelium serves as both a barrier and a depot, and (*b*) the corneal stroma and endothelium are kinetically indistinguishable from the aqueous humor. Table I details the model parameters. The major assumptions introduced while constructing the model were:

1. Instantaneous and complete mixing of instilled drug solution and tears occurs.
2. Pilocarpine metabolism in the tear fluid is negligible.
3. The tissues comprising the compartments are homogeneous.
4. The iris, ciliary body, lens, and vitreous humor constitute the reservoir.

Moreover, the present model will not explicitly consider either pilocarpine protein binding in tear fluid or ocular tissues or the resistance offered by diffusional boundary layers to membrane drug transport.

Proceeding from these assumptions, appropriate differential equations can be written to account for the rate of change in the *mass* of drug in the compartments shown in Scheme III. The volume element of disposition kinetics in the precorneal area is treated in a manner akin to that described previously (12), which is based on the concept of mass balance in open systems advanced earlier (13). Drug transfer, on the other hand, is considered to be a series of simple diffusion steps taking place simultaneously and in succession, with each step governed by Fick's first law of diffusion, in much the same manner as Teorell (14) derived formulas to describe the amount of drug in the body as a function of time. Accordingly, the amount of drug transferred per unit time, M, can be written (15):

$$M = k_p S\,\Delta C \qquad \text{(Eq. 1)}$$

where k_p is the permeability coefficient in centimeters per second, S is the effective surface area in square centimeters, and ΔC is the concentration difference in grams per cubic centimeters. Since k_p and S have not been determined, they are treated in the present model as a single coefficient denoted as p and given by $p = k_p S$ with units of cubic centimeters per second.

Equation 2 describes the rate of change in amount of pilocarpine in the precorneal area:

$$\frac{dV_A(t)[A]}{dt} = -p_p([A] - [B]) - k_d[V_A(t) - V_0][A] - Q_T(t)[A] - p_n[A] \qquad \text{(Eq. 2)}$$

Table I—Parameters of the Model Described in Scheme III

Parameter	Coefficient Associated With[a]
p_p	Transfer of pilocarpine between precorneal area and corneal epithelium
p_n	Nonproductive loss
k_d	Drainage
$Q_T(t)$	Tear flow
p_a	Transfer of pilocarpine between epithelium and corneal stroma–endothelium–aqueous chamber
p_m	Drug loss *via* metabolism in or lateral diffusion from epithelium
p_{ao}	Drug elimination from aqueous humor
p_r	Transfer of pilocarpine between corneal stroma–endothelium–aqueous chamber and reservoir
p_{ro}	Pilocarpine elimination from reservoir

[a] With the exception of k_d, the coefficients have dimensions of microliters per minute. See text for details.

where $[A]$ denotes the drug concentration in the precorneal area (or tear chamber), $[B]$ is the drug concentration in the corneal epithelium, $V_A(t)$ is the volume of fluid in the tear chamber at a given time, V_0 is the normal resident tear volume, and all other symbols are as previously described. Sink conditions are assumed to be maintained in the blood supplying the conjunctiva and related structures.

Thus, from Eq. 2, the change in amount of pilocarpine in the precorneal area is due to corneal absorption, solution drainage, tear flow, and nonproductive loss. As will be evident in the *Discussion* section, nonproductive loss is composed of conjunctival absorption, nonconjunctival loss, and the influence of pilocarpine vasodilation on several of these processes. Likewise, tear flow is composed of normal tear turnover and induced lacrimation.

Induced lacrimation is interpreted here as increased tear flow rate; consequently, it will not change the resident precorneal volume appreciably since a corresponding volume will leave the area. This appears to be the case, as there was no visually apparent fluid accumulation in the precorneal area following dosing. In essence, this treatment views induced lacrimation and instilled volume-dependent drainage as noninteracting entities. This simplification is justifiable based on an earlier study (1) in which the influence of pH on lacrimation could be estimated. The technetium sulfur colloid preparation pH was not reported in that study but was ~6.5, which was close to the pH of most pilocarpine solutions employed in the present study. Therefore, in terms of a change in precorneal fluid volume, the k_d values thus determined account not only for the contribution of instilled volume but also for that of induced lacrimation. Interestingly, the k_d value determined (1) for an instilled volume of 25 μl is consistent with that determined recently (16) by microscintigraphy for a pH 6.24 sodium pertechnetate solution. Combining this observation with the vehicle-induced lacrimation demonstrated in the present study suggests that Eq. 3 is appropriate for describing the rate of change in precorneal fluid volume:

$$\frac{dV_A(t)}{dt} = -k_d[V_A(t) - V_0] \qquad \text{(Eq. 3)}$$

Upon integration, Eq. 3 yields:

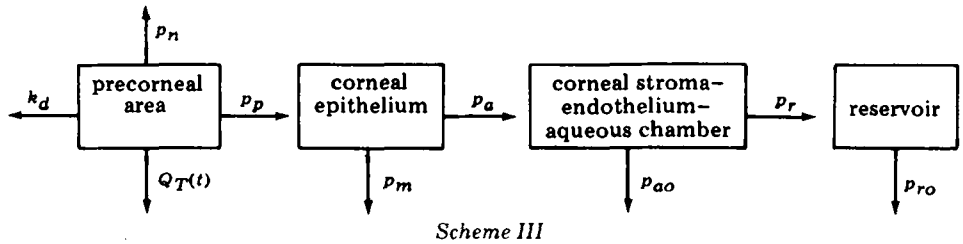
$$V_A(t) = V_0 + V_i \exp(-k_d t) \qquad \text{(Eq. 4)}$$

where V_i is the instilled volume. Equation 3 can be combined with Eq. 2:

$$\frac{d[A]}{dt} = -\left(\frac{p_p + p_n}{V_A(t)} + \frac{Q_T(t)}{V_A(t)}\right)[A] + \frac{p_p}{V_A(t)}[B] \qquad \text{(Eq. 5)}$$

In Eq. 5, $Q_T(t)$, like $V_A(t)$, is a time-dependent quantity, as shown in the empirical expression:

$$\frac{dQ_T(t)}{dt} = -k_l[Q_T(t) - Q_0] \qquad \text{(Eq. 6)}$$



Scheme III

Table II—Apparent Rate Constants for Routes of Precorneal Loss Established for Pilocarpine prior to the Present Study

Loss Route	Associated Rate Constant	Reference
Corneal absorption	0.004 min^{-1}	10, 11
Drainage, 25 μl	0.54 min^{-1}	1
Tear flow	0.66 μl/min	1
Nonproductive loss[a]	0.0217 min^{-1}	7

[a] This reported value was attributed to conjunctival absorption.

which is analogous in form to Eq. 3. Upon integration, Eq. 6 yields:

$$Q_T(t) = Q_0 + Q_i \exp(-k_l t) \qquad \text{(Eq. 7)}$$

According to this equation, the tear flow rate immediately following dosing (*i.e.*, $t = 0$) is the sum of the normal tear flow rate, Q_0, and that due to the instillation of a dose, Q_i. Eventually, the contribution of induced lacrimation to tear flow disappears, and the rate at which this occurs is governed by the rate constant k_l.

The essential feature of Eq. 5 concerns the dimension of the quantity:

$$\left[\frac{p_p + p_n}{V_A(t)} + \frac{Q_T(t)}{V_A(t)}\right]$$

which is that of a first-order rate constant. Nevertheless, it should not be considered as a constant since $V_A(t)$ and $Q_T(t)$ are functions of time. Thus, the quantity derived from the slope of a semilogarithmic plot of tear film drug concentration *versus* time is time averaged. The implication is that to convert the experimental first-order rate constant to the parameters p_p and p_n, knowledge of a time-averaged volume is needed. Of course, if a nonsampling technique that continuously monitors tear film drug concentration is available, $d[A]/dt$ will be known accurately as a function of time and a time-averaged volume is not needed. In this report, the first approach will be adopted, but $V_A(t)$ cannot be construed as a constant in subsequent computer simulations. The procedure for finding the time-averaged volume will be presented under *Discussion*.

For the case in which:

$$\frac{p_p}{V_A(t)}[B] \ll \left(\frac{p_p + p_n + Q_T(t)}{V_A(t)}\right)[A]$$

and $k_l = k_d$, Eq. 5 can be combined with Eqs. 4 and 7 to give an expression which, upon integration, yields a final expression describing the time dependence of drug concentration in the precorneal area following topical instillation:

$$[A] = [A]_i \left(\frac{V_i}{V_A(0)}\right)\left(\frac{V_A(0)}{V_A(t)}\right)^b \exp(-k''t) \qquad \text{(Eq. 8)}$$

where $[A]_i$ is the instilled drug concentration, V_i is the instilled volume, and:

$$b = \left(\frac{p_p + p_n + Q_0}{V_0} - \frac{Q_i}{V_i}\right)\frac{1}{k_d}$$

$$k'' = \frac{p_p + p_n + Q_0}{V_0}$$

$$V_A(0) = V_i + V_0$$

Several features of Eq. 8 are of interest. First, the parameters governing nonproductive loss, p_n, and pilocarpine transfer between the precorneal area and the corneal epithelium, p_p, contribute, along with the parameter governing normal tear flow, Q_0, to the exponent b. This result will not be obtained when one neglects the effect of volume on apparent first-order rate constants (17), in which case only Q_0 contributes. Second, the initial dilution of an instilled dose is accounted for by the term $V_i/V_A(0)$. Third, the equation accounts for the peculiar influence of drainage on drug concentration decline, which is one of deceleration. The key to the preceding statement lies in the terms $[V_A(0)/V_A(t)]^b$ and $\exp(-k''t)$ in Eq. 8. Whereas the term $\exp(-k''t)$ decreases continuously with time, the term $[V_A(0)/V_A(t)]^b$ increases with time [until $V_A(t)$ = normal resident tear volume], thereby counteracting the diminishing effect of the former. Fourth, the term $[V_A(0)/V_A(t)]^b$ yields the expected curvature observed in a semilogarithmic plot of tear film drug concentration *versus* time.

Equation 8 will be employed, as shown in the *Appendix*, to establish an expression relating the coefficient p and the apparent first-order rate constant k_a for a given parameter associated with the decline of the pilocarpine concentration in the precorneal area. Whether it is a good approximate equation to use depends largely on the relative magnitude of b and k''; the approximation improves as b exceeds k'' by a factor of at least 5. For the range of parameter values encountered in this study, the error due to the approximation does not exceed 7%, a tolerable error for these purposes[2].

Finally, mass balance equations similar to Eq. 5 can be written for the other compartments in Scheme III. They are:

$$V_B \frac{d[B]}{dt} = p_p([A] - [B]) - p_m[B] - p_a([B] - [C]) \qquad \text{(Eq. 9)}$$

$$V_C \frac{d[C]}{dt} = p_a([B] - [C]) - p_r([C] - [D]) - p_{ao}[C] \qquad \text{(Eq. 10)}$$

$$V_D \frac{d[D]}{dt} = p_r([C] - [D]) - p_{ro}[D] \qquad \text{(Eq. 11)}$$

In Eqs. 9–11, A represents the precorneal area, B represents the corneal epithelium, C is the corneal stroma–endothelium–aqueous chamber, and D is the reservoir; the V's refer to the volumes of the compartments indicated by the subscripts. Analytical expressions that might be obtained from these equations are too complicated to have practical value. Fortunately, much can be learned about the behavior of pilocarpine in the eye by solving the system of first-order linear differential equations, *i.e.*, Eqs. 3, 5, 6, and 9–11, using numerical methods. This approach was used in the simulation studies.

Simulation studies with the precorneal drug loss parameter values listed in Table II failed to duplicate tear film drug loss, suggesting the need for additional loss routes to complete the profile. Establishing these loss routes and quantifying the influence of all precorneal factors on ocular drug bioavailability are the purposes of this report.

EXPERIMENTAL

Materials—Tritiated pilocarpine alkaloid (specific activity of 4.2 Ci/mmole) in ethanol was obtained commercially[3] and purified by vacuum evaporation immediately prior to each run, as previously described (8). [^{14}C]-Glycerol[3] sterile aqueous solution (specific activity of 96.0 μCi/mg) was used as received. All other chemicals were either reagent or analytical grade and were used as received.

Male albino rabbits[4], 1.8–2.4 kg, were used throughout the studies. They were fed a regular diet with no restrictions on food or water consumed. Lighting and auditory stimuli were maintained on a 24-hr basis in the caging facility.

Solution Preparation—*0.01* M *Pilocarpine Alkaloid Solution*—A 0.01 *M* pilocarpine alkaloid solution, prepared in Sorensen phosphate buffer at the appropriate pH (6.24 or 7.38), was added to the labeled material prior to each experiment. Solutions were made isoosmotic with tears using sodium chloride. Each microliter of the resulting solution had an activity of ~75,000 cpm.

0.14 M *Glycerin Solution*—An aqueous aliquot of the isotopic species was added, prior to each experiment, to a 0.14 *M* glycerin solution prepared in pH 6.24 Sorensen phosphate buffer. The resulting solution was isoosmotic with tear fluid, and each microliter of solution had an activity of ~10,000 cpm.

0.14 M *Glycerin Solution Containing 0.01* M *Pilocarpine Alkaloid*—Equal portions of a 0.28 *M* glycerin solution and a 0.02 *M* pilocarpine alkaloid solution, both in pH 6.24 Sorensen phosphate buffer, were mixed immediately prior to each experiment. An aqueous aliquot of [^{14}C]-glycerin was added to the mixture, and the resulting solution was made isoosmotic with tears using sodium chloride. Each microliter of the final solution had an activity of ~10,000 cpm.

The small amount of labeled substances added to these three solutions did not appreciably alter the molarity of the final solutions. The final counts per minute for each solution was selected to achieve optimal counting efficiency.

0.1% Epinephrine Bitartrate and 0.25% Histamine Dihydrochloride Solutions—A 0.1% epinephrine bitartrate solution was prepared by diluting a commercial solution[5] with isoosmotic pH 7.38 Sorensen phosphate buffer. A 0.25% histamine dihydrochloride solution was prepared by dissolving the salt[6] with the same buffer. To minimize any direct irritating effect from these solutions on precorneal pilocarpine disposition, pilocarpine solutions were not instilled onto the eyes of experimental

animals until 15 min had elapsed following application of the histamine or epinephrine solutions.

Epinephrine bitartrate was employed for its vasoconstrictive effect on blood vessels perfusing the nictitating membrane and the conjunctiva, whereas histamine dihydrochloride was employed for its vasodilating effect. The concentration of each agent was selected based on conventional usage and appeared, by visual inspection, to exert the desired effect over the experiments.

Anesthesia—When necessary, anesthesia was induced and maintained by phenobarbital sodium (50 mg/ml iv) administered *via* the marginal ear vein. The rabbits were anesthetized ~15 min prior to instillation of the pilocarpine solution.

Tear Film Pilocarpine Concentration–Time Profile—Disappearance of pilocarpine from the tear film was monitored under the following experimental conditions: (*a*) normal unanesthetized rabbits, (*b*) normal anesthetized rabbits, (*c*) unanesthetized rabbits whose ocular surfaces were treated with 25 μl of a 0.1% epinephrine bitartrate solution 15 min prior to instillation of the pilocarpine solution, (*d*) anesthetized rabbits whose ocular surfaces were treated as in (*c*), (*e*) unanesthetized rabbits whose ocular surfaces were dosed with 25 μl of a 0.01 *M* nonradioactive pilocarpine solution 15 min prior to instillation of the dosing solution, (*f*) unanesthetized rabbits whose ocular surfaces were dosed with 25 μl of a 0.25% histamine dihydrochloride solution 15 min prior to instillation of the pilocarpine solution, and (*h*) unanesthetized rabbits receiving 25-μl doses of a 0.01 *M* pilocarpine solution at pH 7.38.

During the experiments, all test animals were kept in restraining boxes in a normal upright posture. Both eyes of the rabbit were employed. Pilocarpine solution, 25 μl, was instilled directly onto the cornea of the test animal, collecting in the cul-de-sac. During instillation, the upper lid was slightly raised and the lower lid was pulled slightly away from the globe. The lids were immediately returned to their normal position after instillation.

One-microliter tear samples were removed at 0.25, 1, 2, 3, 4, and 5 min postinstillation using 1-μl disposable glass capillary pipets[7]. The earliest sample was taken 15 sec after instillation to allow for mixing of the instilled solution with the tear fluid. During the early time period following drug instillation, sample removal has a small influence on the overall rate constant governing the decline in pilocarpine concentration since the precorneal tear volume is substantial and the number of samples taken is small. Moreover, removal of a small volume of fluid from the tear film–drug pool has only an indirect influence on drug concentration in subsequent samples.

During sampling, extreme care was exercised to avoid eye irritation. Thus, the capillary pipet tip was placed into the tear pool in contact with the cornea along the lower lid margin without touching any eye tissue. For consistency, all samples were withdrawn from the center of the marginal tear strip. On those rare occasions when the entire pipet was not filled with tear fluid, the volume of sample withdrawn was estimated from the depth to which the capillary pipet was filled. Pipets containing tear samples were transferred to vials[8] containing 5 ml of prerefrigerated scintillation cocktail[9] and counted in a liquid scintillation spectrometer[10] after 24 hr of storage in the dark. The presence of glass capillaries in the scintillation cocktail did not alter the counting efficiency or affect the results in any way, in agreement with earlier findings (18).

After suitable corrections, the data in number of counts per minute per microliter of tear fluid were plotted semilogarithmically as a function of time and subjected to linear regression analysis. First-order rate constants were obtained for the decline of the pilocarpine concentration in the precorneal area of each rabbit.

Tear Film Glycerin Concentration–Time Profile—Only anesthetized rabbits were employed in this portion of the study. The dosing solutions were: (*a*) glycerin solution containing no pilocarpine and (*b*) glycerin solution with 0.01 *M* pilocarpine. Positioning of the test animals, dosing and sampling procedures, and data analysis were as described in the preceding sections.

Influence of Instilled Dose Volume on Pilocarpine Disappearance from Tear Film—Ten microliters of a 0.01 *M* pilocarpine alkaloid solution was instilled onto the cornea of anesthetized rabbits as described. Sampling procedure and data analysis were as described.

Computer Simulation Studies—The computer program to simulate pilocarpine disposition in the albino rabbit eye consists of two major subroutines, DERIVS and INTGRT. The system of differential equations is presented in the subroutine DERIVS, which is introduced into the main program *via* the differential equation routine DEPC[11]. DEPC employs the predictor–corrector method outlined previously (19) to solve numerically initial value problems of ordinary first-order differential equations.

The subroutine INTGRT performs integration by Simpson's rule on the results produced by the differential equation routine. In addition to simulating single-dose situations, the program is capable of treating: (*a*) multiple-dose problems with variable dose size and volume given at intervals that need not be equal and (*b*) situations where the dose is removed before absorption is complete.

All computer calculations were performed on a digital computer[12], and the specific simulations carried out are indicated under *Results* and *Discussion*.

Table III—Compilation of First-Order Rate Constants Governing Initial Decline in Drug (Pilocarpine and Glycerin) Concentration under Various Experimental Conditions

Experimental Condition	k_a, min^{-1}
Pilocarpine (pH 6.24, 25-μl dose)	
Unanesthetized	0.63 (0.06)[a] [10][b]
Pretreated with epinephrine	0.40 (0.050) [7]
Pretreated with pilocarpine	0.68 (0.11) [4]
Pretreated with histamine	1.03 (0.14) [6]
Anesthetized	0.30 (0.05) [5]
Pretreated with epinephrine	0.072 (0.012) [6]
Pilocarpine (pH 6.24, 10-μl dose)	
Anesthetized	0.46 (0.009) [7]
Pilocarpine (pH 7.38, 25-μl dose)	
Unanesthetized	0.43 (0.042) [6]
Glycerin (pH 6.24, 25-μl dose)	
Anesthetized	0.13 (0.014) [8]
Dosing solution incorporated with pilocarpine	0.39 (0.043) [5]

[a] Number in parentheses represents standard error of the mean. [b] Number in brackets represents number of determinations.

RESULTS

Disposition of Pilocarpine and Glycerin in Precorneal Area—With the possible exception of histamine dihydrochloride, the compounds instilled into the cul-de-sac of the rabbits at the concentrations employed do not damage the corneal epithelium (20, 21). Consequently, alteration in apparent rate constants could not be due to enhanced absorption of pilocarpine as a result of corneal damage from these compounds.

In fitting the data to first-order decline by linear regression analysis, no attempt was made to force the best fit line through the theoretical counts per minute per microliter of tear fluid at time zero, due mainly to uncertainties in the mixing efficiency of instilled dose with the resident tear fluid. On the average, the deviations of the time zero values given by these best fit lines from the corresponding values calculated by assuming instantaneous mixing were less than 5%. In most cases, the coefficient of determination for the regression exceeded 0.95.

Following topical instillation of a given volume of pilocarpine solution in the eye, the tear film drug concentration declined rapidly. Figure 1 is an example of a semilogarithmic plot of counts per minute per microliter of tear fluid against time. Table III summarizes the apparent first-order rate constants governing tear film drug concentration decline under various experimental conditions. In normal unanesthetized rabbits, the decline in pilocarpine concentration had an associated rate constant of 0.63 min^{-1}. Changing the instilled solution pH from 6.24 to 7.38 produced a 1.5-fold reduction in the associated rate constant. In contrast, in the presence of anesthesia, the rate constant was reduced by ~50%. Predosing the eye with vasoactive agents also modified the first-order rate constant. Specifically, histamine dihydrochloride, a vasodilator, increased the rate constant by a factor of 1.5; epinephrine bitartrate, a vasoconstrictor, reduced it by the same factor. The reduction in the rate constant due to epinephrine was more prominent when anesthesia was present (Table III).

Table III also shows that, in the presence of anesthesia, glycerin disappeared from the precorneal area with an associated rate constant ~50% less than that for pilocarpine. However, when administered in combination with pilocarpine, the associated rate constant increased and was

statistically indistinguishable from that obtained for pilocarpine at the 95% confidence level (Table IV).

Finally, the first-order rate constant of decline increased by a factor of 1.5 when the instilled volume was reduced from 25 to 10 μl. At the 95% confidence level, this difference was statistically significant (Table IV).

Computer Simulation of Precorneal and Intraocular Pilocarpine Disposition—Table V lists the literature-adapted parameter values used in the initial simulation (1, 7, 11, 17, 22). Each parameter, p, associated with drug transfer between compartments, *e.g.*, aqueous humor → reservoir, was obtained by multiplying the corresponding first-order rate constant by the donor compartment volume. Since the corneal epithelium and stroma volumes were not determined, only their estimates are included. In regard to precorneal factors, the associated first-order rate constants (Table II) were employed. The exception was nonproductive loss, for which a value of 0.258 min^{-1} was shown (17) to yield better agreement with the tear film pilocarpine concentration–time profile established in the present study. For estimating p_p and p_n, a time-averaged precorneal fluid volume was employed; its rationale was discussed earlier. The final version of the precorneal parameter values is presented in Table VI. The initial estimates shown in Table V were modified only slightly.

Table V—Initial Estimates of the Parameter Values Associated with Ocular Distribution of Pilocarpine in the Albino Rabbit

Parameter	Value
Precorneal factors	
p_p	0.13 μl/min
k_d	0.54 min^{-1}
p_n	8.38 μl/min
Q_0	0.66 μl/min
Q_i	2.48 μl/min
k_l	0.54 min^{-1}
Intraocular factors	
p_a	0.6 μl/min
p_{ao}	4.04 μl/min
p_r	2.02 μl/min
p_{ro}	0 μl/min

V_C	250 μl[a,b]
V_D	325 μl[b]

[a] Volume of stroma is assumed to be 32 μl. [b] V_C and V_D add up to the volume of distribution value of 575 μl reported by Conrad and Robinson (22).

Figure 2 displays the simulated tear film drug concentration profile in unanesthetized rabbits for the first 5 min postinstillation. The slight curvature evident was due to drainage. Unless the experimental data are extremely precise, this curvature usually will not be detected. Consequently, the initial decline in drug concentration can often be approximated by a first-order process. The slope of the best-fit line yielded a first-order rate constant of 0.68 min^{-1}, which resided within the 95% confidence interval of the experimental value. This observation, in conjunction with the values reported for previously identified precorneal disposition factors, supported the notion that additional factors are critical to precorneal loss of pilocarpine.

The corresponding plot for the amount of drug in the tear film is depicted in Fig. 3. Here, the slope was approximately 1.5 times larger than that governing the decline in drug concentration. The important point is that the apparent first-order rate constant controlling the decline in drug concentration is not necessarily that controlling the decline in the amount of drug.

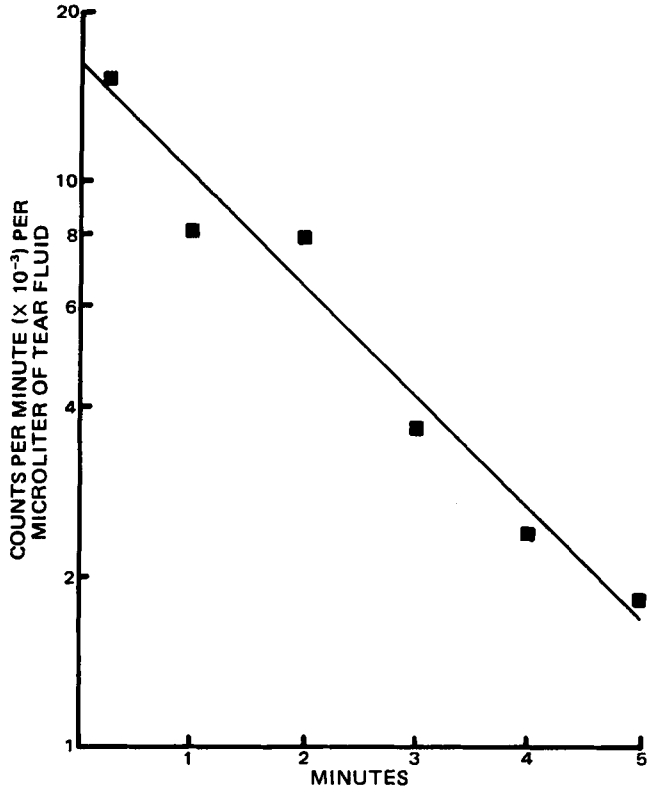

Figure 1—*Decline in the pilocarpine concentration (expressed as counts per minute per microliter of tear fluid) in the tear film following instillation of 10 μl of a 0.01* M *pilocarpine solution in an anesthetized rabbit.*

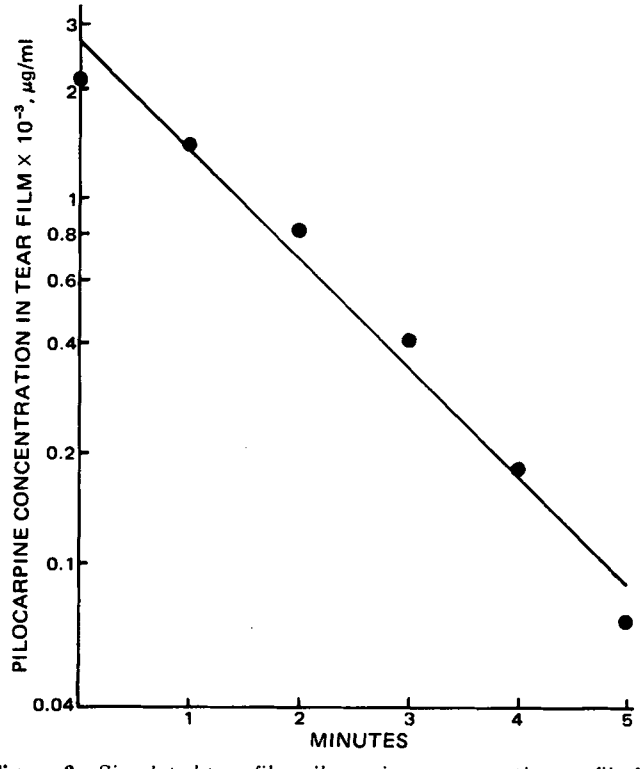

Figure 2—*Simulated tear film pilocarpine concentration profile for the first 5 min postinstillation. The solid circles represent the concentration of drug in the tear film calculated for a given time from the parameter values listed in Table V. The solid line represents the best-fit line, with* $R^2 = 0.98$ *and slope* $= -0.68\ min^{-1}$.

Table VI—Relationship between the Volume-Independent Value and First-Order Rate Constant of Precorneal Drug Loss Parameters

Parameter Associated with	p^a, μl/min	k^b, min^{-1} Unanesthetized	Anesthetized
Corneal absorption	0.13	0.006	0.005
Conjunctival absorption	0.71	0.033	0.025
Nonconjunctival loss	2.80	0.13	0.10
Vasodilation due to pilocarpine	4.76	0.22	0.17
Normal tear flow	0.66	0.031	0
Induced lacrimation	4.75	0.22	0
Decline in induced lacrimation	—	2	0
Drainage	—	0.54	0.18
Equation relating p and k		$k = 0.047p$	$k = 0.036p$

[a] Volume-independent value. [b] Apparent first-order rate constant.

Figure 4 is a simulated aqueous humor drug concentration profile, and the fit to experimental data is good. Based on the profiles displayed in Figs. 2 and 4, the proposed model is excellent in describing precorneal disposition of pilocarpine. A deficiency of the model concerns accounting for pilocarpine disposition within the cornea beyond 20-min postinstillation. In particular, the amount of pilocarpine in the cornea for this time interval, calculated according to the model, is approximately twice that obtained experimentally. As a result of systematically varying the magnitude of relevant parameter values, it becomes clear that a model that satisfactorily describes both precorneal and corneal disposition of pilocarpine must await additional studies on drug movement within the cornea.

DISCUSSION

Mechanisms Governing Precorneal Pilocarpine Disposition—The existence of efficient parallel loss processes acting in concert to remove drug from the precorneal area of the eye is unequivocal. This is attested to by the early peak time established in the corneal epithelium and aqueous humor following instillation of a pilocarpine solution (10, 11) and by the small fraction of an instilled dose that successfully gains access to the internal eye structures (8, 9). The large rate constant, 0.63 min^{-1}, associated with the decline in pilocarpine concentration in the tear film of unanesthetized rabbits provides a quantitative measure of the overall parallel loss effect. Obviously, from the standpoint of improving ocular drug bioavailability by formulating maximally efficacious ocular drug delivery systems, it would be helpful to identify all components of precorneal drug loss as well as the associated rate constants.

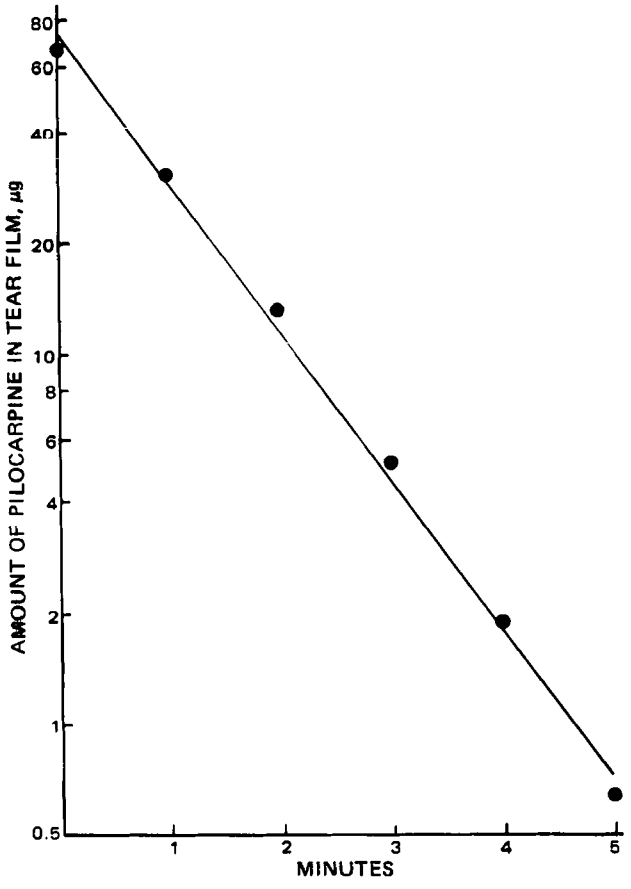

Figure 3—*Simulated profile for amount of pilocarpine in tear film for the first 5 min postinstillation. The solid circles represent the amount of drug in the tear film calculated for a given time from the parameter values listed in Table V. The solid line represents the best-fit line, with* $R^2 = 0.99$ *and slope* $= -0.93\ min^{-1}$.

As mentioned earlier, the reported loss parameters of solution drainage (1, 2), drug protein binding (3–5), tear turnover (1, 6), and conjunctival absorption (7), by themselves, cannot account for the large first-order rate constant governing precorneal pilocarpine loss. To reconcile this discrepancy, several possibilities can be proposed, and each will be examined here in turn.

Incorrect Reported Rate Constants

1. Underestimation of Reported Rate Constants—The two reported loss routes of interest are corneal and conjunctival absorption. Although the rate constant for corneal pilocarpine absorption has not been determined, good estimates place it at least one or two orders of magnitude less than the rate constant governing conjunctival absorption and overall tear film drug loss. As a result, it is of minor consequence to the overall tear film drug loss rate constant.

The 0.0217 min^{-1} rate constant reported for nonproductive loss due to conjunctival pilocarpine absorption is in line with reported values for other substances, including the rate constant (23) for passive diffusion of sodium and chloride ions across the conjunctiva. Additional support comes from a consideration of the difference in surface area of the cornea and conjunctiva available for drug absorption (24) and of the data of a recent study (25) on conjunctival absorption. Therefore, it can be concluded that the reported conjunctival absorption rate constant for pilocarpine (7) is probably accurate.

2. Volume Effect on Apparent First-Order Rate Constants—It is of interest to evaluate the extent to which the discrepancy between 0.30 min^{-1}, observed in the anesthesia experiment[13], and 0.0217 min^{-1}, reported for nonproductive loss, can be attributed to a volume effect on apparent rate constants. In the study by Patton and Robinson (7), the experiment that yielded the nonproductive loss rate constant of 0.0217 min^{-1} was conducted in rabbits whose drainage apparatus were mechanically blocked. Under such circumstances, the precorneal fluid volume at all times would be approximately 32.5 μl, essentially the sum of instilled volume (25 μl) and resident tear fluid volume (7.5 μl). In contrast, the present study was performed with rabbits possessing functional drainage apparatus, meaning that the fluid volume in the precorneal area

[13] Ignoring the additional routes of precorneal drug loss for the moment leaves nonproductive loss as the only loss route available in the presence of anesthesia.

underwent an approximate fourfold change, from 32.5 μl at the moment of drop instillation to 7.5 μl shortly thereafter.

Teorell (14) showed that the first-order rate constant associated with drug movement from one compartment to the next is inversely related to the fluid volume in the donor compartment. In the present study, the effect of instilled volume on k_a was established in the experiment in which a 10-μl rather than a 25-μl dose was instilled into the cul-de-sacs of anesthetized rabbits. Table III shows that k_a underwent a 1.5-fold increase for a 2.5-fold reduction in instilled volume. On this basis, this volume effect by itself can *at most* contribute a factor of approximately 4.5, in which case a rate constant of 0.094 min^{-1} is obtained for nonproductive loss. Clearly, while volume influences the magnitude of the rate constant, it is not the principal explanation for the large rate constant associated with precorneal pilocarpine loss.

Different Mechanism for Corneal Pilocarpine Uptake—Some years ago, Kakemi *et al.* (26–29) reported that the amount of drug absorbed in the GI tract correlated well with its extent of binding to mucin lining the mucosa; they suggested that drug binding to mucin constituted the first step in absorption. Conceivably, the same phenomenon can occur in the mucin layer that coats the corneal surface (30). The anesthesia experiment in the present study, however, minimized the possibility of rapid uptake of pilocarpine by some component(s), including mucin, on the corneal surface as being primarily responsible for the large rate constant, k_a, associated with a decline in precorneal pilocarpine concentration. For this mechanism to be operative, k_a should register no appreciable change in its value under anesthesia.

Additional Loss Routes

1. Induced Lacrimation—If an increase in tear flow rate due to instilling a pilocarpine solution is a parallel loss route, the apparent rate constant, k_a, governing drug loss from the precorneal area must show a reduction in its value in the presence of anesthesia since lacrimation as well as normal tear flow is inhibited under this condition (1). The experimental value of 0.30 min^{-1} obtained in anesthetized rabbits, an appreciable reduction when compared with the value of 0.63 min^{-1}, indicates that induced lacrimation is indeed a pathway of drug loss. It is not the only route, however, because k_a does not converge to the value of 0.0217 min^{-1} determined (7) for nonproductive loss of pilocarpine to tissues surrounding the tear chamber.

The results of the experiment using a pH 7.38 instead of a pH 6.24 solution demonstrate that much of the lacrimation effect is due to vehicle formulation. Although this observation is consistent with other findings (16) on vehicle influence on drug bioavailability, it is inconsistent with those of Patton and Robinson (7). In particular, Patton and Robinson (7) can account fully for the difference in k_a between anesthetized and unanesthetized rabbits, both with blocked drainage apparatus, by merely including normal tear turnover. This apparent inhibition of lacrimation upon blocking the drainage apparatus has also been observed in humans (31). Aside from invoking a compensatory mechanism that resists an increase in tear volume beyond the large volume already present, no explanation is forthcoming at the present time. There is little doubt, however, that in normal unanesthetized rabbits, induced lacrimation is a component of the precorneal pilocarpine loss mechanism.

2. Nonconjunctival Loss of Pilocarpine (Uptake of Drug by Nictitating Membrane)—Examination of the anatomy of the rabbit's tear chamber reveals the nictitating membrane to be a structure that potentially can act in conjunction with the conjunctiva and the cornea to remove drug from the precorneal area. This discussion of nonconjunctival pilocarpine loss will focus on uptake by the nicitating membrane, even though additional components of nonconjunctival loss are possible.

Like the conjunctiva, the nictitating membrane is a vascularized tissue (32). It is not clear what gives it an apparent advantage over the conjunctiva in removing drug from the precorneal area. A direct determination of drug levels in the nictitating membrane as a function of time may not establish if it is the dominant factor in causing drug loss. So long as it is in contact with the fluid bathing the precorneal area, its concentration–time profile will probably show an early peak time of 5 min just like that for the corneal epithelium. On the other hand, surgical removal of the nictitating membrane may change the tear chamber volume and possibly the drainage process, just to name a few. Therefore, a simple approach of manipulating the vascularization of this tissue was adopted.

The role of blood flow on drug absorption was studied in the GI tract (33, 34) and was recently reviewed (35). In the eye, if the nictitating membrane contributes substantially more to precorneal drug loss than does the conjunctiva, in the presence of a vasoconstrictor the apparent rate constant of decline should register a corresponding reduction in value. Indeed, in the anesthetized rabbit, it is reduced by a factor of 4 upon the application of a 0.1% epinephrine bitartrate solution. The change is less dramatic in the unanesthetized rabbit because induced lacrimation due to vehicle formulation, which is not expected to be affected by this procedure, is still present. The difference in the magnitude of the rate constant obtained in unanesthetized and anesthetized rabbits was the same regardless of epinephrine pretreatment (Table III). This difference amounted to 0.33 min^{-1} and may be ascribed to tear flow, of which induced lacrimation is a part.

Just as vasoconstriction is accompanied by a substantial reduction in the apparent rate constant of parallel loss, it is reasonable to expect opposite changes in the aforementioned rate constant when vasodilation or inflammation is present. Indeed, histamine dihydrochloride, a potent vasodilator (36), at an instilled concentration of 0.25% caused an upward shift of the rate constant from 0.63 to 1.03 min^{-1}. This result may not be a pure vasodilation effect, however, because histamine at a concentration as low as 5×10^{-6} *M* loosened the superficial epithelial cells of excised beef corneas after several hours of incubation (37), an effect that could enhance corneal pilocarpine absorption. However, the contact time in the present experiment was short enough to preclude a surface effect.

3. Vasodilation due to Pilocarpine—Since pilocarpine itself is a vasodilator (36), this pharmacological effect is expected to manifest itself in the rate constant governing disappearance of the drug from the precorneal area. The vasodilation effect appears to be immediate since predosing the eye with an equivalent amount of pilocarpine yielded a rate constant that was statistically indistinguishable from that obtained under normal circumstances (Table IV). In contrast, when glycerin, which is devoid of vasodilation properties, was administered in combination with pilocarpine, the rate constant associated with the glycerin concentration decline increased by a factor of 3. Moreover, glycerin then disappeared from the precorneal area with a rate constant similar to that governing pilocarpine decline. Induced lacrimation was not a concern here since anesthetized rabbits were employed.

By taking the difference in rate constants obtained for pilocarpine and glycerin, both in anesthetized rabbits, a value of 0.17 min^{-1} was obtained. This value may be denoted as the rate constant due to vasodilation induced by pilocarpine in *anesthetized* rabbits. Suitable corrections for the influence of anesthesia on the drainage rate constant (1) must be applied in calculating the corresponding value for unanesthetized animals.

An implication associated with vasodilation induced by pilocarpine is its expected variation with instilled concentration. This, if operative, will be reflected in the pilocarpine levels obtained in a given tissue, *e.g.*, aqueous humor, and, obviously, the magnitude of the rate constant governing precorneal drug loss. The linearity of the dose–aqueous humor concentration (at 20 min postinstillation) profile over six orders of magnitude in dose (10^{-6}–10^{-1} *M*) (8) suggests that either the rate constant due to pilocarpine-induced vasodilation is a weak function of instilled concentration or, less likely, maximum vasodilation is attained at the lowest instilled concentration of 10^{-6} *M*. The dose–aqueous humor concentration plot is a log–log plot so that small differences will not be discerned.

Not only does induced lacrimation appear to be suppressed when the drainage apparatus is blocked, but the same is true for pilocarpine-induced vasodilation. This effect can be seen by comparing the magnitude of the rate constants involved: 0.17 min^{-1} for the vasodilation determined in this study *versus* 0.0217 min^{-1} for nonproductive loss reported elsewhere (7). Undoubtedly, a volume effect is making a contribution. Thus, in anesthetized rabbits with blocked drainage apparatus, the rate constant ascribed to vasodilation assumes a theoretical value of 0.11 min^{-1}, which is five times larger than the reported 0.0217-min^{-1} value. The difference can be reconciled, in part, by attributing the preponderance of vasodilator effect to the nictitating membrane, a consideration consistent with the view that the nictitating membrane, in some unknown fashion, does not participate in precorneal drug disposition as soon as the drainage apparatus is blocked. Whether this phenomenon is peculiar to pilocarpine can possibly be disclosed in an experiment involving other drugs such as glycerin.

Thus far, the volume effect on apparent first-order rate constants has been identified, the notion of rapid pilocarpine uptake by some components on the corneal surface has been mentioned, and induced lacrimation due to vehicle formulation, nonconjunctival pilocarpine loss, and vasodilation due to the drug have been established as additional aspects of precorneal pilocarpine disposition. It is still unclear why these additional, and yet critical, parameters controlling precorneal disposition are absent when the drainage apparatus is blocked. Similarly, there is the observation by DeSantis and Schoenwald (38) that disputes the importance of the nictitating membrane as a pathway contributing to pilocarpine loss

Table VII—Influence of Individual Parallel Loss Factors on Bioavailability

Parallel Loss Factor Present	Ratio A[a]	Ratio B[b]
Drainage	0.24	30.4
Normal tear flow	0.18	22.1
Induced lacrimation	0.13	16.4
Conjunctival absorption	0.16	20.9
Vasodilation due to pilocarpine	0.03	3.5
Nonconjunctival loss	0.05	5.9
All factors present	0.007	1.0

[a] Ratio A is referenced to the case when no parallel loss factors are present (*AUC* in aqueous humor is 9716 μg/ml min). [b] Ratio B is referenced to the case when all parallel loss factors are present (*AUC* in aqueous humor is 77.0 μg/ml min).

from the precorneal area. They monitored changes in pupil diameters as a result of surgical removal of the nictitating membrane. However, pupillary diameter measurements, as compared with aqueous humor drug level determinations (8), are not a sensitive indicator for pilocarpine bioavailability.

What remains to be done is to integrate these additional pathways responsible for precorneal pilocarpine loss with the previously identified pathways by assessing the relative importance of each to ocular drug bioavailability. But first it is necessary to derive from the experimental data the coefficients, p, associated with each pathway of loss shown in Scheme III because the experimental results, presented as first-order rate constants, were obtained in both anesthetized and unanesthetized rabbits and the rate of change in precorneal fluid volume differs under these conditions. In other words, the presence of drainage conceals the actual contribution of each pathway to total drug loss. With this background, one can proceed, as outlined in the *Appendix*, to calculate the volume-independent coefficients, p, associated with various routes of precorneal drug loss.

Table VI summarizes the values computed for various parameters associated with precorneal pilocarpine disposition. The corresponding k values for anesthetized and unanesthetized rabbits are obtained by applying Eqs. A1 and A3, respectively (see *Appendix*). From the volume-independent values, one can see that, in terms of effectiveness of removing drug from the precorneal area, the rank order of various precorneal disposition factors appears to be: vasodilation due to pilocarpine > nonconjunctival loss > conjunctival absorption > normal tear turnover > corneal absorption. How induced lacrimation fits into this sequence is not as straightforward because of its time dependence. The same is true of drainage, due to lack of knowledge of an effective volume to properly weight this parameter. Computer simulations will be employed to examine the relative importance of these precorneal factors in effecting drug loss.

Relative Importance of Precorneal Drug Disposition Factors on Extent of Drug Absorption—Tables VII and VIII list the various cases to be considered in an effort to understand the relative importance of precorneal drug disposition factors, alone or in combination, in influencing the extent to which pilocarpine is absorbed across the corneal epithelium. The area under the curve (*AUC*) from 0 to 120 min in the aqueous humor will serve as an indicator for the amount of drug absorbed. Ideally, the entire, rather than the truncated, *AUC* should be used. However, since only relative values are of interest, the *AUC* from 0 to 120 min is used.

Each case listed in Tables VII and VIII is referenced to two special cases. Ratio A is referenced to the ideal case in which no parallel loss factors are present and is, therefore, roughly equivalent to the fraction of dose absorbed in the presence of certain loss factors. Ratio B is referenced to the case corresponding to normal physiological conditions when all parallel loss factors are present and, therefore, reflects the improvement in bioavailability when one or more parallel loss factors are suppressed. As an illustration, Table VII shows that when all parallel loss factors except normal tear flow are suppressed: (*a*) the apparent fraction of dose absorbed (Ratio A) is 0.18, and (*b*) relative to normal physiological conditions, there should be a 22-fold increase in the amount of pilocarpine recovered in aqueous humor (Ratio B).

Consider Ratio A in greater detail. According to Table VII, when only a single parallel loss factor is present, the amount of dose absorbed is reduced by at least 75%. Under the usual circumstances of more than one parallel loss factor being operative, it is reduced by an additional 80% (Table VIII). From these two tables, one can establish, in principle, a single sequence ranking the various parallel loss factors in terms of their effectiveness in removing pilocarpine from the precorneal area. To this end, the most efficient parallel loss factor can be identified as the one possessing a Ratio A that has the smallest value in Table VII but the largest in Table VIII. Quite unexpectedly, two sequences differing only in the ranking of drainage are obtained. Whereas Table VII indicates that drainage is the *least* efficient parallel loss factor, Table VIII indicates that it is the *most* efficient one.

Table VIII—Influence of Combinations of Parallel Loss Factors on Bioavailability

Parallel Loss Factor Absent	Ratio A[a]	Ratio B[b]
Drainage	0.014	1.78
Induced lacrimation	0.0085	1.07
Conjunctival absorption	0.0084	1.06
Vasodilation due to pilocarpine	0.013	1.67
Nonconjunctival loss	0.010	1.29
All factors present	0.007	1.0

[a,b] See footnotes to Table VII for details.

These conflicting results can be explained by noting that the proposed model allows drug diffusion from the epithelium into the tear film, a realistic situation. Within this framework, the portion of drug that has diffused into the tear film is completely available for reabsorption as soon as normal resident tear volume is attained, so long as drainage is the only loss factor present. When factors in addition to drainage are present, the same portion of drug is subjected to continuous removal by routes in addition to corneal absorption. Of relevance here is the first case listed in Table VIII. It can be seen that eliminating drainage brings about the most improvement in bioavailability, equivalent to saying that drainage is the most efficient parallel loss factor.

Simply stated, when parallel loss factors are evaluated in the manner prescribed by Table VII, the conclusion of drainage being the least efficient parallel loss factor is an artifact of the system. Thus, the relative effectiveness of precorneal disposition factors in removing drug should be: drainage ≃ vasodilation > nonconjunctival loss > induced lacrimation ≃ conjunctival absorption > normal tear turnover.

Implications of Precorneal Drug Loss in Ocular Drug Delivery System Design—Having established the contributions of various precorneal drug disposition factors to precorneal loss of pilocarpine, their implications in designing ocular drug delivery systems that optimize ocular pilocarpine bioavailability can be examined. The aforementioned precorneal disposition factors can first be grouped into vehicle- and drug-related categories. Drainage and induced lacrimation belong to the category of vehicle-related factors, whereas conjunctival absorption, nonconjunctival loss, vasodilation, and corneal absorption are drug-related factors. Based on the magnitude associated with each parameter, impairing a single route of loss will not bring about more than a twofold improvement, on the average, in the fraction of dose absorbed (Ratio B, Table VIII).

By far, the route that has received the most attention is drainage. Previous studies (39–41) showed that delaying drainage by a factor of 10 through use of polymer solutions as vehicles results in only a factor of 2 improvement in bioavailability. As an alternative to polymer solutions, one can employ solid or semisolid dosage forms such as ointment (42), soft contact lenses (43–46), and controlled-release devices including the Ocusert (47, 48). With the possible exception of the Ocusert, this approach has thus far not met with satisfactory results.

Induced lacrimation, another vehicle-related loss factor, can be suppressed by formulating the solution at physiological pH and tonicity so long as they are compatible with drug stability. According to the proposed model, this approach alone causes no dramatic improvement in the amount of drug absorbed either. There is a 1.6-fold improvement in aqueous humor pilocarpine levels as the pH is varied (42).

The remaining factors, vasodilation, nonconjunctival loss (of which drug uptake by the nictitating membrane is a component), and conjunctival absorption, are more drug than vehicle related. Unfortunately, they include those factors that play dominant roles in causing drug loss. This finding suggests prodrug derivative formation to minimize vasodilation, thereby improving bioavailability for pilocarpine. Alternatively, administration of vasoconstrictors prior to instillation of pilocarpine solution shows promise for improving its bioavailability. The proposed model, in conjunction with the experimental data obtained in the present study, predicts a 2.5-fold improvement when a 0.1% epinephrine bitartrate solution is administered 15 min prior to instilling the dose. Chrai *et al.* (2) reported only a 1.16-fold increase, but these investigators administered both drugs in combination.

Since the nictitating membrane is absent in humans, drug uptake by this structure is not a concern in designing ocular drug delivery systems for humans.

From this discussion, it is clear that a combination of physical and

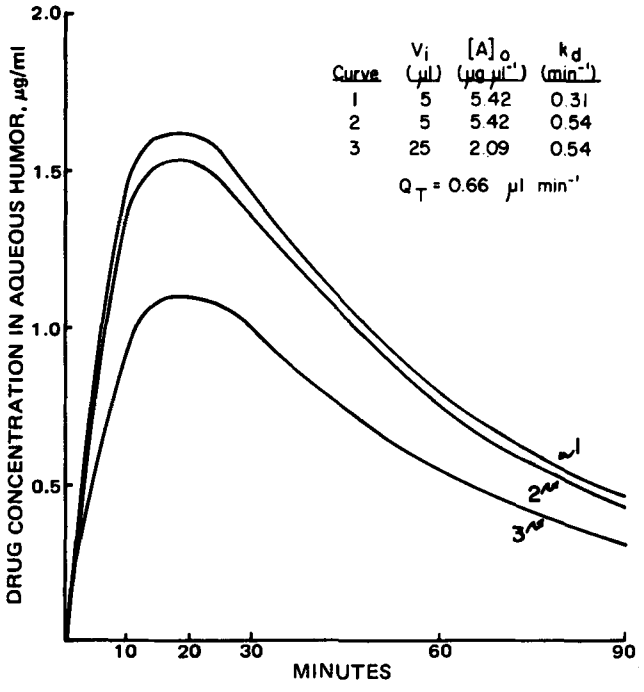

Figure 5—*Effect on aqueous humor drug levels upon varying instilled concentration and volume while holding amount of drug administered constant. Tear flow is present. Key:* V_i, *instilled volume;* $[A]_0$, *initial concentration of drug in tear film; and* k_d, *drainage rate constant. Figure 6—*Effect on aqueous humor drug levels upon varying instilled concentration and volume while holding amount of drug administered constant. Tear flow is absent. Key:* V_i, *instilled volume;* $[A]_0$, *initial concentration of drug in tear film; and* k_d, *drainage rate constant. These profiles were generated for an instilled concentration of 13.56 μg/μl contained in a volume of 5 μl and for 2.71 μg/μl in 25 μl.*

chemical approaches is needed to achieve maximum improvement in bioavailability of topically applied pilocarpine. Assuming that the enzymes necessary for bioconversion are available, one can design a prodrug derivative possessing the desirable attributes of favorable uptake by the corneal epithelium (a highly lipophilic structure), minimal vasodilating properties, and, ideally, minimal uptake by the conjunctiva. Such a derivative can then be placed into a suitable controlled-release device, which must satisfy the anatomical and physiological constraints imposed by the precorneal area of the eye. One may argue that administering larger amounts of drug would give the desired drug levels in ocular tissues, but there exists the concern of systemic toxicity since most of the applied drug is then available for systemic absorption (49).

Important Aspects Relating to Drainage—With the spectrum of of precorneal pilocarpine disposition factors placed in some perspective, the remaining sections of this report are devoted to some important aspects relating to drainage, the factor deemed to be crucial in precorneal drug loss.

Role of Instilled Dose Parameters in Ocular Drug Bioavailability—Given the strategic role of drainage in the parallel loss process and its sensitivity to the volume of dose instilled, it is instructive to compare the concentration–time profiles in a given intraocular tissue when a fixed amount of drug is delivered in various combinations of volume and concentration. Compartment pharmacokinetics will predict identical profiles under these conditions; this result can be seen in Eq. 12, which expresses the concentration, C, of drug in the central compartment as a function of time for a drug that obeys one-compartment model kinetics:

$$C = \frac{FD}{V_d}\left(\frac{k_a}{k_a - k_e}\right)(e^{-k_e t} - e^{-k_a t}) \qquad \text{(Eq. 12)}$$

where k_a is the absorption rate constant, k_e is the elimination rate constant, D is the amount of drug administered, F is the fraction of dose absorbed, and V_d is the apparent volume of distribution. In contrast, our model, like a previous one (12), predicts characteristic intraocular tissue concentration–time profiles for each combination of instilled concentration and volume. Figure 5 illustrates this point. In this figure, two curves (1 and 2) are included for the 5-μl case. Curve 1 represents the case where the drainage rate constant, k_d, possesses a value characteristic of this volume, *i.e.*, $k_d = 0.31$ min^{-1}; curve 2 represents the case where k_d is the same as that for a 25-μl dose, *i.e.*, $k_d = 0.54$ min^{-1}. In both cases, the concentration at any time is higher than that for a 25-μl dose (curve 3). This finding indicates that the differences that arise from the dose volume instilled are not due to a volume-dependent drainage effect alone; the initial concentration established in the tear film also plays a role. Moreover, since the volume instilled indirectly influences the contribution of tear flow, $Q_T(t)$, to parallel loss, it is necessary to see if the profiles would continue to be different even when $Q_T(t)$ is set equal to zero.

The answer is provided by the profiles displayed in Fig. 6. Again, the 5-μl dose gives a higher concentration than the 25-μl dose, indicating that the increase in extent of drug absorption from a smaller dose volume cannot be due largely to the indirect influence exerted by drainage on tear flow. Drainage is present in all these instances. Hence, when it ceases to be a parallel loss factor, the results given by the present model should coincide with those given by the pharmacokinetic treatment described earlier. In essence, the dose volume administered influences the tissue concentration–time profiles only if the fluid volume at the absorption site undergoes a time-dependent change in response to the volume administered. Therefore, this volume effect should be observed in regions of the body, *e.g.*, precorneal area, rectum, and skeletal muscles (50–53), which have a limited capacity to accommodate volume and/or to possess a small resident volume of fluid to begin with. The influence that fluid volumes may exert on the absorption of orally dosed drugs begins to be recognized. This influence is complex, as illustrated by studies on aspirin (54), amoxicillin and ampicillin (55), and erythromycin stearate (56).

For completeness, the role of the initial concentration as it relates to drug bioavailability from topical instillation should be explored. According to Table IX, the *AUC* in aqueous humor, and hence the amount of drug absorbed, is greater for a 25-μl dose than for a 5-μl dose, despite the negative influence of drainage experienced by the larger volume of dose. The increase is due to a larger amount of drug administered with the larger volume of dose. Also of interest in the same table is the higher instilled concentration associated with the 5-μl dose, yet the extent of drug absorbed still favors the 25-μl dose.

Thus, the relationship between instilled concentration and amount relative to drug bioavailability is an intricate one. On an absolute basis, for a given amount of drug, a small volume allows more drug to be absorbed. For a given initial or instilled concentration, the opposite is the case. However, in terms of the fraction of dose absorbed, as reflected by the value obtained on dividing the *AUC* by the instilled amount, a small volume of dose is still more efficient than a large one (Table IX). Such a volume effect was implied by previous studies in this laboratory (1, 2) and, more recently, was confirmed experimentally in rabbits (49, 57) and humans (58).

Table IX—Effect of Initial Concentration in Tear Film on Area under the Curve (*AUC*) in Aqueous Humor

Volume Instilled, μl	Instilled Concentration, μg/μl	Instilled Amount, μg	Initial Concentration, μg/μl	*AUC* in Aqueous Humor[a], μg/ml min	*AUC* ÷ Instilled Amount, μg/ml min/μg

25	2.71	67.82	2.09	77.0	1.14

[a] From 0 to 120 min.

Role of Drainage in Determining Early Peak Time in Corneal Epithelial Drug Concentration–Time Profile—Not only does drainage exercise a definite role in controlling the fraction of instilled dose available for absorption, it also complicates the interpretation of the early peak time observed in the corneal epithelium. Despite the magnitude of the drainage rate constant, the peak time obtained when it is the only parallel loss factor is about three times *longer* than that obtained when it is the only one absent (Table X). This observation says that, by itself, drainage is less effective than the other parallel loss factors combined in causing an early peak time in the epithelium concentration–time profile.

The picture changes when drainage is allowed to act in conjunction with at least one other parallel loss factor. As an example, in the presence of tear flow, drainage gives a peak time of 10 min, as compared with the 20 min obtained otherwise. This example illustrates an additional important point; so long as drainage is an integral component of the precorneal drug loss mechanism, the peak time derived from a corneal epithelial drug concentration–time profile is an insensitive indicator for the existence of such equally efficient parallel loss pathways as vasodilation and uptake of drug into the nictitating membrane. The present study demonstrates that only by directly monitoring tear film drug levels, under a variety of experimental conditions, can a complete picture of precorneal drug disposition emerge.

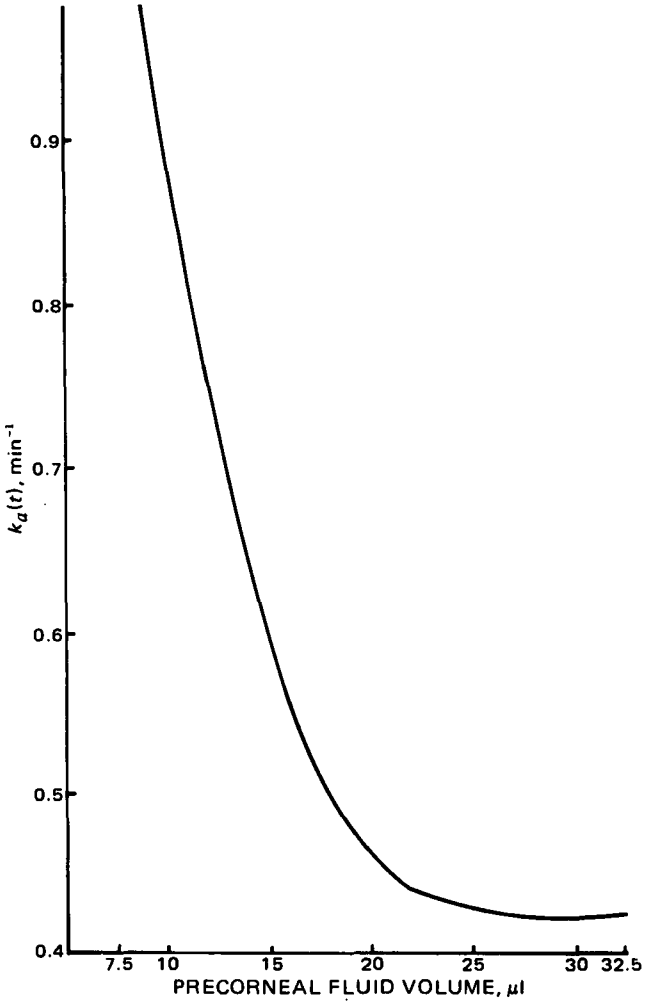

Figure 7—*Plot of* $k_a(t)$ *versus volume,* $V_A(t)$, *of precorneal fluid at a given time. See text for meaning of* $k_a(t)$.

Role of Precorneal Fluid Volume in Influencing Magnitude of Apparent First-Order Rate Constants Associated with Decline in Tear Film Drug Levels—Treatment of data according to compartment pharmacokinetics carries with it the implicit assumption of a single rate constant being adequate to describe the change in both amount and concentration of drug with time. Table XI indicates that this assumption does not hold in the precorneal area of the eye since the volume of fluid there continuously changes with time in an effort to attain resident tear volume. As expected, the apparent rate constant is larger for amount than for concentration, the difference being due to drainage, which exerts a direct influence on amount as opposed to an indirect one on concentration.

Furthermore, this apparent rate constant is time dependent. This is evident in Eq. 13, which describes the change in tear film drug concentration for the first 5 min postinstillation when the drug contribution from the epithelium to tear film drug levels is negligible:

$$\frac{d[A]}{dt} = -\left(\frac{p_p + p_n + Q_T(t)}{V_A(t)}\right)[A] \qquad \text{(Eq. 13)}$$

where the term within parentheses can be identified with the apparent first-order rate constant, $k_a(t)$, governing the decline in drug concentration. Notice that $Q_T(t)$ and $V_A(t)$ are functions of time. Thus:

$$k_a(t) = \frac{p_p + p_n + Q_T(t)}{V_A(t)} \qquad \text{(Eq. 13}a\text{)}$$

The first-order rate constant derived from the slope of a semilogarithmic plot of drug concentration *versus* time is, therefore, a time-averaged quantity, as indicated earlier. It is denoted as $\bar{k}_a$ and, conforming to experimental conditions in the present study, is given by:

$$\bar{k}_a = \frac{1}{V_A(5) - V_A(0)} \int_{V_A(0)}^{V_A(5)} k_a(t)\, dV_A(t) \qquad \text{(Eq. 14)}$$

where $V_A(0)$ is the fluid volume in the precorneal area at time zero and $V_A(5)$ is that at 5 min. Evaluation of the integral in Eq. 14 is simplified if $Q_T(t)$ is constant or zero. The result of the integration by assuming $Q_T(t) = 0$ is:

$$\bar{k}_a = \frac{p_p + p_n}{V_A(5) - V_A(0)} \ln\left(\frac{V_A(5)}{V_A(0)}\right) \qquad \text{(Eq. 15)}$$

For a 25-μl dose:

$$\bar{k}_a = \frac{p_p + p_n}{29.0} \qquad \text{(Eq. 16)}$$

whereas for a 10-μl dose:

$$\bar{k}_a = \frac{p_p + p_n}{18.9} \qquad \text{(Eq. 17)}$$

The conditions leading to Eqs. 16 and 17 are resident tear volume V_0 = 12 μl and drainage rate constant k_d = 0.177 min^{-1}. Equation 16 is very similar to Eq. A1 obtained by the procedure detailed in the *Appendix*. The essence of Eqs. 16 and 17 is twofold. First, contrary to what one might anticipate, the effective volume contributing to $\bar{k}_a$ is neither the instilled volume nor the total volume at time zero. Second, $\bar{k}_a$ is larger for a smaller instilled volume. Dividing Eq. 17 by Eq. 16 gives a ratio of 1.5, in excellent agreement with experimental findings on anesthetized rabbits, thus lending credence to the interpretation of apparent first-order rate constants offered by Eq. 14.

When $Q_T(t)$ is not equal to zero, the integral in Eq. 14 can be evaluated graphically. With the parameter values listed in Table VI, a plot of $k_a(t)$ *versus* $V_A(t)$ can be generated (Fig. 7). From this plot, a $\bar{k}_a$ of 0.41 min^{-1} is derived, which is less than the value of 0.63 min^{-1} obtained from the slope of a semilogarithmic plot of tear film drug concentration *versus* time. The discrepancy can be partly ascribed to rounding-off errors incurred in graphical integration.

An expression analogous to Eq. 15 for the time-averaged rate constant, $\bar{k}'$, governing the decline in amount of drug in the tear film can now be obtained. Equation 2 is cast into its equivalent form:

$$\frac{dA_t}{dt} = -\left(\frac{p_p + p_n + Q_T(t) - k_d V_0}{V_A(t)}\right) A_t - k_d A_t \qquad \text{(Eq. 18)}$$

Table X—Influence of Selected Parallel Loss Factors on Peak Time in Corneal Epithelial Drug Concentration–Time Profile

Parameter	Peak Time, min
Tear flow	9
Drainage	20
Drainage and tear flow	10
All but drainage	6

where A_t is the amount of drug in the tear film. Equation 18 assumes that the contribution from the term $p_p[B]$ is negligible. It follows that the apparent first-order rate constant, $k'(t)$, is given by:

$$k'(t) = \frac{p_p + p_n + Q_T(t)}{V_A(t)} + k_d\left(1 - \frac{V_0}{V_A(t)}\right) \qquad \text{(Eq. 19)}$$

Then:

$$\bar{k}' = \frac{1}{V_A(5) - V_A(0)} \int_{V_A(0)}^{V_A(5)} k'(t)\, dV_A(t) \qquad \text{(Eq. 20)}$$

where the symbols are as previously defined. Again, for $Q_T(t) = 0$, Eq. 20 becomes:

$$\bar{k}' = \frac{p_p + p_n}{V_A(5) - V_A(0)} \ln\left(\frac{V_A(5)}{V_A(0)}\right) + k_d\left[1 - \frac{V_0}{V_A(5) - V_A(0)} \ln\left(\frac{V_A(5)}{V_A(0)}\right)\right] \qquad \text{(Eq. 21)}$$

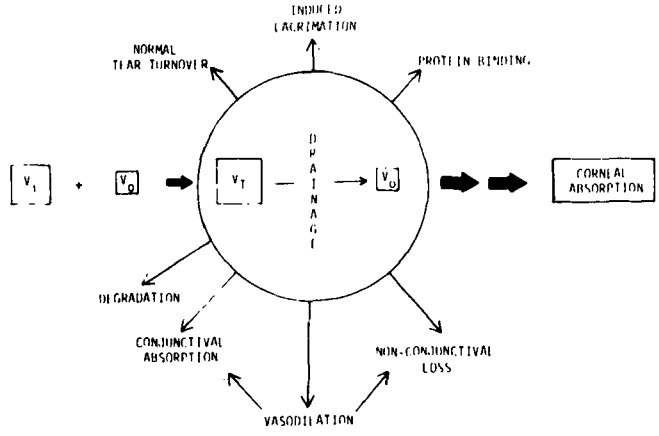
Equation 21 differs from Eq. 15 by the additional term containing k_d. For a 25-μl dose, $\bar{k}' = 0.036p + 0.10$ where $p = p_p + p_n$.

CONCLUSIONS

A picture concerning the mechanisms that control precorneal pilocarpine disposition following topical instillation (Scheme IV) has been presented. Through experimentation and computer simulation, it was found that competing with corneal pilocarpine absorption from the precorneal area are the processes of solution drainage, vasodilation due to the drug, nonconjunctival loss (of which uptake of drug by the nictitating membrane is a component), conjunctival absorption, induced lacrimation, and normal tear turnover, with some of these processes being more efficient than others. The enormous influence of drainage on ocular drug bioavailability was recognized.

Equally as important, the analysis showed that the burden of removing drug from the precorneal area was shared almost equally by drainage, vasodilation due to pilocarpine, and nonconjunctival loss. Consequently, suppressing a single factor only results in a modest improvement in pilocarpine bioavailability. The experience with manipulating drainage is an illuminating example. It follows that the strategy for optimizing absorption efficiency through controlled drug delivery should involve both physical and chemical approaches. This process should be enhanced since estimates on the magnitude of precorneal disposition parameters are now available.

An additional aspect of this study centers on defining the effect of instilled volume on the magnitude of the apparent first-order rate constant governing the decline in concentration and amount of drug in the precorneal area. According to the proposed model, the rate constant controlling drug loss is a time-dependent quantity. Strictly speaking, it should be denoted as a coefficient rather than as a rate constant. The time-average first-order rate constant is shown to be a function of, among other parameters, the initial volume of fluid in the precorneal area. In contrast to the situation where the volume of fluid at the absorption site remains essentially constant with time, the first-order drug loss rate constant viewed in the context of the proposed model varies depending on whether concentration or amount is being considered.



Scheme IV—Precorneal disposition of pilocarpine in the albino rabbit

Table XI—Apparent First-Order Rate Constants Governing Decline in Amount and Concentration of Pilocarpine in Tear Film following Instillation of 25 μl of 0.01 M Solution

Condition	k_a, min^{-1} [a]	
	Amount[b]	Concentration[c]
Unanesthetized	0.90	0.63
Anesthetized	0.40	0.30

[a] For the first 5 min postinstillation. [b] Calculated value. See text for details. [c] Experimental value.

Additionally, as a result of analyzing instilled dose parameters such as volume and concentration in terms of influence on the rate and extent of absorption, the contention that the volume of dose instilled affects ocular drug bioavailability through a combined influence on initial concentration established in the tear film and on the magnitude of drainage that results was put on a relatively definitive basis.

The proposed model is satisfactory from the standpoints of physical meaning as well as a quantitative description concerning precorneal disposition, of accounting for the role of instilled volume in ocular drug bioavailability, and of exposing the hidden aspects of time dependence as it pertains to first-order rate "constants" commonly employed to describe drug distribution.

APPENDIX

This section outlines the procedure for computing the values for various precorneal disposition parameters from experimental results listed in Table III. Of central importance in these calculations is Eq. 8. According to this equation, $[A]$ can be estimated if p_n (the coefficient associated with nonproductive loss) and Q_i (the coefficient associated with induced lacrimation) are known since values for the other parameters are available. Only one unknown remains if the condition of anesthesia is selected, in which case $Q_0 = Q_i = 0$. Thus, one can calculate $[A]$ for a given value of p_n for $t = 0, 1, 2, 3, 4$, and 5 min. These numbers are then plotted semilogarithmically against t. From the slope of this plot, an apparent first-order rate constant is derived. The same procedure is then repeated for other p_n values. On correlating the resulting slopes with the corresponding p_n values, an equation relating the volume-independent value (p, in microliters per minute) and the apparent first-order rate constant (k, in minute^{-1}) for a given parameter is obtained.

Consider now the experiment in which a 25-μl dose of pilocarpine solution was instilled onto the cornea of anesthetized rabbits. Under this condition, the apparent first-order rate constant has a value of 0.30 min^{-1} (Table III). Chrai *et al.* (1) reported that in the presence of anesthesia, the normal resident volume of tear fluid is 12 μl, the drainage rate constant has a value of 0.177 min^{-1}, and tear turnover is inhibited, *i.e.*, $Q_i = Q_0 = 0$ μl min^{-1}. With this information, the equation relating p and k takes the form:

$$k = \frac{p}{28.0} = 0.036p \qquad \text{(Eq. A1)}$$

Equation A1 holds for anesthetized rabbits only. For $k = 0.30$ min^{-1}, $p = 8.40$ μl/min. This, when applied to an instilled dose of 10 μl in anesthetized rabbits, yields $k = 0.46$ min^{-1}, in excellent agreement with the observed value (Table III).

The key elements involved in partitioning $p = 8.40$ μl/min just obtained into its components are as follows. Since $p = p_p + p_n$ and p_p has been estimated to be 0.13 μl/min (Table V), $p_n = 8.27$ μl/min. The parameter p_n is the sum of p_{nc}, p_{nm}, and p_{nd}, where p_{nc} refers to conjunctival absorption, p_{nm} refers to nonconjunctival loss, and p_{nd} refers to vasodilation induced by pilocarpine. Among these values, an estimate for p_{nc} is available. It is 0.71 μl/min, calculated from 0.0217 min^{-1}, the first-order rate constant associated with conjunctival absorption, and 32.5 μl, the volume of fluid under the prevailing experimental conditions (7). The first-order rate constant governing vasodilation is 0.17 min^{-1}. According to Eq. A1, this value corresponds to a p_{nd} of 4.76 μl/min. Now p_{nc} can be shown to take on a value of (8.27 − 0.71 − 4.76) or 2.80 μl/min. The only parameters remaining to be calculated are Q_i and k_l, which will

be discussed after the companion form of Eq. A1 for unanesthetized rabbits is obtained.

In this instance, the procedure is essentially that outlined for anesthetized rabbits, the exception being that the resident tear volume is 7.5 μl. Since Q_i is weighted with V_i instead of V_0 (Eq. 8), it is set equal to zero to simplify calculations. Accordingly, Eq. A2 is the appropriate form relating p and k in unanesthetized rabbits, provided that induced lacrimation is not a loss factor:

$$k = \frac{p}{14.1} = 0.071p \qquad \text{(Eq. A2)}$$

Applying Eq. A2 to the sum of p_p, p_n, and Q_0, *i.e.*, 9.06 μl/min, produces a value of 0.64 min^{-1}, implying that induced lacrimation is not needed to explain the apparent first-order rate constant obtained in normal unanesthetized rabbits. On the one hand, this finding is consistent with the assumption made on induced lacrimation in deriving Eq. A2. On the other hand, it appears to contradict the data on the influence of instilled solution pH on the apparent first-order rate constant. In essence, Eq. A2 is not obeyed by unanesthetized rabbits for whom pH-induced lacrimation constitutes a pathway of drug loss.

To take this factor into account, two assumptions are appropriate: (*a*) no induced lacrimation occurs with an instilled solution at pH 7.38 and (*b*) alterations in solution pH cause no significant changes in the remaining precorneal disposition parameters. By noting that the apparent first-order rate constant for the condition under which these assumptions hold is 0.43 min^{-1} (Table III), Eq. A3 can be obtained:

$$k = \frac{p}{21.1} = 0.047p \qquad \text{(Eq. A3)}$$

With this background, the parameters associated with induced lacrimation can be estimated. In the proposed model, they include the induced lacrimation rate constant, Q_i, and the rate constant, k_l, governing its decline. In the absence of additional information, the situation consists of solving one equation with two unknowns. Consequently, one has less confidence in these computed values as compared with others. In any event, from Eq. A3, one can obtain p = 13.29 μl/min for k = 0.63 min^{-1} (Table III). Subtracting p_p, p_{nm}, p_{nc}, and p_{nd} from p yields a value of 4.89 μl/min, which presumably can be attributed to induced lacrimation. Computer-simulation results suggest a value of 4.75 μl/min for the induced lacrimation rate constant, whose decline appears to be controlled by a rate constant with a value in the order of 2 min^{-1}. Applying these estimates to the case in which the ocular surfaces were pretreated with epinephrine (Table III) generates an apparent first-order rate constant of 0.2 min^{-1}, which is in only fair agreement with the observed value of 0.4 min^{-1}.

Table VI summarizes the values computed for the various parameters associated with precorneal disposition of pilocarpine.

Boron Betaine Analogs: Antitumor Activity and Effects on Ehrlich Ascites Tumor Cell Metabolism

I. H. HALL *x, C. O. STARNES *, B. F. SPIELVOGEL ‡x, P. WISIAN-NEILSON ‡, M. K. DAS ‡, and L. WOJNOWICH ‡

Received March 6, 1978, from the *Division of Medicinal Chemistry, School of Pharmacy, University of North Carolina at Chapel Hill, Chapel Hill, NC 27514, and the ‡Paul M. Gross Chemical Laboratory, Duke University, Durham, NC 27706. Accepted for publication November 15, 1978.

Abstract □ Several newly synthesized boron betaine analogs had antitumor activity in Ehrlich ascites, Walker 256 ascites carcinosarcoma, and Lewis lung screens and marginal activity in the B-16 melanotic melanoma screen. *In vivo* testing demonstrated that trimethylamine-cyanoborane inhibited Ehrlich ascites cell DNA and protein syntheses as well as gene modulation by chromatin protein phosphorylation and methylation. Trimethylamine-cyanoborane increased cyclic-AMP levels. *In vitro* testing showed that nuclear DNA polymerase, thymidylate synthetase, *S*-adenosylmethyltransferase, nonhistone chromatin methylation, deoxyribonuclease, ribonuclease, and cathepsin were inhibited by the boron analogs. These compounds did not demonstrate high antitumor activity at the doses employed, but blockage of methyl transfer from *S*-adenosylmethionine was established as a feasible method for controlling cell proliferation.

Keyphrases □ Antineoplastic agents—betaine, boron analogs, metabolic effects, protein synthesis, nucleic acid synthesis, methyl transfer □ Betaine analogs—boron, antineoplastic activity, metabolic effects, protein synthesis, nucleic acid synthesis, methyl transfer □ Protein synthesis—effect of boron betaine analogs □ Methylation—effect of boron betaine analogs □ Nucleic acid synthesis—effect of boron betaine analogs

Blockage of methyl group transfer from choline *via* betaine to L-homocysteine would ultimately inhibit L-methionine and protein syntheses. Since *S*-adenosyl-L-methionine requires L-methionine as a precursor, its synthesis would be reduced, as would be the availability of the methyl transfer from *S*-adenosyl-L-methionine to transfer or ribosomal RNAs and to ribosomal, regulating enzyme, and chromatin protein amino acid residues (1–4). *S*-Adenosyl-L-methionine may play a minor role as the methyl donor cofactor to the enzyme thymidylate synthetase (1, 2). Cancer cells have more methylated chromatin protein and nucleotide bases, particularly transfer RNA, and higher methyl transferase activity than normal tissue.

Numerous reports cite the utilization of folate cofactor antimetabolites to block the methyl transfer to uracil for thymine synthesis. Few studies have investigated the blockage of methyl transfer from *S*-adenosyl-L-methionine since an initial attempt produced ethionine, the ethyl analog of L-methionine, which is a liver carcinogen. A boron analog series of possible betaine or choline antimetabolites was selected to test this premise.

A previous note reported the synthesis of isoelectronic and isostructural boron α-amino acid analogs (5). Trimethylamine-carboxyborane, the protonated boron analog of betaine [$(CH_3)_3N^+CH_2CO_2^-$], its *N*-ethylamide, and a series of related compounds were prepared from trimethylamine-cyanoborane. Because of their structural similarity to betaine, these compounds will be referred to as boron betaine analogs. These boron analogs were evaluated for their antineoplastic activity in a number of tumor models.

EXPERIMENTAL[1]

Chemistry—*Reagents*—The following compounds were purchased: *tert*-butylamine borane[2] [$(CH_3)_3CNH_2{:}BH_3$] (I), morpholine borane[2] [$O(CH_2CH_2)_2NHBH_3$] (II), trimethylamine borane[3] [$(CH_3)_3N{:}BH_3$] (III), and dimethylamine borane[3] [$(CH_3)_2NH{:}BH_3$] (IV).

Trimethylamine-cyanoborane [$(CH_3)_3NBH_2CN$] (*V*)—Compound V was synthesized in high yields (83%) by reacting sodium cyanoborohydride with trimethylamine hydrochloride in dry tetrahydrofuran (7). The product was purified by sublimation, mp 62° [lit. (8) mp 63°]; ^{1}H-NMR (C_6H_6): δ 2.25 (s, CH_3) ppm; BH_2 not observed.

Dimethylamine-cyanoborane [$(CH_3)_2NHBH_2CN$] (*VI*)—Compound VI was synthesized similarly, except that dimethylamine hydrochloride was used and produced a 53% yield, mp 55–57° [lit. (9) mp 56–57°]; ^{1}H-NMR (CD_3CN): δ 2.0 (q, J_{BH} = 100 Hz, BH_2), 2.35 (t, J_{HNCH} = 6 Hz, CH_3), and 4.48 (s, NH_2) ppm.

Anal.—Calc. for $C_3H_9BN_2$: C, 42.93; H, 10.81; B, 12.88; N, 33.38. Found: C, 43.11; H, 10.57; B, 12.66; N, 33.17.

Trimethylamine-N-ethylamidoborane [$(CH_3)_3NBH_2C(O)N(CH_2CH_3)H$] (*VII*)—A solution of V (11.9 g, 0.12 mole) and $(CH_3CH_2)_3OBF_4$ (250 ml, 0.1 *N* in methylene chloride) was refluxed under nitrogen for 24 hr (Scheme I). The reaction mixture was cooled to 0°, and 1.0 *N* NaOH was added slowly with vigorous stirring until the solution was basic. After stirring for 1 hr at room temperature, the organic layer was separated and the aqueous layer was extracted three times with methylene chloride. The organic portions were combined and dried over magnesium sulfate, and the solvent was removed *in vacuo*.

The remaining viscous liquid was distilled *in vacuo* with minimum heating to give VII (13.1 g, 75% yield, bp 80°/0.15 torr); IR[4]: 3430 (m), 3350 (vs), 3010 (m), 2990 (s), 2950 (s), 2890 (m), 2420 (sh), 2370 (s, br), 2320 (m), 2290 (m), 2240 (w), 2200 (w), 1600 (s), 1480 (s), 1460 (s), 1435 (s), 1400 (m), 1375 (w), 1345 (w), 1295 (w), 1255 (s), 1140 (s), 1100 (s), 1050 (s), 1010 (w), 990 (s), 970 (m), 895 (w), 860 (s), 720 (w), and 670 (w) cm^{-1}; ^{1}H-NMR ($CDCl_3$): δ 1.07 (t, *J* = 8 Hz, CH_2CH_3), 2.75 (s, CH_3N), 3.57 (m, CH_2CH_3), and 5.43 (broad s, NH) ppm; ^{13}C-NMR ($CDCl_3$): δ 15.3 (CH_3CH_2), 31.5 (CH_2CH_3), 51.8 (CH_3N), and 182.8 (CO) ppm; ^{11}B ($CDCl_3$, 50°): δ 7.4 (1:2:1 t, *J* = 90 Hz) ppm.

Trimethylamine-carboxyborane [$(CH_3)_3NBH_2COOH$] (*VIII*)—Compound V (20.8 g, 0.214 mole) and triethyloxonium tetrafluoroborate (450 ml, 0.1 *N* in methylene chloride) were refluxed for 24 hr. The solvent and the reaction by-product, boron trifluoride etherate, were removed *in vacuo*, and water was added to the solid residue. After stirring at room temperature for 2–3 days, the solution was extracted with five 75-ml portions of methylene chloride. The organic extractions were combined and dried over magnesium sulfate, and the solvent was removed *in vacuo*.

The solid residue was recrystallized from hot water and dried under vacuum to give VIII (13.8 g, 55.5% yield, mp 131° dec.); IR[3]: 3050 (vs, br), 2950 (s), 2860 (s, sh), 2720 (m), 2620 (m), 2580 (m), 2380 (s), 2290 (w), 2210

$$V \xrightarrow{(CH_3CH_2)_3OBF_4} (CH_3)_3NBH_2CNCH_2CH_3^+BF_4^- \xrightarrow[NaOH]{1\ N} VII$$

Scheme I

[1] IR spectra were measured on a Perkin-Elmer model 297 spectrometer. Liquid samples were run neat between sodium chloride disks, and solid samples were run as potassium bromide pellets. Elemental analysis was performed by Galbraith Laboratories, Knoxville, Tenn. Triethyloxonium tetrafluoroborate was obtained commercially as 0.1 *N* solutions in methylene chloride or was prepared as described in the literature (6).

Anal.—Calc. for $C_6H_{30}B_6IN_{12}Na$: C, 14.86; H, 6.24; B, 13.38; N, 34.66. Found: C, 15.05; H, 6.37; B, 12.71; N, 34.91.

Pharmacological Screens—Toxicity studies were carried out in CF_1 male mice (~30 g) using a literature method (14).

Antitumor screening was carried out at doses that preliminary screening for V demonstrated to be nontoxic. In the Ehrlich ascites screen, 10^6 tumor cells were implanted intraperitoneally into CF_1 male mice (~30 g). Test compounds were suspended in 0.05% polysorbate 80–water and homogenized. Each compound was injected at 20 mg/kg/day ip. On the 8th day, the mice were sacrificed. The total ascites tumor volume and packed tumor cells (ascrit) volume were determined to calculate the percent inhibition (15). Mercaptopurine and melphalan were used as positive controls for the screen.

In the Walker 256 carcinosarcoma screen, 10^6 tumor cells were implanted intraperitoneally into Sprague–Dawley male rats (~80 g). Test compounds were administered at 2.5 mg/kg/day ip, and the day of death was recorded. The T/C values were calculated according to the NIH protocol (16). Melphalan was used as a positive standard.

Screening was carried out in DBA/2 male mice (~25 g) for the P-388 lymphocytic leukemia model. On Day 0, 10^6 cells were implanted intraperitoneally and test compounds were administered at 20 mg/kg/day. The T/C values were calculated from the group survival times (16). Fluorouracil was used as a positive standard.

In the melanotic melanoma B-16 screens, 1 g of tumor was homogenized in 10 ml of Hanke's balanced salt medium, and 0.5 ml of homogenate was implanted subcutaneously in the inguinal region of C_{57}BL/6 male mice. Test compounds were administered at 20 mg/kg/day ip. The T/C values were calculated (16). Cyclophosphamide was used as a positive control.

In the Lewis lung screen, 2×10^6 tumor cells were implanted intramuscularly in the hindlegs of C_{57}BL/6 male mice. Test compounds were administered at 20 mg/kg/day ip, and T/C values were calculated. Cyclophosphamide was used as an internal standard.

The glioma 26 and 261 and ependymoblastoma brain tumor screens were carried out in a manner analogous to the B-16 screen. Cyclophosphamide and melphalan were the positive controls.

Biochemical Assays—Male CF_1 mice (~30 g) were implanted intraperitoneally on Day 0 with 10^6 Ehrlich ascites tumor cells. For the *in vivo* studies, animals were treated intraperitoneally with 0.25 mg of test compounds on Days 7, 8, and 9. Animals were sacrificed on Day 10, and the ascites fluid was collected from the peritoneal cavity. The number of tumor cells per milliliter and the 0.4% trypan blue uptake were determined with a hemocytometer (17).

In vitro enzymatic and oxidative phosphorylation studies were performed on untreated 10-day Ehrlich ascites cells. Thymidine incorporation into DNA was determined (18). One hour prior to sacrifice, 10 μCi of [methyl-^{14}C]-thymidine (54 mCi/mmole) was injected intraperitoneally. The DNA was isolated, and the ^{14}C content was determined in 0.4% 2,5-diphenyloxazole and 0.01% 1,4-bis[2-(5-phenyloxazolyl)]benzene in a solvent of two parts of toluene and one part of octoxynol, corrected for quenching. DNA concentration was determined by UV spectrophotometry at 260 nm using a calf thymus DNA standard.

Uridine incorporation into RNA was determined in an analogous manner utilizing 10 μCi of 5-^{3}H-uridine (24.2 Ci/mmole). RNA was extracted (19). Leucine incorporation into protein was determined (20) using 1 μCi of 1-^{14}C-leucine (56.9 mCi/mmole). The boron analog effect on 1-^{14}C-acetic acid (57.8 mCi/mmole) incorporation into Ehrlich ascites cell cholesterol was measured also (21, 22). Histone phosphorylation and methylation were determined by injecting intraperitoneally 10 μCi of (γ-^{32}P)-ATP (7.97 Ci/mmole) or [methyl-^{14}C]-choline chloride (49 mCi/mmole) 1 hr prior to sacrifice. The nuclei were isolated (23), and the histone chromatin protein was extracted (24).

Nonhistone chromatin phosphorylation and methylation were determined on isolated nuclei (25) utilizing 2 mmoles of γ-^{32}P-ATP or [methyl-^{14}C]-choline chloride. Chromatin protein was collected on nitrocellulose membrane filters (25). Cyclic-AMP levels were determined by a radioimmunoassay (26) using ^{3}H(G)-cyclic-AMP (39.8 Ci/mmole).

Table II—Trimethylamine-cyanoborane (V) Effects on *In Vivo* Ehrlich Ascites Tumor Metabolism

In Vivo (n = 6)	Percent Control: Control[a]	Percent Control: Treated, 0.25 mg on Days 7, 8, and 9

Control[k]	100 ± 15	100 ± 3	100 ± 15	100 ± 5	100 ± 8	100 ± 19	100 ± 17

Control values for 10-day Ehrlich ascites tumor cells were as follows: [a] 7561 dpm/mg of protein. [b] 103,328 dpm/mg of protein. [c] 3268 dpm/mg of protein. [d] 8000 dpm/mg of chromatin protein. [e] 35 μg of DNA hydrolyzed/mg of protein/30 min. [f] 24 μg of RNA hydrolyzed/mg of protein/30 min. [g] 0.90 mg of protein hydrolyzed/mg of protein/30 min. [h] $p = 0.001$. [i] $p = 0.025$. [j] $p = 0.005$. [k] 0.05% Tween 80–water.

In vitro DNA polymerase activity was determined on washed (three times) isolated nuclei (23). The incubation system was that of Sawada *et al.* (27), except that 2-^{14}C-deoxythymidylate triphosphate (45 mCi/mmole) was used. The insoluble nucleic acids were collected on glass fiber GF/F by vacuum suction. Deoxythymidylate kinase and deoxythymidylate diphosphate kinase activities were determined by a method (28) based on the disappearance of reduced nicotinamide adenosine dinucleotide at 340 nm for 20 min. *In vitro* thymidylate synthetase activity was assayed by a method (29) utilizing a postmitochondrial supernate (9000×*g* for 10 min) and 5 μCi of 5′-^{3}H-deoxyuridine monophosphate (11 Ci/mmole). S-Adenosyl-L-methionine methyltransferase activity was determined (30) using S-[methyl-^{14}C]-adenosyl-L-methionine (53 mCi/mmole).

The effects of the boron analogs on the tumor cell hydrolytic enzymes were also determined. Deoxyribonuclease activity, at pH 5.0, was measured by a modification of the deDuve method (31). Ribonuclease and cathepsin activities, at pH 5.0, were determined by the method of Cho-Chung and Gullino (32). *In vitro* effects of boron analogs on Ehrlich ascites tumor cell oxidative phosphorylation processes were measured (33) in the presence and absence of adenosine diphosphate, utilizing succinate or α-ketoglutarate as the substrate. Protein was determined by the Lowry method (34).

All *in vitro* tests were carried out at 6 μmoles of test compounds/ml of assay mixture. *In vitro* UV binding studies were conducted with test compounds (0.2 μg/ml) and DNA (38 μg/ml) or deoxyguanosine monophosphate (38 μg/ml) in 0.1 *M* phosphate buffer, pH 7.2, over a range of 200–340 nm for 24 hr (22). Data in Tables II and III are the means of control and standard deviation percentages ($\bar{x} \pm SD$). The probable significance level (p) was determined by the Student t test (35).

RESULTS

Compounds III–V and VIII significantly inhibited Ehrlich ascites tumor growth at 1 mg/kg/day. Compounds I–V, VII, and VIII were significantly active (T/C ≧ 125) in the Walker 256 carcinosarcoma survival screen at a relatively low dose, 2.5 mg/kg/day. In the P-388 lymphocytic leukemia screen at 20 mg/kg/day, only VII had significant activity. In the B-16 melanoma screen, III, V, and VII demonstrated significant activity (T/C ≧ 140). In the Lewis lung survival system, IV, V, VII, IX, and X demonstrated activity at 20 mg/kg/day. Compound V was inactive in the brain tumor screens, glioma 26 and 261 and ependymoblastoma (Table I).

Boron analog effects on several biochemical events necessary for rapid cell proliferation were examined. ^{14}C-Thymidine incorporation into DNA for 10-day Ehrlich ascites cells was 280,629 dpm/mg of DNA. DNA synthesis was inhibited 52% by V, 45% by VII, and 60% by VIII (Table II). ^{3}H-Uridine incorporation into Ehrlich ascites cell RNA was unaffected by boron analogs. The UV spectral studies with V, VII, and VIII and DNA or deoxyguanosine monophosphate demonstrated no binding between drugs and nucleotides, indicating that the DNA template was intact for transcription.

^{14}C-Leucine incorporation into protein for the 10-day control Ehrlich ascites cells was 6238 dpm/mg of protein and was inhibited 90% after V administration. Cholesterol synthesis for newly synthesized cell membranes for the control 10-day tumor was 132,809 dpm/mg of protein. Cholesterol synthesis was inhibited 25% by V, 48% by VII, and 62% by VIII. The methyl transfer from choline to transfer and ribosomal RNA for the control animals was 1086 dpm/mg of RNA, which was inhibited 49% by treatment with V.

Protein methylation by the choline donor for the 10-day Ehrlich ascites cells was 1225 dpm/mg of protein. Compound V inhibited protein methylation 58%. Nonhistone chromatin protein methylation for the control was 8118 dpm/mg of chromatin protein; treatment with V resulted in 56% inhibition. Histone methylation was 40,976 dpm/mg of chromatin protein for the control, whereas administration of V caused a 32% elevation. Phosphorylation of the regulatory proteins controlling gene activity was 9803 dpm/mg of nonhistone chromatin protein and 2954 dpm/mg of histone chromatin protein. Treatment with V resulted in a 59 and a 65% reduction, respectively, of chromatin protein phosphorylation.

The cyclic-AMP level for 10-day Ehrlich ascites cells was 3.65 pmoles/10^6 cells, which was elevated 169% by V administration. The number of tumor cells per milliliter on Day 10 was 223 × 10^6, which was suppressed 67% by treatment with V. The boron analogs were also tested for their *in vitro* effects on specific enzymes of 10-day Ehrlich ascites cells (Table III). Nuclei DNA polymerase activities were suppressed by all compounds tested. Compounds V, VII, and VIII possessed the best inhibitory activity: 54, 60, and 63% inhibition, respectively. Thymidylate mono- and diphosphate kinase activities were not affected by the boron analogs. Thymidylate synthetase activity was inhibited significantly by I and V and marginally by III, IV, and VIII. S-Adenosyl-L-methionine transferase activity was inhibited 51% by V and 61% by VIII with marginal inhibition by II–IV and VII. Nonhistone methylation dependent on S-adenosyl-L-methionine-methyltransferase activity was inhibited significantly by V (56%) and VIII (53%), with marginal inhibition by I–IV.

Treatment with the boron analogs reduced the activity of deoxyribonuclease, ribonuclease and cathepsin. Deoxyribonuclease activity was affected the most drastically. Compound I reduced activity 93%, II 72%, III 90%, IV 81%, V 86%, and VIII 75%. Ribonuclease activity was inhibited significantly by V (53%) and II (49%) with marginal inhibition by I, III, IV, and VIII. Cathepsin activity was reduced 47% by II, 56% by III, 67% by IV, 32% by V and VIII, and 81% by VII. Basal and adenosine diphosphate-stimulated respiration of 10-day Ehrlich ascites cells was unaffected by V, VII, and VIII at 6 μmoles.

DISCUSSION

The major boron analog effects were on Ehrlich ascites tumor cell protein and DNA syntheses. Protein synthesis inhibition may be the direct result of the α-amino boron analog on the translocation process or by blocking L-methionine synthesis. Enzymes required for DNA synthesis are synthesized in the early stages of cell proliferation (32). DNA polymerase activity was inhibited significantly whereas thymidylate kinases were unaffected by the boron analogs. Elevated cyclic-AMP levels resulting from boron analog administration are associated with cessation of cholesterol synthesis (36), reduced cellular proliferation, and reduction of H-1 histone phosphorylation, an event necessary for template activity (37).

Other protein kinases that are modulated by cyclic nucleotide levels

are those that phosphorylate nonhistone chromatin proteins which regulate transcription and differentiation. Compound V effectively blocks nonhistone and histone phosphorylation. The necessary phosphorus is derived from the γ-P of ATP, but Ehrlich ascites cell oxidative phosphorylation was not inhibited by the boron analogs. Lysosomal enzymatic activity is high prior to the mitotic apparatus formation, and membrane surface proteolytic activity is increased in cells undergoing rapid proliferation and metastasis (38). Elevated cyclic-AMP levels are associated with lysosomal membrane stabilization and blockage of the hydrolytic enzyme release (39).

Deoxyribonuclease activity was inhibited significantly by the boron analogs. Cathepsin proteolytic activity was inhibited moderately. *S*-Adenosyl-L-methionine transferase activity as well as the *S*-adenosyl-L-methionine-dependent methyl group transfer from choline was inhibited by the boron analogs. Protein and RNA methylation was suppressed significantly by boron analog treatment (1–4). Chromatin methylation is elevated in Novikoff hepatoma (40) and Hela cells (41). Cultured pancreatic anlase cells require *S*-adenosyl-L-methionine for proliferation and differentiation. Conversely, histone methylation by protein methylase III is highest late in the S and G_2 phases, indicating a cessation of replication (42). Boron analogs slightly increased histone methylation. Thymidylate synthetase activity also was inhibited by these agents, apparently producing cell death through thymine deprivation.

Generally, the degree of methyltransferase inhibition followed the antineoplastic activity demonstrated by these boron analogs in the Ehrlich ascites screen, with V having the highest activity in both areas. Boron betaine analogs are potent inhibitors of the protein synthesis and methyl transfer necessary for rapidly proliferating cells.

Controlled Drug Release from Polymeric Delivery Devices V: Hydroxy Group Effects on Drug Release Kinetics and Thermodynamics

Y. W. CHIEN *x, D. M. JEFFERSON, J. G. COONEY, and H. J. LAMBERT

Received August 7, 1978, from the *New Product Development Department, Searle Laboratories, Division of G. D. Searle & Co., Skokie, IL 60077.* Accepted for publication November 15, 1978. *Present address: Pharmaceutical R&D Department, Endo Laboratories, Garden City, NY 11530.

Abstract □ The effects of progesterone hydroxylation on silicone matrix drug release kinetics and thermodynamics were investigated. Hydroxylation at positions 11, 17, and/or 21 substantially reduced progesterone release. The magnitude of this reduction depended on the number and position of the hydroxy groups and could be attributed to decreased polymer matrix diffusivity (D_m) and polymer solubility (C_p). Thermodynamically, hydroxy group addition to positions 11 and/or 21 reduced the activation energy for matrix diffusion ($E_{d,m}$) but increased the solvation energy for dissolution in silicone polymer ($\Delta H_{T,m}$). Adding an hydroxy group to position 17 increased the $E_{d,m}$ but decreased the $\Delta H_{T,m}$. The overall ($E_{d,m} + \Delta H_{T,m}$) values were relatively constant and independent of hydroxylation.

Keyphrases □ Dosage forms—controlled release, progesterone from silicone matrix, effect of hydroxylation, kinetics, thermodynamics □ Progesterone—controlled-release dosage forms, effect of hydroxylation on release from silicone matrix □ Hydroxylation—progesterone, effect on release from silicone matrix □ Steroids—controlled-release dosage forms, progesterone, effect of hydroxylation on release from silicone matrix

The idea of replacing daily drug administration with a polymeric controlled-release device has recently generated much interest (1). The high silicone polymer steroid permeability has led to development of drug-filled and drug-dispersed silicone devices for long-term intrauterine, intravaginal, subcutaneous, and transdermal drug administration (2–15).

An *in vitro* system for direct, rapid drug release characterization was recently developed (16). Two types of drug release mechanisms, matrix controlled and partition controlled, were observed when the drug release profiles from silicone devices were followed daily using this system (17–19). Controlled drug release kinetics and thermodynamics under these two processes were analyzed (18–20).

Normalized steroid permeability coefficients appear to depend on the steroidal structure (21). For drugs with a high permeability coefficient (across the vaginal membrane) (P_m), like progesterone, intravaginal absorption is mainly controlled by the permeability of the vaginal surface aqueous hydrodynamic diffusion layer. For drugs with a low P_m value, such as hydrocortisone, intravaginal uptake is determined mainly by molecular transport across the vaginal membrane. This difference in absorption may be due to the hydroxy groups in the steroid. The transdermal permeability constants were also reported to be influenced by the presence of hydroxy groups on the progesterone molecules (22).

Effects of hydroxy groups on the controlled-release kinetics and thermodynamics of progesterone and its derivatives were studied in this investigation as a step in the design of controlled-release drug delivery systems.

EXPERIMENTAL

Silicone devices were prepared by thoroughly mixing 0.5–2.0 parts of progesterone derivative crystals, 7.5 parts of dimethyl polysiloxane elastomer[1], and one part of silicone fluid[2] with a rotator[3] at 1000 rpm for 7 min. One drop (0.02 ml) of stannous octoate[1], as catalyst, was then incorporated and thoroughly mixed for another minute. The mixture was deaerated under vacuum for 4 min and delivered by an extrusion pump[4] into Tygon tubing[5] (0.63-cm i.d.). The silicone polymer was allowed to cure at 60° for 1 hr. After proper cross-linking, the resulting medicated silicone device was removed from the tubing mold and cut into the desired lengths for *in vitro* drug elution studies.

The *in vitro* drug elution studies were conducted by immersing one medicated silicone device in each test tube containing 10 ml of 50% (v/v) polyethylene glycol 400–water. The test tubes were sealed with screw caps and shaken at a constant 40 oscillations/min in a water bath thermostated at 37, 45, 50, or 55°. The medicated silicone devices were transferred to new elution solution every 24 hr for 7 days. The drug concentration in each test tube was analyzed spectrophotometrically[6] after appropriate dilution with spectral grade methanol. The drug released every 24 hr from each device and the drug released from a unit surface area of the device (Q) were calculated.

The techniques for determining drug solubility in silicone polymer and in 50% (v/v) polyethylene glycol 400–water were reported previously (16).

RESULTS AND DISCUSSION

***In Vitro* Progesterone Derivative Release**—The chemical structures and hydroxy group locations of progesterone derivatives are illustrated in Table I. Their *in vitro* release profiles are shown in Fig. 1. Controlled release of progesterone and its hydroxy derivative from silicone devices at steady state followed the matrix-controlled process previously seen for other progesterone derivatives (6, 19). As expected from Eq. 1, the cumulative amount of progesterone derivative released (Q) is linearly proportional to the square root of time ($t^{1/2}$) (18):

$$Q = [D_m(2A - C_p)C_p t]^{1/2} \quad \text{(Eq. 1)}$$

where D_m is the effective drug diffusivity in the polymer matrix, A is the drug content in a unit volume of silicone device, and C_p is the drug solubility in the silicone polymer. The drug release flux is defined as:

$$Q/t^{1/2} = [D_m(2A - C_p)C_p]^{1/2} \quad \text{(Eq. 2)}$$

and can be estimated from the slope of the Q *versus* $t^{1/2}$ plots (Fig. 1). Hydroxylation of progesterone reduced $Q/t^{1/2}$. This reduction depended on the hydroxy group number and location (Table II). An hydroxy group at either the 11- or 17-position had the most drastic effect on progesterone release from a silicone device, producing a more than fivefold decrease in $Q/t^{1/2}$ compared to a 1.5-fold reduction when the hydroxy group was at the 21-position.

The presence of two hydroxy groups further reduced $Q/t^{1/2}$. Hydroxy groups at the 11- and 21-positions yielded a 13.5-fold reduction in $Q/t^{1/2}$ and hydroxy groups at 17 and 21 resulted in a 28-fold decrease. The addition of a second hydroxy group at the 17-position had a more significant

influence on $Q/t^{1/2}$ than did a second hydroxy group at the 11-position (compare VI with V). With three hydroxy groups (VII), $Q/t^{1/2}$ was reduced by 35 times, from 3.368 mg/cm²/day$^{1/2}$ for progesterone to 0.096 mg/cm²/day$^{1/2}$ for hydrocortisone (Table II).

Mechanistic Analysis of Hydroxy Group Effects—Equation 2 suggests that the reductions in $Q/t^{1/2}$ in response to the addition of hydroxy groups could reflect changes in the progesterone matrix diffusivity (D_m) and/or the polymer solubility (C_p). Theoretically, hydroxy groups should add hydrophilicity and change the progesterone stereochemical configuration.

Equation 2 indicates that $Q/t^{1/2}$ should be linearly dependent on $(2A - C_p)^{1/2}$ (Fig. 2). The slope of $Q/t^{1/2}$ *versus* $(2A - C_p)^{1/2}$ should be defined by $(D_m C_p)^{1/2}$. If the value of C_p, the progesterone derivative solubility in silicone polymer, is known or experimentally determined, the magnitude of D_m, the matrix diffusivity in a silicone device, can be calculated (Table III).

The addition of hydroxy groups to progesterone decreased D_m and C_p but increased C_s, the solubility of progesterone derivatives in 50% (v/v) polyethylene glycol 400–water (Table III). The decrease in matrix diffusivity (D_m) could be due to the alterations in the stereochemical configuration of the progesterone molecule. On the other hand, the increase in C_s and the decrease in C_p could be related to increased progesterone hydrophilicity due to the addition of hydrophilic hydroxy groups.

If hydroxy groups change progesterone hydrophilicity, they also should change the progesterone partitioning behavior from the silicone device toward the elution solution. As expected, the K_{obs} calculated from C_s/C_p varied with the number and position of hydroxy groups added (Table III). The partition coefficient, K_{obs}, is theoretically related to the standard Gibbs free energy (ΔF_d) of desorption, *i.e.*, the energy gained by a molecule on desorption from the polymer phase into the elution solution (23):

$$\Delta F_d = -RT \ln K_{obs} \qquad \text{(Eq. 3)}$$

If it is assumed (24) that ΔF_d can be expressed additively in terms of the individual contributions of the nonpolar progesterone skeleton (ΔF_p) and the polar hydroxy group (ΔF_{OH}), then:

$$\Delta F_d = \Delta F_p + n(\Delta F_{OH}) \qquad \text{(Eq. 4)}$$

It is also known that:

$$\Delta F_p = -RT \ln K_p \qquad \text{(Eq. 5)}$$

where K_p is the solution–polymer partition coefficients for progesterone itself. Combining Eqs. 3–5 yields:

$$\ln K_{obs} = \ln K_p - \frac{n(\Delta F_{OH})}{RT} \qquad \text{(Eq. 6a)}$$

or:

$$\log K_{obs} = \log K_p - \frac{n(\Delta F_{OH})}{2.303RT} \qquad \text{(Eq. 6b)}$$

As expected from Eq. 6*b*, the K_{obs} values were first order dependent on the number (n) of hydroxy groups on the progesterone molecule (Fig. 3). From the slope ($-\Delta F_{OH}/2.303RT$) of the linear log K_{obs} *versus* n plots, the ΔF_{OH} values were computed (Table IV). Depending on the system temperature, the addition of hydroxy groups onto the progesterone molecule yielded a contribution of ΔF_{OH} from −1.419 to −1.684 kcal/mole to the Gibbs free energy of desorption (ΔF_d). Without the hydroxy groups, the progesterone molecule partitioning from a silicone device toward an elution solution required a Gibbs free energy of desorption (ΔF_p) of 0.321–0.108 kcal/mole; with the hydroxy groups, the overall ΔF_d was improved to −1.098–−1.550 kcal/mole (Table IV). In other words, the addition of hydroxy groups enhanced the interfacial partitioning of the progesterone molecule from a silicone device to an elution medium.

As reported previously (24), K_{obs} for monosubstituted hydroxy progesterone was also dependent on the substituent hydroxy group position (Table III). From the following relationship:

$$\Delta F_{OH} = -2.303RT(\log K_{obs} - \log K_p) \qquad \text{(Eq. 7)}$$

the ΔF_{OH} values for 21-OH, 17α-OH, and 11α-OH groups were estimated to be −1.51, −2.06, and −2.88 kcal/mole, respectively, at 37°.

Controlled Drug Release Thermodynamics—The temperature dependency of $Q/t^{1/2}$ is defined by the following relationship (19):

$$\log (Q/t^{1/2}) = \text{constant} - \left(\frac{(E_{d,m} + \Delta H_{T,m})}{4.606R}\right)\left(\frac{1}{T}\right) \quad \text{(Eq. 8)}$$

where $E_{d,m}$ is the activation energy a drug molecule requires to diffuse in a polymer matrix, $\Delta H_{T,m}$ is the energy required for the solvation of drug molecules in the polymer structure, R is the gas constant (1.9872 cal/mole/deg), and T is the absolute temperature. As expected from Eq. 8, the linear log $(Q/t^{1/2})$ *versus* T^{-1} was followed very well (Fig. 4). The values of $(E_{d,m} + \Delta H_{T,m})$ for progesterone and its hydroxy derivatives were similar, ranging from 13.52 (±1.02) to 16.70 (±0.87) kcal/mole (Table V). Compound VI had a slightly higher value (23.62 ± 2.44 kcal/mole). Except for VI, additional hydroxy groups did not significantly affect the total energy requirements for the controlled progesterone derivative release.

Diffusion of drug molecules in the polymer structure is energy dependent (25); the matrix diffusion of progesterone and its hydroxy derivatives requires the activation energy ($E_{d,m}$) defined in the following expression:

$$\log D_m = \log D_m^0 - \left(\frac{E_{d,m}}{2.303R}\right)\left(\frac{1}{T}\right) \quad \text{(Eq. 9)}$$

The linear relationship between log D_m and T^{-1} was followed very well for all compounds tested (Fig. 5). A significant difference in $E_{d,m}$ values was noticed among the progesterone derivatives (Table VI).

The $\Delta H_{T,m}$ values, which were computed from the difference between $(E_{d,m} + \Delta H_{T,m})$ (Table V) and $E_{d,m}$ (Table VI), are also given in Table VI. Again, a significant variation in $\Delta H_{T,m}$ values was observed from one progesterone derivative to another. The results in Table VI suggested that hydroxy group addition to position 11 or 21 reduced the matrix

diffusion activation energy ($E_{d,m}$) but increased the solvation energy ($\Delta H_{T,m}$). Hydroxy group addition to position 17 increased $E_{d,m}$ but decreased $\Delta H_{T,m}$ (Table VI). The addition of more than one hydroxy group to the progesterone molecule gave a composite effect.

The $\Delta H_{T,m}$ values can also be determined from the temperature dependency of drug solubility (C_p) in a liquid silicone polymer (19), as expected from:

$$\log C_p = \text{constant} - \left(\frac{\Delta H_{T,m}}{2.303R}\right)\left(\frac{1}{T}\right) \qquad \text{(Eq. 10)}$$

A good $\log C_p$ *versus* T^{-1} linearity was achieved experimentally (Fig. 6). The $\Delta H_{T,m}$ values determined in the liquid silicone polymer (Table VII) agreed with the data generated in the polymerized, solid silicone matrix (Table VI), except for progesterone derivatives with one hydroxy group

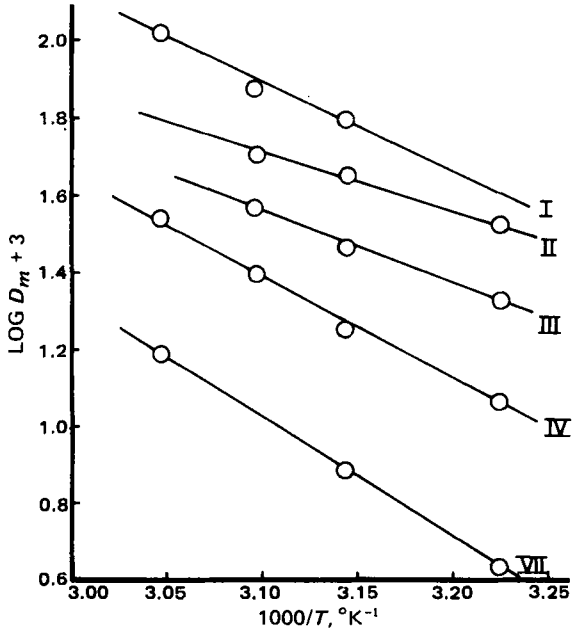

Figure 5—*Temperature dependency of* D_m *(effective diffusivity in silicone matrix) of progesterone derivatives.*

[a] Determined at four temperatures (37–55°). [b] Solvation energy in 50% (v/v) polyethylene glycol 400 solution. [c] Solvation energy in silicone medical fluid (20 cv).

at position 17. Apparently, the addition of an hydroxy group at position 17 produces stereochemical configuration and/or physicochemical changes, which become apparent only in a solid polymer matrix and not in a polymer fluid.

The aqueous solubility (C_s) of progesterone and its hydroxy derivatives was also temperature dependent (19), as defined by:

$$\log C_s = \text{constant} - \left(\frac{\Delta H_{T,S}}{2.303R}\right)\left(\frac{1}{T}\right) \qquad \text{(Eq. 11)}$$

As expected from Eq. 11, $\log C_s$ is linearly dependent on T^{-1} (Fig. 6). The hydroxy group addition reduced $H_{T,s}$, the solvation energy (by 3.48 ± 0.48 kcal/mole) (Table VII), leading to an improvement of aqueous solubility (C_s in Table III). However, the number of hydroxy groups did not

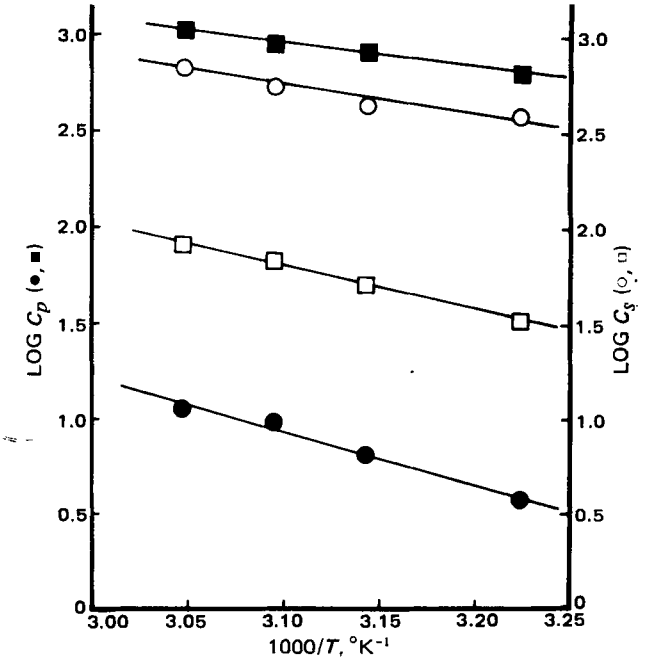

Figure 6—*Temperature dependency of polymer solubility* (C_p) *and aqueous solubility* (C_s) *of progesterone* (■ *or* □) *and hydrocortisone* (● *or* ○). *The* $\Delta H_{T,m}$ *and* $\Delta H_{T,s}$ *values were 5.49 and 10.22 kcal/mole for progesterone and 12.71 and 6.48 kcal/mole for hydrocortisone, respectively.*

change $\Delta H_{T,s}$ [mean value ($\pm SD$) of 6.75 ($\pm$0.48) kcal/mole], although the more hydroxy groups added, the higher the aqueous solubility. The C_s value increased 1.25–11.29-fold.

The data in Table III indicated that the addition of an hydroxy group at position 21 remarkably affected the solution solubility (C_s). With the addition of a 21-OH group, the C_s increased almost fourfold, from 353.3 ($\pm$16.2) (I) to 1402.1 ($\pm$75.4) (II) μg/ml. The significance of the 21-OH group in progesterone derivative solubility enhancement can be demonstrated by removing the 21-OH group by acetylation. Desoxycorticosterone acetate formation reduced C_s substantially to 249.9 ($\pm$2.1) μg/ml. The reduction of C_s was accompanied by an increase in $\Delta H_{T,s}$, the solvation energy, from 7.17 to 10.99 kcal/mole. For desoxycorticosterone acetate, C_s and $\Delta H_{T,s}$ were very close to the value for progesterone (353.3 ± 16.2 μg/ml and 10.22 kcal/mole, respectively). A similar result was achieved when the 21-OH group of hydrocortisone (VII) was acetylated to form hydrocortisone acetate.

Cobaltous Chloride-Induced Hypothermia II: Pretreatment with Sympathoplegics, Antihistamines, and Narcotic Antagonists

DAVID H. BURKE ˣ **and JACK C. BROOKS**

Received August 25, 1978, from the *Divisions of Pharmacology and Physiology, School of Dentistry, Marquette University, Milwaukee, WI 53233.* Accepted for publication November 13, 1978.

Abstract □ Body temperature depression was noted in rats, mice, and hamsters following intraperitoneal cobaltous chloride administration (25 mg/kg). Intracerebral cobalt injection elicited hypothermia in rats and mice but not in hamsters. Body temperature depression appeared to be centrally mediated in rats and mice and peripherally mediated in hamsters. The effect of intraperitoneal and intracerebral pretreatment with phentolamine, diphenhydramine, propranolol, cimetidine, and naloxone on the mouse rectal temperature response to cobalt (25 mg/kg ip) was noted. Systemic phentolamine injection (intraperitoneal) did not alter the cobalt response, whereas intracerebral administration partially antagonized cobalt-induced hypothermia, indicating that antagonism was mediated centrally. Pretreatment with propranolol and cimetidine failed to modify the temperature response. Intracerebral diphenhydramine did not influence cobalt hypothermia. However, this agent reduced the cobalt response when given intraperitoneally, presumably through a peripheral inhibitory mechanism. The intracerebral injection of naloxone 30 min prior to cobalt slightly enhanced hypothermia, apparently through a central action. Intracerebral 6-hydroxydopamine injection depleted brain norepinephrine and dopamine but exhibited no apparent influence on cobalt-induced hypothermia.

Keyphrases □ Hypothermia—cobaltous chloride induced, effect of phentolamine, diphenhydramine, propranolol, cimetidine, naloxone, rats, mice, hamsters, species specificity, central *versus* peripheral effects □ Cobaltous chloride—hypothermia, rats, mice, hamsters, effect of phentolamine, diphenhydramine, propranolol, cimetidine, naloxone, species specificity □ Sympathoplegics—effect on cobaltous chloride-induced hypothermia □ Antihistamines—effect on cobaltous chloride-induced hypothermia □ Narcotic antagonists—effect on cobaltous chloride-induced hypothermia

Many agents interfere with thermoregulatory control as a result of their influence on the central nervous system (CNS). Intracerebral dopamine and norepinephrine injections into conscious mice caused hypothermia (1). Similarly, histamine and oxotremorine injection into the lateral ventricles produced a dose-related fall in body temperature (2–4). Hypothermia, due solely to a decrease in heat production, was reported following a single central morphine injection in rats (5, 6).

Recent studies in this laboratory showed that cobaltous

change $\Delta H_{T,s}$ [mean value ($\pm SD$) of 6.75 ($\pm$0.48) kcal/mole], although the more hydroxy groups added, the higher the aqueous solubility. The C_s value increased 1.25–11.29-fold.

The data in Table III indicated that the addition of an hydroxy group at position 21 remarkably affected the solution solubility (C_s). With the addition of a 21-OH group, the C_s increased almost fourfold, from 353.3 ($\pm$16.2) (I) to 1402.1 ($\pm$75.4) (II) μg/ml. The significance of the 21-OH group in progesterone derivative solubility enhancement can be demonstrated by removing the 21-OH group by acetylation. Desoxycorticosterone acetate formation reduced C_s substantially to 249.9 ($\pm$2.1) μg/ml. The reduction of C_s was accompanied by an increase in $\Delta H_{T,s}$, the solvation energy, from 7.17 to 10.99 kcal/mole. For desoxycorticosterone acetate, C_s and $\Delta H_{T,s}$ were very close to the value for progesterone (353.3 ± 16.2 μg/ml and 10.22 kcal/mole, respectively). A similar result was achieved when the 21-OH group of hydrocortisone (VII) was acetylated to form hydrocortisone acetate.

Table I—Body Temperature Changes 30 min after Itracerebral Cobaltous Chloride Injection in Various Species

Species	Water[a] Initial Temperature	Water[a] Temperature Change (Mean ± SE)[b]	Cobaltous Chloride[a] Initial Temperature	Cobaltous Chloride[a] Temperature Change (Mean ± SE)[b]
Mice	37.19°	−0.12 ± 0.04°	37.24°	−4.08 ± 0.19°[c]
Rats	37.67°	+0.03 ± 0.09°	37.69°	−3.56 ± 0.18°[c]
Hamsters	37.24°	−0.26 ± 0.13°	37.46°	−0.18 ± 0.16°

[a] Each animal received 0.01 ml of water or a 0.25% cobaltous chloride solution. [b] Temperature changes represent the difference between body temperature recorded initially and that obtained 30 min following water or cobalt treatment in groups of 12 animals. [c] Compared to water in the corresponding species, $p < 0.05$.

chloride causes pronounced hypothermia in mice, apparently through a centrally mediated decrease in heat production (7). Although pretreatment with atropine, hexamethonium, and nicotine failed to modify the cobalt response, a partial antagonism was noted after pretreatment with chlorpromazine.

This paper describes cobalt-induced hypothermia and modification of this response by pretreatment with histaminergic, noradrenergic, or "opioid" receptor blocking agents.

EXPERIMENTAL

Animals—The experiments were performed on male Swiss albino mice, 18–25 g, on male Wistar rats, 140–160 g, and on male Syrian hamsters, 50–70 g. The animals were housed in groups of six to 20 with *ad libitum* access to laboratory food[1] and water for at least 3 days prior to use. For 24 hr before and including the time of the experiment, the animals were kept in a room free from drafts at a constant environmental temperature (23 ± 1°).

Drugs—Fresh drug and chemical solutions were prepared with distilled water in concentrations (calculated as the salt) 0.01 ml/g of body weight. Intracerebral injections were administered in a fixed volume of 0.01 ml/animal. Cobaltous chloride[2], phentolamine mesylate[3], propranolol hydrochloride[4], diphenhydramine hydrochloride[5], cimetidine hydrochloride[6], naloxone hydrochloride[7], and 6-hydroxydopamine[8] were used.

Body Temperature Recording—A thermistor thermometer[9] was used for obtaining body temperature. Rectal temperatures were recorded with a thermistor probe inserted ~2.5 cm (5 cm for rats) and held in position until constant readings were attained.

At the start of daily testing, the animals were placed singly in circular wire-mesh cages and individual weights were recorded with a triple-beam balance[10]. Immediately following weight determination, initial temperatures were recorded and treatments were administered. Temperatures were recorded again at various intervals. Unless otherwise stated, treatments were intraperitoneal. Control animals received distilled water (0.01 ml/g). To study the influence of various drugs on cobalt-induced hypothermia, pretreatment injections (water, phentolamine, propranolol, diphenhydramine, cimetidine, naloxone, and 6-hydroxydopamine) were given at specified intervals prior to recording initial temperatures.

Intracerebral Injections—Intracerebral injections were carried out according to a literature method (8). Agents were injected 2 mm lateral to the midline on a line joining the anterior bases of the ears. A 27-gauge needle attached to a microliter syringe[11] was inserted perpendicularly through the skull to a depth of 3 mm. Similar prior injection of several animals with methylene blue (0.5%) resulted in dye localization in the third and fourth ventricles.

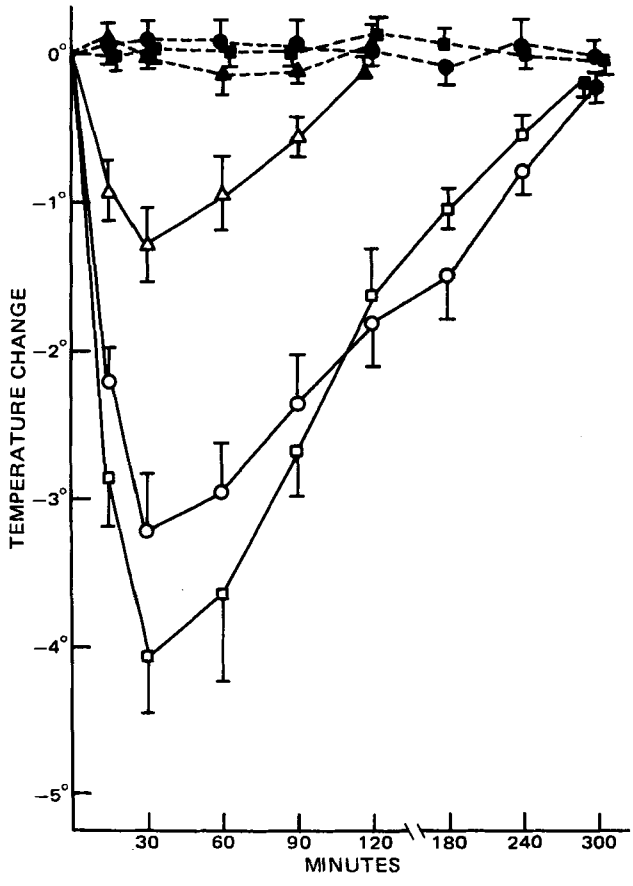

Figure 1—*Time course of the effect of 0.01 ml/g ip distilled water (- - -) and cobaltous chloride (25 mg/kg ip) (—) on rectal temperature in hamsters (▲), rats (●), and mice (■). Water or cobaltous chloride were administered at zero time. Open symbols denote significant difference ($p < 0.05$) from water treatment at the corresponding time interval. Each point represents the average of 12 determinations. Vertical bars represent standard errors.*

Catecholamine Assay—Dopamine and norepinephrine were extracted from the brain and quantitated as the trihydroxyindoles (9). Amines were isolated from deproteinized brain homogenates by chromatography on a cation-exchange resin[12]. The individual amines were quantitated fluorometrically[13] with standard curves relating relative fluorescence to concentration.

Statistics—Results are expressed as mean ± standard error. Significance was calculated using the Student *t* test. Differences were considered significant at the probability level of 5% or less.

RESULTS

Core temperature changes were recorded at various intervals for 5 hr following cobaltous chloride administration (25 mg/kg ip) to unrestrained mice, rats, and hamsters (Fig. 1). Maximum body temperature depression (~1.2°) was evident 30 min after cobalt injection in hamsters. Hypothermia duration in this species was ~90 min. Cobaltous chloride caused more body temperature depression in rats (3.2°) and mice (4.1°). In each case, maximum hypothermia occurred within 30 min. A 4-hr hypothermia duration was noted in rats and mice.

Body temperature changes were noted 30 min after intracerebral cobaltous chloride injection (25 μg) in mice, rats, and hamsters (Table I). Mice and rats exhibited respective drops of 4.08 and 3.56°. Visible shivering and increased muscle tone were absent throughout the body temperature response. In both species, hypothermia was accompanied by depression of locomotor activity. Cobaltous chloride failed to elicit a significant body temperature depression when injected intracerebrally in hamsters.

6-Hydroxydopamine	42	38.78°	−0.30 ± 0.07°	38.81°	−5.34 ± 0.32°

[a] Pretreatments (intracerebral) were administered 14 and 42 days before intraperitoneal water and cobaltous chloride to groups of 18 mice. [b] Temperature changes represent the difference between body temperature recorded initially and that obtained 30 min after treatment. [c] Aqueous ascorbic acid solution (0.5%) with pH adjusted to 5.5. [d] Compared to vehicle–water (pretreatment–treatment) at the 14-day pretreatment–treatment interval, $p < 0.05$. [e] Compared to vehicle–water (pretreatment–treatment) at the 42-day pretreatment–treatment interval, $p < 0.05$.

The effect of intraperitoneal and intracerebral pretreatment with phentolamine mesylate, propranolol hydrochloride, diphenhydramine hydrochloride, cimetidine hydrochloride, and naloxone hydrochloride on the body temperature response to cobaltous chloride (25 mg/kg) in mice is shown in Table II. Pretreatment doses were incapable of causing significant body temperature alteration. Intracerebral phentolamine administration partially attenuated the hypothermic response to cobalt. Phentolamine produced no significant effect upon cobalt hypothermia when given intraperitoneally. Propranolol did not modify cobalt-induced hypothermia by either the intraperitoneal or intracerebral route. Systemic diphenhydramine administration partially inhibited cobalt hypothermia. No antagonism occurred following intracerebral administration. Cobaltous chloride-induced body temperature depression was not significantly altered by intraperitoneal naloxone, but a hypothermia potentiation was observed after intracerebral naloxone.

Table III describes the effect of intracerebral 6-hydroxydopamine pretreatment (100 μg) on the hypothermic response to cobaltous chloride (25 mg/kg ip) in mice. Pretreatment 14 and 42 days prior to cobalt treatment did not affect the body temperature response.

At 14 days following intracerebral 6-hydroxydopamine injection, mouse brain norepinephrine and dopamine concentrations were reduced by 59.09 and 71.43%, respectively (Table IV). A similar reduction in catecholamine concentrations was noted 42 days after the central administration of 6-hydroxydopamine.

DISCUSSION

The body temperature response to cobaltous chloride was species dependent. Hypothermia intensity and duration were greater in rats and mice than in hamsters.

Intracerebral cobalt injection did not produce hypothermia in hamsters but did produce body temperature depression in mice and rats, apparently through a central mechanism. The small drop in hamster body temperature produced by intraperitoneal injection was probably due to peripheral activity.

Since catecholamine, histamine, and opioid receptor stimulation within the CNS is associated with hypothermia in mice (1, 10–12), it seemed logical that cobalt might accomplish body temperature depression through its influence on one or more of these receptive sites. Intracerebral, but not systemic, phentolamine partially antagonized cobalt-induced hypothermia. It is possible, therefore, that cobalt hypothermia is mediated, in part, either through a direct influence on α-adrenergic receptors or through norepinephrine release within the CNS.

The absence of an intracerebral or intraperitoneal propranolol effect on cobalt hypothermia indicates that cobalt does not act through central or peripheral β-receptors.

The H_1 and H_2 receptor blocking agents diphenhydramine and cimetidine did not modify cobalt hypothermia when injected intracerebrally and intraventricularly, respectively. Cobalt hypothermia apparently is not mediated through activity upon central H_1 or H_2 receptors.

On the other hand, intraperitoneal diphenhydramine partially antagonized the temperature response to cobalt. Cobalt-induced hypothermia may be mediated, in part, peripherally either through histamine release or through a direct influence on H_1 receptors.

Intracerebral naloxone slightly enhanced cobalt-induced hypothermia, apparently through a central action.

The catecholamine-depleting agent 6-hydroxydopamine markedly reduced brain norepinephrine and dopamine levels (~59 and 72%, respectively) at 2 and 6 weeks following pretreatment (Table IV). However, 6-hydroxydopamine had no effect on cobalt hypothermia. It is possible, therefore, that cobalt produces hypothermia through mechanisms other than norepinephrine or dopamine release. Over a period of time, however, receptors for these amines may have become "supersensitive." Thus, less released norepinephrine or dopamine could have caused a more intense response.

Little information is available concerning brain dopamine depletion in mice following central 6-hydroxydopamine administration. Tabakoff and Ritzmann (13) reported that intracerebrally administered 6-hydroxydopamine (50 μg) depleted norepinephrine but had little effect on dopamine and serotonin levels. The present results show that intracerebral 6-hydroxydopamine (100 μg) depleted mouse brain dopamine.

Previous experiments in this laboratory showed that cobalt-induced hypothermia is partially attenuated by chlorpromazine pretreatment (7). Antagonism in the case of this phenothiazine was not mediated through a central anticholinergic action, since atropine, as well as nicotine, failed to achieve a similar blockade. In addition to anticholinergic activity,

Table IV—Intracerebral 6-Hydroxydopamine Effect on Norepinephrine and Dopamine Concentration in Mice Brains

Days after Injection[a]	Norepinephrine			Dopamine		
	Vehicle[b], μg/g ± SE	6-Hydroxydopamine, μg/g ± SE	Change, %	Vehicle, μg/g ± SE	6-Hydroxydopamine, μg/g ± SE	Change, %
14	0.308 ± 0.02	0.126 ± 0.03[c]	−59.09	0.287 ± 0.03	0.082 ± 0.03[c]	−71.43
42	0.336 ± 0.01	0.135 ± 0.03[c]	−59.82	0.298 ± 0.02	0.082 ± 0.02[c]	−72.48

[a] The mice brains (groups of six) were removed and assayed for catecholamine content 14 and 42 days following the intracerebral water or 6-hydroxydopamine injection (100 μg). [b] Aqueous ascorbic acid solution (0.5%) with pH adjusted to 5.5. [c] Compared to the appropriate vehicle, $p < 0.05$.

chlorpromazine possesses adrenolytic and antihistaminic qualities (14). Chlorpromazine may partially reverse the cobalt response through a central α-receptor blockade and/or peripheral antihistaminic activity.

Antifertility and Antiproteolytic Activity of Activated *N*-Carbobenzoxy Amino Acid Esters

I. H. HALL ˣ, J. H. DREW, Z. SAJADI, and L. J. LOEFFLER

Received July 31, 1978, from the *Division of Medicinal Chemistry, School of Pharmacy, University of North Carolina, Chapel Hill, NC 27514.* Accepted for publication November 16, 1978.

Abstract □ *N*-Carbobenzoxy L-phenylalanine, glycine, L-leucine, and L-proline derivatives, their vinyl esters, and their 1,2-dibromoethyl esters were tested for antifertility activity in mice. Intraperitoneal administration reduced the pregnancy percentage and the number of fetuses per litter. Intravaginal administration reduced the pregnancy percentage significantly, with *N*-carbobenzoxyglycine vinyl ester, *N*-carbobenzoxyglycine-1,2-dibromoethyl ester, *N*-carbobenzoxy-L-leucine-1,2-dibromoethyl ester, and *N*-carbobenzoxy-L-proline-1,2-dibromoethyl ester producing 100% inhibition at 10 mg/kg/day. Sperm enzyme hydrolysis of the nonspecific substrate azocasein was inhibited significantly by certain *N*-carbobenzoxy amino acid esters *in vitro*. Specific substrate *N*-benzoyl-L-arginine ethyl ester hydrolysis was also inhibited. Compounds that inhibited *N*-benzoyl-L-arginine ethyl ester hydrolysis also demonstrated *in vivo* intravaginal antifertility activity.

Keyphrases □ Carbobenzoxy amino acid esters—contraceptive activity, antiproteolytic activity, mice □ Contraceptives, potential—activated *N*-carbobenzoxy amino acid esters, mice □ Enzyme activity—effect of activated *N*-carbobenzoxy amino acid esters on sperm proteolysis, mice □ Sperm—enzymes, effect of *N*-carbobenzoxy amino acid esters, mice

Recently, numerous activated *N*-protected amino acid esters were synthesized as possible latent proteolytic inhibitors (1, 2). These agents resemble known trypsin and chymotrypsin inhibitors. Certain members of the series effectively inhibited *in vivo* cathepsin activity and *in vitro* chymotrypsin activity (3). Since proteolytic enzyme inhibitors block sperm acrosin activity, capacitation, and fertility, the effects of this series on reproduction were investigated.

EXPERIMENTAL

Chemistry—*N*-Carbobenzoxy-L-phenylalanine (I), *N*-carbobenzoxyglycine (II), *N*-carbobenzoxy-L-leucine (III), and *N*-carbobenzoxy-L-proline (IV) were prepared by the standard procedure (4) (Table I). The *N*-carbobenzoxy amino acids were converted to the corresponding vinyl esters V, VI, VII, and VIII by refluxing with vinyl acetate in the presence of palladium chloride and were purified by column chromatography. The vinyl esters were treated with bromine in chloroform to give the 1,2-dibromo esters IX, X, XI, and XII, which were purified by fractional crystallization or column chromatography (1, 2). *N*-α-Tosyl-L-lysylchloromethyl ketone (XIII), tosyl-L-phenylalanylchloromethyl ketone (XIV), carbobenzoxy-L-phenylalanine chloromethyl ketone (XV), 17-ethinyl estradiol (XVI), and diethylstilbestrol (XVII) were purchased[1].

Antifertility Screens—For 28 days, virgin CF_1 female mice (~28 g), which had been isolated for 4 weeks, were administered test compounds suspended in 1% carboxymethylcellulose at 10 mg/kg/day (0.2 ml) ip. On Day 10, female mice were exposed to male mice (two females per male) for the remainder of the experiment. Male mice were rotated once a week to assure fertility. On gestation Days 17–21, the females were sacrificed;

the viable fetuses, intrauterine deaths, and implantation sites were tabulated (5, 6). Viable fetuses were examined for teratogenic effects as outlined previously (7).

For intravaginal testing, the compounds were homogenized in 40% lactose or 6% carboxymethylcellulose and administered at 10 mg/kg/day (0.03–0.05 ml) for 28 days using a tuberculin syringe without the needle or a low dose (0.5-ml) insulin syringe with a 1–100-μl eppendorf pipet tip modified to fit the syringe. On Day 10 and all subsequent days, females were exposed to males for 1 hr and the previously described protocol was followed. Dose–response curves for intravaginal administration were obtained over the 0.5–10-mg/kg/day range. Activated *N*-protected amino acid ester toxicity (LD_{50}) in CF_1 male mice (~30 g) was determined (8).

Enzymatic Studies—The acrosin enzyme was isolated from the epididymides of four Sprague–Dawley rats (~250 g) or 10 CF_1 mice (~30 g). The epididymides were sliced in 0.25 *M* sucrose–0.001 *M* disodium (ethylenedinitrilo)tetraacetate, pH 6.5. The sperm suspension was filtered through two sterile cheesecloth layers to remove debris, centrifuged at 600×*g* for 15 min using a swinging bucket-type rotor head, and washed twice. The spermatozoa were resuspended in 20 ml of 0.25 *M* sucrose and frozen at −20° (9, 10). After freeze thawing, the tubes were vortexed for 30 sec and centrifuged at 1000×*g* for 15 min at 0°. The spermatozoa were resuspended, vortexed, and centrifuged again. The denuded spermatozoa were taken up in 5 ml of sucrose, and the pH was adjusted to 2.5 with hydrochloric acid. Acrosin was recovered in the supernate after centrifugation at 36,000×*g* for 15 min at 0° (9, 10).

Acrosin proteolytic enzymatic activity was determined (11). The incubation medium contained 0.7 ml of 0.1 *M* phosphate buffer, pH 7.6, and 0.3 ml of extracted crude rat acrosin, which were preincubated for 5 min at 30°. One milliliter of 2% azocasein and 1.5 μmoles of test compound in 0.2 ml of 40% lactose were added, and the mixture was incubated for 10 min at 30°. Tests were run in triplicate. The reaction was stopped with 5% trichloroacetic acid, and the mixture was centrifuged at 3500×*g* for 10 min. Absorbance of the trichloroacetic acid-soluble peptides produced by azocasein hydrolysis was measured at 366 nm. Enzymatic activity was calculated as the increase in absorbance of 0.730 unit/hr/mg of protein (11, 12).

N-Benzoyl-L-arginine ethyl ester hydrolysis was followed as described previously (12). Two milliliters of buffer, 0.3 ml of substrate, 0.1 ml of crude mouse acrosin, and 1.5 μmoles of test sample in 0.2 ml of 40% lactose

[a] All data in table have a $p = 0.001$ as calculated by the Student t test. [b] A 0.730-unit absorbance increase/hr/mg of protein. [c] A 0.328-unit absorbance increase/30 min/mg of protein.

were mixed, and the rise in absorbance at 253 nm was determined at 0 and 30 min. The control resulted in an absorbance increase of 0.328 unit/mg of protein (11, 12).

RESULTS

In the intraperitoneal antifertility screen, I, IV, VI, VIII, and X–XII produced greater than 50% pregnancy inhibition at 10 mg/kg/day compared to diethylstilbestrol and 17-ethinyl estradiol, which produced 100% pregnancy inhibition (Table II).

In the intravaginal antifertility screen, all tested compounds produced 75% or greater fertility inhibition. Compounds VI and X–XII caused 100% inhibition, as did the standard proteolytic inhibitors XIII and XIV. Dose-response curves were determined for VI, X, XI, and XIV at 0.5, 1, 5, and 10 mg/kg/day. Compounds VI, X, and XI caused 100% pregnancy inhibition at 1 mg/kg/day, whereas XIV required 10 mg/kg/day. No teratogenic effects were observed in the viable fetuses. Reabsorptions and intrauterine deaths were within normal limits (Table II).

Compounds I, V–VIII, and X–XV produced 90% rat acrosome proteolytic activity inhibition *in vitro*. Compounds III, VI, and X–XIII produced greater than 80% inhibition of *N*-benzoyl-L-arginine ethyl ester hydrolysis by mouse sperm acrosin *in vitro;* the remaining compounds produced greater than 50% inhibition (Table III).

DISCUSSION

Prior to fertilization, the sperm must undergo capacitation. This process involves sperm hydrolytic enzyme activation to permit penetration of the cervical mucus and external oval membranes as well as labilization of the external sperm membrane. Spermal acrosin (EC 3.4.21.10) has been isolated from various mammalian sperm (13) and apparently is responsible for zona pellucida penetration.

Acrosin, an endopeptidase that cleaves the carboxyl bond of arginyl and lysyl derivatives (13–15), can be inhibited by trypsin inhibitors (16–20). Endogenous acrosin inhibitors have been isolated from seminal plasma (21, 22), cervix uteri secretions (12), and pancreatic tissue (11). Normally, these inhibitors are removed as the sperm moves through the female reproductive tract, allowing the proteolytic enzyme to become active.

Screening demonstrated that the activated *N*-carbobenzoxy amino acid esters possessed antifertility activity in mice. Since the acrosome contains a number of proteolytic enzymes, any of which may hydrolyze azocasein, azocasein hydrolysis inhibition by the test compounds, chymotrypsin inhibitors (XIV and XV), and the trypsin inhibitor (XIII) was not surprising. Compounds VI and X–XII, which caused 100% pregnancy inhibition, also inhibited 80% of the hydrolysis of *N*-benzoyl-L-arginine ethyl ester, a substrate specific for acrosin and trypsin. Carbobenzoxy-activated esters also inhibit cathepsin (3). Thus, in addition to inhibiting sperm acrosin or trypsin, they may be reducing other proteolytic acrosomal enzymes. Since these *N*-carbobenzoxy-activated esters of L-proline, L-leucine, and glycine have no apparent teratogenic or toxic effects, they may have contraceptive potential.

Bioavailability and Dissolution Behavior of Trisulfapyrimidine Suspensions

L. K. MATHUR *§, J. M. JAFFE *¶×, R. I. POUST *, H. BARRY, III *, T. J. GOEHL *‖, V. P. SHAH ‡, and J. L. COLAIZZI *•

Received June 6, 1978, from the **Department of Pharmaceutics, School of Pharmacy, University of Pittsburgh, Pittsburgh, PA 15261*, and the ‡*Division of Biopharmaceutics, Food and Drug Administration, Washington, DC 20204.* Accepted for publication November 20, 1978. §Present address: Wyeth Laboratories, Philadelphia, PA 19101. ¶Present address: Sandoz Pharmaceuticals, East Hanover, NJ 07936. ‖Present address: Division of Biopharmaceutics, Food and Drug Administration, Washington, DC 20204. •Present address: College of Pharmacy, Rutgers—The State University, Piscataway, NJ 08854.

Abstract □ The bioavailability of seven commercial trisulfapyrimidine suspensions was studied in 14 adult male volunteers. Fifteen blood samples were collected over a 48-hr period following administration of a 1-g dose of each suspension. Serum was assayed for each component (sulfadiazine, sulfamerazine, and sulfamethazine) by high-pressure liquid chromatography. Analysis of variance indicated several significant differences among the seven commercial preparations with respect to C_{max}, T_{max}, and *AUC* for sulfadiazine, sulfamerazine, and sulfamethazine. The *in vitro* behavior of each suspension was then studied by the paddle method of the Food and Drug Administration. A 0.5-ml sample was introduced into 900 ml of hydrochloric acid (2.2×10^{-4} *M*) at 37° and dissolved using a paddle speed of 25 rpm. Samples withdrawn at 15 and 30 min were analyzed by high-pressure liquid chromatography, and the percent of sulfadiazine, sulfamerazine, and sulfamethazine was calculated. Significant correlation was obtained between an *in vivo* parameter (C_{max} for sulfadiazine) and an *in vitro* parameter (percent sulfadiazine dissolved in 30 min). Results indicate that this method is suitable for the *in vitro* screening of trisulfapyrimidine suspensions.

Keyphrases □ Bioavailability—trisulfapyrimidine suspensions, compared to *in vitro* dissolution behavior, various commercial preparations, screening methods □ Trisulfapyrimidine suspensions—bioavailability, compared to *in vitro* dissolution behavior, various commercial preparations, screening methods □ Dissolution, *in vitro*—trisulfapyrimidine suspensions, compared to bioavailability, various commercial preparations, screening methods □ Screening methods—trisulfapyrimidine suspensions, bioavailability compared to *in vitro* dissolution behavior, various commercial preparations

In vitro dissolution testing offers a convenient and inexpensive means of predicting bioavailability differences among different tablet and capsule formulations of the same drug. However, *in vitro* studies for suspension dosage forms have not been reported. Because suspensions exposed to aqueous fluids are similar to the disintegrated form of tablets and capsules, these dosage forms also may show dissolution rate-limited absorption. Thus, *in vitro* dissolution rate studies are needed on drugs commonly available on a multisource basis as suspensions. Drugs of this type include various sulfonamide derivatives.

Such studies also require *in vivo* testing of various brands of the same drug to establish comparative bioavailability. The results of *in vitro* testing can then be correlated with *in vivo* results and also can be used as a test of lot-to-lot variability of suspensions produced by the same manufacturer. With this type of information, *in vivo* testing can be eliminated, lot-to-lot specifications can be developed, and rapid screening procedures for new sulfa drug suspensions could become available.

Several reports (1–3) dealt with the dissolution behavior of drugs in suspensions. The bioavailability and dissolution rates of sulfa drugs also were investigated (4–11). Although bioavailability differences among various sulfonamide dosage forms were reported, attempts to correlate *in vitro* dissolution data with *in vivo* bioavailability data were unsuccessful (7–11).

The objective of this research was to establish a suitable dissolution test method for correlating *in vivo* comparative bioavailability data of different commercially available oral trisulfapyrimidine suspensions. This objective required investigation of both the *in vitro* and *in vivo* parameters. By using a specific high-pressure liquid chromatographic (HPLC) method, the behavior of each trisulfapyrimidine component was studied separately.

EXPERIMENTAL

Bioavailability Study—Prior to admission to the study, 14 healthy adult males were given a complete medical examination; a medical history was taken, and laboratory tests were performed, including complete blood and urine tests. Subjects were accepted for the study only if all laboratory test results were within the normal range accepted by the examining physician. The average age of the subjects was 23.4 years (range of 21.2–29.3 years), the mean weight was 77.6 kg (range of 61.2–86.2 kg), and the mean height was 182.5 cm (range of 175.3–193.0 cm). They could not take chronic medications of any kind for a week prior to the study and any drugs during the entire test period.

Subjects were informed of all study details, the potential hazards of participation, and the benefits. They were also informed that they could withdraw from the study at any time for any reason. Toward the latter stages of the study, one subject developed a rash. It probably appeared gradually and was noticed only after administration of the fifth dose of the drug. This subject was not allowed to receive the remaining two scheduled treatments (Weeks 6 and 7), and the missing values were estimated statistically by the method of Li (12).

The seven (A–G) commercial trisulfapyrimidine suspensions[1] were supplied by the Food and Drug Administration (FDA). To eliminate any possible residual effects, each subject received the seven different brands (A–G) in a complete crossover design. A 10-ml dose of each suspension (providing a total of 1.0 g of sulfa drug) was administered in the morning to the subjects after an overnight fast. The suspensions were shaken well, and 10-ml doses were withdrawn into glass syringes. The doses were then administered by emptying the contents of the syringe into the mouth. The syringe was rinsed once with 10 ml of water, which was also emptied into the subject's mouth. Drug dose delivery was accurate to within 0.1% of the stated volume.

Each subject was then instructed to drink an additional 110 ml of water. Subjects were allowed to eat lunch after abstaining from all food for 3 hr after drug administration. Doses were administered every alternate week, the time interval of 2 weeks being considered adequate for virtually complete drug elimination.

Preliminary pharmacokinetic data indicated that 15 blood samples were adequate to obtain a complete blood level profile. Samples were collected at 0, 0.167, 0.332, 0.50, 0.75, 1.0, 2.0, 3.0, 4.0, 6.0, 8.0, 12.0, 24.0, 30.0, and 48.0 hr. All blood samples were obtained by venipuncture with

6-ml silicone-coated vacuum tubes[2]. Samples were refrigerated and allowed to clot before being centrifuged at 3500 rpm. Serum was separated from the clot with the aid of a Pasteur pipet, transferred to a 4-ml glass vial, and frozen until assayed. Samples were assayed for sulfadiazine, sulfamerazine, and sulfamethazine by the HPLC procedure described here.

Dissolution Methodology—The dissolution of seven trisulfapyrimidine suspensions (A–G) was determined at 37° in 900 ml of a dissolution medium (Medium M) consisting of 899 ml of distilled water to which 1.0 ml of 0.2 *M* HCl was added. The medium pH was checked at the start and at the end of each experiment and was fairly constant at 3.4. A low stirring rate of 25 rpm was chosen since other work had demonstrated very rapid dissolution of some trisulfapyrimidine suspensions with higher stirring rates.

The apparatus consisted of a cylindrical 1000-ml round-bottom flask[3], which was secured in a multiple-spindle dissolution drive apparatus[4] and immersed in a controlled-temperature bath[5] maintained at 37°. Each spindle was provided with an independent clutch so that any spindle could be stopped without disturbing the others. The apparatus was capable of achieving speeds from 25 to 250 rpm ± 5% of the preset speed. The flask was equipped with a Plexiglas cover with a center port for entry of the paddle shaft and three side ports for sample introduction and removal. The paddle[6], consisting of a 7.6-cm polytef[7] blade attached to a polytef-coated, 0.95-cm stainless steel shaft, was positioned exactly 2.5 cm above the flask bottom.

The suspension (0.5 ml) was introduced carefully into the bottom of the flask using a 1-ml syringe with an attached 17.8-cm stainless steel needle[8]. Paddle rotation was engaged and controlled at a constant 25 rpm. Previous dissolution trials indicated that Products A–D dissolved at a much greater rate than did Products E and F, and that the dissolution of Product G was very slow. On the basis of the preliminary data, 15- and 30-min sampling times were selected.

Samples were withdrawn with 5-ml glass syringes through an attached 7.6-cm, 20-gauge stainless steel needle[9] secured to the flask cover and positioned to extend 6.8 cm into the dissolution medium. Thirty seconds prior to sample removal, the needle was cleared of any remaining fluid by withdrawing 3 ml of the medium and replacing it into the flask immediately. A 3-ml sample was then removed, filtered through a 13-mm, 0.2-μm membrane filter[10] using a Swinny adaptor, and analyzed by HPLC for sulfadiazine, sulfamerazine, and sulfamethazine. An equal volume of drug-free Medium M was replaced in the flask immediately after sample withdrawal.

After removal of the 30-min sample, the stirring rate was increased 10-fold to ensure complete dissolution of the suspension; a final 90-min sample was removed for analysis. Several additional samples were withdrawn after the 90-min sample in a few cases and were found to contain amounts of drug identical to the 90-min sample. The amount of drug dissolved at 15 and 30 min was expressed as a percentage of this last sample.

Analytical—All samples were analyzed for sulfadiazine, sulfamerazine, and sulfamethazine by an HPLC method developed in this laboratory (13). Samples of sulfadiazine[11], sulfamerazine[12], sulfamethazine[13], and sulfamethizole[14] were used as received. All other materials were reagent grade.

For the *in vivo* study, a stock solution of trisulfapyrimidines was prepared by dissolving 100 mg each of sulfadiazine, sulfamerazine, and sulfamethazine in 0.1 *M* NaOH and adjusting the volume to 50 ml in a volumetric flask. The internal standard stock solution was prepared by dissolving 50 mg of sulfamethizole in 1 *M* NaOH and adjusting to volume in a 100-ml volumetric flask. Serum standards were prepared by taking appropriate small volumes of the stock triple-sulfa solutions and adding these to control serum[15]. Ten microliters of internal standard solution was added to 0.2 ml of sample (standard or unknown) in a 1-ml vial[16] followed by 0.1 ml of a 14% trichloroacetic acid solution. The samples were mixed and centrifuged[17] at 2500 rpm for 15 min.

Five microliters of the clear supernate was injected onto the column[18]. Peak height ratios were calculated by dividing the peak height of the drug by the peak height of the internal standard. Calibration curves were constructed daily from results obtained from spiked control serum samples containing equal amounts of each trisulfapyrimidine in the 1–30-μg/ml range by plotting peak height ratios *versus* concentration of the individual sulfa drug.

For the *in vitro* study, a stock trisulfapyrimidine solution was prepared by dissolving 100 mg each of sulfadiazine, sulfamerazine, and sulfamethazine in 0.1 *N* NaOH and adjusting the volume to 100 ml in a volu-

metric flask. Standards (2, 4, 10, 20, and 30 μg/ml) were prepared by diluting appropriate small volumes of the stock solution with 0.1 *M* NaOH. The internal standard solution was prepared by dissolving 100 mg of acetaminophen[19] in hot water and adjusting the volume to 100 ml in a volumetric flask when cold. The solution prepared in this manner corresponded to a concentration of 1 mg/ml. Ten microliters of internal standard solution was added to 0.2 ml of filtered dissolution medium sample in a 5-ml culture tube. The sample was mixed, and 5 μl was injected onto the column[18]. Standards were treated similarly, calibration plots being constructed daily by plotting individual sulfa drug peak height ratios *versus* concentration.

Data Analysis—The peak serum concentration (C_{max}) and the time of the peak concentration (T_{max}) were obtained from the individual serum level *versus* time curves. The areas under the curve from 0 to 48 hr (AUC_0^{48}) were calculated by the trapezoidal rule and then corrected for the area beyond the last data point to obtain the total area (AUC_0^∞). The individual AUC_0^∞ values were then "normalized" (14) by multiplying the calculated AUC_0^∞ by the elimination rate constant (K_E) obtained from the terminal linear portion of the serum level *versus* time curves. These normalized areas were obtained for each of the three sulfa drugs in the suspensions: sulfadiazine (I), sulfamerazine (II), and sulfamethazine (III).

For each parameter, one-way analysis of variance was carried out by the computerized statistical program BMD 08V (15). A repeated-measures design permitted tests in the same subject of treatment interactions that would not be seen if each treatment were given to a different subject. The *F* ratios were compared with tabulated *F* ratios to determine the level of statistical significance (with seven treatments and 14 subjects, df = 6/76, taking into account two missing values, the minimum *F* value is 2.13 for $p < 0.05$ and 2.89 for $p < 0.01$). Any statistical differences found among treatments were compared further to determine differences between treatment pairs by Tukey's HSD tests (16).

Dissolution data were based on the amount of drug added to the dissolution medium. Thus, the concentration of the last sample (after complete dissolution of the suspension) represented 100%. Concentrations at all other sampling periods were expressed as a percentage of this last sample to obtain the percentage of drug dissolved in 15 and 30 min. For each sulfa drug, the means of 12 determinations for each trisulfapyrimidine suspension were used for calculation of the linear correlation coefficients (r) between these *in vitro* measurements and the *in vivo* data obtained from the subjects. Tables of r values were used for determining the statistical significance of the correlations (with df = 5 for the preparations, the minimum r values are 0.75 for $p < 0.05$ and 0.83 for $p < 0.02$).

RESULTS

For the 14 subjects, mean values of the *in vivo* parameters are summarized in Table I for sulfadiazine (I), sulfamerazine (II), and sulfamethazine (III), respectively, for each of five parameters.

Observed Maximum Serum Concentration (C_{max})—The analysis of variance indicated statistically significant ($p < 0.01$) differences among the seven treatments administered with respect to I–III. The *F* ratios were 21.68 for I, 17.62 for II, and 5.85 for III. Tukey's HSD tests indicated that Product G was significantly ($p < 0.01$) different from all the other products and produced a much lower C_{max} value for I and II but not for III (Fig. 1). With respect to III, significantly low C_{max} values were observed with Product D.

Time for Maximum Serum Concentration (T_{max})—The analysis of variance indicated statistically significant ($p < 0.01$) differences among the seven treatments administered with respect to I–III. The *F* ratios were 3.85 for I, 6.80 for II, and 8.06 for III. Tukey's HSD tests indicated that the T_{max} values were significantly higher with Products E and F for I, with Product G for II, and with Product E for III.

Areas under the Curve—The analysis of variance of normalized areas indicated a significant ($p < 0.01$) difference among the seven treatments only with respect to I (F = 12.53). Tukey's HSD tests applied to I indicated significantly low values for Products G, D, E, and F.

***In Vitro* Study**—The mean (±*SD*) percentage of I–III dissolved in 15 and 30 min is shown in Table II for the seven trisulfapyrimidine suspensions. Analysis of variance of the data indicated large differences among the seven products with respect to I–III. Tukey's HSD tests indicated statistically significant ($p < 0.01$) differences between most pairs of suspensions.

***In Vivo–In Vitro* Correlation**—For the three drugs, each *in vivo* parameter was correlated with the percent of drug dissolved in 15 and 30 min for the seven suspensions. Significant values of the linear correlation coefficient were observed between: (*a*) percent of I dissolved in 30 min and C_{max} ($r = 0.86, p < 0.02$), (*b*) percent of I dissolved in 15 min and C_{max} ($r = 0.80, p < 0.05$), (*c*) percent of II dissolved in 30 min and C_{max} ($r = 0.76, p < 0.05$), (*d*) percent of II dissolved in 30 min and T_{max} ($r = -0.85, p < 0.02$), and (*e*) percent of II dissolved in 15 min and T_{max} ($r = -0.83, p < 0.05$).

DISCUSSION

Significant bioavailability differences among commercial trisulfapyrimidine suspensions were revealed by differences in the rate and extent of absorption of the individual suspension components. A number of differences were observed for C_{max} and T_{max}, but only a few were found for *AUC*. Thus, while the relative trisulfapyrimidine suspension bio-

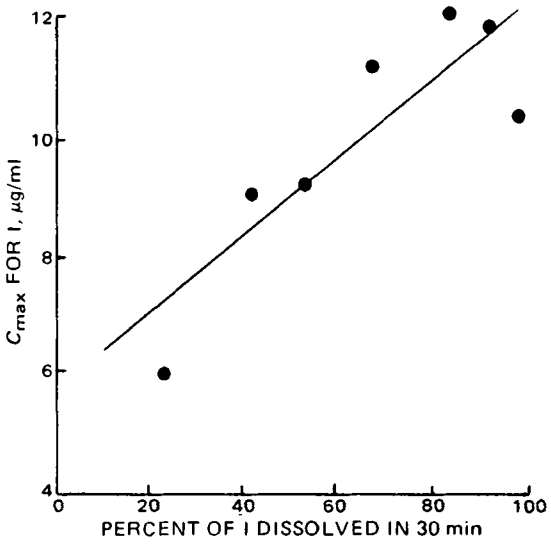

Figure 2—*Relationship between the* in vivo *measure of* C_{max} *and the* in vitro *measure of percentage of sulfadiazine (I) for the seven commercial trisulfapyrimidine suspensions, showing the regression line for the correlation coefficient of* +0.86 ($p < 0.02$).

availability was fairly uniform in terms of the extent of absorption, the absorption rate as shown by C_{max} and T_{max} was more variable.

Of all the statistically significant differences observed for the comparative bioavailability (bioequivalency) of the trisulfapyrimidine suspensions, the largest F ratio was in the C_{max} parameter for I. Product G showed the lowest mean C_{max} value for I. Since significant differences in the AUC values also were observed only for I, the dissolution characteristics of I were the most closely monitored and the variables in the dissolution study were controlled in such a way as to correspond to these *in vivo* study results.

With the FDA paddle method, the dissolution medium (pH 3.4) that was most suitable for the trisulfapyrimidine suspensions contained 2.2×10^{-4} M HCl with no added salts at a 37° temperature and a 25-rpm stirring rate. The dissolution data indicated large significant variations among the products. However, the absence of statistically significant ($p < 0.05$) differences among the 12 determinations on any one product indicated that the dissolution method was very reproducible.

Of all the significant correlations for C_{max} or T_{max} with *in vitro* parameters, the greatest r value was between C_{max} for I and the percent of I dissolved in 30 min (Fig. 2). The greatest bioavailability differences among the products also were observed for the C_{max} parameter for I. The paddle dissolution method thus appeared to be a very strong indicator of the *in vivo* situation and suitable to set standards for the I and II components of trisulfapyrimidine suspensions in terms of the percent of drug dissolved in 30 min.

A suitable guideline for determination of a minimal dissolution standard might be the mean percentage of drug (I or II) dissolved in 30 min for Products A–D. These values were 85% for I and 87% for II. While dissolution standards could be set for I and II, it was not possible to set a dissolution standard for III since a suitable *in vivo–in vitro* correlation was not obtained for this component. However, the establishment of actual standards that require minimal performance of only one or two components of a multicomponent product would be a matter to be decided upon by the appropriate regulatory agency.

Additional work carried out in these laboratories suggests that simple UV measurements for total trisulfapyrimidines could be used by determining dissolution rate profiles of the suspensions. The possibility of correlating *in vitro* data with *in vivo* parameters is being explored.

High-Performance Liquid Chromatographic Assay for Imipramine, Desipramine, and Their 2-Hydroxylated Metabolites

TAMARA A. SUTFIN and WILLIAM J. JUSKO ×

Received August 28, 1978, from the *Clinical Pharmacokinetics Laboratory, Department of Pharmaceutics, School of Pharmacy, State University of New York at Buffalo, and the Millard Fillmore Hospital, Buffalo, NY 14209.* Accepted for publication November 20, 1978.

Abstract □ A high-performance liquid chromatographic method is presented for the simultaneous determination of imipramine, desipramine, and their 2-hydroxylated metabolites in plasma. The method involves a simple plasma extraction at basic pH with organic solvent, chromatography on a silica gel column, and fluorescence detection. Correlation with a GLC–mass spectrometric method for imipramine and desipramine is illustrated. The method can detect 1 ng of each component/ml of plasma, sufficient sensitivity for pharmacokinetic studies.

Keyphrases □ High-performance liquid chromatography—analysis, imipramine, desipramine, 2-hydroxylated metabolites in plasma □ Desipramine—analysis in plasma, high-performance liquid chromatography □ Imipramine—analysis in plasma, high-performance liquid chromatography, metabolites □ Antidepressants, tricyclic—imipramine, desipramine, high-performance liquid chromatographic analysis in plasma

Clinical monitoring of plasma imipramine is complicated by biotransformation of the tricyclic antidepressant into another therapeutic entity, desipramine, and by their low plasma concentrations (1). Recent studies also identified hydroxylated metabolites in the brain following acute intoxication (2) and demonstrated biological activity of the 2-hydroxy metabolites of both compounds (3–7). An appropriate assay is needed to assess the potential importance of these metabolites in psychopharmacological and pharmacokinetic studies.

Several methods for tricyclic antidepressant analysis by TLC (8–10), GLC (11, 12), and high-pressure liquid chromatography (HPLC) (13–16) have been published. However, few were applied to imipramine and desipramine determination in biological specimens, and none dealt with the 2-hydroxy metabolites. The imipramine and desipramine assays required either sophisticated instrumentation not readily available or multistep extraction and/or derivatization. The sensitivity achieved generally was not adequate for pharmacokinetic studies, even when large samples were used.

An HPLC method for the simultaneous determination of plasma imipramine, 2-hydroxyimipramine, desipramine, and 2-hydroxydesipramine was developed. The procedure involves a simple extraction followed by separation of all four components and an internal standard in a single injection. High fluorescence sensitivity permits detection of 1 ng of each drug and metabolite in 1 ml of plasma.

EXPERIMENTAL

Reagents—Acetonitrile[1], ammonium hydroxide[2], *n*-butyl alcohol[1], hexane[1], and methanol[1] were spectroanalytical grade.

Equipment—A high-performance liquid chromatograph[3] with a syringe-loading sample injector[4], a 10-mv recorder[5], and a fluorescence detector[6] were used. An excitation wavelength of 240 nm and a 370-nm emission filter gave optimum fluorescence under the assay conditions. Detector range settings of 0.05–0.2 μamp were sufficient for most analyses; limits of the range settings were 0.01–1.0 μamp. Chromatography was done on a 0.46 × 25-cm, stainless steel column packed with 5-μm (particle diameter) silica B/5[7].

Assay Standards—Stock methanol solutions of desipramine hydrochloride[8] (113 mg/100 ml), imipramine hydrochloride[9] (113 mg/100 ml), 2-hydroxydesipramine free base[10] (10 mg/10 ml), and 2-hydroxyimipramine free base[10] (10 mg/10 ml) were prepared.

Plasma standards were prepared by spiking drug-free plasma with the methanol solutions to give final concentrations of 5–500 ng of imipramine and desipramine/ml and 5–150 ng of the 2-hydroxy metabolites/ml. The internal standard was 200 μg of *N*-desmethylclomipramine hydrochloride[9]/10 ml of methanol.

Extraction—To 1 ml of plasma standard or unknown, 50 μl of internal standard solution and 300 μl of ammonium hydroxide were added in polypropylene test tubes. The mixtures were extracted with 1 ml of 20% *n*-butyl alcohol in hexane for 15 min on a reciprocating shaker. After centrifugation, the upper organic layers were transferred to clean polypropylene tubes and evaporated to dryness at ambient temperature under nitrogen. Each extract was reconstituted just prior to chromatography with 100 μl of methanol, and 50 μl was injected.

Chromatography—All chromatography was done at ambient temperature. The mobile phase was methanol–acetonitrile (1:5) plus am-

monium hydroxide (4 ml/liter). The flow rate was 1.8 ml/min (~1100 psig).

Quantitation—Peak height ratios of the drug or metabolite to the internal standard were plotted against concentration to obtain standard calibration curves for each compound. Plasma standards were included with each assay.

RESULTS AND DISCUSSION

Imipramine, desipramine, and their 2-hydroxy metabolites were separated and eluted in ~21 min (Fig. 1*b*). Blank plasma extracts yielded no interference from endogenous plasma components (Fig. 1*a*).

Detector response was linear to plasma imipramine and desipramine concentrations of 5–500 ng/ml and to plasma 2-hydroxyimipramine and 2-hydroxydesipramine concentrations of at least 5–150 ng/ml. All four lines passed through the origin. At least 1 ng of each component/ml could be detected by injecting the entire 1-ml plasma extract.

Standard curve reproducibility for 1 month is indicated by Table I. The mean peak height ratio variation coefficients were approximately 5–10% for each compound. Plasma with added imipramine and desipramine stored in polypropylene tubes at −4° was stable for at least 3 months. Similarly stored clinical serum specimens also were stable for at least 3 months.

Drug and metabolite recoveries from plasma were estimated by comparing the peak heights from spiked plasma extracts directly with those of methanol solutions. The entire plasma extract was injected, and the methanol solution concentrations were calculated to permit injections of the same volumes. Table II shows reproducible recoveries of each compound over the concentration ranges studied and within-run variability of <5%. Studies of different concentrations were performed on separate days.

Several drugs were tested chromatographically in methanol solutions for use as internal standards and for interference (Table III). Drugs with relative retention times within 10% of the relative retention time of the experimental components could interfere with the assay. Therefore, complete medication histories are recommended before clinical or pharmacokinetic studies.

Two other imipramine and desipramine metabolites, 2-hydroxyiminodibenzyl and didesmethylimipramine, were chromatographed; only the former metabolite was incompletely separated. Previous evidence suggests that this metabolite is present only in small amounts (17) and that its potential interference is insignificant.

Other drugs that did not give fluorescent peaks within the analysis time were nortriptyline, protriptyline, diazepam, flurazepam, clorazepate, chlordiazepoxide, and scopolamine.

N-Desmethylclomipramine was chosen as the internal standard because it eluted near, but was completely separated from, the experimental components and did not add to total analysis time. It is reproducibly extracted from plasma by the method presented but is unlikely to be present in specimens from patients receiving other tricyclics. Figure 2*a* illustrates a chromatogram of a patient specimen with added internal standard. The patient was receiving a daily (150 mg) imipramine main-

Table III—Relative Chromatographed Drug Retention Times

Drug	Relative Retention Time

2-Hydroxydesipramine	2.90

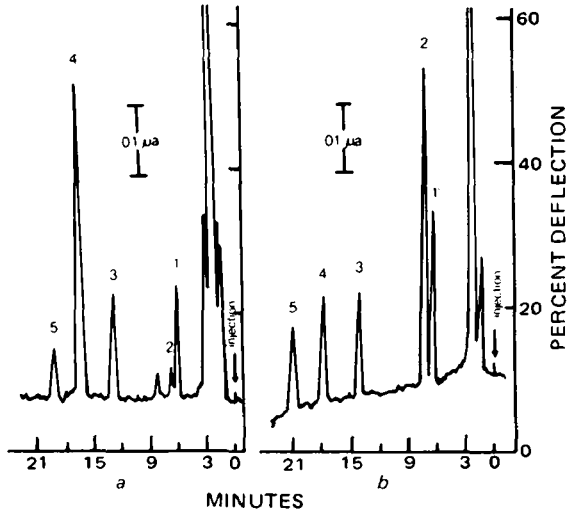

Figure 2—(a) *Chromatogram of the extract of 1 ml of serum from a patient receiving imipramine. The extract was reconstituted with 100 μl of methanol; 50 μl was injected. Concentrations measured were: imipramine (1), 32 ng/ml; 2-hydroxyimipramine (2), 5 ng/ml; internal standard (3); desipramine (4), 134 ng/ml; and 2-hydroxydesipramine (5), 29 ng/ml.* (b) *Chromatogram of a 1-ml blank plasma extract spiked with 50 ng/ml each of the drugs and metabolites. The extract was reconstituted with 100 μl of methanol; 50 μl was injected. Peak identification is the same as in Fig.* 2a.

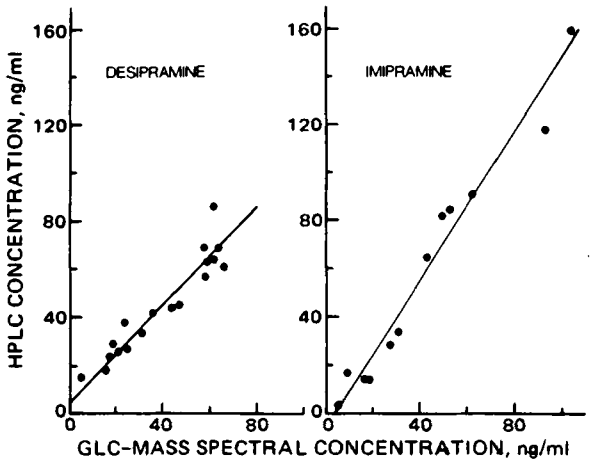

Figure 3—*Correlation between HPLC and GLC–mass spectral methods for plasma imipramine and desipramine analysis. For desipramine, the slope = 1.01, the intercept = 4.7, and the correlation coefficient = 0.943. For imipramine, the slope = 1.55, the intercept = −7.2, and the correlation coefficient = 0.960.*

tenance dose. Figure 2*b* shows a chromatogram of a plasma standard containing 50 ng/ml of each drug and metabolite and added internal standard. One milliliter each of the plasma standard and patient sample were extracted, and one-half of the extract was injected according to the procedure.

Eighteen plasma specimens from seven patients participating in an NIMH study (5) and receiving imipramine or desipramine were assayed by the HPLC method and a GLC–mass spectrometric method (18) (Fig. 3). The two assays showed excellent correlation, with a slope of nearly unity (1.01) for desipramine. The HPLC assay yielded higher results than the GLC–mass spectral method for imipramine. Imipramine and desipramine are stable at least 3 months in plasma stored at −4°. The NIMH samples were 6–15 months old at the time of HPLC analysis; therefore, interference in the fluorescence assay due to some unidentified degradation component(s) may explain the discrepancy between the methods for imipramine. Further comparison studies with fresh patient samples and spiked plasma are in progress. Data for the 2-hydroxy metabolites quantitated by GLC–mass spectra were not available for comparison.

Chemistry of 8-Chloroberberine

JEROME L. MONIOT, TINA M. KRAVETZ, ABD EL RAHMAN H. ABD EL RAHMAN, and MAURICE SHAMMA ˣ

Received June 1, 1978, from the *Department of Chemistry, Pennsylvania State University, University Park, PA 16802.* Accepted for publication November 21, 1978.

Abstract □ 8-Chloroberberine (V), obtained by treatment of oxyberberine (I) with phosphorus oxychloride, is a reactive intermediate. Treatment with ammonia, methylamine, *n*-propylamine, aniline, and *p*-toluidine furnished the 8-berberinylidene derivatives IV and VII–X. Reaction of V with malononitrile, ethyl acetoacetate, and ethyl malonate anions yielded the 8-berberinylidene derivatives XII–XIV. Acid hydrolysis of XIV gave 8-berberinylacetic acid (XV) whose reduction provided 8-canadinylacetic acid (XVI). Grignard reagents react readily with V. Methylmagnesium iodide, ethylmagnesium iodide, and benzylmagnesium iodide led to 8,8-dimethyldihydroberberine (XVII), 8,8-diethyldihydroberberine (XIX), and the benzyl derivative XX, respectively. Sodium borohydride reduction of XX gave rise to 8-benzylcanadine (XXI).

Chemistry of 8-Chloroberberine

JEROME L. MONIOT, TINA M. KRAVETZ, ABD EL RAHMAN H. ABD EL RAHMAN, and MAURICE SHAMMA ˣ

Received June 1, 1978, from the *Department of Chemistry, Pennsylvania State University, University Park, PA 16802.* Accepted for publication November 21, 1978.

Abstract □ 8-Chloroberberine (V), obtained by treatment of oxyberberine (I) with phosphorus oxychloride, is a reactive intermediate. Treatment with ammonia, methylamine, *n*-propylamine, aniline, and *p*-toluidine furnished the 8-berberinylidene derivatives IV and VII–X. Reaction of V with malononitrile, ethyl acetoacetate, and ethyl malonate anions yielded the 8-berberinylidene derivatives XII–XIV. Acid hydrolysis of XIV gave 8-berberinylacetic acid (XV) whose reduction provided 8-canadinylacetic acid (XVI). Grignard reagents react readily with V. Methylmagnesium iodide, ethylmagnesium iodide, and benzylmagnesium iodide led to 8,8-dimethyldihydroberberine (XVII), 8,8-diethyldihydroberberine (XIX), and the benzyl derivative XX, respectively. Sodium borohydride reduction of XX gave rise to 8-benzylcanadine (XXI).

Keyphrases □ Chloroberberine—synthesis, derivatives □ Protoberberine salts—chloroberberine, synthesis, derivatives □ Antibacterials—chloroberberine, synthesis, derivatives □ Antiarrhythmics—chloroberberine, synthesis, derivatives □ Tranquilizers—chloroberberine, synthesis, derivatives

Protoberberine salts and tetrahydroprotoberberine bases have wide pharmacological potency including tranquilizing, antimicrobial, antifungal, hypotensive, antiulcer, uterine, antiarrhythmic, neuroleptic, and antipsychotic effects. Protoberberine salt pharmacology was reviewed recently (1, 2).

The present report describes the structure of 8-chloroberberine (V), a compound characterized partially by

© 1979, American Pharmaceutical Association

previous researchers (3). 8-Chloroberberine was then used as an intermediate in the preparation of new berberine derivatives.

DISCUSSION

Initial investigations of phosphorus oxychloride–oxyberberine (I) reaction products identified oxyberberrubine (II) and a reactive chlorinated derivative, tentatively assigned Structure III (3). Treatment of the chlorinated derivative with ammonia yielded iminoberberine (IV), characterized as its hydrochloride salt. When iminoberberine was subjected to aqueous alkali, hydrolysis to I took place (3).

Refluxing I with phosphorus oxychloride produced the stable but moisture-sensitive orange crystalline salt 8-chloroberberine (V), which readily hydrolyzed to I in water, ethanol, or aqueous alkali. The V high-resolution mass spectrum contained the molecular ion *m/e* 370 for $C_{20}H_{17}NO_4Cl$. The berberine and V trifluoroacetic acid PMR spectra were nearly identical, the major difference being the absence in V of the proton singlet at δ10.1 assigned to H-8 in the spectrum of berberine chloride. Thus, the phosphorus oxychloride product from I is the C-8 monochloro berberine analog V rather than the dichloro compound III. The high V reactivity toward oxygen nucleophiles was extended to other entering groups including primary amines, carbanions, and Grignard reagents.

Reaction of V with anhydrous ammonia produced Perkin's yellow "iminoberberine" (IV), here designated 8-berberinylideneimine. Acetylation of this material produced the yellow *N*-acetyl amide VI. Mild VI hydrolysis with sodium bicarbonate regenerated IV.

Similarly, V reacted with methylamine, *n*-propylamine, aniline, and *p*-toluidine to give the 8-berberinylidene derivatives VII–X. As partial verification of these results, IV methylation with methyl iodide produced 8-berberinylidenemethylimine (VII), identical to that obtained by direct treatment of V with methylamine.

Imine bases VII–X hydrolysis with sodium hydroxide regenerated I while reduction of the bases with sodium borohydride in ethanol supplied canadine (XI) (4).

Since V reacts readily with basic nitrogen nucleophiles, V reaction with carbanions was also investigated. Treatment of V with the malononitrile anion furnished the dark-orange 8-berberinylidenemalononitrile (XII). Reaction of V with ethyl acetoacetate and ethyl malonate anions yielded the 8-berberinylidene derivatives XIII and XIV, respectively. Acid hydrolysis of XIV was accompanied by decarboxylation and produced the orange 8-berberinylacetic acid (XV). Reduction of this quaternary salt with sodium borohydride in ethanol generated 8-canadinylacetic acid (XVI).

Another aspect of V chemistry is its reactivity toward Grignard reagents. With methylmagnesium iodide, a good yield of 8,8-dimethyldihydroberberine (XVII) was obtained; with ethylmagnesium iodide, 8,8-diethyldihydroberberine (XVIII) was produced. The latter compound was reduced with sodium borohydride to 8,8-diethylcanadine (XIX). Monoalkylation of V with the bulkier benzylmagnesium bromide gave the benzyl derivative XX whose borohydride reduction product was identical with 8-benzylcanadine (XXI) (5).

Clearly, the readily available V is a useful synthetic intermediate for the generation of 8-substituted berberine and canadine derivatives.

EXPERIMENTAL[1]

8-Chloroberberine (V)—An oxyberberine (I) slurry (5 g, 14.2 mmoles) in phosphorus oxychloride (10 ml) was refluxed for 2 hr. After cooling, the orange-red crystalline residue was collected, washed with chloroform and then ether, and dried *in vacuo* to yield 4.5 g (85%) of V as orange-red crystals, mp >300°; PMR (trifluoroacetic acid): δ 3.30 (t, 2H, J = 7 Hz, H-5), 4.23 (s, 6H, 2 OCH_3), 5.20 (t, 2H, J = 7 Hz, H-6), 6.13 (s, 2H, OCH_2O), 6.97 (s, 1H, H-4), 7.47 (s, 1H, H-1), 8.10 (s, 2H, H-11,12), and 8.47 (s, 1H, H-13); mass spectrum: *m/e* M^+ 370 (10), 355 (10), and 335 (100); high-resolution mass spectrum: calc. for $C_{20}H_{17}ClNO_4$, 370.0845; found *m/e* 370.0876.

Compound V Hydrolysis—Compound V was decolorized rapidly with water, ethanol, or aqueous alkali and gave I exclusively.

8-Berberinylideneimine (IV)—Anhydrous ammonia gas was bubbled through a V slurry (1 g, 2.7 mmoles) in benzene (20 ml) for 1 hr. Following solvent removal, the residue was washed with water and partitioned between chloroform and aqueous sodium bicarbonate. The organic layer was dried, and the solvent was evaporated to afford yellow needles (0.9 g, 95%), which were recrystallized from chloroform, mp >300° [lit. (2) mp >280°]; IR: $\nu_{max}^{CHCl_3}$ 1640 and 3300 cm^{-1}; UV: $\lambda_{max}^{ethanol}$ 282 (log ε 3.48), 358 (3.76), 377 sh (3.61), and 400 (3.41) nm; UV: $\lambda_{max}^{ethanol,H^+}$ 233 (log ε 4.05), 253 sh (3.77), 343 (3.83), 386 (3.48), and 403 sh (3.40) nm; PMR ($CDCl_3$): δ 2.87 (t, 2H, J = 7 Hz, H-5), 3.88 (s, 3H, OCH_3), 3.92 (s, 3H, OCH_3), 4.23 (t, 2H, H-6), 5.93 (s, 2H, OCH_2O), 6.12 (s, 1H, H-13), 6.63 (s, 1H, H-4), 7.05 (s, 2H, H-11,12), and 7.13 (s, 1H, H-1); PMR (trifluoroacetic acid): δ 3.17 (t, 2H, J = 7 Hz, H-5), 4.14 (s, 3H, OCH_3), 4.27 (s, 3H, OCH_3), 4.35 (t, 2H, H-6), 6.10 (s, 2H, OCH_2O), 5.85 (br s, 3H, NH), 6.91 (s, 1H, H-4), 7.32 (s, 1H, H-1), 7.50 (s, 1H, H-13), and 7.80 (s, 2H, H-11, 12); mass spectrum: *m/e* M^+ 350 (100), 335 (80), 321 (20), and 293 (50).

Sodium borohydride in ethanol reduction of IV provided (±)-canadine (XI), mp 172–173° [lit. (4) mp 170–171°], quantitatively.

The IV·HCl had a melting point of 165–166° (methanol).

Anal.—Calc. for $C_{20}H_{18}N_2O_4$·HCl: C, 62.24; H, 4.93. Found: C, 61.98; H, 5.05.

***N*-Acetyl-8-berberinylideneimine (VI)**—A slurry of IV (1 g, 2.8 mmoles) in pyridine (10 ml) and acetic anhydride (5 ml) was stirred overnight. After solvent removal, the residue crystallized from methanol as tan needles (0.84 g, 2.1 mmoles, 75%), mp 226–228°; IR: ν_{max}^{KBr} 1655 cm^{-1}; UV: $\lambda_{max}^{ethanol}$ 263 (log ε 4.22), 348 (4.23), 408 (3.68), and 420 (3.69) nm; PMR (trifluoroacetic acid): δ 2.70 (s, 3H, CH_3CO), 3.18 (t, 2H, J = 7 Hz, H-5),

[1] PMR spectra were obtained at 60 MHz in deuterochloroform, unless specified otherwise, with tetramethylsilane as the internal standard. Mass spectra were run at 70 ev. TLC utilized Merck 254 silica gel plates. Microanalyses were done at Midwest Microlab, Indianapolis, Ind.

4.24 (s, 3H, OCH_3), 4.37 (s, 3H, OCH_3), 4.72 (t, 2H, J = 7 Hz, H-6), 6.18 (s, 2H, OCH_2O), 6.94 (s, 1H, ring A aromatic H), 7.49 (s, 1H, ring A aromatic H), 8.40 (s, 1H, H-13), and 8.08 (s, 2H, ring D aromatic H); mass spectrum: m/e M^+ 392 (5), 377 (5), 361 (100), 352 (15), 335 (17), 320 (10), 305 (5), and 291 (25); high-resolution mass spectrum: calc. for $C_{22}H_{20}N_2O_5$, 392.1373; found m/e 392.1387.

Compound VI hydrolysis with aqueous sodium bicarbonate and chloroform extraction produced IV in near-quantitative yield.

Preparations of 8-Berberinylidenemethylamine (VII), 8-Berberinylidene-*n*-propylamine (VIII), 8-Berberinylideneaniline (IX), and 8-Berberinylidene-*p*-toluidine (X)—The anhydrous amine, in excess, was added to a stirred V benzene slurry, and the mixture was stirred for 1 hr. After dilution with ether, dry hydrogen chloride gas was added until precipitation was complete. The collected solid was washed with water and dissolved in chloroform, and the solution was dried. Solvent evaporation was followed by crystallization. The yields were around 80%.

Compound VII, $C_{21}H_{20}N_2O_4$, was obtained as light-yellow needles, mp 122° (methanol); IR: $\nu_{max}^{CHCl_3}$ 1570 and 1640 cm^{-1}; UV: $\lambda_{max}^{ethanol}$ 283 (log ϵ 3.83) and 360 (4.16) nm; UV: $\lambda_{max}^{ethanol,\ H^+}$ 253 (log ϵ 4.18), 340 (4.25), and 395 (3.78) nm; PMR (trifluoroacetic acid): δ 3.15 (t, 2H, J = 7, H-5), 3.51 (s, 3H, NCH_3), 4.18 (s, 3H, OCH_3), 4.30 (s, 3H, OCH_3), 4.54 (t, 2H, J = 7 Hz, H-6), 61.0 (s, 2H, OCH_2O), 6.91 (s, 1H, aromatic H), 7.32 (s, 1H, aromatic H), 7.50 (s, 1H, aromatic H), and 7.80 (s, 2H, H-11,12); mass spectrum: m/e M^+ 364 (30), 350 (90), 335 (100), and 291 (10); high-resolution mass spectrum: calc. for $C_{21}H_{20}N_2O_4$, 364.1419; found m/e 364.1446.

The VII·HCl salt had a melting point of 187–189° (methanol).

Compound VIII, $C_{23}H_{24}N_2O_4$, was obtained as light-yellow needles, mp 170–172° (ether); UV: $\lambda_{max}^{ethanol}$ 283 (log ϵ 4.09) and 363 (4.22) nm; UV: $\lambda_{max}^{ethanol,\ H^+}$ 254 (log ϵ 4.36), 340 (4.42), and 397 (3.90) nm; NMR (trifluoroacetic acid): δ 1.13 (t, 3H, J = 7 Hz, $CH_3CH_2CH_2$), 1.90 (m, 2H, $CH_3CH_2CH_2$), 3.10 (t, 2H, J = 7 Hz, H-5), 3.72 (m, 2H, $CH_3CH_2CH_2$), 4.17 (s, 3H, OCH_3), 4.28 (s, 3H, OCH_3), 4.34 (t, 2H, J = 7 Hz, H-6), 6.17 (s, 2H, OCH_2O), 6.97 (s, 1H, H-4), 7.32 (s, 1H, H-13), 7.50 (s, 1H, H-1), and 7.80 (s, 2H, H-11,12); mass spectrum: m/e M^+ 392 (100), 378 (70), 363 (80), 361 (50), 347 (60), 335 (30), 334 (30), 333 (30), 320 (25), 306 (20), 281 (25), and 207 (50).

The VIII·HCl had a melting point of 219–220° (methanol).

Anal.—Calc. for $C_{23}H_{24}N_2O_4$·HCl: C, 64.37; H, 5.88. Found: C, 63.98; H, 6.07.

Compound IX, $C_{26}H_{22}N_2O_4$, was obtained as yellow needles, mp 167–169° (methanol–ether); UV: $\lambda_{max}^{ethanol}$ 285 (log ϵ 3.95), 328 (3.75), and 370 (3.90) nm; UV: $\lambda_{max}^{ethanol,\ H^+}$ 258 (log ϵ 4.06), 343 (4.06), 395 sh (3.48), and 422 (3.54) nm; mass spectrum: m/e M^+ 426 (100), 411 (40), 395 (30), 335 (30), and 321 (25).

The IX·HCl had a melting point of 186–187° (methanol).

Anal.—Calc. for $C_{26}H_{22}N_2O_4$·HCl: C, 67.42; H, 5.01. Found: C, 67.17; H, 5.29.

Compound X, $C_{27}H_{24}N_2O_4$, hydrochloride salt was obtained as gold prisms, mp 160–162° (methanol–water–ether); UV: $\lambda_{max}^{ethanol,\ H^+}$ 236 (log ϵ 4.50), 257 (4.40), 342 (4.38), and 420 (3.90) nm; mass spectrum (free base): m/e M^+ 440 (40), 425 (10), 335 (5), 107 (100), and 106 (98); high-resolution mass spectrum (free base): calc. for $C_{27}H_{24}N_2O_4$, 440.1731; found m/e 440.1749.

Anal.—Calc. for $C_{27}H_{24}N_2O_4$·HCl·H_2O: C, 65.49; H, 5.50. Found: C, 65.27; H, 5.66.

Conversion of IV to VII—A solution of IV (1 g, 2.85 mmoles) in methyl iodide (3 ml) and acetonitrile (10 ml) was refluxed for 0.5 hr and cooled, and the solvent was evaporated. The residue, after basification with aqueous sodium bicarbonate and chloroform extraction, provided VII in high yield.

8-Berberinylidenemalononitrile (XII)—Malononitrile (0.6 g, 9.1 mmoles) was added to dry tetrahydrofuran (20 ml), followed by sodium hydride (0.2 g, 8.3 mmoles). Following gas evolution, V (1.5 g, 4.08 mmoles) was added, and the mixture was stirred for 30 min. The red mixture was diluted with an equal volume of ether and filtered. The solid was slurried in chloroform and filtered, and the filtrate crystallized upon addition of ether. Recrystallization from methanol afforded 1.1 g (2.75 mmoles, 68%) of XII as reddish-orange crystals, mp 276–277°; IR: $\nu_{max}^{CHCl_3}$ 2102 cm^{-1}; UV: $\lambda_{max}^{ethanol}$ 255 sh (log ϵ 3.97), 278 (3.85), 345 (3.84), 368 sh (3.73), and 466 (3.51) nm; PMR (trifluoroacetic acid): δ 3.25 (t, 2H, J = 7 Hz, H-5), 4.90 (t, 2H, J = 7 Hz, H-6), 4.17 (s, 3H, OCH_3), 4.28 (s, 3H, OCH_3), 6.23 (s, 2H, OCH_2O), 6.30 [s, 1H, $HC(CN)_2$], 7.06 (s, 1H, aromatic H), 7.47 (s, 1H, aromatic H), 7.87 (s, 1H, aromatic H), and 8.06 (s, 2H, H-11,12); mass spectrum: m/e M^+ 399 (100), 384 (20), 359 (60), 334 (40), and 322 (40); high-resolution mass spectrum: calc. for $C_{23}H_{17}N_3O_4$, 399.1218; found m/e 399.1225.

Ethyl 8-Berberinylideneacetoacetate (XIII)—Ethyl acetoacetate (1.2 ml, 8.3 mmoles) was added to a stirred slurry of sodium hydride (0.2 g, 8.3 mmoles) in dry tetrahydrofuran (50 ml). After gas evolution, V (1 g, 2.7 mmoles) was added, and the mixture was stirred for 30 min. The product was partitioned between chloroform and water, the organic layer was dried, and the solvent was evaporated. Trituration with ether gave a product, which was recrystallized from methanol to give 1.04 g (2.15 mmoles, 80%) of XIII as dark-red plates, mp 263–264°; IR: ν_{max}^{KBr} 1620 and 1670 cm^{-1}; UV: $\lambda_{max}^{ethanol}$ 232 (log ϵ 4.53), 267 (4.62), 337 (4.33), and 432 (3.73) nm; UV: $\lambda_{max}^{ethanol,H^+}$ 232 (log ϵ 4.60), 267 (4.48), 352 (4.38), and 440 (3.72) nm; mass spectrum: m/e M^+ 463 (5), 432 (100), 403 (50), and 358 (80).

Anal.—Calc. for $C_{26}H_{25}NO_7$·CH_3OH: C, 65.45; H, 5.85. Found: C, 65.37; H, 5.58.

Diethyl 8-Berberinylidenemalonate (XIV)—Salt V (1.5 g, 4 mmoles) was treated with the anion of ethyl malonate as described to yield, after similar workup and treatment with dry methanolic hydrochloric acid, 1.54 g (3.14 mmoles, 79%) of XIV as the hydrochloride salt as light-orange needles, mp >300° (methanol–ether), and red needles of free base, mp 238° (methanol); UV: $\lambda_{max}^{ethanol}$ 260 (log ϵ 4.31), 332 (4.15), 402 (3.78), and 428 sh (3.72) nm; mass spectrum: m/e M^+ 493 (2), 448 (2), 421 (10), 390 (30), 376 (40), 361 (45), 346 (40), 334 (100), and 318 (30).

Anal.—Calc. for $C_{27}H_{27}NO_8$·HCl: C, 61.30; H, 5.11. Found: C, 61.18; H, 4.90.

8-Berberinylacetic Acid (XV) Chloride Salt—A solution of XIV (1.36 g, 2.76 mmoles) in methanol (20 ml) containing concentrated hydrochloric acid (5 ml) was heated at 60° for 1 hr, diluted with water, and extracted with chloroform. The organic layer was dried, filtered, and evaporated. The residue was recrystallized from ethanol–ether to afford 0.85 g (2.16 mmoles, 78%) of XV, mp >300°; IR: ν_{max}^{KBr} 1600, 1720, and 3350 cm^{-1}; UV: $\lambda_{max}^{ethanol}$ 272 (log ϵ 4.26), 353 (4.22), 411 sh (3.70), and 430 sh (3.68) nm; PMR (trifluoroacetic acid): δ 3.32 (t, 2H, J = 7 Hz, H-5), 4.28 (s, 6H, 2 OCH_3), 4.96 (t, 2H, J = 7 Hz, H-6), 5.25 (s, 2H, CH_2COOH), 6.20 (s, 2H, OCH_2O), 7.01 (s, 1H, aromatic H), 7.59 (s, 1H, aromatic H), 8.56 (s, 1H, aromatic H), and 8.14 (s, 2H, H-11,12).

Anal.—Calc. for $C_{22}H_{20}ClNO_6$·C_2H_5OH: C, 60.58; H, 5.46. Found: C, 60.95; H, 5.38.

8-Canadinylacetic Acid (XVI)—A solution of XV (0.9 g, 2.3 mmoles) in ethanol (50 ml) was treated with excess sodium borohydride, giving an oil that crystallized from methanolic hydrogen chloride solution. Recrystallization from methanol afforded 0.8 g (2.0 mmoles, 87%) of XVI as very light-yellow needles of the hydrochloride salt, mp 212–214°; IR: $\nu_{max}^{CHCl_3}$ 1480, 1720, 2400, and 3400 cm^{-1}; UV: $\lambda_{max}^{ethanol,\ H^+}$ 267 sh (log ϵ 3.44) and 287 (3.86) nm; mass spectrum: m/e M^+ 397 (30), 382 (10), 338 (100), 322 (10), 306 (7), 278 (10), 236 (15), 206 (25), 126 (25), and 169 (20).

Anal.—Calc. for $C_{22}H_{23}NO_6$·HCl: C, 60.89; H, 5.57. Found: C, 61.00; H, 5.88.

8,8-Dimethyldihydroberberine (XVII) Hydroiodide—To a rapidly stirred suspension of magnesium turnings (1 g) in ether (20 ml) was added portionwise a solution of methyl iodide (1 ml) in ether (20 ml) at a rate to maintain vigorous reflux. The mixture was cooled, a suspension of V (1 g, 2.67 mmoles) in ether (20 ml) was added, and the mixture was refluxed for 30 min. The product was poured over ice, mixed with concentrated sulfuric acid (5 ml), and extracted with chloroform. The organic layer was worked up and treated with methanolic hydrogen iodide to furnish 0.78 g (60%) of the hydroiodide salt, mp 222° dec.; PMR (trifluoroacetic acid): δ 2.21 (s, 6H, 2 CH_3), 3.26 (t, 2H, J = 7 Hz, H-5), 4.04 (s, 3H, OCH_3), 4.16 (s, 3H, OCH_3), 4.31 (t, 2H, J = 7 Hz, H-6), 4.70 (s, 2H, H-13), 6.19 (s, 2H, OCH_2O), 6.93 (s, 1H, H-4), 7.19 (s, 2H, H-11,12), and 7.50 (s, 1H, H-1).

Anal.—Calc. for $C_{22}H_{23}NO_4$·HI: C, 53.52; H, 4.90. Found: C, 53.12; H, 4.90.

8,8-Diethyldihydroberberine (XVIII) Hydroiodide—By a procedure similar to that described but using ethylmagnesium bromide, XVIII was obtained in 66% yield as orange needles of the hydroiodide salt, mp 290° dec. (methanol).

Anal.—Calc. for $C_{24}H_{27}NO_4$·HI·CH_3OH: C, 54.25; H, 5.68. Found: C, 54.35; H, 5.39.

8-Benzylberberinium Bromide (XX)—An ethereal V suspension (1 g, 2.7 mmoles) was treated with excess ethereal benzylmagnesium bromide. Workup provided 0.99 g (2.32 mmoles, 86%) of XX as light-red needles, mp 232–233° (methanol); UV: $\lambda_{max}^{ethanol}$ 285 (log ϵ 4.04), 365 (3.87), 400 (3.44), and 450 (3.28) nm; PMR (trifluoroacetic acid): δ 3.08 (t, 2H, J = 7 Hz, C-5), 3.85 (s, 3H, OCH_3), 4.20 (s, 3H, OCH_3), 4.87 (t, 2H, J = 7 Hz, H-6), 5.53 (s, 2H, $PhCH_2$), 6.15 (s, 2H, OCH_2O), 6.90 (s, 1H, H-4), 7.08–7.43 (m, 5H, ArH), 7.55 (s, 1H, H-1), 8.10 (s, 2H, H-11,12), and 8.55 (s, 1H, H-13); mass spectrum: m/e M^+ 425 (100), 410 (53), 394 (24), and

334 (80); high-resolution mass spectrum: calc. for $C_{27}H_{23}NO_4$, 425.1627; found *m/e* 425.1615.

8,8-Diethylcanadine (XIX)—A XVIII solution (0.1 g, 0.25 mmole) in ethanol (20 ml) was treated with excess sodium borohydride (0.4 g). Workup and recrystallization from methanol furnished 0.096 g (96%) of XIX as tan plates, mp 168–169°; UV: $\lambda_{max}^{ethanol}$ 233 (log ϵ 4.31) and 288 (3.81) nm; mass spectrum: *m/e* M^+ 395 (5), 367 (100), 335 (10), 220 (35), and 175 (40); high-resolution mass spectrum: calc. for $C_{24}H_{29}NO_4$, 395.2096; found *m/e* 395.2125.

8-Benzylcanadine (XXI)—Sodium borohydride reduction of XX (1 g, 2.3 mmoles) in ethanol yielded 0.98 g (99%) of the known XXI, mp 165–166° (methanol) [lit. (5) mp 163–165°].

Comparative Studies on Eight Dissolution Methods Using 21 Commercial Chloramphenicol Tablets and a Nondisintegrating Benzoic Acid Tablet

HIROYASU OGATA ˣ, TOSHIO SHIBAZAKI, TETSUO INOUE, and AKIRA EJIMA

Received April 25, 1978, from the *Division of Drug, National Institute of Hygienic Sciences, 1-18-1, Kamiyoga Setagaya-ku, Tokyo, Japan.* Accepted for publication November 17, 1978.

Abstract □ Eight dissolution methods (beaker, rotating basket, oscillating basket, solubility simulator, rotating flask, and column) were evaluated using 21 commercial film-coated chloramphenicol (I) tablets and a nondisintegrating benzoic acid (II) tablet. The relative agitating intensities obtained from different dissolution methods were compared through the relative zero-order nondisintegrating tablet dissolution rate constants. Correlation coefficients between I dissolution rate parameters (lag time, T_{20}, T_{50}, and T_{80}) were determined. Significant correlation was observed for the lag time among seven methods, and all pairwise regression lines passed through zero except one. The regression line slopes reflected the relative destructive force intensities produced by each dissolution method on the coated I tablet films. The seven dissolution methods could be classified into two main groups according to correlations of four dissolution rate parameters. This classification criterion agreed well with that based on the agitation method. However, dissolution methods may not be interchangeable even though they belong to the same dissolution method group.

Keyphrases □ Dissolution testing systems—eight systems compared, chloramphenicol tablets and powder, benzoic acid tablet □ Dissolution rates—chloramphenicol tablets and powder, benzoic acid tablet □ Chloramphenicol—dissolution rates, tablets and powder, eight testing systems compared □ Benzoic acid—dissolution rate, tablet, eight testing systems compared

Since the dissolution rate was first recognized as a significant factor in determining *in vivo* drug bioavailability, many methods for testing solid dosage form dissolution have been reported (1, 2). These methods differ in hydrodynamic properties, agitating intensities, and mechanical destructive forces to the intact drug. There are three basic dissolution testing devices (2, 3): the stirred-tank reactor with a mechanical agitator such as Levy's beaker method (4) or the rotating-basket method (5), the rotating vessel reactor such as the rotating flask (6) or the solubility simulator[1], and the stream reactor such as the column method (7–9).

Several investigators compared the relative agitating intensities or hydrodynamic properties of selected dissolution devices by using a nondisintegrating model tablet (10–12). Bathe *et al.* (3) studied dissolution rates by beaker, rotating-basket, and flow column methods under eight different conditions. However, detailed comparisons of disintegrating tablet dissolution methods have not been made.

In the present study, eight representative dissolution testing methods were compared and evaluated. They can be divided into three categories: (*a*) stirrer-tank reactor type (beaker, rotating basket, and oscillating basket), (*b*) rotating-vessel reactor type (rotating flask and solubility simulator[1]), and (*c*) stream reactor type (column). Disintegrating tablets—21 chloramphenicol (I) brands available in Japan—and nondisintegrating tablets—benzoic acid (II)—were used as markers. The two drugs were selected because of their moderate solubilities in acidic solutions (2–4 mg/ml).

EXPERIMENTAL

Materials—Twenty-one different sugar-coated I tablets were obtained from 16 manufacturers in Japan. Tablets A–E each contained 50 mg of I while Tablets F–U each contained 250 mg of I. A powder of I[2] was included for comparison. Nondisintegrating and uncoated tablets containing 100 mg of II[3] were used.

Comparative Studies on Eight Dissolution Methods Using 21 Commercial Chloramphenicol Tablets and a Nondisintegrating Benzoic Acid Tablet

HIROYASU OGATA ˣ, TOSHIO SHIBAZAKI, TETSUO INOUE, and AKIRA EJIMA

Received April 25, 1978, from the *Division of Drug, National Institute of Hygienic Sciences, 1-18-1, Kamiyoga Setagaya-ku, Tokyo, Japan.* Accepted for publication November 17, 1978.

Abstract □ Eight dissolution methods (beaker, rotating basket, oscillating basket, solubility simulator, rotating flask, and column) were evaluated using 21 commercial film-coated chloramphenicol (I) tablets and a nondisintegrating benzoic acid (II) tablet. The relative agitating intensities obtained from different dissolution methods were compared through the relative zero-order nondisintegrating tablet dissolution rate constants. Correlation coefficients between I dissolution rate parameters (lag time, T_{20}, T_{50}, and T_{80}) were determined. Significant correlation was observed for the lag time among seven methods, and all pairwise regression lines passed through zero except one. The regression line slopes reflected the relative destructive force intensities produced by each dissolution method on the coated I tablet films. The seven dissolution methods could be classified into two main groups according to correlations of four dissolution rate parameters. This classification criterion agreed well with that based on the agitation method. However, dissolution methods may not be interchangeable even though they belong to the same dissolution method group.

Keyphrases □ Dissolution testing systems—eight systems compared, chloramphenicol tablets and powder, benzoic acid tablet □ Dissolution rates—chloramphenicol tablets and powder, benzoic acid tablet □ Chloramphenicol—dissolution rates, tablets and powder, eight testing systems compared □ Benzoic acid—dissolution rate, tablet, eight testing systems compared

Since the dissolution rate was first recognized as a significant factor in determining *in vivo* drug bioavailability, many methods for testing solid dosage form dissolution have been reported (1, 2). These methods differ in hydrodynamic properties, agitating intensities, and mechanical destructive forces to the intact drug. There are three basic dissolution testing devices (2, 3): the stirred-tank reactor with a mechanical agitator such as Levy's beaker method (4) or the rotating-basket method (5), the rotating vessel reactor such as the rotating flask (6) or the solubility simulator[1], and the stream reactor such as the column method (7–9).

Several investigators compared the relative agitating intensities or hydrodynamic properties of selected dissolution devices by using a nondisintegrating model tablet (10–12). Bathe *et al.* (3) studied dissolution rates by beaker, rotating-basket, and flow column methods under eight different conditions. However, detailed comparisons of disintegrating tablet dissolution methods have not been made.

In the present study, eight representative dissolution testing methods were compared and evaluated. They can be divided into three categories: (*a*) stirrer-tank reactor type (beaker, rotating basket, and oscillating basket), (*b*) rotating-vessel reactor type (rotating flask and solubility simulator[1]), and (*c*) stream reactor type (column). Disintegrating tablets—21 chloramphenicol (I) brands available in Japan—and nondisintegrating tablets—benzoic acid (II)—were used as markers. The two drugs were selected because of their moderate solubilities in acidic solutions (2–4 mg/ml).

EXPERIMENTAL

Materials—Twenty-one different sugar-coated I tablets were obtained from 16 manufacturers in Japan. Tablets A–E each contained 50 mg of I while Tablets F–U each contained 250 mg of I. A powder of I[2] was included for comparison. Nondisintegrating and uncoated tablets containing 100 mg of II[3] were used.

c-III (in)	1.132	1.26
c-III (out)	0.500	0.56
d	0.974	1.09
e	0.123	0.14
f	0.339	0.38

[a] Tablet was placed in the basket. [b] Tablet was placed out of the basket.

Dissolution Methods—*Beaker: Method a*—A cylindrical flat-bottom vessel for the disintegration test (JP IX) was used. One liter of the dissolution medium kept at 37° was stirred at 120 rpm with a three-bladed impeller (4.5 × 1.5 cm), which was held 4.5 cm from the vessel bottom. The tablets were placed at the vessel bottom during dissolution.

Rotating Basket: Method b—The test was carried out according to USP XIX specifications at 120 rpm.

Oscillating Basket: Method c—The disintegration test (JP IX) device was used, with the basket-rack assembly attached under three different conditions: (*a*) without the disk (c-I), (*b*) with the disk as specified in JP IX (c-II), and (*c*) with the disk located so that it touched the vessel bottom at the lowest point on the downward stroke (c-III). Tablets were placed into one of six open-ended glass tubes. The medium volume was 1 liter.

Rotating Flask: Method d—A 2-liter round-bottom flask was used as the vessel into which 150 g of glass beads (8-mm diameter) and 75 g of butyl rubber pieces (15 × 15 × 5 mm) were added with 900 ml of the medium. The flask was attached to a device for rotation[4] and immersed into the water bath maintained at 37° at 165° angle against the horizontal axis. The flask rotation speed was 18 rpm. The medium was sampled continuously through steel tubing attached to the flask.

Solubility Simulator: Method e—The thermostated (37°) solubility chamber (100 ml), which contained 170 g of glass beads (8-mm diameter) and 100 ml of the medium, was rotated horizontally at 1.2 rpm. A fixed sample volume was automatically removed from the chamber through a membrane filter at definite intervals. As the sample was taken, an identical fresh dissolution medium volume flowed into the chamber. The sampling volume and interval were set at 2.5 ml and 2.5 min, respectively.

Column: Method f—An ultrafiltration[5] cell with support screens[6] on both ends was used. The membrane filter was not used because the high-speed upward flow of the medium caused the dispersed particles to clog the upper filter. Dissolution medium was circulated through the column at 35 ml/min. The effluent was returned to a sink, which was stirred by the same procedure as in Method a. The total dissolution medium volume was 1 liter.

Rate Determination—Dissolution was determined for a single tablet in each procedure. Except in Method e, the dissolution medium was circulated through a flowcell (5-mm cell length) by a microtube pump[7] at 3.0 ml/min, and the medium absorbance was determined spectrophotometrically at two wavelengths[8]. In Methods a and b, the sampling tubing, with a glass filter at its end, was placed on the side and midheight

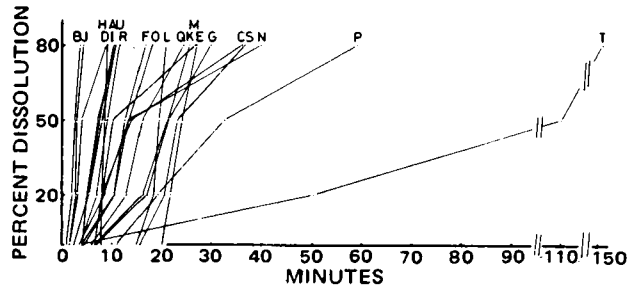

Figure 2—*Dissolution curves of I tablets determined by Method b.*

in the dissolution vessel. In Methods c and d, the filter was attached to the oscillating basket-rack bottom or to the round-bottom flask bottom and immersed into the medium.

In all methods except Method e for I tablets, the asymptotic absorbance was used as the value of 100% dissolution. In Method e, the drug absorbance in the medium removed from the chamber was determined and the cumulative amount dissolved was calculated. The asymptotic value was then substituted as the amount of 100% dissolution.

The I tablet dissolution rates were represented by four parameters: lag time (T_0), T_{20}, T_{50}, and T_{80}, where T_{20}, T_{50}, and T_{80} represent 20, 50, and 80% dissolution times, respectively. In II tablets, the absolute dissolved II amount was determined; the dissolution rate constant (milligrams per minute) was obtained from the slope of the earlier straight line of the dissolution curve. In all experiments, the dissolution medium was simulated gastric fluid without enzymes (JP VIII).

Disintegration and Hardness Measurements—Disintegration measurements were carried out according to JP IX. Hardness was measured by a hardness tester[9]. The disintegration time and hardness values reported are the average values of six tablets.

RESULTS

Dissolution Rate Constant of Nondisintegrating II Tablets—The drug dissolution rate can be represented by the Noyes–Nernst equation (13):

$$J = SK(C_s - C) \qquad \text{(Eq. 1)}$$

where J, S, K, C_s, and C represent the dissolution rate, surface area available to dissolution, dissolution rate constant, solubility, and drug concentration in the medium, respectively. According to the diffusion layer theory (14), the dissolution rate constant is a function of two parameters:

$$K = \frac{D}{h} \qquad \text{(Eq. 2)}$$

where D and h represent the diffusion coefficient and diffusion layer thickness, respectively. When $C_s \gg C$, Eq. 3 is obtained from Eqs. 1 and 2:

$$J = \frac{DS}{h} C_s = K_d \qquad \text{(Eq. 3)}$$

Thus, if the dissolution rate is measured under sink condition, the dissolution process follows apparent zero-order kinetics. When the same nondisintegrating tablet is tested using different dissolution methods, the differences in K_d should reflect only variations in h as a function of the dissolution method because D, S, and C_s are held constant. [a] Significant ($p < 0.05$).

these considerations, the zero-order dissolution rate constant emerges as the parameter reflecting the relative dissolution method agitation intensity. Table I shows the II dissolution rate constants. The relative values were normalized against the value obtained by Method a.

I Tablet Dissolution—Figures 1–7 show the dissolution curves measured by Methods a–e. The curves were constructed by linking the four points used for further treatment: lag time, T_{20}, T_{50}, and T_{80}.

The I dissolution rates were compared pairwise. Correlation coefficients are reported in Table II. Significant correlations ($p < 0.05$) for all four parameters were found for Method a *versus* b and c-II, b *versus* a, c-I *versus* c-II, c-III *versus* c-II, d and e, and disintegration time *versus* c-III and e. The I tablet disintegration and hardness values are listed in Table III.

Table III—Disintegration Times and Hardness of Chloramphenicol Tablets

Tablet	Disintegration Time, min	Hardness, kg
A	9.2	9.9

[a] More than 20 kg.

Interpretation of Lag Time—The dissolution lag time was the time required for the mechanical destruction of the coated tablet film. Thus, a shorter lag time represents a stronger destructive force. Significant correlations among the seven dissolution methods were observed regarding lag time (Table II). Except for the pairwise comparisons involving Method e, the least-squares regression lines passed through the origin. In these cases, the regression line slope obtained with lag time apparently reflected the relative destructive force intensity to the coated tablet film. Table IV shows the regression line slopes calculated for all combinations except those involving Method e. Thus, a slope of 1.64 for Method a *versus* b indicated that Method b gave 1.64 times the destructive force of a.

DISCUSSION

Agitating Intensity—The K_d values from nondisintegrating tablets (Table I) reasonably reflected the relative agitation intensities produced by the different dissolution methods. Method d had the lowest agitating intensity, and Method c-III (in) had the highest among the methods tested. Methods c-III, d, and e gave relatively sharp sigmoidal dissolution curves for all tablets, while Methods a, b, c-I, and c-II gave sigmoidal curves with smaller slopes, especially after 50% dissolution. Although Method e produced the mildest intensity, it gave comparatively sharp dissolution curves (Fig. 6). This finding suggests that the agitating intensity, as represented by the II dissolution rate from a nondisintegrating tablet, was not the rate-determining factor for disintegrating tablets.

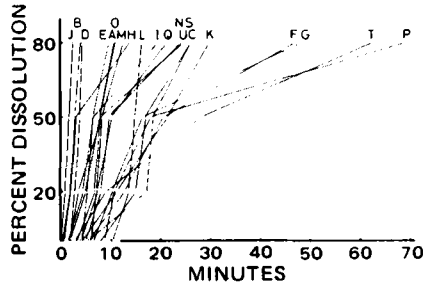

Figure 4—*Dissolution curves of I tablets determined by Method c-II.*

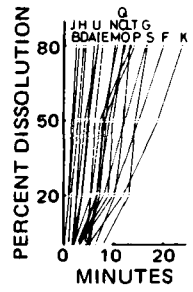

Figure 5—*Dissolution curves of I tablets determined by Method c-III.*

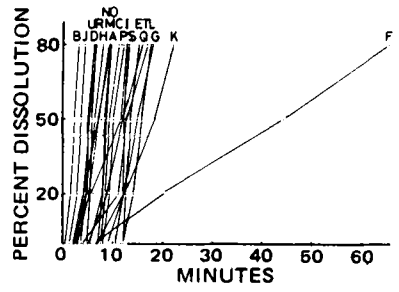

Figure 6—*Dissolution curves of I tablets determined by Method d.*

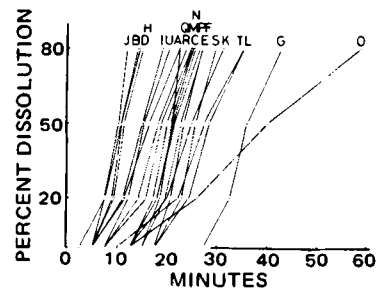

Figure 7—*Dissolution curves of I tablets determined by Method e.*

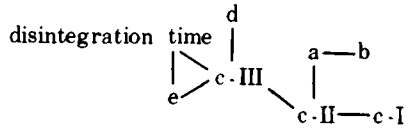
Because Method e used a rotating-vessel type reactor, "mound" formation of particles was prevented in spite of mild agitating intensity.

Tablets T and P showed very slow dissolution rates as determined by Methods a, b, c-I, and c-II but faster rates with Methods c-III, d, and e. The dispersing intensity was highly dependent on the stirring mode. Methods a, b, and c (the stirred-tank reaction type) could not prevent mound formation. On the other hand, the rotating-vessel devices, such as Methods d and e, generated high dispersing intensity in spite of low rotation speed, perhaps because of the unique stirring method.

Destructive Intensity to Coated I Tablet Films—The destructive intensity followed the descending order Method c-III ≥ c-II > d ≥ c-I > b > a (Table IV). Method e was not included in the comparison because of the inaccuracy in the lag time determination due to discontinuous sampling.

Correlation of I Tablet Dissolution Rates—Correlations between hardness and dissolution rates with all four rate parameters (lag time, T_{20}, T_{50}, and T_{80}) were insignificant statistically (Table II). Dissolution rate prediction from hardness is, therefore, impossible in this case. These results differ from those reported for other drugs (15, 16).

The relation among the methods is schematically represented in Scheme I. In this scheme, any two methods having a significant correlation for all four rate parameters were connected with a solid line. The results suggested two conclusions:



Scheme I—Relation among the methods of dissolution

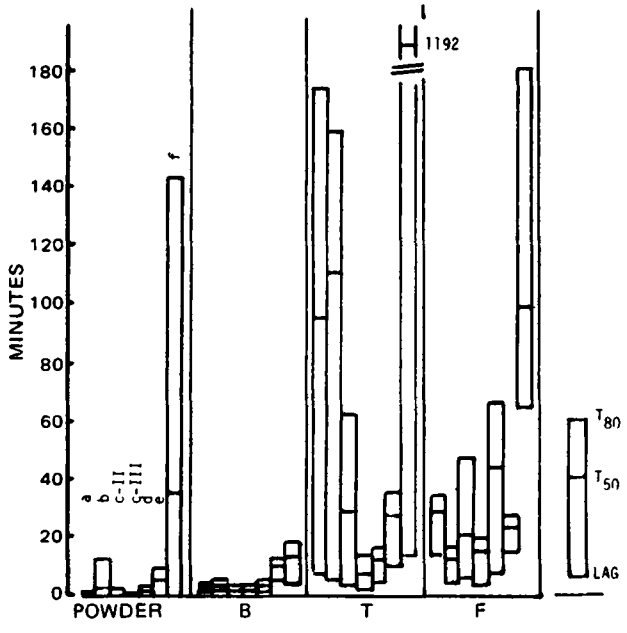


Figure 8—*Schematic representation of the dissolution rates of four samples determined by Method f and other methods.*

Table IV—Regression Line Slope Resulting from Pairwise Comparison of Lag Time Obtained with Different Dissolution Methods

	x-Axis					
y-Axis	a	b	c-I	c-II	c-III	d
a	1.0	1.64	2.50	4.55	3.70	2.00
b	—	1.0	1.61	3.23	2.56	1.20
c-I	—	—	1.0	1.49	2.13	1.32
c-II	—	—	—	1.0	1.20	0.71
c-III	—	—	—	—	1.0	0.50
d	—	—	—	—	—	1.0
Average relative intensity	1.0	1.56	2.33	4.01	4.40	2.40

1. Two different device types were distinguishable: stirred-tank reactors and rotating-vessel reactors. Only Method c-III correlated with both groups.

2. Among similar devices, a significant correlation was not observed among all methods. Thus, dissolution methods are not interchangeable, even if they belong to the same group.

Dissolution Rates Using Method f—Method f was inadequate for disintegrating tablet evaluation due to filter clogging. To avoid this problem, experiments were carried out without the filter. The modified device was similar in nature to that used in Method a for well-dispersed tablets since most disintegrated particles were returned to the impeller-stirred vessel. For poorly dispersed tablets, however, the dissolution rate may be evaluated more accurately with Method f because the drug remained longer in the column. Thus, despite the clogging defect, Method f was used for selected dissolution tests.

Figure 8 shows the dissolution rates of four I samples, *i.e.*, the powder and three commercial tablets, as determined by different methods. Surprisingly, the powder took much longer to dissolve using Method f than with the other methods. This result might have occurred because of the small agitating intensity produced by Method f (Table I) or because the laminar flow produced much less dispersing ability than that achieved with turbulent flow in the other methods. The dissolution lag times observed with Method f were generally longer than those obtained with other methods. This finding suggests that the Method f destructive force to coated film was far less than that of other methods. These data indicate that Method f is suitable for testing the intrinsic dissolution rate of a nondisintegrating drug matrix because of its controlled hydrodynamic flow but is unsuitable for evaluating the drug dissolution rate from disintegrating tablets and capsules.

Dissolution Systems for Chloramphenicol Tablet Bioavailability

HIROYASU OGATA ˣ, TOSHIO SHIBAZAKI, TETSUO INOUE, and AKIRA EJIMA

Received April 25, 1978, from the *Division of Drug, National Institute of Hygienic Sciences, 1-18-1, Kamiyoga Setagaya-ku, Tokyo, Japan.* Accepted for publication November 17, 1978.

Abstract □ The relationship between chloramphenicol (I) tablet bioavailability and *in vitro* dissolution rates was examined. The effect of solid food on the I tablet and powder bioavailability was also studied. Five tablets of I were selected for bioavailability testing on the basis of the dissolution rates of 18 I tablets (250 mg) determined by several methods. Compound I, 500 mg, was administered orally to five subjects, following overnight fasting, according to a crossover design. The bioavailability parameters were obtained from urinary I excretion. Among the five formulations studied, only one tablet (F) showed significantly poorer bioavailability. The dissolution rates at pH 1.2 did not give the same rank order as the bioavailability. The dissolution rate of Tablet F showed remarkable pH dependency. The dissolution rates at pH 4 showed good correlation with *in vivo* bioavailability data. The bioavailability of I powder was not affected by solid food. Tablet F, which had poor bioavailability in the fasting state, showed good bioavailability when administered just after the standard breakfast.

Keyphrases □ Chloramphenicol—various dosage forms, bioavailability correlated with dissolution rates □ Bioavailability—chloramphenicol, various dosage forms, correlated with dissolution rates □ Dissolution rates—chloramphenicol, various dosage forms, correlated with bioavailability □ Antibacterials—chloramphenicol, various dosage forms, bioavailability correlated with dissolution rates

The dissolution rates of 21 chloramphenicol (I) tablets manufactured in Japan were reported previously (1). In this paper, the *in vivo* bioavailability of selected I tablets was correlated with *in vitro* dissolution tests. The bioavailability of nine different I tablets available in Japan was determined previously by Watanabe *et al.* (2, 3), who showed significant correlation of *in vivo* bioavailability with disintegration time and dissolution rate as measured by a disintegration apparatus[1] using water as the medium.

The dissolution devices used in that study (beaker, rotating basket, oscillating basket, and disintegration[1] methods) all belonged to the stirred-tank reactor type (1). *In vivo–in vitro* correlation with rotating-flask type dissolution devices was not attempted. These investigators (2, 3) also reported better correlation of *in vitro* dissolution rate and *AUC* (area under plasma level–time curve) following oral administration of I tablets with water as the dissolution medium instead of the pH 1.2 solution recommended in JP IX. Chloramphenicol dissolution in an unbuffered medium could have complicated the system since the pH value changed as the tablet dissolved.

Comparative bioavailability studies of five I tablets are described in this report. These tablets were selected based on dissolution rates of 18 I tablets (250 mg) and I powder determined by seven methods (1). The relationship between *in vivo* bioavailability and *in vitro* dissolution was examined. The effect of food on the I bioavailability was also studied.

EXPERIMENTAL

Materials—The I tablets and powder were the same as those described previously (1), except for Tablets V and V′ which were of the same brand but different lot numbers.

***In Vitro* Studies**—The methods and procedures for determining the dissolution rate were the same as those reported previously (1): beaker (a), rotating basket (b), oscillating basket (c-II and c-III), rotating flask (d), solubility simulator (e)[2], and column (f). The dissolution medium pH was controlled by a pH stat. No corrections were made for acidic dissolution media adjusted at pH 1.2.

Bioavailability Studies—Six healthy adult male volunteers, 55–72 kg and 29–49 years old, participated after being informed about the study and the drug. All subjects received no barbiturates or other enzyme-inducing agents for 30 days before and for the duration of the studies. They also received no other medication or alcoholic beverages for 7 days before and for the duration of the studies.

Study I—The bioavailability of five I tablets was studied using a Latin square. Treatments were separated by 1 week. Subjects fasted for 10 hr prior to dosing and took two I tablets (total of 500 mg) with 300 ml of water. They took 200 ml of water at 2 hr and had lunch at 4 hr after administration. Urine samples were collected at 0, 0.5, 1, 1.5, 2, 3, 4, 5, 6, 8, 12, 16, 24, and 28 hr after dosing. The exact sampling times and the volume were recorded.

Study II—The effect of solid food on Tablet F and I powder bioavailability was studied with four subjects using a Latin square. Tablet F or I powder (500 mg) was taken either with 300 ml of water in the fasting state or immediately after a standard breakfast of 100 g of toast, 20 g of butter, 35 g of cucumber, 65 g of boiled egg, 200 ml of milk, and 100 ml of water. The urine collection procedure was the same as that for Study I.

Study III—One subject participated in a study of the relationship

Dissolution Systems for Chloramphenicol Tablet Bioavailability

HIROYASU OGATA ˣ, TOSHIO SHIBAZAKI, TETSUO INOUE, and AKIRA EJIMA

Received April 25, 1978, from the *Division of Drug, National Institute of Hygienic Sciences, 1-18-1, Kamiyoga Setagaya-ku, Tokyo, Japan.* Accepted for publication November 17, 1978.

Abstract □ The relationship between chloramphenicol (I) tablet bioavailability and *in vitro* dissolution rates was examined. The effect of solid food on the I tablet and powder bioavailability was also studied. Five tablets of I were selected for bioavailability testing on the basis of the dissolution rates of 18 I tablets (250 mg) determined by several methods. Compound I, 500 mg, was administered orally to five subjects, following overnight fasting, according to a crossover design. The bioavailability parameters were obtained from urinary I excretion. Among the five formulations studied, only one tablet (F) showed significantly poorer bioavailability. The dissolution rates at pH 1.2 did not give the same rank order as the bioavailability. The dissolution rate of Tablet F showed remarkable pH dependency. The dissolution rates at pH 4 showed good correlation with *in vivo* bioavailability data. The bioavailability of I powder was not affected by solid food. Tablet F, which had poor bioavailability in the fasting state, showed good bioavailability when administered just after the standard breakfast.

Keyphrases □ Chloramphenicol—various dosage forms, bioavailability correlated with dissolution rates □ Bioavailability—chloramphenicol, various dosage forms, correlated with dissolution rates □ Dissolution rates—chloramphenicol, various dosage forms, correlated with bioavailability □ Antibacterials—chloramphenicol, various dosage forms, bioavailability correlated with dissolution rates

The dissolution rates of 21 chloramphenicol (I) tablets manufactured in Japan were reported previously (1). In this paper, the *in vivo* bioavailability of selected I tablets was correlated with *in vitro* dissolution tests. The bioavailability of nine different I tablets available in Japan was determined previously by Watanabe *et al.* (2, 3), who showed significant correlation of *in vivo* bioavailability with disintegration time and dissolution rate as measured by a disintegration apparatus[1] using water as the medium.

The dissolution devices used in that study (beaker, rotating basket, oscillating basket, and disintegration[1] methods) all belonged to the stirred-tank reactor type (1). *In vivo–in vitro* correlation with rotating-flask type dissolution devices was not attempted. These investigators (2, 3) also reported better correlation of *in vitro* dissolution rate and *AUC* (area under plasma level–time curve) following oral administration of I tablets with water as the dissolution medium instead of the pH 1.2 solution recommended in JP IX. Chloramphenicol dissolution in an unbuffered medium could have complicated the system since the pH value changed as the tablet dissolved.

Comparative bioavailability studies of five I tablets are described in this report. These tablets were selected based on dissolution rates of 18 I tablets (250 mg) and I powder determined by seven methods (1). The relationship between *in vivo* bioavailability and *in vitro* dissolution was examined. The effect of food on the I bioavailability was also studied.

EXPERIMENTAL

Materials—The I tablets and powder were the same as those described previously (1), except for Tablets V and V′ which were of the same brand but different lot numbers.

***In Vitro* Studies**—The methods and procedures for determining the dissolution rate were the same as those reported previously (1): beaker (a), rotating basket (b), oscillating basket (c-II and c-III), rotating flask (d), solubility simulator (e)[2], and column (f). The dissolution medium pH was controlled by a pH stat. No corrections were made for acidic dissolution media adjusted at pH 1.2.

Bioavailability Studies—Six healthy adult male volunteers, 55–72 kg and 29–49 years old, participated after being informed about the study and the drug. All subjects received no barbiturates or other enzyme-inducing agents for 30 days before and for the duration of the studies. They also received no other medication or alcoholic beverages for 7 days before and for the duration of the studies.

Study I—The bioavailability of five I tablets was studied using a Latin square. Treatments were separated by 1 week. Subjects fasted for 10 hr prior to dosing and took two I tablets (total of 500 mg) with 300 ml of water. They took 200 ml of water at 2 hr and had lunch at 4 hr after administration. Urine samples were collected at 0, 0.5, 1, 1.5, 2, 3, 4, 5, 6, 8, 12, 16, 24, and 28 hr after dosing. The exact sampling times and the volume were recorded.

Study II—The effect of solid food on Tablet F and I powder bioavailability was studied with four subjects using a Latin square. Tablet F or I powder (500 mg) was taken either with 300 ml of water in the fasting state or immediately after a standard breakfast of 100 g of toast, 20 g of butter, 35 g of cucumber, 65 g of boiled egg, 200 ml of milk, and 100 ml of water. The urine collection procedure was the same as that for Study I.

between urinary recovery and dose. Oral I doses of 155, 250, and 500 mg of powder were given according to the protocol described for Study I.

Assay—Unchanged and total urine nitro I compounds were determined by colorimetry as described by Maruyama and Suzuki (4) with slight modifications.

Total Nitro I Compounds—Urine, 1 ml, was diluted to 100 ml with water, and 4 ml of 0.25 *N* NaOH and 0.3 ml of 2% $Na_2S_2O_4$ were added to 1 ml of the solution and mixed well. After the solution stood for 15 min at room temperature, 0.5 ml of 2.5% $NaNO_2$ and 1.0 ml of 4 *N* HCl were added and mixed well. After 5 min, 0.5 ml of 5% sulfamic acid was added; the solution was shaken and allowed to stand for 5 min. Then 0.5 ml of 0.5% Tsuda's reagent solution was added, and the mixture was allowed to stand for 90 min at 37°. The solution absorbance was determined spectrophotometrically[3] at 650 and 560 nm.

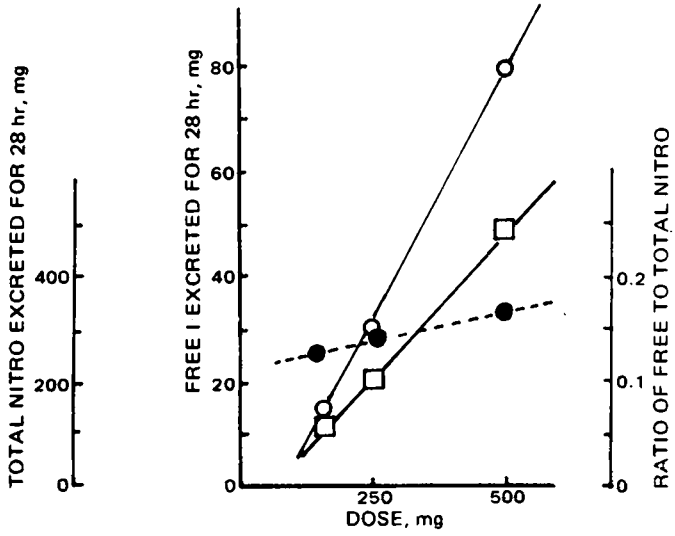

Figure 2—*Dose dependency of urinary excretion of free and total nitro following oral I powder administration. Key:* ○, *free I;* □, *total nitro compounds; and* ●, *ratio of free to total nitro.*

Unchanged I—An aliquot of urine was diluted 20 times with water, 4 ml of pH 6.0 phosphate buffer (0.2 *M*) and 12 ml of ethyl acetate were added to 2 ml of the solution, and the solution was shaken for 10 min mechanically. After centrifugation, the aqueous layer was removed and 10 ml of fresh phosphate buffer (pH 6.0) was added. The mixture was shaken for 10 min and centrifuged. Ten milliliters of the organic layer was evaporated to dryness under reduced pressure in a boiling water bath. Water (4.5 ml) was added, and the solution was heated for 5 min to dissolve I completely. After the solution cooled, 0.5 ml of 1.0 *N* NaOH and 0.3 ml of 2% $Na_2S_2O_4$ were added. The assay then followed the procedure described for total nitro compounds.

Aqueous solutions of 2% $Na_2S_2O_4$ and 2.5% $NaNO_2$ were prepared just prior to addition. The absorbance due to the urine composition was almost constant and very small in comparison with other colorimetric methods (5, 6). The urine sample collected just prior to dosing could be used as the urine blank with very slight error.

RESULTS AND DISCUSSION

***In Vitro* Studies**—Figure 1 shows the relative dissolution rates of the five I tablets and powder as reflected by lag time, time for 50% dissolution (T_{50}), and time for 80% dissolution (T_{80}). Each formulation showed a distinguishing dissolution rate profile. Tablet B had very fast dissolution rates by all seven methods. The powder dissolution behavior was similar to that of Tablet B in all dissolution methods except Method f. Tablet T showed especially slow dissolution rates in Methods a, b, and f, which have poor dispersing intensity (1).

The Tablet T dissolution lag time was small. Tablet V' appeared to

[a] Simulated gastric juice without enzyme, pH 1.2. [b] Distilled water.

have a strongly coated film; its lag time was very long, but dissolution after the lag time was comparatively fast. The rotating vessel reactor dissolution methods (d and e) showed especially poor destructive intensity against Tablet V′. Tablet V showed fast dissolution after the lag time by all methods except Method f. Tablet F showed especially poor dissolution by Method d but comparatively good dissolution by other methods.

Dose Dependency of I Urinary Excretion—Figure 2 shows the relationship between dose and the cumulative amount excreted in 28 hr following oral administration of I powder in one subject (Study III). The excreted free and total nitro I compounds were proportional to the dose administered, but the ratio of free to total nitro compounds increased slightly with dose from 0.128 to 0.162. This result suggested that urinary I excretion in humans can be treated by linear pharmacokinetics within the dose range studied.

Bioavailability—The bioavailability parameters following five different treatments are summarized in Table I. Based on ANOVA (analysis of variance), statistically significant differences were found among the treatments in all parameters except the ratio of free to total nitro I compounds. Tablet F showed significant differences from the other tablets in all parameters except the ratio of free to total nitro compounds excreted. Tablet F showed an excretion lag time of about 5 hr. This tablet took the longest time to reach the maximum excretion rate, which was also the smallest value among the treatments. The total amount excreted in 28 hr after dosing with Tablet F was about one-half of the amount excreted after the other tablets. The poor Tablet F bioavailability, however, appeared not to be due to *in vitro* dissolution rates (Fig. 1).

All dissolution tests in Fig. 1 were carried out at pH 1.2. The *in vitro* dissolution was reexamined using water as the dissolution medium as suggested by Watanabe *et al.* (3).

Table II showed that, with Method d, the Tablet F dissolution rate in water was remarkably slower than that determined at pH 1.2, as were the dissolution rates of Tablets V and V′. With Method c-III, only Tablet F showed a slower dissolution. With water as the dissolution medium, the pH changed as dissolution progressed; the change was dependent on the formulation.

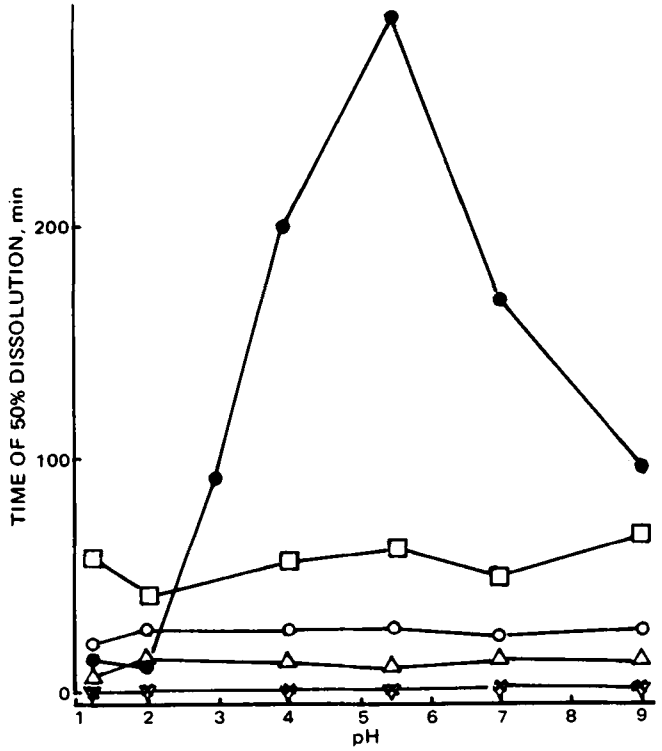

Figure 3—*Effect of pH on time of 50% I formulation dissolution. Key:* ▽, *powder;* ×, *Tablet B;* △, *Tablet T;* ●, *Tablet F;* ○, *Tablet V; and* □, *Tablet V′.*

Figure 3 represents the dissolution rates determined by Method c-III when the medium pH was controlled *via* pH stat. Tablet F was the only tablet whose dissolution showed a remarkable pH dependency. Since the powder dissolution rate was not a function of pH, the pH dependency shown by Tablet F might have been caused by the white shellac tablet coating.

Figure 4 shows the relationship between *in vivo* bioavailability and *in vitro* dissolution of the five tablets tested. The *in vitro* dissolution rates were determined by Method c-III at pH 4.0. From Fig. 4, there appeared to be a critical dissolution rate point distinguishing the equivalent from

Table III—Effect of Food on Chloramphenicol Powder and Tablet F Bioavailabilities

These values were estimated by means of the urinary excretion of unchanged compound.*

the nonequivalent tablets. Since only one tablet was detected as nonequivalent in this study, the critical point could not be determined clearly. However, an approximate critical T_{50} point appeared to be more than 50 min. The critical value occurred surprisingly late, even though the *in vitro* rates were determined by the dissolution method that had the most vigorous agitating, dispersing, and destructive intensities among the seven methods studied.

Effect of Food on Bioavailability—The relative bioavailability of the powder and Tablet F was studied under fasting and nonfasting conditions. Table III shows the bioavailability parameters compared by the paired t test. The powder showed equivalent bioavailability with the tablets, except for Tablet F under fasting condition, and did not show any bioavailability difference between fasting and nonfasting states. Tablet F, which had poor bioavailability after fasting, became equivalent in bioavailability with the other formulations when it was administered just after the standard breakfast. Possibly, the more violent movement of the tablet in the GI tract after food might have increased drug absorption.

CONCLUSIONS

Film-coated I tablet absorption in humans is related to dissolution. The dissolution device that correlated well with bioavailability was one with a comparatively violent destructive force for the coated tablet film and high test medium agitation. The test medium pH must also be considered because dissolution of certain tablet coatings was pH dependent.

Antitumor Agents: Structure–Activity Relationships in Tenulin Series

THOMAS G. WADDELL *x, ANNE-MARIE AUSTIN *, JANICE W. COCHRAN *, KARL G. GERHART *, IRIS H. HALL ‡, and K. H. LEE ‡

Received May 25, 1978, from the **Department of Chemistry, University of Tennessee at Chattanooga, Chattanooga, TN 37401*, and the ‡*Department of Medicinal Chemistry, School of Pharmacy, University of North Carolina, Chapel Hill, NC 27514.* Accepted for publication November 21, 1978.

Abstract □ Systematic structural modifications were performed on the natural sesquiterpene lactone tenulin to define those groupings essential to, or significant in, its *in vivo* antitumor activity. Accordingly, the following tenulin analogs were prepared: dihydrotenulin, 2,3-epoxytenulin, isotenulin, dihydroisotenulin, 2,3-epoxyisotenulin, and tetrahydrodeacetylisotenulin. Both the cyclopentenone and the hemiketal units in tenulin were necessary for high *in vivo* activity.

Keyphrases □ Tenulin—antineoplastic activity, structure-activity relationships, *in vivo* study □ Antineoplastic activity—tenulin, structure-activity relationships, *in vivo study*

The sesquiterpene lactone tenulin (I) is a major bitter principle in several species of the plant genus *Helenium* (Family Compositae) (1–6). High *in vivo* tenulin antitumor activity toward the Ehrlich ascites and Walker 256 carcinosarcoma screens and, to a lesser extent, toward P-388 leukemia has been demonstrated (7, 8). The tenulin cyclopentenone unit may act as a Michael acceptor in cellular enzyme essential sulfhydryl group alkylation.

Tenulin forms a Michael addition product with L-cysteine to give the zwitterionic compound II (7, 8). The adduct II, containing the cyclopentanone group, showed 84% activity loss toward the Ehrlich ascites screen, suggesting that a cyclopentenone unit is important for high activity. Low II activity also might be the result of lower solubility in lipid membranes.

In the present study, the tenulin structure was modified in ways not significantly affecting drug transport. This structure–*in vivo* antitumor activity work reveals those tenulin features necessary for high activity.

RESULTS AND DISCUSSION

Chemistry—Tenulin (I), isolated after extraction of *Helenium amarum* (6, 7), was subjected to catalytic hydrogenation conditions to give dihydrotenulin (III) (1). A new compound, 2,3-epoxytenulin (IV), was prepared in quantitative yield from tenulin upon brief treatment with cold, basic hydrogen peroxide solution. 2,3-Epoxytenulin, $C_{17}H_{22}O_6$ (by exact mass measurement), had a 194–197° melting point and IR ab-

I II III IV V VI VII VIII IX

sorption at 3575 (OH), 1770 (γ-lactone), and 1750 (cyclopentanone) cm^{-1}. The UV spectrum revealed no enone absorption band at 225 nm.

The IV structure was confirmed by a high-resolution mass spectrum. Most significant of several fragment ions (see *Experimental*) were the molecular ion at *m/e* 322, an $M^+ - H_2O$ ion at *m/e* 304 indicating the presence of a hydroxyl group in IV, and the base peak at *m/e* 111 corresponding to the ion V. These and other peaks in the 2,3-epoxytenulin mass spectrum were easily interpretable in terms of Structure IV and principles recently put forth (9) regarding pseudoguaianolide mass spectra (9).

The stereochemistry of the IV 2,3-epoxide was determined by circular dichroism (Table I). The negative Cotton effect at 311 nm ($[\theta] = -6628$) corresponded to the $n \rightarrow \pi^*$ saturated ketone absorption and indicated a β-epoxide according to an inverse octant rule for epoxyketones described in the literature (10–12). This assignment for IV stereochemistry was supported by an analogous epoxidation reaction in the steroid series where 5α-androst-15-en-17-one yielded the corresponding 15β,16β-epoxy-17-ketone as the only product (13, 14).

Tenulin and 5α-androst-15-en-17-one molecular models revealed no definitive difference in steric hindrance between the molecular α- and β-faces. Therefore, an orbital explanation for the exclusive β-epoxide production from tenulin was sought. Both molecular models and circular dichroism measurements (Table I and Ref. 10) indicated that the tenulin and 5α-androst-15-en-17-one enone system was not planar but was skewed with the convex surface on the β-face (15, 16). An application of the orbital distortion technique (17) to this situation indicated that the lobes of the lowest unoccupied enone molecular orbital were distorted toward the β-face. Therefore, the attacking hydroperoxide anion should prefer to approach from this direction, as was observed experimentally.

Isotenulin (VI), prepared from tenulin by a literature method (3), yielded dihydroisotenulin (VII) (6) upon catalytic hydrogenation and 2,3-epoxyisotenulin (VIII) (6) when briefly exposed to cold, basic hydrogen peroxide solution. 2,3-Epoxyisotenulin, $C_{17}H_{22}O_6$, showed a negative Cotton effect at 312 nm (Table I) for the $n \rightarrow \pi^*$ ketone absorption, indicating that the newly introduced oxygen atom was beta. TLC showed that VIII had a higher R_f value than IV.

To prepare a derivative with a reduced ketone or lactone grouping, tenulin was reacted with sodium borohydride and with lithium aluminum hydride. In both experiments, low complex mixture yields were obtained. A sodium borohydride reduction of III produced more satisfactory results, giving, in low yield, a new compound, tetrahydrodeacetylisotenulin (IX). Compound IX, $C_{15}H_{24}O_4$, mp 161–163°, showed IR absorption at 3400 (OH) and 1755 (γ-lactone) cm^{-1}. The IX mass spectrum indicated the molecular ion at *m/e* 268 (M^+) and fragment ions at *m/e* 250 ($M^+ - H_2O$) and 232 ($M^+ - 2H_2O$), supporting the hypothesis of two hydroxyl groups. The NMR spectrum of IX (detailed under *Experimental*) was completely in accord with the assigned structure. Presumably, IX was formed in this reaction by sequential ketone reduction, retro-aldol cleavage of the hemiketal, and reductive cleavage of the resulting acetate ester.

Table I—Ketone $n \rightarrow \pi^*$ Cotton Effects for Tenulin and Derivatives

Compound	λ_{max}, nm	$[\theta]$
I	329	−3169
VI	330	−4850
IV	311	−6628
VIII	312	−9383

Biological Evaluation—Tenulin and the prepared derivatives were assayed for *in vivo* antitumor activity in Sprague–Dawley rats implanted with Walker 256 ascites carcinosarcoma cells and in DBA/2 mice implanted with P-388 lymphocytic leukemia according to published procedures (7) (Table II). Only tenulin showed significant activity in the P-388 screen. Since changes in activity are more pronounced in the sensitive Walker 256 screen, the following structure–activity relationship discussion focuses on those data.

Within the tenulin series (I, III, and IV), modification of the cyclopentenone ring by hydrogenation to III or epoxidation to IV was accompanied by decreased antitumor activity. Although less dramatic, this trend was evident also in the isotenulin series (VI–VIII) where both VII and VIII are less active than VI. These results confirmed that the tenulin and isotenulin cyclopentenone unit is needed for high *in vivo* antitumor activity. These conclusions are in accordance with those of Hall *et al.* (7) and Lee *et al.* (8), who demonstrated the tenulin cyclopentenone unit *S*-alkylating ability and related this reactivity to the action mechanism of antitumor agents bearing this enone system.

Compounds III and IV have nearly identical activities, as do VII and VIII. Furthermore, the epoxides IV and VIII, themselves potential alkylating agents, nevertheless showed decreased antitumor activity when compared to their progenitors I and VI, respectively. These observations suggest that in the tenulin–isotenulin series, the marginally active cyclopentenone epoxides are not acting significantly as *S*-alkylating agents *in vivo*.

Other systematic comparisons revealed the importance of the hemiketal unit to high antitumor activity. Within the hemiketal present–hemiketal absent pairs of I and VI, III and VII, and IV and VIII, the compound with the hemiketal intact was more active than its acetate ester counterpart. The hemiketal hydroxyl grouping may hydrogen bond the sesquiterpene antitumor agent to the cellular receptor site.

Tetrahydrodeacetylisotenulin (IX) inactivity supported the postulates regarding cyclopentenone and hemiketal importance to antitumor activity in the tenulin series.

EXPERIMENTAL[1]

***In Vivo* Tumor Screens**—*In vivo* tumor screens (Walker 256 ascites carcinosarcoma and P-388 lymphocytic leukemia) were performed according to published procedures (7). In the Walker 256 ascites carcinosarcoma screen, 10^6 tumor cells were implanted into 80 ± 10-g Sprague–Dawley male rats. In the P-388 lymphocytic leukemia screen, 10^6 cells were implanted into DBA/2 male mice (~18 g) on Day 0.

Test compounds were homogenized in 0.05% polysorbate 80–water and injected at 2.5 mg/kg/day ip for the rats and at 25 mg/kg/day ip for the mice. The day of death was recorded, and the treated/control (T/C) values for the average days survived were calculated according to the National Institutes of Health protocol 1.500 (18). Melphalan and fluorouracil were used as positive standards in these screens. Controls with 0.05% polysorbate 80–water give T/C = 100.

Isolation of Tenulin (I) from *H. amarum*[2]—A 476-g sample of *H.*

[1] Melting points were determined on a Thomas-Hoover apparatus and are corrected. IR spectra were determined with a Perkin-Elmer model 700 recording spectrophotometer. The circular dichroism curves were taken with methanol as the solvent, $c = 10^{-3}$ g/ml, using a Cary 60 instrument. Elemental analyses were performed by Galbraith Laboratories, Knoxville, Tenn.

[2] The plant material was identified as *Helenium amarum* (Raf.) H. Rock (Compositae) by Dr. Gene S. Van Horn, Department of Biology, University of Tennessee at Chattanooga. A voucher specimen (HAM-81074-FAR) is available for inspection at the Department of Chemistry, University of Tennessee at Chattanooga.

Table II—Antitumor Activity of Test Compounds [a]

Compound	Walker 256 Ascites		P-388 Lymphocytic Leukemia	
	Average Days Survived	T/C[b]	Average Days Survived	T/C[b]
I	22.16/8.33	266	13.8/10.2	135
III	24.0/16.3	147	9.5/10.2	93
IV	13.4/9.6	140	12.4/10.2	122
VI	14.6/9.6	152	11.5/10.2	113
VII	21.0/16.3	129	11.5/10.2	113
VIII	16.5/13.0	127	11.8/10.2	116
IX	15.9/15.6	102	—	—
Melphalan[c]	23.0/7.25	317	—	—
Fluorouracil[d]	—	—	19.7/10.6	186

[a] Six animals were used per group. [b] T/C ≥ 125% for minimum significant activity. [c] Wellcome Research Laboratories, Research Triangle Park, N.C. [d] Calbiochem, La Jolla, Calif.

amarum (Raf.) H. Rock leaves and stems[3] was cut into 1.27-cm pieces and extracted with chloroform by maceration for 4 days at room temperature. After decanting, the plant material was extracted twice in the same manner. The combined extracts were evaporated to dryness, leaving a dark-green tar (48.6 g). The crude extract was stirred for 30 min with 400 ml of water–ethanol (3:1) and filtered through diatomaceous earth.

The aqueous filtrate was extracted with five 100-ml portions of chloroform, and the combined organic phase was dried over anhydrous magnesium sulfate. Filtration and evaporation *in vacuo* left 19.4 g of the final extract as an amber oil. Trituration of this oil with benzene gave 6.27 g of crude I (mp 181–183°), which was recrystallized from ethanol–water, mp 186–188° [lit. (4) mp 184–186°]; IR ($CHCl_3$): 3600–3200 (OH), 1770 (γ-lactone), 1705 (cyclopentenone), and 1590 (C=C) cm^{-1}; UV (ethanol): 225 (ε 8215) nm; circular dichroism (methanol): $[\theta]_{329}$ −3169.

Anal.[4]—Calc. for $C_{17}H_{22}O_5 \cdot 0.20C_6H_6$: C, 67.91; H, 7.21. Found: C, 67.94; H, 6.90.

A direct comparison of this material with authentic I[5] established its identity. The mixed melting point of this sample was not depressed compared to authentic tenulin, the IR spectra were superimposable, and the two samples (mixed or separated) cochromatographed on TLC in numerous solvent systems. The NMR spectrum was identical to published I spectra.

Tenulin used in the experiments described in this paper showed one spot on TLC (R_f 0.50, 20% acetone in chloroform, silica gel).

Dihydrotenulin (III)—Tenulin (0.500 g) was hydrogenated in 25 ml of ethanol containing 0.20 g of 5% palladium-on-charcoal to give III (0.415 g), mp 170–171° [lit. (1) mp 172°]; IR ($CHCl_3$): 1760 (γ-lactone) and 1740 (cyclopentanone) cm^{-1}.

2,3-Epoxytenulin (IV)—To 0.203 g of I in 5 ml of methanol at 0° was added dropwise, with constant stirring, a solution containing 0.25 ml of 30% hydrogen peroxide, 0.60 ml of water, and 0.041 g of sodium carbonate. The cooled reaction mixture was stirred for 10 min, and 10 ml of distilled water was added. This aqueous solution was extracted with two 20-ml portions of chloroform, and the combined organic phase was dried (magnesium sulfate), filtered, and evaporated to dryness under reduced pressure. 2,3-Epoxytenulin was isolated as a clear glass in quantitative yield and showed a single circular spot on TLC in various solvent systems.

Efforts to crystallize this material were initially unsuccessful due to extensive decomposition. However, a crystalline sample of IV, mp 194–197°, was eventually obtained in low yield; IR ($CHCl_3$): 3575 (OH), 1770 (γ-lactone), and 1750 (cyclopentanone) cm^{-1}; circular dichroism (methanol): $[\theta]_{311}$ −6628; mass spectrum (9): *m/e* 322.1412 (M^+), calc. for $C_{17}H_{22}O_6$, 322.1416; 307 ($M^+ - CH_3$), 304 ($M^+ - H_2O$), 280, 279, 262, 261, 251, 235, 234, 233, 207, 191, 189, 163, 137, 135, 124, 123, 122, and 111 (base peak).

Isotenulin (VI)—Isotenulin was prepared in 82% yield from tenulin (3). The product VI was recrystallized from benzene–ether mixtures to give material with a melting point of 154–156° [lit. (2) mp 152–153°]; IR ($CHCl_3$): 1760 (γ-lactone), 1750 (OAc), 1705 (cyclopentenone), and 1580 (C=C) cm^{-1}; circular dichroism (methanol): $[\theta]_{330}$ −4850.

Dihydroisotenulin (VII)—Isotenulin (0.500 g) was hydrogenated in 25 ml of ethanol containing 0.231 g of 5% palladium-on-charcoal to give VII (0.441 g), mp 148–149° [lit. (6) mp 147–149°]; IR ($CHCl_3$): 1740–1760 cm^{-1}, unresolved.

2,3-Epoxyisotenulin (VIII)—2,3-Epoxyisotenulin was prepared in 74% yield from VI by the method of Lucas *et al.* (6), who obtained the product as an amorphous glass. The solid reaction product in the present case was crystallized from ethyl acetate–ether to give material with a 148–149° melting point; IR ($CHCl_3$): 1785–1755 and 1720 (shoulder) cm^{-1}; circular dichroism (methanol): $[\theta]_{312}$ −9383.

Anal.—Calc. for $C_{17}H_{22}O_6$: C, 63.35; H, 6.83. Found: C, 63.53; H, 7.01.

Tetrahydrodeacetylisotenulin (IX)—To 0.415 g of III in 10 ml of methanol was added 0.316 g of sodium borohydride in portions with constant stirring. After 45 min at room temperature, the reaction mixture was diluted to 50 ml with distilled water and extracted with three 25-ml portions of chloroform. The combined organic phase was washed once with 25 ml of water, dried (magnesium sulfate), filtered,and evaporated to dryness under reduced pressure. The crude, oily product (0.321 g) showed four components on TLC and was chromatographed on a column of silica gel (1.5 × 36 cm), eluting with chloroform followed by 20% acetone in chloroform.

From the later fractions, IX (20 mg) crystallized, mp 162–163°; IR ($CHCl_3$): 3400 (OH) and 1755 (γ-lactone) cm^{-1}; NMR ($CDCl_3$): δ 1.14 (3H, s, 5-CH_3), 1.16 (3H, d, J = 7 Hz, 10-CH_3), 1.46 (3H, d, J = 7 Hz, 11-CH_3), 3.24 (1H, m, H-11), 4.10 (1H, br, H-4), 4.18 (1H, d, J = 6 Hz, H-6), and 4.84 (1H, triplet of doublets, J = 3, 11 Hz, H-8); mass spectrum; *m/e* 268.1675 (M^+), calc. for $C_{15}H_{24}O_4$, 268.1673; 250 ($M^+ - H_2O$), 235 ($M^+ - H_2O - CH_3$), 232 ($M^+ - 2H_2O$), 224 ($M^+ - CO_2$), 208, 191, 178, 150, 136, 120, 117, 104, 103, and 102.

Anal.—Calc. for $C_{15}H_{24}O_4$: C, 67.16; H, 8.96. Found: C, 67.24; H, 9.03.

Earlier fractions from the crude reaction product chromatography yielded 3 mg of a second crystalline compound whose IR spectrum (3450, 1760, and 1720 cm^{-1}) was consistent with that expected for tetrahydroisotenulin, a possible intermediate in the production of IX.

GLC Determination of Whole Blood Antimalarial Concentrations

T. NAKAGAWA *§, T. HIGUCHI *, J. L. HASLAM ‡x, R. D. SHAFFER ‡, and D. W. MENDENHALL *

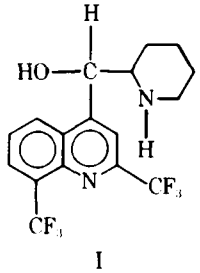
Received April 18, 1977, from the **Department of Pharmaceutical Chemistry, University of Kansas, Lawrence, KS 66045, and ‡INTERx Research Corporation, Lawrence, KS 66044.* Accepted for publication November 21, 1978. §Present address: Faculty of Pharmaceutical Sciences, Kyoto University, Kyoto 606, Japan..

Abstract □ An assay was developed for determining mefloquine (quinolinemethanol) and pyridinemethanol derivative concentrations in whole blood. The method involved ion-pair extraction or usual solvent extraction for drug recovery from whole blood followed by trimethylsilylation. The silylated compounds were then submitted to GLC with electron-capture or flame-ionization detection. Mass spectrometry combined with GLC of the trimethylsilyl derivatives indicated that substitution of one trimethylsilyl group had occurred on the hydroxyl group. A phenyl methyl silicone column with temperature programming separated the drugs from normal blood extracts. The determination limit was 10 ng/ml of whole blood when an electron-capture detector was used with ion-pair extraction. Quantitation was achieved by using one antimalarial as an internal standard for the assay of the other. The utility of the present method was demonstrated by following the whole blood level time course after a single oral 250-mg tablet in beagle dogs.

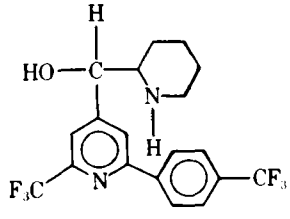
Keyphrases □ Mefloquine—analysis, GLC, blood □ Pyridinemethanol derivatives—analysis, GLC, blood □ Antimalarials—analysis, GLC, blood □ GLC, electron capture—analysis, mefloquine, pyridinemethanol derivatives, blood □ GLC, flame ionization—analysis, mefloquine, pyridinemethanol derivatives, blood

Mefloquine (I), DL-*erythro*-α-(2-piperidyl)-2,8-bis-(trifluoromethyl)-4-quinolinemethanol, is curative for drug-resistant falciparum malaria (1–3). This compound has an extremely long biological half-life and is distributed rapidly into the body tissue (4), suggesting that the amount of the drug circulating in blood is low and persistent.

DL-*threo*-α-2′-Piperidyl-2-(4-trifluoromethylphenyl)-6-trifluoromethyl-4-pyridinemethanol (II) is a new antimalarial with activity against *Plasmodium berghei* (5). Sensitive and specific assays for whole blood concentrations of both compounds were needed.



I



II

Several methods have been used for antimalarial analysis, including high-pressure liquid chromatography (HPLC) (6, 7), GLC (8), fluorometry (8), and liquid scintillation counting (9), but no reports have dealt with GLC determination of I and II in blood. Of these methods, HPLC combines better reproducibility and specificity than the fluorometry or radioactivity methods with a simple pretreatment procedure; it was used for I determination. However, HPLC sensitivity was limited by the relatively low I extinction coefficient at the readily accessible wavelengths, 280 and 254 nm; GLC combined with an electron-capture detector was expected to give more sensitive and specific measurements. This paper describes whole blood I and II determinations by electron-capture GLC.

EXPERIMENTAL

Reagents and Materials—Free bases of I and II were prepared by alkalizing the corresponding hydrochloride salts using equimolar sodium hydroxide in ethanol. The elemental analysis data (I—calc.: C, 53.97; H, 4.26; N, 7.41. Found: C, 54.29; H, 4.09; N, 7.59. II—calc.: C, 56.43; H, 4.49; N, 6.93. Found: C, 56.45; H, 4.47; N, 6.79), TLC, and GLC supported the purity of both free bases. The trimethylsilylating reagent[1] was a mixture of hexamethyldisilazane and trimethylchlorosilane dissolved in pyridine. Fresh human blood was obtained from volunteers. All other chemicals were commercially available analytical grades and were used without further purification.

GLC—The gas chromatograph[2] was equipped with an electron-capture detector and a flame-ionization detector. A U-shaped glass column (183

Table I—Compound I Recovery from Spiked Blood Samples by Ion-Pair Extraction followed by Electron-Capture and Flame-Ionization GLC Determinations

Blood Level, ng/ml	Recovery (Mean ± *SD*), %[a]
1070[b]	87.7 ± 4.6
535[b]	88.3 ± 4.6
107[b]	94.0 ± 5.2
10.4[c]	92.9 ± 9.4
5.3[c]	94.4 ± 15.3
1.04[c]	100.5 ± 19.1
Average	93.0 ± 9.7

[a] From three replicate samples. [b] Flame-ionization detection. [c] Electron-capture detection.

cm × 4 mm i.d.) was packed with 3% phenyl methyl silicone gum[3] coated on a flux-calcined diatomite support[4] (100–200 mesh, acid washed, dimethylchlorosilane treated). The electron-capture detection used an 8 mCi ^{63}Ni-radiation source, a 90-v dc cell voltage, and $1.0–1.2 \times 10^{-9}$ amp standing current. For flame-ionization detection, 30 ml of hydrogen gas/min, 300 ml of dry air/min, and a 300-v dc cell voltage were employed. The temperature was maintained at 250° for both the detector and the injector.

The column temperature was programmed to increase 1°/min from 160 to 250°, followed by flash heating to 280° to elute the high boiling materials from the column. The nitrogen carrier gas was adjusted to a 30-ml/min flow rate with a mass flow controller.

Sample Preparation Procedure—For statistical analysis, human blood was spiked with known amounts of the standard free bases to make 1–1000-ng/ml blood levels and equilibrated by shaking for 30 min. In the dog experiments, a 2- or 5-ml whole blood portion was withdrawn from a beagle dog, transferred immediately to a heavy-duty centrifuge tube, and weighed accurately. Two drops of 15% ethylenediaminetetracarboxylic acid disodium salt solution were added as an anticoagulant. The blood samples thus prepared were then extracted.

Ion-Pair Extraction—To the 5-ml blood sample, 4 ml of 0.2 *N* H_2SO_4 and 10 ml of ether were added. After the mixture had been shaken at room temperature for 10 min, it was centrifuged at 2000 rpm for 15 min. The ether layer was removed and discarded. Four milliliters of aqueous 3% trichloroacetic acid solution was added to the remaining blood layer, which was extracted three times using 10 ml of ether. An additional 1 ml of trichloroacetic acid was added with the ether on the second and third extractions.

For each extraction, the mixture was shaken for 30 min and centrifuged at 2000 rpm for 15 min, after which the ether layer was transferred to a separator. The combined ether extracts were washed with 10 ml of 10% NaOH and 10 ml of 10% aqueous ammonium hydroxide. After the aqueous layer had been drained, the ether layer was transferred to a conical flask and evaporated almost to dryness. The flask was further dried in a desiccator.

Ethyl Acetate Extraction—To a 5-ml blood sample in a centrifuge tube were added 1.8 ml of 0.1 *N* NaOH and 10 ml of ethyl acetate. The

1044	68.7 ± 5.17
104.3	76.3 ± 2.77
10.5	90.1 ± 42.2
Average	78.4 ± 16.7

[a] From three replicate samples.

tube was shaken for 30 min and centrifuged at 3200 rpm for 15 min. The extraction was repeated twice. The ethyl acetate layers were transferred to a conical flask and evaporated almost to dryness. The extracts were completely dried in a desiccator.

Ether Extraction—To a 2-ml blood sample were added 0.5 ml of 0.1 *N* NaOH and 5 ml of ether. After the mixture had been shaken for 15 min at room temperature, the ether layer was separated by centrifugation at 2000 rpm for 10 min and transferred to a conical flask. The remaining layer was extracted two more times with 5 ml of ether. The combined extracts were evaporated to near dryness, and the residue was dried in a desiccator.

Trimethylsilylation—The dried residue was dissolved in ~1 ml of ether and transferred to a small conical test tube. The internal standard solution in ethyl acetate was added to the tube based on an estimated sample compound concentration. After the solvent had been evaporated carefully under a nitrogen stream, 100 μl of the trimethylsilylating reagent (200 μl if the concentration was expected to be about 500 ng/ml) was added, and the solution was left to stand for 10 min at room temperature. An appropriate volume (0.2–2.0 μl) of this solution was injected onto the GLC column.

Quantitation—A peak height ratio method was employed. The weight ratio for the calibration plot was varied by changing the mixing ratio of the standard free bases I and II in ethyl acetate solution. The mixed solution was evaporated to complete dryness and trimethylsilylated according to the described procedure. The calibration plots thus obtained showed good linearity for the flame-ionization detection over 1:5 and 5:1 weight ratios. The electron-capture detection gave a slightly concave curve in the same region; however, a 1:2–2:1 weight ratio range produced a linear electron-capture detection response. The determination limit was 10 ng/ml for I when the electron-capture detection was used in combination with ion-pair extraction, but the flame-ionization detection could detect concentrations of 100 ng/ml for both I and II.

Dog Experiment—An *in vivo* experiment was conducted using three female beagle dogs. Each dog was fasted 24 hr prior to dosing. One dog (7.75 kg) was orally dosed with one 250-mg I tablet; two dogs (13.7 and 9.0 kg) were dosed with one 250-mg II tablet (both drugs as hydrochloride salt). From the dog dosed with I, blood was withdrawn through the jugular vein at 0, 1, 2, 2.5, 3, 3.5, 4, 4.5, 5, 6, 8, 12, 24, 72, and 144 hr, and at 2, 3, 4, 5, 6, 7, and 9 weeks after administration. The blood volume taken was 2 ml for the first 6 days and 5 ml thereafter. From the dogs dosed with II, 2 ml of blood was taken at 0, 1, 2, 3, 4, 5, 6, 8, 12, 48, and 72 hr after dosing.

RESULTS AND DISCUSSION

Since the average blood I level was expected to be lower than the II level from the same dosage, ion-pair extraction was used to obtain a better I recovery. An ethyl acetate extraction was examined as a possible procedural simplification. Tables I and II list the results for the statistical analysis of I recovery from spiked blood by ion-pair extraction and by ethyl acetate extraction, respectively. The ion-pair extraction gave higher I recovery and better reproducibility than ethyl acetate extraction; however, the standard deviation increased gradually at the lower levels. The ethyl acetate extraction was applicable to levels above 100 ng/ml. The recovery of II from the spiked blood was studied by ethyl ether extraction; a very high recovery with good reproducibility was observed for all levels examined (Table III).

In Tables I–III, the electron-capture detection and the flame-ionization detection were used for recovery determination. Electron-capture detection is highly sensitive to antimalarials that contain two trifluoromethyl groups per molecule but has a lower sensitivity to cholesterols, the major extracted blood component. The solvent peak tailing which sometimes interferes with drug peak separation in flame-ionization detection can be reduced by using low electron affinity solvents. Electron-capture detection has a relatively narrow dynamic range compared with flame-ionization detection, and detector stability and sensitivity depend

Table III—Compound II Recovery from Spiked Blood by Ether Extraction followed by Electron-Capture GLC Determination

Spiked Level, ng/ml	Recovery, %
1000	99.6
500	96.2
100	99.6
50	103.8
10	106.0
Mean ± *SD*	101.0 ± 2.8

more subtly on the detector condition than does flame-ionization detection. The detection limits for each drug were 1 ng/ml with the electron-capture detection (the limit of accurate determination is 10 ng/ml, Table I) and 100 ng/ml with the flame-ionization detection under the best condition. Thus, the electron-capture detection was used for blood levels of 10–1000 ng/ml and the flame-ionization detection was limited to levels higher than 100 ng/ml.

The I and II free bases without trimethylsilyl derivative formation gave tailing peaks on the chromatogram, which subsequently overlapped normal blood component background peaks. The trimethylsilyl derivatization produced sharper and higher peaks with shorter retention times, which helped separate the derivatives from the background peaks.

The reaction conditions used to prepare the trimethylsilyl derivatives were studied. The I and II free bases recovered from 2 or 5 ml of whole blood were completely derivatized with 100 μl of the silylating reagent at room temperature. An additional 100 μl of the reagent was used when a higher level of drug was found; the sample was further diluted so as to fall in the electron-capture detection sensitivity range. Silylation reaction time dependence was examined by injecting samples at 1, 5, 10, and 30 min after silylating reagent addition. The 1-min sample indicated about a 50% silyl derivative yield; just a trace amount of the unreacted species was found in the 5-min sample. For reaction times between 10 min and 1 day, neither a peak due to unreacted species nor measurable changes in the peak intensity were observed.

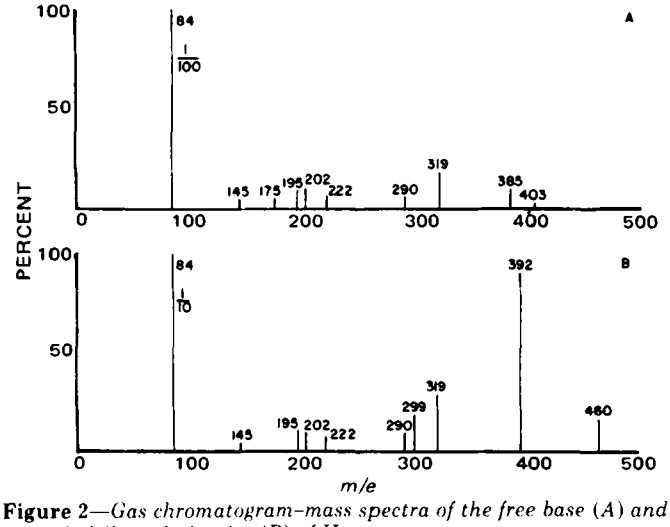

Figure 2—*Gas chromatogram–mass spectra of the free base (A) and trimethylsilane derivative (B) of II.*

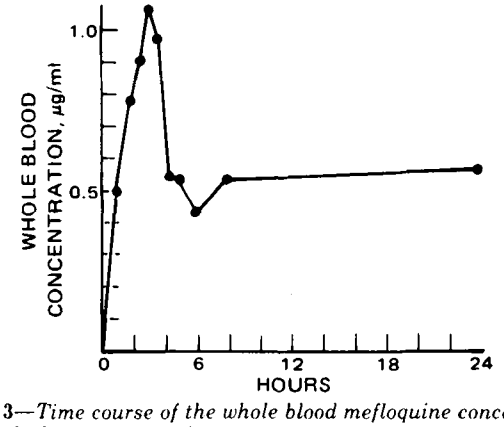

Figure 3—*Time course of the whole blood mefloquine concentration in a beagle dog given a single 250-mg tablet.*

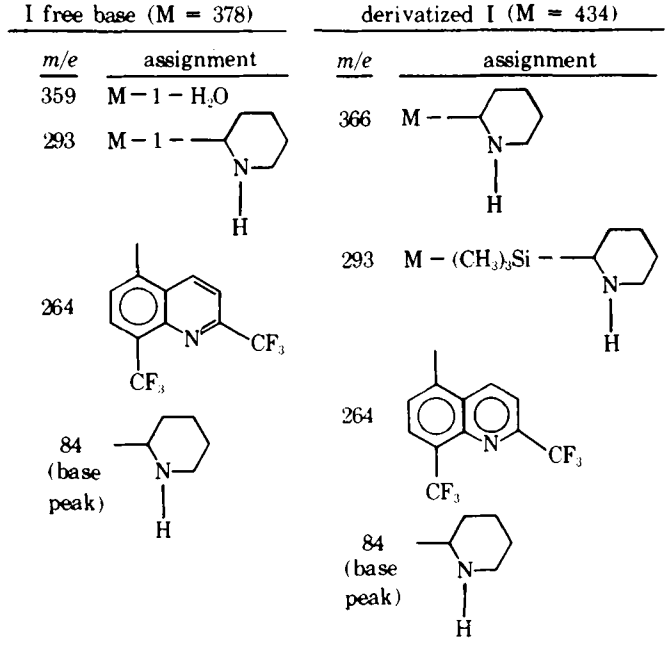
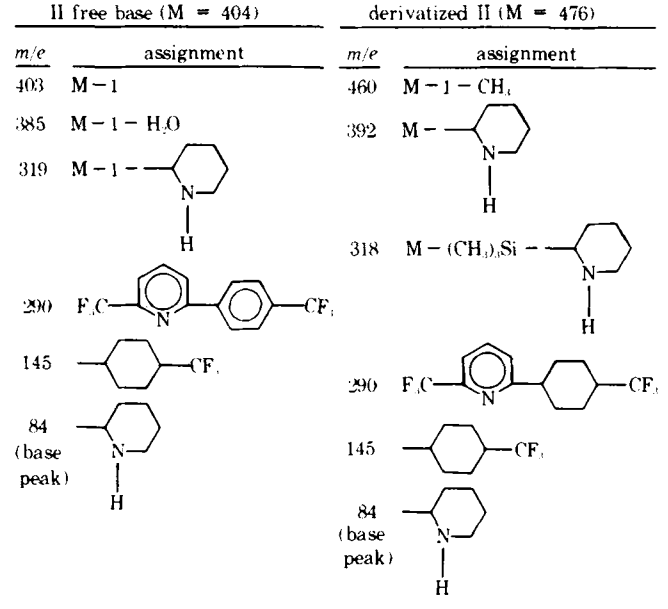
To confirm the structure of the trimethylsilyl derivative, GLC–mass spectra of the derivatized and underivatized free bases were obtained. The spectrum for trimethylsilyl-I (Fig. 1B) indicates the formation of the $(M - 1 - CH_3)^+$ ion at *m/e* 434; the I free base had an $(M - 1)^+$ ion at *m/e* 377 (Fig. 1A). The assignments of some possible fragment ions are summarized as:



The trimethylsilyl-II spectrum (Fig. 2B) similarly indicated $(M - 1 - CH_3)^+$ ion formation at *m/e* 460, and II free base (Fig. 2A) gave the $(M - 1)^+$ ion at *m/e* 403. Some other fragment ions are shown below:



Spectra for free bases and trimethylsilyl derivatives confirmed that one trimethylsilyl group had been substituted at the hydroxy group.

In vivo experiments were carried out to examine the utility of the present method (Figs. 3–5). The flame-ionization detection was used for the samples taken in the 1st week; the electron-capture detection was used for the samples taken thereafter. Figures 3 and 4 indicate the time course of whole blood I levels for the first 24 hr and for the following 42 days, respectively. A rapid increase in the blood I level was observed up to the maximum point at 3 hr, followed by a very slow decrease to a level of 18 ng/ml at 7 weeks. No measurable level was observed in the 9th-week blood sample. A semilogarithmic plot of the data in Figs. 3 and 4 led to a I elimination half-life of 10.2 days with a 0.068 day^{-1} rate constant.

Figure 5 shows the II time course plots given as the mean of two experiments. The blood II level increased during the first 3 hr after administration, reached a maximum level which was maintained for about

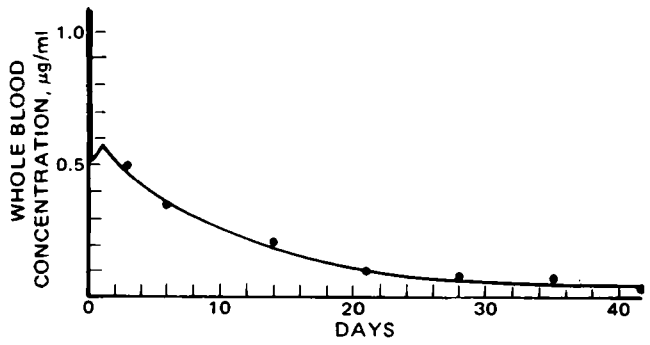


Figure 4—*Time course of the whole blood mefloquine concentration in a beagle dog given a single 250-mg tablet.*

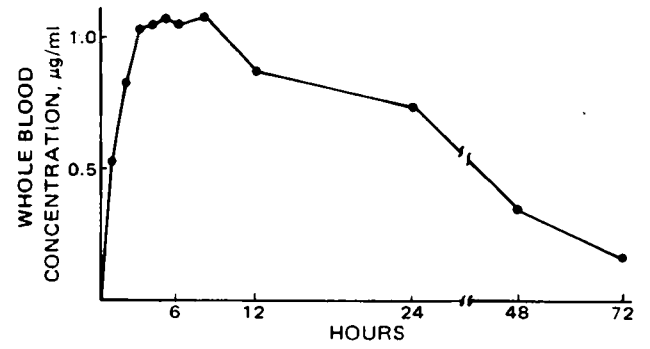

Figure 5—*Time course of the average whole blood II concentration in two beagle dogs given 250-mg tablets.*

5 hr, and then decreased slowly. From the semilogarithmic time course data plot, an elimination half-life and an elimination rate constant for II were estimated to be 24.8 hr and 0.028 hr^{-1}, respectively. The results for I and II suggested that I is about 10 times more persistent than II in its elimination from dogs.

Powder Homogenization Using a Hammer Mill

CHARLES C. YEUNG * **and JOHN A. HERSEY** ‡×

Received September 12, 1978, from the *Victorian College of Pharmacy Ltd. and the ‡Institute of Drug Technology Ltd., Parkville, Victoria, 3052, Australia. Accepted for publication November 30, 1978.

Abstract □ Hammer mill applicability in the comixing milling operation is discussed with reference to a 1:1000 microfine salicylic acid–sucrose binary system. The hammer mill would not serve as a mixing machine under most circumstances because of the low holdup capacity. Grinding of pure materials was preferable to mixture grinding since active ingredients could be lost during the milling operation. Remixing was always necessary following comminution of the mixture in the hammer mill. Grinding followed by remixing considerably enhanced mixture homogeneity. A large size range was produced by comminution, which resulted in the segregation of ordered units such that the final mixture could be described as a randomized ordered mixture.

Keyphrases □ Powders—homogenization using a hammer mill, sucrose–salicylic acid □ Pharmaceutical formulations—powders, homogenization using a hammer mill, sucrose–salicylic acid □ Hammer mill—powder homogenization, sucrose–salicylic acid

Many raw materials are supplied in a form requiring no further processing. However, grinding or cutting may be indicated with waxes and vegetable drugs or when agglomeration of starting materials occurs on storage. If grinding is a necessary stage in manufacturing or is required to attain a desired homogeneity, the hammer mill is frequently used for comminution.

Mixing is impossible when σ_R, the theoretical standard deviation of the fully randomized system, is equal to or greater than σ_A, the specification index (1). The σ_R value can be calculated from the sample size and the known proportions of the powders to be mixed using Lacey's equation (2):

$$\sigma_R^2 = \frac{XY}{N} \qquad \text{(Eq. 1)}$$

where X and Y are the proportions of the two ingredients and N is the number of particles in the samples. The σ_A value is calculated from the desired homogeneity of the powder mixture (3). The value of σ_R can be reduced by increasing the particle number per sample, which implies that size reduction is necessary.

Even though the hammer mill has been extensively used in the pharmaceutical industry for size reduction, limited evaluation has been carried out on the mixing performance of industrial comminution equipment. Most equipment used in comminution was ineffective for powder mixing operations because of the low holdup capacity (4). With nonflowing materials, passing a preblend through a ham-

mer mill increased the mixture homogeneity (5). The main problems associated with grinding were cost, contamination, and segregation (6).

Random mixing theory has been established for 25 years, but, in practice, mixtures rarely attain full randomization due to particulate size, shape, and density differences. Ordered mixtures exist in which one constituent adheres onto the surface of the other in a fixed proportion (7). The purpose of the present work was to investigate the application of the hammer mill to powder mixing operations with particular reference to ordered mixing. The binary system used had previously been shown to give an ordered mixture under some circumstances.

EXPERIMENTAL

Sucrose was the oversized fraction remaining when granulated sugar[1] was sieved through a 630-μm mesh screen[2]. Salicylic acid was previously sized using an air permeability technique (at 3.4-μm average diameter).

[a] Determined by a nest of sieves and a sieve shaker.

The sucrose size distribution was determined using a nest of sieves and a test sieve-shaker[3]. The sucrose and salicylic acid densities were determined by air comparison pycnometry to be 1.44 and 1.59 g/cm, respectively (8).

Preblends were prepared by mixing 3.6 kg of powders (salicylic acid–sucrose, 1:1000) in a 7.5-kg stainless steel revolvo-cube mixer[4] for 1, 2, 4, or 160 min. Each preblend was subsequently passed through the hammer mill[5]. The revolvo-cube mixer was fitted with an internal agitator rotating at 37 rpm while the cube mixer rotated at 17 rpm.

After grinding, the mixture was reloaded into the revolvo-cube mixer and remixed according to the procedure given in Table I. The whole comminution and remixing process was repeated three times. Twenty random samples (250 mg) were taken immediately before grinding and before remixing in the revolvo-cube mixer at each cycle for each preblend. To investigate the sample size effect on the standard deviation, different sample weights were collected using a set of concentric cylindrical sampling thieves. The samples were individually assayed by dissolving the contents in 50% ethanol. The absorbance was measured at 300 nm using a spectrophotometer[6] connected to an autosampling unit. The blank consisted of 50% ethanol with an equivalent amount of sucrose. For

[a] *m* = a single stage of mixing in the cube mixer, and *h* = a single passage through the hammer mill.

comparison, data previously obtained using salicylic acid and sucrose mixtures in a revolvo-cube mixer were used (8).

RESULTS

The sucrose size distribution is shown in Table II; the median diameter was 710 μm. The hammer mill comminution effect resulted in size reduction as the mix was passed through the hammer mill each time (Table II). Mixing was examined by the analysis of the samples removed at various stages, *i.e.*, after mixing and/or milling. The standard sample concentration deviation was calculated from:

$$S = \sqrt{\frac{\Sigma(x_i - \bar{x})^2}{n - 1}} \qquad \text{(Eq. 2)}$$

where x_i was the sample concentration and $\bar{x}$ was the mean sample concentration estimated from n number of samples.

Preblends were investigated after 1, 2, 4, and 160 min (Preblends 1–4, respectively). Figures 1–3 show the effect of passing the four preblends through the hammer mill once, twice, and three times. Preblend 4 was only passed through the hammer mill once. The graphs are plots of standard deviation against time. The *x*-axis is the cumulative time that the mixture was mixed in the revolvo-cube mixer.

Figure 4 shows the mixing of salicylic acid and sucrose or icing sugar in the revolvo-cube mixer. The effect of sample size on the standard deviation for Preblend 3 is shown in Fig. 5. Table III shows the mean salicylic acid content for the four preblends at different stages.

DISCUSSION

Figures 1–3 indicate that grinding should never be the last stage in any mixing operation. The comminution effect of the hammer mill induces segregation due to size differences; since the holdup capacity of the mill

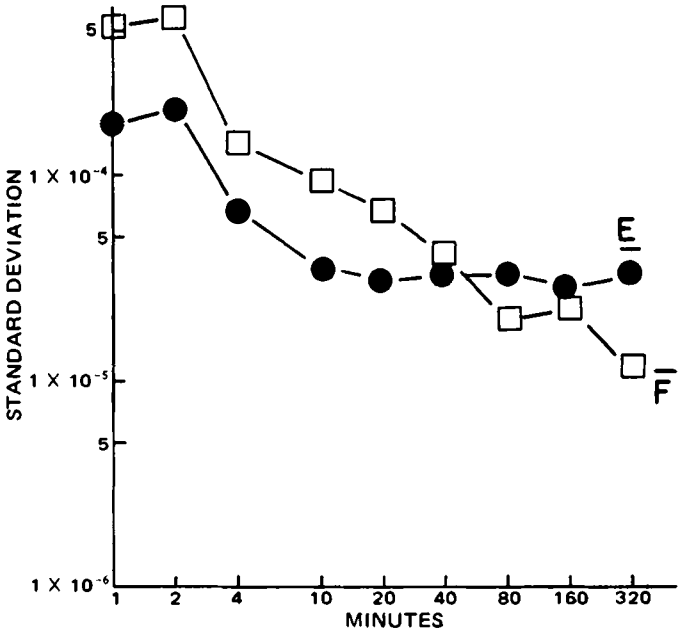

Figure 4—*Mixing of salicylic acid and sucrose/icing sugar (1:1000) in a cube mixer. Key:* E *and* F, *theoretical deviations of fully randomized mixtures of salicylic acid and sucrose and salicylic acid and icing sugar, respectively;* ●, *coarse sucrose system; and* □, *fine icing sugar system.*

is so low, no general mixing is possible. Therefore, before the materials are processed further, they must be mixed to improve homogeneity. Of the four different preblends, homogeneity increased during milling only when the preblend has been mixed in the cube mixer for the very limited period of 1 min.

The value of σ_R, the theoretical standard deviation of a fully randomized system, was calculated (9). There was a slight increase in mixture homogeneity through each cycle. This effect probably was due to the particle-size reduction and particles number increase.

If grinding is a necessary stage in the manufacturing process, it may be desirable to reduce the size of pure materials instead of the whole mixture. Table III shows the slight salicylic acid content decrease at each stage. Because of the highly cohesive microfine salicylic acid, the vigorous hammer grinding action possibly produces electrically charged fine particles and consequent particle attraction onto the mill and collecting bag walls. Thus, the salicylic acid content could vary from batch to batch.

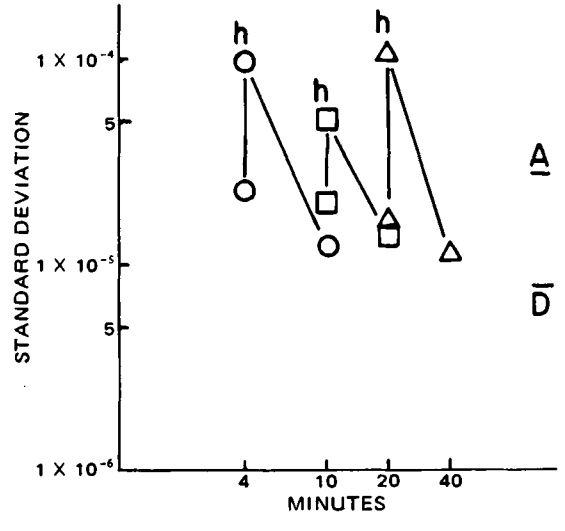

Figure 3—*Effect of passing the salicylic acid–sucrose mixture (1:1000) through the hammer mill three times. Key: A and D, standard deviations of a fully randomized equivalent system before and after passing through the hammer mill three times, respectively;* h, *mixture that has been passed through the hammer mill;* ○, *Preblend 1;* □, *Preblend 2; and* △, *Preblend 3.*

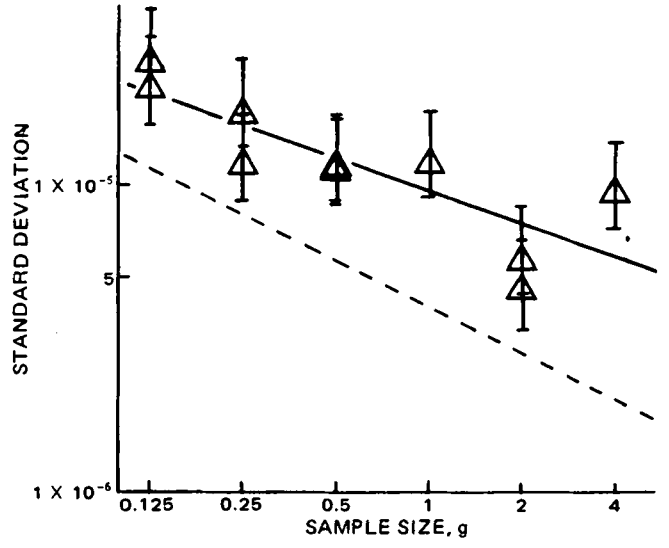

Figure 5—*Effect of sample size on standard deviation for Preblend 3 that was remixed after passing through the hammer mill three times. The dotted line represents the standard deviation for a fully equivalent randomized system. Error bars are 95% confidence limits for individual results.*

The active ingredient loss was only significant after three passes through the hammer mill.

Comparison of Fig. 1 with Fig. 4 shows that if the materials could be purchased in a fine form, it would probably be more economical to mix the preground fine material instead of grinding and mixing the coarser powders. The ordered mixture formation rate is slow when fine–fine components are mixed in a revolvo-cube mixer. With hammer mill mixture grinding, new surfaces are created by fracture of the coarse crystals. This procedure provides more area for drug particle adhesion. Furthermore, aggregates are broken down more rapidly in the hammer mill to facilitate mixing. Nevertheless, the cost of longer mixing time in the revolvo-cube mixer for fine–fine mixtures will be compensated by less handling of the mix than when the hammer mill is used.

Figure 4 also shows the mixing of a fine–coarse system in a revolvo-cube mixer where the desired degree of homogeneity is achieved after 10 min and the ordered mixture is stable and not prone to segregation (8). Even though homogeneity increases for fine particles, other problems such as fine powder flow (10) and storage effects (11) cannot be overlooked.

The sample size effect on the standard deviation for Preblend 3 is shown in Fig. 5. For a randomized mixture, the slope of the line will be −0.5. For an ordered mixture, it will approach zero. The 95% confidence limits for the slope were −0.554–−0.166. The mixture could not be classified as either completely randomized or completely ordered. In fact, it may have been a mixture of both systems, a description that may satisfy most powder mixtures used in pharmaceutical practice. A system with a large particle-size range is unlikely to be fully randomized due to size segregation. In practice, some degree of adhesional-type ordered mixture (12) may be formed. Due to the size differences of carrier particles, they will undergo ordered unit segregation (13, 14). Further mixing of this system will produce the randomized ordered unit powder mixture.

Vehicle Effects on Ocular Drug Bioavailability III: Shear-Facilitated Pilocarpine Release from Ointments

JAMES W. SIEG * and JOSEPH R. ROBINSON ˣ

Received June 5, 1978, from the *School of Pharmacy, University of Wisconsin, Madison, WI 53706.* Accepted for publication November 29, 1978. *Present address: College of Pharmacy, University of Kentucky, Lexington, KY 40506.

Abstract □ Pilocarpine release from water-in-oil emulsion ointments was studied *in vitro* and *in vivo*, using albino rabbits. Pilocarpine release from the vehicle to the ocular fluids was dependent on shear, *i.e.*, blinking, and the dosing system emulsifying efficiency. A mechanical shearing component was vital for correlating corneal drug penetration and the *in vitro* pilocarpine release pattern. Simple diffusion studies with the vehicles did not predict drug *in vivo* release, but the ointment systems were all superior to an aqueous pilocarpine solution. Incorporation of a mechanical shearing component to mimic blinking gave good correlation of *in vitro* and *in vivo* results. Also, increasing the vehicle emulsifying efficiency by surfactant addition decreased shear-facilitated drug release and *in vivo* performance. Finally, increasing the internal aqueous phase volume fraction decreased *in vivo* performance and was linked to the influence of effective drug concentration in the vehicle.

Keyphrases □ Dosage forms, ocular—pilocarpine, shear-facilitated release, ointments □ Pilocarpine—release, shear facilitated, ocular ointments □ Shear—facilitation of pilocarpine release from ocular ointments □ Ointments—pilocarpine, shear-facilitated release, ocular

Important considerations in vehicle design are the anatomical and physiological aspects of the drug delivery site. To improve drug bioavailability, ocular drug delivery system designs are based on comfort, contact time, and dose volume, each of which recognizes an important anatomical/physiological constraint. An additional ocular limitation is blinking, which can both increase and decrease drug bioavailability. On the positive side, blinking spreads instilled solution or ointment across the cornea, thus promoting corneal contact and drug absorption. On the negative side, it forces drug away from the precorneal area and into the drainage apparatus.

An important blinking feature is the shear that occurs when a vehicle is placed in the eye and blinking occurs. The proximity of the eyelids to the eyeball exposes an instilled vehicle to a considerable shearing stress during blinking. Non-Newtonian fluid vehicles should undergo rheological changes during blinking, and ointments should have an altered drug release profile. This report describes an ointment drug release that is dependent on blinking and on the shear created by blinking.

Drug solubility, prolonged contact time, and modest sustained release are some positive features of ointments. Unfortunately, ointments sometimes create blurred vision and are apparently less accepted by the patient than simple aqueous solutions. Nevertheless, one generally has greater control over drug release from an ointment than from a corresponding aqueous based product in terms of drug solubility, emulsion *versus* nonemulsion form, and contact time. Generally, drug release from an ointment is attributed to partitioning and/or diffusion, depending on the drug properties and the specific vehicle selected. A third possibility for drug release, specifically from water-

The active ingredient loss was only significant after three passes through the hammer mill.

Comparison of Fig. 1 with Fig. 4 shows that if the materials could be purchased in a fine form, it would probably be more economical to mix the preground fine material instead of grinding and mixing the coarser powders. The ordered mixture formation rate is slow when fine–fine components are mixed in a revolvo-cube mixer. With hammer mill mixture grinding, new surfaces are created by fracture of the coarse crystals. This procedure provides more area for drug particle adhesion. Furthermore, aggregates are broken down more rapidly in the hammer mill to facilitate mixing. Nevertheless, the cost of longer mixing time in the revolvo-cube mixer for fine–fine mixtures will be compensated by less handling of the mix than when the hammer mill is used.

Figure 4 also shows the mixing of a fine–coarse system in a revolvo-cube mixer where the desired degree of homogeneity is achieved after 10 min and the ordered mixture is stable and not prone to segregation (8). Even though homogeneity increases for fine particles, other problems such as fine powder flow (10) and storage effects (11) cannot be overlooked.

The sample size effect on the standard deviation for Preblend 3 is shown in Fig. 5. For a randomized mixture, the slope of the line will be −0.5. For an ordered mixture, it will approach zero. The 95% confidence limits for the slope were −0.554–−0.166. The mixture could not be classified as either completely randomized or completely ordered. In fact, it may have been a mixture of both systems, a description that may satisfy most powder mixtures used in pharmaceutical practice. A system with a large particle-size range is unlikely to be fully randomized due to size segregation. In practice, some degree of adhesional-type ordered mixture (12) may be formed. Due to the size differences of carrier particles, they will undergo ordered unit segregation (13, 14). Further mixing of this system will produce the randomized ordered unit powder mixture.

in-oil emulsions, is physical exchange of the internal emulsion phase with the neighboring tears. This report describes the properties of, and bioavailability from, such systems.

EXPERIMENTAL

Materials—Tritiated pilocarpine alkaloid (4.1 Ci/mmole) was obtained commercially[1] and purified by vacuum distillation immediately before each experiment to prevent problems with tritium exchange in the solvent. The ophthalmic ointment vehicles were commercially available, petrolatum-based products[2,3].

Male albino rabbits[4], 1.8–2.4 kg, were fed a regular diet with no restrictions on food and water consumption.

Pilocarpine Ointment Preparation—The 5% water-in-oil emulsion ointments were prepared by mixing a 0.05-ml aliquot of distilled water containing 2.08 mg of tritiated pilocarpine with sufficient ointment base to make 1 g of product. This procedure provided a 10^{-2} *M* pilocarpine ointment containing 5% water with a specific activity of 0.25 mCi/g, or approximately 160,000 cpm/mg.

For procedures in which the percent water in the ointment was increased, the ointments were prepared by adding more water in the initial step. The anhydrous ointment was prepared by geometrically mixing the tritiated pilocarpine alkaloid directly with the ointment vehicle. Surfactants were added directly to the ointment vehicles as required.

Drug distribution homogeneity was verified by the reproducibility of measured radioactivity among weighed ointment samples. Ointments were always prepared fresh prior to the experiment.

***In Vivo* Ointment Dosing Technique**—Individual ointment doses were weighed on an analytical balance. A standard 25-mg dose was used throughout the *in vivo* procedures. The weighed dose was carefully transferred to a microspatula and placed inside the center of the lower lid (cul-de-sac), with care being exercised not to irritate the eye or touch the corneal surface. The lower lid was gently moved once across the cornea to spread the dose uniformly and then released. No further manual action was performed, and normal precorneal ointment disposition was allowed to progress.

Aqueous Humor Drug Concentration–Time Profiles—The basic techniques used for monitoring aqueous humor drug levels after topical ocular dosing were described previously (1). Aqueous humor samples, 100 μl, were removed from the anterior chamber at specified times after dosing and analyzed for pilocarpine by liquid scintillation. Prior to sample removal, the precorneal area was rinsed thoroughly and the corneal surface was wiped gently with tissue to avoid contamination by any remaining ointment dose.

***In Vitro* Ointment Drug Release Study**—A 200-mg tritiated pilocarpine ointment sample was placed in the center of a 10-cm petri dish, covering a circular area 15 mm in diameter. The total pilocarpine was 416 μg, and the surface area figure was chosen to correspond to the average rabbit cornea. At the start of each release study, 35 ml of distilled water was added and the system was stirred using a magnetic stirrer and stirring bar positioned away from the ointment mass. One hundred-microliter samples were removed from the system at specified times and transferred to scintillation vials for liquid scintillation counting.

In studies where the ointment was sheared, the shearing action was accomplished manually. The ointment was positioned in the petri dish, as previously described; a microspatula, whose flat end was bent perpendicular to the rest of the handle, was used to shear the ointment against the bottom of the dish. The microspatula was rotated against the ointment, and an attempt was made to keep constant the ointment area exposed to the bathing fluid. Shear rates were predetermined and controlled by the operator. Despite the simplicity and crudeness of the system, very good reproducibility was obtained.

RESULTS

Effect of Ointment Vehicle Emulsifying Efficiency on Ocular Pilocarpine Penetration—In preliminary work (2), it was noted that the Absorption Base A[2] emulsifying efficiency was quite low compared with other hydrophilic absorption bases. Although this ointment vehicle can emulsify water to produce a relatively stable water-in-oil emulsion, 10% water is the limit. Since this vehicle was highly effective for intraocular pilocarpine penetration with a 5% water-in-oil emulsion system, this noteworthy *in vivo* success might be attributable to its low water emulsifying ability.

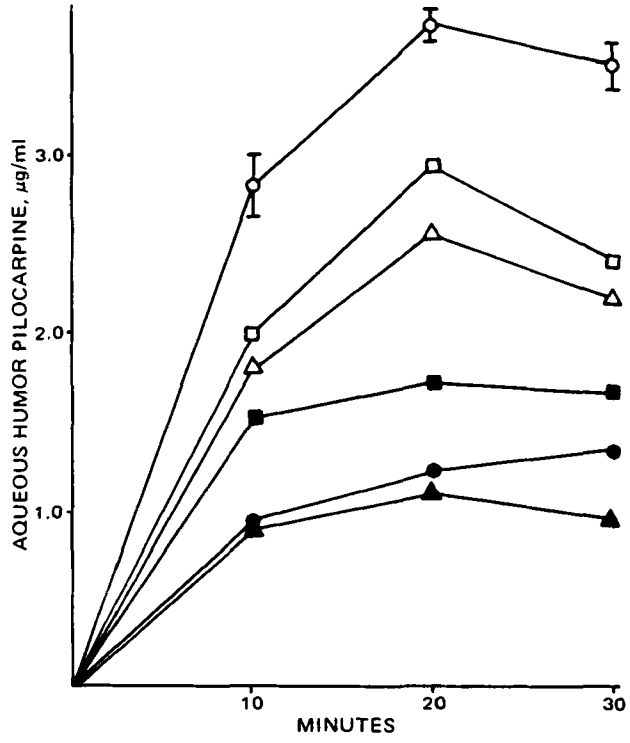

Figure 1—*Pilocarpine concentration in aqueous humor after dosing with various ointment vehicles and aqueous solution. Key:* ○, *Absorption Base A–5% water;* □, *Absorption Base A–2% sorbitan monooleate–5% water;* △, *Absorption Base A anhydrous;* ■, *Absorption Base B–5% water;* ●, *Absorption Base B–25% water; and* ▲, 10^{-2} M *aqueous solution, pH 6.24. Ointment doses were 25 mg, and the solution dose was 25 μl. At least 10 eyes were used for each data point, and representative variation in data is shown for only one system for clarity.*

Figure 1 presents current *in vivo* experiments performed to investigate this parameter. The superiority of the Absorption Base A–5% water system is readily apparent from the figure, especially when it is compared to the profile obtained from a 25-μl dose of 10^{-2} *M* pilocarpine aqueous solution (which contains the same total drug amount as the ointment). Peak aqueous humor pilocarpine levels occurred at 20-min postinstillation for both systems, but these levels are about four times higher for the ointment. The mechanism of transcorneal pilocarpine permeation and vehicle effects were extensively discussed in previous publications (3).

The next step was to incorporate 2% sorbitan monoleate[5] into the Absorption Base A vehicle to improve its emulsifying capability. A qualitative assessment of this parameter was made microscopically, and the base emulsifying efficiency was vastly improved[6] by surfactant addition. The *in vivo* experiments with this vehicle (Fig. 1) showed that aqueous humor pilocarpine levels decreased by about 25%.

At this point, the vehicle was changed to Absorption Base B[3] since its excellent emulsifying ability is well known. This base was mixed 50:50 with liquid petrolatum because the pure base did not melt at the rabbit body temperature. The mixture still possessed extremely good emulsifying efficiency, as indicated by microscopic inspection, while at the same time exhibiting melting and spreading characteristics in the eye similar to Absorption Base A. The data presented in Fig. 1 clearly indicated a further ocular drug penetration reduction when this vehicle was used.

The effect of increasing the vehicle percent water content was also investigated. Absorption Base B was used for these procedures since Absorption Base A would not accept more than about 10% water without serious "bleeding" problems. The 25% water addition decreased aqueous

humor drug levels relative to the Absorption Base B–5% water system (Fig. 1).

To provide a clearer baseline for assessing relative water-in-oil emulsion vehicle effectiveness, an anhydrous pilocarpine ointment was prepared using Absorption Base A. This system was intermediate in its effectiveness for intraocular pilocarpine penetration. The pilocarpine alkaloid was not soluble in this vehicle, as discussed previously (2).

***In Vitro* Pilocarpine Release from Ointment Vehicles under Nonshear and Shear Conditions**—Shearing is an appropriate consideration for the present study with ophthalmic ointments owing to the natural shear forces that arise during blinking. These experiments were designed to determine if shear-facilitated drug release is a characteristic of such systems.

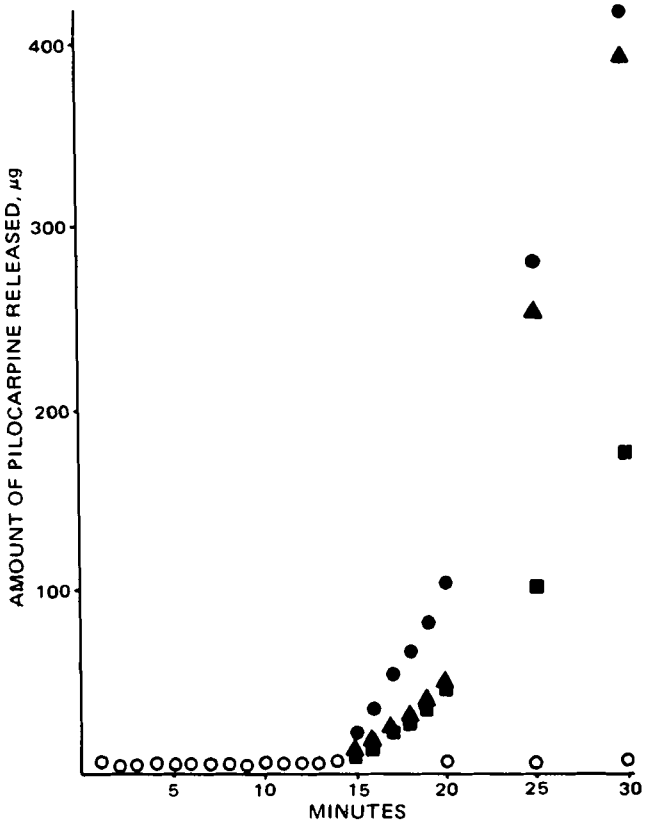

Figure 2—In vitro *pilocarpine release from various ointment vehicles under shear and nonshear conditions. Key:* ○, *Absorption Base A–5% water, no shearing;* ●, *Absorption Base A–5% water, shearing;* ■, *Absorption Base B–5% water, shearing; and* ▲, *Absorption Base A–2% sorbitan monooleate–5% water, shearing. The time interval from 0 to 15 min represents no shearing (simple diffusion), the time interval from 15 to 20 min represents a shear rate of 2/min, and the intervals from 20 to 25 min and from 25 to 30 min represent continuous shear conditions. Total pilocarpine in each system was 416 μg.*

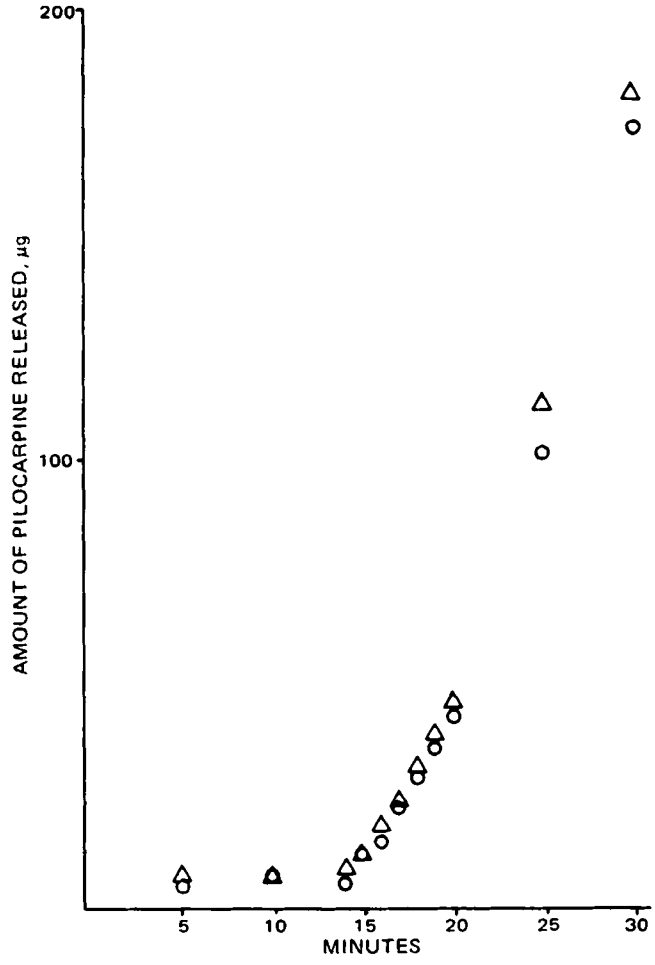

Figure 3—*Shear-facilitated pilocarpine release from absorption base B–5% water (○) and Absorption Base B–25% water (△). The time intervals representing specified shear conditions are the same as those indicated in Fig. 2. Total pilocarpine in each system was 416 μg.*

Figure 2 depicts the *in vitro* pilocarpine release patterns for three ointment vehicles. The data in each case represent an average of at least two determinations. The results of the nonshearing study using the Absorption Base A–5% water vehicle show that pilocarpine was not readily released by simple diffusion. In fact, the initial drug release, which was about 6–8 μg out of 416 μg, remained unchanged for the full 30 min of the studies.

A similar situation was observed with the other ointment vehicles. The interval from 0 to 15 min (Fig. 2) in the shearing experiments was actually a period of nonshear, or simple diffusion, drug release. The 15-min values for all systems are similar; values prior to this time point were omitted from the graph for clarity. The nonshear drug release for each system is presented in Table I.

At times beyond 15 min, addition of a mechanical shearing component to the *in vitro* release study dramatically changed the observed pilocarpine release pattern for each vehicle. The shear rate was 2/min in the interval from 15 to 20 min. The interval from 20 to 30 min represented continuous shear application during which time the operator attempted to liberate the maximum pilocarpine from the systems. The total drug released from each vehicle by the shearing procedures is listed in Table I.

Shearing caused immediate increased pilocarpine release from all vehicles (Fig. 2). The observed shear-facilitated release was consistent with microscopic assessment of the vehicle emulsifying ability. In each case, the shear-facilitated release rate was dependent on the shear rate, as indicated by the changes in slope at the 15- and 20-min points. In addition, within a given time interval with a specific shear rate, the release rate for each vehicle was a function of its emulsifying efficiency. The steepest slopes were observed for vehicles with the poorest emulsifying efficiency.

Figure 3 compares the shear-facilitated *in vitro* release patterns of the Absorption Base B–5% water and Absorption Base B–25% water vehicles.

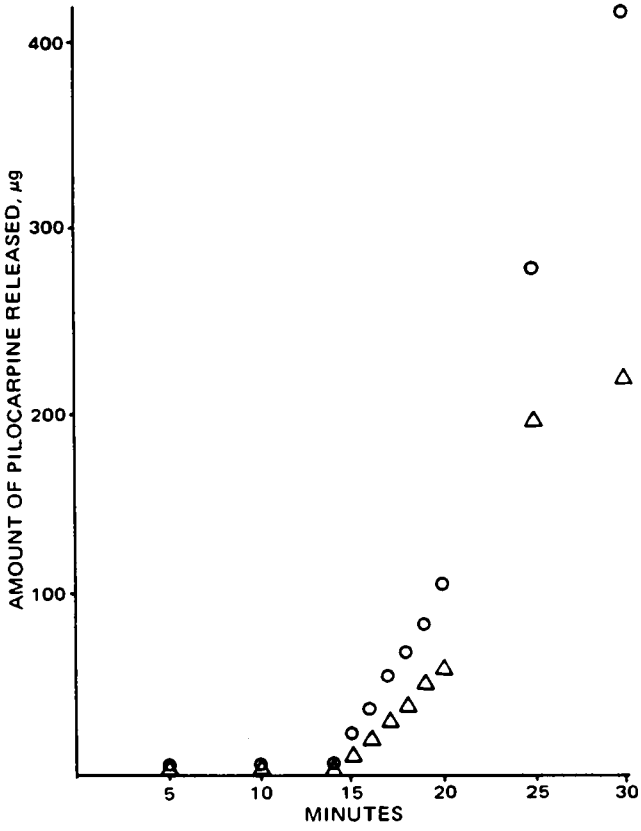

Figure 4—*Shear-facilitated pilocarpine release from Absorption Base A–5% water (○) and Absorption Base A anhydrous (△). The time intervals representing specified shear conditions are the same as those indicated in Fig. 2. Total pilocarpine in each system was 416 μg.*

These two systems showed nearly identical *in vitro* pilocarpine release. Figure 4 compares Absorption Base A–5% water and Absorption Base A anhydrous systems. The water-in-oil emulsion vehicle was clearly superior. This finding is in accord with the results of the *in vivo* experiments. A comparison of the data presented in Fig. 1 and in Table I shows that a good correlation between *in vitro* shear-facilitated drug release and *in vivo* corneal pilocarpine penetration was obtained for all of the vehicles studied. The Absorption Base A anhydrous vehicle also suffered a falloff of pilocarpine release during the terminal period of continuous shear application, a situation that is not apparent in the emulsion system for the time interval studied.

DISCUSSION

The results from *in vitro* and *in vivo* ointment studies show that pilocarpine release from the vehicles to the ocular fluids was dependent on shear and on the dosing system emulsifying efficiency. In particular, the mechanical shearing component was vitally important in correlating *in vitro* release patterns and *in vivo* performance. A literature search did not indicate that this approach had been used with *in vivo–in vitro* correlations for ophthalmic vehicles.

If the pilocarpine ointment studies are considered strictly in terms of simple partition–diffusion considerations, a number of apparent inconsistencies arise:

1. The simple *in vitro* diffusion study (without shearing) using the water-in-oil emulsion ointment vehicles did not indicate that drug release would occur *in vivo;* studies with albino rabbits, however, showed that these were excellent *in vivo* dosing systems and were as much as four times better than an aqueous solution containing the same pilocarpine amount.

2. Additional surfactant incorporation into the absorption vehicle improved the water-in-oil emulsion and increased the internal phase surface area. However, this result decreased the *in vivo* system performance.

3. Increasing the internal phase volume fraction, which decreased the oily diffusion barrier (external phase) thickness, also decreased *in vivo* performance.

A concise review of the parameters governing *in vitro* release of water-soluble drugs from water-in-oil emulsions using a simplified model was presented (4). In developing a qualitative interpretation, the following assumptions are commonly made: (*a*) the emulsion must be stable during the study time, (*b*) drug release occurs by simple diffusion or partition rather than by degradation or breaking of the emulsion, (*c*) the receptor medium acts as a perfect sink for the drug as it is released from the vehicle, and (*d*) the drug is dissolved in the aqueous phase.

Water-in-oil emulsion ointment vehicle stability was verified by checking the final product homogeneity during several storage days. Individually weighed ointment samples were analyzed for radioactivity distribution, and visual assessments of emulsion integrity were made using a microscope. No indications of instability were evident at any time for any of the vehicles studied.

The receptor medium for the *in vitro* release studies was also assumed to approximate a perfect drug sink. The relative amount of ointment and the medium volumes prevented pilocarpine concentration buildup during an individual experiment.

Pilocarpine solubility in the internal (aqueous) phase of the water-in-oil vehicles was verified previously (2). Pilocarpine resided almost totally within the aqueous component, and dissolution in the oleaginous portion of the base was highly unfavorable.

Drug release from ointment vehicles such as those under consideration is dependent upon several processes: (*a*) partitioning, (*b*) diffusion, and (*c*) "facilitated release," which refers to mechanical rupture of dispersed droplets in a water-in-oil emulsion system.

The mechanical shearing action affects each of these processes. The shearing force continually exposes new surface areas to the partitioning process between the vehicle and the receptor phase. Thus, the partitioning interface is altered by each successive shear input. The diffusion process may also be altered by a shearing component, since the diffusion layer thickness is changing. Finally, the mechanical shearing force greatly influences systems in which drug release is facilitated by coalescence and rupture of the dispersed droplets in a water-in-oil emulsion.

These considerations may be included in a discussion of the apparent inconsistencies regarding the *in vitro* and *in vivo* performance of the vehicles used in the present study. The first inconsistency can be eliminated by simply adding a mechanical shearing component to the *in vitro* drug release study. Good correlations between *in vitro* drug release and *in vivo* corneal drug penetration are thus achieved, whereas lack of such a component makes these correlations impossible. Such a shear component is intimately linked to the major drug release mechanism for the systems studied.

A qualitative measure of this shear release mechanism can be inferred from the slopes of the *in vitro* release rate profiles. The slopes are all very steep under shear conditions, suggesting that partitioning and diffusion are probably less important than shear-facilitated release. Undoubtedly, all three mechanisms operate simultaneously, but the shear-dependent mechanism is the more important and releases drug at a faster rate.

The second problem involves the addition of greater amounts of surfactant and the resulting increased internal phase surface area. While an increase in the internal surface area would be expected to increase drug release, this parameter is also a direct consequence of the emulsifying efficiency of the system and the "goodness" of the emulsion. The *in vivo* data correlate with this parameter in a unique manner. The best *in vivo* system (Absorption Base A–5% water) possessed the lowest emulsifying efficiency. Thus, surfactant addition decreased the *in vivo* performance. This observation must reflect the dependence of these systems on the shear component. Shear-facilitated drug release by emulsion rupture seems reasonable.

Finally, the decreased *in vivo* performance resulting from increasing the internal phase volume fraction may be explained on the basis of the effective pilocarpine concentration in the vehicle. A preliminary discussion of this parameter was reported (2). Since the pilocarpine is only soluble in the aqueous component of the water-in-oil emulsion vehicles, the drug will be present almost exclusively in the internal phase. However, since this phase comprises only a fraction of the total volume, the effective pilocarpine concentration in the ointments will be higher than an aqueous solution of the same volume. In other words, a 25-mg dose of 10^{-2} *M* pilocarpine in an Absorption Base A–5% water vehicle will possess an effective aqueous pilocarpine concentration 20 times higher than a 25-μl dose of 10^{-2} *M* aqueous pilocarpine solution. Similarly, the concentrations in the Absorption Base B–5% water and Absorption Base B–25% water vehicles differ by a factor of five due to different internal phase volumes.

The data in Fig. 3 show similar *in vitro* release patterns from these two vehicles, although the *in vivo* data presented in Fig. 1 show that the 5% water vehicle is superior. This finding has important implications re-

garding effective concentration influences. The *in vitro* system for measuring drug release could not distinguish between these two systems due to the large receptor medium volume. The effective concentration parameter was swamped by the excess receptor fluid. However, this result did not occur *in vivo* due to the limited volume (about 7 μl) of precorneal fluid present. This finding also points out problems that can arise when such *in vitro* tests are used to predict *in vivo* performance for systems containing high effective drug concentrations.

The *in vivo* data for these two vehicles (Fig. 1) may not reflect the fivefold difference in effective concentration since the aqueous humor levels produced by the Absorption Base B–25% water vehicle were decreased by less than one-half those values achieved by the Absorption Base B–5% water vehicle. However, these results were quite reasonable if the dilution factor arising from the normal resident tear pool volume (7.5 μl) was considered. The water volume in a 25-mg dose of the Absorption Base B–25% water vehicle was 6.25 μl, with one-fifth this amount (1.25 μl) being present in an equivalent dose of the Absorption Base B–5% water vehicle. If each volume were to be mixed with the tear pool, the calculated decrease in precorneal drug concentration would be no more than 40%. Of course, such mixing would not be instantaneous in either case, but these considerations do explain the observed results.

The data in Fig. 4 show that the Absorption Base A–5% water vehicle was able to release more pilocarpine *in vivo via* shearing than was the Absorption Base A anhydrous vehicle. Inspection of the *in vivo* data presented in Fig. 1 also shows the emulsion system to be superior. The reason for this result may be that as the percent water in the vehicle is reduced to zero, the rate-controlling process is switched from mechanical rupture of the emulsion to dissolution or diffusion control. Further work to determine this mechanism is indicated.

A shearing component is a necessary feature for *in vitro–in vivo* data correlations with ophthalmic ointments. Since some form of shearing action, such as inunction, is common to nearly every semisolid topical dosing system and to many parenteral products, this parameter should have almost universal importance.

These studies show that significant drug bioavailability increases can be achieved by careful design of a system that incorporates shear-facilitated drug release. More importantly, the results also demonstrate that such systems can be used to reduce the total drug amount required for topical ophthalmic dosing. This implies a reduced systemic drug load and decreased side effects, particularly important points for pediatric dosing.

Enhanced Chartreusin Solubility by Hydroxybenzoate Hydrotropy

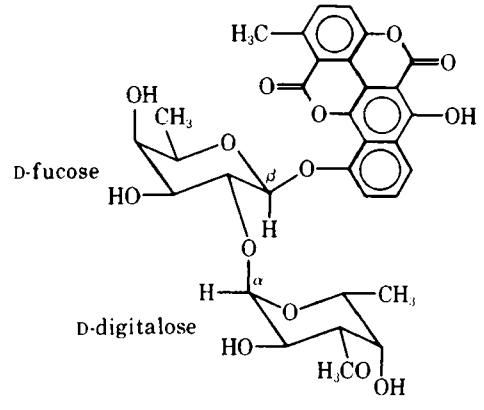
G. K. POOCHIKIAN ˣ and J. C. CRADOCK

Received October 6, 1978, from the *Analytical and Product Development Section, Pharmaceutical Resources Branch, National Cancer Institute, National Institutes of Health, Bethesda, MD 20014.* Accepted for publication November 30, 1978.

Abstract □ The apparent aqueous solubility of the water-insoluble cytotoxic agent, chartreusin, was increased at neutral pH in the presence of hydroxybenzoates. Water molecules play an important role in the chartreusin conformation. Studies included solubility and spectral examinations. The weakest and strongest interactants with chartreusin were sodium benzoate and sodium trihydroxybenzoate, respectively, while the effect of mono- and dihydroxybenzoates was intermediate. A plane-to-plane orientation of chartreusin and the ligand molecules brought together by electrostatic and hydrophobic interactions is postulated. The dramatic chartreusin aqueous solubility increase relative to its aglycone, chartarin, under similar conditions was best rationalized by micellization.

Keyphrases □ Chartreusin—aqueous solubility enhanced by hydroxybenzoates, conformation □ Hydroxybenzoates—electrostatic and hydrophobic interactions, stability constants □ Cytotoxic agents—chartreusin, aqueous solubility enhanced by hydroxybenzoates □ Antineoplastic agents, potential—chartreusin, aqueous solubility enhanced by hydroxybenzoates

Chartreusin[1] (I) produced by *Streptomyces chartreusis* was originally reported in 1953 (1), but its chemical structure was not fully elucidated until 1964 (2, 3). The chartreusin aglycone, chartarin (II), possesses essentially a planar ring system. The phenolic group at C-10 is glycosidically (β) bound to a D-fucose, which, in turn, is linked



I

by an α-glycosidic linkage to D-digitalose. Chartreusin has exhibited substantial chemotherapeutic activity in mice against the P-388 and L-1210 leukemias and, to some extent, against B16 melanoma (4). Biochemical studies demonstrated that I binds to DNA and inhibits RNA and DNA syntheses (5).

Low chartreusin solubility (15 μg/ml) inhibits preparation of reasonably concentrated aqueous solutions. Although the solubility may be increased to 2 mg/ml at a high pH (>9), these solutions may be irritating and incompatible with physiological fluids. More importantly, significant irreversible decomposition of these solutions is evi-

[1] Benzo[*h*][*l*]benzopyrano[5,4,3-*cde*][*l*]benzopyran-5,12-dione, 10-[[6-deoxy-2-*O*-(6-deoxy-3-*O*-methyl-α-D-galactopyranosyl)-β-D-galactopyranosyl]oxy]-6-hydroxy-1-methyl.

garding effective concentration influences. The *in vitro* system for measuring drug release could not distinguish between these two systems due to the large receptor medium volume. The effective concentration parameter was swamped by the excess receptor fluid. However, this result did not occur *in vivo* due to the limited volume (about 7 μl) of precorneal fluid present. This finding also points out problems that can arise when such *in vitro* tests are used to predict *in vivo* performance for systems containing high effective drug concentrations.

The *in vivo* data for these two vehicles (Fig. 1) may not reflect the fivefold difference in effective concentration since the aqueous humor levels produced by the Absorption Base B–25% water vehicle were decreased by less than one-half those values achieved by the Absorption Base B–5% water vehicle. However, these results were quite reasonable if the dilution factor arising from the normal resident tear pool volume (7.5 μl) was considered. The water volume in a 25-mg dose of the Absorption Base B–25% water vehicle was 6.25 μl, with one-fifth this amount (1.25 μl) being present in an equivalent dose of the Absorption Base B–5% water vehicle. If each volume were to be mixed with the tear pool, the calculated decrease in precorneal drug concentration would be no more than 40%. Of course, such mixing would not be instantaneous in either case, but these considerations do explain the observed results.

The data in Fig. 4 show that the Absorption Base A–5% water vehicle was able to release more pilocarpine *in vivo via* shearing than was the Absorption Base A anhydrous vehicle. Inspection of the *in vivo* data presented in Fig. 1 also shows the emulsion system to be superior. The reason for this result may be that as the percent water in the vehicle is reduced to zero, the rate-controlling process is switched from mechanical rupture of the emulsion to dissolution or diffusion control. Further work to determine this mechanism is indicated.

A shearing component is a necessary feature for *in vitro–in vivo* data correlations with ophthalmic ointments. Since some form of shearing action, such as inunction, is common to nearly every semisolid topical dosing system and to many parenteral products, this parameter should have almost universal importance.

These studies show that significant drug bioavailability increases can be achieved by careful design of a system that incorporates shear-facilitated drug release. More importantly, the results also demonstrate that such systems can be used to reduce the total drug amount required for topical ophthalmic dosing. This implies a reduced systemic drug load and decreased side effects, particularly important points for pediatric dosing.

dent within a few hours at room temperature. However, at neutral pH, various hydroxybenzoic acids increase chartreusin solubility.

This report describes the preparation of relatively concentrated aqueous chartreusin solutions and the qualitative and quantitative nature of the interactions with various mono-, di-, and trihydroxybenzoic acid sodium salts.

EXPERIMENTAL

Materials—Benzoic acid, salicylic acid, *m*-hydroxybenzoic acid, *p*-hydroxybenzoic acid, 2,4-dihydroxybenzoic acid, 2,5-dihydroxybenzoic acid, 2,6-dihydroxybenzoic acid, and 2,4,6-trihydroxybenzoic acid from the same commercial source[2] were used directly[3]. Chartreusin[4] (NSC-5159), mp 246–249° (benzene–methylene chloride), and chartarin[5], mp 311–314° [lit. (2) mp 315–316°], were used as received. All other chemicals were analytical reagent grade and were used without further purification.

Solubility Studies—Ligand stock solutions of known concentrations were prepared by dissolving the necessary ligand quantities in equimolar amounts of aqueous sodium bicarbonate solution. Excess chartreusin or chartarin was added to 15-ml screw-capped vials containing different aliquots of the proper stock ligand solution, and sufficient water was added to yield 10 ml of aqueous media. The vials were stirred mechanically in a constant-temperature water bath[6] (25 ± 0.1°). To prevent excessive hydroxybenzoate oxidation and to avoid chartreusin or chartarin hydrolysis, no samples remained in solution for more than 48 hr. Chartreusin and chartarin were stable in these solutions (pH ~ 6.0[7]) during the study period, which was sufficient to ensure equilibrium with all ligands tested.

The mixtures were centrifuged for 5 min at 25° and then filtered[8]. An aliquot of the filtrate was diluted quickly with a small amount of water, and the resulting solution was extracted with fixed volumes of chloroform. The combined organic extracts were dried over anhydrous sodium sulfate, filtered, and diluted to the desired volume with additional dry chloroform. The solubilized chartreusin concentration was then measured spectrophotometrically[9]. The extraction procedure was necessary due to the limited chartarin solubility in water.

Following extraction with chloroform, the ligand concentration in the aqueous phase accounted for most (>98%) of the original ligand present as measured spectrophotometrically in the UV region. These same aqueous solutions had no absorption in the visible region, thus indicating that chartreusin and chartarin had partitioned essentially completely into chloroform and that the measured chloroform solution absorbances were due only to the free forms. The I and II concentrations were calculated from appropriate Beer–Lambert plots; I, λ_{max} (chloroform): 424 (log ϵ 4.31) nm; and II, λ_{max} (chloroform): 427 (log ϵ 4.26) nm.

The chartreusin and chartarin solubility diagrams were obtained at 25 ± 0.1° by plotting the observed solubilities against the added benzoate concentrations. The apparent stability constants for both compounds were calculated by the solubility method (7).

Precise solution surface tension[10] measurements were obtained using the Ring method by direct reading (dynes per centimeter).

RESULTS AND DISCUSSION

The solvent effects on the UV–visible spectra of chartreusin (0.025–0.027 × 10^{-3} *M*) in chloroform, ethanol, and water are shown in Fig. 1. The noticeable spectral perturbations in the strong protic solvent, water, may indicate intramolecular associations. These observations, based on the fact that water molecules can influence macromolecular conformation (8, 9) if they change any of the noncovalent bonds that stabilize macromolecular conformation, may explain the observed low chartreusin aqueous solubility. Such information, along with inspection of models, indicated a conformational change in the chartreusin molecule involving an intramolecular association or the folding up of the sugar portion over the aromatic moiety. Furthermore, the D-fucose 3-hydroxyl hydrogen is conformationally capable of hydrogen bonding to the digitalose pyranoside oxygen (10, 11). Such a possibility would create a cage-type chartreusin molecular conformation and diminish its hydration, resulting in the observed low water solubility.

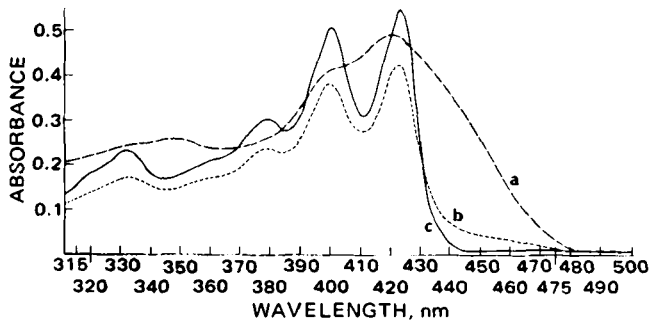

Figure 1—*Chartreusin UV–visible absorption spectra in water (a,– –), 95% ethanol (b,- - -), and chloroform (c,—).*

Hydroxybenzoates have a definite solubilizing action on chartreusin. As shown in Fig. 2, the amount of chartreusin in equilibrium with its solid phase increased progressively with the hydroxybenzoate concentration. The chartreusin solubility increase may be attributed partially to complex formation; however, due to the high reaction product solubilities and instabilities, the exact stoichiometry could not be determined. Nevertheless, the plots indicate that the dependency was nonlinear. The observations strongly support the suggestion that more than one ligand molecule interacts with an individual chartreusin molecule.

The I solubility diagram indicates that, among the ligands studied, the weakest interactant with chartreusin was the unsubstituted benzoate while the strongest was the 2,4,6-trihydroxybenzoate. Between these two were sodium benzoates with different hydroxyl substituents, all increasing I solubility.

The introduction of a hydroxyl group into the ring markedly enhanced the carboxylate "binding" tendencies. With the assumption of 1:1 and 1:2 interactions, the $K_{1:1}$ and $K_{1:2}$ association constants were calculated by the least-squares method (Table I) (7). The *ortho*-substituent had the strongest solubilizing effect on chartreusin. The enhancement effect of *meta*- and *para*-isomers on chartreusin solubility was somewhat less but still appreciable (Fig. 2 and Table I).

The sequential addition of a second or third hydroxyl group at different positions on the aromatic ring intensified chartreusin solubility on a mole to mole basis (Fig. 2). However, due to the limited solubility (0.15 *M*) of sodium 2,4,6-trihydroxybenzoate in water at 25 ± 0.1°, the apparent chartreusin solubility could not be increased more than 120-fold relative to that of water. The additional hydroxyl substitutions may lead to formation of other complexes independent of the original complex or may increase the initial complex strength while maintaining the same structure and, consequently, increase chartreusin solubility. Various ligands may have differently oriented interaction sites with chartreusin, or two complexes of different structures may coexist.

The chartreusin solubility equilibrium in the presence of dihydroxy-

benzoates, contrary to that with benzoate and monohydroxybenzoates, was achieved quickly (5 min) at concentrations up to 0.5 *M*. Higher ligand concentrations required 30 hr for equilibrium (Fig. 3). Moreover, a difference in the chartreusin solubility equilibration time with benzoate and various monohydroxybenzoates existed, the former being the slowest. Hence, the benzoate hydroxyl group(s) must play a key role in solubility equilibrium and in improving chartreusin solubility.

The increased chartreusin solubility in the presence of monohydroxybenzoates may be rationalized as follows. A hydroxyl group would stabilize the carboxylate anion by delocalization of the negative charge in the following order: *o*-hydroxybenzoate > *m*-hydroxybenzoate > *p*-hydroxybenzoate (12). Such a process would create a π-excessive aromatic system. Furthermore, in *o*-hydroxybenzoate, "ion-dipole interaction" between the phenolic hydrogen and the carboxylate anion (13) tends to keep the carbonyl group in a position coplanar with the benzene ring. Consequently, the carboxylate function π-electrons resonate with the aromatic ring π-electrons and thus increase the area of the π-cloud above and below the plane of the aromatic molecule.

Similarly, the two hydroxyl moieties in 2,6-dihydroxybenzoate are

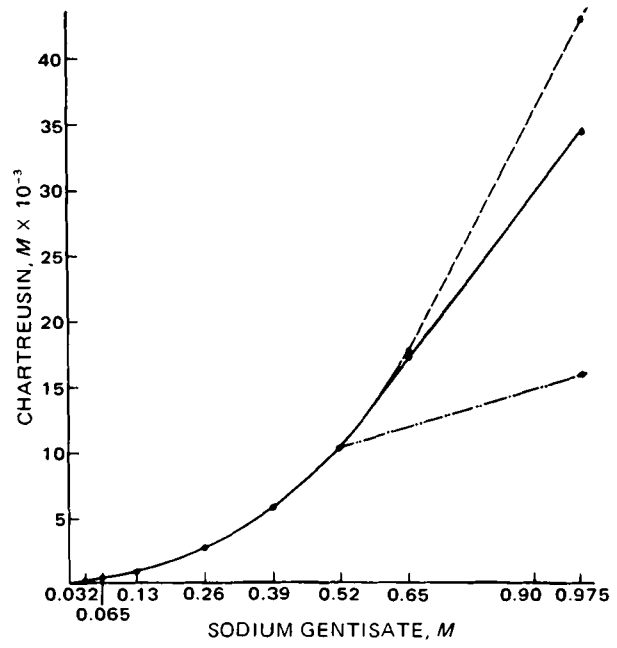

Figure 3—*Chartreusin solubility at 5 min (····), 24 hr (—), and 30 and 48 hr (- -) in the presence of increasing concentrations of sodium gentisate in water at 25 ± 0.1°.*

capable of forming two simultaneous intramolecular hydrogen bonds with the carboxylate anion, resulting in a greater planar π-cloud area relative to the 2,5- and 2,4-dihydroxybenzoates. Such an increase in the benzoate planar surface area may intensify the π–π interaction with the chartreusin aglycone portion, which possesses essentially a planar ring system, and, consequently, explain the observed solubility data: 2,4,6- > 2,6- > 2,5- > 2,4- > *o*- > *m*- > *p*- > sodium benzoate. Thus, charge delocalization on the carboxylate ion coupled with the increase in the ligand molecule π-cloud area would account partially for the difference in apparent chartreusin solubility in the presence of various benzoates. In addition, this relationship parallels the increasing pKa order of their respective acids (14), which reflects the inductive and resonance effects (12, 15).

The area correlation is good evidence for the gross structure of these interactions in solution, which may be described as a plane-to-plane orientation of the substrate and ligand molecules. Such molecular ar-

rangements in solution may also indicate electrostatic interactions. Charge transfer forces have orientational properties (16), and their complexes are formed in simple molecular ratios (17). Figure 4 shows the I spectra in the presence of water and various benzoates. The chartreusin spectrum in the presence of benzoate(s) was modified to the extent that it resembled the chartreusin spectrum in chloroform (Fig. 1). This change was most prominent with di- and trihydroxybenzoates. This may be visualized as the chartreusin molecule unfolding due to its interaction with the benzoate, enabling the sugar portion to interact with water as well as with excess benzoate molecules and resulting in enhanced water solubility. Furthermore, a bathochromic shift (2 nm) of the 399- and 421-nm peaks, as well as a marked hyperchromic shift at 399 nm (Fig. 4), was observed.

These ligand-induced spectral changes suggested orientations favoring intermolecular interaction such as local dipole–dipole or dipole-induced–dipole interactions with perhaps some contact-type charge transfer contribution. Interestingly, the hydroxybenzoate sequence 2,4,6 > 2,6 > 2,5 > 2,4 > *o*-hydroxybenzoate > *m*-hydroxybenzoate > *p*-hydroxybenzoate that increased the chartreusin solubility is in the same order as their electron donor strengths, as would be expected from their

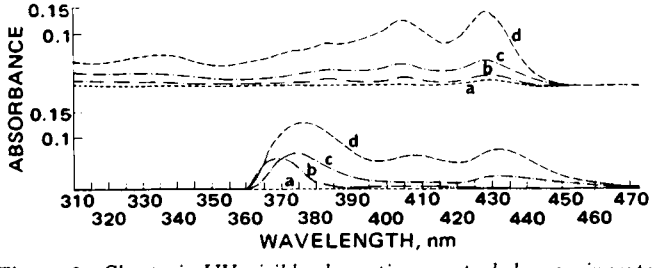

Figure 6—*Chartarin UV-visible absorption spectral changes in water (a, - - -) and in the presence of 0.13* M *(b, ·–·–·), 0.26* M *(c, ·–·), and 0.52* M *(d, – –) sodium gentisate (bottom) and following extraction of these solutions into chloroform (top).*

ionization energies (18–20). Conjugation (21, 22) and electron donor groups decrease the π-electron ionization potential (23). Moreover, the polarization model for substituent effects gives qualitatively correct predictions. The addition of two substituent groups having opposite dipole moment directions with respect to the aromatic ring resulted in an ionization potential increasing in the order *o*-hydroxybenzoate > *m*-hydroxybenzoate > *p*-hydroxybenzoate (23). The effects of such substituents are additive but not necessarily linear. However, when studying electron donor–acceptor interactions in aromatic compounds containing heteroatom(s) capable of ρ–π-conjugation, one should recognize that *n*-donor or π-donor properties depend on certain factors (24).

To shed additional light on the interactions that increased chartreusin solubility, the chartreusin aglycone was studied. Chartarin is virtually water insoluble. The effect of various ligands on chartarin solubility is shown in Fig. 5. The shape of the curves corresponds to that of chartreusin. The order of the ligands that increased chartarin solubility was identical to that of chartreusin: trihydroxybenzoate > dihydroxybenzoate > monohydroxybenzoate. With the assumption of 1:1 and 1:2 interactions between chartarin and the ligand, the $K_{1:1}$ and $K_{1:2}$ stability constants were calculated (7) (Table I).

The characteristic chartarin UV-visible maxima were obtained in chloroform[11]. However, due to the low chartarin solubility, the corresponding UV-visible spectrum in water was unobtainable. Significant chartarin spectral changes were induced in the presence of various aqueous benzoates. These changes were observed as the difference spectra of ligand *versus* chartarin plus ligand. A typical difference spectrum is shown in Fig. 6. The $\lambda_{max}^{H_2O}$ at 404 and 427 nm had a 5-nm bathochromic shift, while all other bands[11] present in chloroform disappeared. However, a new absorption band appeared between λ_{325} and λ_{380} nm, depending on the ligand used (Table II). The new peak became the predominant one in the spectrum.

The magnitude of the bathochromic shift was dependent on the ligand concentration (Table II), and the extent of the red shift was more noticeable in the presence of the ligand with greater binding tendencies. On extraction with chloroform, the spectrum of each organic solution was identical to the original spectrum in chloroform (Fig. 6), while the remaining aqueous phase quantitatively accounted (>98%) for the ligand. The increase in chartarin solubility and the significant spectral changes in the presence of sodium hydroxybenzoate(s) support the charge transfer (24) interaction hypothesis.

There also appears to be hydrophobic contribution to the complex stabilization, since there is a direct relationship between the ligand surface area and the stability constants. Such interactions may be important for the association of solute molecules in water, although they may not be the dominant ones. Water, in addition to its role in hydrophobic bonding, may influence the stability of these complexes. Various investigators (25, 26) observed a qualitative correlation between complex stability and solvent surface tension. The solvent surface tension is the "master variable" in determining the complex stability (27). Chartreusin alone and chartreusin plus gentisic acid in chloroform afforded superimposable spectra in the visible region. In water, however, in addition to a significant reduction in the broadness of the shoulder between λ_{435} and λ_{475} nm, red shifts (5 nm) at λ_{421} and λ_{399} nm were observed.

These interactions, although operable in both chartreusin and chartarin, do not account for the remarkable preferential increase in chartreusin solubility. For example, chartarin solubility in the presence of 0.52 *M* sodium gentisate at 25 ± 0.1° was enhanced 10-fold relative to that in water, while chartreusin solubility was intensified more than 300-fold

[11] Chartarin: λ_{max} ($CHCl_3$) 266 (log ϵ 4.53), 274 (4.48), 338 (3.78), 383 (3.95), 404 (4.20), and 427 (4.26) nm.

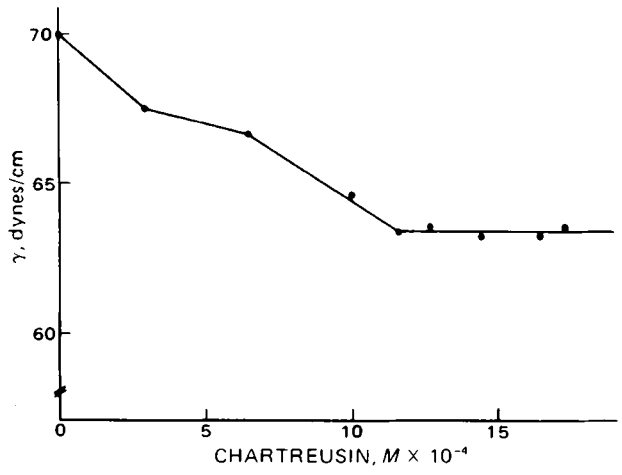

Figure 7—*Surface tension* versus *the chartreusin concentration in 0.26* M *aqueous sodium gentisate solution at 25 ± 0.1°.*

under identical conditions. Such a significant increase may be due to micellization. The commonly accepted picture of micelle structure comes from studies on compounds having a hydrophobic tail joined to a hydrophilic head. The micelles formed by these compounds above the critical micelle concentration (CMC) are nearly spherical aggregates with the heads on the surface and the tails forming a core. Such aggregates are stabilized by hydrophobic interaction between the hydrocarbon tails.

Chartreusin, once unfolded on interaction with the ligand, may be visualized as having a hydrophobic polyaromatic moiety joined to a hydrophilic disaccharide portion. Thus, one can assume that chartreusin molecule aggregates, similar to those of conventional detergent molecules, are built up by hydrophobic interactions between the aromatic surfaces, with the hydrophilic "heads" pointing outward and available to hydrogen bond with the excess ligand as well as with solvent molecules. Where conditions favor the formation of larger secondary micelles, two or more primary micelles could be linked by hydrogen bond donor and acceptor groups. Preliminary surface tension studies of chartreusin and sodium gentisate mixtures indicated possible micelle formation. When the chartreusin concentration was increased ($0–1.72 \times 10^{-5}$ *M*) in the presence of a fixed sodium gentisate concentration (0.26 *M*), a drop in surface tension to a constant minimum value was observed (Fig. 7) (28–30).

Thus, no single mechanism explains hydrotropy, but all of the above-mentioned factors play contributing roles in increasing chartreusin solubility.

Stability-Indicating Analysis of Injectable Estrogen–Androgen Combinations in Formulations Containing Corn Oil

R. ROMAN *x, C. H. YATES, J. F. MILLAR, J. O'NEILL, and J. S. ZWEIG ‡

Received August 25, 1978, from the *Pharmacy Research and Development Department, Merck Frosst Research Laboratories, Point Claire-Dorval, Quebec, Canada.* Accepted for publication November 27, 1978. *Present address: Merck Sharp and Dohme Research Laboratories, West Point, PA 19486. ‡Merck Sharp and Dohme Research Laboratories, Rahway, NJ 07065.

Abstract □ A method was developed for the analysis of testosterone 17-enanthate 3-benzilic acid hydrazone, 17-β-estradiol 3,17-dienanthate, and estradiol benzoate combinations dissolved in an oily vehicle. Testosterone 17-enanthate 3-benzilic acid hydrazone was separated from the other drugs and vehicle components by chromatography on an acetonitrile–infusorial earth column followed by quantitation using UV spectroscopy. The estradiol esters were separated from the oil by an additional chromatographic step using a heptane–silanized infusorial earth column prior to quantitation by GLC. Subjecting formulations to elevated temperatures resulted in detectable losses for testosterone 17-enanthate 3-benzilic acid hydrazone and 17-β-estradiol 3,17-dienanthate. For both drugs, degradation was due to hydrolysis; the degradation products, testosterone 17-enanthate and 17-β-estradiol 17-enanthate, did not interfere with the intact drug determination. Methods also were developed to estimate degradation product levels in the formulation.

Keyphrases □ Estrogens—analysis, stability in formulations containing corn oil, chromatography, separation from degradation products □ Androgens—analysis, stability in formulations containing corn oil, chromatography, separation from degradation products □ Stability—estrogens and androgens in formulations containing corn oil, chromatography, separation from degradation products □ Corn oil—analysis, formulations with estrogens and androgens, stability

Testosterone 17-enanthate 3-benzilic acid hydrazone (I), a novel androgen, produces prolonged hormonal effects following subcutaneous injection (1). This drug is an ingredient in two injectable steroid formulations[1,2] that also contain 17-β-estradiol 3,17-dienanthate (II) and estradiol benzoate (III). One product[1] contains 150 mg of I, 7.5 mg of II, and 1 mg of III/ml; the other[2] contains the same amount of I and II but 3 mg of III/ml. The vehicle for both products is a corn oil–benzyl benzoate–benzyl alcohol mixture.

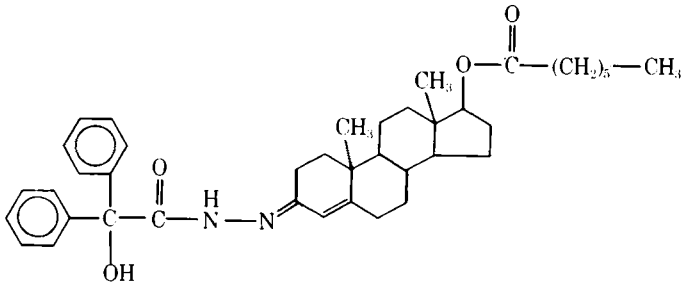
Drug determination in formulations containing vegetable oil usually requires separation of the drug substances from the oil components prior to quantitation (2–6). The added requirement that the method be stability indicating can add to the procedural complexity. In the present study, drug degradation products were characterized to demonstrate method selectivity.

Additional methodology was developed to estimate the degradation product level so as to establish a mass balance between intact ingredient loss and degradate formation.

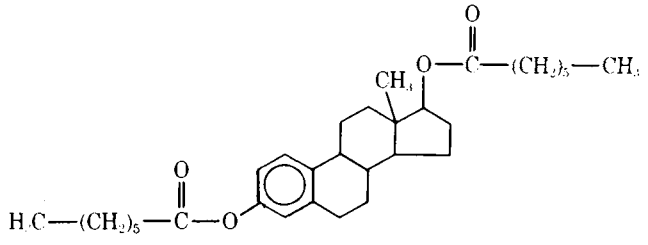
EXPERIMENTAL

Reagents—All solvents and chemicals were reagent grade unless otherwise specified.

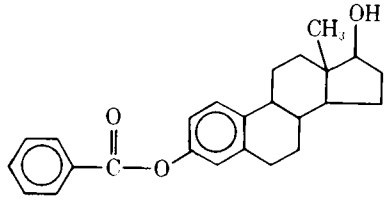
Assay—*Sample Preparation*—Approximately 500 mg of the formulation[1,2] was weighed accurately into a 5-ml volumetric flask. The sample



I



II



III

was dissolved in *n*-heptane (saturated with 90% ethanol) and diluted to volume with the same solvent.

Standard Solutions—For I[3], 0.75 mg/ml in denatured alcohol (ethanol 90%, methanol 10%) was prepared.

For II[3] and III[4], either 0.75 mg of II/ml and 0.1 mg of III/ml in chloroform (formulations containing 1 mg of III/ml) or 0.75 mg of II/ml and 0.3 mg of III/ml in chloroform (formulations containing 3 mg of III/ml) were prepared.

For the internal standard (for II and III determination), 0.75 mg of 17-β-estradiol 3,17-dicaproate (IV[5])/ml of chloroform was prepared.

I Determination—A 1.0-ml aliquot of the sample solution was transferred to the top of a chromatography column[6] containing 9 ml of acetonitrile (saturated with heptane) supported on 8 g of infusorial earth[7]. The column was eluted using 300 ml of heptane (saturated with acetonitrile) at a flow rate of ~8 ml/min. The eluate was retained for II and III determination (Eluate A).

When the solvent level reached the support surface, the elution was continued using 100 ml of chloroform. The eluate (Eluate B) was collected, the solvent was evaporated, the residue was transferred quanti-

tatively to a 100-ml volumetric flask using denatured alcohol, and the solution was diluted to volume with the same solvent. A 5.0-ml aliquot of this solution was transferred into a 50-ml volumetric flask, and the volume was brought to ~40 ml with denatured alcohol. A 1.0-ml aliquot of the standard I solution (0.75 mg/ml) was diluted in a parallel manner. Both flasks were heated to 70° for 0.5 hr, cooled, and diluted to volume with denatured alcohol. The UV spectra[8] for sample and standard were recorded, and the absorbance maximum at 282 nm was used for quantitation.

II and III Determination—A 1.0-ml aliquot of the internal standard solution (0.75 mg of IV/ml) was transferred to the 300 ml of heptane eluate (Eluate A). The solvent was evaporated, the oily residue was dissolved in about 2 ml of heptane (saturated with 90% ethanol), and the bulk of the solution was then transferred to a liquid chromatography column[6] containing 4 ml of heptane (saturated with 90% ethanol) supported on 6 g of silanized infusorial earth (2).

The column was eluted with 90 ml of 90% ethanol (saturated with heptane), the eluate was collected (Eluate C), the solvent was evaporated, and the residue was dissolved in ~1 ml of silylation reagent[9].

One-milliliter aliquots of the standard II–III solution and the IV solution were combined, the solvent was removed, and the residue was dissolved in ~1 ml of silylation reagent.

Approximately 2 μl of the sample was injected into a gas chromatograph[10] equipped with a 1.8-m × 2-mm i.d. glass column packed with 5% OV-101 on Gas Chrom Q[11] (80–100 mesh).

Following the injection, the oven temperature was programmed from 290 to 300° at 2°/min and was maintained at the higher temperature until the diglycerides from the vehicle eluted. The injection and temperature programming were repeated for the silylated standard. Areas[12] of the peaks for II–IV from sample and standard chromatograms were used for quantitation.

Degradation Product Identification and Estimation—*Testosterone Enanthate*—Replicate heat-stressed formulation[1] samples were passed through the normal and reversed-phase partitioning steps of the assay procedure. A series of experiments was performed on the ethanol fractions (Eluate C) to demonstrate the presence of testosterone-17-enanthate (V):

1. The solvent was removed from one sample, the residue was silylated, and 2 μl was injected onto a 5% OV-101[11] column with a column temperature at 290°[10].

2. Two microliters of the silylated residue from 1 was also injected onto a 1% Silar 10C[13] column maintained at 250°[10].

3. The residue from a replicate sample was saponified by heating at reflux in alcoholic sodium hydroxide (1 *N*) for 2 hr. After solvent removal, the organic residue was dissolved in chloroform and injected into a 5% OV-101 column[11] with the oven at 260°[10].

4. Another sample was concentrated to ~1 ml, and a portion was spotted on a TLC plate[14]. The plate was developed with benzene–ether (1:1) and visualized using iodine vapor and UV.

Benzilic Acid Hydrazide—An aged formulation[1] sample was applied to the acetonitrile–infusorial earth column, and the chloroform eluate containing I was taken to dryness. The residue was dissolved in 1 ml of *p*-nitrobenzaldehyde in methanol (2.18 mg/ml), a drop of acetic acid was added, and the solution was refluxed for 15 min. The reaction mixture was transferred to a 100-ml volumetric flask and diluted to volume with methanol–water (1:1). A similar reaction and dilution were performed on pure benzilic acid hydrazide[3] (VI).

The sample was filtered through a 0.4-μm membrane[15] to remove undissolved I, and 50 μl was injected into a high-pressure liquid chromatograph[16]. With a 25-cm × 4.6-mm stainless steel column packed with octadecylsilane permanently bonded to 10-μm silica[17], a mobile phase of methanol–water (1:1), a flow rate of 1.5 ml/min [~1500 psi (105 kg/cm^2)], and a column temperature of 40°, derivatized VI was separated from other formulation components. Quantitation was achieved by comparing the peak area[11] from the sample chromatogram to that for pure VI.

Table I—Formulation[a] Ingredient Elution on an Infusorial Earth–Acetonitrile Column

Component	Elution Volume, ml
Corn oil	<50

I	450

[a] Climacteron Injection, Charles E. Frosst, Montreal, Quebec, Canada.

Estradiol Monoenanthate—A formulation[2] sample stored at 40° for 1 year was subjected to the usual analytical procedure, except that the silanized residue was split into two portions. One portion, analyzed by the routine method using an OV-101 column[11], showed a 12% II loss. Examination of the other portion by GLC–mass spectrometry[18] (Silar 10C[13], 240°) indicated a component with the same retention time and mass spectrum as 17-β-estradiol 17-enanthate (VII). TLC also indicated a component with the R_f and visualization characteristics of VII.

17-β-Estradiol 17-Enanthate Preparation—A II sample dissolved in benzyl benzoate (7.5 mg/ml) was heated at 160° for 4 days. Examination by GLC indicated a 50% II loss with the formation of a more volatile product having 45% of the original II area.

The mixture was chromatographed over alumina, and the degradation product present in the methanol eluate was isolated as an oil in approximately 98% purity (GLC). Maceration of the oil with petroleum ether yielded a solid, mp 96–98°. The solid IR spectrum (chloroform) showed absorption at 3595 cm^{-1} [within the band expected for phenolic —OH stretch, a somewhat longer wavelength than would be expected for a secondary alcohol (7)] and at 1720 cm^{-1} (ester C=O). On TLC[14] with benzene–ether (9:1) as a developing solvent, the substance migrated as a single UV-absorbing spot (R_f 0.5), which gave a positive test when the plate was treated with *p*-nitrobenzenediazonium fluoroborate spray reagent. These data indicate that the product was 17-β-estradiol 17-enanthate.

A GLC–mass spectrometric[18] study gave evidence consistent with this finding. Approximately 500 μg of the solid was dissolved in 200 μl of

[a] Climacteron Injection, Charles E. Frosst, Montreal, Quebec, Canada. [b] There is a 5% overage for II (theoretical input of 7.875 mg/ml).

Sylon-HTP[19]. This solution gave one GLC peak (Silar 10C, 1.4%, 0.91 m × 2 mm, 240°, retention time of 3 min). The mass spectrum showed a very strong molecular ion and the fragmentation pattern expected for the 3-trimethylsilyl ether of estradiol 17-enanthate (8–10) [*m/e* 458 (relative intensity 12%), 457 (37), 456 (M^+, 100), 441 (3), 343 (1), 328 (2), 327 (6), 298 (2), 297 (4), 257 (1), 245 (3), 244 (8), 232 (4), 231 (8), 229 (2), 219 (2), 218 (7), 217 (2), 205 (5), 113 (5), 85 (2), 75 (2), 73 (10), 57 (2), 55 (2), and 43 (11)]. A different fragmentation pattern would be expected if the carboxylate moiety were attached to the steroid aromatic A ring.

RESULTS AND DISCUSSION

Assay—Quantitation of I–III required separation of the three drugs from the other vehicle components.

I Determination—The acetonitrile–infusorial earth column retained I while allowing II, III, corn oil, benzyl alcohol, and benzyl benzoate to be eluted with heptane (Table I). Initial experiments using a nitromethane–infusorial earth column resulted in less effective I and III separation.

Compound I was eluted from the column with chloroform, a solvent of sufficiently high polarity to strip the acetonitrile liquid phase and any retained compounds from the column. The large I quantity in the formulation coupled with its high absorptivity ($A^{1\%}_{1cm}$ 492 at 282 nm) made any interference from other compounds negligible. Prior to UV determination, the eluted I was heated at 70° for 30 min to ensure that the *syn–anti* isomerization had reached equilibrium (11).

Quantitation was achieved by comparing the I sample absorbance to that for a standard I solution that had been similarly equilibrated. The Beer–Lambert law was valid for the equilibrium mixture of the two I isomers in the concentration range used for UV measurements.

II and III Determination—Following elution from the reversed-phase column, the ethanol solution containing II and III was evaporated and treated with silylation reagent. Compound III reacted to form the 17-trimethylsilyl ether (III*a*); the major corn oil components present in this fraction, the diglycerides of oleic and linoleic acid, also reacted to form trimethylsilyl derivatives.

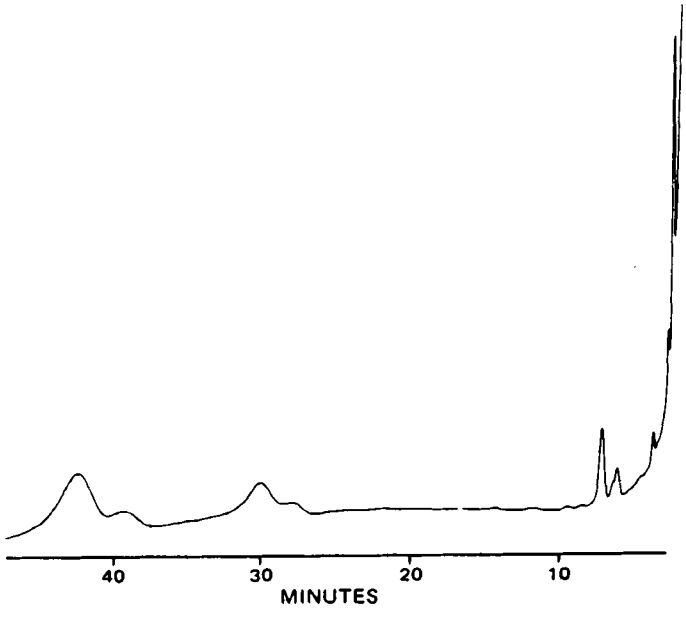

Figure 2—*Chromatogram of pharmaceutical vehicle without drugs. Conditions were the same as for Fig. 1.*

[19] Supelco, Bellefonte, Pa.

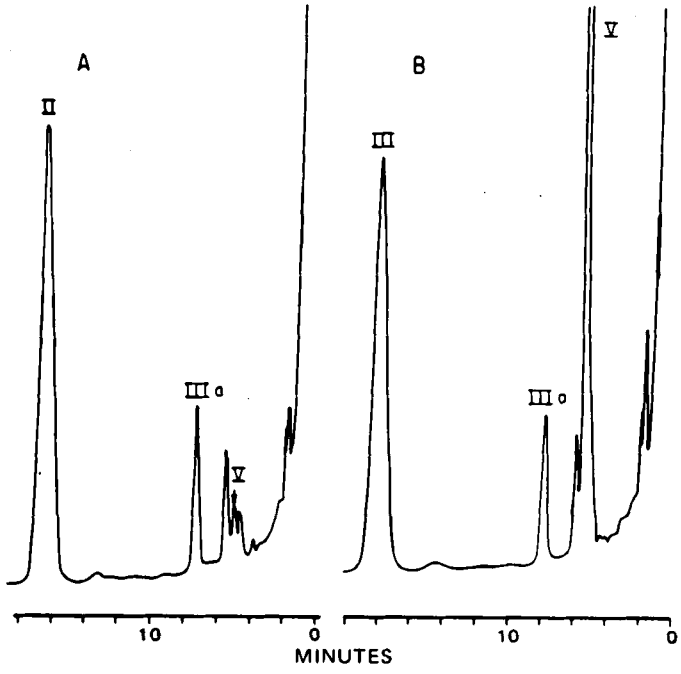

Figure 3—*(A) Chromatogram of the fraction containing II and III from a freshly prepared formulation. (B) Chromatogram of the fraction containing II and III from the same sample after storage for 12 weeks at 50°. Conditions were the same as for Fig. 1.*

A typical gas chromatogram obtained during formulation[1] analysis (Fig. 1) illustrates that II, III*a*, and the internal standard (IV) were well separated from each other as well as from V and the silylated diglycerides. Benzyl benzoate and benzyl alcohol were obscured in the solvent front. A chromatogram for the vehicle alone, after it has passed through the whole analytical procedure, is shown in Fig. 2.

The general method employed for II and III quantitation involved comparing the sample internal standard (IV) peak ratios with the corresponding ratios for a standard solution. GLC response *versus* concentration plots for II and III*a* were linear, demonstrating that a single standard with concentrations approximating those present in the sample is adequate for the quantitative analysis of the two estrogens.

Assay Precision—Results of six replicate assays carried out on a single formulation[1] over several weeks are shown in Table II. Between assays, the sample was stored at −20° to eliminate degradation. The method had adequate precision, and the drug recovery posed no problem.

Degradation Product Identification and Estimation—*I Degradation*—Benzilic acid hydrazones undergo acid hydrolysis (12). For I, this reaction would produce V and VI. Compound V could be readily detected in the formulation during the GLC analysis of II and III. Like II and III, V was eluted from both normal and reversed-phase liquid chromatographic columns. A V peak can be seen in Fig. 1.

Compound I degradation could be monitored by the size of the V peak in the chromatogram, although interfering components from the corn oil prevented accurate V quantitation. Figure 3A shows a chromatogram obtained from freshly prepared formulation[1]. A small V peak, representing less than 0.2% of the I content, was barely discernible. A chromatogram obtained after storing the sample for 12 weeks at 50° is shown in Fig. 3B. Comparison of the V peak area to that of authentic material indicated about 6.2 mg/ml (equivalent to a loss of 9.2 mg/ml for I) while the UV I assay indicated a 10.8-mg/ml loss from the initial value.

The component shown in Fig. 3 was V and not a product formed from corn oil degradation. The retention time of the component was compared to that for an authentic V sample on a 5% OV-101 column and on a 1% Silar 10C column. The latter column was prepared with a very polar cyanosilicone liquid phase and had markedly different selectivity than the nonpolar OV-101 column. On both columns, there was good agreement between the retention times for V and the component from the heat-stressed formulation[1]. Additionally, a sample of this heat-stressed for-

mulation was saponified and analyzed by GLC. The reaction mixture showed a component with the same retention time as testosterone. A spot characteristic of V was observed also when the heat-stressed sample was examined by TLC.

The other fragment (VI) from the hydrolytic I degradation was not routinely detected during the assay. A very polar compound, VI is retained on the acetonitrile–infusorial earth column and is eluted with I by chloroform. Since VI had a weak absorbance at the I maximum, $A^{1\%}_{1cm} < 1$ at 282 nm, its presence did not interfere significantly with the I determination.

The VI in a heat-stressed formulation[1] sample was detected by allowing the hydrazide to react with excess *p*-nitrobenzaldehyde and subjecting the mixture to HPLC analysis. This analysis indicated the presence of 2.6 mg of VI/ml (equivalent to hydrolysis of 6.8 mg of I/ml). UV assay showed 141.2 mg of I/ml (a loss of 8.8 mg/ml).

II and III Degradation—Hydrolysis would be expected to be the major mode of degradation for II and III, as it is for I. Compound II would be expected to give 17-β-estradiol 17-enanthate (VII) and/or 17-β-estradiol 3-enanthate (VIII). Compound III would be expected to give 17-β-estradiol. Since III was stable under extremely stressful conditions (120° for 48 hr), its decomposition was not considered further. On the other hand, II decomposed demonstrably with time.

A VII sample was prepared by heating II in benzyl benzoate. The isolated material's structure was verified by IR, GLC–mass spectrometry, and TLC. Examination of a severely stressed formulation[2] by GLC–mass spectrometry indicated a component with the same retention time and mass spectrum as VII. Evidence confirming the presence of VII in the stressed formulation was obtained by TLC.

The VII retention time on the OV-101 column was similar to that for V; when mixed, the two components eluted as a single peak. Thus, if present in the formulations, VII would not be detected in a normal analysis. The two steroids were separated on a Silar 10C column. Analysis of a heat-stressed formulation[2] using this column showed the presence of 0.85 mg of VII/ml (equivalent to a loss of 0.95 mg of II/ml) while the analysis for II using the OV-101 column resulted in a value of 6.94 mg/ml (a loss of 0.96 mg/ml from the initial value).

syn–anti Isomerization in Testosterone 17-Enanthate 3-Benzilic Acid Hydrazone

R. ROMAN *x, C. H. YATES, and J. F. MILLAR

Received August 25, 1978, from the *Pharmacy Research and Development Department, Merck Frosst Research Laboratories, Point Claire-Dorval, Quebec, Canada.* Accepted for publication November 28, 1978. *Present address: Merck Sharp and Dohme Research Laboratories, West Point, PA 19486.

Abstract □ UV spectrophotometry, high-pressure liquid chromatography, and NMR were used to investigate *syn–anti* isomerization in testosterone 17-enanthate 3-benzilic acid hydrazone. In the crystalline state, the isomeric ratio is dependent on the crystallization solvent. In solutions, including injectable pharmaceutical formulations, an equilibrium isomer mixture (2:1) is formed.

Keyphrases □ Testosterone hydrazones—isomerization, UV spectrophotometry, high-pressure liquid chromatography, NMR, effect of crystallization solvent □ Isomerization—testosterone hydrazones, effect of crystallization solvent

Compounds containing an azo function can exist in *syn*- or *anti*-configuration. Most phenylhydrazones, semicarbazones, and thiosemicarbazones form equilibrium isomer mixtures in solution (1). *syn–anti* Isomerization was detected by NMR in the 3-oximes of a series of testosterone derivatives (2). Separation of 17α-ethynyl-17β-acetoxy-19-norandrost-4-en-3-one oxime isomers using high-pressure liquid chromatography (HPLC) was also reported (3).

The object of the present study was to determine whether testosterone 17-enanthate 3-benzilic acid hydrazone (I), a long-acting androgen, exists as a single isomer or as a *syn–anti* mixture.

EXPERIMENTAL

Stock solutions of I[1] in methanol or ethanol, ~0.75 mg/ml, were used for equilibration studies. These solutions were diluted 1 to 50 prior to UV measurement[2].

High-pressure liquid chromatograms were obtained using an instrument[3] with a 254-nm fixed-wavelength detector and a column[4] (25 cm × 2 mm i.d.) packed with 6-μm silica particles. The mobile phase was

This analysis indicated the presence of 2.6 mg of VI/ml (equivalent to hydrolysis of 6.8 mg of I/ml). UV assay showed 141.2 mg of I/ml (a loss of 8.8 mg/ml).

II and III Degradation—Hydrolysis would be expected to be the major mode of degradation for II and III, as it is for I. Compound II would be expected to give 17-β-estradiol 17-enanthate (VII) and/or 17-β-estradiol 3-enanthate (VIII). Compound III would be expected to give 17-β-estradiol. Since III was stable under extremely stressful conditions (120° for 48 hr), its decomposition was not considered further. On the other hand, II decomposed demonstrably with time.

A VII sample was prepared by heating II in benzyl benzoate. The isolated material's structure was verified by IR, GLC–mass spectrometry, and TLC. Examination of a severely stressed formulation[2] by GLC–mass spectrometry indicated a component with the same retention time and mass spectrum as VII. Evidence confirming the presence of VII in the stressed formulation was obtained by TLC.

The VII retention time on the OV-101 column was similar to that for V; when mixed, the two components eluted as a single peak. Thus, if present in the formulations, VII would not be detected in a normal analysis. The two steroids were separated on a Silar 10C column. Analysis of a heat-stressed formulation[2] using this column showed the presence of 0.85 mg of VII/ml (equivalent to a loss of 0.95 mg of II/ml) while the analysis for II using the OV-101 column resulted in a value of 6.94 mg/ml (a loss of 0.96 mg/ml from the initial value).

syn–anti Isomerization in Testosterone 17-Enanthate 3-Benzilic Acid Hydrazone

R. ROMAN *x, C. H. YATES, and J. F. MILLAR

Received August 25, 1978, from the *Pharmacy Research and Development Department, Merck Frosst Research Laboratories, Point Claire-Dorval, Quebec, Canada.* Accepted for publication November 28, 1978. *Present address: Merck Sharp and Dohme Research Laboratories, West Point, PA 19486.

Abstract □ UV spectrophotometry, high-pressure liquid chromatography, and NMR were used to investigate *syn–anti* isomerization in testosterone 17-enanthate 3-benzilic acid hydrazone. In the crystalline state, the isomeric ratio is dependent on the crystallization solvent. In solutions, including injectable pharmaceutical formulations, an equilibrium isomer mixture (2:1) is formed.

Keyphrases □ Testosterone hydrazones—isomerization, UV spectrophotometry, high-pressure liquid chromatography, NMR, effect of crystallization solvent □ Isomerization—testosterone hydrazones, effect of crystallization solvent

Compounds containing an azo function can exist in *syn*- or *anti*-configuration. Most phenylhydrazones, semicarbazones, and thiosemicarbazones form equilibrium isomer mixtures in solution (1). *syn–anti* Isomerization was detected by NMR in the 3-oximes of a series of testosterone derivatives (2). Separation of 17α-ethynyl-17β-acetoxy-19-norandrost-4-en-3-one oxime isomers using high-pressure liquid chromatography (HPLC) was also reported (3).

The object of the present study was to determine whether testosterone 17-enanthate 3-benzilic acid hydrazone (I), a long-acting androgen, exists as a single isomer or as a *syn–anti* mixture.

EXPERIMENTAL

Stock solutions of I[1] in methanol or ethanol, ~0.75 mg/ml, were used for equilibration studies. These solutions were diluted 1 to 50 prior to UV measurement[2].

High-pressure liquid chromatograms were obtained using an instrument[3] with a 254-nm fixed-wavelength detector and a column[4] (25 cm × 2 mm i.d.) packed with 6-μm silica particles. The mobile phase was

pentane–ether–concentrated ammonia (50:50:1). The flow rate was 0.5 ml/min. Continual column use led to resolution loss and changing retention times due to mobile phase water absorption by the silica. The column could be regenerated with anhydrous ether as the mobile phase.

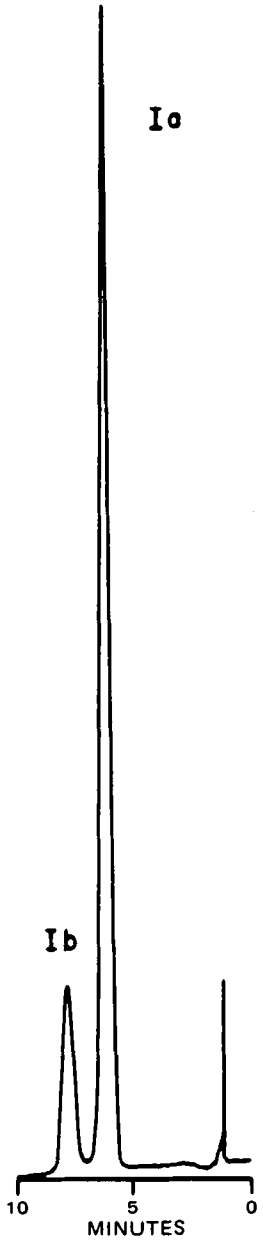

Figure 2—*Chromatograms of I stored for 2 months in methanol (0.75 mg/ml). The chromatographic conditions were: column, Zorbax-SIL; mobile phase, pentane–ether–concentrated ammonia (50:50:1); flow, 0.5 ml/min; pressure, 1000 psi; injection volume, 3 μl; wavelength, 254 nm; and attenuation, 0.08 aufs.*

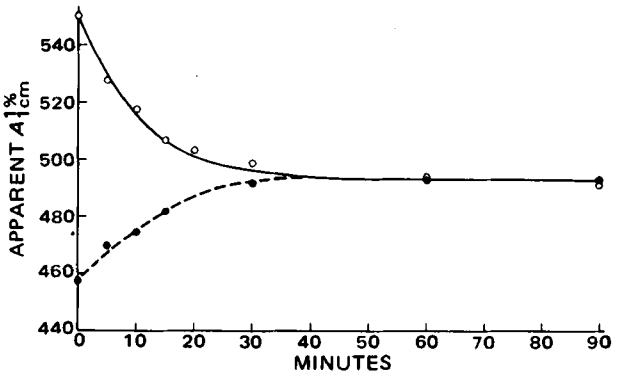

Figure 3—*Apparent* $A^{1\%}_{1cm}$ *at 282 nm* versus *time for I crystallized from aqueous acetone (○) and for I crystallized from aqueous ethanol (●) dissolved in ethanol at 70°.*

A 60-MHz NMR spectrometer[5] was used to record NMR spectra. Solutions were prepared by dissolving ~60 mg of the samples in 0.6 ml of deuterated chloroform. Tetramethylsilane was used as an internal reference standard.

RESULTS AND DISCUSSION

Since the azo group of I is conjugated to the 4,5-double bond, *syn*-(I*a*) and *anti*-(I*b*) isomers might be expected to have different UV spectra,

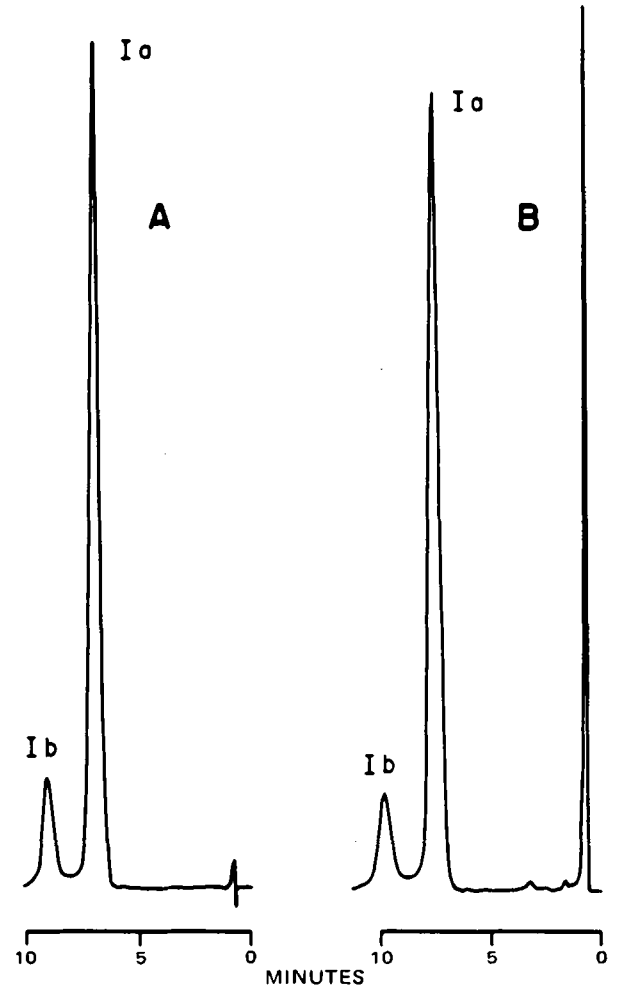

Figure 4—*(A) Chromatogram of I equilibrated in methanol (0.75 mg/ml). (B) Chromatogram of dilute formulation (1:200 in chloroform). Conditions were as in Fig. 2.*

as was observed for 2,4-dinitrophenyl hydrazones (4). In fact, the first indication for the presence of two I isomers was the observation that the absorbance (at the UV maximum near 282 nm) of a methanolic I solution decreased with time. After a loss of 7.5%, the absorbance remained constant (Fig. 1). That this decrease in absorbance was due to a reversible equilibrium was shown by the following experiment. The methanol was evaporated from a I solution in which the absorbance had decreased ~7.5%, and the residue was crystallized from isopropyl ether. This solvent was then evaporated, and the entire residue was redissolved in methanol. The absorbance of this solution was the same as that observed for the freshly prepared solution. On storage, the solution absorbance again decreased.

Figure 2 illustrates the HPLC separation of the two isomers present in an aged I solution in methanol. Examination of a number of I solutions indicated a correlation between the UV properties and the amount of I*b* determined by HPLC. On standing, the apparent $A^{1\%}_{1cm}$ of the solutions decreased as the amount of I*b* increased.

Freshly prepared I solutions also indicated a small amount of I*b*. The extent of this isomerization depended on the method used to crystallize I. For pharmaceutical formulations, I is crystallized from isopropyl ether. A freshly prepared solution of this material had an apparent $A^{1\%}_{1cm}$ of 523 at 282 nm with ~5% isomer I*b* by area on HPLC; I crystallized from acetone–water (10:2) had an apparent $A^{1\%}_{1cm}$ of 550 at 282 nm with ~1% I*b*. The apparent $A^{1\%}_{1cm}$ of I crystallized from aqueous ethanol varied from 465 to 430. These values are lower than those measured for the equilibrium mixture dissolved in ethanol ($A^{1\%}_{1cm}$ 492 at 282 nm).

The solution equilibration rate was increased by exposure to UV radiation and heat. The elevated temperature effect is shown in Fig. 3 where I crystallized from aqueous acetone ($A^{1\%}_{1cm}$ 550) and I crystallized from aqueous ethanol ($A^{1\%}_{1cm}$ 457) equilibrated to the same isomer ratio in 30 min at 70°. This heating period was incorporated into the analysis of I in pharmaceutical formulations to assure complete equilibration prior to UV measurement (5).

The extent of isomerization in a marketed pharmaceutical formulation was determined. A chromatogram obtained from the HPLC analysis of a formulation[6] freshly dissolved in chloroform was compared to a chromatogram from an equilibrated I solution in methanol (Fig. 4). The similarity of the two chromatograms indicates that the equilibrium isomer ratio is the same in the formulation and in methanol.

Although crystallization from acetone yielded isomer I in reasonable purity, a pure sample of the thermodynamically less stable isomer was unobtainable. Without knowledge of the I*b* UV spectrum, the amounts

[6] Climacteron Injection, Charles E. Frosst, Montreal, Quebec, Canada.

of the two isomers could not be determined by UV measurement. This determination was possible using NMR. As observed for the testosterone oxime (2), the vinyl proton had a different chemical shift for the two isomers. The spectra (over the 4–8-ppm range) for I crystallized from acetone and from aqueous ethanol are shown in Fig. 5. Crystallized I from acetone had a single resonance attributable to the vinyl proton at 5.95 ppm; I crystallized from aqueous ethanol ($A^{1\%}_{1cm}$ 457 at 282 nm) had resonances at 5.95 and 5.60 ppm. That the resonance at 5.60 ppm was due to *Ib* was confirmed by monitoring changes in the two resonances with time. After storage for 144 hr with exposure to daily diffuse sunlight, the acetone-crystallized I had developed a resonance at 5.60 ppm (Fig. 6A). In the sample crystallized from aqueous ethanol, the resonance at 5.60 ppm had become smaller and the one at 5.95 ppm had become larger than in the initial spectrum (Fig. 6B).

The vinyl resonance integration values for the aqueous ethanol-crystallized sample showed the mixture to be 50% *Ia* and 50% *Ib*. After 144 hr in solution, both crystal types showed 67% *Ia* and 33% *Ib*. Using these ratios along with an apparent $A^{1\%}_{1cm}$ of 457 for I crystallized from ethanol and an apparent $A^{1\%}_{1cm}$ of 492 for the equilibrium mixture, the $A^{1\%}_{1cm}$ of *Ia* was calculated as 554 and that for *Ib* was 365 at 282 nm.

For the oximes of testosterone derivatives, Mazur (2) observed that the vinyl proton in the *anti*-isomer always resonated about 40 Hz upfield from the *syn*-isomer. For I, the 22-Hz upfield shift of *Ib* relative to *Ia* suggests that *Ia* is the *syn*-isomer and *Ib* is *anti*. This assignment is consistent with an ~20-Hz shift to lower field predicted when the vinyl proton is *cis* to the azo group(*syn*) compared to *trans* (*anti*) (1).

Spectrophotometric Determination of Tolbutamide, Thiamine Hydrochloride, and Pyridoxine Hydrochloride in Combination Products

M. ABDEL-HADY ELSAYED *x, SAIED F. BELAL, ABDEL-FATTAH M. ELWALILY, and HASSAN ABDINE

Received April 26, 1978, from the *Faculty of Pharmacy, University of Alexandria, Alexandria, Egypt.* Accepted for publication December 4, 1978.

*Present address: Department of Pharmacy, University of Nigeria, Nsukka, Nigeria.

Abstract □ The first derivative curve is used for tolbutamide determination in unit-dose tablets and in combination products. The absorbance contribution from tablet excipient and coexisting components, thiamine and pyridoxine, is thereby nullified. The interference from tolbutamide during thiamine and pyridoxine determination is eliminated by solvent extraction and pH-induced differential spectrophotometry. Thiamine is measured at the isosbestic point of pyridoxine. The latter is determined by the differential absorbance measurement at two wavelengths with the consequent computation of the delta absorbance value.

Keyphrases □ Tolbutamide—analysis, combination tablets with thiamine and pyroxidine, spectrophotometry, first derivative curve □ Thiamine—analysis, combination tablets with tolbutamide and pyridoxine, spectrophotometry, first derivative curve □ Pyridoxine—analysis, combination tablets with thiamine and tolbutamide, spectrophotometry, first derivative curve □ Spectrophotometry—analysis, tolbutamide in combination tablets □ Antidiabetic agents—tolbutamide, spectrophotometric analysis, in combination tablets

Spectrophotometric determination of a weakly absorbing compound like tolbutamide in tablets without any interference from the tablet excipients is challenging. The problem is made more difficult when such a compound is combined with thiamine hydrochloride and pyridoxine hydrochloride.

Quantitation methods for multicomponent mixtures often employ multiple separation steps using chromatography or solvent extraction (1, 2). UV spectrophotometric methods that demand solution of simultaneous equations have also been used (3). Mixtures of two known absorbing substances have been determined spectrophotometrically (4). This method was modified (5) in terms of the extinction ratio. The application of the absorbance ratio to binary mixture analysis was recommended (6, 7).

The orthogonal function method was proposed in two-component spectrophotometric analysis (8). Recently, dual wavelength spectrophotometry (9) was applied to the simultaneous determination of mixtures (10) and to masking of unwanted components (11). The first derivative curve was useful in distinguishing substances with overlapping spectra (12) and in the quantitative analysis of two-component mixtures (13).

The present investigation was concerned with tolbutamide determination in unit-dose tablets and combination products by use of the first derivative curve. pH-Induced difference spectrophotometry (14–16) was utilized for thiamine and pyridoxine determination by independent absorbance measurements.

EXPERIMENTAL

Materials—Tolbutamide[1], thiamine hydrochloride[2], and pyridoxine hydrochloride[1] unit-dose tablets[3] contained 500 mg of tolbutamide/tablet. The combination product[4] contained 500 mg of tolbutamide, 5 mg of thiamine hydrochloride, and 3 mg of pyridoxine hydrochloride.

Reagents—All reagents were analytical grade, and solvents were spectroscopic grade.

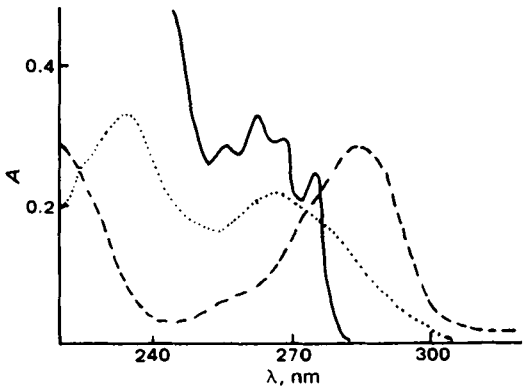

Figure 1—*UV absorption spectra of 0.15 mg of tolbutamide/ml (—), 0.01 mg of thiamine hydrochloride/ml (···), and 0.01 mg of pyridoxine hydrochloride/ml (- -). The solvent was 95% ethanol.*

Instruments—A photoelectric spectrophotometer[5] with 1-cm silica cells was used for all measurements.

Assay of Tolbutamide in Unit-Dose Tablets—Twenty tablets were powdered and mixed, and an accurately weighed quantity (~0.6 g) was extracted with 95% ethanol. The solution was diluted with ethanol to give ~0.25 mg of tolbutamide/ml. The absorbance was measured at 274 and 276 nm using 95% ethanol in the reference cell. The absorbance difference between 274 and 276 nm, $\Delta A(274 - 276)$, was computed.

Assay for Combination Product—For the tolbutamide component, the above-mentioned method was used. For the thiamine and pyridoxine components, another ~0.6-g powdered tablet portion was weighed accurately, extracted, and diluted with water. Two equal volumes were suitably diluted, with 0.1 *N* H_2SO_4 or 0.01 *N* NaOH, to give ~0.016 mg of thiamine/ml and 0.01 mg of pyridoxine/ml. The acid solution absorbance was measured at 265 nm using an alkaline solution in the reference cell (thiamine component). The alkaline solution absorbance was measured at 300 and 310 nm using an acid solution in the reference cell (pyridoxine component).

RESULTS AND DISCUSSION

The tolbutamide absorption spectrum (Fig. 1) showed three absorption maxima at 256, 262, and 274 nm and a shoulder at 268 nm. The first derivative curve, obtained by plotting $\Delta A(\lambda_1 - \lambda_2)$ *versus* λ_m [where $\lambda_m = (\lambda_1 + \lambda_2)/2$], is presented in Fig. 2. The working wavelengths chosen for the tolbutamide assay were 274 and 276 nm rather than the peaks located at shorter wavelengths.

The choice of these wavelengths was based on the high $\Delta A(274 - 276)$ with a consequent increase in sensitivity. The absorbance contribution from tablet excipients (mostly nonbenzenoid) at longer wavelengths was expected to be nil since the diverse components were characterized by constant absorption spectra (*i.e.*, with zero slope). More important, the absorption spectrum slopes of the coexisting components (thiamine and pyridoxine) in the compound tablets were opposite to each other and distinctly lower (Fig. 1) than the tolbutamide spectrum slope. Consequently, the first derivative curves of thiamine and pyridoxine contribute equally but with opposite signs (Fig. 2). Therefore, they canceled each other with the net result of no interference from these compounds. The first derivative curve in the tolbutamide determination in unit-dose tablets and in combination products gave highly accurate results (Tables I and II).

The tolbutamide concentration was calculated from the following regression equation[6], derived by using the least-squares method (17):

$$\Delta A(274 - 276) = 0.0053 + 0.915C \qquad \text{(Eq. 1)}$$

with[7] $r = 0.9998$, which was obtained by application of the procedure described for tolbutamide assay in tablets to known tolbutamide concentrations. Within a 0.1–0.7-mg/ml range, $\Delta A(274 - 276)$ *versus* C was linear.

Thiamine and pyridoxine in combination products could be determined using their pH-induced spectral changes. The interference from the major component, tolbutamide, was thereby eliminated since it is barely soluble in water, the solvent used for the tablet powder extraction. More important, tolbutamide exhibits virtually identical spectra in acid and alkaline media. Consequently, the pH-induced tolbutamide solution differential spectrum (prepared by extracting 500 mg of tolbutamide with water and subsequent acidification or alkalinization) displayed a negligible contribution (Fig. 3).

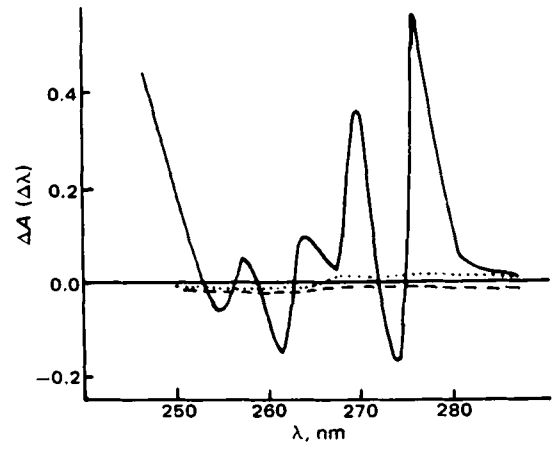

Figure 2—*First derivative curves from absorption spectra of tolbutamide (—), thiamine hydrochloride (···), and pyridoxine hydrochloride (- -).*

When the acid solution absorbance was measured against that of alkaline solution at 265 nm, thiamine could be determined without interference from pyridoxine since the latter showed an isosbestic point (Fig. 3). The delta absorbance measurement [A(acid) − A(alkaline)] at 265 nm was linearly related to the thiamine concentration over the 0.008–0.056-mg/ml range. The following regression equation, derived from ΔA_{265} measurements of known thiamine concentrations, describes the calibration curve:

$$\Delta A_{265} = -0.0108 + 3.03C \qquad \text{(Eq. 2)}$$

where $r = 0.9998$. For pyridoxine estimation, the delta absorbance at two wavelengths (300 and 310 nm) was measured with subsequent subtraction to obtain a value of $\Delta(\Delta A)(310 - 300)$. Such a choice for the two wavelengths satisfied the following fundamental conditions. The coexisting

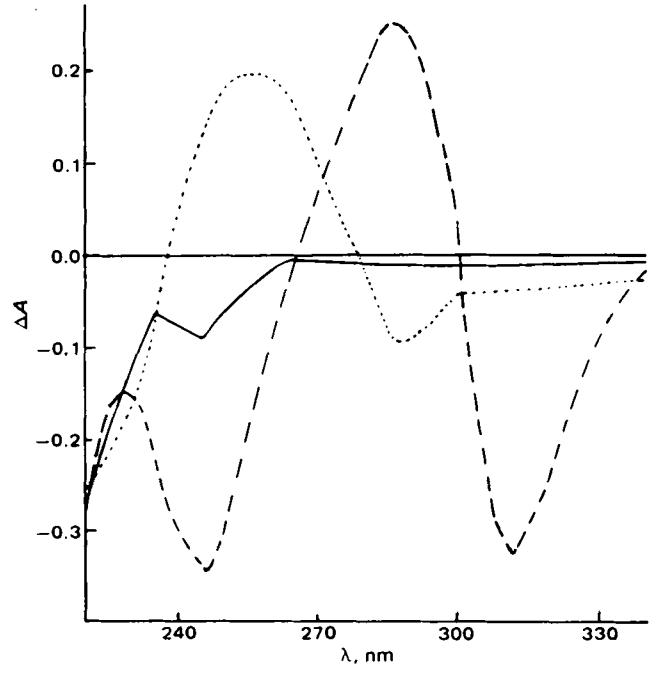

Figure 3—*Differential curves of 0.15 mg of tolbutamide/ml (—), 0.01 mg of thiamine hydrochloride/ml (···), and 0.01 mg of pyridoxine hydrochloride/ml (- -).*

[5] Prolabo, Paris.

[6] Concentrations in this equation and in subsequent equations are in milligrams per milliliter.

Table I—Tolbutamide in Unit-Dose Tablets

Tablet	Mean[a] Percentage[b] ± *SD*	
	A_{max} Method	$\Delta A(274 - 276)$ Method
Laboratory made	101.78 ± 0.42	100.58 ± 0.59
	9.476[c]	2.198[c]
Commercial product[d]	101.38 ± 0.47	100.07 ± 0.36
	6.565[c]	4.16[c]

[a] Mean of five determinations. [b] Percentage recovery in laboratory made and percentage found in commercial. [c] Calculated t-value for which theoretical t at 99% confidence level ($\alpha = 0.01$) = 4.604. [d] Rastinon.

components (thiamine and the soluble portion of tolbutamide) exhibited the same absorbance at these wavelengths [*i.e.*, $\Delta(\Delta A)(310 - 300)$ = zero], so variations in their concentrations had no influence on absorbance measurements. Furthermore, $\Delta(\Delta A)(310 - 300)$ was linearly related to concentration in the 0.004–0.028-mg/ml range of pyridoxine, thus permitting its determination. The regression equation derived from the data obtained is as follows:

$$\Delta(\Delta A)(310 - 300) = 0.0058 + 26.89C \qquad \text{(Eq. 3)}$$

where $r = 0.9999$.

The applicability of Eq. 1 in the tolbutamide assay and of Eqs. 2 and 3 in thiamine and pyridoxine determination was tested by analysis of laboratory-made mixtures. The results obtained are of good accuracy and reproducibility (Table II).

The first derivative curve method [$\Delta A(274 - 276)$] for tolbutamide determination in unit-dose tablets was compared with the traditional spectrophotometric method (A_{max} method). The latter was carried out by direct absorbance measurement at λ_{max} 262 nm, and the following equation was used for the concentration calculation:

$$A_{262} = 0.019 + 2.170C \qquad \text{(Eq. 4)}$$

where $r = 0.9999$.

The unit-dose tablets were analyzed using $\Delta A(274 - 276)$ and A_{max} methods (Table I). By applying the t test (17), the results were subjected to statistical analysis. At the 99% confidence level ($p = 0.01$), the ΔA method gave a value not significantly different from the true value whereas the A_{max} method gave a value significantly different from the true value. Therefore, the former method was more accurate than the latter method.

In combination tablets, tolbutamide–thiamine–pyridoxine were present in the ratio 166:1.66:1. Although tolbutamide represented the major component, the interference from strongly absorbing coexisting components was significant because of the weak absorptivity of tolbutamide (Fig. 1). In term of absorbance, the interference from thiamine and pyridoxine was about 20%. The first derivative curve method diminished such interference since the slope of the tolbutamide absorption curve was distinctly higher than the slopes of the coexisting component spectra (Figs. 1 and 2). The interference from the coexisting components was eliminated completely because of the opposite slopes of the thiamine and pyridoxine curves.

Table II—Three Components in Tolbutamide Combination Tablets

Preparation	Mean Percentage[a] ± *SD*		
	Tolbutamide[b]	Thiamine[c]	Pyridoxine[c]

Effect of Serum Protein Binding on Sulfisoxazole Distribution, Metabolism, and Excretion in Rats

AVRAHAM YACOBI and GERHARD LEVY ×

Received July 17, 1978, from the *Department of Pharmaceutics, School of Pharmacy, State University of New York at Buffalo, Amherst, NY 14260.* Accepted for publication December 13, 1978.

Abstract □ This investigation determined the effect of serum protein binding on the kinetics of sulfisoxazole distribution, metabolism, and excretion. Adult rats, whose serum free fraction of sulfisoxazole (at a total concentration of 81 ± 6 μg/ml) was 0.05–0.24, received a rapid intravenous injection of 20 mg/kg. Sulfisoxazole concentrations in plasma declined biexponentially with time. There were pronounced and reproducible interindividual differences in the total, metabolic, and renal sulfisoxazole clearances, each positively correlated with the serum free fraction of sulfisoxazole. The renal sulfisoxazole clearance had a component unaffected by serum protein binding. The apparent central compartment volume increased with an increasing serum free sulfisoxazole fraction, but the latter had no apparent effect on the first exponential term of the biexponential equation describing sulfisoxazole elimination kinetics in rats. Serum protein binding was a major determinant of intersubject differences in sulfisoxazole excretion and biotransformation kinetics.

Keyphrases □ Protein binding, serum—sulfisoxazole, distribution, metabolism, excretion, rats □ Serum proteins—binding, sulfisoxazole, distribution, metabolism, excretion, rats □ Sulfisoxazole—distribution, metabolism, excretion, effect of serum protein binding, rats □ Antibacterials—sulfisoxazole, distribution, metabolism, excretion, effect of serum protein binding

The pharmacokinetic characteristics of drugs can be markedly influenced by serum protein binding (1–3). For drugs with linear, not blood flow rate-limited, elimination kinetics, total clearance is proportional to the serum or plasma free fraction (4–8). Since there are pronounced interindividual differences in the serum protein binding of some drugs even among healthy animals and humans (9–12), serum protein binding can be a major determinant of interindividual differences in drug elimination kinetics.

Previous studies focused on the relationship between the serum free fraction and the pharmacokinetic constants that describe the multiexponential decline of plasma dicumarol (12) and warfarin (4) concentrations in rats after rapid intravenous injection. These studies have now been extended to sulfisoxazole.

The selection of sulfisoxazole was based primarily on the following considerations:

1. The average serum free sulfisoxazole fraction value in rats is one to two orders of magnitude larger than that of warfarin, which, in turn, is one to two orders of magnitude larger than that of dicumarol.
2. Significant interindividual differences in the serum free sulfisoxazole fraction have been demonstrated in rats (13) and humans (9).
3. Sulfisoxazole serum protein binding in humans is affected by their pathophysiologic status (14).
4. Unlike dicumarol and warfarin, which are eliminated almost entirely by biotransformation, sulfisoxazole is eliminated largely by renal excretion.

The investigation was designed to permit assessment not only of total clearance but also of metabolic and renal clearance values individually.

EXPERIMENTAL

Adult male Sprague–Dawley rats[1], 360–475 g, were used. A two-piece silicone rubber–polyethylene cannula was implanted in the right jugular vein under light ether anesthesia (15, 16). One or 2 days later, the rats were placed in individual metabolism cages with food and water freely available. They received a single sulfisoxazole injection, 20 mg/kg iv, through the cannula; blood samples (0.25 ml) were then obtained at 0.1, 0.25, 0.5, 1.0, 1.5, 2.0, 3.0, 4.0, 6.0, 8.0, and 10.0 hr, using a technique described previously (16).

Plasma was separated and assayed for sulfisoxazole by the Bratton–Marshall method (17). At the end of the experiment, 3 ml of blood was obtained for the determination of the serum free sulfisoxazole fraction by equilibrium dialysis (14) at 37° against pH 7.4 phosphate buffer containing sulfisoxazole, 100 μg/ml. Urine was collected for 24 hr and assayed for sulfisoxazole and its acetylated and conjugated metabolites following selective extraction with and without prior hydrolysis (18). However, rather than performing the Bratton–Marshall reaction in the ethyl acetate phase with solutions of reagents in acetone (18), the ethyl acetate solution was evaporated under nitrogen, the residue was redissolved in 0.5 ml of 3 *N* HCl and 0.2 ml of 30% trichloroacetic acid, and the Bratton–Marshall reaction was carried out in the usual manner. This modification obviated the stability problems encountered previously (18) and resulted in excellent reproducibility.

The sulfisoxazole concentration data for individual animals were fitted to the equation $C_t = Ae^{-\alpha t} + Be^{-\beta t}$ for plasma concentration C_t at time t by nonlinear least-squares regression (19). Convergence was defined as a relative change in the residual sum of squares $<10^{-4}$. Data in all functions were weighted numerically equal. Apparent distribution volumes and total clearance values were determined from the biexponential equation constants (20). Renal and metabolic clearance values were determined from the product of the total clearance and the dose fraction excreted in the urine as sulfisoxazole and as sulfisoxazole metabolite(s), respectively. The product of the total clearance and the dose fraction not recovered in the urine was designated as the clearance of an unknown.

RESULTS

The free sulfisoxazole fraction in the serum of the 13 rats used ranged from 0.052 to 0.235 at an average ± *SD* total concentration of 81 ± 6 μg/ml. Plasma sulfisoxazole concentrations declined biexponentially with time after rapid intravenous injection (Fig. 1). Excellent replication of plasma concentrations was obtained in six rats that received intravenous sulfisoxazole on two occasions, 1 week apart (Fig. 2). The correlations between total clearance values obtained in the two experiments on each of the six rats and between the serum free fraction values were very strong; there was little quantitative difference between values in any one animal (Figs. 3 and 4). An average of ~88% of the dose was recovered in the urine within 24 hr after injection; the 24–48-hr urine (collected from some animals) contained less than 3% of the dose. About 10% of the amount excreted was in the form of metabolite(s) [*i.e.*, substance(s) assayable by the Bratton–Marshall procedure following organic solvent extraction only after acid hydrolysis].

Table I summarizes the pharmacokinetic data obtained from 13 rats in the first experiment. The renal and metabolic clearance values were determined on the basis of the fraction of the dose excreted in the urine as sulfisoxazole and sulfisoxazole metabolites, respectively, during 24 hr after drug injection. The unknown clearance, based on the fraction of the dose not recovered in the urine, is a reflection of possible extrarenal elimination, conversion of the drug to metabolites that are not determinable by the Bratton–Marshall procedure even upon hydrolysis, and (probably largely) technical imperfections such as incomplete urine re-

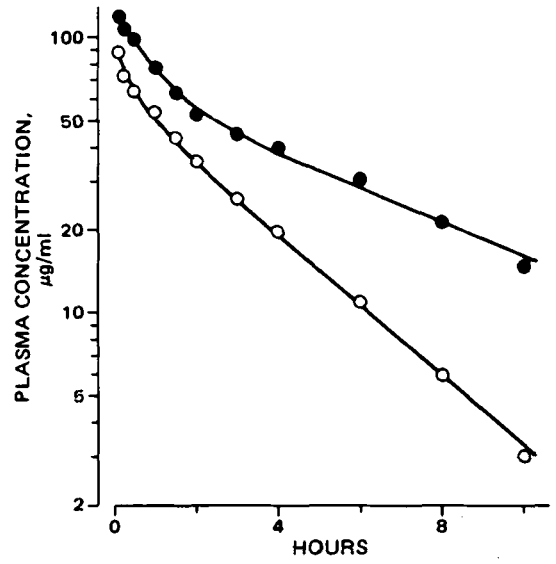

Figure 1—*Time course of plasma sulfisoxazole concentrations of the rat with the lowest serum free fraction (f) value (●, f = 0.052) and the rat with the highest f value (○, f = 0.235) after 20 mg/kg iv. Curves were fitted by nonlinear least-squares regression.*

covery. Consequently, the range of unknown clearance values is wide. More important, there were substantial interindividual differences in the total, renal, and metabolic sulfisoxazole clearances. Therefore, the relationship between these clearance values and the serum free sulfisoxazole fraction in individual animals can be examined.

Figure 5 is a plot of the total sulfisoxazole clearance against the serum free drug fraction. A highly significant correlation was obtained when only data from the first experiment on 13 animals were used for the statistical analysis (a procedure followed also in all subsequent analyses). The total clearance *versus* the free fraction relationship appeared linear but exhibited a substantial positive intercept on the clearance axis. A similarly high correlation and apparently linear relationship were observed between the renal clearance and serum free sulfisoxazole fraction, again with a pronounced positive intercept on the clearance axis (Fig. 6). A highly statistically significant correlation existed between metabolic clearance and serum free fraction, but a plot of these parameters had an intercept close to zero if the animal with the highest metabolic clearance, an apparent outlier, was excluded (Fig. 7). There was no statistically

significant correlation between unknown clearance and the serum free sulfisoxazole fraction.

The volume of the apparent central compartment for sulfisoxazole increased significantly with an increasing serum free fraction (Fig. 8, lower panel). A similar trend was evident for the apparent distribution volume (V_{area}), but the relationship was not statistically significant (Fig. 8, upper panel). An examination of the relationships between each biexponential equation constant describing the time course of plasma sulfisoxazole concentrations and the serum free fraction value in individual animals indicated that there was a statistically significant negative correlation between A and the free fraction ($r = -0.666$, $p < 0.02$) but no apparent correlation between B and the free fraction and that there was a statistically very significant positive correlation between β and the free fraction but no apparent correlation between α and the free fraction (Fig. 9).

DISCUSSION

Theoretically, the metabolic clearance of drugs with linear pharmacokinetics should be proportional to their serum free fraction provided that the clearance is much lower than the blood flow rate to the metabolizing organ or tissue (1–3). A linear relationship between *in vivo* total clearance and serum free fraction in rats was demonstrated previously with respect to dicumarol (5), warfarin (1, 4), and bilirubin (6), all of which are eliminated almost entirely by biotransformation.

The hepatic and renal blood flow rates in rats are about 1.7 ml/min/g of liver and 4 ml/min/g of kidneys (21). Based on a liver weight of 30 g/kg

Free fraction in serum	0.144	0.052–0.235
Total clearance, ml/hr/kg	66.5	38.4–92.7
Renal clearance, ml/hr/kg	51.9	27.7–77.9
Metabolic clearance, ml/hr/kg	6.15	2.37–14.1
Unknown clearance[c], ml/hr/kg	8.35	0.742–12.2

[a] $n = 13$. [b] For a 20-mg/kg dose. [c] Total clearance times the fraction of dose not recovered in urine.

of body weight and a kidney weight of 5.7 g/kg of body weight (22), about 3000 ml of blood/hr/kg of body weight flows through the liver, and about 1400 ml of blood/hr/kg of body weight flows through the kidneys. These flow rates are much higher than the total sulfisoxazole clearance observed in this investigation. Consistent with theoretical predictions, the metabolic sulfisoxazole clearance increased proportionately with the serum free drug fraction. Considering the results of this study and of previous investigations on other drugs (4, 5), the proportionality between metabolic clearance and serum free fraction has now been demonstrated at serum free fraction values ranging over three orders of magnitude.

An important discovery in this investigation was the pronounced positive intercept on the clearance axis when renal clearance (and, therefore, also total clearance) was plotted against the serum free fraction. Pending the outcome of studies now in progress, these observations suggest that renal clearance has at least one component that is independent of the serum free sulfisoxazole fraction and at least one other component that is proportional to the serum free fraction. To confirm this preliminary conclusion, it will be necessary to determine the intrinsic and "conventional" renal sulfisoxazole clearances as functions of urine flow rate, urine pH, and drug concentration in plasma so that possible artifacts can be ruled out.

Renal sulfonamide excretion is the net result of glomerular filtration, renal tubular secretion, and partial nonionic back-diffusion from the renal tubular lumen. There is some indirect evidence that the first two of these processes are functions of the plasma free drug concentration and that tubular secretion is describable by Michaelis-Menten kinetics in rabbits (23). Further studies are needed, but this investigation did show that the

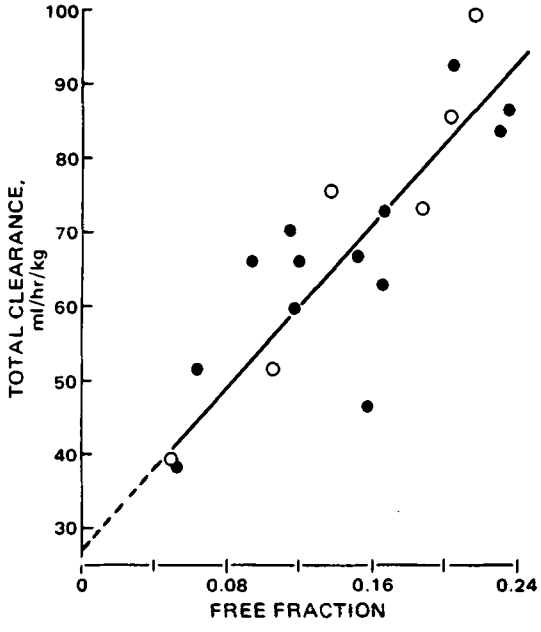

Figure 5—*Relationship between total clearance and serum free sulfisoxazole fraction in 13 rats (●) and in six of these rats retested 1 week later (○). Regression line and correlation coefficient (r) are based on data from first experiment only: r = 0.792, p < 0.005.*

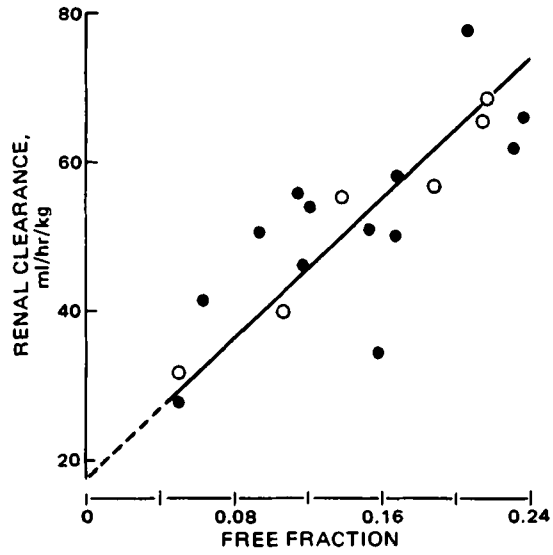

Figure 6—*Relationship between renal clearance and serum free sulfisoxazole fraction. See legend of Fig. 5 for other information; r = 0.732, p < 0.005.*

renal sulfisoxazole clearance increases with increasing serum free fraction.

As previously found with warfarin (4) but not with dicumarol (12), the volume of the apparent central compartment (V_c) for sulfisoxazole increases with an increasing serum free fraction. Therefore, this apparent volume is not the volume of a distinct homogeneous, instantaneously accessible (by intravenous injection) physiologic space such as plasma water. Consistent with this view, the V_c for sulfisoxazole is much larger than the plasma water space, even when extrapolated to a serum free fraction value of zero (Fig. 8).

There is no correlation between α, the exponent of the biexponential equation that characterizes the slope of what is conventionally considered to be the distribution phase of sulfisoxazole elimination, and the serum free sulfisoxazole fraction. A similar lack of correlation was found for dicumarol and warfarin (4, 12). On the other hand, and consistent with previous observations on dicumarol and warfarin (4, 12), there is a strong positive relationship between β and the serum free sulfisoxazole fraction.

Theoretical considerations indicate that β is primarily a function of the free drug fraction in tissues rather than in plasma (24). The weighted

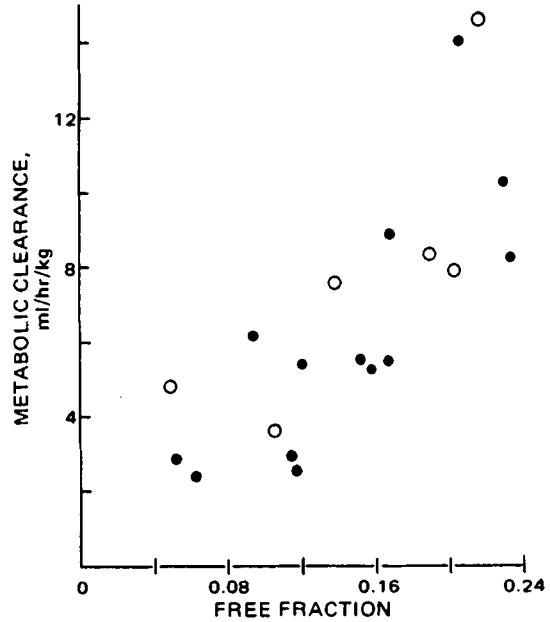

Figure 7—*Relationship between metabolic clearance and serum free sulfisoxazole fraction. See legend of Fig. 5 for other information; r = 0.784, p < 0.005.*

Table II—Serum Protein Binding and Estimated Tissue Binding of Dicumarol, Warfarin, and Sulfisoxazole in Rats[a]

Parameter	Dicumarol	Warfarin	Sulfisoxazole
f_p	0.000497	0.0123	0.144
f_T	0.00258	0.0610	0.399
f_T/f_p	5.19	4.96	2.77

[a] See text for method of tissue binding estimation and sources of data; f_p is the free fraction of drug in plasma or serum, and f_T is the free fraction of drug in tissues.

average apparent free drug fraction in tissues (f_T) can be estimated from the apparent distribution volume (V_{ss}), the free fraction in plasma or serum (f_p), and the real volumes of the body water space (V_w) and the plasma water space (V_p) according to the following relationship (25, 26):

$$V_{ss} = V_p + \frac{f_p}{f_T}(V_w - V_p) \qquad \text{(Eq. 1)}$$

Values of f_T for dicumarol, warfarin, and sulfisoxazole in adult rats were estimated on the basis of average data obtained in this and previous (4, 12) studies, assuming V_w = 700 ml/kg and V_p = 30 ml/kg. These estimates (Table II) indicate substantial binding of all three drugs in tissues. Previously, it was also established that interindividual differences in dicumarol and warfarin f_p are associated with corresponding differences in f_T such that the ratio of f_T to f_p for any one drug is relatively constant over a wide f_p range (27). The β of dicumarol and warfarin increases with increasing f_p, presumably because of the relatively constant relationship between f_p and f_T. The strong positive correlation between sulfisoxazole β and f_p and the inferential indication of significant ($\simeq$ 60%) tissue drug binding suggest that interindividual differences in sulfisoxazole f_p may be associated with corresponding differences in f_T.

The estimated f_T/f_p ratios of dicumarol, warfarin, and sulfisoxazole are quite similar despite large differences in their average f_p values (Table II). The drug f_T/f_p ratio can remain relatively unaffected by compounds that displace the drug from plasma protein binding sites since similar

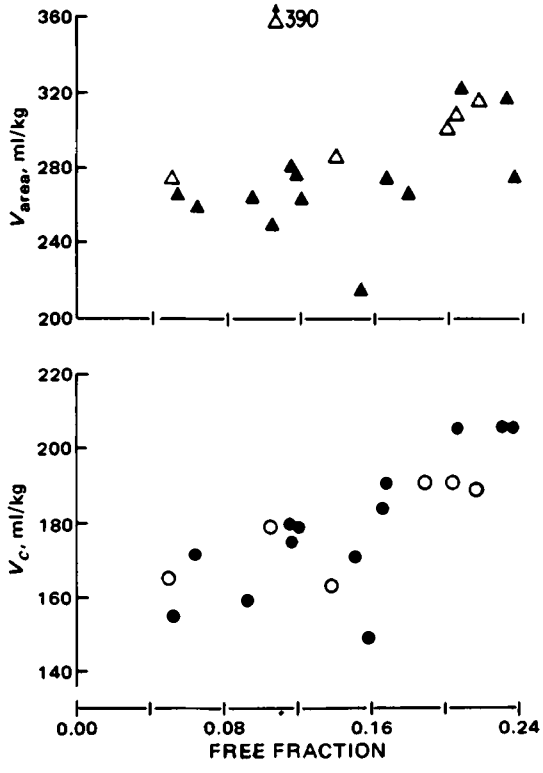

Figure 8—*Relationship between serum free fraction and apparent volume of distribution (V_{area}, upper panel) or apparent volume of the hypothetical central compartment (V_c, lower panel) of sulfisoxazole in rats. Solid symbols are for the first experiment, and open symbols are for the second experiment. Correlation between free fraction and V_c is statistically significant: r = 0.766, p < 0.005. (Correlation between free fraction and V_{area} is not significant: r = 0.454).*

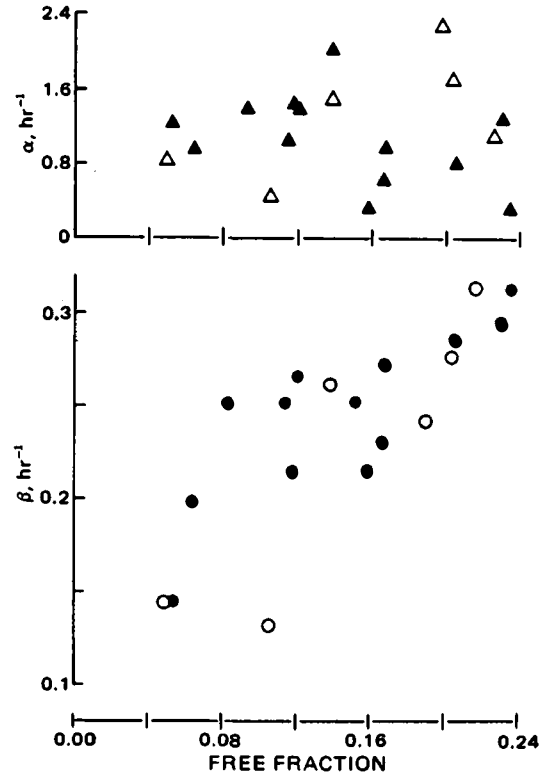

Figure 9—*Relationship between serum free fraction and α (upper panel) or β (lower panel), the exponential constants of the biexponential equation describing the elimination kinetics of sulfisoxazole in rats. Solid symbols are for the first experiment, and open symbols are for the second experiment. Correlation between free fraction and β is statistically significant: r = 0.821, p < 0.001.*

displacement from tissue binding sites may occur (28). This would increase β with little or no change in the apparent distribution volume. The situation is more complicated when drug binding is nonlinear (29).

The serum free sulfisoxazole fraction in 22 healthy adult humans varied from 0.082 to 0.125 at a total concentration of ~9 mg/100 ml (9); it was substantially larger in patients with impaired renal function (14). Serum protein binding may, therefore, be an important determinant of interindividual differences in human sulfisoxazole clearance. The same consideration probably applies to certain other sulfonamides. Consequently, *in vitro–in vivo* correlations, pharmacogenetic characterizations, and similar pharmacokinetic interpretations of the biotransformation of extensively protein-bound sulfonamides should be based on their intrinsic rather than on their total clearance values.

Analysis of Hydrophobic Amine Antimalarials in Biological Fluids with the Plastic Ion-Selective Electrode

DOUGLAS W. MENDENHALL, TAKERU HIGUCHI, and LARRY A. STERNSON ˣ

Received September 11, 1978, from the *Department of Pharmaceutical Chemistry, University of Kansas, Lawrence, KS 66045.* Accepted for publication December 5, 1978.

Abstract □ Plastic ion-selective electrode analysis of the hydrophobic amine antimalarial mefloquine in blood samples was investigated. The direct electrode response in plasma samples provided poor drug sensitivity due to high mefloquine protein binding. The drug was analyzed in whole blood by initial extraction into ether as its trichloroacetate ion-pair. Mefloquine was monitored in whole blood extracts with the electrode to moderately low levels (to 0.4 μg/ml). Rapid blood mefloquine level monitoring by this electrode was demonstrated in a bioavailability study. Mefloquine alkylation with various alkyl halides produced derivatives detectable by the electrode at much lower levels (up to two orders of magnitude) than the parent. A kinetic study of this alkylation reaction revealed that an alkyl amine base was necessary to scavenge the acid produced during reaction and to allow the reaction to go to completion. At room temperature, with benzyl bromide as the reagent, reaction was 99% complete in 30 min and mefloquine could be detected to $\sim 10^{-8}$ *M*, a 100-fold improvement in sensitivity over electrode monitoring of underivatized mefloquine.

Keyphrases □ Electrodes, plastic ion selective—analysis, mefloquine and derivatives in blood, dogs, hydrophobic amines □ Mefloquine—analysis, in blood, plastic ion-selective electrodes, derivatives □ Hydrophobic amines—mefloquine, analysis in blood, plastic ion-selective electrodes □ Antimalarials—mefloquine, analysis in blood, plastic ion-selective electrodes

Recent interest in routine drug level monitoring in biological samples (*e.g.*, blood, plasma, and urine) for determining pharmacokinetic parameters and individualizing dosage regimens had produced a need for analytical methods that can be practically applied in the clinical laboratory. These methods should be rapid, simple, and sensitive, should require minimal sample preparation, and should employ inexpensive instrumentation.

One such method recently was reported (1) from these laboratories for urine methadone analysis. A plastic ion-selective electrode was used that detects hydrophobic cations in aqueous solutions (2, 3). This report describes further studies quantitating hydrophobic amines to low levels in whole blood samples. Amines could be derivatized for detection by the plastic ion-selective electrode, increasing sensitivity up to two orders of magnitude.

The model compounds selected for these studies were the quinolinemethanol antimalarial series mefloquine (I), II, and III, presently under investigation for the treatment of persistent disease caused by *Plasmodia* strains. Problems associated with the blood concentration determination of such hydrophobic amines include glass adsorption, protein binding, and poor sensitivity by conventional detection methods [*e.g.*, high-performance liquid chromatography (HPLC) using UV detection].

EXPERIMENTAL

Materials—Mefloquine, II, and III were used as obtained[1]. The free mefloquine base was precipitated from an alkaline salt solution and recrystallized from water–ethanol to a constant melting point (174–175°). Dodecyl, octyl, and hexyl iodides and tetrabutylammonium bromide were used as obtained from commercial sources. Benzyl bromide was freshly distilled (55–56°/0.03 mm Hg) under nitrogen and stored protected from light under nitrogen until used; at the first sign of a yellow color, fresh reagent was distilled. Methanol and acetonitrile were reagent grade and were distilled in glass prior to use. Electrodes were fabricated as described previously (1).

Fresh whole blood was obtained from beagle dogs and maintained under refrigeration until used, usually within 48 hr. Anticoagulants (usually sodium citrate) were added at collection. Plasma was prepared from whole blood by centrifugation at 5000 rpm for 40 min and collection of the clear supernatant fraction.

Electrodes—Coated wire electrodes were prepared as previously described (1). All electrodes were checked for response to tetrabutylammonium ion before use, and a minimum −56-mv/decade slope (*versus* theoretical −59 mv) was required for electrode acceptability.

Apparatus—All potentiometric measurements were made with a

Analysis of Hydrophobic Amine Antimalarials in Biological Fluids with the Plastic Ion-Selective Electrode

DOUGLAS W. MENDENHALL, TAKERU HIGUCHI, and LARRY A. STERNSON ˣ

Received September 11, 1978, from the *Department of Pharmaceutical Chemistry, University of Kansas, Lawrence, KS 66045.* Accepted for publication December 5, 1978.

Abstract □ Plastic ion-selective electrode analysis of the hydrophobic amine antimalarial mefloquine in blood samples was investigated. The direct electrode response in plasma samples provided poor drug sensitivity due to high mefloquine protein binding. The drug was analyzed in whole blood by initial extraction into ether as its trichloroacetate ion-pair. Mefloquine was monitored in whole blood extracts with the electrode to moderately low levels (to 0.4 μg/ml). Rapid blood mefloquine level monitoring by this electrode was demonstrated in a bioavailability study. Mefloquine alkylation with various alkyl halides produced derivatives detectable by the electrode at much lower levels (up to two orders of magnitude) than the parent. A kinetic study of this alkylation reaction revealed that an alkyl amine base was necessary to scavenge the acid produced during reaction and to allow the reaction to go to completion. At room temperature, with benzyl bromide as the reagent, reaction was 99% complete in 30 min and mefloquine could be detected to $\sim 10^{-8}$ *M*, a 100-fold improvement in sensitivity over electrode monitoring of underivatized mefloquine.

Keyphrases □ Electrodes, plastic ion selective—analysis, mefloquine and derivatives in blood, dogs, hydrophobic amines □ Mefloquine—analysis, in blood, plastic ion-selective electrodes, derivatives □ Hydrophobic amines—mefloquine, analysis in blood, plastic ion-selective electrodes □ Antimalarials—mefloquine, analysis in blood, plastic ion-selective electrodes

Recent interest in routine drug level monitoring in biological samples (*e.g.*, blood, plasma, and urine) for determining pharmacokinetic parameters and individualizing dosage regimens had produced a need for analytical methods that can be practically applied in the clinical laboratory. These methods should be rapid, simple, and sensitive, should require minimal sample preparation, and should employ inexpensive instrumentation.

One such method recently was reported (1) from these laboratories for urine methadone analysis. A plastic ion-selective electrode was used that detects hydrophobic cations in aqueous solutions (2, 3). This report describes further studies quantitating hydrophobic amines to low levels in whole blood samples. Amines could be derivatized for detection by the plastic ion-selective electrode, increasing sensitivity up to two orders of magnitude.

The model compounds selected for these studies were the quinolinemethanol antimalarial series mefloquine (I), II, and III, presently under investigation for the treatment of persistent disease caused by *Plasmodia* strains. Problems associated with the blood concentration determination of such hydrophobic amines include glass adsorption, protein binding, and poor sensitivity by conventional detection methods [*e.g.*, high-performance liquid chromatography (HPLC) using UV detection].

EXPERIMENTAL

Materials—Mefloquine, II, and III were used as obtained[1]. The free mefloquine base was precipitated from an alkaline salt solution and recrystallized from water–ethanol to a constant melting point (174–175°). Dodecyl, octyl, and hexyl iodides and tetrabutylammonium bromide were used as obtained from commercial sources. Benzyl bromide was freshly distilled (55–56°/0.03 mm Hg) under nitrogen and stored protected from light under nitrogen until used; at the first sign of a yellow color, fresh reagent was distilled. Methanol and acetonitrile were reagent grade and were distilled in glass prior to use. Electrodes were fabricated as described previously (1).

Fresh whole blood was obtained from beagle dogs and maintained under refrigeration until used, usually within 48 hr. Anticoagulants (usually sodium citrate) were added at collection. Plasma was prepared from whole blood by centrifugation at 5000 rpm for 40 min and collection of the clear supernatant fraction.

Electrodes—Coated wire electrodes were prepared as previously described (1). All electrodes were checked for response to tetrabutylammonium ion before use, and a minimum −56-mv/decade slope (*versus* theoretical −59 mv) was required for electrode acceptability.

Apparatus—All potentiometric measurements were made with a

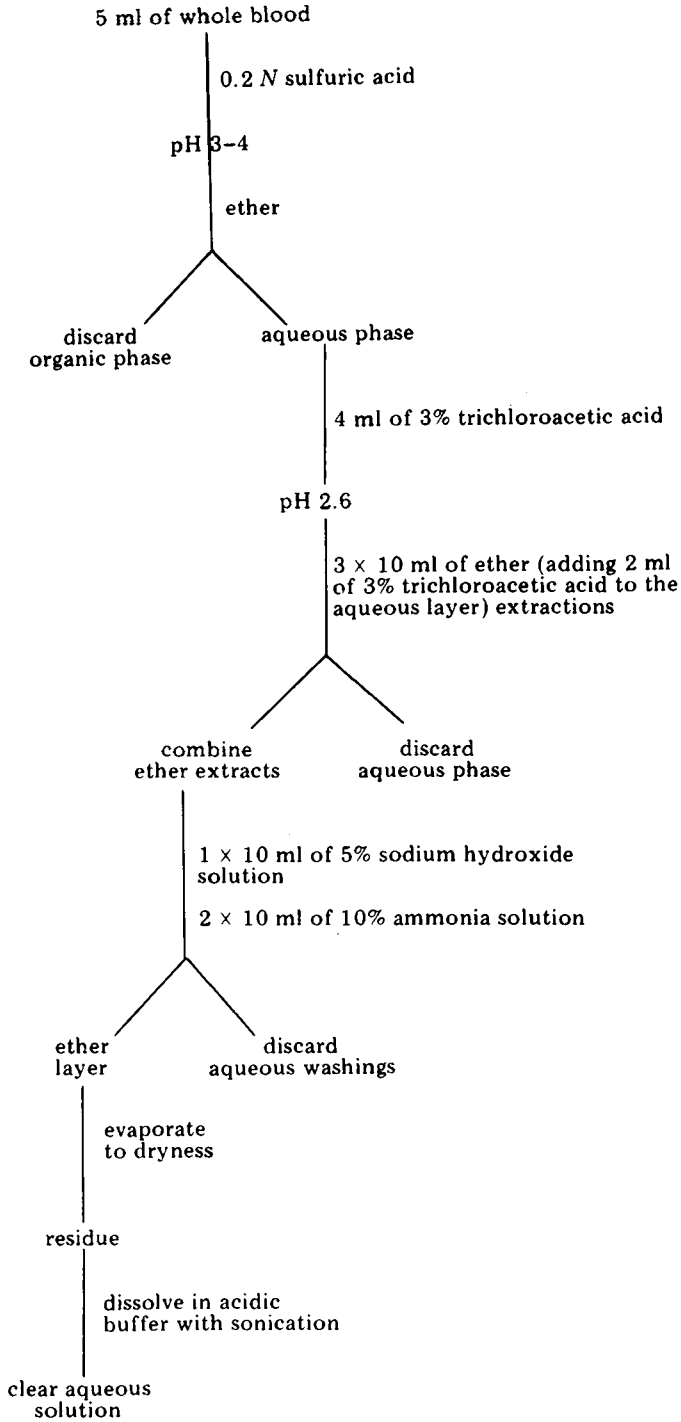
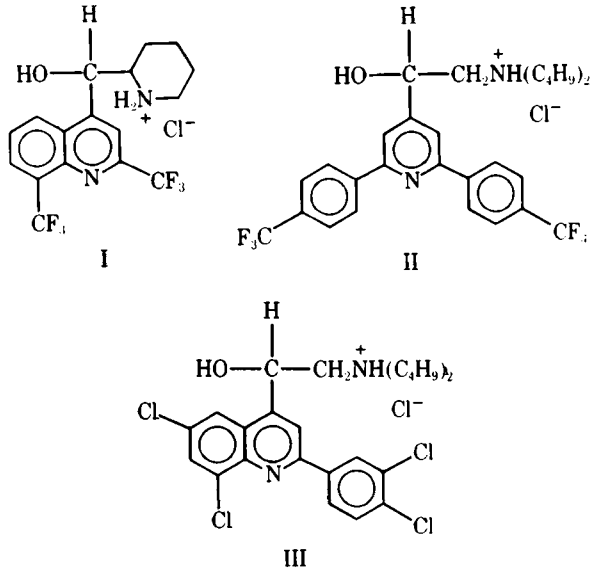


Scheme I—Ion-pair extraction scheme for mefloquine from whole blood.

digital ionanalyzer equipped with a miniature saturated calomel electrode (fiber junction[2]).

HPLC analysis was carried out with a component system[3] fitted with a column containing 10-μm silica with bonded octadecylsilane and an absorbance detector (280-nm phosphor). Detector output was monitored on a 10-mv strip-chart recorder, and peak areas were determined with a polar planimeter.

Plastic Ion-Selective Electrode Determination—The plastic electrode–calomel electrode pair was immersed in a stirred aqueous sample solution, and the potential was measured after the electrode equilibrated for 3 min. Electrodes were removed from the sample solution and washed thoroughly with deionized water before reuse. Analytes were



I II III

quantitated by comparison of the unknown solution potential with a standard curve constructed after plastic electrode analysis of a series of samples containing known analyte amounts prepared in the matrix (*e.g.*, plasma, whole blood, or water) in which the unknown was present.

Direct Plastic Ion-Selective Electrode Determination in Plasma—Plasma samples (1.0 ml) spiked with mefloquine (0.414–414 μg/ml) were adjusted to pH 4–5 with 0.3 ml of 0.1 *N* HCl, and the solution was diluted to 10 ml with water. Potentials were determined with the plastic electrode. Samples containing II were treated similarly; however, the pH was adjusted to 3 prior to electrode monitoring.

Blood Mefloquine Analysis—Fresh whole blood samples containing mefloquine were transferred to 35-ml heavy duty screw-capped culture tubes and extracted by the ion-pair technique (4) (Scheme I). The extracts were evaporated to dryness, and the residue was redissolved in 250 μl of acetone and 4.75 ml of 0.001 *M* phosphate buffer (pH 6.0). Extracted blanks, used as standards, were spiked with known mefloquine amounts before dilution with buffer. The plastic electrode response was determined and transformed to concentration units by comparison of the response with a standard curve constructed by analysis of whole blood samples spiked with known mefloquine amounts (0.414–41.4 μg/ml).

Mefloquine Derivation with Benzyl Bromide—Alkylation kinetics were determined with 2-ml samples containing mefloquine (7×10^{-4} *M*) dissolved in acetonitrile to which was added 200 μl of benzyl bromide. The mixture was analyzed by HPLC. Samples (50 μl) were withdrawn at timed intervals and diluted with methanol (to 1.0 ml), and a 50-μl aliquot was chromatographed. Components were eluted isocratically with methanol–0.012 *M* ammonium dihydrogen phosphate (69:31) pumped through the system at 2 ml/min. Standard methanolic mefloquine (V_r = 9.1 ml) and *N*-benzylmefloquine (V_r = 11.5 ml) solutions were injected periodically to determine if instrument performance was deteriorating.

For characterization purposes, *N*-alkylmefloquines were synthesized by refluxing equimolar alkyl halide and I in acetone (acetonitrile for benzyl bromide) for 48 hr. The mixture was cooled and diluted threefold with ether, and the product was precipitated as the hydrochloride salt by the addition of one volume of 5% hydrochloric acid. The solid was collected and recrystallized from ether–acetone or methanol–water, and its structure was confirmed by elemental analysis.

Animal Studies—Beagle dogs were given mefloquine orally as a 250-mg tablet[4] followed by 100 ml of water by gastric lavage or as an intravenous bolus of 50 mg of mefloquine in 5 ml of 20% propylene glycol–6% dextrose solution into one jugular vein over 2 min. Blood samples (5 ml) taken from the other jugular vein just prior to drug administration and at various times postadministration were processed by ion-pair extraction and were analyzed with the plastic ion-selective electrode.

RESULTS AND DISCUSSION

Solutions containing mefloquine, II, or III prepared in dilute aqueous acid (10^{-4} *N* H_2SO_4) could be quantified by direct measurement with

[2] Corning 476017.

the plastic ion-selective electrode. The potential response was linearly related to analyte concentration over three orders of magnitude (Fig. 1). In this simple aqueous matrix, measurements could be made with ±4% accuracy and ±2% precision over the linear concentration range.

Electrodes were thoroughly washed with deionized water (*e.g.*, 5 min) after removal from sample solutions to achieve this accuracy and precision. After determinations in more concentrated solutions, electrodes were immersed in stirred deionized water for 3 hr and air dried before reuse on a dilute sample. Failure to take such precautions reduced accuracy and precision and produced meaningless results.

The electrode response increased with the analyte hydrophobicity. For the more hydrophobic drugs (II and III), sensitivity approaching 10^{-9} *M* could be achieved; mefloquine could be quantified to 10^{-7} *M*. The Nernst equation predicts a change of 59 mv/decade in the activity of a species to which the electrode responds (5). A near-Nernstian linear response was observed in aqueous acid. The slightly super-Nernstian slopes (>59 mv) seen with the more hydrophobic compounds may arise from alterations in the membrane caused by adsorbed analyte, producing a more favorable environment for subsequent analyte partitioning into the membrane phase, an explanation consistent with the proposed mechanism for the plastic ion-selective electrode (3).

Direct Determination of Plasma Antimalarials—Compared with aqueous solutions, a loss of two orders of magnitude in sensitivity was observed for plastic ion-selective electrode response to mefloquine and II in buffered plasma. In both cases, linear responses were observed, although slopes were sub-Nernstian (I, −49 mv; and II, −53 mv). This loss in sensitivity is accounted for by the extensive protein binding observed with hydrophobic molecules (6), which reduces the free drug activity in solution. Mefloquine is 98% protein bound in plasma (7).

Attempts to dislodge mefloquine from protein binding sites and thereby to allow detection at lower levels by pH manipulation or heat denaturation were unsuccessful. Sample matrix effects severely hampered

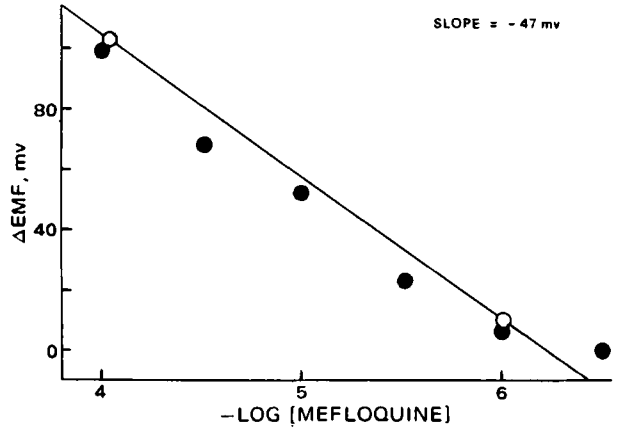

Figure 2—*Plastic ion-selective electrode determination of mefloquine in ion-pair extracts of whole blood dissolved in 5% acetone-pH 6 buffer spiked before (●) and after (○) extraction. Potential was measured versus a saturated calomel electrode.*

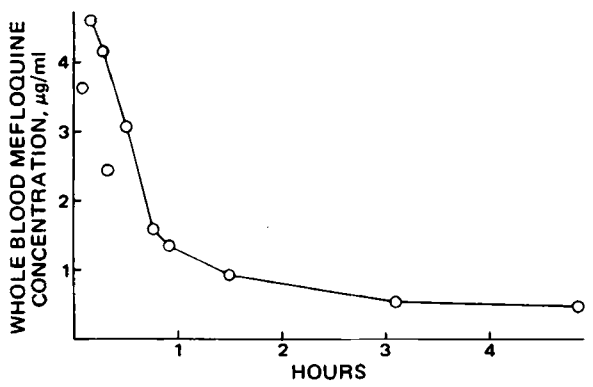

Figure 3—*Blood mefloquine level versus time profile after intravenous administration of 50 mg of the drug (as the hydrochloride) to a beagle dog.*

the assay accuracy (±25%) and precision when carried out directly in biological fluid. Therefore, methods were necessary to remove the drug from the biological matrix prior to plastic ion-selective electrode monitoring.

Blood Mefloquine Analysis—The drug was separated from blood components by extraction. Direct extraction from neutral or basic solution was ineffective because of drug loss due to adsorption to glass surfaces; interference from endogenous amines coextracted from blood, especially when derivatization with alkyl halides was indicated; and incomplete dissolution into aqueous acid after evaporation of the extracts to dryness, apparently due to lipid material coextracted with the drug. Therefore, a more selective, ion-pair extraction was used for mefloquine isolation (Scheme I).

Nakagawa *et al.* (4) showed that mefloquine was extracted into ether from blood acidified to pH 3 as a 1:1 ion-pair with trichloroacetate, giving excellent recoveries (88–100%) over a broad concentration range (1–1000 ng/ml). Initial extraction of acidified blood with ether in the absence of an ion-pairing agent removed acidic compounds, lipids, and other neutral materials that may otherwise have interfered with subsequent drug detection. The extraction scheme (Scheme I) utilized ether, an electron-donating species, as the extractant instead of the proton-donating solvent (*e.g.*, chloroform) normally indicated for solvation (extraction) of a large cation–small anion ion-pair (8). This procedure minimized extraction of potentially interfering, less hydrophobic amines while maintaining efficient analyte recovery (9).

The extracted drug was reconstituted in aqueous buffer (pH 6.0), and the concentration was determined using the plastic electrode. The plastic electrode potential *versus* the log of the spiked blood sample-concentration curve (Fig. 2) indicated a linear response to 10^{-6} *M* drug (0.4 μg/ml free base), the same limit found in aqueous systems. Extractive mefloquine removal from biological fluid returned the analyte to a more uniform matrix. Measurements could be made with ±8% accuracy and ±6% precision. These statistics also reflect the sample to sample variation (±5%) in mefloquine extraction efficiency from a biological sample.

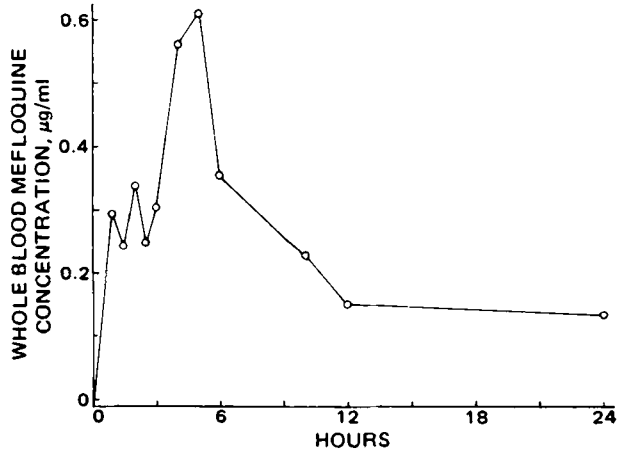

Figure 4—*Blood mefloquine level versus time profile after oral administration of 250-mg mefloquine hydrochloride tablet to a beagle dog.*

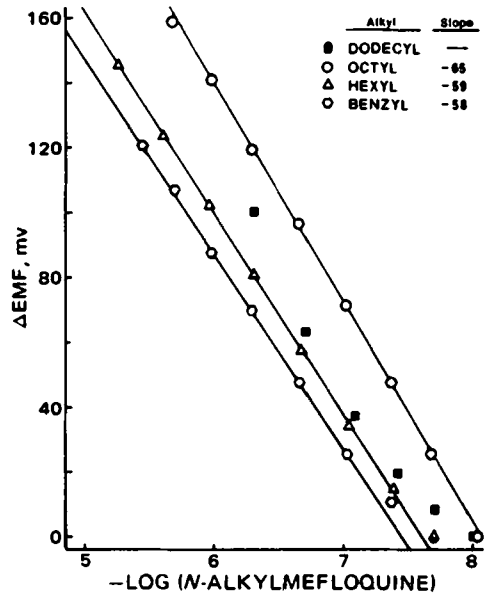

Figure 5—*Plastic ion-selective electrode response to* N-*alkylmefloquines in* 10^{-4} N H_2SO_4 *(dodecyl solutions contained 1% methanol). Potential was measured* versus *a saturated calomel electrode.*

The depressed slope (−47 mv *versus* a theoretical slope of −59 mv) was consistently seen with blood extracts and may have been due to some undefined effect of coextracted blood components on electrode response. Nonetheless, a linear response over the range of interest is adequate as a useful analytical detector. Blank blood samples were alternatively spiked after ion-pair extraction and used to generate a standard response curve (open circles in Fig. 2). An apparent consistent ~85% recovery (as determined by deviations from the theoretical 100% response line in Fig. 2) was indicated by this method, in good agreement with literature results over this concentration range (4).

The use of this method for bioavailability studies evaluating various mefloquine formulations in dogs was demonstrated by analyzing blood samples drawn from two beagles after administration of two experimental formulations. The results (Figs. 3 and 4) indicate adequate sensitivity for formulations having good availability but limited accuracy beyond peak levels for poorly absorbed formulations.

Amine Derivatization for Plastic Ion-Selective Electrode Detection—After hydrophobic amine isolation by a relatively selective procedure such as ion-pair extraction, simple alkylation with a relatively lipophilic alkyl halide prior to plastic ion-selective electrode detection provided a rapid method for dramatically increasing detector sensitivity. Figure 5 illustrates the increased sensitivity limits to various *N*-alkylated mefloquine derivatives, showing up to two orders of magnitude improvement in sensitivity over the parent compound. *N*-Dodecylmefloquine required an organic cosolvent (1% methanol) to achieve dissolution and showed an erratic response to the plastic electrode. The octyl derivative showed the same super-Nernstian slope (−65 mv) previously observed for II and III and may be similarly explained.

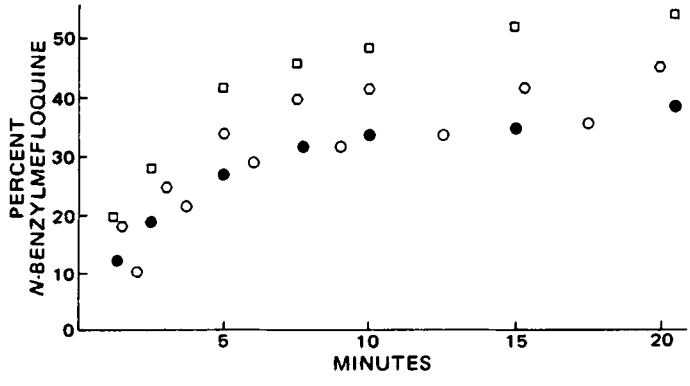

Figure 6—*Effect of added hydrobromic acid and 2,6-di-*tert*-butylpyridine on the percent of mefloquine ([mefloquine]*$_0$ *=* 7×10^{-4} *M) converted to* N*-benzylmefloquine as a function of time. Figure 7—*Plastic electrode response to 2,2,6,6-tetramethylpiperidine (○) and to* N*-benzylmefloquine in the presence (□) and absence (○) of excess benzyl bromide in* 10^{-4} N H_2SO_4. *Potential was measured* versus *a saturated calomel electrode.*

To optimize reaction conditions for alkylation of nanogram quantities of mefloquine from blood extracts, a brief study of alkylation reaction kinetics was undertaken. Of the alkylated mefloquines, the octyl and benzyl derivatives were the most likely derivatives for plastic electrode detection, the former because of its greater sensitivity and the latter because of its anticipated faster formation rate from I. Only the benzyl bromide–mefloquine reaction kinetics were studied in detail since preliminary experiments indicated that the reaction rate between octyl iodide and the drug was too slow to be useful as a derivatization procedure.

Amine alkylation rates involving bulky reactants are slow (10). Therefore, a large (10,000-fold) alkyl halide excess was used to accelerate the reaction rate since the amine concentration available for the presumed second-order reaction was small. Benzyl bromide (neat) was added to stirred mefloquine free base solutions in acetonitrile; aliquots were periodically removed, the reaction was quenched in methanol, and the mefloquine and *N*-benzylmefloquine concentrations were determined by HPLC. Essentially 100% of the initial mefloquine concentration could be accounted for by the parent and *N*-benzylmefloquine peaks in all experiments, indicating that no unexpected side reactions were occurring; no detectable benzyl bromide loss was observed under the reaction conditions, indicating that the reagent was stable over the reaction period.

Initial mefloquine benzylation studies gave unexpected results. The reaction proceeded rapidly initially, but the rate declined substantially after less than half the mefloquine had been consumed. Furthermore, the data could not be plotted in the expected pseudo-first-order manner. The reaction could be of a higher order than the assumed first-order dependency, which would produce an exaggerated drop in rate as amine was consumed. Variation in initial mefloquine concentration, however, failed to show the concentration dependence that would be expected for such a mechanism.

If the reaction proceeded by an S_N1 mechanism and bromide ion effectively competed with the amine for the reactive benzyl carbonium ion, a depression in rate would be expected as the bromide-ion concentration increased over the reaction course. Addition of relatively high bromide-ion concentrations (two times the initial mefloquine concentration) failed to depress the reaction rate, eliminating this possibility. Addition of hydrogen bromide to the reaction mixture, however, depressed the reaction rate (Fig. 6), indicating that hydrogen bromide produced during the reaction was protonating the secondary amine, effectively reducing the mefloquine concentration available for alkylation and, therefore, the rate. Addition of a sterically hindered (to prevent alkylation) pyridine base (2,6-di-*tert*-butylpyridine) failed to reverse the hydrogen bromide effect (Fig. 6). However, when 2,2,6,6-tetramethylpiperidine was added to the reaction mixture, the expected first-order plot was obtained, indicating that piperidine is a significantly stronger base in acetonitrile than pyridine and, therefore, capable of more effectively trapping the liberated hydrogen bromide.

Under the reaction conditions employed (5 μl of benzyl bromide/50 μl of acetonitrile solution of the amine to be determined, containing 0.001 *M* piperidine base), the pseudo-first-order rate constant (0.146 min^{-1})

predicts that the reaction is essentially (~99%) complete after 30 min at room temperature.

As shown in Fig. 7, 100:1 dilution of this reaction mixture with 10^{-4} N H_2SO_4 allowed direct plastic electrode determination of the alkylated amine without separation from the excess reactants since no interference from benzyl bromide or the piperidine base was seen.

CONCLUSION

Previous reports reviewed the many difficulties in handling and analyzing hydrophobic amines in biological samples, including glass adsorption, protein binding, and poor detector sensitivity (11–15). Coupled with ion-pair extraction, the plastic ion-selective electrode detection method described here offers potential advantages for efficient isolation and quantitation of hydrophobic drugs in whole blood at low levels. Furthermore, the derivatization procedure affords a means of enhancing plastic electrode detector sensitivity up to two orders of magnitude and may, therefore, extend the applicability of the method to other, less hydrophobic primary and secondary amines.

Colorimetric Acetaminophen Determination in Pharmaceutical Formulations

S. BELAL ˣ, M. ABDEL-HADY ELSAYED *, A. EL-WALIELY, and H. ABDINE

Received April 14, 1978, from the *Pharmaceutical Analytical Chemistry Department, Faculty of Pharmacy, University of Alexandria, Alexandria, Egypt.* Accepted for publication December 6, 1978.

*Present address: Department of Pharmacy, University of Nigeria, Nsukka, Nigeria.

Abstract □ Different approaches for the colorimetric determination of acetaminophen, based on its coupling with diazotized *o*-nitroaniline, are described. Copper(II) chelation with the coupled compound makes the method highly selective. Sensitivity is increased when the acetaminophen assay is carried out indirectly through the determination of the chelate's copper content. Optimum conditions for performing the different approaches are described. The stoichiometric balance for the reactants in the coupled compound and chelate is determined. The degree of dissociation and the instability constant are computed. The rectilinear relationship between the absorbance of the different products and the concentration of acetaminophen allows for its determination in different pharmaceutical formulations. Compared with the official method, the proposed methods give more accurate results.

Keyphrases □ Acetaminophen—analysis, colorimetry, various pharmaceutical formulations □ Colorimetry—analysis, acetaminophen in various pharmaceutical formulations □ Analgesics—acetaminophen, analysis, colorimetry, various pharmaceutical formulations □ Antipyretics—acetaminophen, analysis, colorimetry, various pharmaceutical formulations

Acetaminophen hydrolysis with subsequent condensation with anisaldehyde (1), *p*-dimethylaminobenzaldehyde (2), *p*-dimethylaminocinnamaldehyde (3), or vanillin (4) or reaction with alkaline 2-naphthol (5) has been used for colorimetric acetaminophen determination in unit-dose formulations. Other methods were based on the reaction with phenol together with hypobromite (6), hypochlorite in the presence of metaarsenite (7), or ferricyanide (8). Nitrosatin (9) and nitration (10, 11) were utilized also for colorimetric determination. Most of these methods are not selective.

The fluorometric method, based on acetaminophen oxidation with alkali ferricyanide (12, 13) or on its hydrolysis followed by reaction with benzylamine (14), is sensitive to many interfering substances present in pharmaceutical formulations.

Acetaminophen was also determined by cerimetric titration (15, 16), gravimetry (17), titration of the hydrolytic product with nitrite (18), and polarography (19). These methods are not sufficiently sensitive.

Acetaminophen, containing the acetamido group $NHCOCH_3$, was determined by hydrolysis, diazotization

Abstract □ Different approaches for the colorimetric determination of acetaminophen, based on its coupling with diazotized *o*-nitroaniline, are described. Copper(II) chelation with the coupled compound makes the method highly selective. Sensitivity is increased when the acetaminophen assay is carried out indirectly through the determination of the chelate's copper content. Optimum conditions for performing the different approaches are described. The stoichiometric balance for the reactants in the coupled compound and chelate is determined. The degree of dissociation and the instability constant are computed. The rectilinear relationship between the absorbance of the different products and the concentration of acetaminophen allows for its determination in different pharmaceutical formulations. Compared with the official method, the proposed methods give more accurate results.

Keyphrases □ Acetaminophen—analysis, colorimetry, various pharmaceutical formulations □ Colorimetry—analysis, acetaminophen in various pharmaceutical formulations □ Analgesics—acetaminophen, analysis, colorimetry, various pharmaceutical formulations □ Antipyretics—acetaminophen, analysis, colorimetry, various pharmaceutical formulations

Acetaminophen hydrolysis with subsequent condensation with anisaldehyde (1), *p*-dimethylaminobenzaldehyde (2), *p*-dimethylaminocinnamaldehyde (3), or vanillin (4) or reaction with alkaline 2-naphthol (5) has been used for colorimetric acetaminophen determination in unit-dose formulations. Other methods were based on the reaction with phenol together with hypobromite (6), hypochlorite in the presence of metaarsenite (7), or ferricyanide (8). Nitrosatin (9) and nitration (10, 11) were utilized also for colorimetric determination. Most of these methods are not selective.

The fluorometric method, based on acetaminophen oxidation with alkali ferricyanide (12, 13) or on its hydrolysis followed by reaction with benzylamine (14), is sensitive to many interfering substances present in pharmaceutical formulations.

Acetaminophen was also determined by cerimetric titration (15, 16), gravimetry (17), titration of the hydrolytic product with nitrite (18), and polarography (19). These methods are not sufficiently sensitive.

Acetaminophen, containing the acetamido group $NHCOCH_3$, was determined by hydrolysis, diazotization

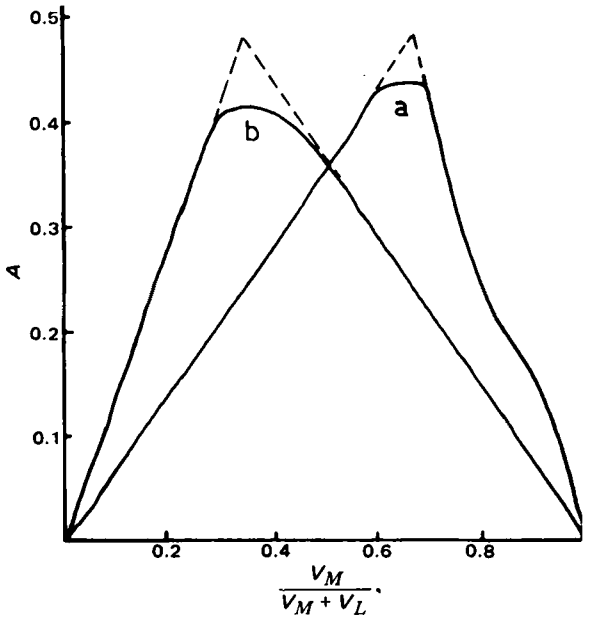

Figure 1—*Continuous variation plot for:* (a) *diazotized* o-*nitroaniline* (V_M)-*acetaminophen* (V_L) *coupled compound, and* (b) *2,6-di-(o-nitrophenylazo)-4-acetamidophenol* (V_L)-*copper(II) ion* (V_M).

of the resulting amine, and subsequent coupling with *N*-1-naphthylethylenediamine (20).

Acetaminophen as a phenolic compound can couple with a chromogenic reagent, diazotized *o*-nitroaniline. The coupled compound can be used as a chelating agent to copper(II) ion. These approaches constitute the bases for the acetaminophen assay described in this article.

EXPERIMENTAL

Apparatus, Reagents, and Materials—All reagents were analytical grade.

A photoelectric spectrophotometer[1] with 1-cm cells was used.

Acetaminophen[2] (BP 1973), acetaminophen tablets[3], acetaminophen syrup[4], and acetaminophen drops[5] were used.

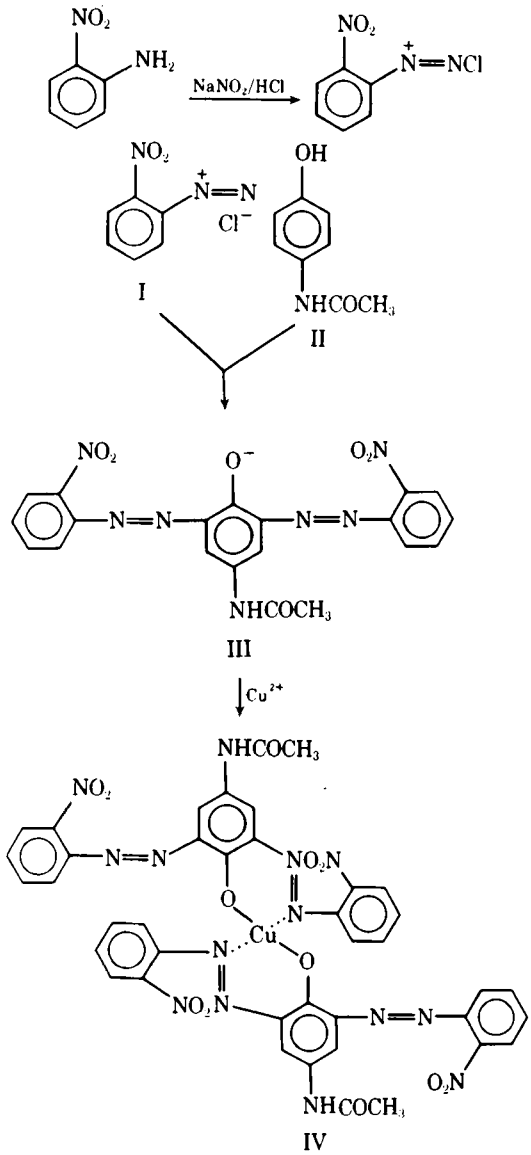
Preparation of Assay Solution—*Tablets*—Twenty tablets were powdered and mixed; an accurately weighed amount, equivalent to one tablet, was transferred to a 100-ml graduated flask. The sample was dissolved as completely as possible in water, diluted to volume, and filtered. An aliquot of filtrate was removed, after the first portion was discarded, measured, suitably diluted, and treated as described for Procedure A, B, or C.

Syrups or Drops—An aliquot was diluted with water to attain a concentration suitable for Procedure A, B, or C.

Procedure A—*Coupling with Diazotized Nitroaniline*—One milliliter of *o*-nitroaniline solution (1 mg/ml of 1.5 *N* HCl) was transferred to a 25-ml graduated flask to which 2 ml of sodium nitrite solution (3% aqueous) had been added. The contents were mixed and left for 10 min. An aliquot of acetaminophen solution (0.4 mg in water) was added, followed by 3 ml of 1 *N* NaOH. The contents were mixed, left for 5 min, and diluted to volume with water. The absorbance was measured at 426 nm against a blank.

Stoichiometric Reactant Balance—Using Procedure A, 0.5–4.5 ml of 2×10^{-3} *M* (V_M) samples of *o*-nitroaniline were diazotized and coupled with the corresponding complementary volume of 2×10^{-3} *M* acetaminophen (V_L) to make a total 5-ml volume for $V_M + V_L$.

Procedure B—*Subsequent Chelation with Copper(II) Ion*—*o*-Nitroaniline (1 ml) and sodium nitrite solution (2 ml) were transferred to a 100-ml separator. The contents were mixed and left to stand for 10 min.



Scheme I

Acetaminophen solution (0.3 mg/5.0 ml of water) was added followed by 3 ml of 1 *N* NaOH. The contents were mixed and left to stand for 5 min. A copper(II) sulfate solution (5 ml, 0.125 *M*) was added followed by 6 ml of 1 *N* H_2SO_4. The mixture was extracted three times with a total of 25 ml of chloroform. The absorbance was measured at 400 nm against a blank.

Stoichiometric Balance—Procedure B was used on 0.5–4.5 ml of 2×10^{-3} *M* acetaminophen (V_L) previously coupled with diazotized *o*-nitroaniline and treated with the corresponding complementary volume of copper(II) sulfate (V_M) to give a total volume of 5 ml for V_M and V_L in each case.

Procedure C: Indirect Determination—The copper(II) chelate chloroform extract (5.0 ml) obtained by applying Procedure B was transferred to a 10-ml graduated flask. The volume was completed with 5.0 ml of sodium diethyldithiocarbamate solution (0.5 g % in ethanol). The contents were mixed, and the absorbance was measured at 442 nm against a blank.

RESULTS

Coupling with Diazotized *o*-Nitroaniline—The phenolic hydroxyl group *para* to the acetamido group ($NHCOCH_3$) in acetaminophen causes coupling with diazotized *o*-nitroaniline to occur *ortho* to the hydroxyl group. To investigate the molecular reactant ratio, Job's method of continuous variation (21) was employed (Fig. 1*a*). The maximum absorbance was attained when $V_M/(V_L + V_M)$ equaled 0.66. This finding indicated that the diazonium salt-acetaminophen molecular ratio was

Table I—Acetaminophen in Different Pharmaceutical Formulations

Pharmaceutical Formulation	Mean Percentage ± *SD*			
	Official Method (n = 12)[a]	Procedure A (n = 14)	Procedure B (n = 16)	Procedure C (n = 14)
Laboratory-made tablet	—	100.24 ± 0.28	100.35 ± 0.51	100.37 ± 0.67
Acetaminophen tablets	101.02 ± 0.8	99.56 ± 0.41 (5.99)[b]	99.60 ± 0.60 (5.38)	99.54 ± 0.45 (5.93)
Acetaminophen syrup	101.75 ± 1.09	103.71 ± 0.29 (3.44)	103.77 ± 51.0 (3.18)	103.46 ± 0.39 (4.14)
Acetaminophen syrup	107.53 ± 0.73	105.38 ± 0.24 (10.41)	105.25 ± 0.44 (10.28)	105.57 ± 0.38 (8.77)
Acetaminophen drops	102.32 ± 0.20	101.36 ± 0.32 (8.98)	101.72 ± 0.37 (5.07)	101.57 ± 0.31 (7.19)

[a] n = number of experiments. [b] Figures in parentheses are the calculated values for which theoretical value $t_{0.975}$ equals 2.06.

2:1, as was anticipated due to the two free positions *ortho* to the acetaminophen hydroxyl when the diazonium salt coupling was assumed to occur (Compound III, Scheme I).

The coupled product stability was attained by: (*a*) keeping the *o*-nitroaniline with nitrous acid under the conditions previously mentioned for 10 min; (*b*) making the medium alkaline after addition of acetaminophen since the alkaline medium was essential for the coupling reaction, and (*c*) leaving the coupled product for 5 min before dilution with water. For alkalinization, 3 ml of 1 *N* NaOH was the optimum; a lower concentration was not sufficient for the full color development, and a higher concentration caused azo dye precipitation.

The colored azo dye (λ_{max} 426 nm) was stable for 6 hr. The dissociation degree, α, and the instability constant, K_i (22), equaled 0.0952 and 6.1105 × 10^{-6}, respectively.

Coupling and Subsequent Chelation—The investigation was extended to utilize the coupled compound as a chelating agent for copper(II) ion since the former has a free hydroxyl group with an easily replaceable proton and a diazo group (—N=N—) that offers a lone electron pair. The copper (II) chelate was hardly soluble in water but was easily extracted with chloroform to give a yellow solution (λ_{max} 400 nm).

The stoichiometric balance (Fig. 1*b*) determined by Job's method of continuous variation equaled 2:1 [2,6-di-(*o*-nitrophenylazo)-4-acetamidophenol–copper(II) ion]. The copper(II) ion satisfied its four coordination valency by combination with two free acetaminophen hydroxyl groups and with two diazo groups (Compound IV, Scheme I). The chelate was stable in chloroform for at least 4 hr after extraction. The dissociation degree, α, and the instability constant, K_i, for the chelate equaled 0.1375 and 19.2899 × 10^{-6}, respectively.

An acidic medium favored copper(II) chelate formation. Addition of 6 ml of 1 *N* H_2SO_4 ensured maximum quantitative chelate extraction. More important, the order of reagent addition (copper sulfate followed by sulfuric acid) was essential since addition of acid before copper(II) sulfate destroyed the azo dye.

Linearity of Beer's Plots—Standard curves for the azo dye and its copper(II) chelate were constructed by plotting observed absorbance readings *versus* the acetaminophen concentration treated similarly as described for Procedures A and B. Such a relationship followed Beer's law within a concentration range of 0.4–2.8 mg % (Procedure A) or 0.4–4 mg (Procedure B) of acetaminophen calculated in the final dilution. The regression equations, derived by the least-squares method (23), for the calibration curves were:

$$A_{426} = -0.0020 + 0.2503C \quad \text{(Procedure A)} \qquad \text{(Eq. 1)}$$

$$A_{400} = -0.0025 + 0.1216C \quad \text{(Procedure B)} \qquad \text{(Eq. 2)}$$

for which the percentage fits (24) were 99.97 and 99.91, respectively.

The validity of these equations was tested by analyzing known acetaminophen amounts mixed with common tablet excipients or additives in a ratio approximating sample commercial tablet weights. The results (Table I) were highly accurate, indicating no interference from tablet base ingredients.

Indirect Method—In spite of the high copper(II) chelate stability in chloroform, addition of 5 ml of diethyldithiocarbamate (0.5 g % ethanolic solution) displaced 2,6-di-(*o*-nitrophenylazo)-4-acetamidophenol to give copper(II) diethyldithiocarbamate, a complex of λ_{max} 442 nm. The absorbance was proportional to the acetaminophen concentration in the 0.2–2 mg % range. The calibration curve was described by the following regression equation:

$$A_{442} = -0.0047 + 0.3081C \quad \text{(Procedure C)} \qquad \text{(Eq. 3)}$$

for which the percentage fits equaled 99.59.

DISCUSSION

Acetaminophen coupling with diazotized *o*-nitroaniline had an advantage over the method involving acetaminophen hydrolysis with subsequent diazotization and coupling (20, 21). In the latter technique, any hydrolytic product present in pharmaceutical formulations during unsuitable storage interfered during the analysis. Any phenolic compound could interfere with Procedure A. To increase the method selectivity, coupling with subsequent chelation was proposed. The common analgesic–antipyretics likely to be present with acetaminophen exhibited no interference. Aspirin, codeine, caffeine, and salicylamide did not interfere[6].

The slope of the calibration curve for Procedure C was 1.23- or 2.53-fold higher than that for Procedure A or B, respectively. This finding indicated the high indirect method sensitivity.

BP 1973 (25) described a UV assay for acetaminophen in which diluents and binders in tablets or sweetening agents, preservatives, and coloring matter in syrups interfere during analysis. Therefore, it is not surprising that the proposed procedures give more accurate results than the official method since t-calculated exceeds t-theoretical (Table I).

Pharmacokinetics of Morphine and Its Surrogates III: Morphine and Morphine 3-Monoglucuronide Pharmacokinetics in the Dog as a Function of Dose

EDWARD R. GARRETT ˣ **and ANDRÉ J. JACKSON** *

Received September 12, 1978, from *The Beehive, College of Pharmacy, J. Hillis Miller Health Center, University of Florida, Gainesville, FL 32610.* Accepted for publication November 21, 1978. *Present address: College of Pharmacy, Howard University, Washington, DC 20059.

Abstract □ The pharmacokinetics of morphine and its derived metabolite, morphine 3-monoglucuronide, were studied in normal and bile-cannulated dogs. High doses (7.2–7.7 mg/kg iv) caused renal and biliary shutdowns and time lags in urinary drug and metabolite excretion and in biliary secretion of the hepatically formed conjugate. Intermediate doses (0.41–0.47 mg/kg iv) inhibited urine flow but not renal clearance. Low doses (0.019–0.07 mg/kg iv) had no apparent effect. Dose-related effects on the total, metabolic, and biliary clearances imply saturable enzymes and/or dose-inhibited hepatic flows, accounting for the major elimination half-lives of 83 ± 8 and 37 ± 13 min at the high and low doses, respectively. The slow terminal phase in plasma morphine and metabolite elimination and urinary accumulation is due apparently to the enterohepatic metabolite recirculation after biliary excretion, gastrointestinal hydrolysis, and hepatic first-pass reconjugation. Bile-cannulated dogs showed no fecal drug and no slow terminal plasma and urine elimination phases. Intravenous morphine 3-monoglucuronide was eliminated only renally and showed neither biliary excretion nor prolonged hepatically formed glucuronide elimination. Hepatic morphine clearances at normal therapeutic doses parallel hepatic blood flow and explain the lack of oral morphine bioavailability by anticipating complete first-pass liver metabolism. Renal morphine and morphine conjugate clearances were 85 (± 9 *SEM*) and 41 (± 4 *SEM*) ml/min, respectively, indicating glomerular filtration for the latter and glomerular filtration plus tubular secretion for the former. Urinary morphine and morphine conjugate excretion accounted for ~83% of the dose. Biliary secretion accounted for 11–14% of the dose. Morphine showed dose-independent plasma protein binding of 36 (± 1 *SEM*) % and a red cell–plasma water partition coefficient of 1.11 ± 0.04 *SD*. New equations were developed to model the discontinuous morphine and morphine metabolite pharmacokinetics.

Keyphrases □ Morphine—pharmacokinetics, dose related, dogs □ Morphine monoglucuronide—pharmacokinetics, dose related, dogs □ Pharmacokinetics—morphine, morphine monoglucuronide, dose related, dogs

Early studies on the distribution and disposition of morphine were largely descriptive (1–6). Rigorous pharmacokinetic studies were limited and usually only related to the parent compound at high doses. Early time course studies (7–10) in the dog were conducted at large time intervals and at high 30-mg/kg levels (human therapeutic dose is 0.14 mg/kg) due to color complex assay sensitivity limitations (10). Early morphine studies (9) estimated that 78–97% of the administered morphine was recoverable in urinary and fecal excretions, 14% as free morphine and 55% as presumed glucuronide conjugate in the urine, and 6–26% in the feces with less than 2% of the total drug as the conjugate. The plasma [*N*-^{14}C-*methyl*]morphine half-life was estimated at ~1 hr (11).

BACKGROUND

A fluorometric method with a sensitivity of 1 μg/ml of plasma was used by Kupferberg *et al.* (12) in a single rabbit study of six time samples at 15 mg/kg to demonstrate apparent biphasic morphine decay in plasma with a terminal half-life that could be roughly estimated as 1 hr.

Only in the last decade has the morphine time course been monitored with sufficient attention to warrant any pharmacokinetic data analysis.

A highly sensitive GLC method was used to monitor the time course of morphine at 2.5 mg/kg iv in the rat (13). At least three exponentials were needed to fit the plasma level–time curve.

Radioimmunoassay was used to monitor morphine, 0.14 mg/kg iv, in human plasma (14, 15), and the results indicated an apparent triphasic loss that included a rapid initial decline during the first 5–10 min, a subsequent slower but precipitous decline with a half-life of 1.0–3.1 hr, and a terminal slow disappearance of 10–44 hr at plasma levels of <10 ng/ml. A separate study (16) at 1 mg/kg infused over 12 min could only demonstrate a two-compartment body model when conducted for 2 hr after the completion of the infusion. Total clearance was 378 ± 63 ml/min. The apparent half-lives were similar to those of the previous studies; mean values were 1 ± 1 and 137 ± 14 min, with the latter phase ranging from 1.3 to 3.5 hr. These half-lives were similar to those for the lower 0.14-mg/kg dose and suggested that the assumption of a saturable or capacity-limited process for morphine was not warranted. Since different subjects were used for the different doses, this concept cannot be rigorously concluded. Mean apparent volumes of distribution of the central compartment and the total apparent distribution space were 9 and 102% of body weight, respectively.

Radiolabeled morphine at 0.14 mg/kg in humans (17, 18) showed an initially fast distribution phase and an apparent terminal half-life of 2.1–2.6 hr. The sensitivity of 20–30 ng/ml of plasma may not have permitted the observation of a slow terminal phase. Conjugate quickly appeared in the plasma close to its maximum value at ~40 min. Cumulative urinary excretion of free morphine and of the conjugate was 8.5–9.3 and 66–70% of the dose, respectively. The renal drug and metabolite clearances were given as 109–171 and 50–115 ml/min, respectively. The qualitative formation of *N*-demethylated morphine was observed by following the time course of expired $^{14}CO_2$.

Catlin (19) investigated morphine pharmacokinetics in the rabbit by morphine radioimmunoassay methods with the intent of confirming the presence of multiphasic pharmacokinetics as indicated by previous studies that apparently demonstrated a terminal half-life of many hours or days. He clearly demonstrated that a two- or three-compartment body model in the rabbit could be observed, dependent on antiserum specificity and on possible interaction with metabolites. He stated that he would reject the third compartment for the rabbit and retain only two half-lives of 13 and 72 min. No pharmacokinetic dose dependency was observed between the 1- and 10-mg/kg doses. Catlin (19) issued the caveat for the previously cited radioimmunoassay studies in humans (14, 15), where an apparently long terminal half-life was observed, that "providing the antiserum used . . . did not seriously cross-react with morphine metabolites, it appears that in man the two compartment model is not sufficient

The sensitivity of 20–30 ng/ml of plasma may not have permitted the observation of a slow terminal phase. Conjugate quickly appeared in the plasma close to its maximum value at ~40 min. Cumulative urinary excretion of free morphine and of the conjugate was 8.5–9.3 and 66–70% of the dose, respectively. The renal drug and metabolite clearances were given as 109–171 and 50–115 ml/min, respectively. The qualitative formation of *N*-demethylated morphine was observed by following the time course of expired $^{14}CO_2$.

Catlin (19) investigated morphine pharmacokinetics in the rabbit by morphine radioimmunoassay methods with the intent of confirming the presence of multiphasic pharmacokinetics as indicated by previous studies that apparently demonstrated a terminal half-life of many hours or days. He clearly demonstrated that a two- or three-compartment body model in the rabbit could be observed, dependent on antiserum specificity and on possible interaction with metabolites. He stated that he would reject the third compartment for the rabbit and retain only two half-lives of 13 and 72 min. No pharmacokinetic dose dependency was observed between the 1- and 10-mg/kg doses. Catlin (19) issued the caveat for the previously cited radioimmunoassay studies in humans (14, 15), where an apparently long terminal half-life was observed, that "providing the antiserum used . . . did not seriously cross-react with morphine metabolites, it appears that in man the two compartment model is not sufficient

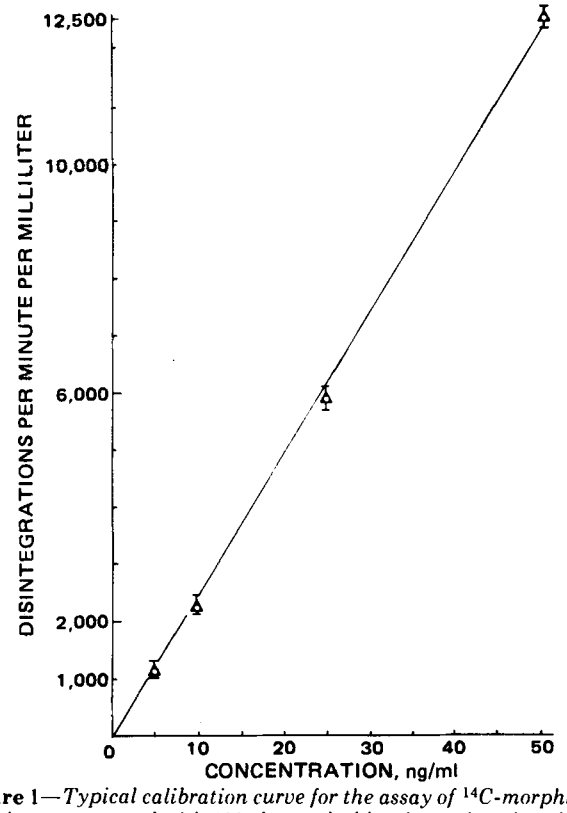

Figure 1—*Typical calibration curve for the assay of ^{14}C-morphine in dog plasma extracted with 10% butanol–chloroform after the addition of 0.5 g of $NaHCO_3$ to 2 ml of plasma by liquid scintillation spectrometry in the absence (△) and presence (○) of 100 ng/ml of ^{14}C-morphine-3-glucuronide. The vertical bars give the ± SD of four replicate determinations.*

to describe the data." Stripped of its niceties, the statement implies that radioimmunoassay assays for low morphine levels in the presence of metabolites are suspect and that the assumption of a deep compartment in humans is not assured.

Definitive pharmacokinetic studies in other animal species and humans still are needed to prove the presence of a deep compartment characterized by a slow terminal release of administered morphine from the body. The reported studies were designed to challenge the hypothesis of a deep morphine compartment with slow terminal release.

The only attempt to challenge systematically dose-dependent morphine pharmacokinetics was made by Catlin (19) in the rabbit. His conclusion of nondose dependence is surprising in the light of known morphine pharmacology. Although morphine is used primarily as an analgesic agent, it elicits many other pharmacodynamic responses (20) including cardiovascular and respiratory effects such as peripheral vasodilation, blood pressure decrease, blood compartment volume changes, and respiratory depression. Morphine increased biliary pressure and caused biliary tract spasms which could impede biliary excretion.

Handley and Moyer (21) showed that intravenous doses of 1 mg/kg or more to the dog produced not only a pronounced fall in mean blood pressure but also an abrupt and sustained depression of the glomerular filtration rate and renal plasma flow and a maximal rate of dextrose reabsorption by the renal tubules. Such pharmacological effects should have a decided "feedback" effect on morphine pharmacokinetics as a function of dose. This paper reports on the apparent perturbations of morphine pharmacokinetics by its dose-dependent pharmacological effects.

These potential problems offer a challenge in proper pharmacokinetic modeling. Not only must nonlinearities that may not conform to simple saturation models be taken into account, but discontinuities in pharmacokinetic processes must be considered. Such discontinuities can be caused by shutdowns in renal and biliary processes and the holdup of significant drug and metabolite quantities in the kidneys and bile.

Pharmacokinetic studies have not monitored the constancies of renal and metabolic clearances of morphine and its metabolites as a function of dose. These canine studies were designed to permit a pharmacokinetically unified appraisal of the time courses of intravenous morphine and its principal metabolite (2, 3), morphine-3-monoglucuronide, in plasma, urine, bile, and feces over a wide spectrum of doses. It is believed (2, 3, 6) that the formation of other metabolites in the dog is negligible.

The separation techniques used here permit the specific monitoring of radiolabeled morphine and its conjugates in the various biological fluid studied (22). The analytical methods used were equivalent to several independent nonradioactive assays.

EXPERIMENTAL

Materials—The following were used: nanograde chloroform[1], analytical grade butanol[1], *N*-^{14}C-*methyl*-morphine hydrochloride[2], morphine sulfate USP[3], silicone solution[4], thin-layer plates[5], chromatogram sheets[6], a scintillant (Handifluor[1]), sodium bicarbonate[1], *tert*-butylhydroperoxide[7], heparin sodium[8] (10,000 units/ml), and pentobarbital sodium[9].

Purity of *N*-^{14}C-*methyl*-Morphine—Vendor analysis of the *N*-^{14}C-*methyl*-morphine hydrochloride (143 μCi/mg) (1 μCi = 2.2 × 10^6 dpm) stated a 98% radiolabeled purity in carbon tetrachloride–*n*-butanol–methanol–5 *N* ammonia (40:30:30:4). TLC[6] in the system of *n*-propanol–acetone–acetic acid–5% ammonium hydroxide–water (9:3:2:2:4) (23) separated morphine (R_f 0.67) from the other alkaloids. One-centimeter sections of the developed chromatogram were scraped into vials, dissolved in 1.0 ml of water, and counted in a scintillation counter[10].

^{14}C-Morphine and ^{14}C-Morphine Glucuronide Assay in Biological Fluids—All glassware was silylated because of morphine adsorption by glass at low concentrations (24). Sodium bicarbonate (0.5 g) was added to 2 ml of plasma, urine, or bile containing morphine. This solution was shaken with 9 ml of 10% butanol–chloroform for 10 min and separated by centrifugation[11] at 1000 rpm. The upper aqueous phase was removed by aspiration, and an appropriate organic phase aliquot was evaporated in a scintillation vial under nitrogen in a water bath at 50°. Scintillant (10 ml)[12] was added, and the resultant ^{14}C-morphine solution was counted.

The original plasma, urine, or bile ^{14}C-morphine concentration was calculated by dividing by the extraction efficiency and the specific activity. A typical linear calibration curve for ^{14}C-morphine in dog plasma in the absence and presence of ^{14}C-morphine-3-glucuronide is given in Fig. 1.

The morphine extraction efficiency from a buffered 2.0-ml plasma sample with 9 ml of 10% butanol–chloroform was 0.84 ± 0.03 (*SD*). The solvent–plasma partition coefficient was 1.17, calculated from:

$$K = \frac{A_o V_w}{V_o(A - A_o)} = \frac{C_o}{C_w} \qquad \text{(Eq. 1)}$$

where $A_o/(A - A_o)$ is the ratio of the organic phase concentration (0.84 *A*) to the aqueous plasma concentration (0.16 *A*); V_w (2 ml) and V_o (9 ml) are the plasma and organic solution volumes, respectively; and *A* is the total plasma concentration before extraction. Where the organic solvent volume (V_o) and/or the extracted plasma volume (V_w) were varied, the total extracted plasma morphine fraction (f_{ex}) was calculated from:

$$f_{ex} = A_o/A = 1/(1 + V_w/V_oK) \qquad \text{(Eq. 2)}$$

where K = 1.167.

The extraction efficiency of morphine from buffered urine (2 ml with 9 ml of organic solvent) was 0.87 ± 0.02 to give a partition coefficient from urine of K = 1.49 (Eq. 1). The fraction extracted from a different volume of urine was calculated from Eq. 2.

The plasma, urine, or bile concentration (disintegrations per minute per milliliter) of the unextractable morphine metabolite was determined from the difference between the experimentally determined total disintegrations per minute per milliliter of unextracted plasma, urine, or bile and the calculated disintegrations per minute per milliliter assigned to the morphine concentration in these biological fluids. Unextracted

plasma, urine, or bile (0.2 ml) was counted by adding 1.0 ml of water plus 10 ml of scintillant.

All counts per minute were converted to disintegrations per minute by dividing by the counting efficiencies. Nanogram morphine base equivalents were determined by dividing the disintegration per minute values by the specific activity of the morphine free base. The counting efficiencies of plasma, urine, bile, fecal slurries (10% w/v homogenate in water), and their extracts were determined by adding a known standard ^{14}C-toluene amount to previously counted samples and recounting. The counting efficiency was the ratio of the difference in counts per minute values to the disintegrations per minute added. Blood and bile samples were digested with 0.5 ml of 1 *N* NaOH and bleached with 0.5 ml of *tert*-butylhydroperoxide prior to extraction and counting.

^{14}C-Morphine-3-monoglucuronide Isolation—The metabolite was isolated from the urine of dogs administered ^{14}C-morphine. A literature procedure (24) was used, except that TLC was substituted for anionic-exchange separation. Urine (30 ml) was shaken with 2 g of charcoal in a 50-ml centrifuge tube for 1 hr and centrifuged for 3 min. The aqueous layer was decanted, and the residual charcoal was washed twice with 30 ml of water. The adsorbed morphine and metabolites were extracted from the charcoal by shaking it with 10 ml of acetic acid for 30 min and centrifuging for 10 min. This procedure was repeated three times.

The resulting extracts were collected and filtered through filter paper to remove the finer charcoal particles. The clear liquid was evaporated under reduced pressure[13], and the residue was dissolved in 10 ml of water. This solution was chromatographed[5] in *n*-propanol–acetone–acetic acid–5% ammonium hydroxide–water (9:3:2:2:4) to separate morphine from its metabolite. The chromatogram was developed for 15 cm, and the metabolite spot (R_f 0.48) was scraped from the plate and eluted with hot water. The silica gel slurry was filtered to give a metabolite solution.

Metabolite Purity—The purity of the radiolabeled morphine-3-monoglucuronide metabolite was based on the R_f values of the isolated compound *versus* an authentic nonradioactive standard[14]. The following systems were used to verify the purity: System I (R_f 0.48), *n*-propanol–acetone–acetic acid–5% ammonium hydroxide–water (9:3:2:4:4) (3); and System II (R_f 0.0), chloroform–ethanol–water–acetic acid (20:10:15:1) (4). The morphine-3-monoglucuronide was visualized under UV light, and 1-cm sections were scraped into scintillation vials and counted. The chromatographic purity was 96%.

Metabolite Purity by Extraction—One hundred nanograms (10 μl) of the radiolabeled metabolite was added to each of three test tubes containing 2 ml of water to give a final concentration of the metabolite of 50 ng/ml. Each tube was extracted three times after the addition of 0.5 g of $NaHCO_3$ with 9 ml of 10% butanol–chloroform. Then 8 ml of each total extract was collected, dried, and counted. Less than 1.4% (1.1, 1.4, and 1.2) was extracted by this procedure.

Attempted Identification of Additional Major Metabolites—Plasma ultrafiltrates and urine samples from several dogs administered morphine were analyzed by TLC (System I). Two compounds were visualized, and their R_f values were determined by radioactive analysis of scrapings. They were morphine glucuronide (R_f 0.48) and morphine (R_f 0.67). These plasma and urine samples were also extracted with tetrahydrofuran at pH 1, 8, and 10, and the extracts were chromatographed in System I. Each chromatogram was developed to 15 cm, and 1-cm sections were scraped into scintillation vials and counted after the addition of 1 ml of water. Additional compounds were not observed at other R_f values.

Protein Binding—The binding of ^{14}C-morphine and ^{14}C-morphine 3-monoglucuronide was studied by an ultrafiltration method (25). When these drugs were dissolved in buffer and ultrafiltered through the cone membrane[15], no significant cone binding of drugs was observed. Standard morphine solutions were prepared in plasma at 10 and 100 ng/ml and at 2.48 μg/ml. The ultrafiltration cones were soaked in water and spun dry prior to use. The dried cones were placed in ultrafiltration cone supports in centrifuge tubes.

One milliliter of 0.05 *M* phosphate buffer, at ionic strength 0.154 and pH values of 7.4, 7.5, and 7.8, was placed in each cone. The appropriate standard plasma solution concentration was added, with agitation to effect mixing, until a volume of 5.0 ml was obtained. An aliquot (0.2 ml) was analyzed for total radioactivity. The samples were allowed to stand at room temperature for 3 min, 12 min, or 1 hr and then were centrifuged at 2000 rpm for 10 min to half-filtration. The ultrafiltrates were assayed by liquid scintillation spectrophotometry.

Similar studies were conducted with dog plasma at 100 ng of morphine-3-glucuronide/ml at pH values of 7.1 and 7.4.

Red Blood Cell Partition—The partition of ^{14}C-morphine and ^{14}C-morphine-3-monoglucuronide into the red blood cells was studied as a function of drug concentration and time. Fresh heparinized dog blood was added with gentle shaking to 10-ml volumetric flasks containing enough ^{14}C-morphine to achieve concentrations of 1, 10, 100, and 1000 ng/ml. Dog blood also was added to another set of volumetric flasks containing sufficient ^{14}C-metabolite to achieve concentrations of 50 and 500 ng/ml. Hematocrits were determined, and aliquots (3 ml) were taken after 30 sec and 30 min at room temperature and assayed for total radioactivity. The remaining blood was centrifuged at 1000 rpm for 10 min, and the plasma was analyzed for total radioactivity.

Pharmacokinetics of Morphine and Its Derived Metabolite—The dogs were fasted for 24 hr before each experiment and then weighed. Chronic jugular vein catheterization was done with medical grade tubing[16] at least 48 hr before the scheduled experiment. All blood sampling was done through this catheter.

On the day of the experiment, the dog was placed on a table in a standing position and restrained by separate straps around the fore- and hindlegs, which were fixed to a horizontal bar above. A water load of 15 ml/kg was administered through stomach tubing. A continuous 0.9% NaCl drip (1 ml/min) was maintained for 500 min. A transurethral catheter[17] was used to collect bladder urine for the first 12 hr. After 12 hr, urine was collected from the metabolic cages, with completeness achieved by acute catheterization. After anaerobic collection, the blood pH and P_{CO_2} were routinely determined on the gas analyzer[18]. Hematocrits were determined utilizing a microhematocrit centrifuge and reader[19].

Sterile procedures were used for blood handling when red blood cells were to be readministered. After separation from plasma, the packed cells were stored at 5°. At the end of the experiment, they were resuspended in normal saline and reinfused into the animal; 200,000 units of procaine penicillin G in dihydrostreptomycin sulfate[20] solution were administered intramuscularly.

Hematology showed negative results for microfilaria. Body weights and the intravenous morphine doses are listed in Table I. A minimum period of 2 weeks was allowed between any two experiments on the same dog.

^{14}C-Morphine hydrochloride was diluted with morphine sulfate USP, and the specific activity of the final mixture determined. The morphine was administered intravenously, as freshly prepared solutions in plasma, into the jugular catheter over 10 sec for the 0.02- and 0.07-mg/kg doses; it was injected into the cephalic vein for the 0.4–0.5- and 7.2–7.7-mg/kg doses. Drug administration was followed by a 5-ml flush of normal saline to free the catheter of residual drug. At the highest dose, the dogs exhibited a phenomenon known as sham rage and had to be physically restrained so that blood could be sampled.

Blood samples were taken from the jugular catheter after the dead space volume was removed and the catheter was filled with fresh undiluted blood. Sterile disposable syringes containing approximately 50 μl of heparin (10,000 units/ml) were used to collect blood samples. The blood was transferred to a 15-ml centrifuge tube and centrifuged at 1500 rpm for 10 min, with 2 ml of the supernatant plasma being transferred to tubes containing 0.5 g of sodium bicarbonate for extraction. Blood samples (5 ml) were taken at 0.5, 1, 2, 5, 10, and 20 min after the morphine injection; 8-ml samples were taken at 30, 45, 75, 110, and 180 min; 1-ml samples were taken hourly thereafter to 12 hr and finally every 12 hr up to 50 hr. When pH and hematocrit values were to be evaluated, a small portion of the sample was left in the syringe.

Urine was collected every 10 min up to 1 hr, then hourly up to 12 hr, and then every 12 hr up to 100 hr. The volume was noted, and the urine was stored in bottles and refrigerated at 5°.

Feces were collected at 24-hr intervals.

Pharmacokinetics of ^{14}C-Morphine-3-monoglucuronide—The purified metabolite morphine-3-monoglucuronide was administered intravenously to Dog A, which had not been used in a previous phar-

[a] Parameters estimated from best fit of $[M]_{exp}$ as morphine base in plasma against time to $[M] = Ae^{-\alpha t} + Be^{-\beta t} + Ce^{-\gamma t}$ or from urine data where the γ parameter was determinable solely from slopes of plots of ln $|\Sigma U_\infty - \Sigma U|$ *versus* time t and ln $\Delta U_M/\Delta t$ *versus* time t_{mid}, where ΣU_M is the cumulative morphine base excreted into urine at time t and $\Delta U_M/\Delta t$ is the amount of morphine base excreted in a time interval of midtime, t_{mid}. A C and γ of 20 ng/ml and 8.7×10^{-4} min^{-1} ($t_{1/2}$ = 798 min), respectively, could be estimated from plasma for Dog C, not bile cannulated, at the 109-mg dose in column 2. With the two intermediate doses, a quickly vanishing exponential $A'e^{-\alpha' t}$ should also be added to best fit the plasma–time data where the values of A' and α' ($t_{1/2})_{\alpha'}$ were 212 ng/ml and 0.242 min^{-1} (2.9 min), respectively, for the 6.43-mg dose in the bile-cannulated Dog C and 930 ng/ml and 0.921 min^{-1} (0.75 min), respectively, for the 5.70-mg dose in the non-bile-cannulated Dog D. [b] Total morphine base clearance estimated from ratio of dose to total area under plasma $[M]$ *versus* t curve, D_0/AUC_M^∞. [c] Renal morphine base clearance estimated from the slope of $\Delta U/\Delta t$ *versus* $[M]$ plots and the best fit of ΣU *versus* t data generated from $Cl_{ren}^M (AUC_M^t - AUC_M^{t_0})$, where AUC_M is the area under the plasma $[M]$ *versus* t curve up to time t and $AUC_M^{t_0}$ is the area up to a time, t_0, where renal processes start at the high doses. [d] Estimated metabolic clearance of morphine base to morphine conjugate, MG, normally calculated from $Cl_{tot}^M - Cl_{ren}^M$. The parenthetical values were determined from appropriate plots of:

$$\frac{\Sigma U_{MG}^{exp} + \Sigma B_{MG}^{exp}}{[MG]_{exp}} = Cl_{met}^M \frac{AUC_M}{[MG]} - V_{MG} \quad \text{or} \quad \frac{\Sigma U_{MG}^{exp} + \Sigma B_{MG}^{exp}}{AUC_M} = -V_{MG} \frac{[MG]_{exp}}{AUC_M} + Cl_{met}^M$$

where the ΣB_{MG}^{exp} data were the cumulative excretions of the conjugate in the bile experimentally determined for the study in the bile-cannulated dog at the same dose. [e] Obtained from appropriate data plots in accordance with $\Sigma U_{MG}^{exp}/AUC_M = V_{MG}[MG]_{exp}/AUC_M + (Cl_{met}^M - Cl_B)$ or $\Sigma U_{MG}^{exp}/[MG]_{exp} = (Cl_{met}^M - Cl_B) AUC_M/[MG]_{exp} - V_{MG}$ on the assumption of a constant immediate biliary clearance, Cl_B, of the formed conjugate. [f] Calculated constant biliary conjugate clearance, immediately after formation, obtained from the difference between $Cl_{met}^M = Cl_{tot}^M - Cl_{ren}^M$ and the $Cl_{met}^M - Cl_B$ value defined in footnote *e*. [g] This parenthetical biliary clearance value is from the best fit of the ΣB_{exp} *versus* t data from the bile-cannulated study from $Cl_B(AUC_M^t - AUC_M^{t_0})$, where $AUC_M^{t_0}$ is the area up to a time, t_0, where biliary clearance is presumed to start at this high dose. [h] Renal conjugate clearance (as morphine base equivalents) from the slope of $\Delta U_{MG}/\Delta t$ *versus* $[MG]$ plots and the best fit of ΣU_{MG} *versus* t data generated from $Cl_{ren}^{MG} (AUC_M^t - AUC_M^{t_0})$, where renal processes start at t_0. [i] $1 - (\Sigma U_{MG}^\infty + \Sigma U_M^\infty)/D_0$. [j] $\Sigma B_{calc}^{tot} = Cl_B AUC_M^\infty$ on the assumption of constant biliary clearance, Cl_B, and no enterohepatic recirculation. [k] Fraction of drug enterohepatically recirculated is calculated from $\Sigma MG_{ent}^\infty = \Sigma B^{tot} - \Sigma B'_\infty$ where $\Sigma B'_\infty = Cl_{met}^M AUC_M^\infty - \Sigma U_{MG}^\infty$. [l] Theoretical fraction excreted elsewhere, most probably in feces, from $\Sigma MG_{feces}^{theo} = \Sigma B'_\infty = Cl_{met}^M AUC_M^\infty - \Sigma U_{MG}^\infty$. [m] Apparent central compartment volume referenced to morphine base concentration in plasma, $V_c^m = [(D_0)/(A' + A + B)]$. [n] Apparent overall distribution volume, referenced to morphine base concentration in plasma, $V_d^m = [(D_0)/(AUC_M^\infty)(\beta)]$. [o] Apparent volume of distribution on assumption of rapid equilibration so that α or α' is extremely fast, *i.e.*, $V_{extrap} = D_0/B$, or for the intermediate doses where an α' existed, $V_{extrap} = (D_0)/(A + B)$. [p] Apparent overall distribution volume for the formed conjugate, MG, as determined from appropriate plots as specified in footnote *e*. The parenthetical estimates of this volume were determined from the appropriate plots as specified in footnote *d*.

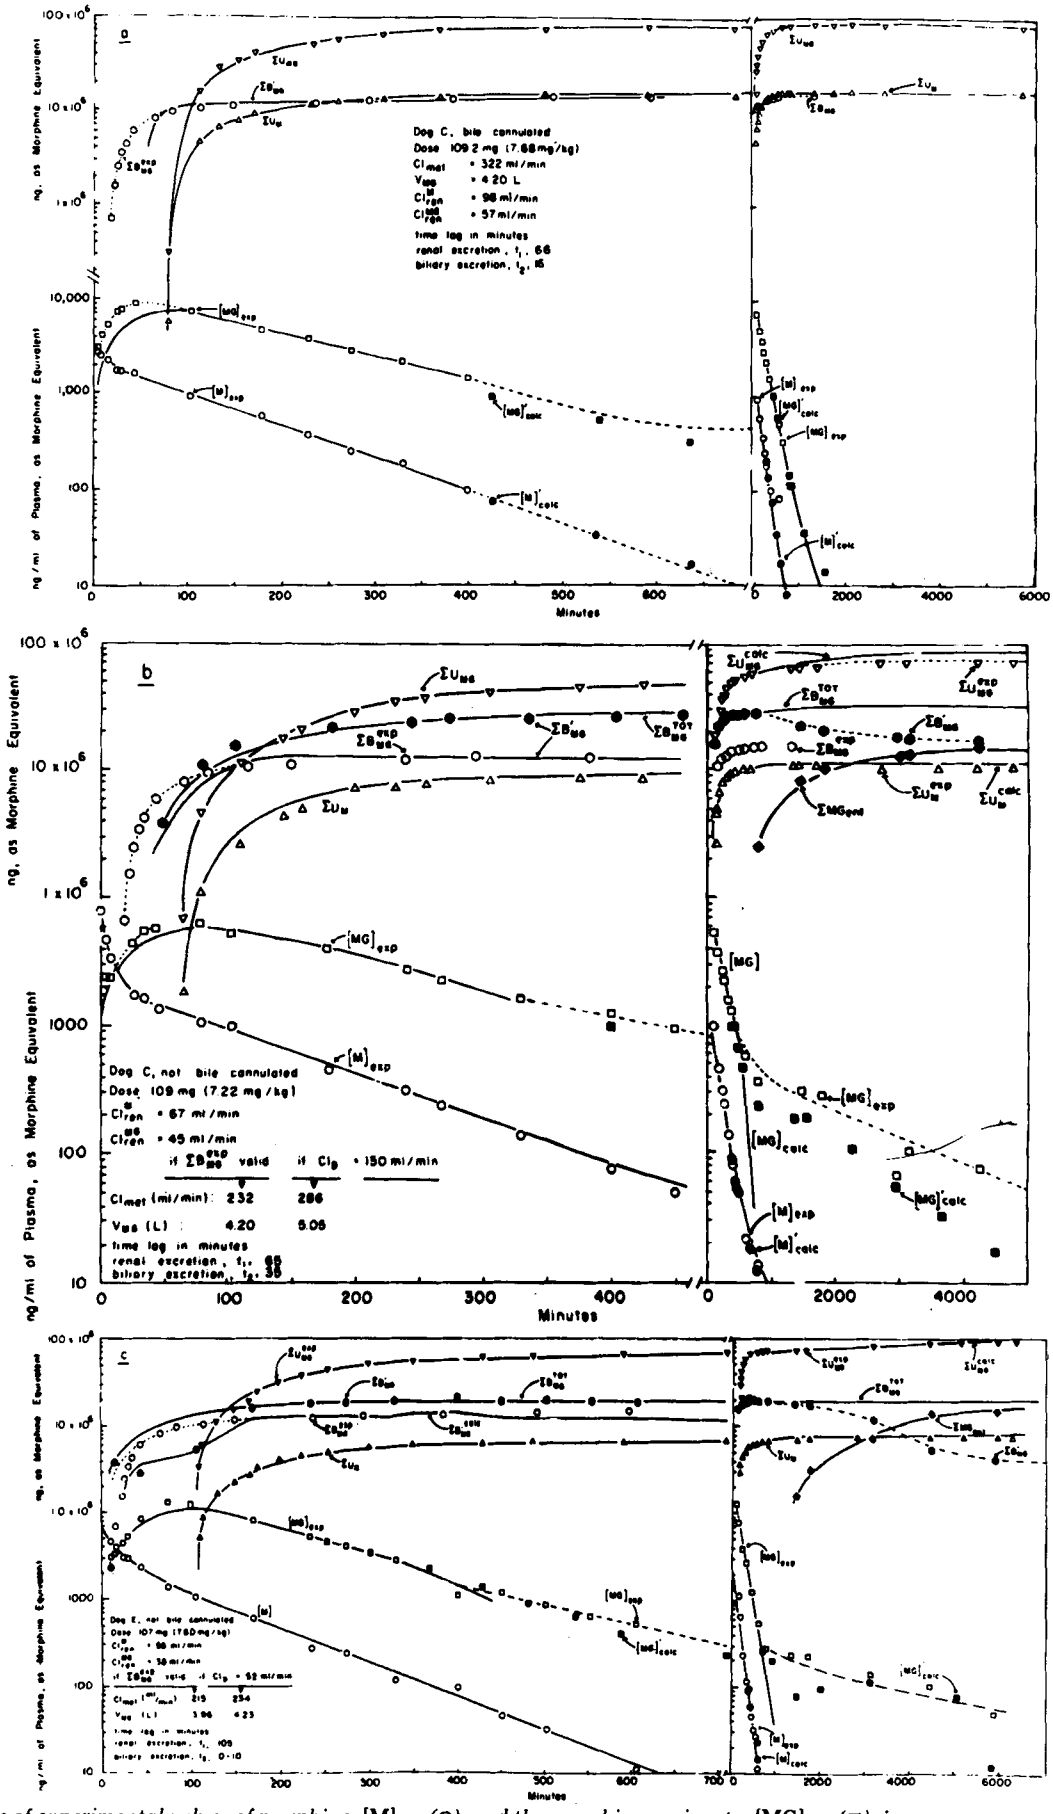

Figure 2—*Plots of experimental values of morphine,* $[M]_{exp}$ (⊙), *and the morphine conjugate,* $[MG]_{exp}$ (⊡), *in nanograms per milliliter of plasma as morphine equivalents against time at high morphine base doses, ~7.5 mg/kg iv. The solid line through the experimental* [M] *values was calculated*

from the polyexponential fit, $[M] = Ae^{-\alpha t} + Be^{-\beta t} + Ce^{-\gamma t}$. *(See Table I for parameters.) The solid line through the experimental* $[MG]_{exp}$ *values was calculated on the assumption of a constant metabolic morphine clearanee,* Cl^{M}_{met}, *so that* $[MG] = (Cl_{met}AUC_M - \Sigma B_{MG} - \Sigma U^{exp}_{MG})/V_{MG}$ *as in Eq. A13. The* Cl_{met} *and* V_{MG} *values for each dog could be obtained from appropriate plots of the data in accordance with Eqs. A11 and A12 (Fig. 7) based on the assumed validity of the* ΣB^{exp}_{MG} *data (○) from the bile-cannulated dog for the normal dog. The* [MG] *values were also calculated for the normal dog from estimates of* $Cl_{met} = Cl_{tot} - Cl^{ren}_{M}$, *where* $Cl_{tot} = dose/AUC_M$, *and* $\Sigma B_{MG} = Cl_B AUC_M$, *where* $Cl_{met} - Cl_B$ *and* V_{MG} *values were estimated from plots in accordance with Eqs. A16 and A17 (Figs. 8 and 9).*

The experimental values of cumulative morphine, ΣU^{exp}_{M} *(△), and its conjugate,* ΣU^{exp}_{MG} *(▽), in urine are also plotted against time. The solid lines through the data points are the theoretical values calculated from* $\Sigma U_M = Cl^{M}_{ren}(AUC_M - AUC^{u}_{M})$ *and* $\Sigma U_{MG} = Cl^{MG}_{ren}(AUC_{MG} - AUC^{u}_{MG})$, *where* AUC^{u}_{M} *and* AUC^{u}_{MG} *are the respective areas under the* [M] *and* [MG] versus *time curves up to the time,* t_1, *of onset of renal excretion. The renal clearances,* Cl^{M}_{ren} *and* Cl^{MG}_{ren}, *were consistent with the values obtained from the slopes of the renal clearance plots of* $\Delta U/\Delta t$ versus *plasma level (Fig. 5).*

The calculated values of $\Sigma B'_{MG} = Cl^{M}_{met} AUC_M - \Sigma U^{exp}_{MG} - V_{MG}[MG]_{exp}$ *of Eq. A22 are represented by the solid line through the experimental values of* ΣB^{exp}_{MG} *(○), which were obtained from studies with the bile-cannulated dog at the same dose (Fig. 2a). The* Cl_{met} *and* V_{MG} *values were obtained from appropriate plots of the data in accordance with Eqs. A11 and A12 (Fig. 7).*

Alternative estimates of cumulative conjugate in the bile, $\Sigma B'_{MG}$ *(●), of the normal (not bile cannulated) dog (Figs. 2b and 2c) were based on the* Cl_{met} *and* V_{MG} *values obtained from appropriate data plots in accordance with Eqs. A16 and A17 (Figs. 8 and 9). The solid line through these data (●) was based on the assumed constant biliary clearance obtained from these plots and was calculated from* $\Sigma B^{tot}_{MG} = Cl_B(AUC_M - AUC^{t_2}_{M})$, *where* $AUC^{t_2}_{M}$ *is the area under the* [M] versus *time curve up to the time,* t_2, *of onset of biliary excretion. The difference between this total amount of conjugate excreted in the bile,* ΣB^{tot}_{MG}, *and the amount presumed to remain there,* $\Sigma B'_{MG}$, *estimates the amount of conjugate enterohepatically recirculated to the systemic circulation,* $\Sigma MG_{ent} = \Sigma B^{tot}_{MG} - \Sigma B'_{MG}$.

Terminal values of $[M]_{exp}$ *(○) and* $[MG]_{exp}$ *(□) tend to have larger errors since the liquid scintillation counts approach background. The respective solid symbols are the plasma level of* $[M]'_{calc}$ *(●) and* $[MG]'_{calc}$ *(■) calculated from the estimated renal clearances and the observed* ΣU^{exp}_{M} *and* ΣU^{exp}_{MG} *values, respectively (Eq. A27).*

macokinetic study. A freshly prepared solution of the material containing 50% plasma was injected into the jugular catheter over 10 sec.

The same sampling schedule as for morphine was used. Urine was collected for 800 min. The dog was kept in the sling support for 8 hr and then placed in the metabolic cage.

Biliary Excretion—Dog C was anesthetized with 30 mg/kg of pentobarbital sodium, a laparotomy was performed, the cystic duct was tied and cut, and the common bile duct was cannulated with tubing[21] (0.2 cm i.d. and 0.3 cm o.d.). The other end was used to cannulate the caudal end of the common bile duct to provide for normal bile flow into the duodenum. The tubing loop resulting from the cannulation was pulled cephalically subcutaneously and brought to the surface through an incision in the skin at the back of the neck. This loop was cut, and a connecting piece of tubing was inserted which, when removed, allowed for continuous bile sampling.

The animal was allowed to recover from the surgical procedure and was administered a 7.7-mg/kg dose. After 3 weeks, this bile-cannulated animal was given a 0.41-mg/kg dose. Blood and urine were collected as in other experiments. Bile was collected under heptane at 4.7, 7.8, 10, 13, 16, 20, 25, 31, 43, 57, 86, 176, 290, 382, 520, 600, 730, and 800 min. The volume was measured, and the bile was stored at 0° until analyzed by liquid scintillation counting in the manner described previously.

Infusion Study—The procedure for this study was the same as for the other pharmacokinetic studies with the following changes. The infusion line was connected to the jugular vein catheter, using a 19-gauge needle introduced through the flash ball injection site of the Plexitron administration set[22] for the chloride drip. This apparatus was attached to the catheter by a 14-gauge needle[23] and a three-way stopcock. The drug (3750 μg of ^{14}C-morphine) was prepared in 286.6 ml of sterile 75% isotonic saline plasma solution. The infusion rate (10 μg/min) was attained using an infusion pump[24].

Blood (5 ml) was sampled at 30, 60, 90, 180, 280, 300, 310, 320, and 340 min during the infusion. Postinfusion samples were collected at 3 and 9 min, then at 30-min intervals up to 150-min postinfusion, and then at 90-min intervals up to 1200-min postinfusion. Urine was collected every 20 min during the infusion. Following the infusion, urine was collected every 40 min for the 1st hr, then at 2-hr intervals up to 700-min postinfusion, and subsequently every 8 hr up to 4000-min postinfusion.

RESULTS AND DISCUSSION

Protein Binding—The results of these studies in dog plasma are given in Table II. There was no significant concentration or pH effect on the 36 ± 1% (*SEM*) morphine binding to plasma protein. No significant differences were observed among the samples centrifuged at different times after the spiking of dog plasma, so equilibration at least within 3 min, the earliest time studied, must be concluded. No significant protein binding (<2%) in dog plasma of morphine-3-monoglucuronide (100 ng/ml) was observed at pH 7.1 and 7.4.

The protein binding of 32.8% at 2.5 μg/ml (Table I) is consistent with the estimates of 30% (26) for dog plasma studied in the ranges of 2.5–15 μg of morphine/ml and is not too different from the 35.7 ± 0.9% given for normal human plasma (27).

Red Blood Cell–Plasma Water Partition Coefficient—This coefficient, *D*, the ratio of the drug concentration in the red blood cells, $[A_{RBC}]$, to that in the plasma water, $[A^u_p]$, can be calculated (28) from the experimentally determined concentration, $[A_p]$, of drug in the plasma when the concentration in whole blood, $[A_B]$, the fraction bound to plasma protein, *f*, and the hematocrit, *H*, are known:

$$D = \frac{[A_{RBC}]}{[A^u_p]} = \left\{\frac{[A_B]}{[A_p](1-f)(1-H)} - \frac{f}{(1-f)} - 1\right\}\frac{1-H}{H} \quad \text{(Eq. 3)}$$

There was no apparent time or concentration dependence for the red blood cell–plasma water partition coefficient of morphine (1.11 ± 0.04 *SD*) or its glucuronide metabolite (0.66 ± 0.05) (Table III).

The following cited equations, labeled with the prefix A, are derived and given in *Appendix I.* The symbols used are defined in *Appendix II.* The experimental disposition of various morphine doses, the clearances, and the best fit pharmacokinetic parameters are given in Table I, and the fitting is demonstrated in Figs. 2–4.

Morphine Pharmacokinetics at High Doses—Plasma morphine levels, [*M*], with time in the bile-cannulated dog, C, where the bile was completely collected, were best fitted by the two-compartment body model (Fig. 2a and Table I). There was no significant terminal plateau in $[MG]_{exp}$ or $[MG]'_{calc}$ values that could be assigned to the return of the conjugate or its precursor, *M*, from a deep compartment. Significant urine flow was not observed until after 53 min of drug administration at this 7.7-mg/kg dose when 1.5 ml was obtained.

Significant morphine, ΣU_M, and conjugate, ΣU_{MG}, in the urine were first observed in the interval of 53–80 min. The calculated amounts (Eqs. A6 and A8) of ΣU_M and ΣU_{MG} renally excreted (solid lines in Fig. 2a) were consistent only with the experimental data, the obtained renal clearances (Fig. 5) and areas, AUC_M, under the morphine and conjugate

Table III—Dog Red Blood Cell–Plasma Water Partition Coefficients (*D*)[a] of Morphine and Its Glucuronide Metabolite

Time of Measurement	Morphine, ng/ml				Morphine-3-monoglucuronide, ng/ml	
	1	10	100	1000	50	500
30 sec	1.03	1.13	1.13	1.14	0.71	0.63
30 min	1.10	1.10	1.12	1.11	0.60	0.70
Average ± *SD*	1.11 ± 0.35				0.66 ± 0.53	

[a] The values used in Eq. 3 for these calculations were $H = 0.35$ and $f = 0.32$ for morphine and $f = 0$ for the glucuronide.

The respective solid symbols are the plasma levels of* $[M]'_{calc}$ (●) *and* $[MG]'_{calc}$ (■) *calculated from the estimated renal clearances and the observed* ΣU^{exp}_M *and* ΣU^{exp}_{MG} *values, respectively (Eq. A27).*

plasma level–time curves when renal processes were not considered operative until a time, t_0, of 65 min after drug administration.

The only major discrepancy in the fitting of the data for the bile-cannulated dog in Fig. 2*a* was that the calculated $\Sigma B'^{calc}_{MG}$ (Eq. A14) and $[MG]_{calc}$ (Eq. A13) values based on the 4200-ml value of V_{MG} underestimated the experimental values of ΣB^{exp}_{MG} and $[MG]_{exp}$, respectively, for the first 45 min, even when ΣU_{MG} was taken as zero for this time. The assumption of an average V_{MG} of 2500 ml for this interval improved the fit (dashed lines before 45 min in Fig. 2*a*) with the experimental data. This finding strongly indicates that the apparent conjugate distribution volume may have increased during this interval, which is not consistent with the assumption of a one-compartment body model for $[MG]$ immediately after its production. A period of time may be necessary for the conjugate to equilibrate in its apparent overall distribution volume.

Biliary conjugate secretion also was inhibited at the high morphine doses. The use of a time lag of 16 min and the determined variable biliary clearance, Cl_B (Fig. 6), which depended on the bile flow, gave the fit to the ΣB^{exp}_{MG} data demonstrated by the dashed line before 45 min in accordance with $\Sigma B^{calc}_{MG} = \Sigma Cl_B(AUC'_M - AUC'^{t_0=16\,min}_M)$ as described in Eq. A3.

The fact that no radioactivity was observed in the collected feces of this bile-collected dog shows that the fecal source of drug must be assigned to the biliary excretion.

Studies (Fig. 2*b*) of both the same Dog C at a similar dose, 7.2 mg/kg, and Dog E at 7.6 mg/kg (Fig. 2*c*) without biliary cannulation showed similar pharmacokinetic patterns, except for terminal elevations of plasma metabolite levels and pronounced drug and metabolite in the feces (Table I). Direct plasma conjugate measurements were consistent, $[MG]_{exp}$, with $[MG]'_{calc}$ values calculated by Eq. A27 from the presumed renal clearance, Cl'_{ren}, of the conjugate and the cumulative amount, ΣU^{exp}_{MG}, excreted in the urine.

This elevation in plasma and concomitant urine conjugate in the non-bile-cannulated dog can be assigned to material returned to the system by enterohepatic recirculation of the bile contents.

The cumulative amounts of enterohepatically recirculated drug in normal Dogs C and E, ΣMG_{ent}, are plotted in Figs. 2*b* and 2*c* as based on Eqs. A21–A23. The premise for the calculation is that the intravenously administered morphine was almost completely cleared by 100 min, as indicated by the data for bile-cannulated Dog C (Fig. 2*a*).

The data for the normal dogs in Figs. 2*b* and 2*c* were fitted in two manners. In one, the same biliary excretion, ΣB^{exp}_{MG}, was postulated as when the dog was biliary cannulated and the total bile was collected (Fig. 2*a*). The estimated V_{MG} and Cl_{met} values for the normal dogs at this dose (Eqs. A11 and A12) were 4.2 liters and 232 ml/min, respectively, for Dog C and 3.96 liters and 215 ml/min, respectively, for Dog E (Fig. 7). The solid lines ($\Sigma B'_{MG}$) in Figs. 2*b* and 2*c* through the ΣB^{exp}_{MG} data obtained from the bile-cannulated Dog C at the same dose were calculated from Eq. A22 with these parameters and fit well except at the early times. The solid lines for $[MG]_{calc}$ through the $[MG]_{exp}$ data were calculated from Eq. A13 with these parameters and were reasonable for all times up to when enterohepatic return from the bile was postulated, as indicated by the plotting of terminal dashed lines. A better fit of the initial $[MG]_{exp}$ data up to 45 min in Fig. 2*b* is given by the dashed lines when it was postulated that no drug was eliminated in the bile until ~50 min.

The alternative manner of fitting was to postulate a constant biliary clearance which only commenced a specified time after drug administration. This premise does not demand a specific knowledge of the amount of conjugate in the bile (Eqs. A16 and A17). The obtained respective values of V_{MG} and Cl_{met} were 5.05 liters and 292 ml/min for Dog C (Figs. 8 and 9) and 4.23 liters and 234 ml/min for Dog E. The calculated $\Sigma B'^{calc}_{MG}$ values (Eq. A22) based on these parameters are given in Figs. 2*b* and 2*c*. The solid lines through these data (ΣB^{tot}_{MG}) assumed a constant biliary clearance, Cl_B (Eq. A3), and no enterohepatic conjugate recirculation in the bile. Obviously, when these values diverged from the $\Sigma B'^{calc}_{MG}$ values, the difference could be attributed to those amounts returned from the bile to the systemic circulation, *i.e.*, ΣMG_{ent}.

Morphine Pharmacokinetics at Intermediate Doses—The plasma morphine levels, $[M]$, with time in the bile-cannulated Dog C at the 0.406-mg/kg dose were consistent with those observed with the high dose and were best fitted by the two-compartment body model (Fig. 3*d* and Table I). Again, no significant drug appeared in the feces, and there was no significant terminal plateau in $[MG]_{exp}$ or $[MG]'_{calc}$ values that could be assigned to the return of the conjugate or its precursor, M, from a deep compartment in the bile-cannulated dog. The non-bile-cannulated dog at the same dose (Fig. 3*e*) showed terminal plasma metabolite elevations and pronounced drug and metabolite in the feces (Table I).

Although the urine flow was negligible up to 75 min after morphine administration in both the bile-cannulated and normal dogs at this dose, the calculated amounts (Eqs. A6 and A8) of ΣU_M and ΣU_{MG} renally excreted after that time were consistent with the experimental data, the obtained renal clearances (Fig. 5) and the *total* areas (*i.e.*, uncorrected for a time lag in commencement of renal processes) under the morphine and conjugate plasma level–time curves. Thus, in contrast with the higher dose, complete renal shutdown by the drug does not have to be postulated. The delay in renal morphine and conjugate excretion can be attributed solely to the lack of urine flow necessary to eliminate the morphine and metabolite trapped in the tubules.

The solid line, $\Sigma B'^{calc}_{MG}$, in Fig. 3*d* through the experimentally obtained cumulative conjugate excreted in the bile, ΣB^{exp}_{MG} (dashed line), obtained from the bile-cannulated dog was calculated from Eq. A22 where the pertinent Cl_{met} and V_{MG} values were obtained by application of Eqs. A11 and A12 (Figs. 8 and 9). The solid line, ΣB^{tot}_{MG}, in Fig. 3*e* through the calculated (Eq. A22) cumulative conjugate in the biliary system of the noncannulated dog, $\Sigma B'^{calc}_{MG}$, was estimated on the premises of a constant biliary clearance, Cl_B, of immediately formed metabolite and nonenterohepatic return to the system. The pertinent Cl_{met}, Cl_B, and V_{MG} values were obtained by application of Eqs. A16–A20; the values of the pharmacokinetic parameters are given in Table I. The difference between ΣB^{tot}_{MG} and $\Sigma B'^{calc}_{MG}$ (Eq. A23) estimates the cumulative amounts of drug returned to the systemic circulation, ΣMG_{ent}.

Morphine Pharmacokinetics at Low Doses—The pharmacokinetics at these doses in normal animals (Figs. 4*f*–4*h*) were similar to those for the normal animal at the intermediate dose, except that urine flow was not highly inhibited and no tubular entrapment of morphine and/or its metabolite had to be postulated. There was only one minor anomaly in the fitting of these data. Although the calculated (Eq. A8) and experimentally determined amounts of conjugate in the urine, ΣU_{MG}, were reasonably consistent until 500–700 min, less was excreted than anticipated with the presumption of the constant renal clearance, which conformed to the greatest extent of the clearance plots (Fig. 5). This finding could indicate a lessened renal clearance of ΣU_{MG} when the values of $[MG]$ were less than 1.0–2.0 ng/ml of plasma. Alternatively, this result could be an artifact of studies at high morphine specific activities. The terminal values of unextracted radioactivity considered as $[MG]_{exp}$ after ~600 min could contain a higher quantity of radiolabeled impurities or other long-lived undefinable, unextractable morphine metabolites in plasma and could give an anomalous terminal radioactivity elevation that would overestimate the urine metabolite accumulation for a presumed constant clearance.

Renal Clearances and Eliminations of Morphine and Its Metabolite—The morphine and metabolite clearances showed remarkable constancies as long as the renal function was operative and there was adequate urine flow (Fig. 5). There were no significant dose effects on these clearances (Table I), which averaged to significantly different values

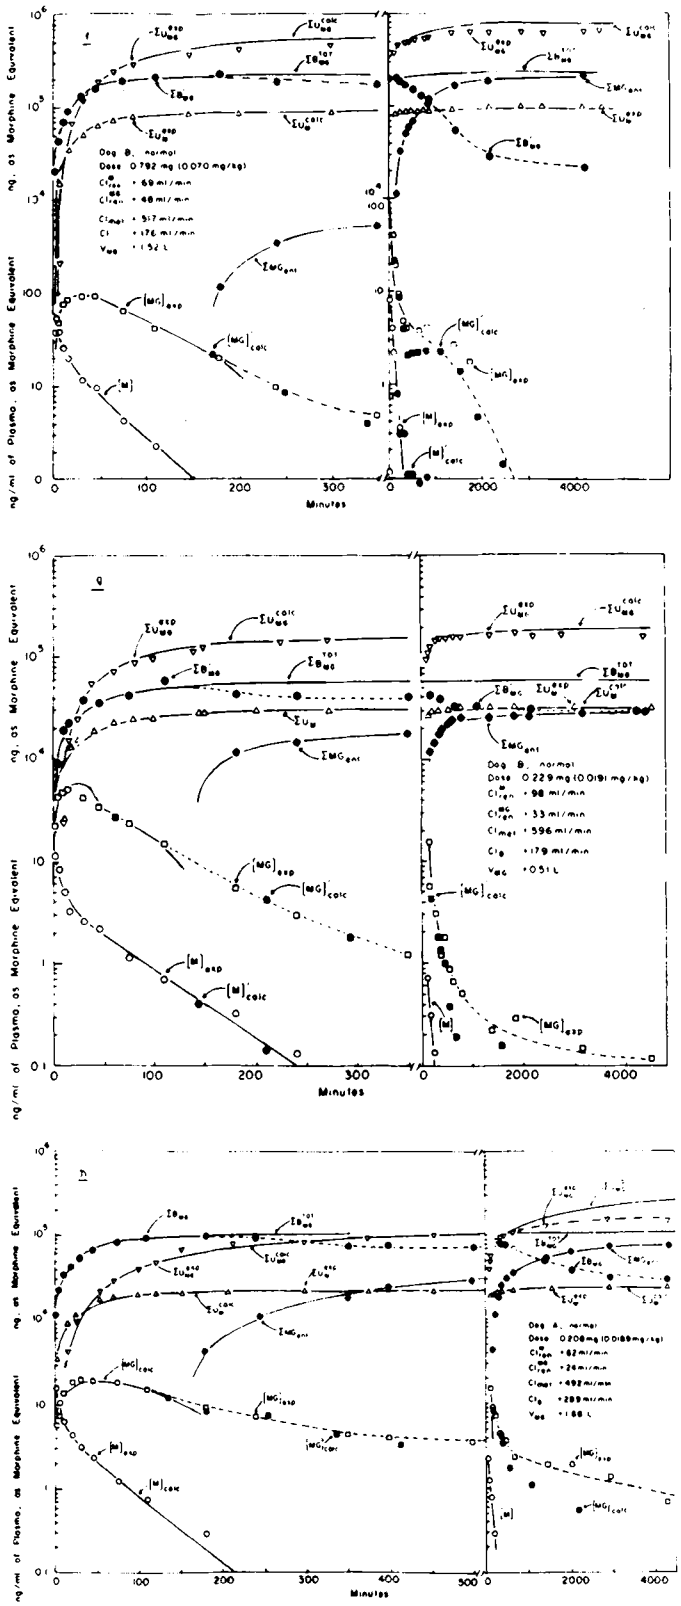

Figure 4—*Plots of experimental values of morphine, $[M]_{exp}$ (⊙), and the morphine conjugate, $[MG]_{exp}$ (⊡), in nanograms per milliliter of plasma as morphine equivalents against time at low morphine base doses, 0.07 and ~0.019 mg/kg iv. The solid line through the experimental [M] values was calculated from the polyexponential fit, $[M] = Ae^{-\alpha t} + Be^{-\beta t}$. (See Table I for parameters.) The solid line through the experimental $[MG]_{exp}$ values was calculated on the assumption of a constant metabolic morphine clearance, Cl^{M}_{met}, so that $[MG] = (Cl_{met}AUC_M - \Sigma B_{MG} - \Sigma U^{exp}_{MG})/V_{MG}$. The [MG] values were calculated for the normal dog from estimates of $Cl_{met} = Cl_{tot} - Cl^{ren}_{M}$, where $Cl_{tot} = dose/AUC_M$, and $\Sigma B_{MG} = Cl_B AUC_M$, where $Cl_{met} - Cl_B$ and V_{MG} values were estimated from plots in accordance with Eqs. A16 and A17 (Figs. 8 and 9).*

The experimental values of cumulative morphine, ΣU^{exp}_{M} (△), and its conjugate, ΣU^{exp}_{MG} (▽), in urine are also plotted against time. The solid lines through the data points are the theoretical values calculated from $\Sigma U_M = Cl^{M}_{ren}AUC_M$ and $\Sigma U_{MG} = Cl^{MG}_{ren}AUC_{MG}$. The renal clearances, Cl^{M}_{ren} and Cl^{MG}_{ren}, were consistent with the values obtained from the slopes of the renal clearance plots of $\Delta U/\Delta t$ versus plasma level (Fig. 5).

Estimates of cumulative conjugate in the bile, $\Sigma B'_{MG} = Cl^{M}_{met}AUC_M - \Sigma U^{exp}_{MG} - V_{MG}[MG]_{exp}$, were based on the Cl_{met} and V_{MG} values obtained from appropriate data plots in accordance with Eqs. A16 and A17 (Figs. 8 and 9). The solid line through these data (●) was based on the assumed biliary clearance obtained from these plots and was calculated from $\Sigma B^{tot}_{MG} = Cl_B AUC_M$. The difference between this total amount of conjugate excreted in the bile, ΣB^{tot}_{MG}, and the amount presumed to remain there, $\Sigma B'_{MG}$, estimates the amount of conjugate enterohepatically recirculated to the systemic circulation (◆), $\Sigma MG_{ent} = \Sigma B^{tot}_{MG} - \Sigma B'_{MG}$.

Terminal values of $[M]_{exp}$ (○) and $[MG]_{exp}$ (□) tend to have larger errors since the liquid scintillation counts approach background. The respective solid symbols are the plasma levels of $[M]_{calc}$ (●) and $[MG]_{calc}$ (■) calculated from the estimated renal clearances and the observed ΣU^{exp}_{M} and ΣU^{exp}_{MG} values, respectively (Eq. A27).

for Cl^{M}_{ren} of 85 ± 9 and 41 ± 4 (*SEM*) ml/min, respectively, in contrast to the respective values of 66 and 80 ml/min cited previously for the dog (3). The morphine clearance with respect to drug unbound to plasma proteins (67%) was 127 ± 13 (*SEM*) ml/min; the morphine glucuronide showed negligible protein binding.

These differences in renal clearances imply different processes for the drug and its conjugate. Since the calculated renal clearance for inulin (glomerular filtration) for a 12-kg dog is 51 ± 12 ml/min (29), the glucuronide probably was eliminated solely by glomerular filtration and the intravenously administered morphine probably was eliminated by both filtration and tubular secretion.

No pronounced differences in fractions of the intravenous dose excreted in the urine were observed among doses (Table I): 12 ± 3 (*SD*) % as unchanged morphine and 71 ± 10 (*SD*) % as morphine conjugate.

In the three noncannulated dogs (C, 109 mg; E, 107 mg; and D, 0.471 mg) where feces were collected, 9, 5, and 14% of the total radioactivity were found in the feces, respectively, with 47, 43, and 5% of the excreted amounts extractable as morphine, respectively. These values contrast with those previously reported (9), where negligible conjugate was observed in the feces of dogs. Unfortunately, the possibility of fecal conjugate hydrolysis or fecal morphine degradation does not provide incontrovertible proof of high degrees of GI hydrolysis of biliary secreted conjugate, the major drug form in bile. Less than 0.5% of the total drug excreted into bile was as free morphine in the two studies with the bile-cannulated dog.

The fraction of the administered radioactivity that appeared in the saliva drippings collected from Dog D at the 5.7-mg dose was an extremely low 0.087%.

"Deep" Compartment for Morphine—The plasma morphine levels with time generally could be fit to a sum of two exponentials. However, the data in the normal dog showed a terminal positive deviation in $[M]_{exp}$ from this fitting in some instances (Figs. 2*b*, 4*g*, and 4*h*), indicating the presence of a slower elimination process. The radioactive counts of extracted morphine were too close to background levels to make a definite conclusion. Conclusive demonstration of such a slower elimination process was clearly manifested in urinary morphine elimination, ΣU^{exp}_{M}. The semilogarithmic plots of amounts yet to be excreted against time (Figs. 10 and 11) showed a terminal phase, γ (Table I), whose half-lives averaged 994 ± 16 (*SEM*) min for all studies in the normal dog, with no apparent dose dependency. The fact that no such terminal phase was observable with the urinary data (Fig. 10) from the cannulated dog where total bile was collected is strong evidence that this slow morphine elimination is due to the recycling of amounts secreted into the bile. Since negligible free morphine is bile secreted, the conjugate must be gastrointestinally hydrolyzed, either in the lumen or gut wall, before reabsorption into the systemic circulation.

When 3.7 mg of morphine was infused at a constant rate of 10.7 μg/min into a dog, reasonable steady-state values of plasma morphine were achieved by 60 min and maintained during the 350 min of infusion at an average of 57 ± 4 (*SEM*) ng/ml. At cessation of infusion, there was a

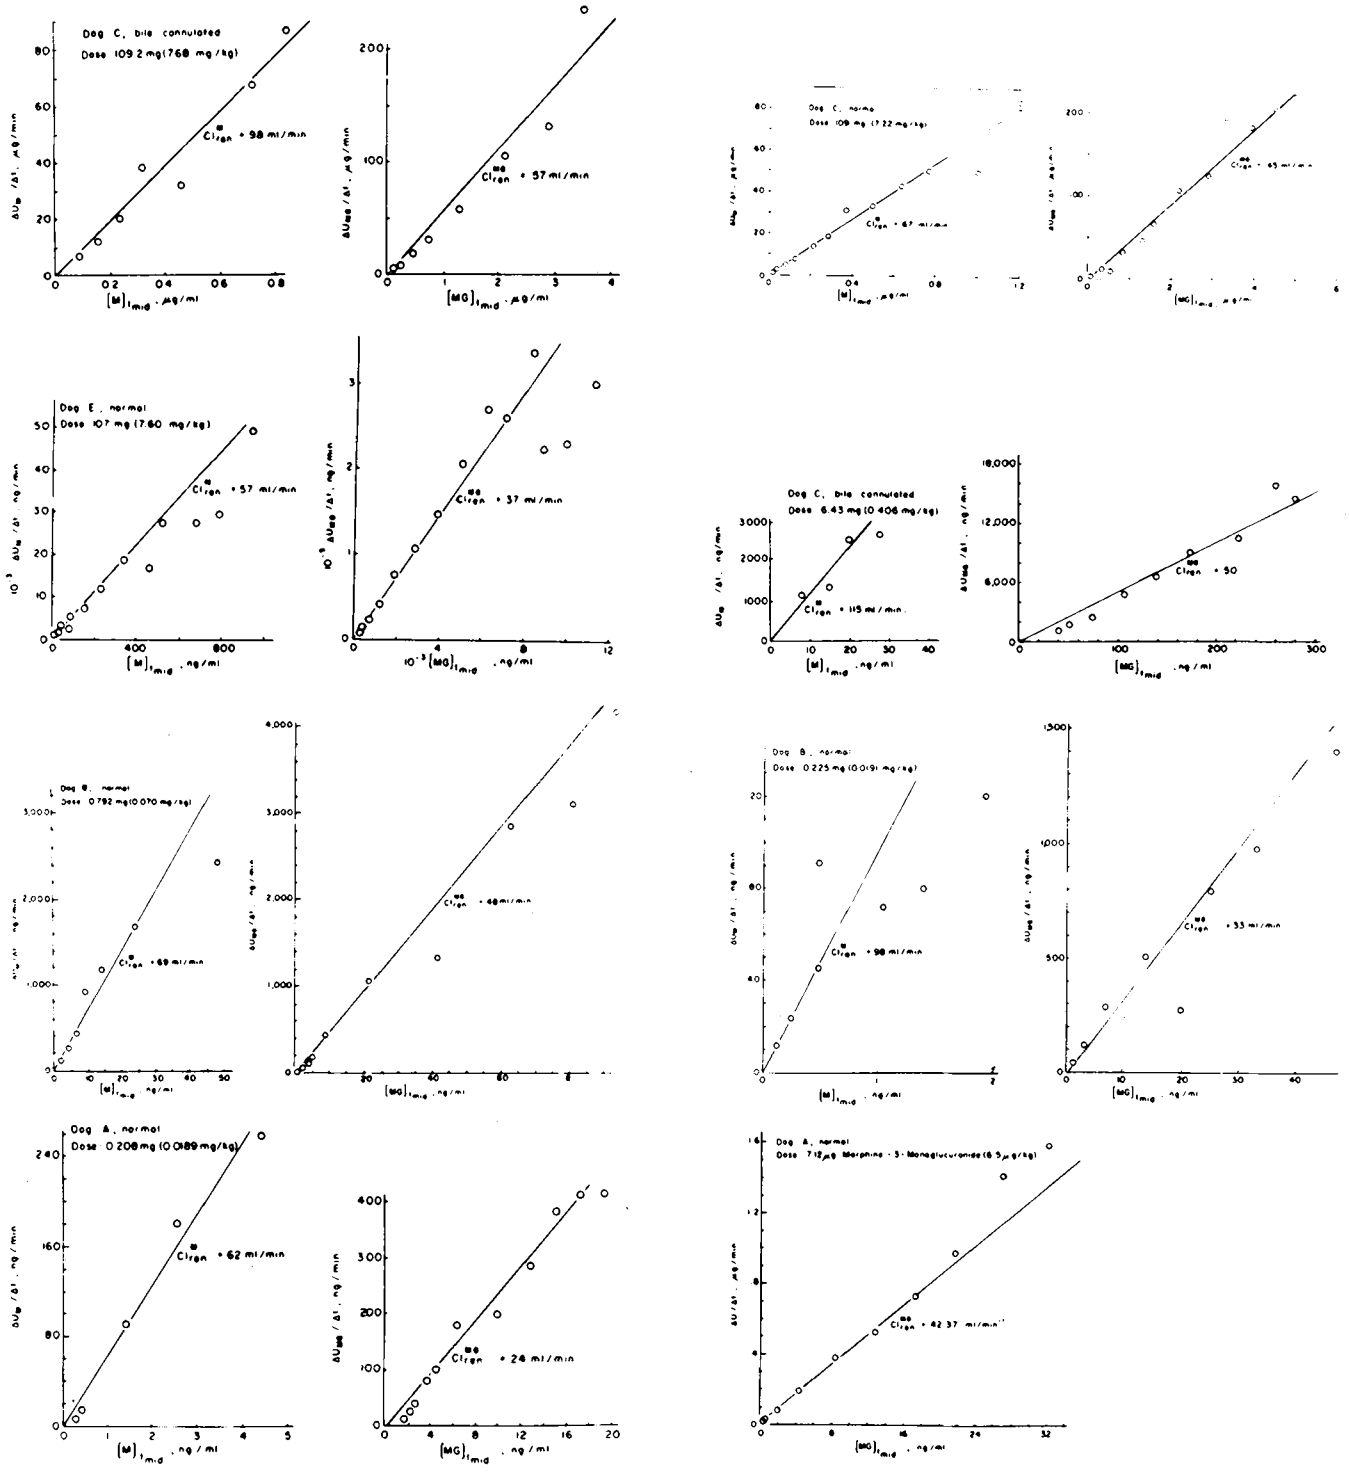

Figure 5—*Renal clearance plots for morphine,* M *(left), and its conjugate,* MG *(right), when morphine was administered. Rates of drug amounts excreted* versus *plasma levels were obtained at the midtimes of the urine-collection intervals. The lower right clearance plot is for morphine-3-glucuronide administration.*

precipitous drop until plasma levels of both morphine [0.45 ± 0.03 (*SEM*) ng/ml of plasma, $n = 7$] and glucuronide [34.1 ± 0.9 (*SEM*) ng/ml of plasma] remained invariant over the studied period from 250 to 850 min after the cessation of the infusion. The plasma morphine levels monitored by liquid scintillation counting were four times the background radiation level. This evidence is considered valid for the slow enterohepatic return of both morphine and its conjugate from bile to show an apparent deep compartment in the dog. The total percent of the dose excreted in the urine was 85.8%, 68.5% as the conjugate and 17.3% as unchanged morphine.

The terminal elevation in plasma and urine morphine glucuronide levels in normal dogs (Figs. 2–4) was in decided contrast to the studies in the bile-cannulated dog and is proper evidence for enterohepatic recirculation. The lack of morphine and the conjugate in the feces of the cannulated dog, but not in the normal, confirms this hypothesis and agrees with the observations of Woods (8). The conjugate, even when significantly hydrolyzed in the lumen or gut wall, must be largely reconjugated in the liver prior to its return to the systemic circulation for this hypothesis to be true. The return of small amounts of morphine could be responsible for the frequent observation of a slow terminal morphine loss in the plasma. It is estimated (Table I) that 27 ± 0.05 (*SEM*) % of the dose is enterohepatically recirculated at doses less than 0.5 mg/kg. It is possible that the 15% observed in the two studies at 7–8 mg/kg may signify a dose dependency.

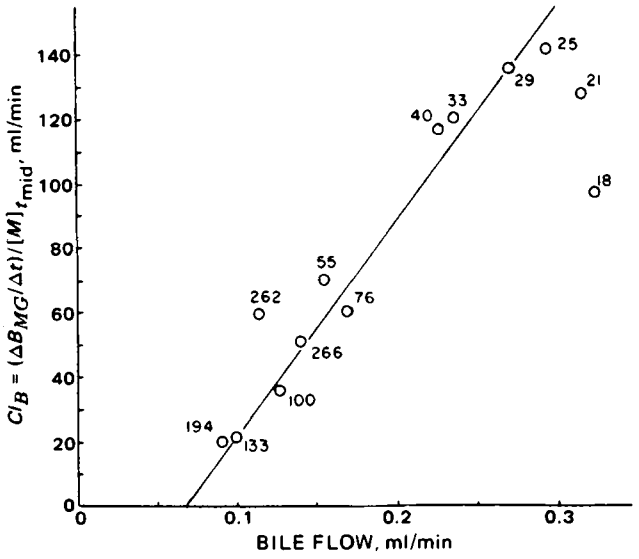

Figure 6—*Demonstration of the linear dependence of the apparent biliary clearance,* Cl_B, *of immediately formed metabolite,* MG, *on the rate of bile flow for the bile-cannulated Dog C at the 109.2-mg dose (7.68 mg/kg):* Cl_B *(ml/min) = 671 × bile flow (ml/min) − 45.6. The values are labeled with the measured times in minutes.*

Dose Effects in Morphine Pharmacokinetics—The anticipated "feedback" effects of morphine's pharmacology (20, 21) on its pharmacokinetics in the dog were observed. The 7.2–7.7-mg/kg doses of morphine caused an instantaneous cessation of renal processes (Figs. 2*a*–2*c*) that did not resume until 60–105 min after intravenous administration when the plasma morphine level reached 1000 ng/ml. At these doses, the dogs were completely unconscious for at least 3 hr after administration and lay supine upon the table.

The same doses inhibited biliary secretion for 10–35 min after intravenous administration and demonstrated uneven bile flows and concomitant uneven biliary clearances thereafter (Fig. 6), which readily confirmed the statements (20) that the drug causes biliary tract spasms and constrictions that can impede biliary excretion. The estimated average biliary clearances, Cl_B (Eqs. A16–A20), of formed metabolite were 52 and 87 ml/min at these high doses in the normal dog and 213 ± 36 (*SEM*) ml/min (range of 176–285) at the lowest doses of 0.019–0.07 mg/kg.

Morphine at the intermediate doses of 0.4–0.5 mg/kg (Figs. 3*d* and 3*e*) did not shut down the renal processes but did have a pronounced effect on urine flow. The time courses of the drug and its metabolite could best be fit on the premise of maintained viable renal processes with delayed elimination into the urine. The time courses at the lowest doses studied could be fit (Figs. 4*f* and 4*g*) without the postulations of such drug-induced discontinuities in pharmacokinetic processes.

Total morphine clearance is clearly dose related (Table I). At the highest doses of 7.2–7.7 mg/kg, Cl_{tot} averaged 340 ± 43 (*SD*) for the range of 290–370 ml/min in contrast to the average of 701 ± 138 (*SD*) for the range of 554–886 ml/min at doses below 0.5 mg/kg. Since renal clearances are relatively invariant with dose, this finding implies that the hepatic metabolism of morphine is dose dependent. The estimated average ± *SD* (*SEM*) (range) values for Cl_{met} were 261 ± 41 (17) (215–322) ml/min at the high dose and 609 ± 114 (51) (492–771) at the other doses. The fraction of formed metabolite partitioned into the bile, Cl_B/Cl_{met}, cannot be concluded to be dose dependent, however. About 25% was partitioned into the bile in two high-dose and two low-dose cases.

The hepatic blood flow in the 14-kg dog is in the range of 420–630 ml/min (30) and is the same as the range of metabolic clearances at the low doses. This finding could imply that the high dose of 7 mg/kg decreases blood flow to the liver and/or that the metabolizing enzymes are saturable. However, the fact that negligible plasma morphine levels occur in the dog orally administered 30 mg/kg (9) is indicative of the complete metabolism of orally administered drug by its first pass in the liver even at these enormous doses.

The dose dependencies of total and metabolic clearances are clearly reflected in the apparent rate constants and half-lives for the elimination of the major morphine fraction in the β-phase of the two-compartment body model (Table I). Excellent agreement was obtained with the urinary data for this phase when semilogarithmic plots of amounts yet to be excreted (after correction for the slow terminal phase) and rates of urinary elimination were made against time (Figs. 10 and 11). The half-lives for the high dose (7–8 mg/kg) were 83 ± 6 (*SD*) min from plasma and 82 ± 8 (*SD*) min from urine. They were 39 ± 6 (*SD*) min from plasma and 37 ± 13 (*SD*) min from urine for the lowest doses.

There were no significant differences among the apparent morphine distribution volumes. The estimated central compartment volume is 15.3 ± 2.8 (*SEM*) liters, and the overall volume is 44 ± 6 (*SEM*) liters.

Pharmacokinetics of Morphine-3-monoglucuronide and Its Significance in Morphine Pharmacokinetics—The intravenous administration of ^{14}C-morphine-3-monoglucuronide to the 11-kg Dog A (71.2 μg, 6.5 μg/kg, specific activity of 273 dpm/ng) clearly demonstrated a two-compartment body model (Fig. 12), where the plasma level could be defined for time, *t*, in minutes as:

$$[MG],\ \text{ng/ml} = 33.3e^{-0.245t} + 26.4e^{-1.46\times10^{-2}t} \qquad \text{(Eq. 4)}$$

and the respective half-lives of the α- and β-phases were 2.8 and 47.6 min, respectively. The semilogarithmic plots of amounts yet to be excreted and amounts per unit of time against time showed respective rate constants of 56 and 51 min, in agreement with the terminal phase. The recovery of the total radioactivity in the urine was complete; the actual calculation was 116%. No free morphine was extractable either from the plasma or urine. The total clearance from the ratio of dose and the area under the curve was 37.1 ml/min, and the renal clearance from the classical plot (Fig. 5) was consistent at 42 ml/min. The conclusion is that renal excretion is the sole route of systemic glucuronide elimination. The apparent overall glucuronide distribution volume from the ratio of the total clearance and the terminal rate constant was 2541 ml, whereas the value from the quotient of the dose and the intercept of the extrapolated β-phase was 2696 ml.

The fact that there was not the prolonged terminal phase in the plasma or urine for the administered glucuronide that appeared when morphine was injected (Figs. 2–4) demonstrates that its appearance is a consequence of a process unique to morphine metabolism. The hepatically conjugated morphine is partitioned into bile in the liver, whereas the systemic conjugate is not. This hepatically formed conjugate is gut hydrolyzed to be slowly reabsorbed as morphine, whereas the systemic conjugate is not. The time lag in the enterohepatic recirculation with concomitant gallbladder storage (3) postpones the return of biliary secreted drug and metabolite to maintain persistent levels in plasma and urine.

The calculated 2500 ml of apparent overall distribution volume in intravenous glucuronide administration, V_{MG}, is consistent with the volumes calculated for morphine doses below 0.5 mg/kg from Eqs. A11, A12, A16, and A17 and validate the premises upon which they were based. The significantly greater calculated volumes of 4200–5050 ml for glucuronide at 7.2–7.7 mg of morphine/kg must be related to the demonstrated extreme pharmacological effects at this dose.

APPENDIX I: METHODS AND PROCEDURES FOR PHARMACOKINETIC ANALYSES

Renal Clearances and Time Durations of Drug Inhibitions of Such Processes—When the drug concentration time course in the plasma, such as morphine [*M*], can be monitored, the cumulative drug excreted unchanged into the urine (ΣU_M) and bile (ΣB_M) and metabolized into a metabolite such as morphine glucuronide (ΣMG) at a time *t* can be estimated from the respective clearances Cl^M_{ren}, Cl^M_B, and Cl^M_{met}, provided that these clearances are not plasma level dependent. Thus, the cumulative amounts excreted at time *t* would be:

$$\Sigma U_M = Cl^M_{ren}\int_{t_0}^{t}[M]dt = Cl^M_{ren}\,AUC^{t-t_0}_M \qquad \text{(Eq. A1)}$$

$$\Sigma MG = Cl^M_{met}\int_{t_0}^{t}[M]dt = Cl^M_{met}\,AUC^{t-t_0}_M \qquad \text{(Eq. A2)}$$

$$\Sigma B_M = Cl^M_B\int_{t_0}^{t}[M]dt = Cl^M_B AUC^{t-t_0}_M \qquad \text{(Eq. A3)}$$

where AUC_M is the needed area under the morphine plasma level–time curve from t_0 to *t*, where t_0 is the time of onset of the specific clearance process. These equations are a consequence of first-order differential equations such as:

$$d(MG)/dt = k_{M,MG}V[M] = Cl_{met}[M] \qquad \text{(Eq. A4)}$$

which, on integration, gives:

$$\Sigma MG = \int_0^{MG} d(MG) = Cl^M_{met}\int_{t_0}^{t}[M]dt$$

$$= Cl^M_{met}\,AUC^{t-t_0}_M \qquad \text{(Eq. A5)}$$

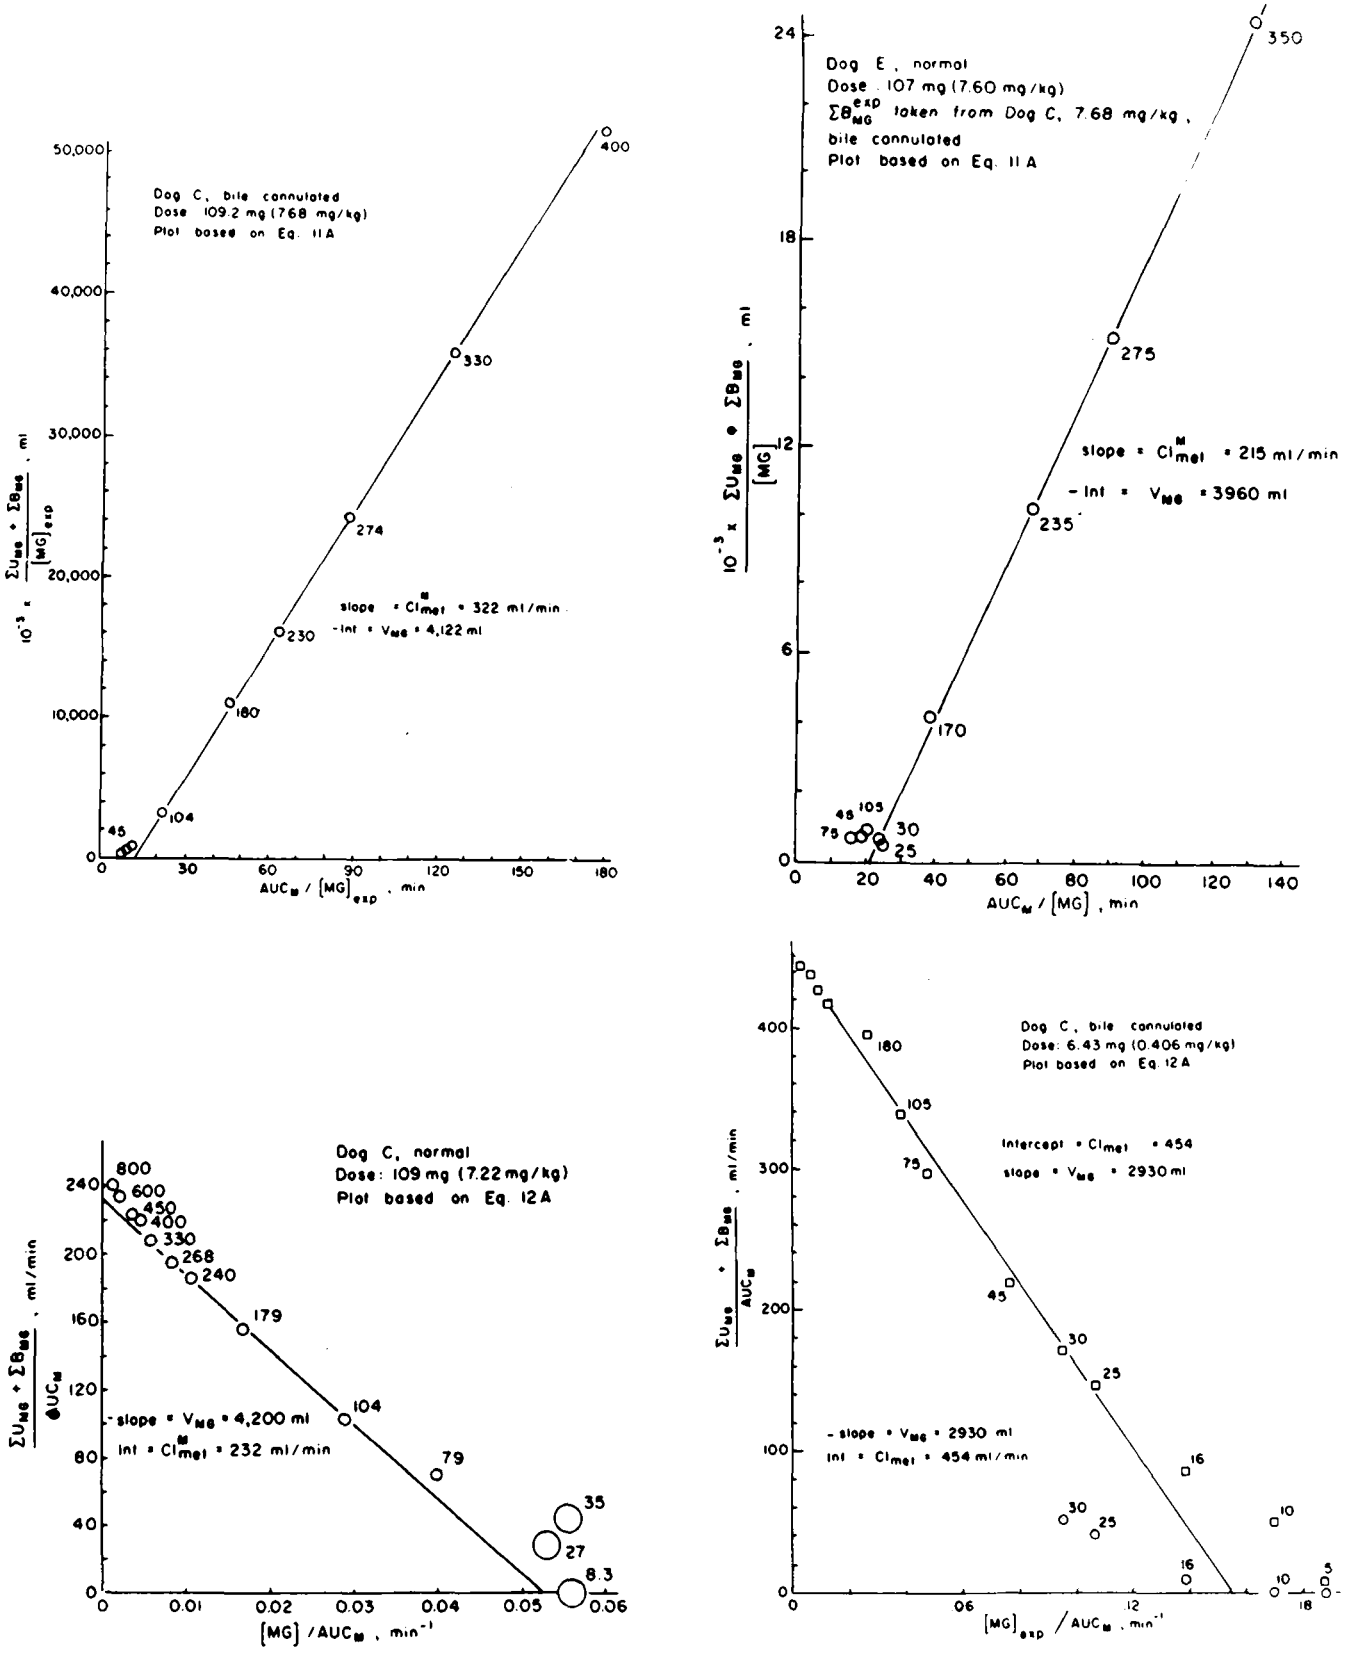

Figure 7—*Data for dogs administered morphine in accordance with the premise that the amounts of cumulative conjugate excreted in the bile, ΣB_{MG}^{exp}, were monitored (Eqs. A11 and A12). The ΣB_{MG} values used in the normal dogs were taken from the studies on the bile-cannulated Dog C at the high dose. The values are labeled with the times at which the AUC_M and $[MG]_{exp}$ values were taken. The ΣU_{MG}^{exp} and ΣB_{MG}^{exp} values were estimated for these same times from interpolations in the respective plots of their values against time. The experimental values at the earlier times in these plots are expected to be aberrant because inadequate urine flow at the high systemic drug levels did not permit proper estimates of ΣU_{MG} values. Deviations of experimental values at the later times in the non-bile-cannulated dogs were due to the perturbations effected by enterohepatic recirculation that gave estimates of ΣU_{MG}^{exp} and $[MG]_{exp}$ in excess of those anticipated by the premises underlying the equation used, which did not take such delayed return to the system into account.*

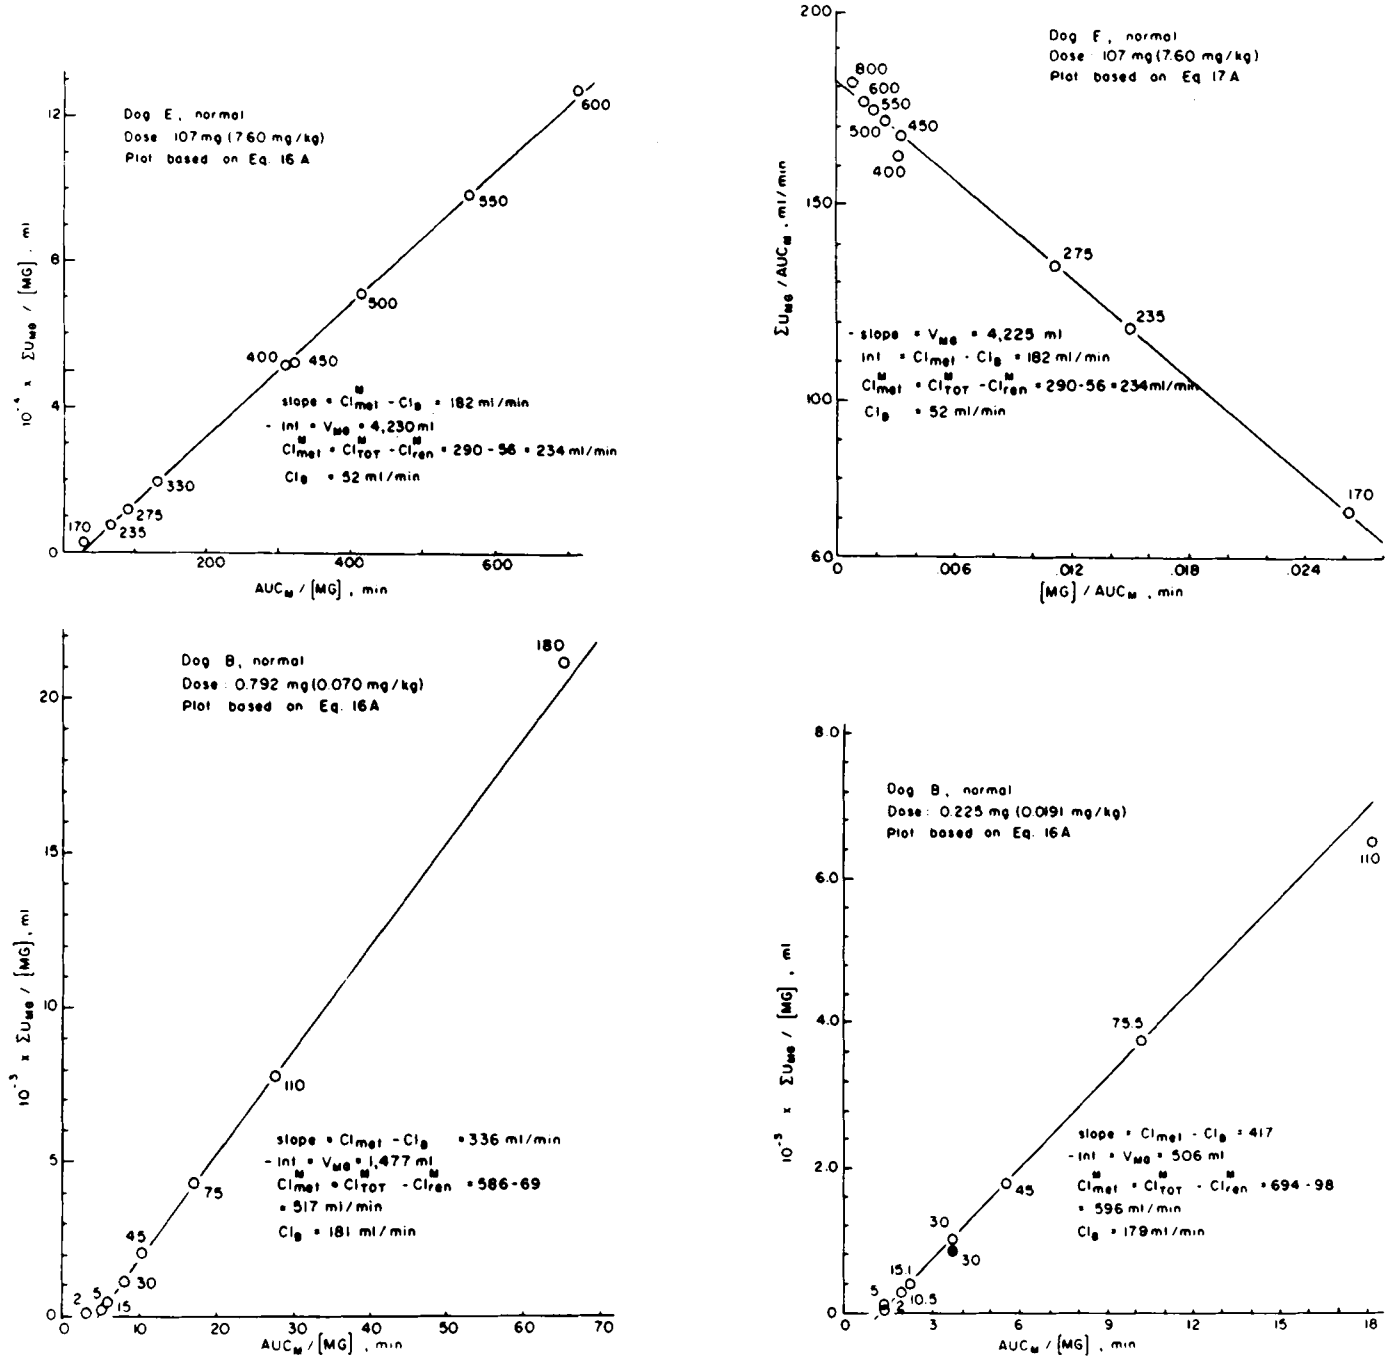

Figure 8—*Data for normal, non-bile-cannulated dogs in accordance with* $\Sigma U^{exp}_{MG}/[MG]_{exp} = (Cl_{met} - Cl_B)(AUC_M/[MG]_{exp}) - V_{MG}$ *(Eq. A16) or Eq. A17 on the premises that biliary clearance,* Cl_B*, of the metabolite is a constant fraction of the metabolic clearance,* Cl_{met}*, of morphine and that there is a negligible time lag in biliary process initiations. The values are labeled with the times at which the* AUC_M *and* $[MG]_{exp}$ *values were taken. The* ΣU^{exp}_{MG} *values were estimated for these same times from interpolations in plots of these values against time. Deviations of experimental values at the later times are due to the perturbations effected by enterohepatic recirculation that gave estimates of* ΣU^{exp}_{MG} *and* $[MG]_{exp}$ *in excess of those anticipated by the premises underlying Eq. A16, which did not take such delayed return to the system into account.*

The metabolism of morphine to the conjugate is apparently initiated at a time, t_0, of zero since there appears to be no lag in conjugate appearance, $[MG]$, in plasma at any studied dose (Figs. 2–4).

However, the renal excretion of the drug and conjugate at high morphine doses (Figs. 2 and 10) may be inhibited by the action of the drug so that:

$$\Sigma U_M = Cl^M_{ren}\left(\int_0^t [M]dt - \int_0^{t_0} [M]dt\right) = Cl^M_{ren}(AUC^t_M - AUC^{t_0}_M) \quad \text{(Eq. A6)}$$

where the parenthetical expression represents the difference between the total area under the plasma morphine concentration–time curve up to time t and the area up to time t_0 when the renal process commenced.

As a consequence of:

$$dU_{MG}/dt = Cl^{MG}_{ren}[MG] \quad \text{(Eq. A7)}$$

the cumulative renal excretion of the metabolite (ΣU_{MG}) would be related to a similar difference in the areas under the plasma metabolite concentration–time curve:

$$\Sigma U_{MG} = Cl^{MG}_{ren}\left(\int_0^t [MG]dt - \int_0^{t_0} [MG]dt\right) = Cl^{MG}_{ren}(AUC^t_{MG} - AUC^{t_0}_{MG}) = Cl^{MG}_{ren}(AUC^{t-t_0}_{MG}) \quad \text{(Eq. A8)}$$

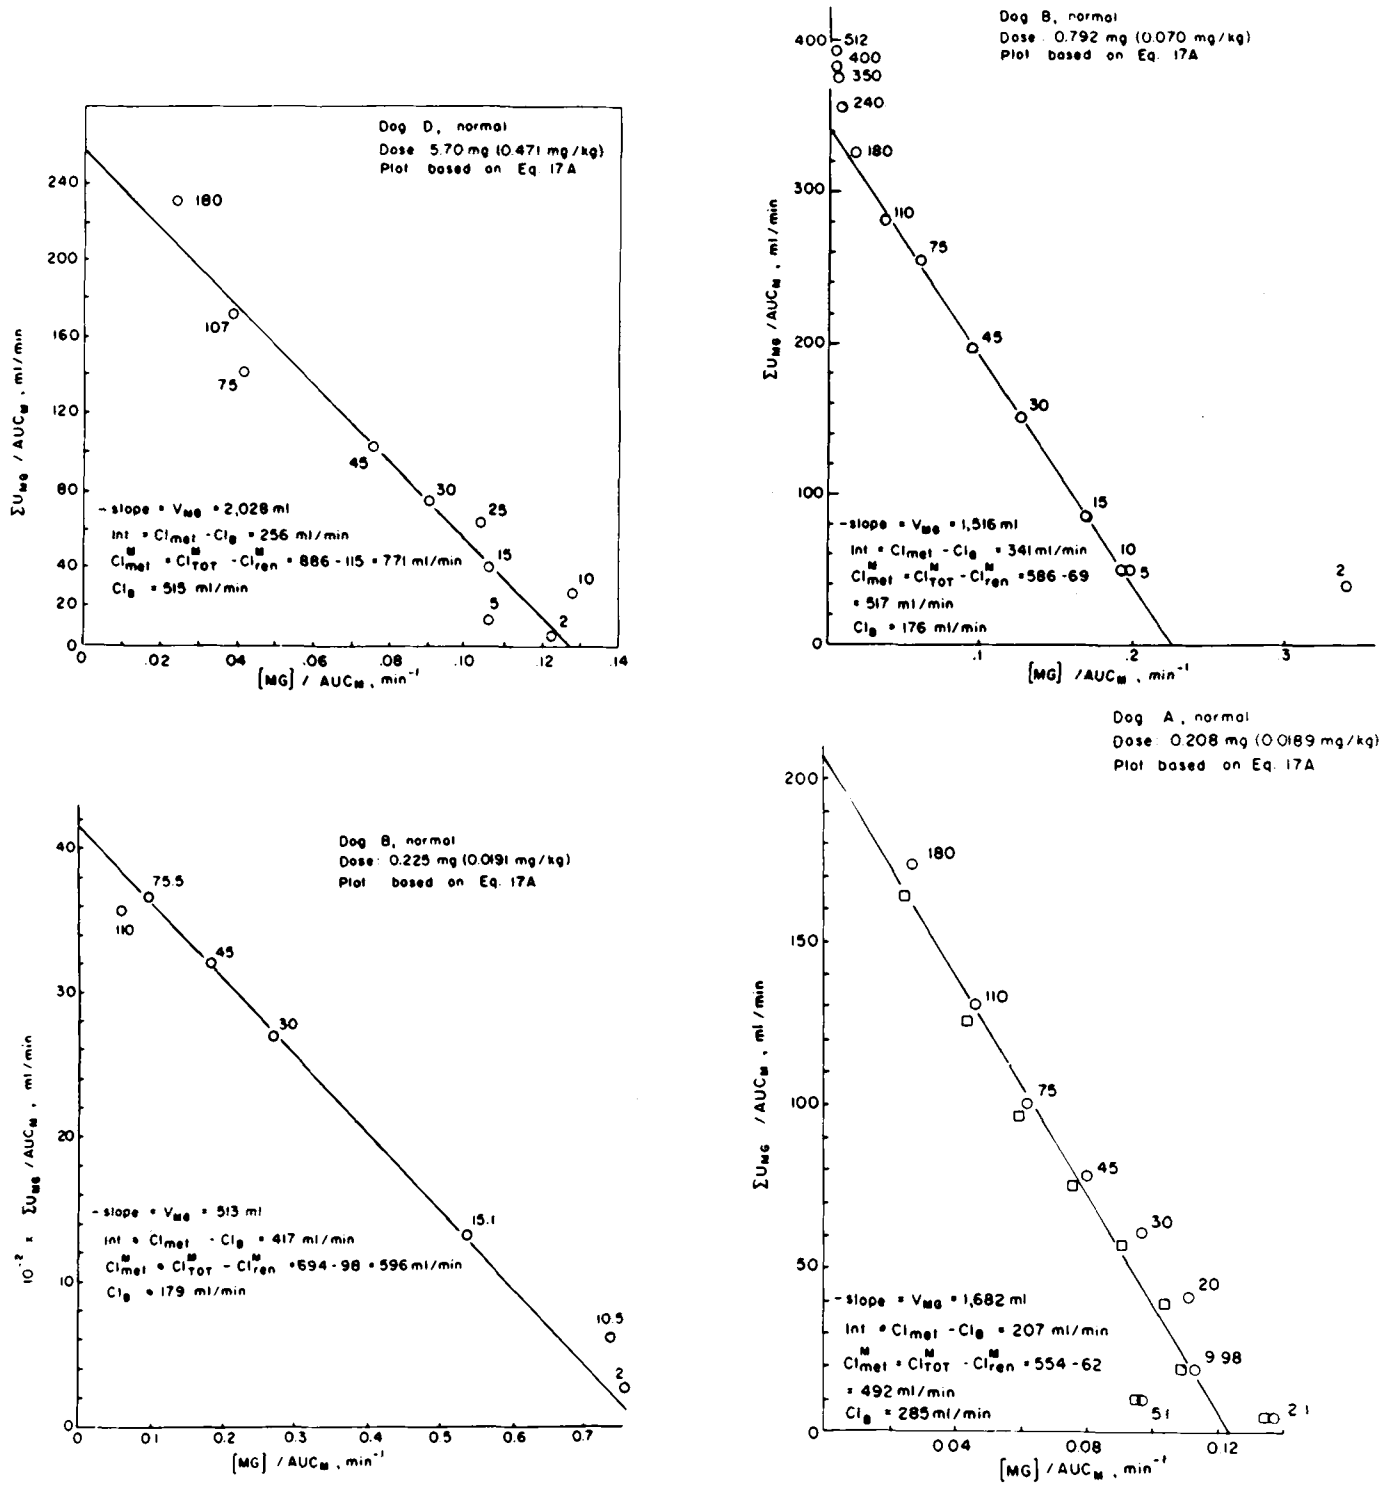

Figure 9—*Data for normal, non-bile-cannulated dogs in accordance with* $\Sigma U^{exp}_{MG}/AUC_M = V_{MG}([MG]_{exp}/AUC_M) + Cl_{met} - Cl_B$ *(Eq. A17) on the premises that biliary clearance,* Cl_B*, of the metabolite is a constant fraction of the metabolic clearance,* Cl_{met}*, of morphine and that there is a negligible time lag in biliary process initiation. The values are labeled with the times at which the* AUC_M *and* $[MG]_{exp}$ *values were taken. The* ΣU^{exp}_{MG} *values were estimated for those same times from interpolations in plots of these values against time. Deviations of experimental values at the later times are due to the perturbations effected by enterohepatic recirculation that gave estimates of* ΣU^{exp}_{MG} *and* $[MG]_{exp}$ *in excess of those anticipated by the premises underlying Eq. A17, which did not take such delayed return to the system into account. The values plotted for Dog A (0.208-mg dose) are based on two estimates of* AUC_M*: that calculated from the best-fit sum of exponentials (○) and that estimated by the trapezoidal rule (□) for* $[M]_{exp}$ *values with time.*

The clearances can be estimated from the slopes of $\Delta U_M/\Delta t$ ($\sim dU_M/dt$) *versus* $[M]_{t_{mid}}$ and $\Delta U_{MG}/\Delta t$ ($\sim dU_{MG}/dt$) *versus* $[MG]_{t_{mid}}$ in accordance with relations such as Eq. A7 where the plasma concentrations are taken at the midtime of the monitored excretory interval, Δt. Such anticipated linear plots were obtained (Fig. 5) and permitted the estimation of plasma level-independent renal clearances (Table I).

Thus, the values of ΣU_M and ΣU_{MG} could be generated from Eqs. A6 and A8. The appropriate choice of a time, t_0, for the renal process commencement should permit the generated values to agree with the experimental (Figs. 2–4).

It is possible that an amount of morphine in bile, ΣB_M, could be generated by a similar equation with a time of commencement of such a

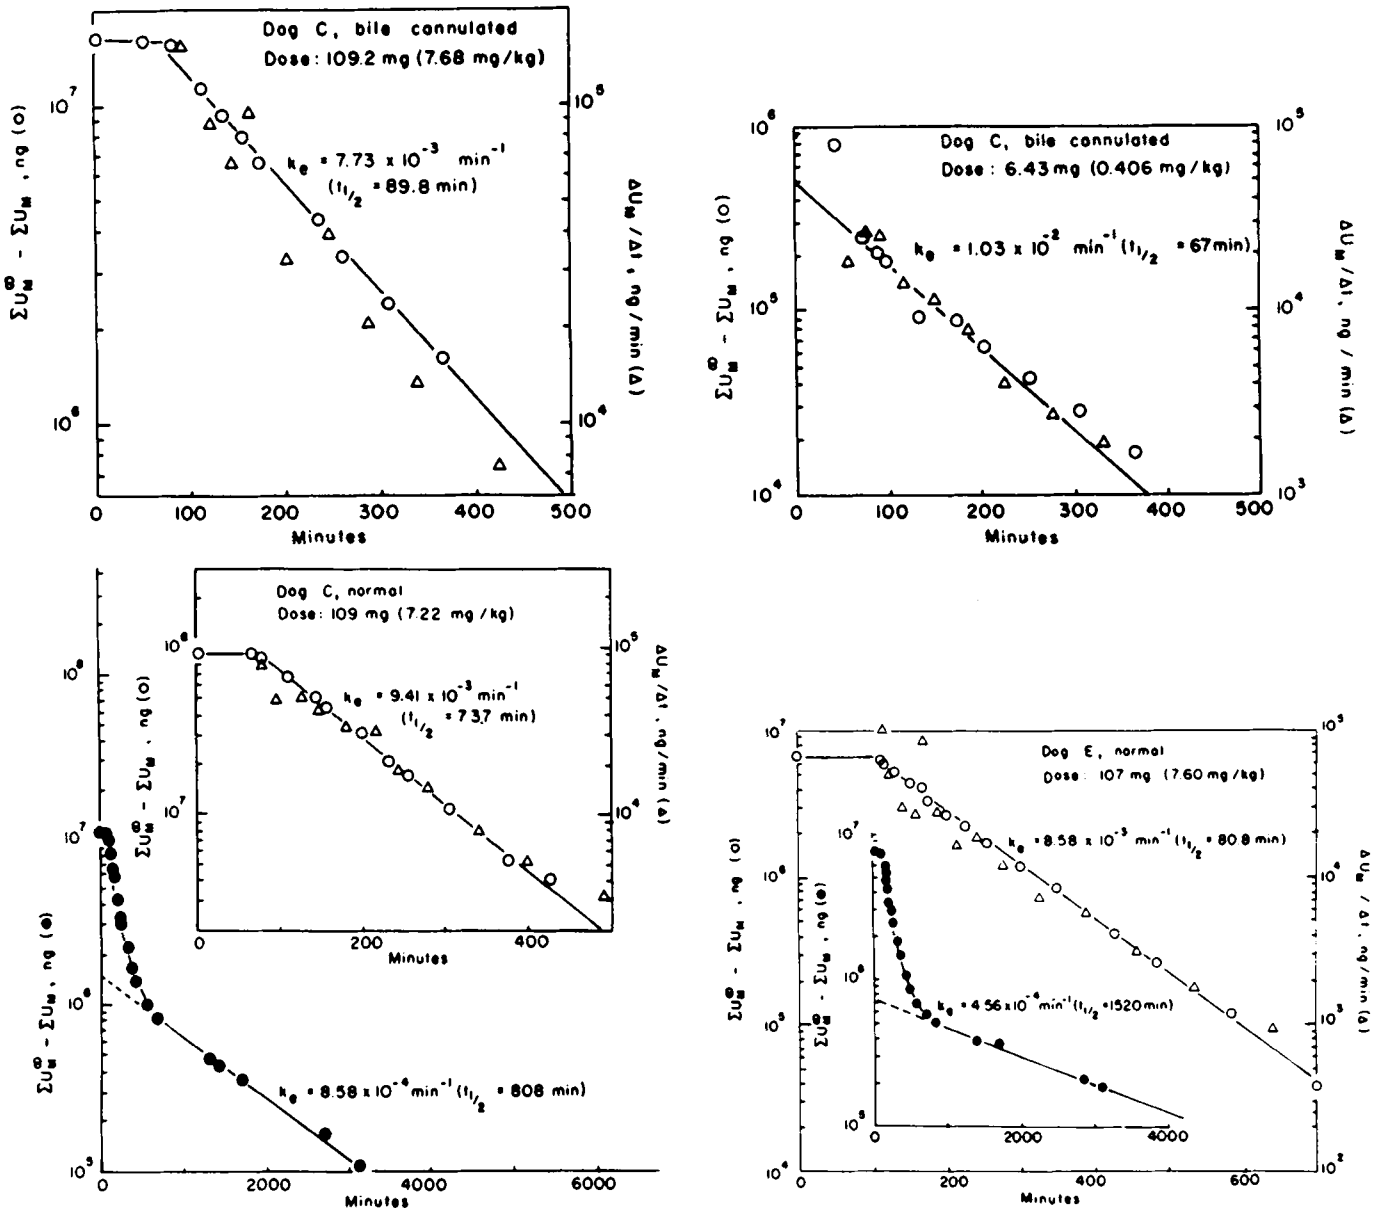

Figure 10—*Estimation of first-order rate constants, k_e, of urinary elimination from semilogarithmic plots of unchanged morphine not yet excreted, $\Sigma U_M^\infty - \Sigma U^M$ (○, ●), and rates of elimination, $\Delta U_M/\Delta t$ (Δ), against time in the bile-cannulated dog and at high doses in the normal dog. The former were plotted over the entire time interval (●) and then plotted according to the method of residuals (○). The time delay in elimination can be clearly noted.*

process at time t_0 (Eq. A3). However, the total amount of unchanged morphine that was experimentally determined in the bile was less than 0.005 of the dose in the two bile cannulation studies and was considered negligible.

Evaluation of Metabolic Clearances of Morphine in Bile-Cannulated Animal—The challenging of the validity of Eq. A2 for metabolite formation is not as simple. The metabolic clearance, Cl^M_{met}, is not readily obtained since the total metabolite produced, ΣMG, at a given time has to be constructed from the sums of amounts of the metabolite in the body, bile, and urine, respectively:

$$\Sigma MG = V_{MG}[MG]_{exp} + \Sigma B^{exp}_{MG} + \Sigma U^{exp}_{MG} \qquad \text{(Eq. A9)}$$

where V_{MG} is the apparent metabolite distribution volume on the postulation of instantaneous equilibration in the body fluids on its formation.

In the intact animal, ΣB_{MG} at a given time and V_{MG} are not readily obtainable. The ΣB^{exp}_{MG} value can be estimated from studies on a bile-cannulated dog. Substitution of Eq. A9 into Eq. A2 on the presumption of a constant metabolic clearance starting at time $t_0 = 0$ gives:

$$V_{MG}[MG]_{exp} + \Sigma B^{exp}_{MG} + \Sigma U^{exp}_{MG} = Cl^M_{met} AUC_M \qquad \text{(Eq. A10)}$$

which can be rearranged to:

$$\frac{\Sigma U_{MG} + \Sigma B_{MG}}{[MG]} = Cl^M_{met}\frac{AUC_M}{[MG]} - V_{MG} \qquad \text{(Eq. A11)}$$

or:

$$\frac{\Sigma U_{MG} + \Sigma B_{MG}}{AUC_M} = -V_{MG}\frac{[MG]}{AUC_M} + Cl^M_{met} \qquad \text{(Eq. A12)}$$

Thus, plots of the experimentally available $(\Sigma U_{MG} + \Sigma B_{MG})/[MG]$ or $(\Sigma U_{MG} + \Sigma B_{MG})/AUC_M$ against $AUC_M/[MG]$ or $[MG]/AUC_M$, respectively, can permit the estimation of V_{MG} and Cl^M_{met} values (Table I) from the slope and intercept of such plots (Fig. 7). The validity of these values can be ascertained by generating $[MG]_{calc}$ from a modification of Eq. A11 or A12:

$$[MG]_{calc} = \frac{\Sigma MG - \Sigma B^{exp}_{MG} - \Sigma U^{exp}_{MG}}{V_{MG}} = \frac{Cl^M_{met}AUC_M - \Sigma B^{exp}_{MG} - \Sigma U^{exp}_{MG}}{V_{MG}} \qquad \text{(Eq. A13)}$$

and the resultant calculated values of plasma metabolite concentration can be compared to those obtained experimentally, $[MG]_{exp}$ (Figs. 2–4).

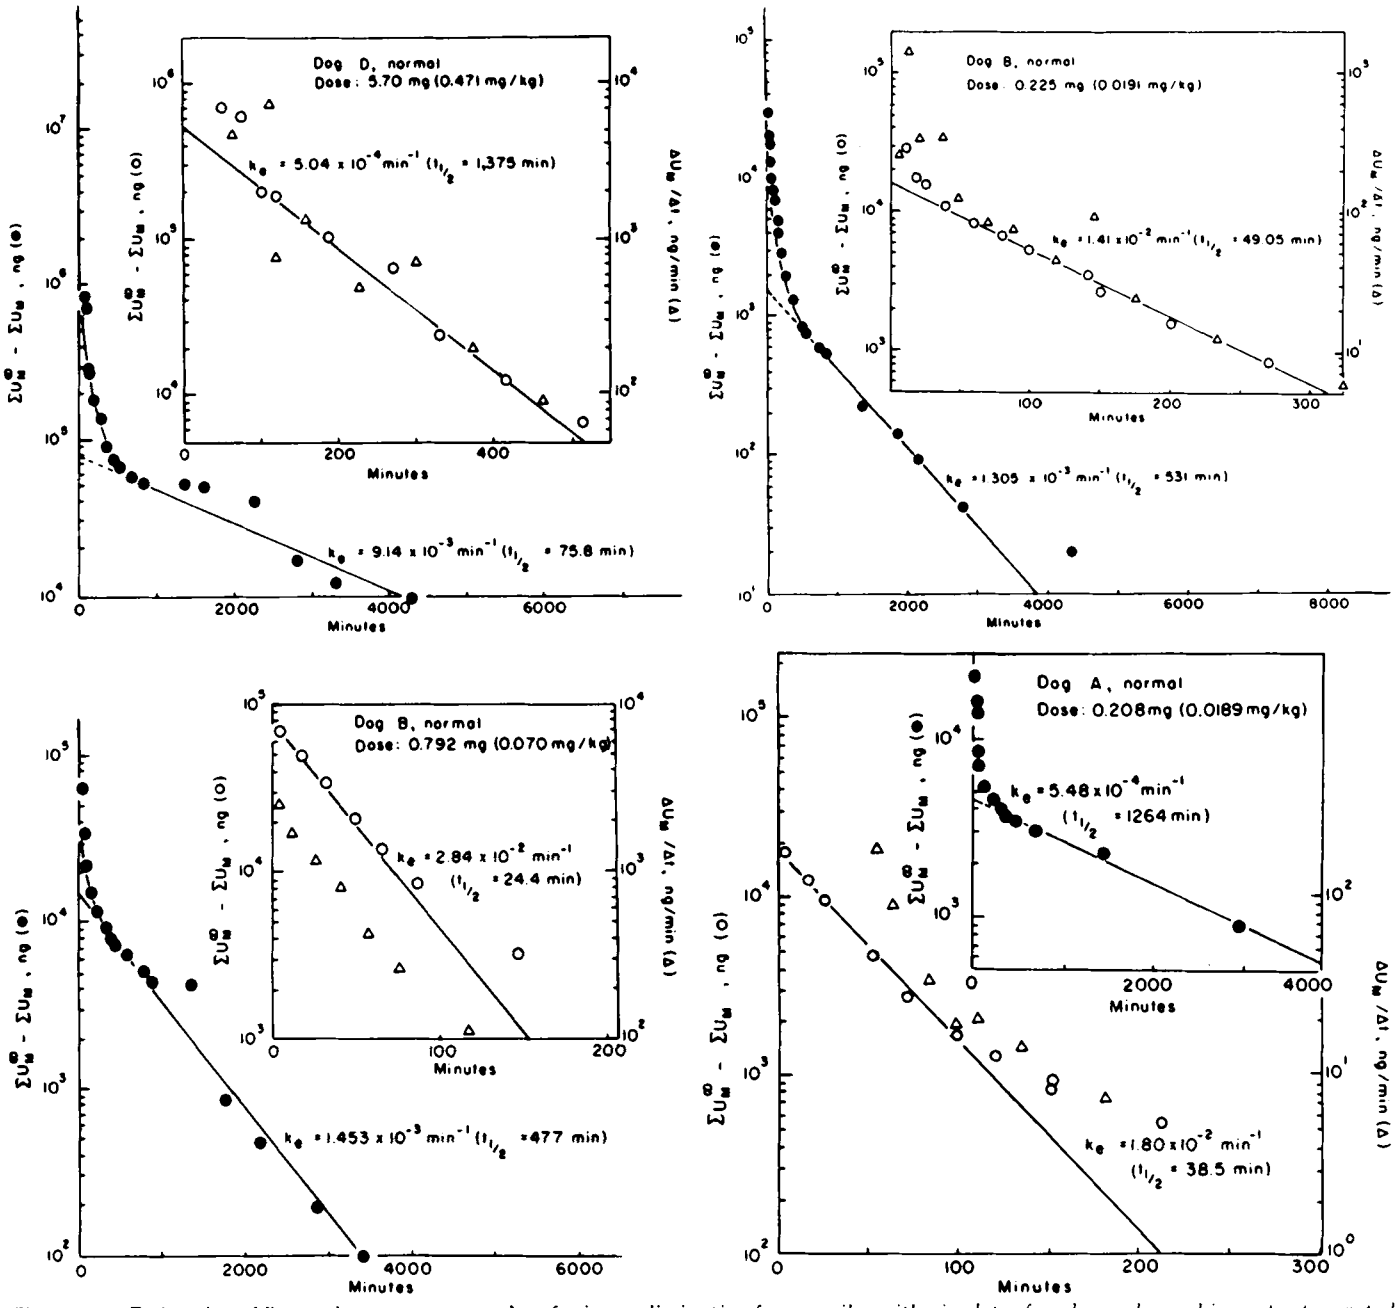

Figure 11—*Estimation of first-order rate constants, k_e, of urinary elimination from semilogarithmic plots of unchanged morphine not yet excreted, $\Sigma U_M - \Sigma U^M$ (○, ●), and rates of elimination, $\Delta U_M/\Delta t$ (Δ), against time at intermediate and low doses in the normal dog. The former were plotted over the entire time interval (●) and then plotted according to the method of residuals (○).*

Alternatively, the experimental values of metabolite concentration can be used to estimate the amounts of the metabolite, $\Sigma' B^{calc}_{MG}$, bile excreted from these estimates of Cl^M_{met} and V_{MG} (Eqs. A11 and A12) since:

$$\sum B^{calc}_{MG} = \sum MG - \sum U^{exp}_{MG} - V_{MG}[MG]_{exp}$$
$$= Cl^M_{met} AUC_M - \sum U^{exp}_{MG} - V_{MG}[MG]_{exp} \quad \text{(Eq. A14)}$$

Thus, the coincidences of $\Sigma' B^{calc}_{MG}$ with ΣB^{exp}_{MG} values and $[MG]_{calc}$ with $[MG]_{exp}$ can confirm or deny the validity of these postulates.

Evaluation of Metabolic Morphine Clearances in the Non-Bile-Cannulated Animal—If the amount of conjugate excreted in the bile is not specifically known, a constant biliary clearance, Cl_B, of hepatically formed conjugate can be postulated and Eq. A10 can be modified to:

$$V_{MG}[MG]_{exp} + Cl_B AUC_M + \sum U^{exp}_{MG} = Cl_{met} AUC_M \quad \text{(Eq. A15)}$$

where $Cl_B AUC_M/\Sigma MG = Cl_B/Cl_{met}$ is the fraction of conjugate formed in the liver that is partitioned immediately into the bile. If the biliary process is drug affected, a more accurate definition of the second term would be $Cl_B(AUC^t_M - AUC^{t_0}_M)$, where $AUC^{t_0}_M$ is the area under the plasma morphine level curve up to the time, t_0, of initiation of the biliary processes.

Thus, Eq. 15A can be rearranged to:

$$\frac{\sum U^{exp}_{MG}}{[MG]_{exp}} = (Cl_{met} - Cl_B)\frac{AUC_M}{[MG]_{exp}} - V_{MG} + \frac{Cl_B AUC^{t_0}_M}{[MG]_{exp}} \quad \text{(Eq. A16)}$$

or:

$$\frac{\sum U^{exp}_{MG}}{AUC_M} = -V_{MG}\frac{[MG]_{exp}}{AUC_M} + (Cl_{met} - Cl_B) + \frac{Cl_B AUC^{t_0}_M}{AUC_M} \quad \text{(Eq. A17)}$$

where the last term of both Eqs. A16 and A17 vanishes if there is no time lag in the initiation of the biliary process.

In the absence of such a time lag and the maintenance of a constant biliary partitioning of formed metabolite, V_{MG} and $I = Cl_{met} - Cl_B$ can

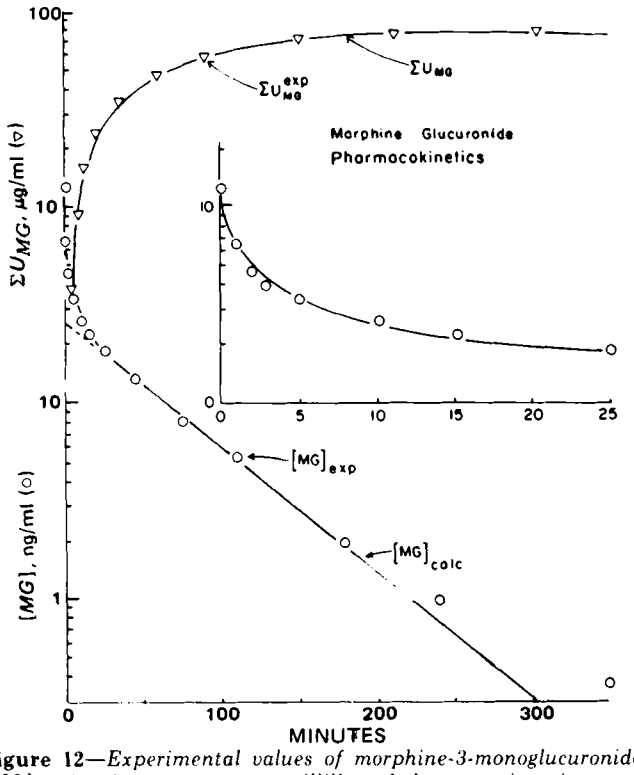

Figure 12—*Experimental values of morphine-3-monoglucuronide,* $[MG]_{exp}$ *(○), in nanograms per milliliter of plasma against time at an intravenous dose of 71.2 μg (6.5 μg/kg) to Dog A. The solid line through the experimental values was calculated from the polyexponential fit of Eq. 4. The solid line through the experimental values of cumulative conjugate in the urine,* ΣU_{MG}^{exp}*, are the theoretical values calculated from* $\Sigma U_{MG}^{calc} = Cl_{ren}^{MG} AUC_{MG}$ *for a renal clearance of 40 ml/min.*

be obtained from the slopes and intercepts of appropriate data plots in accordance with Eqs. A16 (Fig. 8) and A17 (Fig. 9), where $AUC_M^{\infty} = 0$. If the total clearance of morphine can be estimated from:

$$Cl_{tot} = \text{dose}/AUC_M \qquad \text{(Eq. A18)}$$

then:

$$Cl_{met} = Cl_{tot} - Cl_{ren}^{M} \qquad \text{(Eq. A19)}$$

and:

$$Cl_B = Cl_{met} - I = Cl_{met} - (Cl_{met} - Cl_B) \qquad \text{(Eq. A20)}$$

The premises for the absolute validity of these relations of Eqs. A18–A20 demand constant metabolic, biliary, and renal clearances of the drug and metabolite and no time lags in their initiation.

The levels of the conjugate $[MG]_{calc}$ in the normal dog also can be estimated from Eq. A13. However, the cumulative amount of formed metabolite totally secreted in the bile must be calculated from:

$$\Sigma B_{MG}^{tot} = Cl_B AUC_M \qquad \text{(Eq. A21)}$$

The $[MG]_{calc}$ and $[MG]_{exp}$ values will diverge if and when there is significant enterohepatic recirculation of the conjugate secreted into the bile.

Evaluation of Extent of Enterohepatic Recirculation of Morphine Metabolite (*MG*)—The biliary partition of the hepatically formed conjugate can be calculated in the normal animal from the determined Cl_B value by Eq. A21, which gives the amount secreted into the bile.

On the postulation of stoichiometry being preserved, the *actual* amount of conjugate in the biliary system would be:

$$\Sigma B_{MG}^{'calc} = \Sigma MG_{formed}^{tot} - \Sigma U_{MG}^{exp} - MG_{body}$$
$$= Cl_{met} AUC_M - \Sigma U_{MG}^{exp} - V_{MG}[MG]_{exp} \qquad \text{(Eq. A22)}$$

The difference between the calculated values of Eqs. A21 and A22 estimates the amount of conjugate at any given time that has been enterohepatically recirculated into the systemic circulation:

$$\Sigma MG_{ent} = \Sigma B_{MG}^{calc} - \Sigma B_{MG}^{'calc} \qquad \text{(Eq. A23)}$$

Estimation of Low Values of Morphine and Its Metabolite in Plasma—The estimates of the experimentally determined terminal plasma values of morphine, $[M]_{exp}$, and its conjugate, $[MG]_{exp}$, tend to have large errors since their estimates by liquid scintillation counting approach background. Alternative estimates are $[M]'_{calc}$ and $[MG]'_{calc}$, which can be determined from the estimated renal clearances, Cl_{ren}^{M} and Cl_{ren}^{MG}, and the experimentally determined values of cumulative urinary excretions, ΣU_M^{exp} and ΣU_{MG}^{exp}.

The area under the plasma level–time curve at time $t_{(i+1)}$ can be estimated from the quotient of the cumulative drug in the urine at that time and the renal clearance:

$$AUC_{t_{(i+1)}} = (\Sigma U)_{t_{(i+1)}}/Cl_{ren} = AUC_{t_i} + \Delta AUC \qquad \text{(Eq. A24)}$$

This area is the sum of a known area, AUC_{t_i}, where the plasma concentration is C_{t_i} at time t_i and an increase in area, ΔAUC, which can be defined as:

$$\Delta AUC = AUC_{t_{(i+1)}} - AUC_{t_i} = \left(\frac{C_{t_i} + C_{t_{(i+1)}}}{2}\right)\Delta t$$
$$= \frac{C_{t_i} + C_{t_{(i+1)}}}{2}(t_{(i+1)} - t_i) \qquad \text{(Eq. A25)}$$

Thus, the plasma drug concentration at time $t_{(i+1)}$ can be estimated from:

$$C_{t_{i+1}} = \frac{2(\Delta AUC)}{t_{(i+1)} - t_i} - C_{t_i} \qquad \text{(Eq. A26)}$$

so that, on consideration of Eq. A24:

$$C_{t_{i+1}} = \frac{2[(\Sigma U)t_{(i+1)}/Cl_{ren} - AUC_{t_i}]}{(t_{(i+1)} - t_i)} - C_{t_i} \qquad \text{(Eq. A27)}$$

where $C_{t_{i+1}}$ can be $[M]'_{calc}$ or $[MG]'_{calc}$ plasma values at t_{i+1}. It is necessary to have one initial experimental set of values of C_{t_1} and AUC_{t_1} at time t_1 to substitute into Eq. A27 for the first calculation of a plasma concentration of C_{t_2} at t_2 from $(\Sigma U)_{t_2}$ and t_2. Subsequent calculations of $C_{t_3}, C_{t_4}, \ldots, C_{t_{(i+1)}}$ can then be made in accordance with Eq. A27 since prior $C_{t_2}, C_{t_3}, \ldots, C_{t_i}$ and AUC_{t_i} values were available. The new AUC_{t_i} can be estimated by adding the calculated ΔAUC obtained from Eq. A25 to the prior estimated AUC at a previous time, $AUC_{(t_{i-1})}$. Plasma values obtained in this manner tended to oscillate unless averaged. Thus:

$$\overline{C}_{t_i} = \frac{C_{t_{(i+1)}} + C_{t_i}}{2} \qquad \text{for } t'_i = \frac{t_{(i+1)} + t_i}{2} \qquad \text{(Eq. A28)}$$

$$\overline{C}_{t'_{(i+1)}} = \frac{C_{t_{(i+2)}} + C_{t_{(i+1)}}}{2} \qquad \text{for } t'_{(i+1)} = \frac{t_{(i+2)} + t_{(i+1)}}{2} \qquad \text{(Eq. A29)}$$

etc., can provide monotonically decreasing values of $[M]'_{calc}$ and $[MG]'_{calc}$ with time with minimum scatter about a smooth curve drawn through the points.

APPENDIX II: GLOSSARY OF SYMBOLS

Concentrations of morphine, *M*, and morphine conjugate, *MG*, are given as nanograms of equivalent morphine base in plasma, whereas amounts in urine or bile are given as nanograms of equivalent morphine base.

$[M]_{exp}$—experimental morphine concentration per milliliter of plasma.

$[M]'_{calc}$—morphine concentration per milliliter of plasma calculated from experimental values of $\Sigma U_{M_{t_{(i+1)}}}$ at a time, $t_{(i+1)}$, from a known renal clearance, Cl_{ren}^{M}, and the known AUC_M and $[M]$ values of previous time, t_i (Eq. A27).

$[M]$—morphine concentration per milliliter of plasma calculated at a time, t, from a best-fitted linear sum of exponentials, $[M] = Ae^{-\alpha t} + Be^{-\beta t} + Ce^{-\gamma t}$.

$[MG]_{exp}$—experimental morphine conjugate concentration per milliliter of plasma.

$[MG]'_{calc}$—morphine conjugate concentration per milliliter of plasma as calculated from experimental values of $\Sigma U_{MG_{t_{(i+1)}}}$ at a time, $t_{(i+1)}$, from a known renal clearance, Cl_{ren}^{MG}, and the known AUC_{MG} and $[MG]$ values at a previous time, t_i (Eq. A27).

$[MG]$ or $[MG]_{calc}$—morphine conjugate concentration per milliliter of plasma as calculated from the difference between the cumulative amount of conjugate generated, ΣU_{MG}, and the experimental cumulative amounts of conjugate in bile and urine and divided by a volume of distribution, V_{MG} (Eq. A13). In the non-bile-cannulated dog, the

cumulative amount of conjugate in the bile must be calculated on the assumption of a constant biliary clearance of metabolized morphine (Eq. A21).

ΣMG or ΣMG^{tot}—cumulative morphine conjugate produced by metabolic morphine clearance, Cl^{M}_{met} (Eqs. A2, A5, and A9).

ΣU^{exp}_{M}—cumulative experimental morphine excreted in urine.

ΣU^{calc}_{M}—calculated cumulative morphine excreted in urine, based on renal clearance, Cl^{M}_{ren}, of plasma morphine (Eqs. A1 and A6).

ΣU^{exp}_{MG}—cumulative experimental morphine conjugate excreted in urine.

ΣU^{calc}_{MG}—calculated cumulative morphine conjugate excreted in urine, based on renal clearance, Cl^{MG}_{ren}, of plasma conjugate (Eq. A8).

ΣB^{exp}_{MG}—experimental cumulative morphine conjugate excreted in bile in the bile-cannulated dog.

ΣB^{calc}_{MG} or ΣB^{tot}_{MG}—calculated total cumulative morphine conjugate excreted in bile, based on biliary clearance, Cl_B, of metabolized morphine (Eqs. A3 and A21).

$\Sigma B'^{calc}_{MG}$—actual morphine conjugate in the biliary system calculated from the difference in the total formed, ΣMG, and the amounts of conjugate experimentally determined in the urine and in the body (Eq. A22).

ΣMG_{ent}—conjugate presumably enterohepatically recirculated from the bile to the systemic circulation as estimated from the difference between ΣB^{calc}_{MG} and $\Sigma B'^{calc}_{MG}$ (Eq. A23).

ΣMG^{exp}_{feces}—experimental conjugate excreted in feces.

ΣMG^{theo}_{feces}—conjugate calculated to be in feces based on the difference in calculated total conjugate formation and total amount excreted in urine.

ΣU^{∞} or ΣB^{∞}—total drug or metabolite in urine or bile at infinite time.

Cl^{M}_{tot}—total morphine clearance, in milliliters per minute (Eq. A18).

Cl^{M}_{ren}—renal morphine clearance, in milliliters per minute, basically estimated from $\Delta\Sigma U_M/\Delta t/[M]_{t_{mid}}$.

Cl^{MG}_{ren}—renal morphine conjugate clearance, in milliliters per minute, basically estimated from $\Delta\Sigma U_{MG}/\Delta t/[MG]_{t_{mid}}$.

Cl_{met} or Cl^{M}_{met}—metabolic morphine clearance, in milliliters per minute, which can be estimated directly in the bile-cannulated dog (Eqs. A11 and A12) and indirectly in the non-bile-cannulated dog (Eq. A19).

Cl_B or Cl^{M}_{B}—biliary clearance of a morphine conjugate fraction formed by morphine metabolism, in milliliters per minute, which can be estimated from $\Delta\Sigma B^{exp}_{MG}/\Delta t/[M]_{exp}$ in the bile-cannulated dog and indirectly estimated on the assumption of dose independence in the non-bile-cannulated dog (Eqs. A16, A17, and A20). The biliary clearance of systemic morphine conjugate is not presumed.

V^{M}_{C}—apparent distribution volume, in liters, of central compartment referenced to morphine base concentration in plasma.

V^{M}_{d}—apparent overall distribution volume, in liters, referenced to morphine base concentration in plasma.

V^{M}_{extrap}—apparent distribution volume, in liters, referenced to morphine based concentration in plasma on assumption of instantaneous equilibration in body fluids.

V_{MG}—apparent overall distribution volume, in liters, for the formed conjugate, MG, of morphine (Eqs. A11, A12, A16, and A17).

Monoamine Oxidase Inhibition by β-Carbolines: A Quantum Chemical Approach

FRANCISCO TOMÁS [x] **and JOSÉ M. AULLÓ**

Received July 8, 1977, from the *Departamento de Química Física, Facultad de Ciencias, Universidad de Valencia, Burjasot, Valencia, Spain.* Accepted for publication December 5, 1978.

Abstract □ Monoamine oxidase inhibition by β-carboline derivatives is related to the energy change, ΔE, arising from complex formation between the inhibitor and the enzyme. The energy change was expressed in terms of electronic indexes, which were estimated for a set of aromatic β-carbolines. The electronic indexes were correlated to the experimental activity indexes by a simplified quantum chemical perturbational treatment with a multiple regression procedure. A characteristic structure for the inhibitor–enzyme complex was derived from the correlation. The molecules are linked by two kinds of bond. One involves the lone pyridine nitrogen pair of β-carbolines; the other is due to a π-electronic interaction between the inhibitor indole fragment and a suitable area of the enzyme. Such a model explains the competitive inhibition by β-carbolines compared to tryptamine and other aromatic amines that are monoamine oxidase substrates.

Keyphrases □ β-Carbolines—monoamine oxidase inhibition, quantum chemistry □ Monoamine oxidase—inhibition by β-carbolines, quantum chemistry □ Monoamine oxidase inhibitors—β-carbolines, quantum chemistry

Some β-carboline (9*H*-pyrido[3,4-*b*]indole) derivatives are inhibitors of monoamine oxidase in oxidative cerebral amine deamination. *In vitro* studies using tryptamine as the substrate in deamination found that some derivatives were potent competitive inhibitors (1–8). The common β-carboline structure is the tricyclic aromatic system. Substituents enhance or diminish activity.

The present work was designed to relate the inhibitory activity to the aromatic β-carboline derivative electronic structure. An inhibition mechanism was derived from the correlation between experimental data and estimated electronic properties.

EXPERIMENTAL

Molecular Orbital Calculations—The "valence shell" molecular orbital theory and the INDO (intermediate neglect of differential overlap) semiempirical method (9) were used. Calculations were performed with the CNINDO program (10) using the parameters implicit in the program.

The molecular conformation was built according to the following criteria:

1. Molecular tricyclic structure was considered to be planar, as inferred from electronic delocalization.
2. Substituents did not alter the tricyclic system conformation significantly.
3. The tricyclic system geometry derived from that of the glycyl-L-tryptophan (11) and pyridine (12) cyclic fragments.

The substituent bond lengths are given in Table I. The geometric parameters used in the calculations are given in Table I and Fig. 1.

Theoretical Considerations on Inhibitory Activity—The inhibitory activity is expressed by I_{50}, the inhibitor concentration that diminishes the enzyme activity by 50%. To compare all β-carbolines, the I_{50} must be measured using the same experimental conditions. With the assumption that the β-carboline derivatives inhibit the catalytic action of monoamine oxidase on tryptamine oxidation by a competitive mechanism, such a mechanism was analyzed considering the formation of the inhibitor–enzyme complex. The equilibrium constant for complex formation can be derived from experimental I_{50} data (1–8) and also can be estimated from theoretical electronic structure calculations. The aim is to find a correlation between the complex equilibrium constant and the inhibitor electronic properties.

The equilibrium constant can be derived from reported I_{50} values. Literature studies (1–8) suggested that the inhibitor and the substrate (tryptamine) are competitive toward the same enzyme centers. The competitive mechanism can be expressed by:

$$S + E \underset{k_2}{\overset{k_1}{\rightleftarrows}} SE \xrightarrow{k_3} P + E$$

Scheme I

$$B + E \overset{K_i}{\rightleftarrows} BE$$

Scheme II

where *S*, *E*, *B*, *SE*, and *BE* are the substrate, the enzyme, the inhibitor, the substrate–enzyme complex, and the inhibitor–enzyme complex, re-

spectively; k_1, k_2, and k_3 are the rate constants; and K_i is the equilibrium constant:

$$K_i = \frac{[BE]}{[B][E]} \qquad \text{(Eq. 1)}$$

By applying the steady-state hypothesis, the degree of inhibition, i, is (20):

$$i = \frac{K_A K_i [B]}{K_A(1 + K_i[B]) + [S]} \qquad \text{(Eq. 2)}$$

where $K_A = k_2 + k_3/k_1$, the Michaelis constant, referred to the substrate; and S and B are the concentrations of the substrate and inhibitor, respectively, in the experiment.

From the I_{50} definition, Eq. 2 can be written:

$$K_i = \frac{K_A + [S]}{K_A I_{50}} \qquad \text{(Eq. 3)}$$

This expression can be simplified by suitable planning of the experiment. The value $K_A = 8.1 \times 10^{-5}$ was reported when the same initial tryptamine concentration, $[S] = 6 \times 10^{-2}$ mole/liter, was used for every experiment (1). Under these experimental conditions when $[S] > 100 \times K_A$, the oxidation kinetics can be considered to be zero order (with less than 1% deviation). Consequently, Eq. 3 reduces to:

$$K_i = \frac{K_{AS}}{I_{50}} \qquad \text{(Eq. 4)}$$

where:

$$K_{AS} = \frac{K_A + [S]}{K_A} \qquad \text{(Eq. 5)}$$

Obviously, K_{AS} depends on the experimental conditions, but it will be constant if $[S]$ is constant. In the experiments quoted, the conditions were constant for all β-carbolines. Thus, Eq. 4 or its logarithmic form:

$$\log K_i = \log K_{AS} + pI_{50} \qquad \text{(Eq. 6)}$$

where:

$$pI_{50} = -\log I_{50} \qquad \text{(Eq. 7)}$$

can be used to estimate the equilibrium constants for inhibitor–enzyme complex formation. From the experimental data (1), $\log K_{AS} = 2.870$. The values of pI_{50} and K_i derived by applying Eq. 6 to the experimental data are given in Table II.

Quantum Chemical Treatment of Inhibition—After an experimental estimate of the equilibrium constant K_i was obtained, the next step was to relate K_i to electronic and/or structural properties. No correlation was found between atomic electronic properties and β-carboline inhibitory activity in any previous work (21).

According to statistical thermodynamics, K_i is expressed by:

$$K_i = \frac{f_{BE}}{f_B f_E} \exp(-\Delta E_i/kT) \qquad \text{(Eq. 8)}$$

where ΔE_i is the difference between the complex energy and the separate enzyme and inhibitor energies, all at ground state; f is the partition function, and k is the Boltzmann constant. Structural similarities permit the simplification of Eq. 8 for the entire β-carboline set. The partition quotient can be considered nearly constant for all β-carbolines (22).

[a] Reference 6. [b] This work.

The energy variation in complex formation can be developed into several components:

$$\Delta E_i = \Delta E_n^i + \Delta E_e^i + \Delta E_{st}^i + \Delta E_{sv}^i \qquad \text{(Eq. 9)}$$

where ΔE_n^i represents the difference due to nuclear rotation and vibration, ΔE_{st}^i expresses the variation from steric rearrangements, ΔE_{sv}^i concerns the solvation phenomenon, and ΔE_e^i expresses the change of electronic energy. The most important contribution to ΔE_i is ΔE_e^i (23). It is also the differential factor of each molecule in the ΔE_i estimation because the formation mechanism must be equal for all compounds. Equation 9 can be simplified to:

$$\Delta E_i = \Delta E_e^i + C \qquad \text{(Eq. 10)}$$

where C includes all contributions except the electronic ones and is constant for the β-carbolines.

From these considerations, the equilibrium constant is:

$$K_i = D(T) \exp(-\Delta E_e^i/kT) \qquad \text{(Eq. 11)}$$

where:

$$D(T) = \frac{f_{BE}}{f_B f_E} \exp(-C/kT) \qquad \text{(Eq. 12)}$$

$D(T)$ depends on temperature but is the same for all β-carbolines. In a logarithmic form, Eq. 11 can be written:

$$\log K_i = A(T) - \frac{\Delta E_e^i}{kT} \qquad \text{(Eq. 13)}$$

where $A(T) = \log D(T)$. Finally, from Eqs. 6 and 13, the inhibitory activity expressed by pI_{50} can be related to the complex formation electronic energy by:

$$pI_{50}^i = a + b\,\Delta E_e^i \qquad \text{(Eq. 14)}$$

where $a = A(T) - \log K_{AS}$ and $b = -1/kT$; a and b are constants for a temperature and for the entire β-carboline set.

Unfortunately, the direct ΔE_e^i calculation is not feasible. The monoamine oxidase molecular structure is unknown, and the electronic energy cannot be calculated. A greater difficulty appears in the electronic energy calculation of the inhibitor–enzyme complex, because the nature of the complex is unknown. The only energy that can be calculated is the inhibitor electronic energy in the geometrical conformations proposed.

Nevertheless, perturbational treatment (24, 25) was performed on the complex, considering its nature and stability. The important features observed in the β-carbolines were:

1. All compounds inhibited monoamine oxidase catalysis on aromatic amines and, more precisely, on tryptamine.
2. The inhibitory mechanism seemed to be common.
3. The inhibition was produced because the β-carbolines blocked the enzyme active centers on which the substrate was to be fixed.
4. The inhibitory mechanism reversibility implied molecular attraction rather than covalent bonding between molecules.
5. The pyridine nitrogen as well as the delocalized electronic system was essential for the inhibitory behavior. Carbazole, having a similar electronic structure to β-carboline but lacking the pyridine nitrogen, does not present inhibitory properties (26).
6. Substituents only altered the activity located at the delocalized tricyclic system.

The electronic interaction energy between a pair of atoms, b from the inhibitor B and e from the enzyme E, can be expressed (27) by:

$$\Delta E_{be} = Q_b Q_e (bb|ee) + \sum_m \sum_{n'} \frac{d_{mb} d_{n'e}}{\epsilon_m - \epsilon_{n'}} \beta_{be}^2 + \sum_{m'} \sum_n \frac{d_{m'b} d_{ne}}{\epsilon_{m'} - \epsilon_n} \beta_{be}^2 \quad \text{(Eq. 15)}$$

where Q_b and Q_e are the net charges over the atoms and β_{be} is the resonance integral; $d_{ks} = \Sigma_j 2c_{kj}$ is the orbital charge of atom s in molecular orbital ϕ_k, where c_{kj} are the coefficients of the atomic orbitals from the atom s in ϕ_k. The indexes m' and n' denote the virtual orbitals of inhibitor and enzyme, respectively, and m and n stand for the doubly occupied orbitals of the corresponding molecules. The ϵ values are the molecular orbital energies; $(bb|ee)$ is the repulsion energy between the electrons occupying orbitals centered on b and e atoms. The hypothesis of INDO formalism gives a constant value for the repulsion integral $(bb|ee)$ among the atoms b and e valence orbitals despite the kind of such orbitals. The value of β_{be} is independent of the kind of atomic orbitals because the molecular nature of the complex does not involve covalent bonds.

By extending Eq. 15 to all pairs of interacting atoms, p, it can be written:

$$\Delta E_e^i = \sum_p \left\{ Q_b^p Q_e^p (bb|ee) + \beta_{be}^2 \sum_m \frac{d_{mb}^p}{\epsilon_m - \bar{\epsilon}_{n'}} \sum_{n'} d_{n'e}^p + \beta_{be}^2 \sum_{m'} \frac{d_{m'b}^p}{\epsilon_{m'} - \bar{\epsilon}_n} \sum_n d_{ne}^p \right\} \quad \text{(Eq. 16)}$$

This expression has been written with the consideration that the occupied molecular orbitals of one molecule and the virtual orbitals of the other have very different energies, as in a charge controlled process. The following approach may be used:

$$\epsilon_m - \epsilon_{n'} = \epsilon_m - \bar{\epsilon}_{n'} \quad \text{(Eq. 17)}$$

$$\epsilon_{m'} - \epsilon_n = \epsilon_{m'} - \bar{\epsilon}_n \quad \text{(Eq. 18)}$$

where $\bar{\epsilon}$ is the average of the corresponding energies.

Since the atoms from the tricyclic system, which are the same for all β-carbolines, are the only ones involved in complex formation and since the complexes are formed with the same atoms of the enzyme, some of the magnitudes appearing in Eq. 16 probably are constant for all β-carbolines. The integrals $(bb|ee)$, the resonance integrals β_{be}, the summations referring the enzyme coefficients, and the average enzyme orbital energies may be considered constant.

Otherwise, the summations concerning the β-carboline orbitals are closely related to the generalized superdelocalizability indexes (28, 29) and are expressed by:

$$S_b^{(e)} = \sum_m \frac{d_{mb}}{\epsilon_m} \quad \text{(Eq. 19}a\text{)}$$

$$S_b^{(n)} = \sum_{m'} \frac{d_{m'b}}{\epsilon_{m'}} \quad \text{(Eq. 19}b\text{)}$$

where $S^{(e)}$ is the electrophilic index and $S^{(n)}$ is the nucleophilic index.

Since the enzymatic terms in Eqs. 16 and 19 are constant, the following expression for the electronic energy variation can be written:

$$\Delta E_e^i = \sum_p \{A_p Q_p^2 + B_p S_b^{(e)p} + C_p S_b^{(n)p}\} \quad \text{(Eq. 20)}$$

The coefficients A_p, B_p, and C_p are constants for all β-carbolines, and the indexes Q and S are variables for each complex.

Finally, by introducing Eq. 20 in Eq. 14 and rearranging, the following expression can be found:

$$pI_{50} = a + \sum_p (c_{1p} Q_p + c_{2p} S_p^{(e)} + c_{3p} S_p^{(n)}) \quad \text{(Eq. 21)}$$

In this equation, the summation is extended over all of the atoms of the aromatic β-carboline tricyclic system, and the coefficients c_{ip} are constant. Equation 21 relates the experimentally found inhibitory activity to the theoretically estimated electronic indexes. This equation holds if the enzyme–β-carboline complex is well approximated by the proposed molecular model, *i.e.*, if it is a molecular charge-controlled complex without covalent bonds. A statistical study of the applicability of Eq. 21 to the molecules considered was performed to identify the coefficients that gave the best statistical correlation.

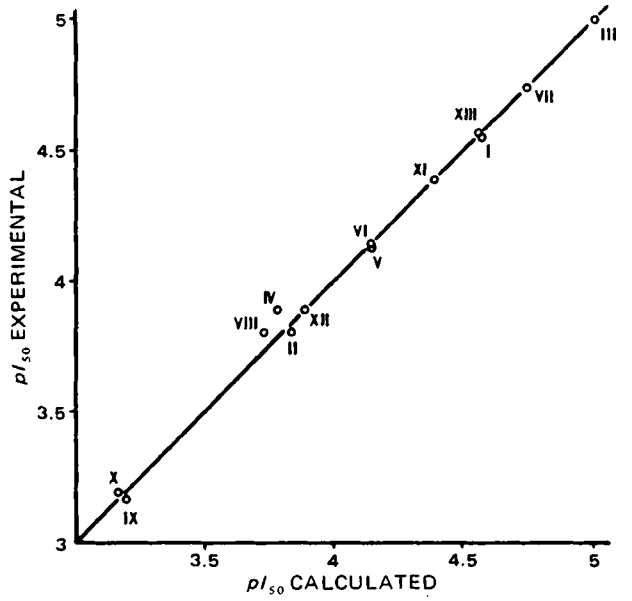

Figure 2—*Experimental* pI_{50} *values* versus *calculated values from Eq. 22.*

RESULTS AND DISCUSSION

The calculated values for the electronic indexes appearing in Eq. 21 are summarized in Tables III and IV. The statistical fitting of Eq. 21 was performed by means of stepwise linear regression techniques with pI_{50} as the dependent variable and the electronic indexes as independent variables. More than 400 combinations of electronic indexes were performed; the best correlated expression found is Eq. 2 , where the numerical values for the coefficients of Eq. 21 are shown:

$$pI_{50} = 31.806 + 11.782\, Q_9 + 140.546\, S_9^{(e)} + 14.405\, Q_6 + 18.199\, S_6^{(e)} + 42.378\, Q_5 - 28.496\, S_5^{(e)} + 22.284\, Q_{13} - 101.543\, S_{13}^{(e)} + 63.959\, S_8^{(e)} \quad \text{(Eq. 22)}$$

Table V—t-Test for Significance of Coefficients in Eq. 22

Variable	t Value	p
Q_9	13.003	<0.0005
$S_9^{(e)}$	10.307	<0.0025
Q_6	10.165	<0.0025
$S_2^{(e)}$	2.32	= 0.05
$S_8^{(e)}$	10.684	<0.0025
Q_5	10.491	<0.0025
$S_5^{(e)}$	9.291	<0.0025
Q_{13}	10.608	<0.0025
$S_{13}^{(e)}$	13.067	<0.005

Equation 22 has a multiple correlation coefficient (R) of 0.999 that represents a significance better than 99.9%, a mean standard deviation (MSD) of 0.011_7, and a residual standard deviation (RSD) of 0.042_4. A detailed statistical analysis is given in the *Appendix*.

The next best correlation is given by:

$$pI_{50} = 34.157 + 16.215\,Q_9 + 139.164\,S_9^{(e)} + 10.245\,Q_6 + 24.402\,Q_5 + 14.753\,Q_{13} - 75.452\,S_{13}^{(e)} + 32.385\,S_8^{(e)} \quad \text{(Eq. 23)}$$

with the following statistical parameters: $R = 0.972$, $MSD = 0.053_2$, and $RSD = 0.192$.

The pI_{50} values taken from the literature (1–8) and the ones estimated by Eq. 22 are summarized in Table II, which also shows the estimated equilibrium constants. The experimental pI_{50} values are fitted *versus* the calculated ones in Fig. 2.

As can be derived from Eq. 22, the inhibitory activity was not closely related to any individual atomic property but to a definite set of electronic indexes located on some tricyclic system atoms. The electrophilic index $S_9^{(e)}$ was the most important term influencing the activity. The inhibitory activity of any aromatic β-carboline could be predicted from the corresponding electronic indexes of its ring atoms using Eq. 22. The significant features from the statistical analysis were:

1. The electronic indexes corresponding to pyridine nitrogen, N_2, did not appear in any tested regression giving an acceptable statistical analysis.
2. The same circumstance was observed for C_1, C_3, and C_4 belonging to the pyridine β-carboline fragment.
3. The benzene fragment electronic indexes, as well as the pyrrole fragment indexes, showed the best correlation found for the entire β-carboline indolic part.
4. In all significant regressions studied, the Q_9 and $S_9^{(e)}$ indexes gave important contributions to the regression.

Only the indole fragment is involved in β-carboline–enzyme complex formation. The pyridine nitrogen, N_2, is essential to the inhibitory activity of β-carbolines but does not contribute to the complex formation.

From an electronic point of view, the indole group exhibited a delocalized charge with some accumulations and depletions over its atoms (Table III); it was a good system to form molecular or π-electronic complexes. The pyridine nitrogen is an electron donor system, responsible for the basicity of β-carbolines. The electronic characteristics of both molecular regions are responsible for the interaction with monoamine oxidase. β-Carbolines and monoamine oxidase form a molecular complex on which the molecules are linked by two interactions. The first one arises from the molecular electronic complex between the β-carboline indole fragment and a suitable fixing region of monoamine oxidase (Fig. 3). This

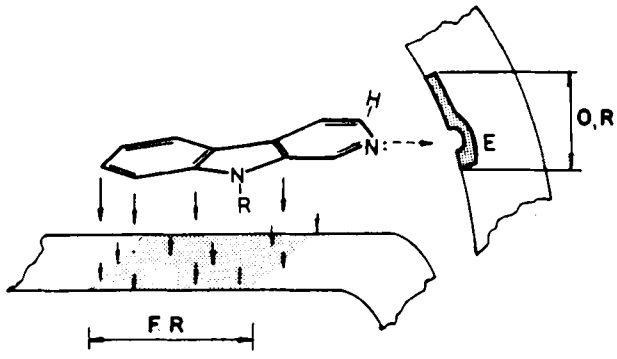

Figure 3—*Interaction model between inhibitor and enzyme. FR = fixing region, and OR = oxidizing region.*

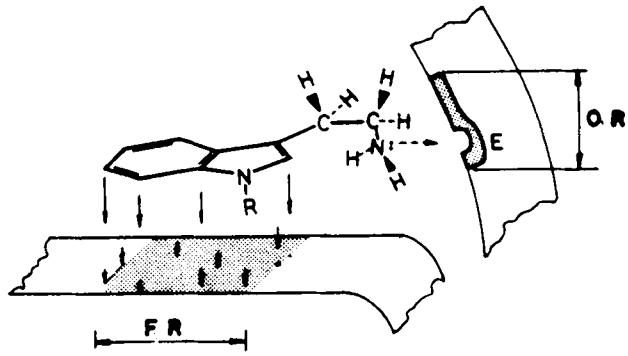

Figure 4—*Interaction model between tryptamine and the enzyme.*

complex has π-complex characteristics, like Mulliken's external complex ($b\pi$–$a\pi$) (30). The indole system acts as an electron donor by means of N_9, C_6, and C_8.

The second interaction is due to pyridine nitrogen, N_2, which acts as an electron donor over an electrophilic monoamine oxidase center located in a region identified as OR (oxidizing region) (Fig. 3). This interaction must be stronger than the former because of its electronic nature. Such a model involves specific structures at the enzyme interaction regions, the so-called FR and OR. The OR interacts with N_2 by means of a strong bond (dative covalent, hydrogen bonding, *etc.*). The FR must have a delocalized structure to match the electronic singularities of the inhibitor indole fragment. Some kind of conformational change is involved in the enzyme itself in order to bind adequately to the inhibitor.

Such a model adequately explains the competitive inhibition of tryptamine and probably of other aromatic cerebral amines. Tryptamine has an indole structure that can form a complex with the enzyme FR in a similar mode to β-carboline. Also, the tryptamine side chain can take a suitable conformation facing the nitrogen of the amino group to the enzyme OR (Fig. 4). In such a conformation, the nitrogen atom reacts, breaking the C–N bond and initiating the oxidative degradation that inactivates the amine. After the oxidation, the complex between the indole fragment and the FR region opens again, releasing the inactivated product.

The inhibitory β-carboline behavior can be explained as the result of a mimetic mechanism forming the same bonds with the same enzymatic regions; the difference is that β-carboline cannot be oxidized because of the stability of its delocalized electronic structure. If such a model works, the competition for the formation of the complex with the enzyme and, consequently, the inhibitory activity are due to the more stable complexes formed by β-carbolines with the enzyme FR than by tryptamine. Thus, the tryptamine–FR complex stability is estimated using Eq. 22, with the electronic indexes corresponding to the indole group of tryptamine (Tables III and IV). A value of 3.15×10^6 liters/mole was found for the equilibrium constant in the reaction tryptamine + FR(enzyme) ⇌ complex.

This value is similar to those found for β-carbolines (Table II). From Table II, it can be seen that the greatest inhibitory activity belongs to the greatest difference between the estimated equilibrium constants of β-carboline and tryptamine. Such a result sustains the model proposed.

APPENDIX

The analysis of variance of Eq. 22 gives $F_{9,3} = 208.53$, giving a very high significance for this equation ($p < 0.0005$). The t-test values of the coefficients of Eq. 22 are shown in Table V. All of them are significant (significance limits of 95–99.9%); consequently, the corresponding indexes influence the values of pI_{50} and K_i.

The introduction or elimination of any other index decreases substantially the regression equation significance level.

Finally, the regression equation referring to the β-carboline benzene ring atoms, together with their most important statistical parameters, are:

$$pI_{50} = 33.991 + 31.452\,S_6^{(e)} + 8.732\,Q_6 + 16.228\,S_7^{(e)} + 97.778\,Q_7 - 28.030\,S_{13}^{(e)} + 14.143\,Q_{13} - 30.809\,S_5^{(e)} + 172.652\,S_8^{(e)} + 133.849\,Q_{12} \quad \text{(Eq. A1)}$$

with $RSD = 0.100$, $R = 0.995$, $MSD = 0.028$, $F_{9,3} = 37.12$, and $p < 0.01$. The equation of regression and the statistical parameters for the atoms

of the pyrrole fragment are:

$$pI_{50} = 105.773 + 503.033\,S_9^{(e)} + 27.992\,Q_9 - 183.106\,S_{13}^{(e)} + 8.801\,Q_{13} - 62.903\,S_{11}^{(e)} - 176.198\,Q_{11} - 46.928\,Q_{12} - 63.207\,Q_{10} \quad \text{(Eq. A2)}$$

with $RSD = 0.10$, $R = 0.994$, $MSD = 0.028$, $F_{8,4} = 41.67$, and $p < 0.005$. These correlations are poorer than the one found for the indole group.

New Biphenyl Derivatives II: 1-(4-Biphenylyl)-1-hydroxy-2-aminoethanes and 1-(4-Biphenylyl)-1-chloro-2-aminoethanes as Potential β-Adrenoceptor Blocking Agents

RAGAB M. SHAFIK ˣ and ABDEL-FATTAH A. A. ASKAR

Received September 6, 1978, from the *Department of Pharmaceutical Chemistry, Faculty of Pharmacy, University of Alexandria, Alexandria, Egypt.* Accepted for publication December 5, 1978.

Abstract □ Series of 1-(4-biphenylyl)-1-hydroxy-2-aminoethanes and 1-(4-biphenylyl)-1-chloro-2-aminoethanes were synthesized. Newly developed reaction conditions for aryl aminomethyl ketone reduction and reductive alkylation, using sodium borohydride, are described. The prepared compounds were examined for adrenergic blocking activity on an anesthetized dog blood pressure preparation and on isolated toad hearts. β-Adrenergic blockade was investigated using isoproterenol as the agonist. The benzylamino and cyclohexylamino analogs exhibited marked β-adrenoceptor blocking activity, for which the latter derivatives were more potent.

Keyphrases □ β-Adrenergic blocking activity—biphenyl derivatives, synthesis, structure–activity relationships □ Biphenyl derivatives, various—synthesized, evaluated for β-adrenergic blocking activity, structure–activity relationships □ Structure–activity relationships—biphenyl derivatives, β-adrenergic blocking activity

Optimum β-adrenoceptor blockade occurs when 1-phenyl-1-hydroxy-2-aminoethane structures (I) bear certain substituents at the phenyl 4- or 3,4-position and an isopropyl grouping on the amine head (1). 1-(3,4-Dichlorophenyl)-1-hydroxy-2-isopropylaminoethane (2) (II), 1-(2-naphthyl)-1-hydroxy-2-isopropylaminoethane (pronethalol) (3, 4) (III), and 1-(4-nitrophenyl)-1-hydroxy-2-isopropylaminoethane (5) (IV) are well-known examples.

In vitro hydrolysis of 1-aryl-1-chloro-2-aminoethanes to 1-aryl-1-hydroxy-2-aminoethanes was used to prepare a series of 1-chloro-2-aminoethanes related to III (6, 7).

I: $R_1 = R_2 = R_3 = H$
II: $R_1 = R_2 = Cl$, $R_3 = CH(CH_3)_2$
III: R_1 and R_2 = parts in naphthalene ring, $R_3 = CH(CH_3)_2$
IV: $R_1 = NO_2$, $R_2 = H$, $R_3 = CH(CH_3)_2$

Their β-adrenergic blockade was concordant with that given by their corresponding 1-hydroxy-2-aminoethanes, thus proving the presumed *in vivo* hydrolysis. β-Adrenergic blockade studies on compounds possessing other phenyl or substituted phenyl groupings on the I aromatic function were unreported. Interest in new biphenyl derivatives (8) prompted the synthesis and subsequent pharmacological testing of some 1-biphenylyl-2-aminoethane (V) derivatives. The present investigation describes the preparation and preliminary biological evaluation of 1-(4-biphenylyl)-1-hydroxy-2-aminoethanes (VI) and their corresponding 1-chloro analogs (VII).

RESULTS AND DISCUSSION

Chemistry—Halohydrin amination and aminomethyl ketone reduction and/or reductive alkylation using any previously reported conditions (9), were unreliable for production of VI. The present work is confined to the reduction and reductive alkylation approaches using sodium borohydride. In this respect, the observed differences in reactivities for the various aryl aminomethyl ketones is believed to result from a shift in the keto–enol equilibrium that should exist at pH 8 (Scheme I) and which might be due to the aromatic function resonance contribution.

The most pronounced effect was given by the biphenylyl radical; its aminomethyl ketone could exist almost entirely as the enol (X). The latter would be converted completely to the enolate anion (XI) at pH > 8, leading to decomposition demonstrated by a darkening in the solution color. The predominance of X at pH 8 was substantiated by primary aminomethyl ketone stability at such a pH and by the failure of 4-biphenylyl aminomethyl ketone hydrochloride (XIII) acetylation at pH > 8.

These observations also were supported by the similarity in chemical behavior between derivatives of 2-aminophenol and X. The most important properties were the ability of both groups to undergo diazotization (10) and to give the characteristic phenol ferric chloride test. The enol form of the secondary aminomethyl ketone derivative, 4-biphenylyl isopropylaminomethyl ketone (XVI*a*), solubilized in caustic alkali solutions without appreciable decomposition. Moreover, a stable enol form for the secondary amino derivative 4-biphenylyl anilinomethyl ketone (XVI*b*), namely 1-(4-biphenylyl)-1-hydroxy-2-anilinoethene (XVII), could be isolated.

Sodium borohydride ketonic group reduction *via* hydride-ion transfer followed by exchange with the hydroxylic solvent requires reactive borohydride anion production through sodium borohydride alkalinity (11). Such alkalinity ordinarily would not interfere with the reduction if the equilibrium (Scheme I) were shifted toward the keto form (IX); otherwise, an increase in the enol form (X) equilibrium shift would effect the conversion to the enolate anion (XI), resulting in decomposition rather than reduction of the aminomethyl ketone. The latter effect was prominent with XIII due to its relatively strong acidic enol form.

To maintain the medium pH at ≃ 8, polyhydroxy compounds, *e.g.*, glycerol and mannitol, were incorporated into the reaction mixture. Their ability to react with the liberated boric acid from sodium borohydride produced stronger acids. The best reduction medium was methanol–glycerol–water. For reductive alkylation, the produced glyceroboric acid could also catalyze the initial Schiff-base formation step with aldehydes or ketones. Water provided H^+ and OH^- ions necessary for the reaction. The described reductive alkylation procedure was applied successfully with aliphatic and aromatic aldehydes as well as with aliphatic and alicyclic ketones.

The synthesis of VI and VII (Table I) is outlined in Scheme II. The required 4-biphenylylaminomethyl ketones (XVI) were obtained by 4-biphenylylbromomethyl ketone amination (XII) (12). The primary aminomethyl ketone (XIII) key intermediate was prepared by reacting XII with hexamine in carbon tetrachloride followed by hydrolysis of the separated adduct. Treatment of a cooled aqueous XIII suspension with acetic anhydride and sodium acetate afforded the 4-biphenylylacetamidomethyl ketone (XIV).

The unexpected strong liability for dehydration of XIV to 5-(4-biphenylyl)-2-methyloxazole (XV) was seen upon treatment with aluminum isopropoxide in isopropanol under the usual Meerwein–Ponndorf–Verley reduction conditions. Unequivocal synthesis of XV was achieved by refluxing a XIV solution in acetic anhydride. The described reduction and reductive alkylation processes were applied for the preparation of the different 1-(4-biphenylyl)-1-hydroxy-2-aminoethanes (VI)

[a] Recrystallization was done from methanol–ethyl acetate. [b] Hydrochloride. [c] Lit. (16) mp 209–211° dec. [d] Acetone was used. [e] Admixture of the products obtained by Methods C and D showed no melting-point depression. [f] Lit. (16) mp 175–177°. [g] Isobutyraldehyde was used. [h] Methyl ethyl ketone was used. [i] Hydrobromide. [j] Benzaldehyde was used. [k] Cyclohexyl. [l] Cyclohexanone was used.

from XIII and XVI*a*. The 1-(4-biphenylyl)-1-chloro-2-aminoethanes (VII) were produced by reacting the appropriate VI with thionyl chloride, either in chloroform or benzene (6). Structures were confirmed by IR and PMR studies.

Pharmacology—Compounds VI*a*–VI*f* and VII*a*–VII*f* were tested for cardiovascular activity on an anesthetized dog blood pressure preparation and isolated toad hearts. β-Adrenoceptor blocking was investigated using isoproterenol as the agonist.

For the anesthetized dog blood pressure method (13), anesthesia was induced by ether inhalation and was maintained by intravenous chloralose–urethan. The compounds were dissolved in water and injected into the femoral vein, and blood pressure was recorded from the carotid artery. The dose levels were 3×10^{-5} and 15×10^{-4} mole/kg. Each biphenylylhydroxyaminoethane and its chloro analog (VI*b* and VII*b*) gave the same type and magnitude of biological activity. No hypotensive effect was observed for the primary amine derivatives (VI*a* and VII*a*).

Table II compares the hypotensive effects obtained for VI*b*–VI*f* and VII*b*–VII*f*. With the exception of the cyclohexylamino derivatives (VI*f* and VII*f*), the hypotensive effects for all other *N*-substituted analogs (VI*b*–VI*e* and VII*b*–VII*e*) were not antagonized by pronethalol. On the other hand, they antagonized the epinephrine agonist effect in the order isopropylamino (VI*b* and VII*b*) > benzylamino (VI*e* and VII*e*) > *sec*-butylamino (VI*c* and VII*c*) > isobutylamino (VI*d* and VII*d*) derivatives.

Compounds VI*b* and VII*b* did not display any isoproterenol antagonism. The other *N*-substituted analogs (VI*c*–VI*f* and VII*c*–VII*f*) exhibited isoproterenol antagonism of the order cyclohexylamino (VI*f* and VII*f*) > benzylamino (VI*e* and VII*e*) ≫ *sec*-butylamino (VI*c* and VII*c*) > isobutylamino (VI*d* and VII*d*) derivatives. In all cases, gradual β-blockade onset was observed. Table II indicates that VI*b* and VII*b* might possess α-adrenoceptor blocking activity whereas VI*e*, VI*f*, VII*e*, and VII*f* revealed significant β-adrenoceptor blockades.

For the isolated toad heart method (14), the doses were 3×10^{-5} and 3×10^{-4} mole/ml. The experiments showed hypotensive effects for all tested compounds. This effect could not be blocked by atropine (3×10^{-5} mole/ml) and thus indicated direct myocardial depression. Isoproterenol antagonism, *i.e.*, β-blockade, was only exhibited by VI*e* and VII*e* and VI*f* and VII*f* analogs. The most pronounced effect was produced by VI*f* and VII*f*.

EXPERIMENTAL[1]

4-Biphenylylaminomethyl Ketone Hydrochloride (XIII)—A hot suspension of hexamine (9.8 g, 0.07 mole) in carbon tetrachloride (100 ml) was gradually added to a hot stirred XII solution (13.8 g, 0.05 mole) in carbon tetrachloride (50 ml). The reaction mixture was stirred for 1.5

[1] IR spectra were determined on a Unicam SP 200 spectrophotometer with Nujol mulls. PMR spectra were determined on a Perkin-Elmer R 12 spectrometer with tetramethylsilane as the internal standard. Melting points were determined in open glass capillaries and are uncorrected. Microanalyses were performed by the Microanalytical Unit, Faculty of Science, University of Cairo, Cairo, Egypt.

Table II—Comparison of the Hypotensive Effects[a] of VIb–VIf and VIIb–VIIf Using the Anesthetized Dog Blood Pressure Method

Compound[b,c]	Mean Percent Reduction[d] of Agonist Response ± SE: Epinephrine[b] Antagonism	Isoproterenol[e] Antagonism

VIIe	12.50 ± 1.44	47.50 ± 1.44
VIIf[f]	—	64.17 ± 0.83

[a] Not antagonized by pronethalol (3×10^{-5} mole/kg). [b] The dose used was 15×10^{-4} mole/kg. [c] Aqueous solutions were used. [d] Average of three experiments. [e] The dose was 3×10^{-5} mole/kg. [f] The hypotensive effect was antagonized by pronethalol (3×10^{-5} mole/kg).

hr. It was then refluxed for 1 hr, cooled, diluted with acetone (50 ml), and filtered. The crude adduct, 4-biphenylylhexamethylene tetraammonium methyl ketone bromide, was triturated with cold ethanol, filtered, and dried in air. The yield was 17.5 g (84%), mp 162°.

Hydrolysis of the adduct (12.5 g, 0.03 mole) was affected by brief heating on a water bath with ethanol (50 ml) and concentrated hydrochloric acid (9 ml). The reaction mixture was treated with 10% HCl dropwise until turbidity appeared. It was then decolorized by boiling with charcoal, filtered, concentrated *in vacuo*, and left to crystallize. The product was recrystallized from 10% HCl to yield 5.6 g (74%) of product, mp > 300°; IR: 3000 (b, NH_3^+) and 1680 (C=O) cm^{-1}.

Anal.—Calc. for $C_{14}H_{14}ClNO$: C, 67.8; H, 5.7; Cl, 14.4; N, 5.6. Found: C, 67.4; H, 5.8; Cl, 14.0; N, 5.3.

4-Biphenylylacetamidomethyl Ketone (XIV)—Acetic anhydride (3.1 g, 0.03 mole) was added, in one portion, to a XIII suspension (3.7 g, 0.015 mole) in water (25 ml) and crushed ice (50 g). The mixture was treated dropwise, while being stirred, with a sodium acetate solution (5 g, 0.06 mole) in water (20 ml) at a rate such that the temperature was not allowed to rise above 5°. The reaction mixture was allowed to reach room temperature and was treated with 10% HCl (20 ml).

The product was filtered, washed with water several times, dried, and recrystallized from benzene–petroleum ether (bp 40–60°). The yield was 2.6 g (71%), mp 164–166° [lit. (15) mp 151°]; IR: 3400 (NH), 1685 (C=O), and 1645, 1550, and 1295 (amide I, II, and III, respectively) cm^{-1}.

Anal.—Calc. for $C_{16}H_{15}NO_2$: C, 75.9; H, 6.0; N, 5.4. Found: C, 75.7; H, 5.9; N, 5.3.

5-(4-Biphenylyl)-2-methyloxazole (XV)—*Method A*—Under strictly anhydrous conditions, a stirred mixture of XIV (1.2 g, 0.005 mole) and an aluminum isopropoxide solution (1.5 g, 0.0075 mole) in dry isopropanol (50 ml) was heated at 90° in a 100-ml flat-bottom flask. The flask was fitted with a reflux air condenser and an upper distillation head, which was attached to a downside condenser connected to a water pump *via* a buchner receiver. The reaction mixture was distilled slowly, at a rate not exceeding 7–10 drops/min at 40 mm Hg. No acetone was detected in the distillate collected during 1.5 hr.

The residue was cooled, and the remaining complex was treated with crushed ice. The mixture was extracted with benzene, washed with water, dried over anhydrous sodium sulfate, and filtered; then the solvent was removed *in vacuo*. The product was recrystallized from benzene–petroleum ether (bp 40–60°) to yield 0.9 g (76%), mp 167°.

Method B—A mixture of XIV (1.2 g, 0.005 mole) and acetic anhydride (20 g, 0.2 mole) was refluxed for 30 min. The reaction mixture was concentrated *in vacuo* to a small volume and then treated with crushed ice. The medium was made alkaline with sodium carbonate, and the product was filtered, washed with water, dried, and recrystallized from benzene–petroleum ether (bp 40–60°). The yield was 0.95 g (80%), mp 167°.

Admixture of the products obtained by Methods A and B showed no melting-point depression; IR: 1670 (C=N) and 1240 (aromatic C–O–C) cm^{-1}.

Anal.—Calc. for $C_{16}H_{13}NO$: C, 81.7; H, 5.6; N, 6.0. Found: C, 82.0; H, 5.2; N, 6.0.

4-Biphenylylisopropylaminomethyl Ketone (XVIa) Hydrochloride—A solution of isopropylamine (0.59 g, 0.01 mole) in carbon tetrachloride (20 ml) was gradually added, with stirring, to a solution of XII (2.8 g, 0.01 mole) in carbon tetrachloride (20 ml) at 0°. The stirring was maintained for an additional 2 hr. The reaction mixture was refluxed for 30 min, cooled, and extracted with 5 *N* NaOH. The alkaline extract was washed twice with benzene and made strongly acidic with concentrated hydrochloric acid. The product was filtered, washed with acetone, and recrystallized from methanol–ethyl acetate. The yield was 0.5 g (17%); IR: 2750 (NH_2^+) and 1680 (C=O) cm^{-1}.

Anal.—Calc. for $C_{17}H_{20}ClNO$: C, 70.4; H, 6.9; Cl, 12.2; N, 4.9. Found: C, 70.2; H, 6.6; Cl, 12.5; N, 4.5.

4-Biphenylylanilinomethyl Ketone (XVIb) and 1-(4-Biphenylyl)-1-hydroxy-2-anilinoethene (XVII)—A solution of aniline (0.93 g, 0.01 mole) in carbon tetrachloride (20 ml) was gradually added, with stirring, to a solution of XII (2.8 g, 0.01 mole) in carbon tetrachloride (20 ml) at 0°. The stirring was maintained for an additional 2 hr. The reaction mixture was refluxed for 30 min, cooled, and shaken with 5 *N* NaOH (20 ml). The carbon tetrachloride layer was washed twice with water and dried over anhydrous sodium sulfate, and the solvent was removed *in vacuo*.

The residue was boiled with methanol and filtered. From the methanolic extract, XVIb was crystallized out as colorless needles to yield 0.3 g (10%), mp 125–128°. The methanol-insoluble fraction was recrystallized from acetone as bright-yellow flakes (XVII) to yield 2.1 g (70%), mp 185–186°. The colorless XVIb changed to the yellow XVII within 84 hr at room temperature; IR (XVIb): 3390 (C=O) cm^{-1}; IR (XVII): 3410 (NH) and 3100 (b, OH) cm^{-1}; PMR (XVII, $CDCl_3$): δ 4.60 (s, 1H, OH), 4.90 (b, 1H, NH), 7.20 (m, 1H, CH), and 8.10 (m, 14H, aromatic) ppm.

Anal.—Calc. for $C_{20}H_{17}NO$: C, 83.6; H, 6.0; N, 4.9. Found: C, 83.3; H, 6.1; N, 4.8.

1-(4-Biphenylyl)-1-hydroxy-2-aminoethanes—*Method C (VIa and VIb)*—Sodium borohydride (0.95 g, 0.025 mole) was added in portions during 1.5 hr to a 0° cooled and stirred mixture of the appropriate 4-biphenylylaminomethyl ketone (XIII and XVIa, 0.01 mole), glycerol (23 g, 0.25 mole), water (2 ml), and methanol (100 ml). Cooling and stirring were maintained for 3 hr, and the reaction mixture was stirred at room temperature for a further 15 hr. It was then treated with concentrated hydrochloric acid dropwise until just acidic to litmus, concentrated *in vacuo*, and made strongly alkaline with 5 *N* NaOH. The product was extracted with benzene, washed twice with water, dried over anhydrous sodium sulfate, and filtered. Dry hydrogen chloride gas was bubbled into the filtrate, and the separated salt was collected and recrystallized.

Method D (VIb–VIf)—Sodium borohydride (1.4 g, 0.036 mole) was added in portions during 1.5 hr to a 0° cooled and stirred mixture of XIII (2.75 g, 0.01 mole), the proper aldehyde or ketone (0.1 mole), glycerol (33.2 g, 0.36 mole), water (2 ml), and methanol (100 ml). The reaction mixture was worked up as detailed under *Method C*, and the appropriate salt was prepared in the usual manner and recrystallized; IR (VIa–VIf): 3350–3300 (OH) and 2500–2400 (with several splits, NH_2^+) cm^{-1}; PMR (VIb, CD_3OD–$CDCl_3$): δ 1.35 (d, 6H, $2CH_3$ of isopropyl), 3.10 (m, 2H, methylene), 3.40 (m, 1H, CH of isopropyl), 5.15 (m, 1H, CH), 6.85 (b, 1H, OH), 7.45 (m, 9H, aromatic), and 8.15 (b, 1H, NH) ppm.

1-(4-Biphenylyl)-1-chloro-2-aminoethanes (VII)—*Method E*—Thionyl chloride (2.4 g, 0.02 mole) was added dropwise to a stirred suspension of the proper VI (0.01 mole) in either chloroform or benzene (75 ml). The reaction mixture was refluxed for 1.5 hr, and the solvent was removed *in vacuo*. The residue was recrystallized.

Modified USP Assay for Simultaneous Determination of Aspirin and Nonaspirin Salicylates in Aspirin and Buffered Aspirin Tablets

JOSEPH R. LUBER ˣ, ANTHONY J. VISALLI, and DAHYABHAI M. PATEL

Received October 6, 1978, from the *Analytical and Physical Chemistry Department, Research and Development Division, William H. Rorer, Inc., Fort Washington, PA 19034.* Accepted for publication December 14, 1978.

Abstract □ Modified USP procedures are described for the simultaneous determination of nonaspirin salicylates and aspirin in aspirin and buffered aspirin tablets. The existing USP procedures are not stability indicating for intact aspirin when significant levels of nonaspirin salicylates are present, as is often the case in short-term, high temperature stability programs. The modified procedures yield considerably shorter analysis times and stability-indicating assays for intact aspirin without the need for sophisticated equipment other than that presently required by USP XIX.

Keyphrases □ Aspirin—analysis, modified USP method, liquid chromatography, spectrophotometry, stability, buffered and unbuffered tablets □ Liquid chromatography—analysis, aspirin in buffered and unbuffered tablets, modified USP method, stability □ Analgesics—aspirin, analysis, buffered and unbuffered tablets, modified USP method, liquid chromatography, spectrophotometry, stability

The USP methods (1) for the quantitative determination of aspirin and nonaspirin salicylates in aspirin and buffered aspirin tablets are time consuming and nonspecific for evaluation of intact aspirin stability. The aspirin assay is based mainly on the work of Levine (2). A sample preparation in chloroform is passed through a sodium bicarbonate-treated, infusorial earth-packed column, which separates aspirin from tablet excipients. Following its elution, the aspirin is quantitated spectrophotometrically.

Although the method is reliable for production control, its accuracy as a stability-indicating assay is questionable because it does not isolate aspirin from its degradation product salicylic acid. Since the bicarbonate column concurrently traps both aspirin and salicylic acid, the result of their simultaneous elution is a positive interference in the aspirin UV absorption at 280 nm.

Another weakness in the USP method is that separate procedures are required for the aspirin and nonaspirin salicylates assays; hence, the complete analysis of aspirin tablets is quite lengthy. The USP nonaspirin salicylates assay is based on several studies (3–7). A sample is triturated in chloroform in the presence of citric acid monohydrate. Insoluble salts of aspirin or salicylic acid, if present, are converted to chloroform-extractable free acids by hydrochloric acid. Finally, the salicylic acid is separated from aspirin using an infusorial earth column treated with ferric chloride and urea, which complexes salicylic acid. The salicylic acid is eluted and quantitated spectrophotometrically.

This paper reports a modified USP method that simultaneously determined aspirin and nonaspirin salicylates in aspirin and buffered aspirin dosage forms. Complexing the nonaspirin salicylates on a ferric chloride–urea infusorial earth column and collecting the intact aspirin eluate achieved effective separation. Aspirin in the eluate was determined spectrophotometrically. The complexed nonaspirin salicylates were eluted and likewise determined spectrophotometrically. The results of this modification were a considerably shorter analysis time, a stability-indicating assay for aspirin, and a method that could be performed without sophisticated equipment other than that already required by the USP.

EXPERIMENTAL

Reagents and Chemicals—All chemicals and reagents were USP or ACS grade and were used without further purification.

Aspirin Tablet Assay—*Chromatographic Column*—A column was packed as described under the nonaspirin salicylates procedure in the USP. It was washed with a 25-ml portion of chloroform.

Aspirin Standard Preparation—About 50 mg of USP aspirin reference standard, accurately weighed, was dissolved in glacial acetic acid–chloroform (1:99) and diluted to 50 ml in a volumetric flask. A 5.0-ml portion was transferred to a 100-ml volumetric flask containing 2.0 ml of methanol, diluted to volume with glacial acetic acid–chloroform, and mixed.

Salicylic Acid Standard Preparation—A suitable, accurately weighed, quantity of salicylic acid was dissolved in chloroform to obtain a solution containing 30 μg of salicylic acid/ml. A 5.0-ml portion was transferred

Table I—Recovery of Added Aspirin (50.00 mg) by USP Procedure

Salicylic Acid Added, mg	Aspirin Recovered, mg	Recovery, %
0.00	50.00	100.0
0.75	50.35	100.7
1.50	50.95	101.9
2.25	51.50	103.0
3.00	52.10	104.2

Modified USP Assay for Simultaneous Determination of Aspirin and Nonaspirin Salicylates in Aspirin and Buffered Aspirin Tablets

JOSEPH R. LUBER ˣ, ANTHONY J. VISALLI, and DAHYABHAI M. PATEL

Received October 6, 1978, from the *Analytical and Physical Chemistry Department, Research and Development Division, William H. Rorer, Inc., Fort Washington, PA 19034.* Accepted for publication December 14, 1978.

Abstract □ Modified USP procedures are described for the simultaneous determination of nonaspirin salicylates and aspirin in aspirin and buffered aspirin tablets. The existing USP procedures are not stability indicating for intact aspirin when significant levels of nonaspirin salicylates are present, as is often the case in short-term, high temperature stability programs. The modified procedures yield considerably shorter analysis times and stability-indicating assays for intact aspirin without the need for sophisticated equipment other than that presently required by USP XIX.

Keyphrases □ Aspirin—analysis, modified USP method, liquid chromatography, spectrophotometry, stability, buffered and unbuffered tablets □ Liquid chromatography—analysis, aspirin in buffered and unbuffered tablets, modified USP method, stability □ Analgesics—aspirin, analysis, buffered and unbuffered tablets, modified USP method, liquid chromatography, spectrophotometry, stability

The USP methods (1) for the quantitative determination of aspirin and nonaspirin salicylates in aspirin and buffered aspirin tablets are time consuming and nonspecific for evaluation of intact aspirin stability. The aspirin assay is based mainly on the work of Levine (2). A sample preparation in chloroform is passed through a sodium bicarbonate-treated, infusorial earth-packed column, which separates aspirin from tablet excipients. Following its elution, the aspirin is quantitated spectrophotometrically.

Although the method is reliable for production control, its accuracy as a stability-indicating assay is questionable because it does not isolate aspirin from its degradation product salicylic acid. Since the bicarbonate column concurrently traps both aspirin and salicylic acid, the result of their simultaneous elution is a positive interference in the aspirin UV absorption at 280 nm.

Another weakness in the USP method is that separate procedures are required for the aspirin and nonaspirin salicylates assays; hence, the complete analysis of aspirin tablets is quite lengthy. The USP nonaspirin salicylates assay is based on several studies (3–7). A sample is triturated in chloroform in the presence of citric acid monohydrate. Insoluble salts of aspirin or salicylic acid, if present, are converted to chloroform-extractable free acids by hydrochloric acid. Finally, the salicylic acid is separated from aspirin using an infusorial earth column treated with ferric chloride and urea, which complexes salicylic acid. The salicylic acid is eluted and quantitated spectrophotometrically.

This paper reports a modified USP method that simultaneously determined aspirin and nonaspirin salicylates in aspirin and buffered aspirin dosage forms. Complexing the nonaspirin salicylates on a ferric chloride–urea infusorial earth column and collecting the intact aspirin eluate achieved effective separation. Aspirin in the eluate was determined spectrophotometrically. The complexed nonaspirin salicylates were eluted and likewise determined spectrophotometrically. The results of this modification were a considerably shorter analysis time, a stability-indicating assay for aspirin, and a method that could be performed without sophisticated equipment other than that already required by the USP.

EXPERIMENTAL

Reagents and Chemicals—All chemicals and reagents were USP or ACS grade and were used without further purification.

Aspirin Tablet Assay—*Chromatographic Column*—A column was packed as described under the nonaspirin salicylates procedure in the USP. It was washed with a 25-ml portion of chloroform.

Aspirin Standard Preparation—About 50 mg of USP aspirin reference standard, accurately weighed, was dissolved in glacial acetic acid–chloroform (1:99) and diluted to 50 ml in a volumetric flask. A 5.0-ml portion was transferred to a 100-ml volumetric flask containing 2.0 ml of methanol, diluted to volume with glacial acetic acid–chloroform, and mixed.

Salicylic Acid Standard Preparation—A suitable, accurately weighed, quantity of salicylic acid was dissolved in chloroform to obtain a solution containing 30 μg of salicylic acid/ml. A 5.0-ml portion was transferred

Table I—Recovery of Added Aspirin (50.00 mg) by USP Procedure

Salicylic Acid Added, mg	Aspirin Recovered, mg	Recovery, %

to a 100-ml volumetric flask containing 20.0 ml of methanol, 5 drops of concentrated hydrochloric acid, and 20.0 ml of a 1:9 solution of glacial acetic acid in water-saturated ether. Chloroform was added to volume and mixed.

Assay Preparation—A quantity of finely ground tablets equivalent to 50 mg of aspirin was weighed accurately in a 50-ml beaker. Then 10 ml of chloroform was added, and the beaker was swirled for 3 min. The entire sample was transferred onto the chromatographic column.

Procedure—Without delay, the beaker and column were washed, in portions, with 90 ml of chloroform. The washings were collected in a 100-ml volumetric flask containing 1.0 ml of glacial acetic acid, diluted to volume with chloroform, and mixed. A 10.0-ml portion was transferred to a 100-ml volumetric flask containing 1.0 ml of glacial acetic acid and 2.0 ml of methanol. Chloroform was added to volume and mixed. The absorbances of the assay preparation and the aspirin standard preparation were determined at 278 nm in 1-cm cells *versus* chloroform as the blank.

To the column containing the ferric–salicylate complex was added 20.0 ml of a 1:9 solution of glacial acetic acid in water-saturated ether, followed by 60 ml of chloroform. The eluate was collected in a 100-ml volumetric flask containing 20.0 ml of methanol and 5 drops of concentrated hydrochloric acid. Chloroform was added to volume and mixed. The absorbances of the assay preparation and the salicylic acid standard preparation were determined at 306 nm in 5-cm cells *versus* a blank of the same solvent composition as that of the salicylic acid standard preparation.

Calculations—The quantity, in milligrams, of aspirin per tablet was calculated as follows:

$$\text{mg of aspirin/tablet} = \frac{C(A_u/A_s)(A.W.)}{W} \qquad \text{(Eq. 1)}$$

where C is the concentration, in micrograms of aspirin per milliliter, in the standard preparation; A_u and A_s are the absorbances of the assay preparation and the standard preparation at 278 nm, respectively; $A.W.$ is the average tablet weight; and W is the weight of sample in the assay preparation.

The quantity, in milligrams, of salicylic acid per tablet was calculated as follows:

$$\text{mg of salicylic acid/tablet} = \frac{C(A_u/A_s)(A.W.)}{W} \qquad \text{(Eq. 2)}$$

where C is the concentration, in milligrams of salicylic acid per 100 ml, in the standard preparation; A_u and A_s are the absorbances of the assay preparation and the standard preparation at 306 nm, respectively; $A.W.$ is the average tablet weight; and W is the weight of sample in the assay preparation.

Buffered Aspirin Tablet Assay—*Chromatographic Column*—The column was prepared as directed under *Aspirin Tablet Assay*.

Aspirin Standard Preparation and Salicylic Acid Standard Preparation—These standards were prepared as directed under *Aspirin Tablet Assay* except that the concentrations were doubled.

Table III—Effect of Methanol on Aspirin Assay

Methanol Added, ml	Wavelength Maximum, nm	Absorbance
0.0	279	0.802
2.0	278	0.740
6.0	277	0.702
10.0	276	0.690

Table IV—Assay Results on Commercial Aspirin Tablets

Product	Aspirin, %: Modified Method	Aspirin, %: USP Method	Nonaspirin Salicylates, %: Modified Method	Nonaspirin Salicylates, %: USP Method
A	99.2	99.4	0.09	0.05
B	99.9	99.5	0.10	0.09
C	100.2	99.6	0.07	0.07
D	98.1	98.6	0.04	0.06
E	100.1	100.7	0.04	0.04

Assay Preparation—A quantity of finely ground tablets equivalent to 100 mg of aspirin was weighed accurately in a 50-ml beaker. About 700 mg of citric acid monohydrate and 40 ml of chloroform were added, and the beaker was swirled for 1 min. The mixture was filtered through coarse filter paper into a 200-ml volumetric flask. The beaker and filter paper were rinsed with two 25-ml portions of chloroform, and the rinsings were collected in the volumetric flask.

The filter paper was allowed to dry, and the residue was transferred to a 125-ml separator containing 10 ml of 1 *N* HCl. It was then extracted with two 25-ml portions of chloroform and passed through nonabsorbent cotton into the 200-ml volumetric flask. Chloroform was added to volume and mixed.

Procedure—A 20.0-ml portion of the assay preparation was transferred onto the chromatographic column, and, without delay, the column was washed in portions with 90 ml of chloroform. The washings were collected in a 100-ml volumetric flask containing 1.0 ml of glacial acetic acid and 2.0 ml of methanol, diluted to volume with chloroform, and mixed. The absorbances of the assay preparation and the aspirin standard preparation were determined at 278 nm in 1-cm cells *versus* chloroform as the blank.

The ferric–salicylate complex was eluted from the column, and the absorbance was determined as described under *Aspirin Tablet Assay*.

Calculations—The quantity, in milligrams, of aspirin per tablet was calculated as follows:

$$\text{mg of aspirin/tablet} = \frac{C(A_u/A_s)(10)(A.W.)}{W} \qquad \text{(Eq. 3)}$$

where C is the concentration, in micrograms of aspirin per milliliter, in the standard preparation; A_u and A_s are the absorbances of the assay preparation and the standard preparation at 278 nm, respectively; $A.W.$ is the average tablet weight; and W is the weight of sample in the assay preparation.

The quantity, in milligrams, of salicylic acid per tablet was calculated as follows:

$$\text{mg of salicylic acid/tablet} = \frac{C(A_u/A_s)(10)(A.W.)}{W} \qquad \text{(Eq. 4)}$$

where C is the concentration, in milligrams of salicylic acid per 100 ml, in the standard preparation; A_u and A_s are the absorbances of the assay preparation and the standard preparation at 306 nm, respectively; $A.W.$ is the average tablet weight; and W is the weight of sample in the assay preparation.

RESULTS AND DISCUSSION

Aspirin Recovery by USP Procedure—The interference of salicylic acid with aspirin recovery was studied. Mixtures were prepared in chloroform containing 50.00 mg of aspirin and various amounts of salicylic acid. One milliliter of hydrochloric acid–methanol (1:49) was added to each mixture. The solution was diluted to 50.0 ml with chloroform.

The mixtures were assayed for aspirin content by the USP procedure. As shown in Table I, a positive interference was introduced in the USP aspirin assay, making it nonspecific for stability evaluation of aspirin products.

Table V—Assay Results on Commercial Buffered Aspirin Tablets

Product	Aspirin, %: Modified Method	Aspirin, %: USP Method	Nonaspirin Salicylates, %: Modified Method	Nonaspirin Salicylates, %: USP Method
A	99.4	100.9	0.65	0.64
B	97.1	97.6	0.32	0.37
C	96.6	97.4	0.84	0.82
D	99.2	100.4	0.73	0.73
E	97.3	96.5	0.82	0.82

Linearity of Modified USP Procedure—The linearity for the aspirin tablet and buffered aspirin tablet assays was examined. For the aspirin assay, mixtures of varying amounts of aspirin with 0.15 mg of salicylic acid for the aspirin tablet assay and 3.0 mg of salicylic acid for the buffered aspirin tablet assay were determined. The amounts of salicylic acid added were equivalent to the maximum amount allowed by the USP, assuming sample weights equivalent to 50 and 100 mg of aspirin, respectively. For the nonaspirin salicylates assay, mixtures of varying amounts of salicylic acid with 50 mg of aspirin for the aspirin tablet assay and 100 mg of aspirin for the buffered aspirin assay were determined. The amounts of aspirin added represented the quantity specified in the modified USP procedures.

The aspirin assay was linear in the 0–75- and 0–130-mg ranges for the aspirin tablet assay and the buffered aspirin tablet assay, respectively. The nonaspirin salicylates assay was linear in the 0–0.3- and 0–5.0-mg ranges for the aspirin tablet assay and the buffered aspirin tablet assay, respectively.

Precision of Modified USP Procedures—A statistical evaluation of the precision of the modified methods was performed on the assay results of two sets of six accurately weighed preparations. The sets used contained either ~0.15 mg of salicylic acid and 50 mg of aspirin or 0.30 mg of salicylic acid and 100 mg of aspirin (Table II).

Effects of Methanol on Aspirin Assay—Methanol was used in the modified USP aspirin assay to clarify the column eluate, which was often turbid due to the physical removal of water by chloroform from the chromatographic column. Methanol had to be added accurately to both the assay preparation and the standard preparation since the presence of methanol affected the magnitude of the absorbance and the wavelength maximum of the aspirin peak (Table III). Aspirin was stable in this solvent mixture for at least 6 hr. The absorbance of an aspirin solution at 278 nm after this time was 99.5% of the initial value. After 24 hr, however, the absorbance dropped to 75% of the initial value.

Comparison of Modified USP Assay and USP Assay—The results of studies on several commercially available aspirin and buffered aspirin tablets are summarized in Tables IV and V. The results indicate a good correlation between methods.

Evaluation of Lanolin Alcohol Films and Kinetics of Triamcinolone Acetonide Release

BALASUBRAMANIAN V. IYER and RAVINDRA C. VASAVADA ×

Received June 26, 1978, from the *School of Pharmacy, University of the Pacific, Stockton, CA 95211.* Accepted for publication December 15, 1978.

Abstract □ The film-forming potential of lanolin alcohol was evaluated. Inclusion of ethylcellulose in lanolin alcohol improved film integrity. The hardness and modulus of elasticity of these lanolin alcohol–ethylcellulose films were improved by incorporating propylene glycol or cetyl alcohol. *Triamcinolone acetonide release from selected film compositions was* investigated. The data were analyzed from the viewpoint of the first-order kinetic theory and the release from a planar system having a homogeneous or granular matrix. The results suggest that the drug release follows a diffusion-controlled matrix model and a square root of time release profile. The release rate constants were proportional to drug concentration. Drug release was maximal from a system containing the drug in a near-saturated solution.

Keyphrases □ Lanolin alcohol—films, kinetics of triamcinolone acetonide release, topical dosage forms □ Triamcinolone acetonide—release from lanolin alcohol films, kinetics, topical dosage forms, □ Dosage forms, topical—lanolin alcohol films, kinetics of triamcinolone acetonide release □ Glucocorticoids—triamcinolone acetonide, release from lanolin alcohol films, kinetics

Protective films containing therapeutically active agents have been used for dermatological and surgical applications (1–3). An inert polymeric matrix impregnated with pilocarpine has been utilized to achieve prolonged and steady release of the drug for ocular administration (4). In certain dermatological applications, polymeric films containing a drug could offer advantages over conventional dosage forms. These potential advantages include enhanced therapeutic effect, predictable control over rate and extent of absorption, occlusion of the skin surface, and improved patient acceptance.

Although several polymeric substances have been studied for their film-forming characteristics (5–7) and potential application in topical drug delivery systems, the nonpolymeric, high molecular weight substances apparently have not been investigated. Furthermore, the applicability of this concept to topical drug delivery system design has not been explored fully.

THEORETICAL

Drug release from a planar system having a drug dispersed in a homogeneous insoluble matrix was shown (8) to follow:

$$Q = \sqrt{Dt(2A - C_s)C_s} \qquad \text{(Eq. 1)}$$

where Q is the amount of drug released per unit area at time t, D is the drug diffusion coefficient in the matrix, A is the total amount of drug present in the matrix per unit volume, and C_s is the drug solubility in the matrix. The relationship for release from a planar system having a granular matrix was shown to be (9) diffusion controlled and is given by:

$$Q = \sqrt{\frac{D\epsilon}{\tau}(2A - \epsilon C_s)C_s t} \qquad \text{(Eq. 2)}$$

where D and C_s refer to the diffusion coefficient and drug solubility in the permeating fluid, τ is the tortuosity of the matrix, and ϵ is the porosity of the matrix.

Both these equations describe drug release as being linear with the square root of time:

$$Q = kt^{1/2} \qquad \text{(Eq. 3)}$$

where k is the release rate constant. For a homogeneous matrix system:

$$k = \sqrt{D(2A - C_s)C_s} \qquad \text{(Eq. 4)}$$

and for a granular matrix system:

$$k = \sqrt{\frac{D\epsilon}{\tau}(2A - C_s)C_s} \qquad \text{(Eq. 5)}$$

These relationships were confirmed experimentally using plastic and wax matrixes (10–15).

[a] All films were cast from a 10% (w/v) solution of film formers in isopropyl alcohol. [b] Thicknesses are expressed as mean values of five measurements. [c] Sward hardnesses are expressed as mean values of three measurements rounded to the nearest whole number.

This paper reports a preliminary evaluation of films formed by lanolin alcohol. Propylene glycol or cetyl alcohol was used as the plasticizer and primary solvent for the test drug. The films formed by lanolin alcohol in combination with a known film former, ethylcellulose (16), also were tested in the presence of the mentioned plasticizers. The prepared films were evaluated by measuring the hardness and modulus of elasticity.

This paper also describes studies of drug release from the films of selected compositions, showing the effect of change in proportion of film formers and the plasticizer and the nature of the plasticizer. Triamcinolone acetonide was chosen as the model drug.

EXPERIMENTAL

Materials—The materials used for the preparation of the films were lanolin alcohol[1] (mp 61–64°), ethylcellulose[2], propylene glycol USP[3], and cetyl (hexadecyl) alcohol (cosmetic grade, d 0.84)[4]. Triamcinolone acetonide USP (solubility in distilled water at 37° is 0.03 mg/ml)[5] and 1,2,3(n)-^{3}H-triamcinolone acetonide[6] were used as the drugs. The solvents were isopropyl alcohol NF[7] and anhydrous methanol[7] (spectral grade). A premade dioxane cocktail[8] was the scintillation fluid.

Film Preparations—For the initial screening, all films were cast from a 10% (w/v) solution of film former(s) and plasticizer in isopropyl alcohol. The films were cast on the mercury substrate. Sufficient solution was poured within a stainless steel ring (9.2-cm i.d., 3-mm height, which had been placed on a mercury surface contained in a 140 × 10-mm glass petri dish, and the solution was spread evenly across the mercury surface within the area bound by the ring. The petri dish was partially covered with its lid, and the solvent was allowed to evaporate overnight.

The entire operation was carried out in a humidity-controlled room at 30° and 40% relative humidity (RH). Partially covering the petri dish helped to control the solvent evaporation rate and the blistering of the deposited film surface. Film formation was easily noted by observing the mercury substrate after complete solvent evaporation. The film could be retrieved intact by slowly lifting the ring from the mercury substrate. The isolated films were stored between sheets of wax paper in a desiccator.

Determination of Film Hardness and Modulus of Elasticity—Film hardness was determined on film cast on aluminum plates. For each composition tested, a 10% (w/v) solution of film former(s) and plasticizer was prepared in isopropyl alcohol and was cast on an aluminum plate using an applicator[9] with a wet film thickness of ~1 mm. These plates were then dried in a humidity-controlled room at 30° and 40% RH. The exact thickness of the dried film was determined using a thickness measuring gauge[10]. Film hardness was determined using a hardness tester[11]. The rocker was calibrated before each measurement by checking for 100 oscillations on a standard glass plate. From the Sward hardness R (number of oscillations of rocker on the test film), the modulus of elasticity (E) was calculated with:

$$E = \frac{KR^3}{T^3} \qquad \text{(Eq. 6)}$$

The values of the constant K for thickness (T) were obtained from the literature (17).

Solubility Studies—The solubilities of triamcinolone acetonide in propylene glycol and cetyl alcohol were determined at room temperature (22°) and at 37°.

Solubility was determined by adding excess steroid to 25 ml of propylene glycol or cetyl alcohol in 50-ml glass bottles with screw caps. A polytef-coated magnetic bar was placed in each bottle prior to capping it tightly. The bottles were kept in water baths on magnetic stirrers for 6 days. All studies were conducted in triplicate.

Prior to sampling, the stirring was stopped and the excess steroid was allowed to settle. An aliquot was filtered using a filter[12] with 0.22-μm filter paper. The filtration and sampling apparatus was allowed to equilibrate for 48 hr prior to use. The first 5 ml of the filtrate was rejected in each case to avoid any reduction in solubility values due to steroid adsorption in the filter paper (18). All operations were conducted in a constant-temperature room.

The steroid concentration in the solvent was determined using a scanning spectrophotometer[13] after appropriate dilutions of the solvent

[a] All films were cast from a 10% (w/v) solution of film formers in isopropyl alcohol. [b] Thicknesses are expressed as mean values of five measurements. [c] Sward hardnesses are expressed as mean values of three measurements rounded to the nearest whole number.

with anhydrous methanol. The steroid solubility was determined at 239 nm in propylene glycol and at 265 nm in cetyl alcohol.

Apparent Solubility in Lanolin Alcohol—The apparent solubility was estimated by determining the effective partition coefficient of the steroid in a lanolin alcohol–water system at 22 and 37°.

About 100–200 mg of the melted lanolin alcohol was coated as a thin film in the bottom of a preweighed, 50-ml, flat-bottom polypropylene beaker and allowed to cool to room temperature. The beaker was weighed again to determine the exact film weight. Then 20 ml of a 0.002% (w/v) mixture of cold and radiolabeled triamcinolone acetonide was added. The beaker was covered with Parafilm and kept in a temperature-controlled water bath until equilibrium was reached. One-milliliter samples were withdrawn from the aqueous phase at suitable intervals into a scintillation vial, and 10 ml of scintillation fluid was added to each. They were then analyzed radiochemically using a liquid scintillation counter[14].

The apparent partition coefficient, K_e, was then determined using the equation proposed previously (19):

$$K_e = \frac{A_1/W_1}{A_a/W_a} = \frac{(A_a' - A_a)W_a}{A_a W_1} \qquad \text{(Eq. 7)}$$

where A_1 and A_a are the amounts of the drug in the lanolin alcohol and in the aqueous phase, respectively; A_a' is the initial amount of drug in water; and W_1 and W_a are the weights of lanolin alcohol and water, respectively.

The apparent solubility was calculated from:

$$K_e = \frac{C_s^1}{C_s^w} \qquad \text{(Eq. 8)}$$

where C_s^1 is the apparent solubility in lanolin alcohol and C_s^w is the solubility in water.

Determination of Release Rate—Lanolin alcohol, ethylcellulose, and propylene glycol or cetyl alcohol were added in required quantities to 5 ml of isopropyl alcohol and allowed to go into solution by gentle heating. The solution was cooled to room temperature, and the required concentration of cold triamcinolone acetonide was added and allowed to go into solution. The radiolabeled steroid (10 μCi) in isopropyl alcohol was added to this solution, and the total volume was made up to 10 ml in a volumetric flask. Two milliliters of this solution was pipetted into a preweighed aluminum petri dish and allowed to spread evenly on the flat bottom (7.5 cm in diameter; area of 44.2 cm^2).

The petri dish was kept on a level surface for 24 hr, and the solvent was allowed to evaporate to form a uniform film of 5–8-μm thickness. Complete solvent evaporation was confirmed by weighing the petri dish to a constant weight. The film-coated petri dish was stored in a desiccator containing anhydrous calcium chloride for at least 24 hr prior to the release studies. The good adherence of the film to the petri dish ensured that only the exposed surface area (44.2 cm^2) was available for release. The film was examined visually at the end of each experiment. No visible pores or "peeling" of the film from the petri dish was observed.

The release studies were conducted in a dissolution assembly[15] with the following modifications. The dissolution flasks were replaced by 1000-ml flat-bottom polypropylene beakers, and the dissolution basket assemblies were replaced by stainless steel stirrers with a propeller diameter of 4.5 cm. The film-coated petri dishes were placed in the bottom of the beakers. The beakers were held in position by Plexiglas disks with central circular ports for the stirrers and a small sampling port. The stirring assembly was set in position, 300 ml of preheated (37°) distilled water was added carefully to each, and the stirring was maintained at 40 rpm. The water bath was maintained at 37°.

One-milliliter samples were drawn frequently over 24 hr and were replaced by 1 ml of distilled water. Each sample was pipetted into a scintillation vial to which 10 ml of scintillation fluid was added. The samples were then analyzed using a liquid scintillation counter. The external standard ratio method was employed for calculation of counting efficiency using a standard quench curve.

The release data were computed and analyzed by a computer[16] using a FORTRAN program. Appropriate corrections were applied for the sample withdrawn, and medium was added. All release studies were conducted in triplicate.

RESULTS AND DISCUSSION

Film Characteristics—Lanolin alcohol was found to form thin, isolatable films. The lanolin alcohol films with a minimum thickness of 65 μm could be easily recovered intact from the mercury substrate. The lanolin alcohol films with less than 65-μm thickness were fragile, and their uniformity and integrity during isolation could not be assured due, in part, to associated tackiness. The inclusion of appropriate amounts of solvent-plasticizer, *e.g.*, propylene glycol or cetyl alcohol, reduced film tackiness. The lanolin alcohol film integrity was enhanced by ethylcellulose. When the solvent-plasticizer concentration was kept constant at 5% (w/w), the modulus of elasticity increased with the increasing proportion of ethylcellulose and a corresponding decrease in the proportion of lanolin alcohol. The modulus of elasticity reached a maximum value at an ethylcellulose concentration of 15% (w/w) with a corresponding lanolin alcohol concentration of 80% (w/w) (Tables I and II).

The effect of variation in the lanolin alcohol–propylene glycol ratio on film properties also was studied while the ethylcellulose content was held constant at 15% (w/w) (Table III). Compositions with 75–77.5% (w/w) lanolin alcohol and 7.5–10% (w/w) propylene glycol produced films with a high modulus of elasticity (Table III). These compositions also gave perceptibly good films. A further increase in the proportion of propylene glycol up to 25% (w/w) with a corresponding decrease in the proportion of lanolin alcohol did not substantially alter the film characteristics. However, an increase in the propylene glycol concentration beyond 25% (w/w) resulted in films that were definitely tacky and had a low modulus of elasticity.

Solubility Studies—Triamcinolone acetonide solubility in propylene glycol at 22 and 37° was 8.04 ± 0.19 and 12.09 ± 0.18 mg/ml, respectively. The solubility in cetyl alcohol at 22 and 37° was 0.92 ± 0.3 and 1.25 ± 0.05 mg/ml, respectively. The solubility values are expressed as the mean ± *SD* of three determinations. The attainment of equilibrium solubility in 3 days was noted by the fact that there was no difference in absorbance between the samples analyzed at the end of 3 and 6 days. Since the cetyl alcohol had a strong absorption at 239 nm, the side of the absorption band was used. Actual measurements of steroid concentration were made at 265 nm after verifying compliance with Beer's law.

[a] Weight of drug per weight of dry film. Drug concentration exceeded solubility in all cases. [b] All correlation coefficients and k and K values were computed from the regression line drawn from the data obtained by triplicate runs at each level by using the TEKTRONIX (model 4005-1) graphics terminal.

The apparent solubility of triamcinolone acetonide in lanolin alcohol at 22 and 37° was 0.13 ± 0.01 and 0.41 ± 0.01 mg/g, respectively. The attainment of equilibrium in 5 days was noted by running the partitioning experiment for 8 days with daily sampling of the aqueous phase. No further reduction in aqueous phase radioactivity was observed after 5 days.

Release Kinetics—Higuchi (9) showed that the *Q versus* $t^{1/2}$ relationship is common to homogeneous as well as to granular matrix systems during unidirectional leaching or extraction from a simple planar surface (Eqs. 1–5). It is necessary that A be greater than C_s (for homogeneous) or ϵC_s (for granular matrix) by a factor of three or four. A first-order release mechanism in which the release rate is proportional to the amount of drug left in the matrix also might be considered possible for drug release from polymeric systems of this type (11, 15, 16). This can be shown as:

$$\log (Q_\infty - Q) = \frac{-Kt}{2.303} + \log Q_\infty \qquad \text{(Eq. 9)}$$

where Q_∞ is the initial amount of drug present per unit area of the film, Q is the amount of drug present per unit area at time t, and K is the first-order rate constant.

In this study, the release data were analyzed to determine which release mechanism might be operative. The data comparing both of these treatments for triamcinolone acetonide release from matrixes containing propylene glycol as plasticizer are shown in Table IV and Figs. 1 and 2. The linear square root of time plots had high correlation coefficients. The observed lag times were relatively small, and the release rate constant, k, increased with the increase in drug concentration, as predicted by Eqs. 1 and 2. On the other hand, relatively high correlation coefficients also were obtained for the first-order treatment of the release data. However, highly negative lag times and a lack of constancy in the first-order constants (Table IV) strongly point against this mechanism. An initial curvature effect also was noticed in all first-order treatments of the data. A representative plot of the first-order data is shown in Fig. 5. Similar results were seen with systems containing cetyl alcohol as the plasticizer.

Figures 1–4 show the *Q versus* $t^{1/2}$ treatment of the data for different concentrations of triamcinolone acetonide in matrixes containing propylene glycol or cetyl alcohol. All plots show the mean of three observations because of small standard deviations involved in most cases. The maximum amount of drug released varied from 7.6 to 46.0% of its solubility in distilled water at 37°. A good linear fit was observed in all cases, with slight negative deviation at longer time intervals and for higher drug concentrations. This deviation might be due to the exhaustion of the drug in the suspension phase and to the increase in diffusion distance for the

drug in the film. The observed lag times never exceeded 1.7% of the total release period (24 hr).

Effect of Drug Concentration—The densities of lanolin alcohol and ethylcellulose were determined to be 0.98 and 1.38 g/ml using the pycnometric method. The weight per weight drug concentrations (Tables IV and V) were converted to weight per volume (A values) concentrations. The effect of the changing the drug concentration on the release rate constant, k, was tested using these concentrations of triamcinolone acetonide for each composition of the film tested. In all cases, the k *versus* A plots were slightly more linear (r = 0.992) than the k *versus* $A^{1/2}$ plots (r = 0.960). While Eqs. 4 and 5 predict a linear relationship between k and $A^{1/2}$, the observed results also could be explained in terms of a granular matrix system alone if the initial porosity were assumed to be very small. Such as assumption appears to be reasonable since these matrixes contain a plasticizer. Higuchi (9) showed that in those instances where initial porosity is very small or where the fraction of the matrix volume occupied by the drug is relatively large, $\epsilon \cong KA$ and Eq. 5 reduces to:

$$k = A\sqrt{\frac{DK}{\tau}(2 - KC_s)C_s} \qquad \text{(Eq. 10)}$$

where K is equal to the specific volume of the drug if A is expressed in terms of grams of drug per milliliter.

Effect of Change in Plasticizer—According to Eq. 4, one would expect k to decrease substantially when the solvent-plasticizer is changed from propylene glycol to cetyl alcohol in view of the nearly eightfold difference in drug solubility in that vehicle. This expectation would be valid if D, the diffusion coefficient of the drug in the matrix, were not altered significantly by the change of the solvent-plasticizer. Alternatively, in the same release medium, Eq. 5 would predict comparable k values for the two systems differing only in the nature of solvent-plasticizer, provided that volume, porosity, and tortuosity of the matrix are not significantly altered. This might well be the case for the systems studied since the k values for the cetyl alcohol systems (Table V) were comparable to those for the propylene glycol systems (Table IV).

Effect of Vehicle Composition—Table VI describes the effect of drug solubilization on drug release by varying the propylene glycol–lanolin alcohol concentration. The steroid concentration (0.10%, w/w) was chosen, in part, to permit this study in films of sufficient integrity. The

Table VI—Release of 0.10% (w/w) Triamcinolone Acetonide from Matrixes Containing Different Percentages of Propylene Glycol after 6 hr at 37°

Lanolin Alcohol–Ethylcellulose–Propylene Glycol Ratio	Amount[a] Released, %
8.5:1.5:0.0	37.11 ± 0.62
8.0:1.5:0.5	40.46 ± 1.12
7.7:1.5:0.8	32.38 ± 0.71
7.0:1.5:1.5	30.48 ± 0.29

[a] All values are expressed as the means ± *SD* of three runs.

maximum release of drug was obtained with systems containing the drug in a near-saturated solution (5% propylene glycol). The release rate decreased with systems containing no propylene glycol (major solubilizer) as well as with systems containing the solubilizer in excess of that required to dissolve the steroid completely (8 and 15% propylene glycol). These vehicle effects are consistent with those reported for fluocinolone acetonide from propylene glycol–water gels (20).

Conclusion—This film-forming capability of lanolin alcohol is potentially significant and appears to have remained unrecognized in spite of the use of this material in cosmetic and dermatologic preparations. Additional work is planned to explain its film-forming ability.

The release of suspended triamcinolone acetonide from films of lanolin alcohol in combination with ethylcellulose and propylene glycol or cetyl alcohol followed the diffusion-controlled granular matrix model (9). The *in vitro* skin penetration work in progress may help to determine the rate-limiting step during topical drug absorption.

Nortropacocaine Hydrochloride Conformation in Aqueous and Hydrophobic Media

ALEXANDROS MAKRIYANNIS ˣ **and GILBERT HITE**

Received August 14, 1978, from the *Department of Medicinal Chemistry, School of Pharmacy, and the Institute of Materials Science, University of Connecticut, Storrs, CT 06268.* Accepted for publication December 7, 1978.

Abstract □ The nortropacocaine hydrochloride PMR spectra in deuterium oxide and in deuterochloroform differed markedly. A detailed conformational analysis using vicinal ^1H-^1H coupling constants revealed the molecular conformation to be identical in both solvents. The preferred conformation was one in which the piperidine component existed as a deformed chair. The spectral differences were due to a decreased deshielding of the protonated nitrogen on the neighboring bicyclic ring protons, resulting in chemical shift changes.

Keyphrases □ Nortropacocaine—conformation, effect of solvents, PMR spectra, structure-activity relationships □ Cocaine analogs—nortropacocaine, conformation, structure-activity relationships, effect of solvents, PMR spectra □ Anesthetics, local—nortropacocaine, conformation, structure-activity relationships □ Stimulants, central—nortropacocaine, conformation, structure-activity relationships

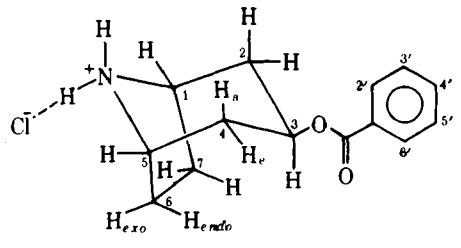
Cocaine, the most prominent tropane alkaloid obtained from *Erythroxylon coca* leaves, possesses dual pharmacological activity (1). Systemic administration interferes with the uptake of catecholamines by adrenergic nerve terminals, and local application blocks nerve conduction. Therefore, the drug has central nervous system stimulant as well as local anesthetic properties.

One explanation for this dual activity is that cocaine interacts in two different conformations (2, 3). The catecholamine uptake inhibition is associated with a noncontiguous transoid phenethylamine cocaine conformation (2) while the local anesthetic activity is associated with a piperidine boat conformation (3). This hypothesis is similar to that of Schueler (4), according to which acetylcholine in a "cisoid" conformation stimulates the nicotinic receptors while acetylcholine in a "transoid" conformation stimulates the muscarinic receptors.

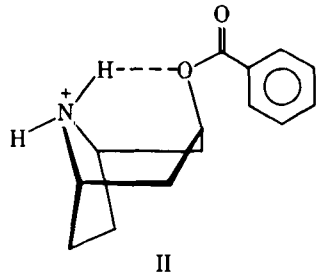
BACKGROUND

Although examples of 4-piperidinols in boat conformations have been reported (5, 6), no tropane analogs have been shown to possess such a conformation. X-ray diffraction studies on salts of cocaine (7) and its analogs (8) provided no evidence for a piperidine boat. Similarly, cocaine free base was found in a conformation having the piperidine ring in a chair form. However, a boat conformation was reported (9) to be a necessary intermediate during the reversible acid-catalyzed N → O acyl migration in *N*-benzoylnortropine and several of its analogs.

This study investigated the conformation of *O*-benzoylnortropine (nortropacocaine) (Structure I) hydrochloride, a monosubstituted tropane analog resembling cocaine only in those structural features believed to favor a piperidine boat conformation (Structure II). Such a boat conformation would be stabilized through an interaction—electrostatic or hydrogen bonding—between the ^+NH group and the *O*-benzoyloxy oxygen.



I



II

Conformational analyses of several tropane alkaloid free bases in deuterochloroform (8) and of tropane salts in deuterium oxide (10–12) have been carried out from their PMR spectra. However, the conformations of tropane salts in hydrophobic media have not been investigated. The present study represents a detailed conformational analysis of a cocaine analog salt in aqueous and in hydrophobic media, with special emphasis on the possible role of the solvent. This study is also the first conformational analysis of a tropane salt in hydrophobic media.

Solvent changes have been reported to produce pronounced effects on some molecular conformations (6, 13). To observe any such solvent effects, the nortropacocaine hydrochloride conformation was determined in deuterium oxide and in deuterochloroform using high-resolution PMR. Nonpolar solvents, in addition to representing more accurately the nerve membrane hydrophobic environment, should favor the boat conformation by enhancing the H_2N^+–O interaction. This study is further justified by the great interest in tropane analogs as models of various drug pharmacophoric conformations (14).

EXPERIMENTAL

The ^1H resonance spectra were measured at 270 MHz (Figs. 1*a* and 1*b*) using 0.10 *M* solutions in deuterochloroform and in deuterium oxide at an ambient temperature of 20°. Chemical shifts were measured from tetramethylsilane and sodium 2,2-dimethyl-2-silatane-5-sulfonate, which were used as internal standards. Nortropacocaine hydrochloride (9) was obtained by *N*-demethylating tropacocaine using 2,2,2-trichloroethylchloroformate (15). Tropacocaine hydrochloride was obtained commercially.

All of the ^1H chemical shifts and ^1H-^1H coupling constants for the protons in the piperidine component of the tropane nucleus could be

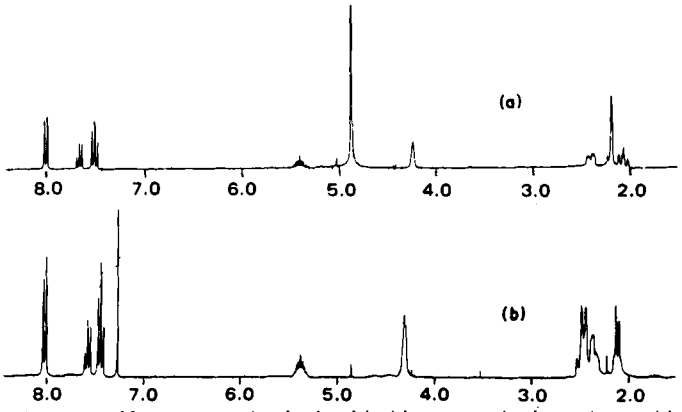


Figure 1—*Nortropacocaine hydrochloride spectra in deuterium oxide* (a) *and in deuterochloroform* (b).

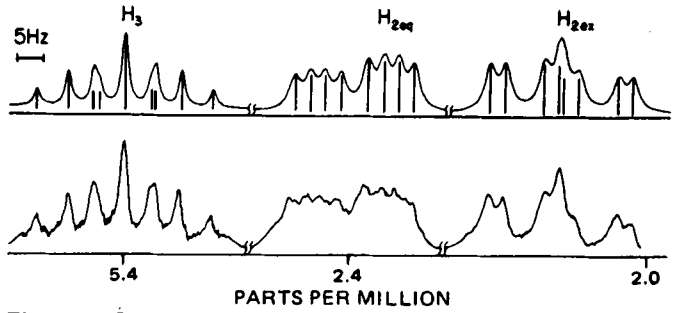

Figure 2—*Real (bottom) and simulated (top) spectral regions from the ^1H-nortropacocaine hydrochloride spectrum in deuterium oxide.*

extracted by analyzing the spectral portions due to the methine proton on C_3 and the methylene protons on C_2. The absorption signals due to the H_3 methine proton were analyzed as the *C* portion of an *AA'BB'C* system. Signals due to each geminal proton on C_2 were sufficiently separated to allow their analysis as the *AB* portion of an *ABCD* system. In the preliminary analysis, the *AA'BB'C* and *ABCD* spectra were correspondingly approximated as $(AB)_2X$ and *ABKY* systems. Initial spectral parameter estimates were obtained by standard methods (16) with the aid of ^1H-^1H spin decoupling, when necessary, and were then refined by spectral simulation and iteration using the ITRCAL program. This program is an implementation of the LAOCN 3 algorithm (17) on a minicomputer. It requires a 12K computer system and a disk memory. Experimental and "best-fit" simulated spectra are shown in Figs. 2 and 3.

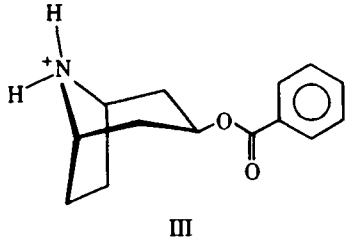
Due to overlap, the spectral portions corresponding to the protons on C_6 and C_7 of the ethylene bridge were not amenable to detailed analysis. Only approximate individual chemical shifts could be extracted directly from the spectra with the help of ^1H-^1H spin decoupling.

RESULTS AND DISCUSSION

The nortropacocaine hydrochloride spectra in deuterium oxide (Figs. 1*a* and 2) and in deuterochloroform (Figs. 1*b* and 3) had similar H_3 proton resonances but varied markedly in other regions. Spectral assignments in the crucial $H_{2,4}$ region (Figs. 2 and 3) could be made only after ^1H-^1H spin decoupling. The variations between the two spectra could be attributed to differences in coupling constants, chemical shifts, or both.

Coupling Constants—The preferred molecular conformation could be determined unambiguously from the piperidine ring proton coupling constants. In both solvents, the coupling constants showed no appreciable differences, indicating that no significant conformational changes occurred when an aqueous medium was substituted for a hydrophobic solvent. The most direct information on this tropane analog conformation came from the C_3 proton signal. The coupling constants ($J_{2ax,3}$ and $J_{2eq,3}$) between this proton and its neighboring methylene protons are consistent with H_{ax}-H_{ax} and H_{ax}-H_{eq} coupling, indicating that the piperidine ring exists as a slightly distorted chair (Structure III). In this chair, the H_3 proton occupies an axial position. Consequently, the benzoyloxy group is equatorial. The $J_{2eq,3}$ and $J_{2ax,3}$ were assumed to have like signs and to be positive since vicinal couplings in substituted ethanes have the same sign and are regarded as positive (18). The $J_{2ax,2eq}$ was assumed to be negative since the geminal proton coupling is negative for most CH_2 groups (18). Additional evidence for a distorted piperidine chair conformation was provided by the coupling constants ($J_{1,2ax}$ and $J_{1,2eq}$) of the C_2 protons with the C_1 bridge carbon proton.

If nortropacocaine hydrochloride is assumed to exist as a single conformer in solution, the piperidine ring distortion can be evaluated by comparing the vicinal ^1H-^1H coupling constants with the coupling constants calculated for a "perfect" chair. This procedure, which makes use of substituent electronegativities (19), was developed (20) for perfectly staggered 1,2-disubstituted ethanes and has given good results in the past



III

Table I—^1H Vicinal Coupling Constants for Nortropacocaine Hydrochloride

Constant	Deuterochloroform	Deuterium Oxide	Calculated
$J_{1,2eq}$	2.9	3.25	2.37
$J_{1,2ax}$	2.35	2.85	3.63
$J_{2eq,3}$	5.8	5.75	5.19
$J_{2ax,3}$	10.8	10.75	12.70
$J_{2ax,2eq}$	−13.95	−13.85	—

(21). First, coupling constants for a perfectly staggered piperidine ring were calculated (20). The values thus obtained were compared to the experimentally determined coupling constants of the piperidine ring in nortropacocaine hydrochloride (Table I), and the following dihedral angles were calculated for nortropacocaine hydrochloride in deuterochloroform and in deuterium oxide, respectively: $\phi(H_1C_1C_1$-$H_{2ax}) = 66$ and 64°, $\phi(H_1C_1C_2H_{2eq}) = 56$ and 54°, $\phi(H_{2ax}C_2C_3H_{3ax}) = 158$ and 157°, and $\phi(H_{2eq}C_2C_3H_3) = 58$ and 58°.

Because of the dangers involved in using quantitative correlations to obtain precise dihedral angles, such values are only approximate. The dihedral angles deviations from ideality were compatible with a piperidine ring slightly flattened at the C_3 position and more puckered at the $^+NH_2$ group (Structure III).

Similar conclusions about the piperidine ring distortion were reached using a method (22, 23) for the qualitative determination of six-membered ring distortions from the ratios of J_{trans}-J_{cis} vicinal coupling constants.

Chemical Shifts—The pronounced changes that the nortropacocaine hydrochloride proton spectrum underwent when the solvent was changed from deuterochloroform to deuterium oxide were due almost exclusively to different individual proton chemical shift changes. The variation in these chemical shift changes could be attributed to a reduction in the protonated nitrogen deshielding influence on the neighboring protons in the bicyclic ring when deuterochloroform was replaced with deuterium oxide. Such solvent modification of the charged nitrogen deshielding influence was demonstrated elsewhere (24). The highly polar deuterium oxide presumably (24) decreases the effect of the positive charge through direct solvation of the positive ion. The result is that in deuterium oxide the protons in close proximity to the protonated nitrogen are shifted upfield relative to the corresponding protons in the less polar deuterochloroform.

An attempt was made to relate the chemical shift differences in the

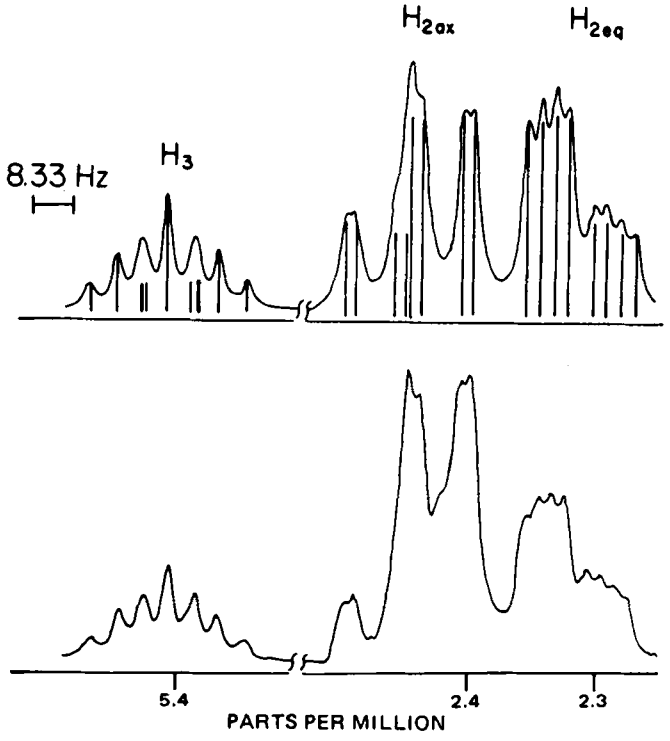


Figure 3—*Real (bottom) and simulated (top) spectral regions from the ^1H-nortropacocaine hydrochloride spectrum in deuterochloroform. In the real spectrum, H_{2ax} and H_7 protons are overlapping.*

Table II—^{1}H Chemical Shifts for Nortropacocaine Hydrochloride (270 MHz)

Proton	Chemical Shift, ppm		Difference, Hz
	Deuterochloroform	Deuterium Oxide	
$H_{1,5}$	4.29	4.24	14
$H_{2eq,4eq}$	2.31	2.39	−22
$H_{2ax,4ax}$	2.44	2.06	103
H_3	5.37	5.40	−8
$H_{6endo,7endo}$	2.07	2.18	−30
$H_{6exo,7exo}$	2.42	2.18	65
$H_{2',6'}$	8.08	8.04	11
$H_{3',5'}$	7.45	7.54	−24
$H_{4'}$	7.59	7.70	−30

two solvents to the relative distances between the protonated nitrogen and the neighboring protons based on the described conformation. Examination of the chemical shift differences (Table II) revealed that the $H_{2ax,4ax}$ as well as the $H_{6exo,7exo}$ protons that showed large downfield shifts lay in close proximity to the positively charged nitrogen. On the other hand, the $H_{2eq,4eq}$, $H_{6endo,7endo}$, and H_3 protons that were farthest removed from the nitrogen showed the small upfield shifts generally observed when the solvent was changed from deuterium oxide to deuterochloroform. On the whole, the correlation between chemical shift differences and nitrogen–proton distances was very good and supported the conformational assignments.

The chemical shift changes on the phenyl ring protons could be explained by using a similar argument. The carbonyl group contributes to the deshielding of the ring protons, which lie in the same plane with it (25). The diminished deshielding resulting from carbonyl group solvation when deuterium oxide was used as a solvent was more pronounced on the nearest *ortho*-protons and decreased progressively with the *meta*- and *para*-protons.

Reports of changes in the proton chemical shifts following a solvent change were interpreted as a conformational change in the molecule. The results reported here point out that conformational interpretations based solely on changes in chemical shifts should be made cautiously. Preferably, such results should be supplemented with coupling constant measurements, still the most reliable information source on the conformations of small molecules in solution.

Failure to demonstrate significant quantities of a piperidine boat conformation in this cocaine-like molecule in solution indicated that such a species is unstable and suggested that it does not participate in events leading to local anesthesia. The occurrence of a chair to boat conformational change when the molecule comes in contact with the nerve membrane could not, however, be excluded. The conformation of cocaine and its analogs in the presence of membrane preparations is currently under investigation.

Dissolution Rate of *p*-Aminobenzoates from Solid Xylitol Dispersions

ILARI SIRENIUS, VELI E. KROGERUS ˣ, and TUULA LEPPÄNEN

Received July 25, 1978, from the *Division of Pharmaceutical Technology, School of Pharmacy, University of Helsinki, Fabianinkatu 35, SF-00170 Helsinki 17, Finland.* Accepted for publication November 15, 1978.

Abstract □ Xylitol was studied as a carrier in solid dispersions because of its low melting point and stability up to 180°. It is more stable than sucrose and does not enter into Maillard reactions. Solid dispersions were prepared from esters of *p*-aminobenzoic acid and xylitol by the melting method and were compressed into tablets. The *p*-aminobenzoate dissolution rates were determined by a modified beaker method. The increase in the dissolution rates was greatest at the lowest drug levels. When the dispersion drug content exceeded 20–30%, the dissolution rate per unit area remained nearly constant. In the latter case, the increase in the dissolution rate was primarily due to an increase in area. When the carbon chain length was increased in the homologous series, the dissolution rate from the xylitol dispersions showed a nearly linear decrease.

Keyphrases □ *p*-Aminobenzoic acid—rate of dissolution from solid xylitol dispersions □ Xylitol—carrier, solid dispersions of *p*-aminobenzoic acid esters □ Dissolution rate—*p*-aminobenzoic acid esters from solid xylitol dispersions □ Dosage forms, solid—dispersions, *p*-aminobenzoic acid esters in xylitol, dissolution rate

Solid dispersions have been used to increase the dissolution rate and bioavailability of drugs that are only slightly water soluble. The carriers used have been physiologically inert compounds that are readily water soluble. To reduce sulfathiazole particle size, eutectic mixtures, for example, have been prepared from urea and slightly water-soluble sulfathiazole by the melting method (1). However, the high temperatures required by the melting method may cause either the drug or the carrier to decompose.

p-Aminobenzoic acid esters, particularly the higher homologous ones, are only slightly soluble in water (2). Xylitol was studied as a carrier for solid dispersions of *p*-aminobenzoates because of its low melting point and stability up to 180°. Xylitol is almost equal to sucrose in water solubility and is more stable chemically; when xylitol is heated in the presence of amino groups, it does not undergo the Maillard ("browning") reaction (3, 4).

The melting range of xylitol is 93–94.5°, and it begins to decompose at 179–186° (3). When xylitol is used as the dispersing medium, the dissolution process is endothermic. The relatively high negative heat of xylitol solution is 145.7 J/g (3).

EXPERIMENTAL

Materials—The *p*-aminobenzoic acid esters studied were methyl *p*-aminobenzoate[1], ethyl *p*-aminobenzoate[1] (benzocaine), propyl *p*-aminobenzoate[2] (risocaine), and butyl *p*-aminobenzoate[1] (butamben). Xylitol[3] was used as a carrier.

Solid Dispersion Preparation—Solid dispersions were prepared using the direct melting method (1). A physical mixture of the drug and xylitol was made, and this mixture was heated in an IR bath[4]. The mixture of xylitol and methyl *p*-aminobenzoate was heated to 114°, and the other mixtures were heated to 96–98°. The molten mixture was cooled quickly by pouring it onto a stainless steel plate in an ice bath. The mixture was left to stabilize for 24 hr at room temperature.

Sample Preparation—The dispersion used in the tablets was pulverized to 0.71-mm particles. For dissolution rate determination, the solid dispersions were compressed into cylindrical tablets (18 mm in diameter; 750 mg) using a hydraulic press[5] in the same way as potassium bromide disks are prepared for IR spectroscopy. Pure drug tablets were prepared using the same pressure, 400 MPa.

Dissolution Rate Determination—The dissolution rates were determined using a modified beaker method (5). Each determination was run in 600 ml of distilled water in a 800-ml beaker at 37°. The tablet was placed on a sieve net (mesh 2.0 mm) positioned 2 cm from the bottom of the beaker. A sieve net basket (4 × 4 × 1 cm) was placed over the tablet (6). A three-blade stirrer[6] was placed 5 cm from the bottom of the beaker. The stirring speed was 60 rpm.

The tablet was placed on the sieve net, and the solvent was poured into the beaker. The dissolution test time was 3 min. Samples were taken at the stirring blade level through a filter[7] using a peristaltic pump which let the sample solution into the spectrophotometer flow-through cells[8]. The sample solution absorbance was registered automatically at 284 nm. Xylitol did not interfere. The dissolution rate was determined per tablet unit area (milligrams per square centimeter per hour).

RESULTS AND DISCUSSION

At a low drug content (<10%), the molten mixture solidification was slow. When the drug content was increased, however, the dispersion solidified quickly. A solid dispersion of xylitol–*p*-aminobenzoates increased

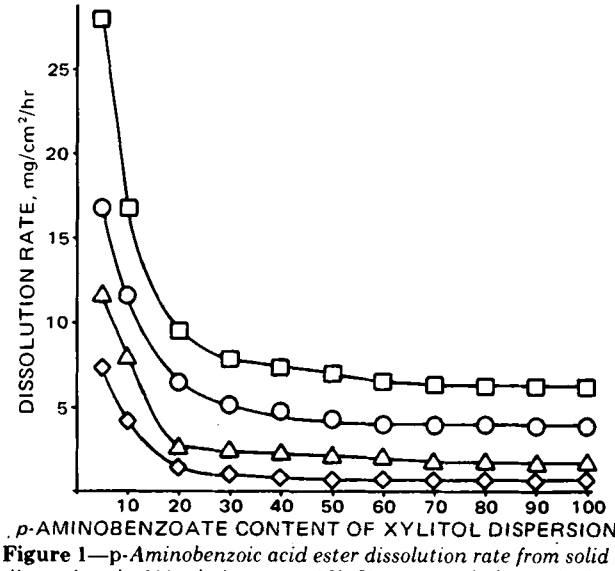

Figure 1—p-*Aminobenzoic acid ester dissolution rate from solid xylitol dispersions in 600 ml of water at 37°. Key:* □, *methyl* p-*aminobenzoate;* ○, *ethyl* p-*aminobenzoate;* △, *propyl* p-*aminobenzoate; and* ◇, *butyl* p-*aminobenzoate.*

the *p*-aminobenzoate dissolution rate. The difference between several dissolution rate tests was less than ±5% during the first 3 min of dissolution when the surface areas of the tablets were still nearly identical. The dissolution rate was calculated over the portion of the dissolution profile that followed zero-order kinetics.

The increase in the dissolution rate as compared with that of pure drug tablets was greatest when the drug content was lowest. The dissolution rate of a xylitol dispersion containing 5% butyl *p*-aminobenzoate was about 10 times, per unit area, the pure drug dissolution rate. When the increase in area caused by dispersion of the drug with xylitol (1:20) was considered, the dissolution rate of a 5% dispersion was about 200-fold that of the pure drug. The dissolution rate of the methyl *p*-aminobenzoate dispersion was fivefold per unit area, which corresponds to a 100-fold increase in the dissolution rate of the pure drug when the increase in area is considered. When the dispersion drug content was 20–30%, the changes in the dissolution rate per unit area decreased. In this case, the increase in the dissolution rate was primarily due to an increase in area.

A curve depicting the dissolution rates as a function of the drug content of the dispersion was of nearly the same shape for each compound (Fig. 1). When the *p*-aminobenzoic acid ester alkyl group carbon chain was increased, the xylitol dispersion dissolution rate showed a nearly linear decrease.

Pharmacokinetics of Drugs Subject to Enterohepatic Circulation

HSIAO-SHENG GEORGE CHEN and JOSEPH F. GROSS ×

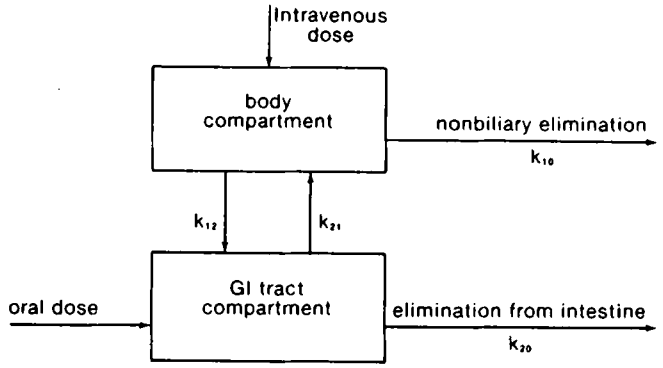
Received October 16, 1978, from the *Department of Internal Medicine and the Department of Chemical Engineering, University of Arizona, Tucson, AZ 85721.* Accepted for publication November 15, 1978.

Abstract □ The influence of the changes in biliary excretion and reabsorption rates on the pharmacokinetics of drugs subject to enterohepatic circulation was examined analytically. A recently proposed two-compartment model with drug elimination occurring in each compartment was adapted to represent the body and the GI tract. Enhanced reabsorption was equivalent to biliary excretion rate reduction, except that the latter always decreased α and prolonged the α-phase half-life while the former always increased α and shortened the half-life. However, depending on the relative values of the two elimination rate constants, biliary excretion reduction (or reabsorption enhancement) could either increase or decrease the terminal drug half-life (β-phase). Whether the terminal drug half-life was prolonged or shortened, a biliary excretion reduction always increased the area under the plasma decay curve for intravenous and oral doses and also raised the steady-state drug level in the body for constant-rate intravenous infusion. As a consequence, the lethality, toxicity, or effectiveness of the drug will be increased for patients with impaired bile flow or enhanced drug reabsorption; therefore, the clinical dosage may have to be reduced.

Keyphrases □ Enterohepatic circulation—effect of biliary excretion and reabsorption rates on drug pharmacokinetics, two-compartment model □ Distribution—enterohepatic circulation, effect of biliary excretion and reabsorption rates, pharmacokinetics, two-compartment model □ Pharmacokinetics—enterohepatic circulation, effect of biliary excretion and reabsorption rates, two-compartment model

When a substance is excreted into the bile, passes through the lumen of the intestine, is reabsorbed, and then is carried to the liver *via* blood flow, it undergoes enterohepatic circulation or cycling. Many endogenous and exogenous substances (bile salts, morphine, methadone, methotrexate, digitoxin, *etc.*) can undergo enterohepatic circulation (1). Pharmacokinetic study of drugs subject to enterohepatic circulation has gained importance in recent years.

A two-compartment model representing the body and the GI tract was recently proposed by Harrison and Gibaldi (2) to describe the influence of cholestasis (bile flow reduction or discontinuance) on the elimination of drugs undergoing enterohepatic circulation. Scheme I shows the



Scheme I—Pharmacokinetic model for a drug subject to enterohepatic circulation.

pharmacokinetic model of the biliary excretion (k_{12}) and reabsorption process (k_{21}) of a drug eliminated by both compartments. Cholestasis was simulated numerically by reducing the transfer rate constant k_{12}. Results (2) suggested that cholestasis can either increase or decrease the terminal drug half-life ($T^{\beta}_{1/2}$), depending on the ratio of the two elimination rate constants k_{10}/k_{20}. If the ratio is greater than unity, cholestasis will increase β and reduce the drug half-life. The reverse is true if the ratio is less than unity. In contrast, a biliary excretion reduction will always decrease α and prolong the α-phase half-life.

Although the terminal drug half-life may be decreased, many experiments showed that drug lethality and toxicity are greater in animals with a ligated bile duct than in normal animals (1). Furthermore, since enterohepatic circulation is characterized by biliary excretion and reabsorption, the reabsorption influence on drug disposition should also be studied. In the present work, the effects of both processes on the pharmacokinetics of drugs undergoing enterohepatic circulation were examined analytically. The dependence of the drug half-lives, the area

In contrast, a biliary excretion reduction will always decrease α and prolong the α-phase half-life.

Although the terminal drug half-life may be decreased, many experiments showed that drug lethality and toxicity are greater in animals with a ligated bile duct than in normal animals (1). Furthermore, since enterohepatic circulation is characterized by biliary excretion and reabsorption, the reabsorption influence on drug disposition should also be studied. In the present work, the effects of both processes on the pharmacokinetics of drugs undergoing enterohepatic circulation were examined analytically. The dependence of the drug half-lives, the area

under the plasma decay curve, and the steady-state drug level after intravenous infusion on changes in biliary drug excretion and reabsorption rates were studied.

THEORETICAL

The model used by Harrison and Gibaldi (2) was adopted, although it involved the assumption that the bile flow is a continuous process. The drug can be administered either as an intravenous bolus injection into the body compartment or as an oral bolus dose into the GI tract. Drug elimination occurs linearly in both compartments. The rate constant k_{10} represents the sum of all first-order rate constants associated with nonbiliary elimination; the constant k_{20} is the drug disappearance rate from the reabsorption sites (intestine) by biotransformation in the intestine or by fecal elimination.

The biliary excretion and reabsorption rates are represented by the constants k_{12} and k_{21} separately. Disease states like cholestasis that reduce biliary excretion or mechanisms (1) that enhance bile flow can all be simulated by corresponding changes in k_{12}. Similarly, changes in the conjugate hydrolysis rate due to intestinal microorganisms and subsequent deconjugated product reabsorption can be simulated by changing the value of k_{21}.

The amount of drug in the body, A, as a function of time after different administration routes can be solved easily to yield the following analytic expressions.

After intravenous bolus injection of dose D, the drug level in the body is:

$$A_{iv} = \frac{(\alpha - k_{21} - k_{20})D}{\alpha - \beta}\exp(-\alpha t) + \frac{(k_{21} + k_{20} - \beta)D}{\alpha - \beta}\exp(-\beta t) \quad \text{(Eq. 1)}$$

where:

$$\alpha = \tfrac{1}{2}(k_{21} + k_{20} + k_{12} + k_{10} + \nabla) \quad \text{(Eq. 2)}$$

$$\beta = \tfrac{1}{2}(k_{21} + k_{20} + k_{12} + k_{10} - \nabla) \quad \text{(Eq. 3)}$$

and:

$$\nabla^2 = (k_{21} + k_{20} + k_{12} + k_{10})^2 - 4(k_{12}k_{20} + k_{10}k_{21} + k_{10}k_{20}) \quad \text{(Eq. 4)}$$

The area under the intravenous injection plasma decay curve is then obtained by integrating Eq. 1:

$$CXT_{iv} = \left(\frac{D}{V}\right)\left(\frac{k_{21} + k_{20}}{k_{12}k_{20} + k_{21}k_{10} + k_{10}k_{20}}\right) \quad \text{(Eq. 5)}$$

where V is the distribution volume.

After oral administration of dose D, the drug level in the body is:

$$A_{oral} = \frac{Dk_{21}}{\alpha - \beta}[\exp(-\beta t) - \exp(-\alpha t)] \quad \text{(Eq. 6)}$$

Since the area under the plasma decay curve for oral dosing is:

$$CXT_{oral} = \left(\frac{D}{V}\right)\left(\frac{k_{21}}{k_{12}k_{20} + k_{21}k_{10} + k_{10}k_{20}}\right) \quad \text{(Eq. 7)}$$

the oral dose availability (or the fraction absorbed into the body) is:

$$F = \frac{k_{21}}{k_{21} + k_{20}} \quad \text{(Eq. 8)}$$

Following the oral dose, the peak drug level and the time required to reach it are:

$$A_{max} = \frac{Dk_{21}}{\alpha}\left(\frac{\alpha}{\beta}\right)^{-\beta/\alpha-\beta} \quad \text{(Eq. 9)}$$

$$t_{peak} = \frac{1}{\alpha - \beta}\ln\frac{\alpha}{\beta} \quad \text{(Eq. 10)}$$

Following intravenous drug infusion at constant rate k_0, the drug level in the body as a function of time is:

$$A_{infusion} = \frac{k_0(k_{21} + k_{20})}{\alpha\beta} - \frac{k_0(\alpha - k_{21} - k_{20})}{\alpha(\alpha - \beta)}\exp(-\alpha t) - \frac{k_0(k_{21} + k_{20} - \beta)}{\beta(\alpha - \beta)}\exp(-\beta t) \quad \text{(Eq. 11)}$$

As time proceeds, the drug level reaches a steady state:

$$A_{ss} = \frac{k_0(k_{21} + k_{20})}{k_{21}k_{10} + k_{12}k_{20} + k_{10}k_{20}} \quad \text{(Eq. 12)}$$

The drug half-lives are then given by:

$$T^{\alpha}_{1/2} = \frac{\ln 2}{\alpha} \quad \text{(Eq. 13)}$$

and:

$$T^{\beta}_{1/2} = \frac{\ln 2}{\beta} \quad \text{(Eq. 14)}$$

where $T^{\beta}_{1/2}$ is the terminal drug half-life.

The influences of biliary excretion and reabsorption processes on drug disposition can be simulated by changing the rate constants k_{12} and k_{21}. It can be shown (*Appendix*) that:

$$\frac{\partial\beta}{\partial k_{12}} > 0 \quad \text{if } k_{20} > k_{10} \quad \text{(Eq. 15)}$$

$$\frac{\partial\beta}{\partial k_{12}} = 0 \quad \text{if } k_{20} = k_{10} \quad \text{(Eq. 16)}$$

$$\frac{\partial\beta}{\partial k_{12}} < 0 \quad \text{if } k_{20} < k_{10} \quad \text{(Eq. 17)}$$

The physical meaning of a multivariable function partial differentiation with respect to one of its variables is the rate of change of that function with respect to the variable while the other variables are held constant. Therefore, β will increase as k_{12} increases and will decrease as k_{12} decreases if $k_{20} > k_{10}$. If $k_{20} < k_{10}$, β will decrease while k_{12} is increased. If $k_{20} = k_{10}$, the value of β will be independent of the changes in k_{12}.

Similarly, no matter what the relative values of k_{20} and k_{10}, the partial derivative of α with respect to k_{12} is always greater than zero. Thus, a biliary excretion reduction will decrease α and produce a longer α-phase half-life. However, by observing Eqs. 5, 7, and 12, it is obvious that a reduction of k_{12} will increase CXT_{iv}, CXT_{oral}, and A_{ss}.

The influence of changing the reabsorption rate k_{21} on the drug elimination can be studied similarly. It can be proved that:

$$\frac{\partial\beta}{\partial k_{21}} < 0 \quad \text{if } k_{20} > k_{10} \quad \text{(Eq. 18)}$$

$$\frac{\partial\beta}{\partial k_{21}} = 0 \quad \text{if } k_{20} = k_{10} \quad \text{(Eq. 19)}$$

$$\frac{\partial\beta}{\partial k_{21}} > 0 \quad \text{if } k_{20} < k_{10} \quad \text{(Eq. 20)}$$

Thus, an increase in the drug reabsorption rate will have the same effect on β and $T^{\beta}_{1/2}$ as a biliary excretion reduction. However, $\partial\alpha/\partial k_{21}$ is always positive for any combination of variables. An enhancement in the reabsorption rate will thus increase α and shorten the α-phase half-life.

The effect of k_{21} on the values of CXT_{iv}, CXT_{oral}, and A_{ss} cannot be as easily observed as with k_{12}. However, Eqs. 5, 7, and 12 can be rewritten in the form:

$$CXT_{iv} = \left(\frac{D}{V}\right)\left[\frac{1}{k_{10}} - \frac{k_{12}k_{20}}{k_{10}(k_{12}k_{20} + k_{21}k_{10} + k_{10}k_{20})}\right] \quad \text{(Eq. 21)}$$

An increase in k_{21} will decrease the second term in the parenthesis and increase CXT_{iv}. Hence, an increase in the drug reabsorption rate will increase CXT_{iv}, CXT_{oral}, and A_{ss} while a reduction of k_{21} will decrease these quantities.

DISCUSSION

The influence of the biliary excretion and reabsorption rates on the disposition of drugs subject to enterohepatic circulation was studied analytically using the model of Harrison and Gibaldi (2). The results are:

1. If $k_{20} > k_{10}$, a biliary excretion reduction or reabsorption rate increase will decrease β and produce a longer half-life $T^{\beta}_{1/2}$. If $k_{20} < k_{10}$, a decrease in biliary excretion or reabsorption enhancement will increase β and shorten the drug half-life. If $k_{20} = k_{10}$, the terminal half-life will be independent of the changes in either rate.
2. A reduction of biliary drug excretion will always decrease the value of α and increase the α-phase half-life, while an increase in the reabsorption rate will have the reverse effects, regardless of the combination of variables.
3. A biliary excretion reduction or an increase in the reabsorption rate will always increase the area under the plasma decay curve for intravenous and oral doses and will also raise the steady-state drug level in the body following a constant-rate intravenous infusion.

Biliary excretion enhancement or drug reabsorption decrease will produce the opposite effects on drug disposition.

Although the terminal half-life may be reduced by biliary dysfunction or reabsorption enhancement (when $k_{20} < k_{10}$), CXT_{iv}, CXT_{oral}, and A_{ss} will always be increased by these changes. Since drug effectiveness and toxicity are closely related to CXT values after intravenous or oral dosing and to A_{ss}, the steady-state drug level, after infusion, they will increase for patients with biliary dysfunction or enhanced reabsorption. To avoid toxicity, the drug dosage may have to be reduced accordingly.

APPENDIX

From Eq. 3, partial differentiation of β with respect to k_{12} yields:

$$\frac{\partial\beta}{\partial k_{12}} = \frac{1}{2\nabla}[\nabla - (k_{21} + k_{12} + k_{10} - k_{20})] \quad \text{(Eq. A1)}$$

Since ∇ is always positive, if $k_{20} \geq k_{21} + k_{12} + k_{10}$, then $\partial\beta/\partial k_{12}$ will be positive. If $k_{21} + k_{12} + k_{10} > k_{20}$, $\partial\beta/\partial k_{12}$ has the same sign as $\nabla^2 - (k_{21} + k_{12} + k_{10} - k_{20})^2$. Thus:

$$\nabla^2 - (k_{21} + k_{12} + k_{10} - k_{20})^2 = 4k_{21}(k_{20} - k_{10}) \quad \text{(Eq. A2)}$$

and, therefore:

$$\frac{\partial\beta}{\partial k_{12}} > 0 \quad \text{if } k_{20} > k_{10} \quad \text{(Eq. A3)}$$

$$\frac{\partial\beta}{\partial k_{12}} = 0 \quad \text{if } k_{20} = k_{10} \quad \text{(Eq. A4)}$$

$$\frac{\partial\beta}{\partial k_{12}} < 0 \quad \text{if } k_{20} < k_{10} \quad \text{(Eq. A5)}$$

Similarly, partial differentiation of β with respect to k_{21} gives:

$$\frac{\partial\beta}{\partial k_{21}} = \frac{1}{2\nabla}[\nabla - (k_{21} + k_{12} + k_{20} - k_{10})] \quad \text{(Eq. A6)}$$

which is similar to Eq. A1 except that the order of k_{20} and k_{10} is reversed. Therefore:

$$\frac{\partial\beta}{\partial k_{21}} < 0 \quad \text{if } k_{20} > k_{10} \quad \text{(Eq. A7)}$$

$$\frac{\partial\beta}{\partial k_{21}} = 0 \quad \text{if } k_{20} = k_{10} \quad \text{(Eq. A8)}$$

$$\frac{\partial\beta}{\partial k_{21}} > 0 \quad \text{if } k_{20} < k_{10} \quad \text{(Eq. A9)}$$

Progestin Permeation through Polymer Membranes III: Polymerization Solvent Effect on Progesterone Permeation through Hydrogel Membranes

G. M. ZENTNER, J. R. CARDINAL ˣ, and D. E. GREGONIS

Received August 4, 1978, from the *Department of Pharmaceutics, College of Pharmacy, University of Utah, Salt Lake City, UT 84112.* Accepted for publication November 13, 1978.

Abstract □ Hydrogels prepared from poly(hydroxyethyl methacrylate) are biocompatible and highly permeable to low molecular weight solutes. Permeation rates can be varied by altering the cross-linker concentration or using copolymers; the latter are chosen to alter the hydrogel equilibrium hydration. These factors suggest that hydrogels are good candidates for controlled-release drug delivery devices. Hydrogels may be synthesized using various temperatures, initiators (nature and concentration), and solvents (nature and concentration). This study demonstrated that progesterone permeation through poly(hydroxyethyl methacrylate) films is independent of polymerization solvent (nature and concentration) for the solvents, water, ethanol, and *tert*-butyl alcohol. The importance of hydrogel equilibrium hydration in progesterone permeation is emphasized.

Keyphrases □ Hydrogels, poly(hydroxyethyl methacrylate)—progesterone permeation, effect of various nonaqueous polymerization solvents □ Hydroxyethyl methacrylate—hydrogel films, progesterone permeation, effect of various nonaqueous polymerization solvents □ Progesterone—permeation through hydrogel membranes, effect of various nonaqueous polymerization solvents □ Delivery devices, controlled—hydrogel membranes, progesterone permeation, effect of various nonaqueous polymerization solvents

Hydrogels are biocompatible (1) and potentially useful for controlled-release drug delivery systems (2–9). Monomer composition and cross-linker type and composition determine hydrogel drug release rates.

The physical–chemical properties of hydrogels depend on polymerization conditions (10). In poly(hydroxyalkyl methacrylate) synthesis, polymerization at the gel equilibrium water content is convenient. However, varying the initial solvent composition is often advantageous in fabricating controlled-release drug delivery devices. Certain fabrication problems may be overcome through nonaqueous polymerization (4, 7). However, polymer chain organization, degree of cross-linking, and other properties may be altered, resulting in a different polymer when water is omitted. These changes could affect the permeability of these films relative to those polymerized in the presence of water.

For these reasons, a systematic study of polymerization solvent effects on progesterone permeability through films polymerized from hydroxyethyl methacrylate was undertaken. Films prepared without cross-linker were chosen because the permeabilities of these films are highly sensitive to small changes in cross-link density (9, 11, 12).

Also included in the present study are the effects of the solvents ethanol and *tert*-butyl alcohol. Based on thermodynamic (13) and swelling arguments (14), ethanol and, to a greater extent, *tert*-butyl alcohol are better solvents for poly(hydroxyethyl methacrylate) than is water. These solvents are expected to offer certain advantages in the polymerization of films containing high concentrations of cross-linking agents and aid in dissolving drugs that nor-

mally are not soluble in hydroxyethyl methacrylate–water solutions during polymerization. When water is used as the polymerization solvent, phase separation tends to occur during polymerization, a problem that is overcome through the use of ethanol or *tert*-butyl alcohol.

EXPERIMENTAL

Hydrogel films were prepared by free radical polymerization using azobis(methyl isobutyrate) (15) (7.84 mmoles/liter of monomer) as the initiator. Hydroxyethyl methacrylate[1] was used as received and contained the major impurities methacrylic acid (0.06%), ethylene glycol dimethacrylate (0.024%), and diethylene glycol methacrylate (0.29%).

Hydroxyethyl methacrylate mixtures with 0, 5, 10, 20, and 40% (v/v) deionized water, 20 and 40% (v/v) ethanol[2], and 20 and 40% (v/v) *tert*-butyl alcohol[3] were polymerized between sealed polyethylene plates at 60° for 24 hr. All films were transparent and homogeneous after polymerization. Subsequent to polymerization, all films were equilibrated in water (changed repeatedly) for 3–4 weeks prior to the permeation studies.

Unlabeled progesterone[4] and 1,2-^{3}H-progesterone[5] were used as received to prepare aqueous 11.2-μg of progesterone/ml solutions for the permeation and partition experiments.

Diffusion and partition experiments were conducted as described previously (8, 9). Film thicknesses, ~0.07 cm, were measured on the water-swollen hydrogels using a lightwave micrometer[6].

Hydration values were obtained as described previously (11).

RESULTS AND DISCUSSION

Progesterone diffusion coefficients in the hydrogel films were calculated using (16):

$$\ln\left(1 - \frac{2C_t}{C_0}\right) = -\left(\frac{1}{V_1} + \frac{1}{V_2}\right)\frac{AUt}{l} \qquad \text{(Eq. 1)}$$

where C_t is the progesterone concentration at time t, C_0 is the initial progesterone concentration, A is the polymer film area (14.9 cm²), l is the film thickness, V_1 and V_2 are the compartment volumes (176 ml), and U is the permeation coefficient defined as:

$$U = DK_d \qquad \text{(Eq. 2)}$$

where D is the diffusion coefficient and K_d is the partition coefficient.

Values for U, D, K_d, and H [the membrane hydration, defined as (film water concentration/bulk water concentration)] are given in Table I, as are the average values and standard deviations for each parameter. The values in each row represent results from a single polymer film.

Progesterone permeability, diffusivity, and partitioning in poly(hydroxyethyl methacrylate) films did not change when: (*a*) the initial polymerization mixture water content was varied from 0 to 40% (v/v), (*b*) the polymerization solvent was changed from water to ethanol or *tert*-butyl alcohol, and (*c*) the alcohol concentration was changed from 20 to 40% (Table I). The equilibrium hydration of the poly(hydroxyethyl methacrylate) films in water was independent of the polymerization conditions.

It was demonstrated previously (14) that the equilibrium water swelling of hydrogels polymerized in different solvents was independent of the solvent type and was dependent only on the monomer volume fraction present in the polymerization medium. This conclusion is consistent with the present study, which demonstrates that polymer hydration is independent of both solvent type and concentration, regardless of the dimensional changes that occur with water equilibration.

Hydration and permeability of hydrogel films have been theoretically related (17) and experimentally verified (9). Mechanistic interpretations of poly(hydroxyethyl methacrylate) film permeation suggest a "pore-flow" mechanism for progesterone (9). This information and the present data indicate that equally hydrated gels display an "effective porosity" independent of the polymerization solvent. Hydration is an inherent property of the gel network formed under conditions of fixed monomer type, temperature, and initiator type and concentration. Furthermore, it appears that any differences in the gel network organization that arise from polymerization solvent changes are secondary to hydration in determining progesterone permeability in hydrogel films.

High-Pressure Liquid Chromatographic Analysis of Veterinary Anthelmintics I: Quantitative Determination of Tetramisole

D. MOUROT ˣ, B. DELÉPINE, J. BOISSEAU, and G. GAYOT

Received May 3, 1978, from the *Laboratoire National des Médicaments Vétérinaires, Direction de la Qualité, Ministère de l'Agriculture, Javené 35300 Fougeres, France.* Accepted for publication November 15, 1978.

Abstract □ High-pressure liquid chromatography was used with a 10-μm C_8-type bonded silica gel column to quantitate the tetramisole in veterinary anthelmintic preparations. The chromatographic elution time was less than 10 min, and other compounds present in the products analyzed did not interefere.

Keyphrases □ Tetramisole—high-pressure liquid chromatographic analysis, veterinary preparations □ High-pressure liquid chromatography—analysis, tetramisole in veterinary preparations □ Anthelmintics—tetramisole, high-pressure liquid chromatographic analysis in veterinary preparations

Tetramisole (*dl*-2,3,5,6-tetrahydro-6-phenylimidazo[2,1-*b*]thiazole) hydrochloride (1) is a potent, broad-spectrum anthelmintic; it exhibits high activity against several GI and pulmonary nematode species. Tetramisole is often used in veterinary therapeutics, either alone or with other anthelmintics such as bithionol, bithionol sulfoxide, and oxyclozanide.

UV spectrophotometry cannot be used directly for identifying tetramisole because the tetramisole absorption maximum (214 nm) is shared by other organic substances. TLC separation of tetramisole from its thermal degradation products was reported (2) but was not quantitative. A partition column chromatographic method (3) resolved tetramisole from other interfering substances prior to UV measurement but was time consuming and unsuitable for routine analysis.

High-pressure liquid chromatography (HPLC) offers a viable alternative for the quantitative analysis of tetramisole in commercial products and is applicable to various formulations.

EXPERIMENTAL

Equipment—The liquid chromatograph[1] was operated at ambient temperature and was equipped with a UV detector for monitoring the column effluent at 254 nm. The stainless steel column, 15 cm × 4.7 mm (i.d.), was packed with a C_8-type permanently bonded silica gel[2]. The liquid chromatographic detector was connected to a computing integrator[3] for obtaining the chromatogram peak areas.

Reagents—Tetramisole hydrochloride[4] and phenol[5] were the reference and internal standards, respectively.

Analytical reagent grade acetonitrile[5] and sulfuric acid[5] were used for the mobile phase preparation.

Mobile Phase—A mixture of 1% concentrated sulfuric acid in water–acetonitrile (80:20 v/v) was used.

Internal Standard Solution—Accurately weighed phenol (~500 mg) in a 100-ml volumetric flask was dissolved in, and diluted to volume with, the mobile phase.

Standard Solution—Accurately weighed tetramisole standard (~100 mg) in a 100-ml volumetric flask was dissolved in, and diluted to volume with, water. A tetramisole standard–phenol solution mixture (1:1) in a suitable vessel was mixed well.

Sample Solution—An anthelmintic sample equivalent to 100 mg of tetramisole was pipetted accurately into a 100-ml volumetric flask and diluted to volume with water. A 1:1 sample solution–phenol solution mixture in a suitable vessel was mixed well.

Formulations Containing Bithionol and Oxyclozanide—Veterinary formulations containing tetramisole–bithionol or tetramisole–oxyclozanide are suspensions. The formulation was mixed thoroughly, and an aliquot equivalent to 100 mg of tetramisole was pipetted quickly into a 50-ml glass-stoppered centrifuge tube. Water (25 ml) was added, and the solution was mixed thoroughly and centrifuged at 2000 rpm for 5 min. The supernate was transferred into a 100-ml volumetric flask, and the residue was extracted with 4 × 10 ml of water. The combined extracts in the 100-ml flask were diluted to volume with water.

Chromatography—The column was conditioned 0.5 hr with mobile phase (flow rate of 1.6 ml/min). Four-microliter standard solution aliquots were injected onto the column, and the tetramisole (2.4 min) and phenol (6.0 min) peaks were identified. The relative area response ratio was determined by replicate standard solution injections. When the response ratio deviation was less than 2%, the sample dilution was injected.

Linearity—The method was evaluated for tetramisole response linearity at concentrations ranging from 0.02 to 2% of tetramisole. Four microliters of each solution was injected into the chromatograph, and the tetramisole–internal standard area ratio was calculated and plotted *versus* the tetramisole concentration. The chromatographic response was linear up to the highest tetramisole concentration tested (2%).

RESULTS AND DISCUSSION

The results (Table I) show that tetramisole can be assayed in veterinary anthelmintic formulations using a simple HPLC method. However, these results could not be tested against an alternative (tested or official) method because no such method exists. The HPLC analyses gave a linear response with tetramisole concentrations between 0.02 and 2%. An aqueous 0.1% tetramisole standard was assayed with each batch of samples, and the sample concentration calculations were based upon this standard.

The commercial anthelmintic preparations generally contained bithionol, bithionol sulfoxide, or oxyclozanide in addition to tetramisole, but these agents did not interfere with the tetramisole assay since they were not eluted under the conditions described. Bithionol, bithionol sulfoxide, and oxyclozanide remaining on the column were subsequently eluted by changing the mobile phase to acetonitrile (1 ml/min) and eluting for 20 min after every series of 20 samples had been run.

Although 254 nm is the most commonly used wavelength, tetramisole elution was monitored at its absorption maximum (214 nm); detection

Table I—Percent Tetramisole Concentration in Anthelmintic Veterinary Formulations

Sample	Labeled Tetramisole	Found Tetramisole[a]
1[b]	7.5	7.9 ± 0.1

Possibility for Error in FDA Diffusion Assays

M. A. FOGLESONG ˣ, F. KAVANAGH, and J. V. DIETZ

Received September 26, 1978, from *Eli Lilly and Company, Indianapolis, IN 46206.* Accepted for publication November 20, 1978.

Abstract □ Computational procedures specified for the FDA single-dose diffusion assay for antibiotics may cause substantial error in estimated sample potency. An unrecognized mistake in reference solution concentration is the source of error. It is caused by correcting responses from standard and sample plates differently. The error can be avoided by correcting both standard and sample responses to the observed reference response.

Keyphrases □ FDA—assay, antibiotics, correction □ Antibiotics—analysis, FDA diffusion assay, corrections

The single-dose diffusion assay of the Food and Drug Administration (FDA) has been a satisfactory antibiotic assay for more than 30 years. The method is about as accurate as any other diffusion method.

Since samples and standards are on different petri plates, sample responses must be corrected for variations in zone sizes attributable to plates. To this end, one-half of the responses on sample plates are from a reference solution, which is also the middle concentration of the standard line.

The correction procedures specified in the FDA regulations (1) are different for standards and samples and can cause substantial error under certain circumstances. Causes of errors, their sizes, and procedures for avoiding them will be discussed.

DISCUSSION

The standard line used in this assay was relatively short to avoid complication caused by excessive curvature. Standard concentrations did not follow a 1.35 multiplier exactly but were adjusted to concentrations that could be prepared accurately using volumetric pipets and flasks. The standard lines were computed by linear regression analysis and not by the modified least-squares formula of the "Code of Federal Regulations" (CFR) 436.105 (1).

The data for this investigation were obtained from a *Bacillus subtilis* (ATCC 6633) pen-cylinder agar diffusion assay for cephalexin. For the assay, plastic petri plates (100 × 15 mm) contained a single 10-ml layer of Medium 1 (2) seeded with *B. subtilis* spores. Standard and sample solutions were made from a freshly prepared stock solution in pH 6.0 buffer. Standards containing 2.00, 2.75, 3.75, 5.00, or 6.50 μg of cephalexin activity/ml and samples containing 2.75, 3.00, 4.00, or 6.00 μg of activity/ml were applied at a dosage of 0.2 ml/cylinder. The solution used for the 2.75-μg/ml sample was the same solution used for the 2.75-μg/ml standard. Plates were incubated at 30° for 16–18 hr, and inhibition zones were measured to the nearest 0.01 mm with an antibiotic zone reader[1] as described elsewhere (3).

Zone diameters are given in Table I. A standard line graph is given in

Table I—Standard and Sample Responses

Standard, μg/ml	Response, mm	
	Standard	Reference

Table II—Potencies Computed by FDA and Lilly Procedures from the Best Straight Lines

Sample	True Concentration, μg/ml	Five-Point Line, Including Reference Point		Four-Point Line Excluding Reference Point, Lilly
		FDA	Lilly	
1	3.00	3.69	3.15	3.02
2	6.00	7.36	6.27	6.02
3	4.00	4.99	4.26	4.09
4	2.75	3.40	2.90	2.79
Reference, mm		16.79	16.12	16.12
Mean computational error, %		+24	+5	0

Standard responses were corrected to the observed mean reference concentration response ("3.75" μg/ml) on all standard plates. Sample plate responses were corrected to the theoretical reference response, the 3.75-μg/ml point on the best straight line through the five standards as required by regulations (1). These results are given in the "FDA" column of Table II.

A second set of potencies was obtained from the same data by correcting sample zones to the observed reference as was done for standards and interpolating from the same straight line. These results are given in the "Lilly" column of Table II. A third set of potencies was obtained by correcting to the observed reference and by rejecting the obviously erroneous reference response when computing the best straight line. These results were taken as the true sample assay.

The computational error of +24% in the FDA procedure was caused by the computed reference diameter required by the CFR (1). The error caused by including the erroneous reference point in the calculation of the best straight line was about 5%.

The plates for Sample 4 were incubated at a temperature slightly different from that of the standard plates. Since each response was corrected to the reference concentration, this difference in temperature and the resultant reduction in zone diameters had no effect on the calculated sample potency.

The correction procedure of Ref. 1 is without error only when the observed mean reference diameter is identical with that interpolated from the best straight line. Since this is an unlikely occurrence, a different correction scheme should be used. Correcting both standard and sample responses to the response observed for the reference and then calculating estimated potencies from the regression equation will avoid the errors of the CFR (1).

Proper plate correction is of more than academic interest because computational errors as great as 40% have been reported from other laboratories[2]. Such an error was caused by using a reference about three-fourths as concentrated as it was thought to be. Large errors seem to be rare, but smaller ones are not. In one series of 40 response lines from 16 laboratories, seven of the reference zones, including the one just mentioned, were obviously in error and nine other standard zones had errors. Except for the reference, errors were evenly distributed among the other four standards. Three calibration lines had two obvious errors in them. All of these lines were used in the laboratories reporting the work.

High-Pressure Liquid Chromatographic Feprazone Determination in Pharmaceutical Formulations

ANGELO BONORA ˣ and PIER ANDREA BOREA

Received September 12, 1978, from the *Istituto di Farmacologia, Università di Ferrara, 44100 Ferrara, Italy.* Accepted for publication November 30, 1978.

Abstract □ A high-pressure liquid chromatographic method was developed for the quantitative determination of feprazone, a nonsteroidal anti-inflammatory agent, in different pharmaceutical formulations. The results agree with those obtained with GLC and UV spectrophotometric assays.

Keyphrases □ High-pressure liquid chromatography—analysis, feprazone in various pharmaceutical formulations □ Feprazone—analysis, high-pressure liquid chromatography, various pharmaceutical formulations □ Analgesics—feprazone, analysis in various pharmaceutical formulations, high-pressure liquid chromatography

Feprazone (4-prenyl-1,2-diphenyl-3,5-pyrazolidinedione) is a nonsteroidal analgesic, antipyretic, and anti-inflammatory agent with a low ulcerogenic potential. Feprazone has been determined in pharmaceutical formulations and in body fluids by potentiometric titration (1), UV spectrophotometry (2), TLC (3), GLC (4–6), and radioisotopic techniques (7).

This paper describes the quantitative determination of feprazone in capsule, suppository, and cream formulations by a simple and rapid high-pressure liquid chromatographic (HPLC) procedure.

The proposed HPLC method was compared to GLC (5) and UV spectrophotometric (2) assays.

EXPERIMENTAL[1]

HPLC—*Equipment and Operating Conditions*—A liquid chromatograph[2], equipped with a UV–visible detector[3] and with a septum injector[2], was used. The column[4] was 50 cm × 2.2 mm i.d., and the microcell[5] volume was 8 μl. The flow rate was 0.49 ml/min under a constant pressure

[1] All solvents were BDH AnalaR grade and were used without further purification.

8	4.87	4.98	5.00
Average	4.97	4.93	4.96
SD	0.10	0.09	0.10

[a] All results are reported as milligrams percent based on a pool of five cream samples.

of 1000 psi (70.3 kg/cm^2). Detection was by UV absorbance at 265 nm.

The optimum wavelength was determined from the UV spectrum of feprazone obtained by a stop-flow technique (8). The flow was interrupted by means of a two-stem valve[6] placed between the constant pressure pump and the septum injector when an absorbance, previously determined by comparison with the solvent absorbance (and, therefore, belonging to the substance under examination), was detected. The complete sample spectrum was then recorded in the 320–220-nm range.

Reagents—As a reference standard, pure feprazone[7] was used. Promethazine chlorhydrate[8] was the internal standard. The mobile phase was methanol–32% ammonia (150:2 v/v).

Standard Solutions—Standard feprazone solutions were prepared by dissolving accurately weighed aliquots of the pure substance in the mobile phase to produce final concentrations of 0.1–3.2 mg/ml. All standard solutions contained 2.5 mg of promethazine/ml.

Capsules—Pools of five capsules[7] were crushed in a porcelain mortar to a fine powder. Then aliquots of 25 mg of powder plus 50 mg of the internal standard were dissolved in 25 ml of chloroform. After filtration, the solution was evaporated at 40° and the residue was dissolved in 25 ml of mobile phase.

Suppositories—An aliquot of a suppository[7] mixture, one-third of the weight of a suppository, and 200 mg of the internal standard were dissolved in 50 ml of carbon disulfide. After filtration and evaporation, the residue was dissolved in the mobile phase.

Cream—Cream (0.50 g) and 50 mg of the internal standard were dissolved in a water bath in 25 ml of ethanol. Then 1 ml of this solution was filtered, evaporated, and redissolved in 1 ml of mobile phase.

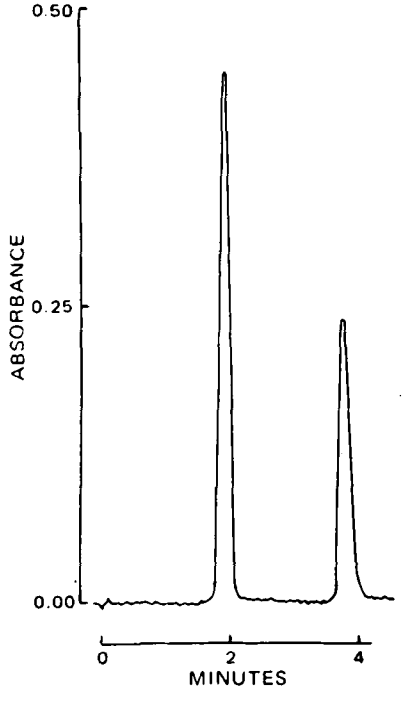

Figure 1—*Typical liquid chromatogram of feprazone (left) and internal standard (right) from capsules.*

GLC—A gas chromatograph[9], fitted with a dual-flame ionization detector and coiled glass columns[9] (1500 × 40 mm) packed with 2.5% SE-30 on 100–120-mesh Gas Chrom Q[9], was used. All working conditions were as described previously (5).

UV Spectrophotometry—A UV-visible spectrophotometer[3] was used, and the absorbance of feprazone was determined at 263 nm in 0.1 *N* NaOH. All working conditions were as described previously (2).

RESULTS AND DISCUSSION

Standard Curve—Linearity was shown by injecting into the column various amounts of feprazone over the concentration range 0.1–3.2 mg/ml with a constant amount of the internal standard (2.5 mg/ml). The mobile phase was methanol–32% ammonia (150:2 v/v). The standard curve was calculated by regression analysis as $y = 0.02 + 0.43x$ ($r = 1.0$), where y is the ratio of the feprazone peak area to the internal standard peak area, calculated at a sensitivity of 0.5 aufs deflection, and x is milligrams of feprazone per milliliter. To estimate the peak area standard deviations, five determinations were carried out for each concentration. Standard deviations were 3.1%.

HPLC—Eight samples of each pharmaceutical formulation were injected into the column using the stop-flow technique. Figure 1 shows a typical chromatogram of feprazone and the internal standard obtained from the capsule extraction. The retention times were 1.52 min for feprazone and 3.46 min for the internal standard. All measurements were carried out at room temperature (25°).

Recovery—Feprazone recovery from the pharmaceutical formulations was estimated. Formulations to which known feprazone amounts were added prior to extraction had an average percent recovery of 99.9, 99.9, and 99.8 with 95% confidence limits of 99.5–100.3, 99.4–100.4, and 99.2–100.4, respectively, for capsules, suppositories, and cream.

Peak Identification—Feprazone identification was accomplished by comparison with the pure standard retention times.

Suitable quantities of the liquid chromatograph cell effluent were collected corresponding to the drug chromatographic peak and were tested for homogeneity by qualitative monodimensional TLC using silica gel precoated glass plates (20 × 20 cm, 0.25 mm thick). Three solvents

[6] Whitey Co., Oakland, Calif.
[7] De Angeli Institute, Milan, Italy.
[8] Farmitalia Pharmaceuticals, Milan, Italy.
[9] Carlo Erba, Milan, Italy.

were used: (*a*) chloroform–acetone–ethanol (70:30:3 v/v); (*b*) cyclohexane–ethyl acetate–methanol–water (100:100:60:8 v/v); and (*c*) benzene–acetic acid (95:5 v/v). After each development, the plates were dried at 110° and spots were visualized in iodine vapors. The chromatograms corresponded perfectly in color (brown) and R_f values to those obtained with the reference compounds.

Comparison of HPLC, GLC, and UV Methods—The proposed HPLC method was compared to GLC (5) and UV spectrophotometric (2) assays. The results (Tables I–III) show that the proposed method is in good agreement with the GLC and UV assays.

The HPLC procedure described here provides a rapid, sensitive (the lower sensitivity limit is about 10 ng on the column), and precise assay of feprazone in pharmaceutical formulations.

GLC–Mass Spectrometry of *Teucrium polium* Oil

M. M. A. HASSAN ˣ, F. J. MUHTADI, and A. A. AL-BADR

Received June 6, 1978, from the *Faculty of Pharmacy, University of Riyad, Riyad, Saudi Arabia.* Accepted for publication December 14, 1978.

Abstract □ The essential oil of *Teucrium polium*, growing in Saudi Arabia, was thoroughly investigated for its constituents by GLC–mass spectrometry, TLC, and spectrophotometric methods. This investigation revealed the presence of 10 terpenoidal compounds including the hydrocarbons β-pinene, limonene, α-phellandrene, and γ- and δ-cadinenes and the alcohols linalool, terpine-4-ol, cedrol, cedrenol, and guaiol. The oil was rich in alcohols and devoid of esters. Preliminary pharmacological screening showed that the oil possesses powerful antispasmodic activity.

Keyphrases □ GLC–mass spectrometry—analysis, *Teucrium polium* oil, antispasmodics, folk medicine □ *Teucrium polium*—oil, GLC–mass spectrometry □ Antispasmodics—analysis, *Teucrium polium* oil, GLC–mass spectrometry, folk medicine □ Folk medicine—antispasmodics, *Teucrium polium* oil, GLC–mass spectrometry

Teucrium polium (Family Labiatae) is one of the most fragrant plants in Saudi Arabia and is fairly distributed throughout the country (1). In folk medicine, it is used as an antispasmodic, antirheumatic, carminative, and flavoring agent. In an admixture with other powdered herbs, it is claimed to be therapeutic for peptic ulcer.

The aroma of this plant is due to its essential oil content (2). A literature review revealed that the oil constituents had not been investigated thoroughly (4). The present work was carried out to investigate the composition of this potentially therapeutic plant oil.

EXPERIMENTAL

Material—The plant was collected in the spring at the flowering stage from Sudair (Central Zone), 180 km from Riyad. Its identity as *T. polium* was confirmed[1]. It was dried and powdered.

Successive quantities (1 kg each) were subjected to steam distillation, which produced a volatile oil (average yield, 1.55 g).

The physical properties of the oil are presented in Table I.

TLC—TLC was done on precoated silica gel thin-layer plates[2] developed in chloroform–benzene (1:1) and chloroform–benzene (4:1) solvent systems (3). After development, the spots were visualized by spraying with anisaldehyde reagent (3).

Table I—Comparative Physicochemical Data

Property	Isolated Oil	Sardinian Oil
Color	Light yellow, darkens upon standing	Blue
Odor	Fragrant, characteristic	Agreeable, pungent
Refractive index[a]	n_D^{24}, 1.4850	n_D^{20}, 1.475 and 1.488
Optical rotation[b]	$[\alpha]_D^{24}$ +4.7° (10% in ethanol)	$[\alpha]_D^{20}$ +12.75°
Acetyl value[c]	117	47.45–47.59
IR[d]	1633, 1655, 1700, 2900, and 3400 cm^{-1}	—
NMR[e]	Broad singlets at 332, 306, 280, and 268 Hz; broad singlet at 217 Hz; singlet at 98 Hz; doublet at 73 Hz; two overlapping doublets centered at 58 Hz	—

[a] Zeiss Abbe refractometer. [b] Bellingham and Stanley polarimeter. [c] According to the BP method (5). [d] As film on Perkin-Elmer 567 grating IR spectrophotometer. [e] In deuterochloroform on Varian T 60A with tetramethylsilane as the internal standard.

GLC–Mass Spectrometry—Mass spectra of the volatile oil constituents were obtained using a gas chromatograph–mass spectrometer[3]. The chromatographic column (1.8 m long) was packed with 3% OV-17. The column was conditioned isothermally at 100° for 10 min, and then the temperature was programmed at 5 min until 260°. The injection port temperature was 185°, the separation temperature was 252°, and the ion source temperature was 290°. Mass spectra were obtained by operating at 60 MHz and with an ionization energy of 70 ev.

RESULTS AND DISCUSSION

The isolated oil was compared with Saridinian *T. polium* oil (4) (Table I). The IR and NMR data revealed free alcohols (3400 cm^{-1}; broad singlet at 217 Hz, disappeared on deuteration), alkene and highly conjugated

[1] The plant material was identified as *Teucrium polium* Linneus (Labiatae) by Dr. A. M. Migahid, Department of Botany, Faculty of Science, University of Riyad, Riyad, Saudi Arabia. A voucher specimen is available in the herbarium of Riyad University.

Table II—Constituents of the Oil by GLC-Mass Spectrometry

Compound	Retention Time, min	Molecular Weight	M^+
1 β-Pinene	1.0	136.23	136
2 Limonene	1.3	136.23	136
3 α-Phellandrene	1.6	136.23	136
4 Linalool	2.3	154.24	136
5 Terpine-4-ol	3.9	154.24	154
6 γ-Cadinene	17.2	204.34	204
7 Cedrenol	20.7	222.36	220
8 δ-Cadinene	22.5	204.34	204
9 Guaiol	22.9	222.36	222
10 Cedrol	23.4	222.36	222

alkenes [1633 (m)[4] and 1655 (m) cm^{-1}; broad peaks at 332, 306, 280, 268 Hz], alicyclic structures (singlet at 98 Hz, doublet at 73 Hz, and triplet formed of two overlapping doublets at 58 Hz), and the absence of esters, other carbonyl compounds, and aromatic functions. TLC screening of the oil showed both hydrocarbons and alcohols.

GLC–mass spectrometry studies indicated the presence of several compounds (Table II and Fig. 1). The major components on the GLC trace (Fig. 1) are identified by sequence numbers that correspond to the mass spectral sequence numbers.

The mass spectra so obtained were compared with the authentic compounds and demonstrated almost identical fragmentation characteristics (6). The mass fragmentation pattern of most components showed molecular ion peaks at atomic mass units equivalent to their molecular weights. The linalool mass fragmentation pattern exhibited an M^+ at 136 amu instead of at 154 amu. The M − 18 fragment was attributed to the formation of a triene compound from the parent ion by the loss of water (7).

The cedrenol mass spectrum did not show an M^+ at 222 amu; the M − 2 fragment at 220 amu represented the loss of two hydrogen atoms (7).

From the data obtained, the volatile oil was considered to be one of the alcoholic volatile oils since 50% of the components were alcohols. The absence of esters may indicate that the plant is unable to esterify these alcohols.

Preliminary pharmacological screening of the isolated oil showed that it possessed potent antispasmodic activity and that it markedly antagonized the effects of the agonists nicotine, acetylcholine, histamine, and serotonin.

[4] Medium.

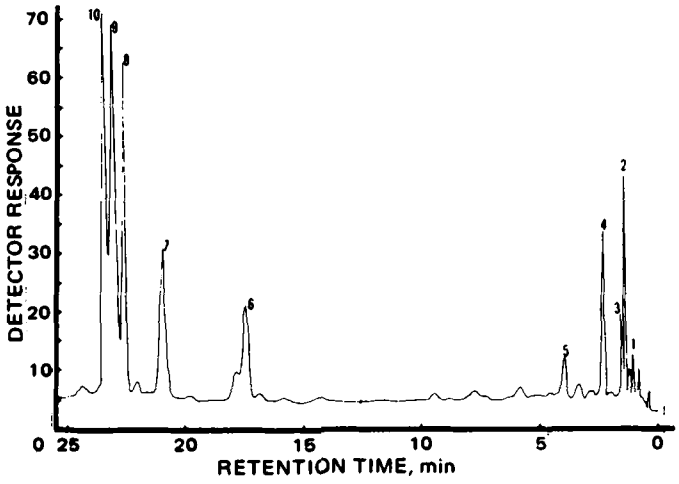

Figure 1—*Gas chromatogram of the isolated oil.*

The aqueous extract of the herb had low antispasmodic activity compared to the oil. The results of this study partially justified the use of this plant in folk medicine.

Comparison of High-Pressure Liquid Chromatographic and Ion-Exchange Membrane Methods for Creatinine

Keyphrases □ High-pressure liquid chromatography—analysis of creatinine, membrane method □ Creatinine—high-pressure liquid chromatography analysis, membrane method

To the Editor:

Chiou *et al.* (1) described a high-pressure liquid chromatographic (HPLC) method for creatinine and stated that previously published methods "lack specificity" or are "subject to interferences." In particular, they stated that in the cation-exchange membrane method of Vedsø *et al.* (2), the membrane is used "to remove proteins and interfering substances from serum samples . . . . Acetoacetate and possibly some other interfering substances are not removed. Therefore, interferences occur at least in samples from ketotic patients."

In fact, the cation-exchange membrane is used to *remove creatininium ions* from diluted serum at pH 3.1. Acetoacetate, acetone, glucose, and pyruvate are not removed (3); therefore, interference by these substances does *not* occur. (This is clearly stated in the original article.)

Chiou *et al.* (1) also stated that the membrane method "would probably take about 30 min for each assay," while their own method requires "only about 5 min for completion." In fact, an assay with the membrane method takes about 1.5 hr (the original article clearly stated that ion exchange takes 1 hr and desorption requires 20 min). Since the membrane method is a batch technique, a routine workload of 250 determinations (representing 100 sample duplicates) can be accomplished by one technician in 2.5 hr. This quantity is in contrast to the method of Chiou *et al.* (1) in which the throughput appears to be about 12 determinations/chromatograph hr, which is hardly suitable for routine workloads.

The membrane method has been improved since publication in 1974. The picrate reagent now contains 9.8 mmoles of picric acid/liter and 82 mmoles of sodium hydroxide/liter. The reagent blank is now about 0.030*A*, and the slope of the standard curve is about 2.0*A* mole^{-1} liter $\times 10^3$. With the improved method, the coefficient of variation at 50 μmoles/liter (0.57 mg %) is about 5%; in the normal range, it is about 4%. These values are in sharp contrast to those of Moss *et al.* (4), who found a coefficient of variation of 14% for creatinine values of 67 μmoles/liter (0.76 mg %).

Chiou *et al.* (1) erroneously stated that Moss *et al.* (4) did not report on the reproducibility of measurements of concentrations below 1 mg %. In fact, the article of Moss *et al.* is one of the few that *does* give this information. However, Chiou *et al.* do not report the reproducibility of their method below 1 mg %.

Creatinine IX: Specificity and Sensitivity of High-Performance Liquid Chromatographic and Ion-Exchange Membrane Methods for Determination of Endogenous Creatinine

Keyphrases □ Creatinine—analysis, high-performance liquid chromatography, ion-exchange membrane assay □ High-performance liquid chromatography—analysis, creatinine

To the Editor:

In commenting on our extensive studies (1) on the development of a simple, rapid, and micro high-pressure liquid chromatographic (HPLC) method for the determination of endogenous "true" creatinine, it appears that Place (2) has misunderstood the content of our paper. Our paper clearly stated that in the ion-exchange membrane method by Vedsø *et al.* (3), "the subsequent reaction of creatinine desorbed from the membrane with the alkaline picrate." Although the ion-exchange membrane method was claimed to be specific (3), it can only be considered more specific than some other published methods using the alkaline picrate reagent. This is obvious since there is no guarantee that other endogenous substance(s) not tested by them or other workers cannot react with the alkaline picrate in their method. In commenting on the kinetic method of Larsen (4), Vedsø *et al.* (3) erroneously implied that they achieved a *total specificity* in their membrane method.

The accuracy and specificity of the original membrane method (1) also can be questioned due to the unusually high absorbance for their blank sample. The blank absorbance, calculated by this author, is equivalent to 1.70 mg % of creatinine. Plasma or serum creatinine levels ranging from 0.4 to 0.8 mg % are quite commonly found in patients.

There should be no doubt that the HPLC methods (1, 5, 6) for the assay of creatinine in serum or plasma should be more specific than the other assays published to date. The automated analyzer method, generally considered to be quite specific, overestimated creatinine by as much as 45% in our studies and ~200% in others (5) in certain samples when compared with the HPLC methods. In our laboratory, a range of ~20–70% of overestimation also was recently found in many serum samples with low creatinine

In fact, an assay with the membrane method takes about 1.5 hr (the original article clearly stated that ion exchange takes 1 hr and desorption requires 20 min). Since the membrane method is a batch technique, a routine workload of 250 determinations (representing 100 sample duplicates) can be accomplished by one technician in 2.5 hr. This quantity is in contrast to the method of Chiou *et al.* (1) in which the throughput appears to be about 12 determinations/chromatograph hr, which is hardly suitable for routine workloads.

The membrane method has been improved since publication in 1974. The picrate reagent now contains 9.8 mmoles of picric acid/liter and 82 mmoles of sodium hydroxide/liter. The reagent blank is now about 0.030*A*, and the slope of the standard curve is about 2.0*A* mole^{-1} liter $\times 10^3$. With the improved method, the coefficient of variation at 50 μmoles/liter (0.57 mg %) is about 5%; in the normal range, it is about 4%. These values are in sharp contrast to those of Moss *et al.* (4), who found a coefficient of variation of 14% for creatinine values of 67 μmoles/liter (0.76 mg %).

Chiou *et al.* (1) erroneously stated that Moss *et al.* (4) did not report on the reproducibility of measurements of concentrations below 1 mg %. In fact, the article of Moss *et al.* is one of the few that *does* give this information. However, Chiou *et al.* do not report the reproducibility of their method below 1 mg %.

Creatinine IX: Specificity and Sensitivity of High-Performance Liquid Chromatographic and Ion-Exchange Membrane Methods for Determination of Endogenous Creatinine

Keyphrases □ Creatinine—analysis, high-performance liquid chromatography, ion-exchange membrane assay □ High-performance liquid chromatography—analysis, creatinine

To the Editor:

In commenting on our extensive studies (1) on the development of a simple, rapid, and micro high-pressure liquid chromatographic (HPLC) method for the determination of endogenous "true" creatinine, it appears that Place (2) has misunderstood the content of our paper. Our paper clearly stated that in the ion-exchange membrane method by Vedsø *et al.* (3), "the subsequent reaction of creatinine desorbed from the membrane with the alkaline picrate." Although the ion-exchange membrane method was claimed to be specific (3), it can only be considered more specific than some other published methods using the alkaline picrate reagent. This is obvious since there is no guarantee that other endogenous substance(s) not tested by them or other workers cannot react with the alkaline picrate in their method. In commenting on the kinetic method of Larsen (4), Vedsø *et al.* (3) erroneously implied that they achieved a *total specificity* in their membrane method.

The accuracy and specificity of the original membrane method (1) also can be questioned due to the unusually high absorbance for their blank sample. The blank absorbance, calculated by this author, is equivalent to 1.70 mg % of creatinine. Plasma or serum creatinine levels ranging from 0.4 to 0.8 mg % are quite commonly found in patients.

There should be no doubt that the HPLC methods (1, 5, 6) for the assay of creatinine in serum or plasma should be more specific than the other assays published to date. The automated analyzer method, generally considered to be quite specific, overestimated creatinine by as much as 45% in our studies and ~200% in others (5) in certain samples when compared with the HPLC methods. In our laboratory, a range of ~20–70% of overestimation also was recently found in many serum samples with low creatinine

0022-3549/79/0600-0802$01.00/0
© 1979, American Pharmaceutical Association

levels[1]. A boiling alkaline picrate method claimed for the determination of "true" creatinine has also been shown to give an average 32.4 ± 27.2% (*SD*) overestimation, with the highest overestimation being 102% (7).

We did not advocate that our method be used routinely for all creatinine determinations in patients. Since plasma or serum samples as small as 10 μl are sufficient in our method, we suggested that the method would be "particularly valuable to the monitoring of the renal function in premature and mature infants, children, and adults with collapsed vascular veins. In these patients, the sample required can be obtained easily from the fingertip or the heel in the case of tiny, premature infants."

Place misunderstood our paper regarding the analysis time for each sample. We stated in the Abstract that: "Each assay required only about 5 min for completion." This statement was mistaken by Place to mean 5 min per chromatographic time. In fact, we meant that the time from the receipt of a plasma or serum sample to the reporting of the creatinine level of the sample is ~5 min. Less time is required for multiple-sample analyses. This time compares favorably with the membrane method, which requires ~90 min for emergency cases. The proposed HPLC method can certainly be modified and automated. The potential clinical application of the HPLC method for creatinine assay was examined in two recent papers (5, 6).

Regarding Place's (2) comment on the work of Moss *et al.* (8), it should be pointed out that the lowest creatinine concentration shown in their standard curve is 2 mg %, although the use of a 1 mg % solution was mentioned in the text. Certainly, it is not most desirable to perform the reproducibility study using the creatinine level below the range used for the standard curve.

Although the data on reproducibility of measurements of concentrations <1 mg % were not presented explicitly in our papers (1, 7), they were clearly implied. Excellent reproducible results were always obtained for low creatinine levels in our many standard curve and plasma level studies (1, 7). Using a modified mobile phase and a 254-nm fixed wavelength detector, the coefficient of variation for 0.5 mg % serum sample is only about 2% (9). Our comment (1) on the interferences in samples from ketotic patients should have been directed to the colorimetric method of Heinegård and Tiderström (10) and not to the ion-exchange membrane method.

It is important to point out that in using our HPLC method (1) for creatinine, the filter device[2] to separate plasma or serum from blood cells should not be used; chemicals leached out from the device will interfere with the assay. The possibility of such interference in other HPLC methods should be studied prior to their use.

Effect of Sodium Sulfate on Acetaminophen Elimination by Rats

Keyphrases □ Sodium sulfate—effect on acetaminophen elimination, protection against acetaminophen toxicity, rats □ Acetaminophen—toxicity, prevention by sodium sulfate, effect on elimination □ Analgesics—acetaminophen, toxicity, prevention by sodium sulfate

To the Editor:

Accidental or intentional ingestion of large acetaminophen overdoses can cause hepatotoxicity and damage to other vital organs, sometimes with lethal outcome (1, 2). This toxic effect is produced by a reactive metabolite, which is formed in parallel with acetaminophen glucuronide and acetaminophen sulfate, the two major drug metabolites (3). Pharmacokinetic analysis of acetaminophen disposition in acutely intoxicated patients and certain other evidence from studies in humans indicate that the reactive acetaminophen metabolite is formed by apparent first-order kinetics while the two major conjugated metabolites are formed by capacity-limited kinetics (4, 5). Results of acetaminophen conjugation interaction studies in humans suggest that the availability of sulfate is rate limiting in the formation of acetaminophen sulfate (6, 7). If the formation of acetaminophen sulfate can be accelerated by administration of sodium sulfate or another suitable sulfate source, then the amount of reactive metabolite formed and, therefore, the acetaminophen toxicity should be decreased.

Preliminary studies in mice showed that intraperitoneal administration of sodium sulfate significantly increased the median lethal dose (*i.e.*, decreased the toxicity) of acetaminophen (8), but the effect of sodium sulfate on acetaminophen disposition was not determined. There is some indication that acetaminophen sulfate formation by rats is capacity limited and that treatment with sodium sulfate increases the urinary excretion of the conjugate (9, 10). However, the reported data do not establish definitively the effect of sodium sulfate on acetaminophen elimination kinetics since acetaminophen concentrations in plasma were not determined and urine collections were terminated before the excretion of drug and metabolites was completed.

In view of the potential clinical utility of sodium sulfate

Effect of Sodium Sulfate on Acetaminophen Elimination by Rats

Keyphrases □ Sodium sulfate—effect on acetaminophen elimination, protection against acetaminophen toxicity, rats □ Acetaminophen—toxicity, prevention by sodium sulfate, effect on elimination □ Analgesics—acetaminophen, toxicity, prevention by sodium sulfate

To the Editor:

Accidental or intentional ingestion of large acetaminophen overdoses can cause hepatotoxicity and damage to other vital organs, sometimes with lethal outcome (1, 2). This toxic effect is produced by a reactive metabolite, which is formed in parallel with acetaminophen glucuronide and acetaminophen sulfate, the two major drug metabolites (3). Pharmacokinetic analysis of acetaminophen disposition in acutely intoxicated patients and certain other evidence from studies in humans indicate that the reactive acetaminophen metabolite is formed by apparent first-order kinetics while the two major conjugated metabolites are formed by capacity-limited kinetics (4, 5). Results of acetaminophen conjugation interaction studies in humans suggest that the availability of sulfate is rate limiting in the formation of acetaminophen sulfate (6, 7). If the formation of acetaminophen sulfate can be accelerated by administration of sodium sulfate or another suitable sulfate source, then the amount of reactive metabolite formed and, therefore, the acetaminophen toxicity should be decreased.

Preliminary studies in mice showed that intraperitoneal administration of sodium sulfate significantly increased the median lethal dose (*i.e.*, decreased the toxicity) of acetaminophen (8), but the effect of sodium sulfate on acetaminophen disposition was not determined. There is some indication that acetaminophen sulfate formation by rats is capacity limited and that treatment with sodium sulfate increases the urinary excretion of the conjugate (9, 10). However, the reported data do not establish definitively the effect of sodium sulfate on acetaminophen elimination kinetics since acetaminophen concentrations in plasma were not determined and urine collections were terminated before the excretion of drug and metabolites was completed.

In view of the potential clinical utility of sodium sulfate

© 1979, American Pharmaceutical Association

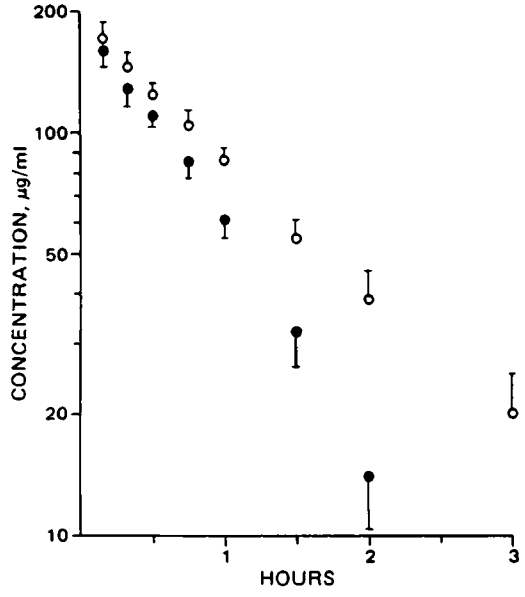

Figure 1—*Effect of sodium sulfate on elimination of acetaminophen, 150 mg/kg iv, by male Sprague–Dawley rats. Sodium sulfate was administered intraperitoneally (142 mg/kg 15 min before acetaminophen) and by intravenous infusion (about 21 mg/kg/hr for 2 hr, starting at the time of acetaminophen injection). Shown are the acetaminophen concentrations in plasma (mean + or − SD, n = 7) as a function of time in control (○) and sulfate-treated (●) animals. Concentrations differed significantly (p < 0.02) from 20 min on.*

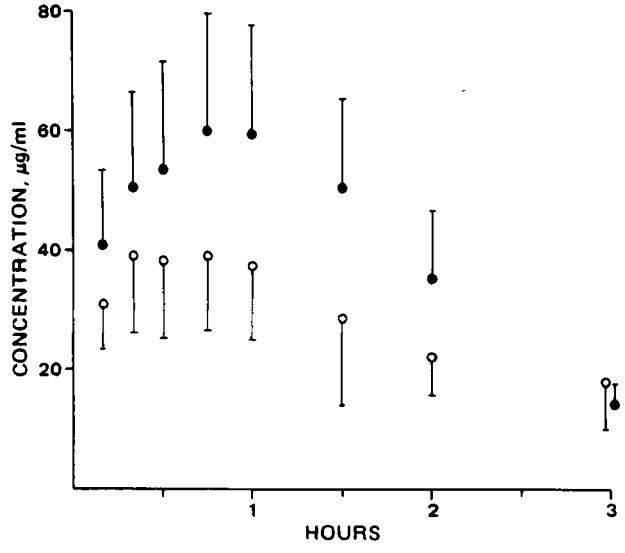

Figure 2—*Acetaminophen sulfate concentrations (expressed in terms of acetaminophen) as a function of time in plasma of control (○) and sodium sulfate-treated (●) rats (mean + or − SD, n = 7). The areas under the two curves from zero time to 3 hr differed significantly (p < 0.05).*

for preventing or reducing acetaminophen toxicity (5), a comprehensive study of the effect of sodium sulfate on acetaminophen elimination kinetics has been instituted. Reported here are results of a preliminary study which showed that sodium sulfate does substantially accelerate acetaminophen elimination in rats.

Fourteen adult male Sprague–Dawley rats, 280–320 g, had a cannula implanted in the right jugular vein (11, 12) 1 day before the study. Food and water were withdrawn in the morning at the beginning of the experiment. Acetaminophen, 150 mg/kg (25 mg dissolved in 1 ml of 40% propylene glycol in water at 40°), was injected intravenously. Seven animals received a bolus dose of sodium sulfate, 142 mg in 3 ml of water/kg ip 15 min before acetaminophen and an intravenous sodium sulfate infusion, 142 mg in 10 ml of water, over 2 hr beginning at the time of acetaminophen injection. Seven control rats received an intraperitoneal injection and an intravenous infusion of sodium chloride solution containing the same sodium concentrations as the sodium sulfate solutions.

Blood samples (0.45 ml) were obtained periodically over 4 hr. Plasma was separated and assayed for acetaminophen and acetaminophen sulfate by high-performance liquid chromatography. The assay was a modification of a published procedure (13) with the following changes: μBondapak C-18 column[1], 4-fluorophenol as the internal standard, 2-ml/min flow rate, isopropanol in the mobile phase reduced to 1.0 part, and 50% trichloroacetic acid (1 part/2 parts of plasma) for plasma protein precipitation.

Sodium sulfate caused plasma acetaminophen concentrations to decline much more rapidly in the experimental animals than in control rats (Fig. 1). Other data, to be reported later, show that acetaminophen elimination is dose dependent even though the plasma drug concentration decline is apparently exponential. The time required for acetaminophen concentrations to decrease by 50% was 55 ± 7 min in control rats and 32 ± 5 min in sodium sulfate-treated rats (mean ± *SD*, $p < 0.001$) under the experimental conditions. Conversely, plasma acetaminophen sulfate concentrations were significantly higher in sodium sulfate-treated than in control animals (Fig. 2).

This study demonstrated that sodium sulfate increases acetaminophen sulfate formation and thereby accelerates acetaminophen elimination in rats. Inferentially, such treatment should reduce the formation of other metabolites by competing pathways, particularly those, like the reactive acetaminophen metabolite, that are formed by apparently linear kinetics. These conclusions are consistent with the observation that sodium sulfate reduces acetaminophen toxicity in mice (8). If clinical studies, now in progress, yield similar results, then incorporating sodium sulfate or another sulfate source in pharmaceutical products containing acetaminophen (14) will deserve serious consideration.

BOOKS

REVIEWS

Essentials of Toxicology, 3rd Ed. By TED A. LOOMIS. Lea & Febiger, 600 Washington Square, Philadelphia, PA 19106. 1978. 245 pp. 15 × 24 cm. Price $12.50.

The newest edition of this basic toxicology text differs little from the previous edition in both form and content. The type is slightly larger and thus easier to read. Many chapters have few, if any, alterations. Some of the additional or revised material to be found includes: updated statistics on poisoning and mortality from chemical exposure; an amplified section on the influence of the microsomal P-450 enzyme system on chemical toxicity; a table of genetically based alterations which account for individual variations in response to drugs and chemicals; a section differentiating the concepts of biological half-life of a compound *versus* "half-life for toxicity," using as an example fatty deposition in liver after exposure to ethanol; and a brief description of behavioral toxicity studies in animals.

A table on page 60 lists formaldehyde as the toxic metabolite of methanol, although recently published data indicated that formate, and not formaldehyde, is responsible for ocular toxicity in monkeys and presumably in humans.

Each chapter is adequately referenced to provide the interested student with sources of more detailed information. This book cannot be compared to other texts such as Casarett and Doull's "Toxicology, The Basic Science of Poisons" (Macmillan) or portions of Goldstein, Aronow, and Kalman's "Principles of Drug Action" (Wiley), both of which deal more extensively with toxicologic subject matter. However, "Essentials of Toxicology" provides a well-organized introductory approach to toxicology and can serve a useful purpose in an orientation course to this highly diversified science.

Blood Drugs and Other Analytical Challenges (in Methodological Surveys in Biochemistry), Vol. 7. Edited by E. REID. Ellis Horwood Ltd., Market Cross House, 1 Cooper Street, Chichester, Sussex, England (U.S. distributor: Halstead Press, a division of John Wiley & Sons, 605 Third Avenue, New York, NY 10016). 1978. 355 pp. 14.8 × 22.6 cm. Price $47.50.

This volume (Volume 7) compliments its predecessor (Volume 5) and is based on the papers presented at Bioanalytical Forum held at the University of Surrey in 1977. The book provides practical information of value to the bioanalytical researcher and attempts to present methodological rationale rather than mere recipes. The first four chapters are subdivided into sections, and the fifth chapter represents the notes, comments, and discussion in the form of questions and answers on the preceding four chapters.

The first chapter, "The Framework," sets out the general philosophy for development of analytical methods, discusses quality control and sources of errors in assays, and presents an overview on analytical method evaluation. The second chapter describes aspects of gas chromatography (GLC) with problems associated with capillary and packed columns and detectors (AFID and ECD). Their applications in drug analysis as well as derivatization procedures are discussed also.

In the third chapter, mass spectrometric methods for drug and endogenous compound analyses in biological fluids are presented, with suitable examples, together with considerations concerning accuracy and precision. Discussions of more recent approaches in this field such as negative-ion mass spectrometry and HPLC—mass spectrometry are particularly valuable.

The fourth chapter discusses the applications of HPLC to drug analysis. Interesting and useful discussions with relevant examples are provided on ion-pair HPLC of acid and basic drugs, metabolites, and endogenous compounds. Various aspects of HPLC such as electrochemical detection, sample handling, chemical derivatization including fluorescence labeling, and prechromatographic methods in biomedical trace analysis are presented with useful comments and suitable examples.

The analytical case histories on the assays of bendrofluzide, biperidin, and labetalol and its metabolites are interesting and informative. The notes and comments in the fifth chapter along with analytical case histories of drugs including metoclopramide, procetofenic acid, tienlilic acid, practolol, amitriptyline, nortriptyline and benzodiazepines make particularly enjoyable reading for the analyst.

In summary, the reviewer found this book to be a well-balanced blend of the theoretical and practical aspects of present techniques and their potential applications of trace drug analysis in biological fluids.

The book is effective in its scope, variety of experiments, and presentation style. It is well planned, emphasizes the rationale of developing successful analytical methods for drug analysis by chromatographic techniques, and should be useful to analytical chemists working with biological fluids.

Lange's Handbook of Chemistry, Twelfth Edition. Edited by JOHN A. DEAN. McGraw-Hill, New York, NY 10020. 1978. 1470 pp. 15 × 23 cm. Price $28.50.

This new edition of *Lange's Handbook of Chemistry* is a valuable updating of a classic one-volume reference.

A major improvement on the previous edition is the revised section on thermodynamics. The new section reflects currently recommended values for heats of formation and Gibbs energies of formation, entropies, heat capacities at five different temperatures, and heats of melting, vaporization, and sublimation for 2400 inorganic and 1500 organic compounds.

Interesting and useful discussions with relevant examples are provided on ion-pair HPLC of acid and basic drugs, metabolites, and endogenous compounds. Various aspects of HPLC such as electrochemical detection, sample handling, chemical derivatization including fluorescence labeling, and prechromatographic methods in biomedical trace analysis are presented with useful comments and suitable examples.

The analytical case histories on the assays of bendrofluzide, biperidin, and labetalol and its metabolites are interesting and informative. The notes and comments in the fifth chapter along with analytical case histories of drugs including metoclopramide, procetofenic acid, tienlilic acid, practolol, amitriptyline, nortriptyline and benzodiazepines make particularly enjoyable reading for the analyst.

In summary, the reviewer found this book to be a well-balanced blend of the theoretical and practical aspects of present techniques and their potential applications of trace drug analysis in biological fluids.

The book is effective in its scope, variety of experiments, and presentation style. It is well planned, emphasizes the rationale of developing successful analytical methods for drug analysis by chromatographic techniques, and should be useful to analytical chemists working with biological fluids.

Lange's Handbook of Chemistry, Twelfth Edition. Edited by JOHN A. DEAN. McGraw-Hill, New York, NY 10020. 1978. 1470 pp. 15 × 23 cm. Price $28.50.

This new edition of *Lange's Handbook of Chemistry* is a valuable updating of a classic one-volume reference.

A major improvement on the previous edition is the revised section on thermodynamics. The new section reflects currently recommended values for heats of formation and Gibbs energies of formation, entropies, heat capacities at five different temperatures, and heats of melting, vaporization, and sublimation for 2400 inorganic and 1500 organic compounds.

87 (1978).

BOOKS

REVIEWS

Essentials of Toxicology, 3rd Ed. By TED A. LOOMIS. Lea & Febiger, 600 Washington Square, Philadelphia, PA 19106. 1978. 245 pp. 15 × 24 cm. Price $12.50.

The newest edition of this basic toxicology text differs little from the previous edition in both form and content. The type is slightly larger and thus easier to read. Many chapters have few, if any, alterations. Some of the additional or revised material to be found includes: updated statistics on poisoning and mortality from chemical exposure; an amplified section on the influence of the microsomal P-450 enzyme system on chemical toxicity; a table of genetically based alterations which account for individual variations in response to drugs and chemicals; a section differentiating the concepts of biological half-life of a compound *versus* "half-life for toxicity," using as an example fatty deposition in liver after exposure to ethanol; and a brief description of behavioral toxicity studies in animals.

A table on page 60 lists formaldehyde as the toxic metabolite of methanol, although recently published data indicated that formate, and not formaldehyde, is responsible for ocular toxicity in monkeys and presumably in humans.

Each chapter is adequately referenced to provide the interested student with sources of more detailed information. This book cannot be compared to other texts such as Casarett and Doull's "Toxicology, The Basic Science of Poisons" (Macmillan) or portions of Goldstein, Aronow, and Kalman's "Principles of Drug Action" (Wiley), both of which deal more extensively with toxicologic subject matter. However, "Essentials of Toxicology" provides a well-organized introductory approach to toxicology and can serve a useful purpose in an orientation course to this highly diversified science.

Blood Drugs and Other Analytical Challenges (in Methodological Surveys in Biochemistry), Vol. 7. Edited by E. REID. Ellis Horwood Ltd., Market Cross House, 1 Cooper Street, Chichester, Sussex, England (U.S. distributor: Halstead Press, a division of John Wiley & Sons, 605 Third Avenue, New York, NY 10016). 1978. 355 pp. 14.8 × 22.6 cm. Price $47.50.

This volume (Volume 7) compliments its predecessor (Volume 5) and is based on the papers presented at Bioanalytical Forum held at the University of Surrey in 1977. The book provides practical information of value to the bioanalytical researcher and attempts to present methodological rationale rather than mere recipes. The first four chapters are subdivided into sections, and the fifth chapter represents the notes, comments, and discussion in the form of questions and answers on the preceding four chapters.

The first chapter, "The Framework," sets out the general philosophy for development of analytical methods, discusses quality control and sources of errors in assays, and presents an overview on analytical method evaluation. The second chapter describes aspects of gas chromatography (GLC) with problems associated with capillary and packed columns and detectors (AFID and ECD). Their applications in drug analysis as well as derivatization procedures are discussed also.

In the third chapter, mass spectrometric methods for drug and endogenous compound analyses in biological fluids are presented, with suitable examples, together with considerations concerning accuracy and precision. Discussions of more recent approaches in this field such as negative-ion mass spectrometry and HPLC—mass spectrometry are particularly valuable.

The fourth chapter discusses the applications of HPLC to drug analysis. Interesting and useful discussions with relevant examples are provided on ion-pair HPLC of acid and basic drugs, metabolites, and endogenous compounds. Various aspects of HPLC such as electrochemical detection, sample handling, chemical derivatization including fluorescence labeling, and prechromatographic methods in biomedical trace analysis are presented with useful comments and suitable examples.

The analytical case histories on the assays of bendrofluzide, biperidin, and labetalol and its metabolites are interesting and informative. The new section reflects currently recommended values for heats of formation and Gibbs energies of formation, entropies, heat capacities at five different temperatures, and heats of melting, vaporization, and sublimation for 2400 inorganic and 1500 organic compounds.

New to this edition are structure-correlation tables for PMR and IR spectroscopy, ionization potentials of molecular and radical species, potentials of reference electrodes for water–organic solvent mixtures, and a wavenumber/wavelength conversion table.

In the original edition of this handbook, Dr. N. A. Lange described his effort "to select material to meet the needs of chemists who cannot command the unlimited time available to the research specialist, or who lack the facilities of a large technical library . . . (or who) may find this volume of value as a time-saver because of the many tables of numerical data which have been especially computed for this purpose." The present edition contains clear, comprehensive tables entirely consistent with the original editor's purpose. The compilations of commonly used information in mathematics, atomic and molecular structure, inorganic chemistry, analytical chemistry, electrochemistry, organic chemistry, and spectroscopy are complemented by succinct, well-written summaries of basic theory in each area.

This excellent, relatively inexpensive volume would be a useful addition to the library of anyone involved in pharmaceutical research.

Staff Review

Progress in Drug Research, Vol. 22. Edited by ERNST JUCKER. Birkhauser Verlag, P.O. Box 34, CH-4010, Basel, Switzerland. 1978. 412 pp. 16 × 24 cm. Price Fr. 168.

This volume of "Progress in Drug Research" contains eight chapters of diverse character and subject matter. However, all are expert accounts of recent progress or current activity in a particular area of drug research.

The first contribution, "Aspects of Social Pharmacology," discusses this emerging discipline. Social pharmacology is described as drawing on disciplines (*e.g.*, sociology and economics) outside pharmacology in order to better evaluate the effects of drugs as they are usually employed, *i.e.*, after controlled clinical studies. The second contribution, "Fundamental Structures in Drug Research II," is a companion piece to Part I, which appeared in Vol. 19 of "Progress in Drug Research." The basic approach is one of showing how the structures of members of a therapeutic group evolve from a lead or prototypical compound. Included in Part II are antimicrobials, antiprotozoals, anthelmintics, antibiotics, antivirals, antineoplastics, steroidal and peptidal hormones, prostaglandins, and vitamins. This work can be useful in several ways, one of which is as an efficient summary or outline of structural types associated with particular pharmacological activity.

Chapter three, "Antifungal Agents," is a good treatment of the clinically useful antifungal agents. For each agent, there is a summary of pertinent chemistry and thorough reviews of mechanism(s) of action, mechanism(s) of resistance, and assessments of current clinical utility. Chapter four, "Analgesics and Their Antagonists: Recent Developments," covers the literature since 1970 in a thorough and well-written review of synthesis and structure-activity relationships among opium alkaloids and synthetic analgesics. A good account of the opioid peptides is included also.

The fifth contribution, "The Benzodiazepine Story," recounts interesting personal research experiences of Leo H. Sternbach in the development of this field of medicinal agents. Additionally, this chapter is a good overview of the development of, and the present directions of research in, benzodiazepines and related compounds. Chapter six, "Antiviral Agents," carefully reviews recent advances. The agents are grouped by chemical type where feasible. Chemical modifications and antiviral activities for each group are given.

The seventh contribution, "Klinisch-Pharmakologische Kriterien in der Bewertung Eines Neuen Antibiotikums. Grundlagen and Methodische Gesichtspunkte," describes problems encountered and procedures involved in the clinical evaluation of new drug entities. A good general treatment of the factors involved in antibiotics evaluation is presented. The concluding chapter, "Drug Research and Human Sleep," is a concise account of the state of the art in the study of the drug effects on sleep in human subjects. Included are discussions of factors to be considered in accurately measuring drug effects on sleep and the problem of determining the significance of these effects.

The present volume offers a high quality and varied bill of fare. Each contribution is current and is authoritatively written. Volume 22 upholds the series' reputation as one of the classic and indispensable reference works for any college of pharmacy library.

Animal Health Products: Design and Evaluation. DONALD C. MONKHOUSE. American Pharmaceutical Association, 2215 Constitution Ave., N.W., Washington, DC 20037. 152 pp. 15 × 23 cm, soft cover, $14.00 ($9.00 APhA Member Rate).

The increasing likelihood of a global food shortage is drawing more attention to the area of animal health products, particularly those designed to improve agricultural productivity. *Animal Health Products: Design and Evaluation* is the first booklength compilation of concepts and ideas related to research in this field and will doubtless serve as a reference text for teaching and for defining future research. As such, it is an important and readable contribution to an area largely neglected in pharmaceutical journals and texts and rarely addressed by the curricula of schools of pharmacy.

The APhA Annual Meeting symposium from which this volume evolved was designed to acquaint scientists working primarily in human therapeutics with the rapidly expanding area of veterinary research. The growing importance of pharmaceutical support for animal husbandry is one reason this volume should be of interest to scientists in this and in related fields. Another reason is that the growth of government regulatory requirements for animal products—which are generally stiffer than those for human products—is increasing the need for cooperative work between scientists in various areas, particularly in toxicology and metabolic studies.

A final attraction is the pure intellectual challenge of this area of pharmacy. As Dr. Lloyd H. Conover wrote in the "overview" Chapter:

> *"The dip-bath constitutes the greatest challenge I know to the art and science of pharmacy. Dip-baths are water-filled vats in which cattle or sheep take periodic involuntary 'dips.' The active ectoparasiticidal agent, usually in the form of an emulsifiable concentrate, is maintained at an effective concentration by periodic additions to the bath. Thousands of animals may pass through a dip-bath in the course of a week, and as they do, excreta, soil, microorganisms and other miscellaneous debris accumulate. The emulsion must retain its chemical and physical integrity in the murky bath for months, while the ectoparasiticidal film left on the skin and hair of dipped animals must withstand tropical rains and sun for at least a week. Think on this, if you are accustomed to working with elegant human dosage forms!"*

Animal Health Products covers several of the major problems in veterinary pharmacy, with particularly good information on the pharmacokinetics of oral dosage forms in multigastric animals, the analyses and metabolism of tissue residues, the problems of incorporating drugs into feed, and the special stability problems of veterinary formulations.

A PLEA FOR FDA STABILITY

Kings, popes, and presidents come and go with the passing of time. It should not be strange, therefore, that the same is true of Food and Drug Administration Commissioners.

Nevertheless, the departure of the last several FDA Commissioners has seemed to us to have come too soon, too abruptly, and all too unexpectedly. Indeed, each of them seems to have little more than arrived, got settled in office, established an operating style, developed a rapport with the health professions and the regulated industry, when "poof!"—they were gone from office!

Our editorial comments in the November 1976 issue were written on the occasion of the previous Commissioner's (Alexander M. Schmidt) departure. Under the column heading "Passing the Baton at FDA," we recounted the strengths, weaknesses, and operating styles of the succession of modern era FDA Commissioners beginning with the celebrated James L. Goddard, the first noncareer official to ascend to the office in the agency's history. We concluded on a plaintive note that what the agency most needed at that point was "someone at the helm 'who can get it all together!' "

Well, whoever the Almighty has in charge of answering such prayers evidently heard our plea, with the rather unexpected and unlikely selection of an academic research biologist in the person of Ph.D., Donald Kennedy.

The initial Washington reaction to this choice was that the primary qualification possessed by Dr. Kennedy was that he was virtually unknown to the respective Washington political, scientific, and health communities, and therefore no one had a significant basis for mounting opposition to his appointment. Given the operating process in this politically sensitive city, there was much logic to this line of reasoning.

But it was no time at all until Dr. Kennedy had demonstrated himself to be a very energetic, articulate, and personable individual, as well as one with a quick mind and the intellectual ability to grasp the peculiar facets of FDA's regulatory responsibilities and the difficult policy issues with which it was grappling. After his two years in office, there is almost a universal consensus that he proved to be a very able Commissioner.

Moreover, if we were to single out one special achievement that he made, we would cite his "humanization" of FDA. He met with countless groups, engaging them in the most lively and informal discussion and inspiring such a feeling of openness and credibility that he came to be nicknamed "The Visible Commissioner."

So, his announcement that he would be resigning in late June to return to Stanford University as Provost and Vice-President for Academic Affairs was met with widespread disappointment. In discussing his resignation with the press, it is reported that the timing of his decision was at least in part due to the Ethics in Government Act. This is a new federal statute that becomes effective July 1, 1979. The Act is designed to restrict former federal employees in their postemployment contacts with their former agencies. The objective is to prevent even the appearance of conflict-of-interest or other undue influence. It is this Ethics in Government Act that has led to a whole rash of other recent resignations from federal office, particularly within the Department of HEW.

In discussing the impact of this new law on personnel recruiting efforts, an HEW representative recently stated that it has become much more difficult to find people on the outside who are willing to fill these high level vacancies. The pay scale for such positions is generally below that of comparable levels in the private sector; the security is tenuously tied to the fortunes of the elected Administration; and now the Ethics Act will prevent such people from easily returning to employment where their knowledge, skills, and experience would be most suited. Both Dr. Schmidt and Dr. Kennedy had simply taken leaves of absence to serve in FDA, which made it readily convenient for them to return to their respective academic institutions at such time as they felt the situation might dictate. The HEW representative went on to state that this effect of much greater difficulty in recruiting qualified outside persons would probably necessitate substantially more appointments from within the present career staff of the respective agencies.

Our first reaction is that such an outcome would be unfortunate because it deprives the agency of new thinking, fresh ideas, and the broadest choice of qualified people from which to select. However, there is another likely result that would generally be beneficial. In short, people will be far less inclined to bounce in and out of high level federal positions, for the simple reason that there will be little place for them to bounce to—at least for one year.

If this result contributes to greater stability in the FDA Commissionership, it will at least constitute one very significant compensating feature—one that our experience over the past decade has taught us to value.

Drug Repackaging

I would like to comment on the editorial[1] "Bureaucratic Overkill," which appeared in the May issue of this Journal. I feel strongly that some agency must regulate drug repackaging in hospital pharmacies.

I am actively engaged with a local hospital in determining the stability of drugs after repackaging in unit dose forms. We have found that serious stability problems are possible unless proper quality control procedures are followed. For example, a number of tablets had rusty spots because the repackaging machine was not cleaned properly. Furthermore, repacked neomycin sulfate tablets had absorbed about 4.5% of moisture in less than 1 month and had become discolored. Tablets in the original container (same lot) did not change color and absorbed very little moisture. The expiration date was still a couple of years away. Moreover, aminophylline tablets had problems similar to neomycin sulfate tablets. Needless to say, all of these dosage forms had to be removed from the shelves.

Thiazide Bioavailability Studies

There is a paucity of reports on the absorption and mode of elimination of the thiazide diuretics. However, there is general agreement[1,2] that when a thiazide is dissolved in water (in which it is slightly soluble), hydrolysis occurs and an equilibrium is established. The extent of this hydrolysis *in vivo* varies with the thiazide. Our studies reveal that for cyclothiazide and methyclothiazide, it varies from one individual to another and even in the same individual at different times.

The hydrolysis product common to the thiazides is 4-amino-6-chloro-*m*-benzenedisulfonamide (I). This compound, which is more soluble in water than the thiazides, is absorbed and displays diuretic activity[3]. According to Tust[4], "in saline-loaded rats the diuretic activity is equivalent to chlorothiazide." We found that I is excreted slowly in humans and can be measured in urine 96 hr after a 250-mg dose of chlorothiazide.

The more potent thiazides normally hydrolyze more extensively *in vivo* to furnish I in the urine. Examination of the urine of 28 male subjects who had been dosed with cyclothiazide, using the Bratton–Marshall colorimetric method, revealed that the 24-hr urinary excretions of I plus cyclothiazide, calculated as thiazide, ranged from 10.3 to 57.8% (average 25.4) of the ingested dose. Most of the urines were also assayed by a high-performance liquid chromatographic (HPLC) method to measure cyclothiazide and I. The urines examined contained 5–35% of the cyclothiazide as I.

When urines are extracted with ethyl acetate to recover thiazide, I, even as its hydrochloride salt from urines acidified with hydrochloric acid, is also essentially quantitatively recovered. The Bratton–Marshall method measures the I formed by hydrolysis of the thiazide both *in vivo* and *in vitro* and, therefore, usually furnishes higher urinary levels than the HPLC method when only thiazide is assayed.

Interferences by urinary constituents when the Bratton–Marshall method was used for the determination of sulfonamides in the urine were recognized early by Marshall *et al.*[5]. As more potent thiazide diuretics than chlorothiazide were subsequently introduced, less dilution of the urine was possible and these interferences became more troublesome[6]. The purple color, which develops more slowly (and is more stable) than the red color from the Bratton–Marshall, is produced by certain urinary constituents[1]. The purple color from human urine displays a broad absorption band with a maximum at 545 nm. However, by a special extraction procedure and measurement of the red color at 500 nm, the interference from urinary constituents in humans can be substantially eliminated.

Urine samples are made alkaline with sodium hydroxide solution and heated on a steam bath for about 3 hr to destroy emulsifying components, which frequently produce very stable emulsions with urine and ethyl acetate. The urine samples are then made acidic with an excess of hydrochloric acid, which increases the salt concentration and favors more complete extraction of the thiazide and I hydrochloride by ethyl acetate. The ethyl acetate is separated, washed with a small volume of distilled water, and then extracted quickly (10–15 sec) with two portions of 0.1 *N* NaOH.

The sodium hydroxide extracts are combined and allowed to stand for about 30 min, which permits hydrolysis of dissolved ethyl acetate and a drop in pH to about 8.0. This slightly alkaline solution is then extracted with fresh ethyl acetate. The ethyl acetate layer is separated and evaporated to dryness with a stream of air or nitrogen. The residue is completely hydrolyzed to I by treatment with 5 *N* NaOH and evaporation to dryness on a steam bath. The residue from this treatment is dissolved in strong hydrochloric acid[1] to a predetermined volume, and the I is diazotized in the usual manner and coupled with *N*-1-naphthylethylenediamine. The absorbance at 500 nm is determined 15–30 min after the diamine solution has been added.

This reaction is more complex than a simple diazotization[2]. Examination of the red color produced by TLC on silica gel revealed the presence of at least four components. The absorption maximum of the red color is 510 nm; by measuring absorbance at 500 nm instead of at 518 nm, as is frequently used, less than a 4% loss in intensity is encountered. However, measurement at 500 nm decreases any small interference from human urinary constituents by about 40%.

Although the HPLC method will measure a thiazide in the urine with good precision[7], I believe a more meaningful measure of bioavailability of the thiazide diuretics, especially those given in smaller doses where more of the drug is hydrolyzed, requires an HPLC method that measures both I and the thiazide. My recommendation is that all thiazide obtained from urine be converted to I and that I be measured by an HPLC method to give maximum precision and sensitivity.

5-Azacytidine Hydrolysis Kinetics Measured by High-Pressure Liquid Chromatography and ^{13}C-NMR Spectroscopy

KENNETH K. CHAN [x], DONALD D. GIANNINI *, JAMES A. STAROSCIK, and WOLFGANG SADEE [‡]

Received August 18, 1978, from the *School of Pharmacy, Stauffer Pharmaceutical Sciences Center, University of Southern California, Los Angeles, CA 90033.* Accepted for publication January 22, 1979. *Postdoctoral fellow, Chemistry Department, California Institute of Technology. Present address: Eastman Kodak Research Laboratory, Rochester, NY 14650. [‡]School of Pharmacy, University of California, San Francisco, CA 94143.

Abstract □ Hydrolysis of 5-azacytidine, an experimental anticancer drug, in aqueous buffers was measured using a high-pressure liquid chromatographic (HPLC) procedure and a ^{13}C-NMR method. The former utilized a 17.5-μm Aminex A-6 strong cation-exchanger column eluted with 0.4 *M*, pH 4.6 ammonium formate buffer at a flow rate of 0.4 ml/min. The hydrolysis sequence as well as the existence of a labile intermediate, *N*-formylguanylribosylurea, was unequivocally established using 6-^{13}C-5-azacytidine and NMR spectral techniques. A reversible ring opening step to the *N*-formylguanylribosylurea with an equilibrium constant of 0.58 ± 0.03 between pH 5.6 and 8.5, followed by an irreversible formation of guanylribosylurea, was found by HPLC. The data confirm previous assumptions on the hydrolytic kinetics. The pH dependency of hydrolysis was examined, and the hydrolysis profile gave a normal V shape with the most stable pH at 7.0. Rather stable intravenous dosage forms can be formulated.

Keyphrases □ 5-Azacytidine—hydrolysis kinetics, aqueous solutions, high-pressure liquid chromatography, ^{13}C-NMR □ Hydrolysis kinetics—5-azacytidine, aqueous solutions □ Antineoplastic agents—5-azacytidine, hydrolysis kinetics, aqueous solutions

A cytidine analog, 5-azacytidine[1] (I), first synthesized in 1964 (1) and subsequently isolated from *Streptoverticillium ladakanus* (2, 3), has shown antitumor activity against several animal neoplasms including L-1210 leukemia (4) and T-4 lymphoma (5). Clinically, it has also demonstrated activity against various solid tumors (6) as well as leukemias (7) and is currently undergoing phase II trials (8).

This compound has long been known to be unstable in aqueous solution. Its lability has been attributed to the facile hydrolytic cleavage across the 5,6-bond (9–11). Consequently, proper formulation has been a problem in its clinical use. In addition, not only has the metabolic evidence indicated that ring cleavage is a major process of its disposition (12–14), the facile process may have a possible relationship to its still unclear overall biological activity. Therefore, the nature and sequence of its hydrolysis must be understood. While hydrolysis of I has been investigated (9–11, 15), the lack of a suitable analytical method has hampered a complete and unequivocal kinetic analysis, although certain information concerning hydrolysis has been obtained through spectroscopic resolution in a complex hydrolytic mixture (10).

Recently, specific information was obtained through TLC, NMR (11), and high-pressure liquid chromatography (HPLC) (15), including the isolation and identification of the labile intermediate; however, a systematic kinetic analysis is still lacking. This paper describes an HPLC method for the simultaneous analysis of I and its labile intermediate, *N*-formylribosylguanylurea (II), which occurs during formation of the hydrolytic product 1-β-D-ribofuranosyl-3-guanylurea (III). Corroborated with Fourier transform ^{13}C-NMR, using a 6-^{13}C-5-azacytidine previously synthesized in this laboratory (14), a detailed kinetic analysis of the hydrolysis of I in aqueous solution is presented.

EXPERIMENTAL

Chemicals and Reagents—All solvents were either analytical or liquid chromatographic grade. 5-Azacytidine was greater than 99% pure by HPLC and was used without further purification. Ninety percent labeled 6-^{13}C-5-azacytidine was synthesized as described previously (14). 1-β-D-Ribofuranosyl-3-guanylurea (III) was synthesized according to

[1] 4-Amino-1-β-D-ribofuranosyl-1,3,5-triazin-2-one, NSC-102816, CAS Reg. No. 320-67-2. Supplied by the Drug Synthesis and Chemistry Branch, Developmental Therapeutics Program, Division of Cancer Treatment, National Cancer Institute, Bethesda, MD 20014.

the procedure of Pithova *et al.* (9). Sodium formate[2] and 90% enriched 1-^{13}C-sodium acetate[3], used as internal standards, were also pure by ^{13}C-NMR.

Analytical Procedure—Methanolic or aqueous solutions of 5-azacytidine were injected into a liquid chromatograph[4,5] *via* a 20-μl high-pressure sample injection valve[5]. The solution was eluted into a 500 × 2-mm i.d. stainless steel column[5] packed with 17.5-μm Aminex A-6[6] strong cation-exchanger with 0.40 *M*, pH 4.6 ammonium formate buffer at a flow rate of 0.4 ml/min. The components emerging from the column were detected *via* a UV detector[5] set at 254 nm. The UV-absorbing components were quantitated using either peak height or peak area as estimated *via* a mechanical disk integrator on a strip-chart recorder[7]. No significant difference was observed between these two quantitative methods.

^{13}C-NMR—NMR studies of 5-azacytidine, 6-^{13}C-5-azacytidine, and guanylribosylurea were recorded in dimethyl sulfoxide or in aqueous buffers at pH 8.0 *via* a 25.2-MHz Fourier transform NMR spectrometer[8]. Typical parameters for the measurements were: acquisition time, 0.8 sec; pulse delay, 1.2 sec; sweep width, 5000 Hz, 8 K data points; and tip angle, 30°.

For kinetic measurements, an aqueous solution of 90% enriched 6-^{13}C-5-azacytidine, 0.1 *M* in pH 8.0, 0.067 *M* phosphate buffer, was placed in the sample tube, which was inserted into the spectrometer probe. The probe temperature was maintained at 38 ± 0.1°. Rapid pulses at a pulse width of 8 were generated, and the appropriate number of transients was accumulated to acquire an adequate signal-to-noise ratio. A timer was started when the 5-azacytidine solution was mixed and placed inside the spectrometer. At the end of each accumulation, the time was noted.

Kinetic Measurements—The hydrolytic degradation of 5-azacytidine was studied quantitatively by HPLC at 25 and 37° in 0.067 *M* sodium phosphate buffer and acetate buffer at pH 4.5–9.1.

All experiments were duplicated. A gas-tight syringe was filled with a solution of 5-azacytidine at either 4.10×10^{-4} or 8.20×10^{-4} *M* in a phosphate buffer of the desired pH. For the 25° runs, the filled syringe was allowed to remain at room temperature in the high-pressure injector valve module. At approximately 10-min intervals, aliquots were pushed into the sample loop and injected immediately. For the 37° runs, the syringe was filled, capped, and placed in a constant-temperature bath. It was then removed at specific intervals to fill the injector loop and quickly replaced in the bath.

The 5-azacytidine concentrations were followed by either the peak height or the peak area method. Stability evaluations were made in Ringer's lactate and in normal saline at room temperature as well as at refrigerated temperature (5°).

RESULTS

Drug Assay—With either methanolic or aqueous solutions of 5-azacytidine kept at ice temperature before injection, a straight line was observed in the $0.041–8.20 \times 10^{-4}$ *M* range when either peak heights or peak areas were plotted against concentrations. The variance of 10 separate injections at 0.20×10^{-4} *M* was less than 1%.

When 5-azacytidine was dissolved in a phosphate buffer, 0.067 *M* at pH 8.0, and chromatographed, in addition to a peak emerging at 3.4 min (peak 1) corresponding to 5-azacytidine, a small, slower running peak emerged at 7.3 min (peak 2) and the intensity of peak 2 appeared to increase with time (Fig. 1). Their peak height ratio (peak 1 to peak 2) appeared to be constant at approximately 3:2 after 150 min. The intensities of these two peaks then diminished with time while maintaining an essentially constant ratio.

Each component was collected into a separate tube at room temperature. Reinjection of peak 1 immediately following collection yielded a single peak corresponding to 5-azacytidine. However, similar treatment of peak 2 gave two components corresponding to peaks 1 and 2, the latter at a higher intensity. After a longer period, repetition of the injection of either peak 1 or 2 revealed two peaks, this time with a peak 1 to peak 2 ratio of approximately 3:2 but with both at much diminished intensities. Collection of peak 2 at ice temperature did not appear to change the reversal of peak 2 to peak 1.

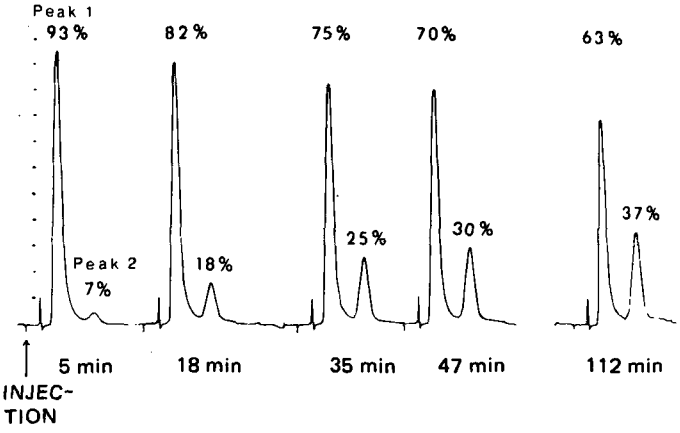

Figure 1—*High-pressure liquid chromatograms of 5-azacytidine, 8.2 × 10^{-4} M in pH 8.0, 0.067 M potassium phosphate at 25°, using 0.4 M, pH 4.6 ammonium formate at 0.4 ml/min.*

Attempts to isolate peak 2 by collecting it into a tube in a dry ice–acetone bath followed by lyophilization failed[9]. Dissolving the residue in water and injecting it into the liquid chromatograph did not give significant amounts of a UV-absorbing peak (254 nm). TLC analysis of the residue using the literature procedure (14) indicated that guanylribosylurea (III) was a major component.

^{13}C-NMR Analysis—The naturally abundant proton-decoupled NMR spectra of 5-azacytidine and guanylribosylurea spiked with formate in aqueous buffer are shown in Figs. 2 and 3, respectively. The chemical shift assignments of 5-azacytidine under the present conditions were referenced from reported values (16), and those for guanylribosylurea were assigned by direct comparison with those of I (Table I). Differences of the chemical shifts of guanylribosylurea from 5-azacytidine were seen in C-2, C-4, and C-1, as expected from the structure.

When a 5-azacytidine solution in pH 8 phosphate buffer was subjected to Fourier transform NMR analysis, new sets of signals not accounted for on the basis of the 5-azacytidine and ribosylguanylurea spectra appeared with time. A new signal appeared at 171.7 ppm, subsequently identified as formate by signal enhancement with the addition of sodium formate. Furthermore, the signal at 157.5 ppm was particularly broadened (Fig. 4).

The kinetic detections of 6-^{13}C-5-azacytidine hydrolysis in a buffered solution are shown in Fig. 5. A known concentration of ^{13}C-sodium acetate was added to the buffered solution in an attempt to quantitate the decomposition kinetics. The signals ratio between the C-6 of 5-azacytidine and the C-1 of sodium acetate was essentially constant until after 17 min. A small signal appeared at 167.8 ppm and increased with time. After 90 min, a second signal at 171.7 ppm appeared. Both new signals increased at the expense of the C-6 of 5-azacytidine, as indicated by slowly decreasing ratios of the signal intensity of the C-6 of 5-azacytidine to the C-1 of acetate. After 270 min, the intensity of the lower field signal exceeded that of the higher field one. The time course of the ratios between the C-6 signal of 5-azacytidine and the C-1 of acetate, an added internal standard, is shown in Fig. 6.

The identity of these new signals was confirmed by off-resonance decoupled NMR measurements, which assess the ^{13}C–H coupling. In this experiment, all signals exhibited a doublet except the signal of acetate (Fig. 5*h*), which indicated the attachment of one proton to each carbon. The chemical shift of the signal at 171.7 ppm coincided with that of the formate. On the basis of the chemical rationale of hydrolysis, UV absorption property *via* HPLC, and C–H coupling *via* the NMR off-resonance decoupling experiments, the signal at 167.8 ppm was assigned as derived from the formyl carbon of the labile intermediate, *N*-formylguanylribosylurea.

Kinetic Analysis—5-Azacytidine hydrolysis was carried out in 0.067 *M* phosphate buffers at pH 4.5–9.1 and at 25 and 37°. Selected hydrolysis profiles as measured by concentrations of 5-azacytidine *versus* times are shown in Fig. 7. Either monophasic or biphasic profiles were observed in all of the pH and temperature studies on semilog plots. At low pH as well as in the vicinity of neutral pH, biphasic profiles were observed, with

[9] Recently, Beisler (11) was able to isolate and characterize *N*-formylribosylguanylurea by HPLC using a C-18 reversed-phase column and water as the eluant. In the present case, the low pH and high salt content during the lyophilization procedure may have caused the decomposition of this labile intermediate.

Table I—Chemical Shifts [a] of 5-Azacytidine and Guanylribosylurea

Carbon	I	III
C-4	166.4	162.2
C-6	157.5	—
C-2	156.1	165.4
C-1′	91.8	85.5
C-4′	84.6	83.9
C-3′	74.9	74.3
C-2′	69.6	71.2
C-5′	61.1	62.7

[a] Measured in dimethyl sulfoxide and expressed in parts per million with tetramethylsilane as the internal standard.

the most pronounced being at pH 7 and 8. At high pH, *i.e.*, 9.1, the first phase was too rapid to be discernible so that an apparently monophasic profile was observed. Similar biphasic profiles of 5-azacytidine were observed in Ringer's lactate as well as in normal saline, although the terminal phases declined very slowly.

From this evidence for the existence of an initial equilibrium phase between *N*-formylguanylribosylurea and 5-azacytidine, the biphasic behavior of these hydrolysis profiles were attributed to the kinetic scheme of Pithova *et al.* (9) (Path A, Scheme I).

The appropriate rate constants can be solved by making several assumptions: (*a*) the initial process is a rapid equilibrium, (*b*) *N*-formylguanylribosylurea exists at an approximate steady state throughout the hydrolysis, and (*c*) $k_{-1} \gg k_2$. These assumptions were supported by subsequent estimated data, generating a self-consistency. Then k_1 and k_{-1} are solvable by:

$$K_{eq} = \frac{k_1}{k_{-1}} \qquad \text{(Eq. 1)}$$

and (17, 18):

$$\log\left(\frac{A_0 - A_{eq}}{A - A_{eq}}\right) = \frac{k_1 + k_{-1}}{2.303} t \qquad \text{(Eq. 2)}$$

k_2 is solvable by the first-order degradation of the second phase:

$$A = A_0 e^{-Kt} \qquad \text{(Eq. 3)}$$

$$K = K_{eq} k_2 \qquad \text{(Eq. 4)}$$

The estimated rate constants for 5-azacytidine hydrolysis in aqueous buffer solutions at different pH values and at two temperatures are shown in Table II. The stability profile at 25 and 37° as expressed by plotting log k_1 *versus* pH is shown in Fig. 8. The profile at both temperatures followed a typical V shape, with the most stable pH at 7.0.

DISCUSSION

As was first proposed by Pithova *et al.* (9), 5-azacytidine in aqueous solution undergoes hydrolysis according to Scheme I in strong aqueous acid. Glycosidic linkage cleavage to yield 5-azacytosine, 5-azauracil, and D-ribose (Path B) was the major degradative pathway. In neutral and basic media, a facile ring cleavage to yield an instable *N*-formylguanylribosylurea intermediate followed by a loss of formate to form ribosylguanylurea was proposed as the major degradative pathway (Path A). Notari and DeYoung (10) proposed a refined scheme to include the hydration step across the 5,6-double bond as the first step.

In those studies, UV spectral techniques were used to quantify the hydrolysis kinetics of I. Using a TLC and PMR method, Israili *et al.* (15) studied the hydrolysis of 5-azacytidine and found that its degradation in aqueous buffers as well as in human plasma under various conditions followed first-order kinetics, but only monoexponential declines were reported.

[a] Calculations were based on the molar concentrations of remaining 5-azacytidine since the *N*-formyl intermediate possesses different extinction coefficients (10, 11). At those times where initial equilibrium was observed and used for calculation, insignificant amounts of irreversible degradation occurred, consistent with the assumptions made, *i.e.*, $k_{-1} \gg k_2$, and with the experimental observations (^{13}C-NMR). This finding is also consistent with the observations in Ref. 11.

None of the previous studies isolated and characterized the *N*-formylguanylribosylurea intermediate. In a preliminary study (19) in this laboratory, the *N*-formyl intermediate was isolated and characterized by ^{13}C-NMR. Recently, using HPLC and PMR, Beisler (11) also isolated and characterized the *N*-formyl intermediate and reported its biological activity. However, no detailed kinetic analysis of the hydrolysis of I was presented.

The aims of this study were to use ^{13}C-NMR coupled with specific stable isotopic labeling to demonstrate unequivocally the existence of the unstable intermediates and the sequence of the degradation and to use an assay method to quantitate the kinetics and hydrolysis of 5-azacytidine as a function of pH and temperature.

^{13}C-NMR—Because of the high sensitivity and speed in data acquisition, Fourier transform ^{13}C-NMR has been used in studying reaction mechanisms (20, 21). In the present studies, the large differences in chemical shifts among the imino carbon of I, the *N*-formyl carbon of II, and the formic acid carbon were utilized for analysis. The C–H coupling (*i.e.*, doublet) should provide a positive identification of their location. Initially, it was anticipated that NMR studies on the basis of naturally abundant C-13 would provide the necessary evidence for the hydrolysis; however, no additional signals at the low field region except the formate carbon have been revealed in the hydrolysate. Subsequently, it was found that, due to the overlapping signal between the C-6 of *N*-formyl carbon and the C-4 and 5-azacytidine, it was not possible to follow the kinetics of the generation of II using naturally abundant ^{13}C-compounds. This problem was circumvented by the use of ^{13}C-5-azacytidine labeled at the C-6 position synthesized previously (14).

Use of 90% labeled 6-^{13}C-5-azacytidine revealed the generation of *N*-formylribosylguanylurea and subsequently formic acid from a solution of 5-azacytidine in pH 8.0 phosphate buffer. The chemical shifts and multiplicity in off-resonance decoupled ^{13}C-NMR and UV absorption characteristics detected from the HPLC studies are all consistent with the assigned *N*-formylguanylribosylurea structure. In addition to the off-resonance decoupled experiment, the formate carbon identity comes from enhancement of signal intensity with addition of sodium formate. On the basis of the timed ^{13}C-NMR studies, the generation sequence of *N*-formylguanylribosylurea and formate was proven unequivocally. Although carbinolamine formation as the first step of hydration across the 5,6-double bond (10) appeared to be reasonable, its detection by ^{13}C-NMR has not yet been accomplished, possibly because of its short life or very low concentration. Thus, this study also demonstrates the use of stable isotope labeling and ^{13}C-NMR in the study of reaction mechanisms.

Since the relaxation mechanism and T_1 of 5-azacytidine and *N*-formylguanylribosylurea are likely to be similar, it was thought that by selecting a reference atom with a similar chemical shift, the degradation kinetics could be followed. Thus, 90% 1-^{13}C-sodium acetate equimolar to 6-^{13}C-5-azacytidine was added to the solution for the kinetic measurement. Decomposition kinetics were followed by a change in the signal ratios between the C-6 of 5-azacytidine and the C-1 of acetate (Fig. 6). However, as shown, the ratio remained relatively constant for the initial several minutes and declined afterwards. The kinetic profile was not consistent with the HPLC data and remained difficult to interpret. The difference was perhaps due to in part to errors in Fourier transform NMR arising from limitations because of the number of data points available in the computer system and from the nonuniformity in numbers of pulses for each time spent. Therefore, steady state may not have been achieved in the experiments with few pulses.

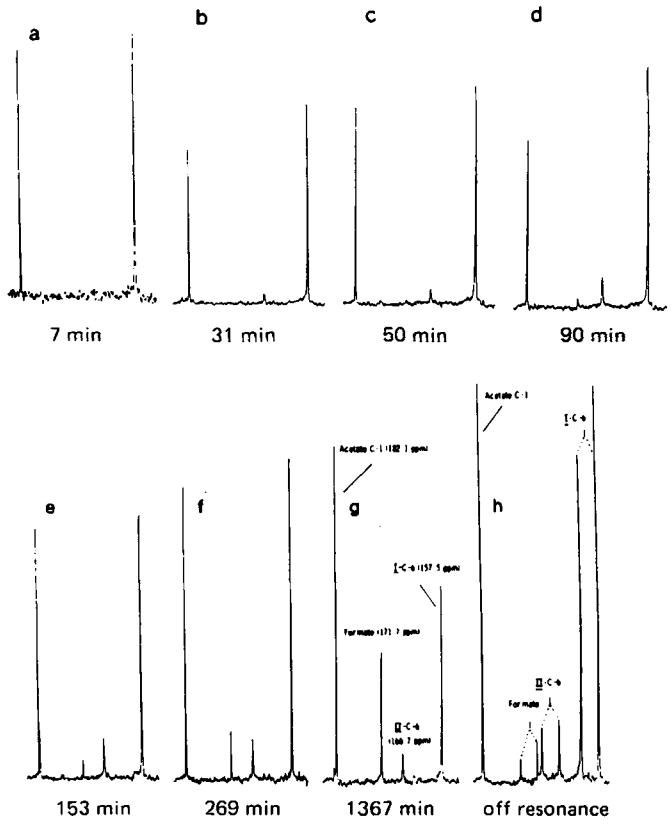

Figure 5—*^{13}C-NMR spectrum of 90% enriched 6-^{13}C-5-azacytidine (0.148 M) in pH 8.0, 0.067 M potassium phosphate buffer containing 30% deuterium oxide and ^{13}C-sodium acetate (0.20 M) at 27°. Figures 5a–5h are spectra at selected times. For complete number of time points, see Fig. 6.*

Kinetics Studies—Using UV measurement at 242 nm, Pithova *et al.* (9) first observed an initial increase followed by a subsequent decline when the extinction coefficient of 5-azacytidine in pH 6.6–7.8 borate buffers was plotted against time. Using similar UV measurements at two different wavelengths, Notari and De Young (10) observed biphasic profiles when 5-azacytidine absorbances in buffer solutions were plotted against time; the decrease or increase with time of the initial phase depended on whether the sample was acidified initially or not. The initial phase decreased with time using initially acidified sample and increased using nonacidified 5-azacytidine.

In the present study (Fig. 7), in buffers from pH 4.5 to 8.5, biphasic declines were observed when 5-azacytidine concentrations were plotted against time. At pH 9.1, the profile appeared to be monophasic and probably resulted from a very rapid equilibrium so that the first phase was not readily discernible. On the basis of the kinetic scheme (Scheme I), the individual rate constants were estimated (Table II). The direct kinetic measurements showed a rapid equilibrium between 5-azacytidine and *N*-formylribosylguanylurea, followed by a slower degradation of the latter to ribosylguanylurea.

As was evident at room temperature and various pH values, the rate constants, k_{-1}, for the ring closure were several times larger than those of the guanylribosylurea formation, k_2, consistent with the assumption made. This observation is reasonable in view of the chemical nature of the cleavages since the latter step requires the breakage of an amide bond. The k_{-1} values were also slightly greater than the k_2 values, the rate constant for the ring opening, yielding an equilibrium constant of 0.58 ± 0.03 between pH 5.6 and 8.5. This value is close to the constant ratio of 0.41 between II and I reported in water (pH unknown) (11). At 37° the equilibrium constants (0.58 ± 0.01) remained essentially unchanged (pH 5.6–8.0). The equilibrium constant decreased slightly at a lower pH (4.5). These observations are qualitatively consistent with the HPLC and PMR observations as well as with reported data (10, 11).

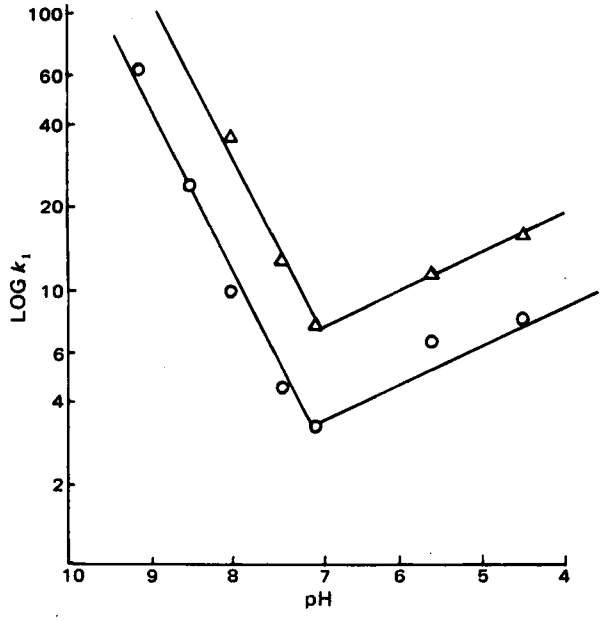

Figure 8—*The pH stability profile of 5-azacytidine (8.2 × 10^{-4} M) in aqueous buffers (potassium phosphate buffer, 0.067 M) at 25° (○) and 37° (△).*

pH-Dependent Hydrolysis—As shown in Table II, the rate constants of the hydrolysis varied with pH. When log k values were plotted against pH at 25 and 37°, a V-shaped curve resulted with both minima at pH 7.0 (Fig. 8), a value slightly different than the pH 6.5 reported (10). The slopes on the basic and acidic portions of the curve were +0.630 and −0.152, respectively. A similar trend was also observed if log k_2 values were plotted against pH. The hydrolysis, therefore, appears to be acid and base catalyzed, similar to the other known examples (22, 23). The deviation of the slopes from +1 and −1 on the basic and acidic pH portions of the curve, respectively, suggests that the hydrolysis may be susceptible to general acid and base catalyses (17). These pH profiles of the hydrolyses were markedly different from those reported by Notari and De Young (10) who described a more complex profile not readily interpretable on the basis of acid and base catalyses.

The hydrolysis kinetics observed were qualitatively similar to those reported using HPLC, PMR, and UV; however, quantitation differences were observed with those reported and may be attributed to differences in experimental conditions as well as methodologies. Under comparable experimental conditions such as those in Ringer's lactate, comparable results were obtained.

Stability Evaluation of 5-Azacytidine in Aqueous Buffers and Other Solutions—Although 5-azacytidine hydrolysis is subject to acid and base catalyses, the rate constants for the reversible formation of *N*-formlyribosylguanylurea as well as for the irreversible formation of ribosylguanylurea are smaller in magnitude than at the basic pH. Since ribosylguanylurea itself does not seem to possess significant cytotoxicity, rapid degradation of 5-azacytidine to this compound will result in a loss of efficacy. Recent biological data suggest that *N*-formylribosylguanylurea also has little cytotoxicity (11), although the evidence was not clearcut. However, other researchers found that aqueous solutions of 5-azacytidine, after long standing at room temperature, resulted in higher cytotoxicity (24, 25). Although formation of *N*-formylribosylguanylurea is reversible, in the absence of more definitive data it is desirable to formulate 5-azacytidine in media where the ring opening reaction is retarded. The pH profile of hydrolysis and kinetic data in Table II show that the rate constants for the hydrolysis in acidic pH are smaller in magnitude than those in basic pH. Therefore, a pH lower than 7.0 will result in slower ring hydrolysis.

In patients, slow infusion of 5-azacytidine in Ringer's lactate has lowered GI toxicity. The present study demonstrated that 5-azacytidine is very stable in this medium (pH 6.4), yielding a terminal $t_{1/2}$ of 4.8 days at room temperature, a value close to the reported one of 4.2 days (15). The $t_{1/2}$ in this medium at refrigerated temperature (0–5°) was considerably longer (31.3 days).

GI Absorption of β-Lactam Antibiotics III: Kinetic Evidence for *In Situ* Absorption of Ionized Species of Monobasic Penicillins and Cefazolin from the Rat Small Intestine and Structure–Absorption Rate Relationships

AKIRA TSUJI, ETSUKO MIYAMOTO, OSAMU KUBO, and TSUKINAKA YAMANA ˣ

Received July 6, 1978, from the *Faculty of Pharmaceutical Sciences, Kanazawa University, Takara-machi, Kanazawa 920, Japan.* Accepted for publication December 20, 1978.

Abstract □ Absorption rates of monobasic β-lactam antibiotics were measured as a function of lumen solution pH between 4 and 9 by utilizing the rat intestinal recirculating method *in situ*. Between pH 6.5 and 9, the absorption rate constants of ionized antibiotics were almost identical; but, at pH 4, the unionized species were highly absorbed, depending on their lipophilicity through the GI membrane lipoidal barrier. The structure-absorption rate relationship was established with the unstirred layer model.

Keyphrases □ Absorption, GI—various monobasic penicillins and cefazolin, effect of ionization, pH, structure–activity relationships □ Penicillins, various—GI absorption, effect of ionization, structure–activity relationships □ Cefazolin—GI absorption, effect of ionization, structure–activity relationships □ Antibiotics—penicillins and cefazolin, GI absorption, effect of ionization, structure–activity relationships

The GI absorption rate of a monobasic penicillin in rats deviated significantly from the pH-partition hypothesis (1). This shift was interpreted successfully by the absorption mechanism of penicillins through the aqueous diffusion layer of the lumen side of the GI membrane, which is restricted by the lipophilicity of the undissociated species (1).

In *in vitro* experiments utilizing an isolated gut technique, the transport of phenoxypenicillin derivatives exhibited a saturable process, but additional study did not produce evidence of active transport (2). A similar *in vitro* study (3) provided evidence for the passive transport of β-lactam antibiotics at pH 7.4. Perrier and Gibaldi (4) attributed the larger absorption of dicloxacillin than of penicillin G and ampicillin from the *in situ* rat intestinal loop to the larger lipophilicity of dicloxacillin. A good correlation was found (5) between the rate of *in situ* intestinal cephalexin and cefazolin absorption in rats and their *in vitro* release rate from liposomes.

Recent studies in this laboratory on the *in situ* absorption kinetics of low lipophilic and completely ionized amphoteric β-lactam antibiotics, such as amoxicillin (6), cyclacillin (7), and cephradine (7), indicated that their intestinal absorption is governed by simple diffusion fol-

GI Absorption of β-Lactam Antibiotics III: Kinetic Evidence for *In Situ* Absorption of Ionized Species of Monobasic Penicillins and Cefazolin from the Rat Small Intestine and Structure–Absorption Rate Relationships

AKIRA TSUJI, ETSUKO MIYAMOTO, OSAMU KUBO, and TSUKINAKA YAMANA ˣ

Received July 6, 1978, from the *Faculty of Pharmaceutical Sciences, Kanazawa University, Takara-machi, Kanazawa 920, Japan.* Accepted for publication December 20, 1978.

Abstract □ Absorption rates of monobasic β-lactam antibiotics were measured as a function of lumen solution pH between 4 and 9 by utilizing the rat intestinal recirculating method *in situ*. Between pH 6.5 and 9, the absorption rate constants of ionized antibiotics were almost identical; but, at pH 4, the unionized species were highly absorbed, depending on their lipophilicity through the GI membrane lipoidal barrier. The structure-absorption rate relationship was established with the unstirred layer model.

Keyphrases □ Absorption, GI—various monobasic penicillins and cefazolin, effect of ionization, pH, structure–activity relationships □ Penicillins, various—GI absorption, effect of ionization, structure–activity relationships □ Cefazolin—GI absorption, effect of ionization, structure–activity relationships □ Antibiotics—penicillins and cefazolin, GI absorption, effect of ionization, structure–activity relationships

The GI absorption rate of a monobasic penicillin in rats deviated significantly from the pH-partition hypothesis (1). This shift was interpreted successfully by the absorption mechanism of penicillins through the aqueous diffusion layer of the lumen side of the GI membrane, which is restricted by the lipophilicity of the undissociated species (1).

In *in vitro* experiments utilizing an isolated gut technique, the transport of phenoxypenicillin derivatives exhibited a saturable process, but additional study did not produce evidence of active transport (2). A similar *in vitro* study (3) provided evidence for the passive transport of β-lactam antibiotics at pH 7.4. Perrier and Gibaldi (4) attributed the larger absorption of dicloxacillin than of penicillin G and ampicillin from the *in situ* rat intestinal loop to the larger lipophilicity of dicloxacillin. A good correlation was found (5) between the rate of *in situ* intestinal cephalexin and cefazolin absorption in rats and their *in vitro* release rate from liposomes.

Recent studies in this laboratory on the *in situ* absorption kinetics of low lipophilic and completely ionized amphoteric β-lactam antibiotics, such as amoxicillin (6), cyclacillin (7), and cephradine (7), indicated that their intestinal absorption is governed by simple diffusion fol-

lowing first-order kinetics at a high dose and is favored by some forms of a carrier-mediated transport process following Michaelis–Menten kinetics at low doses. However, the kinetics and mechanism for the transport of ionized species of monobasic β-lactam antibiotics across the intestinal mucosa are not clearly understood.

In the present absorption study, attention was paid to lumen solution pH, and simultaneous absorption and degradation were assessed. Discussion by others (4) on the absorption of ionized penicillin species seems to harbor some questions because of the pH change and β-lactam ring degradation, both of which may occur during absorption experiments, especially with the *in situ* method. In this report, kinetic evidence is presented for the *in situ* intestinal absorption of ionized forms of monobasic penicillins and cefazolin. Furthermore, based on the unstirred layer theory, which is applicable to the absorption of undissociated β-lactam antibiotic molecules (1), the relationship between the absorption rate of antibiotics and their oil–water partition coefficients has been established.

EXPERIMENTAL

Materials—The following β-lactam antibiotics were used as supplied: penicillin V potassium[1] (1490 units/mg), phenethicillin potassium[1] (1444 units/mg), propicillin potassium[2] (993 μg/mg), oxacillin sodium[3] (840 μg/mg), cloxacillin sodium[1] (907 μg/mg), dicloxacillin sodium[1] (900 μg/mg), floxacillin sodium[4] (893 μg/mg), and cefazolin sodium[4] (966 μg/mg). Solutions of penicilloic acids of propicillin and dicloxacillin were prepared according to the method of Schwartz and Delduce (8).

All other chemicals were reagent grade and were used without further purification, except for imidazole which was purified by double recrystallization from benzene followed by thorough washing with ether.

***In Situ* Intestinal Absorption Procedure**—Male albino Wistar rats, 225 ± 25 g, were fasted over 20 hr prior to the experiments, but water was given freely. The rats were anesthetized with urethan, 1.3 g/kg ip.

The recirculating perfusion procedure for studying *in situ* intestinal absorption was essentially the same as that described previously (1, 9), except for the use of the upper 30-cm portion of the small intestine. The bile duct was ligated in all experiments. The small intestine was washed with 50 ml of perfusion solution, and a 5-ml solution of a penicillin or of a penicilloic acid (5 mg/ml, unless otherwise stated) was recirculatingly perfused at 2 ml/min. The drug solution was prepared with isotonic buffer (10), and the lumen solution pH was maintained at the desired pH with a pH-stat[5] (1, 9) during the absorption experiments.

The perfusion periods were 1 hr at pH 4.0 and 2 hr at other pH values. At the end of the absorption experiment, the recirculating drug solution of about 9 ml and a fresh isotonic buffer perfused to wash the intestine were collected into a 50-ml volumetric flask; the required amount of the same buffer was added to obtain 50 ml. To obtain a final sample, the solution was passed through a 0.45-μm filter[6] to remove any solid materials. The initial sample was prepared by diluting 5 ml of the initial drug solution (5 mg/ml) with the isotonic buffer to obtain 50 ml.

Analytical Procedures—The antibiotic concentration was determined by three methods: UV spectrophotometry (11), high-pressure liquid chromatography (HPLC), and spectrofluorometry (12). Due to the interference by unknown materials with UV absorbance in the sample solution of penicillins having an isoxazole group (oxacillin, cloxacillin, dicloxacillin, and floxacillin) (4), these samples were analyzed only by HPLC.

HPLC—The chromatograph[7] was equipped with a variable-wavelength UV detector[8] set at 210 or 254 nm. A reversed-phase column[9], prepacked with octadecylsilane chemically bonded on totally porous silica gel, was used for the determination of unchanged β-lactam antibiotics. The eluent was 10–30% (v/v) aqueous acetonitrile containing 0.01 *M* ammonium acetate. For the determination of penicilloic acids, an anion-exchange column[10] was utilized with 0.02 *M* KH_2PO_4 adjusted to pH 5 as the eluent; a 100-μl sample was injected through a loop injector on flow. Peak heights were used for quantification. A standard solution of the corresponding penicilloic acids was prepared according to the procedure described by Schwartz and Delduce (8).

Spectrofluorometry—Spectrofluorometry was used in the analysis of relatively lower propicillin concentrations and of the sample from the absorption experiment with penicilloic acid. This analytical method was based on the formation of a fluorescent Schiff base resulting from the reaction between 5-dimethylaminonaphthalene-1-sulfonylhydrazine and penilloaldehyde (12), which can be produced from the reaction of penicilloic acid and mercuric chloride at pH 2.5. This method has the advantage of simultaneous determination of the intact penicillin and its product, penicilloic acid (12). The detailed procedure was described elsewhere (12)[11].

RESULTS AND DISCUSSION

Simultaneous Absorption and Degradation—Table I shows the percentage of remaining penicillins and the percentage of penicilloic acids that appeared after 2 hr in the *in situ* intestinal recirculating absorption experiments for propicillin, dicloxacillin, penicillin V, and cefazolin. Samples were analyzed by HPLC for all penicillins and cefazolin and by spectrofluorometry for propicillin and penicilloic acids. There were significant degradations in the β-lactam moiety of penicillin derivatives. Cefazolin degradation was negligible during the experiments since the corresponding product peak, which was observed in *in vitro* degradation for a sufficiently long period under the same condition, was not detected.

Possible absorption of penicilloic acids was examined under similar conditions. Both penicilloic acids of propicillin and dicloxacillin were absorbed to the same extent (16.1 ± 6.8%) at the end of 2 hr at pH 7.4. From these results, the overall pathway of β-lactam antibiotics in the intestinal lumen solution can be represented as in Scheme I.

As seen in Table I, the widespread change of the initial propicillin concentration between 100 and 5000 μg/ml produced an almost constant disappearance of 23% and an appearance of 10% of the penicilloic acid at pH 7.4. A similar result was reported (2) for penicillin V disappearance in the 0.6–160-μg/ml range from rat intestinal lumen solution at pH 7.4. These findings indicate that all rate processes in Scheme I follow apparent first-order kinetics, at least for propicillin and penicillin V. If one assumes that a similar kinetic process applies to other β-lactam antibiotics according to Scheme I, the ratios of a remaining antibiotic (α_1) and an apparent penicilloic acid (α_2) at time t to the initial antibiotic dose would be expressed by:

$$\alpha_1 = e^{-(k_a + k_d)t} \qquad \text{(Eq. 1)}$$

[a] Determined at the end of 2-hr experiments. [b] Calculated from Eqs. 4 and 5 by use of $\alpha_0 = 0.839$, which is the average of values determined for penicilloic acids of propicillin and dicloxacillin.

$$\alpha_2 = \frac{k_d}{(k_a + k_d) - k'_a}\left[e^{-k'_a t} - e^{-(k_a + k_d)t}\right] \qquad \text{(Eq. 2)}$$

where k_a and k'_a represent the apparent first-order absorption rate constants of a penicillin and its penicilloic acid, respectively, and k_d is the apparent first-order penicillin degradation rate constant. The absorption rate constant, k'_a, can be calculated from:

$$\alpha_0 = e^{-k'_a t} \qquad \text{(Eq. 3)}$$

where α_0 is the ratio of the remaining penicilloic acid to the initial dose, which is determined under the same conditions in a separate absorption experiment for penicilloic acid. In the present kinetic treatment, the value of k'_a or α_0 was regarded as independent of lumen solution pH and of the kind of penicilloic acids, being equal to 1.46×10^{-3} min^{-1} or 0.839 of the mean value of k'_a or α_0 as determined for the penicilloic acids of dicloxacillin and propicillin. By using the data of α_1, α_2, and α_0, the penicillin absorption rate constant, k_a, and degradation rate constant, k_d, could be calculated from Eqs. 1–3 using:

$$k_a = -\frac{1}{t}\left(\ln \alpha_1 + \frac{\alpha_2}{\alpha_0 - \alpha_1} \ln \alpha_0/\alpha_1\right) \qquad \text{(Eq. 4)}$$

$$k_d = \frac{\alpha_2}{t(\alpha_0 - \alpha_1)} \ln \alpha_0/\alpha_1 \qquad \text{(Eq. 5)}$$

The raw data of α_1, α_2, and α_0 and k_a and k_d of penicillins and cefazolin determined under various conditions are summarized in Table I, and their mean values are listed in Table II.

The rate constants of chemical degradation under similar conditions were known to be almost independent of the kinds of penicillins but dependent on lumen solution pH. They were evaluated, based on previous kinetic data (13), as 1.0×10^{-4}, 1.3×10^{-4}, and 6.0×10^{-4} min^{-1} in isotonic buffer of pH 6.5, 7.4, and 9.0, respectively. When comparing the degradation rate constants of penicillins under *in situ* and *in vitro* conditions, it must be emphasized that, at pH 9.0, both were in a similar range. At a neutral pH of 6.5–7.4, however, the degradation rate constants *in situ* were ~6–10 times greater than those *in vitro*. These results suggest that in the intestinal lumen and/or at the intestinal mucosa, β-lactam cleavage other than chemical reaction takes place in an apparently first-order kinetic fashion under physiological pH conditions.

The present kinetic study provided evidence for the significant absorption of ionized penicillins and cefazolin and also for the absorption of penicilloic acids. If the intestinal absorption of ionized β-lactam antibiotics is the result of transport through the lipoidal barrier, as was verified (1) for the undissociated forms, significant differences in the extent of absorption may be expected among penicillins. In spite of the 10-fold difference at maximum in the oil–water partition coefficient (14) of the ionized forms of penicillin V, propicillin, and dicloxacillin, the ionized species of these penicillins and cefazolin were absorbed to an almost identical extent (Table II).

This result suggests that intestinal absorption of ionized β-lactam antibiotics below the concentration of 5 mg/ml follows apparent first-order kinetics such as, for example, simple diffusion through water channels in the membrane and that it is almost insensitive to the lipophilicity of transport molecules. However, due to the slight decrease of propicillin absorption at 10 mg/ml (Table II), the possibility cannot be

[a] Observed values at the end of 2-hr experiments. [b] Calculated value by Eqs. 4 and 5. [c] Averaged value at pH 7.4. [d] Averaged value between pH 6.5 and 9. [e] Penicilloic acids of propicillin and dicloxacillin prepared by Schwartz and Delduce (8).

excluded that a specialized mechanism of intestinal carrier-mediated transport of the ionized species exists, as was proposed for the intestinal absorption of completely ionized and highly hydrophilic aminopenicillins and aminocephalosporins (6, 7).

Effect of pH on Intestinal Absorption and Structure–Absorption Rate Relationships—Figure 1 shows the plots of *in situ* absorption rate constants, k_a, of penicillins *versus* perfusion solution pH, which was maintained with a pH-stat (1, 9). Absorption rate constants at pH 4.0 were calculated, assuming the degradation to be negligible in comparison to absorption, while those at other pH values were derived from Eq. 4.

Between pH 6.5 and 9, the penicillin absorption was independent of the lumen solution pH, with average rate constants, k_a, of 1.27×10^{-3} min^{-1}; it was almost identical among penicillin molecules (Table II). Below pH 6, the rate constants increased significantly with a decrease of the lumen solution pH depending on the lipophilicity of the undissociated species. Therefore, k_a can be expressed as:

$$k_a = k_u + k_i \qquad \text{(Eq. 6)}$$

where k_u and k_i are the apparent first-order absorption rate constants for unionized and ionized species of penicillins, respectively. A previous study (1) verified that k_u can be expressed by Eq. 7, which is derived from the kinetic model of membrane permeation across the lipoidal barrier of undissociated penicillin species transported through the aqueous diffusion layer with thickness L_I adjacent to the surface of the lipoidal membrane with thickness L_{II}:

$$k_u = \frac{SD_{aq}}{VL_I}\left(\frac{f_u}{T + f_u}\right) \qquad \text{(Eq. 7)}$$

where:

$$T = \frac{L_{II}D_{aq}}{L_I D_{lip} Pl_u R} \qquad \text{(Eq. 8)}$$

$$f_u = \frac{a_{H^+}}{K_a + a_{H^+}} \qquad \text{(Eq. 9)}$$

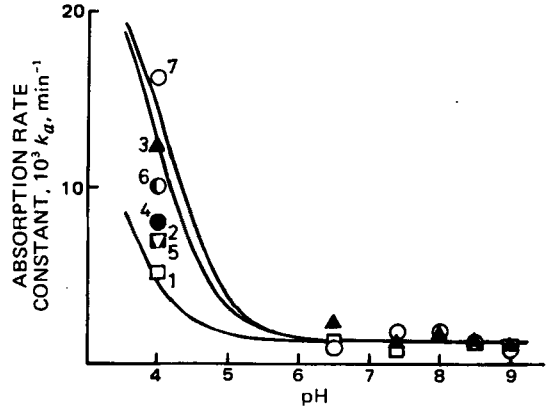

Figure 1—*Plots of* in situ *rat intestinal absorption rate constants,* k_a, *for penicillins* versus *pH of the perfusion solution at 37°. The compounds are numbered as in Table III. The points are experimental values, and the solid lines were generated from Eqs. 6, 12, and 14;* k_i = 1.27×10^{-3} min^{-1} *for Compounds 1, 3, and 7.*

where V is the volume of the recirculating drug solution; D_{aq} and D_{lip} are the diffusion coefficients of the drug in water and lipid, respectively; Pl_u is the partition coefficient of the undissociated drug between the lipid membrane and aqueous solution; f_u is the fraction of undissociated species; a_{H^+} is the hydrogen-ion activity of the lumen solution; K_a is the penicillin dissociation constant; and R is the ratio of the true interfacial area to the geometrical area, S, of the membrane.

Parameters V, L_I, L_{II}, S, and R can be regarded as constant since V and L_I depend only on experimental conditions and the others depend on the membrane. By using the relationship of Eq. 10 (10, 15) for a diffusion coefficient, D, and of Eq. 11 (10) for a partition coefficient, Pl_u, Eq. 7 can be simplified to Eq. 12:

$$D = \beta_1(\sqrt{MW})^{-1} \qquad \text{(Eq. 10)}$$

$$Pl_u = \beta_2 P_u \qquad \text{(Eq. 11)}$$

$$k_u = k_a - k_i = \frac{1}{a\sqrt{MW}}\left(\frac{f_u P_u}{b + f_u P_u}\right) \qquad \text{(Eq. 12)}$$

where MW and P_u represent the molecular weight and the partition coefficient between two immiscible liquids of the undissociated species of the transport antibiotics, respectively, and β_1 and β_2 are proportionality constants.

The rearrangement of Eq. 12 leads to:

$$(k_u\sqrt{MW})^{-1} = ab(f_u P_u)^{-1} + a \qquad \text{(Eq. 13)}$$

To verify Eq. 13, the intestinal absorption of several penicillins at pH 4.0 was examined (Table III and Fig. 2). The P_u values in the octanol–water system and the K_a values used for the calculation were determined previously (14). The plots of $1/(k_u\sqrt{MW})$ *versus* $1/(f_u P_u)$ according to Eq. 13 gave a good linear relationship (Fig. 2), and the following equation was obtained:

$$(k_u\sqrt{MW})^{-1} = 70.0(f_u P_u)^{-1} + 1.95 \qquad \text{(Eq. 14)}$$

The solid line in Fig. 1 was calculated for dicloxacillin, propicillin, and penicillin V from Eqs. 6, 12, and 14 and was in fair agreement with ex-

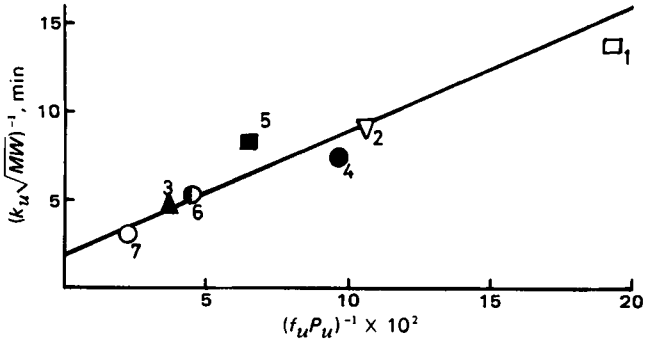

Figure 2—*Plots of* $(k_u\sqrt{MW})^{-1}$ *against* $(f_u P_u)^{-1}$ *for penicillins in* in situ *perfusion experiments at pH 4. The compounds are numbered as in Table III.*

perimental values. This finding indicates that the absorption of monobasic penicillins, excluding amphoteric ones such as amoxicillin and cyclacillin (6, 7), follows the common mechanisms of: (*a*) the lipoidal membrane transport of the undissociated species permeating the aqueous diffusion layer barrier and (*b*) the apparent first-order transport of the ionized species permeating some forms of the barrier almost insensitive to antibiotic lipophilicity.

A previous study (1) revealed that, below pH 6, the intestinal absorption rate of propicillin is about 100 times faster than the gastric absorption rate. This significant difference is undoubtedly due to the relative surface area in the alimentary tract. Naturally, other monobasic β-lactam antibiotics can be expected to exhibit absorption behavior similar to propicillin. The present and previous results (1, 9) indicate that a small amount of these orally ingested antibiotics may be absorbed in the stomach while almost all absorption takes place in the duodenum, where the fluid pH is relatively lower, and that absorption occurs *via* passive diffusion of the undissociated species, largely dependent on their lipophilicity. A small amount may be also absorbed by ionic transport during the slow transit through the intestine. Poor absorbability (16) of orally ingested cephalosporins such as cefazolin, the P_u of which is about one-thirtieth lower than that of penicillin V (17), may be due to the considerable reduction of k_u values effective both in the stomach and upper duodenum.

Pyridones as Potential Antitumor Agents

DENG RUEY HWANG * and JOHN S. DRISCOLL ˣ

Received September 28, 1978, from the *Drug Design and Chemistry Section, Laboratory of Medicinal Chemistry and Biology, Developmental Therapeutics Program, Division of Cancer Treatment, National Cancer Institute, National Institutes of Health, Bethesda, MD 20014.* Accepted for publication December 20, 1978. *Present address: Technicon Inc., Tarrytown, NY 10591.

Abstract □ Based on the finding that 3-acetoxy-2-pyridone had reproducible activity against murine P-388 lymphocytic leukemia, derivatives in this series were synthesized and evaluated to determine structural parameters important for activity. Of the 32 compounds tested, 10 were active. At least two oxygen-containing functional groups are required for P-388 activity, and the 2,3-isomeric arrangement provides the greatest activity. Carbamate or acyloxy groups in the 3-position produced the most active 2-pyridones.

Keyphrases □ Pyridone derivatives—antineoplastic activity, structure–activity relationships, mice □ Antineoplastic agents, potential—pyridone derivatives, structure–activity relationships, mice □ Structure–activity relationships—pyridone derivatives, antineoplastic activity, mice

During an investigation of hydroxypyridine derivatives, it was discovered that 3-acetoxy-2-pyridone (I) possessed reproducible activity against P-388 leukemia in mice. There are other scattered reports of pyridone antitumor activity. A nucleoside presently undergoing clinical evaluation, which can be classed as a pyridone, is 3-deazauridine (1, 2). Mimosine, a naturally occurring 4-pyridone, was reported as active against Walker 256 carcinosarcoma (3) and B16 melanotic melanoma (4). Other pyridones studied possess less antitumor activity (5–8). Based on the antitumor properties of I, a study was undertaken to determine the structural parameters important for activity.

RESULTS AND DISCUSSION

Compounds I–XXXII were evaluated. 3-Hydroxy-2-pyridone (II) was reacted with various acid chlorides, anhydrides, and isocyanates to produce 3-substituted and 1,3-disubstituted 2-pyridones. 2-Pyridone (VII) was oxidized to 5-hydroxy-2-pyridone (IV) by the Elbs persulfate reaction. UV and other spectral data were consistent with those expected for 2-pyridones (9, 10). The properties of these compounds are shown in Table I.

Antitumor activity was evaluated in the P-388 lymphocytic leukemia system using standard protocols (11) of the National Cancer Institute. Multiple biological tests were carried out with each compound using a dose response on the QD 1–9 treatment schedule. Physiological saline was the vehicle. Drugs were administered intraperitoneally to mice with

intraperitoneally implanted tumors. Active compounds are defined (11) as those that produce a T/C value[1] equal to or greater than 125%.

Antitumor data for the 10 reproducibly active compounds (*i.e.*, two or more T/C values ≥ 125%) are given in Table II. The compounds shown in Table I but not Table II were inactive in duplicate or two of three tests.

The initial part of this study involved a determination of whether both oxygen functions were necessary for activity and the importance of the isomeric relationship of these two groups.

That none of the monooxygenated pyridine analogs (VII–X) related to I possessed P-388 antitumor activity was readily established.

Evaluation of the isomeric hydroxy-2-pyridones (III–VI) related to I showed that the 5-hydroxy (IV) but not the 4- or 6-hydroxy (III or VI) analogs were active. This finding is consistent with the chemical similarity of the 3- and 5-positions of the pyridine ring. The activity of the 5-acetoxy derivative (V) was variable (T/C 132, 121, and 119%). Neither 5-hydroxy analog was as active as the corresponding 3-substituted isomer. 4-Hy-

droxy-2-pyridone (III), the parent base for 3-deazauridine, had no P-388 activity, in contrast to the activity shown by both that nucleoside and II in this tumor system.

With the knowledge that at least two oxygen functions were required for antitumor activity and that 2,3-substitution was optimum, several derivatives of II were planned, prepared, and evaluated. Based on the observation that I was more active than II, several different types of derivatives were prepared at the 3-hydroxy position. Most of the derivatives were capable of hydrolysis since it was established early in the series that the ethers prepared in the 3-position were not active.

3-Acetoxy-2-pyridone (I) had good activity at high doses (Table II). The parent compound, 3-hydroxy-2-pyridone (II), also was active but somewhat less so than I. *N*-Methylation of I to give XII provided an active but toxic compound.

Variations in the alkyl portion of the acyl group in the 3-position produced both active and inactive materials. An ethyl group (XI) provided reproducible activity, while the cyclopropyl (VIII), methoxymethyl (XVI), *tert*-butyl (XIV), and adamantyl (XV) compounds were inactive. The aryl substitution (XVII–XXI), which was chosen to affect the ester hydrolysis rate, produced no activity differences and uniformly abolished activity.

The reaction of II with isocyanates to provide alkyl- or arylaminocarbonyl analogs (carbamates) produced several active compounds (XXII–XXIV, XXVIII, and XXIX). In some instances (XXIII and XXVI), *N*- as well as *O*-substitution occurred. The methylamino and ethylamino compounds (XXII and XXIV) were active, but the cyclohexylamino (XXV) and dimethylamino (XXVII) analogs were not. Although 2-chloroethylisocyanate formed a diadduct (XXVI), which was inactive, the methylisocyanate diadduct (XXIII) was one of the most active derivatives prepared. Neither the monoadduct (XXXI) nor the diadduct (XXXII) from methanesulfonyl chloride was active. While the ethylcarbamate (XXIV) was active, the corresponding carbonate (XXX) was not.

This investigation indicates that derivatives of 3-hydroxy-2-pyridone can provide moderate activity against P-388 leukemia. At least two oxygen functions are required, with the 2,3-isomer being the most active.

Table II—2-Pyridones Reproducibly Active against P-388 Lymphocytic Leukemia [a]

Compound	Optimum Dose[b], mg/kg/day	T/C[c]	T − C[d]

XXVIII	100	132	−4.6
XXIX	25	134	−2.0

[a] With 10^6 cells implanted intraperitoneally in CDF_1 mice. [b] Dose giving the maximum T/C value on the intraperitoneal QD 1–9 treatment schedule. [c] At least one other active test (T/C ≥ 125%) was obtained in a separate, duplicate experiment. [d] Weight difference between treated and control animals 5 days after tumor implant.

Bioisosteres, 4-pyridones, and pyridone nucleosides are being studied currently. Also under investigation is the possibility that biological oxidation of the hydroxypyridones to quinoid forms may be involved in antitumor activity.

EXPERIMENTAL[2]

5-Hydroxy-2(1*H*)-pyridone (IV)—This compound was prepared in a 20% yield from 0.4 mole of VII using the Elbs peroxydisulfate oxidation procedure of Behrman and Pitt (12), mp 245–250° dec. [lit. (12) mp 250–260° dec.].

5-Acetoxy-2(1*H*)-pyridone (V)—To a stirred dry mixture of IV (1.67 g, 0.015 mole) and pyridine (1.30 ml, 0.016 mole) in dry benzene (10 ml) was added acetic anhydride (1.5 ml, 0.016 mole) by syringe through a septum. The mixture was refluxed for 26 hr. After the solvent was removed *in vacuo*, ethyl acetate was added to the dark-brown semisolid. Cooling at 3° gave a gray precipitate, which was decolorized with charcoal in a small volume of ethyl acetate–ethanol to give 0.91 g (39%) of a white solid, mp 166–168°; NMR: δ 2.27 (s, 3H, CH_3), 6.33 (m, 1H, CH), 6.97 (m, 2H, CH), and 11.48 (broad, 1H, NH) ppm; UV: 306 (log ε 3.83) and 231 (4.05) nm; IR: 1740, 1665, and 1625 cm^{-1}.

3-Propionyloxy-2(1*H*)-pyridone (XI)—A mixture of II (27.75 g, 0.25 mole), propionic anhydride (80 ml), and dry pyridine (50 ml) was refluxed for 89 hr, and the solvent was evaporated *in vacuo* to yield a crude solid product, which was washed with ethyl acetate. Recrystallization from anhydrous ethanol gave white crystals (30.90 g, 74%), mp 150–151°; NMR: δ 1.08 (t, 3H, CH_3), 2.48 (m, 2H, CH_2), 6.15 (t, 1H, CH), 7.28 (d, 2H, CH), and 11.98 (broad, 1H, NH) ppm; UV: 226 (log ε 3.79) and 297 (3.81) nm; IR: 1760 and 1655 cm^{-1}.

1-Methyl-3-acetyloxy-2(1*H*)-pyridone (XII)—To a cold, stirred solution of I (12.25 g, 0.08 mole) in dry dimethylformamide (50 ml) was slowly added (35 min) sodium hydride (50% mineral oil suspension, 3.86 g, 0.16 mole) under nitrogen. As the mixture became harder to stir, additional dry dimethylformamide (30 ml) was added. The mixture was stirred in an ice water bath for 3 hr, at which time methyl iodide (5.05 ml, 11.51 g, 0.081 mole) was added by syringe over 15 min. Sodium iodide separated during the addition. The mixture was stirred for 2.5 hr at room temperature. Acetic acid (7 ml), followed by portions of methylene chloride, was added.

The combined methylene chloride extracts were quickly washed with water and dried (sodium sulfate). After solvent evaporation *in vacuo*, the resulting red oil was distilled (ambient to 150° at 0.1 torr) to give a yellow oil, which was triturated with petroleum ether to remove mineral oil. Upon cooling, a solid precipitated. This solid was dissolved in methylene chloride and reprecipitated by addition to petroleum ether. The resulting solid was a light-sensitive, white, crystalline material (1.48 g, 10%), mp

[2] All melting points were recorded on a Thomas-Hoover capillary apparatus and are uncorrected. Elemental analyses were performed by the National Institute of Arthritis, Metabolism, and Digestive Diseases, National Institutes of Health, Bethesda, Md. Compounds I–III, VI, and VII–X were obtained commercially. When several compounds were prepared by comparable procedures, only one representative example is included in this section. Reference should be made to Table I for supplementary information.

New compounds were identified by NMR, UV, and IR spectra. These spectra were determined in dimethyl sulfoxide-d_6, 95% ethanol, and Nujol, respectively, unless otherwise indicated. NMR data are relative to tetramethylsilane.

84–88° [lit. (13) mp 99–101°]; NMR (deuterochloroform): δ 2.30 (s, 3H, NCH_3), 3.53 (s, 3H, CH_3), 6.05, and 7.11 (m, 3H, aromatic) ppm; UV: 236.5 (log ε 3.65) and 298 (3.94) nm; IR (chloroform): 1775 and 1665 cm^{-1}.

1,2-Dihydro-2-oxo-cyclopropanecarboxylic Acid-3-pyridinyl Ester (XIII) (General Procedure for XV, XVI, XVIII–XXI, XXVII, XXX, and XXXI)—A mixture of II (5.56 g, 0.05 mole), cyclopropanecarboxylic acid chloride (4.63 ml, 0.05 mole), dry pyridine (4.04 ml, 0.05 mole), and dry tetrahydrofuran (50 ml) was refluxed for 24 hr under nitrogen. Addition of methylene chloride to the ambient solution produced a solid, which was a mixture of XIII and pyridine hydrochloride. Recrystallization from absolute ethanol with charcoal gave 6.42 g (72%) of XIII as white crystals, mp 196–198°; NMR: 0.97 (m, 4H, CH_2), 1.80 (m, 1H, CH), 6.12 (t, 1H, CH), 7.25 (d, 2H, CH), and 11.88 (broad, 1H, NH) ppm; UV: 226.5 (log ε 3.79) and 297.5 (3.81) nm; IR: 1750 and 1650 cm^{-1}.

3-Benzoyloxy-2(1*H*)-pyridone (XVII) (General Procedure for XIV and XXXII)—A mixture of II (2.22 g, 0.02 mole), benzoyl chloride (2.44 ml, 0.021 mole), anhydrous potassium carbonate (2.90 g, 0.021 mole), and dry acetone (15 ml) was refluxed for 28 hr. Methylene chloride (20 ml) was added, followed by water (5 ml). Additional methylene chloride was added, and the mixture was thoroughly stirred. The layers were separated, the suspended solid was discarded, and the aqueous phase was extracted with two 20-ml portions of methylene chloride.

The combined organic extracts were washed with water (3 × 20 ml), dried over sodium sulfate, and evaporated *in vacuo*. Trituration of the resulting solid with toluene gave a white solid, which was recrystallized from ethyl acetate to give white crystals (2.51 g, 59%), mp 174–176°; NMR (deuterochloroform): 6.18 (t, 1H, CH), 7.40 (m, 5H, CH), 8.17 (m, 2H, CH), and 13.32 (broad, 1H, NH) ppm; UV: 228 (log ε 4.26) and 297 (3.92) nm; IR (chloroform): 1735, 1655, and 1615 cm^{-1}.

3-[[(Methylamino)carbonyl]oxy]-2(1*H*)-pyridone (XXII) (General Procedure for XXIV, XXV, XXVIII, and XXIX)—A mixture of II (5.51 g, 0.05 mole), methyl isocyanate (3.1 ml, 0.052 mole), dry triethylamine (8 drops), and dry dimethylformamide (35 ml) was stirred at room temperature for 44 hr. Solvent evaporation gave a red-brown material, which was stirred with hot ethyl acetate to remove 0.39 g of the disubstituted product, XXIII, mp 159–160°. The material insoluble in ethyl acetate was dissolved in warm ethanol. Scratching the cold filtrate produced XXII (4.28 g, 51%), mp 164–165°; NMR: 2.63 (d, 3H, CH_3), 6.08 (t, 1H, CH), 7.17 (d, 2H, CH), 7.45 (broad, 1H, NH), and 11.67 (broad, 1H, NH) ppm; UV: 227 (log ε 3.77) and 297 (3.81) nm; IR: 1725 and 1665 cm^{-1}.

***N*-Methyl-3-[[(methylamino)carbonyl]oxy]-2-oxo-1(2*H*)-pyridinecarboxamide (XXIII)**—Compound XXIII, mp 161–162°, was prepared in a 49% yield using a 1:2 molar ratio of II to methylisocyanate and the procedure described for XXII; NMR (deuterochloroform): 2.75 (d, 3H, CH_3), 2.87 (d, 3H, CH_3), 5.15 (broad, 1H, NH), 6.17 (t, 1H, CH), 7.15 (m, 1H, CH), 8.18 (m, 1H, CH), and 10.08 (broad, 1H, NH) ppm; UV: 220 (shoulder) and 306 (log ε 3.70) nm; IR (chloroform): 3430, 3160, 1745, and 1655 cm^{-1}.

***N*-(2-Chloroethyl)-3-[[(2-chloroethylamino)carbonyl]oxy]-1(2*H*)-pyridinecarboxamide (XXVI)**—A mixture of II (5.56 g, 0.05 mole), 2-chloroethylisocyanate (5.38 g, 0.051 mole), dry triethylamine (8 drops), and dry dimethylformamide (30 ml) was stirred at room temperature for 19 hr with occasional warming to 40° to dissolve suspended solids. The solvents were removed *in vacuo*, ethyl acetate (50 ml) was added to the residue, and the mixture was cooled to 0° overnight. The resulting solid (II, 2.4 g) was removed, the ethyl acetate was evaporated, and chloroform was added. This solution was extracted with three 30-ml portions of water, dried with sodium sulfate, and evaporated *in vacuo* to give a gray solid. Dissolution in ethyl acetate, followed by the addition of petroleum ether, yielded a gray-white solid (4.97 g, 55%), mp 111–113°; NMR (deuterochloroform): 3.52 (m, 8H, CH_2), 5.83 (broad, 1H, NH), 7.28 (m, 1H, CH), 8.25 (m, 1H, CH), and 10.72 (broad, 1H, NH) ppm; UV: 226 (shoulder) and 305 (log ε 3.83) nm; IR: 3410, 3120, 1730, and 1655 cm^{-1}.
